Little is known about the prevention of pyelonephritis or renal abscess. Presumably, the same measures that can be recommended to noncompromised women who wish to reduce their risk of uncomplicated recurrent cystitis (e.g. avoiding spermicide-diaphragm contraception, use of chronic antimicrobial prophylaxis or early patient-initiated therapy for UTI symptoms) should decrease the risk of uncomplicated pyelonephritis.[35] Postmenopausal women can reduce their risk of bacteriuria with vaginal estrogen treatment;[36] this might also prevent pyelonephritis. Complicated pyelonephritis may be prevented by removing the precipitating factor. Urinary catheters should be avoided whenever possible, used according to current guidelines when unavoidable and removed as soon as no longer essential.[24] Correction of urologic abnormalities (whether surgically or medically) may reduce the associated infection risk but treatment decisions must be carefully individualized and based on the expected risks and benefits of the planned intervention(s). It is not known whether improved glycemic control among patients who

have diabetes reduces their increased risk of pyelonephritis but the other documented benefits of this therapy provide ample rationale for its use.

Prophylactic antimicrobial therapy is useful in women who have recurrent uncomplicated cystitis[37] and in certain compromised hosts, for example renal transplant recipients in the early post-transplant period.[38] However, in many other compromised hosts antibiotic prophylaxis is without clear benefit and often selects for resistant organisms and causes drug-related adverse effects.[39] Whether the experimental anti-UTI vaccines that are currently being evaluated will prevent cystitis or pyelonephritis is unknown.[17] [40] At present there is no medically defined role for vaccines, cranberry juice, receptor analogue therapy, *Lactobacillus* preparations or yoghurt in the prevention of UTI or pyelonephritis.[35]

CLINICAL FEATURES

The clinical manifestations of acute pyelonephritis vary considerably depending on the characteristics of the host and pathogen. A typical history for the classic pyelonephritis syndrome, which is most commonly observed with kidney infections in otherwise healthy young women, includes several days of progressive flank pain, malaise, fever and chills, prostration and possibly nausea and vomiting, often preceded and/or accompanied by symptoms of acute cystitis.[2] [5]

The physical examination characteristically shows an ill-appearing, febrile, tachycardic patient, often with evidence of volume contraction. The pathognomonic physical finding of acute pyelonephritis is tenderness to palpation or percussion over one or both costovertebral angles. Mild to moderate abdominal and suprapubic tenderness are often also present.

Atypical presentations are common. Even otherwise healthy young women who have pyelonephritis may not have all of the classic symptoms or examination findings, and infants or young children, elderly or debilitated patients and patients who have underlying systemic illnesses or neurologic impairment often have an even less characteristic clinical picture.[2] [5] Abdominal pain, headache, nonspecific constitutional symptoms, diffuse back pain, pelvic pain or respiratory complaints may predominate, obscuring the diagnosis and suggesting other processes. A deceptively benign presentation, including sometimes even the complete absence of suggestive symptoms, can mask the presence of severe renal infections in immunocompromised or sensory-impaired hosts.[2] [5] [41] On the other hand, even in patients who have a classic presentation for acute pyelonephritis, other entities must be considered in the differential diagnosis, including (in the appropriate setting) pelvic inflammatory disease, acute appendicitis, urolithiasis, basal pneumonia and acute pancreatitis or biliary tract disease. The decision whether to perform a pelvic examination in a woman suspected of having pyelonephritis must be individualized, taking into consideration the patient's demographic characteristics, the specifics of the history (including the sexual history) and the findings on general physical examination.

In addition to the varied combinations of symptoms and physical findings encountered in patients who have acute pyelonephritis, a wide range of severity of illness is seen. At one extreme, patients who seem healthy and have what otherwise appears clinically to be acute cystitis may demonstrate a slight elevation of body temperature or report mild malaise, suggesting early renal involvement. At the other extreme, patients may present in full-blown septic shock, with multisystem organ failure. The severity of illness has a significant influence on subsequent management, as described below.

Abscess

The initial history and physical examination usually provide few clues as to the presence of an intrarenal or perinephric abscess, although these entities should be kept in mind in high-risk patients. The presence of a palpable mass is suggestive of renal abscess but is neither a sensitive nor a specific finding. [11] Failure of a patient who is thought to have ordinary pyelonephritis to improve substantially after treatment for 48 hours increases the likelihood of abscess sufficiently to warrant further diagnostic studies.[2] [5]

DIAGNOSIS

Urinalysis and urine culture

Acute pyelonephritis is a clinical diagnosis based on a combination of characteristic symptoms and signs together with supporting laboratory tests.[2] [5] The minimal laboratory evaluation needed to make this diagnosis in the appropriate clinical setting is microscopic examination (whether by urinalysis or Gram stain) of a voided urine specimen to evaluate for the presence of pyuria, followed by quantitative urine culture. The Gram stain is also helpful by confirming the presence of bacteria in the urine (which are seen in unconcentrated urine specimens when the urine bacterial concentration is $>10^5$ cfu/ml) [42] and by suggesting the likely bacterial type, although effective empiric treatment often can be selected without this information. [43]

In the absence of prior antimicrobial therapy, the urine culture almost always shows high concentrations ($>10^5$ cfu/ml) of one or more bacterial species. Pure growth of a single uropathogenic organism is typical of infections in noncompromised hosts, whereas polymicrobial infections are more common in compromised hosts. Lesser bacterial concentrations are occasionally encountered, and in the appropriate clinical context (e.g. a patient who has typical symptoms and examination findings, plus pyuria) do not exclude the diagnosis of pyelonephritis. Antimicrobial susceptibility testing of urine isolates is essential, both to confirm that the empirically selected treatment regimen is appropriate, and for guiding selection of an effective oral agent for patients treated initially with a parenteral antimicrobial regimen.[43]

Ancillary tests

Other tests may be indicated depending on the severity of illness, the range of alternative diagnoses being considered and the presence of comorbid conditions. Pre-therapy blood cultures are commonly collected although, interestingly, bacteremia (if present) predictably clears with appropriate therapy directed toward the urinary infection, and clinical outcomes are similar regardless of the presence or absence of bacteremia.[5] A pregnancy test is useful if the patient might be pregnant and treatment is being considered with an agent (such as an aminoglycoside or a fluoroquinolone) that might be toxic to the fetus.[34]

Imaging studies

Imaging studies are not routinely indicated for the diagnosis or management of acute pyelonephritis.[30] For patients in whom the initial diagnosis is unclear, those who fail to respond appropriately to therapy and those in whom abscess or obstruction are suspected for other reasons, computerized tomography (CT) can be used to clarify the anatomy and guide a mechanical intervention.[2] [5] [44] [45] [46] [47] Of all urinary tract imaging modalities, contrast-enhanced CT provides the best anatomic definition of inflammatory processes in the urinary tract, including sensitive detection of abscesses and differentiation of abscesses (water density) from simple inflamed tissue (tissue density; Fig 69.5 Fig 69.6 Fig 69.7 Fig 69.8).[44] [45] [46] [47] Inflamed regions of the pyelonephritic kidney appear on enhanced CT as streaky or wedge-shaped hypodense areas that fail to concentrate contrast material normally in comparison with surrounding renal tissue. Focal bulges or diffuse swelling of the entire kidney are common, as is inflammatory stranding in the perinephric

Figure 69-5 Febrile urinary tract infection with white blood cell count of 36,000/ml (girl, 3 years). (a) Precontrast CT scan: left kidney is diffusely swollen; parenchymal attenuation is the same as that of the right kidney. (b) Postcontrast CT scan: wedge-shaped regions of hypoenhancing parenchyma in the left kidney are most pronounced in the posterior portion. Inflamed parenchyma enhances from 32 to 93 Hounsfield units (HU), whereas normal kidney enhances from 33 to 140HU. The right kidney shows normal cortical enhancement and pronounced medullary blush. *With permission from Talner.*[45]

Figure 69-6 Woman with clinical signs of acute pyelonephritis. (a) Precontrast CT scan: focal bulge present in anterolateral aspect of left kidney. Attenuation is the same as that of normal kidney parenchyma. (b) Postcontrast CT scan: rounded and streaky regions of hypoenhancing parenchyma in the left kidney are most pronounced anterolaterally. Attenuation in the region of interest (cursor) was 22HU on precontrast scans and increased to 93HU on postcontrast scans. Normal parenchyma increased from 25–130HU. *With permission from Talner.*[45]

Figure 69-7 Acute pyelonephritis with small intrarenal abscess. (a) Precontrast CT scan shows small region of low attenuation (arrows). (b) On the postcontrast CT scan, the abscess (A) fails to enhance at all. Surrounding inflamed parenchyma bulges and enhances less than adjacent normal parenchyma. (c) Follow-up CT scan obtained after prolonged antibiotic therapy. The abscess has resolved without drainage. The focal swelling is gone but the parenchyma still shows hypoenhancement. *With permission from Talner.*[45]

fat. Terms coined by radiologists in the 1980s for these changes, such as 'focal' (or 'lobar') nephronia and 'focal' (or 'diffuse') bacterial nephritis, were often confusing to the clinician and were applied inconsistently by different radiologists. The Society of Uroradiology has defined a new uniform terminology according to which all such changes are reported under the umbrella term 'acute pyelonephritis', with modifiers that describe the observed anatomic abnormalities.[45] The extent and severity of such CT findings at the time of presentation are predictive of the clinical course, including the likelihood of bacteremia, progression to abscess formation and death.[47]

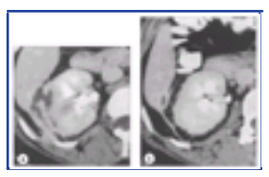

Figure 69-8 Renal abscess perforating into subcapsular and perinephric spaces (woman, 29 years). (a) Postcontrast CT scan. Dumbbell-shaped nonenhancing region laterally in right kidney represents parenchymal abscess breaking through subcapsular and perinephric spaces. Note marked thickening of perinephric fascia posterolaterally. (b) CT section obtained caudal to (a). Note thickening of perinephric inflammation. At this level there is a small pararenal abscess pocket adjacent to the liver. *With permission from Talner.*[45]

Ultrasonography, although commonly used as an initial imaging test for patients who have a suspected focal infectious complication during pyelonephritis, is comparatively insensitive[2] [5] [46] and is often followed by a CT scan irrespective of the ultrasound results. Consequently, it may be best to omit this test and proceed directly to CT. (However, serial directed sonographic examinations can be used subsequently to follow the response of abscesses or hydronephrosis to therapy, without the higher cost and exposure to radiation and contrast material of repeated CT scans.) Single photon emission CT (SPECT) using technetium-99 dimercaptosuccinate (^{99} Tc-DMSA), the newest imaging modality for use in pyelonephritis, is slightly more sensitive than CT for identifying areas of inflammation within the kidney, which can be advantageous if the initial diagnosis is in question.[45] However, it cannot distinguish between frank abscesses and inflamed but viable tissue, and so it is of little help in evaluating the patient who fails to respond to the therapy. Excretory urography and magnetic resonance imaging (MRI) have little role in the management even of complicated pyelonephritis.[2] [5] Nonenhanced spiral CT is more sensitive than excretory urography in detecting urinary calculi, and avoids exposing the patient to contrast material, and so may be the modality of choice (when available) if urolithiasis is a concern (Talner LB, personal communication). Occasionally, antegrade or retrograde ureterography may be indicated, usually when stent placement or calculus removal is needed to relieve obstruction.[46]

MANAGEMENT

In comparison with the treatment of acute cystitis, which has been extensively studied, there have been relatively few large, high-quality treatment trials for acute pyelonephritis on which to base therapeutic recommendations.[43] [48] [49] Much of the prevailing wisdom regarding the treatment of pyelonephritis comes from tradition, anecdotal experience, extrapolation from animal models or pharmacokinetic studies, small clinical trials involving heterogeneous patient populations and in-vitro susceptibility test results. Nonetheless, some guidelines can be suggested for key management issues.

Inpatient versus outpatient and parenteral versus oral therapy

Traditionally, most patients who have pyelonephritis have been hospitalized and given intravenous antimicrobial therapy, at least initially. However,

TABLE 69-1 -- Indications for hospital admission in patients with acute pyelonephritis.

INDICATIONS FOR HOSPITAL ADMISSION IN PATIENTS WITH ACUTE PYELONEPHRITIS	
Indication	**Rationale**
Severely ill, unstable (1)	Needs close monitoring, aggressive resuscitation
Moderate or severe host compromise	At risk of poor response to therapy, progression to 1
Suspected abscess, obstruction, stone	Needs diagnostic evaluation ± intervention; at risk of progression to 1
Pregnant women*	At risk of progression to 1
Children* , men*	At risk of poor response to therapy, progression to 1
Persistent vomiting (despite antipyretic therapy and intravenous hydration)	Needs iv or im therapy†
No suitable oral therapy available	Needs iv or im therapy†
Unsuitable home situation, unreliable follow-up, or unreliable/noncompliant patient	At risk of progression to 1

* Selected patients with mild illness and suitable home situations may be treated orally as outpatients, with or without a first iv dose in the emergency department or clinic.
†Home parental therapy acceptable (where available) for mildly or moderately ill patients.

evidence is accumulating that oral therapy on an ambulatory basis (with or without initial parenteral treatment and observation in the emergency department or short-stay unit) is acceptable for selected patients who have acute pyelonephritis.[49] [50] [51] [52] Outcomes with oral therapy for otherwise healthy ambulatory patients who are clinically stable and can take medications by mouth have been similar to those obtained with sicker patients given traditional in-hospital parenteral therapy, at a considerable cost saving.[52] Oral therapy has even been used successfully with pregnant women,[53] [54] in whom pyelonephritis has traditionally been considered to require in-hospital management.

Thus, there is no single right answer to the question of the optimal setting for treatment. The management plan must be individualized to the patient, taking into consideration the severity of illness (including the presence of nausea or vomiting), the patient's underlying host status and reliability level, and the availability of a support system at home and a mechanism for medical follow-up (Table 69.1). Women who have uncomplicated pyelonephritis and who are only mildly ill can sometimes be treated successfully from the outset with oral therapy alone (Table 69.2). Moderately ill patients can be can be rehydrated with intravenous fluids (if needed) in the clinic or emergency department, given an initial parenteral dose of antibiotic and observed. If after several hours their condition has failed to improve sufficiently they can be admitted to the hospital for continued parenteral therapy, whereas if they are feeling better and are able to take fluids by mouth they can be discharged to home with an appropriate oral antibiotic regimen (Table 69.2), with close follow-up arranged.

There is no published experience using oral therapy for pyelonephritis in men, children or women who have complicating factors other than pregnancy. Clinical judgment may identify suitable cases even within these populations (e.g. mildly ill patients who have only minor compromising conditions). However, most such patients should be admitted to the hospital initially for parenteral therapy, particularly if they are more than minimally ill.

TABLE 69-2 -- Suggested empiric initial treatment regimens for acute pyelonephritis.[§]

SUGGESTED EMPIRIC INITIAL TREATMENT REGIMENS FOR ACUTE PYELONEPHRITIS		
Modifying circumstances	**Treatment setting**	**Empiric treatment options**
Uncomplicated pyelonephritis		
Mild to moderate illness, no nausea or vomiting	Outpatient therapy acceptable	Oral[*] fluoroquinolone (not in children), TMP-SMX caution[‡] or amoxicillin-clavulanate (co-amoxiclav) caution[‡] for 7–14 days (Co-amoxiclav preferred if Gram-positive cocci present)
Severe illness or possible urosepsis	Hospitalization required	Parenteral[†] fluoroquinolone (not in children), third-generation cephalosporin, gentamicin (± ampicillin or piperacillin), piperacillin-tazobactam, aztreonam or carbapenem, TMP-SMX caution[‡] until patient is better; then oral[*] agent (see above) to complete 14 days of therapy (Initial regimen should include ampicillin or piperacillin if Gram-positive cocci are present)
Complicated pyelonephritis		
Pregnancy, mild illness	Outpatient therapy acceptable	Oral[*] co-amoxiclav, cephalosporin or TMP-SMX caution[‡] for 10–14 days (Co-amoxiclav preferred if Gram-positive cocci present)
Pregnancy with mild to moderate illness	Hospitalization required	Parenteral[†] third-generation cephalosporin, gentamicin (±ampicillin or piperacillin) caution;[‡] piperacillin-tazobactam or TMP-SMX caution[‡] until patient is better; then oral[*] amoxicillin, co-amoxiclav, a cephalosporin or TMP-SMX caution[‡] for 14 days (Initial regimen should include ampicillin or piperacillin if pre-therapy Gram stain shows Gram-positive cocci or no organisms, or is not done
Not pregnant, mild illness, no nausea or vomiting	Outpatient therapy acceptable	Oral[*] fluoroquinolone (not in children) for 10–14 days
Not pregnant with moderate to severe illness or possible urosepsis	Hospitalization required; imaging studies and urologic consultation often needed	Parenteral[†] gentamicin (±ampicillin or piperacillin), fluoroquinolone, third-generation cephalosporin, aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam or carbapenem until patient is better; then oral[*] agent (see above) for 14–21 days (Initial regimen should include ampicillin, piperacillin or a carbapenem if pre-therapy Gram stain shows Gram-positive cocci or no organisms, or is not done
'Uncomplicated' is usually limited to noncompromised, nonpregnant adult women but can include carefully selected men and children who lack compromising conditions and are only mildly ill.		

§ *Adapted with permission from Stamm and Hooton.*[48]

* **Oral regimens:** TMP-SMX, 160mg + 800mg q12h; norfloxacin, 400mg q12h; ciprofloxacin, 500mg q12h; ofloxacin 200–300mg q12h;lomefloxacin 400mg q24h; levofloxacin, 500mg q24h; gatifloxacin, 400mg q24h; amoxicillin 500mg q8h; amoxicillin-clavulanate (co-amoxiclav) 850mg q12h or 500mg q8h; cefpodoxime proxetil, 200mg q12h

‡ **Cautions:** fluoroquinolones (norfloxacin, ciprofloxacin, ofloxacin, gatifloxacin, levofloxacin and lomefloxacin) should not be used in pregnancy or in young children. TMP-SMX, although not approved for use in pregnancy, has been widely used (but should be avoided in the first trimester and near term). TMP-SMX and co-amoxiclav should be used only if susceptibility of urine organism is known or is highly (>95%) likely. Gentamicin should be used with caution in pregnancy because of its possible toxicity to eighth-nerve development in the fetus. The fluoroquinolones norfloxacin and lomefloxacin can only be administered po; ciprofloxacin, gatifloxacin, levofloxacin and ofloxacin can be administered iv or po.

† **Parenteral regimens:** TMP-SMX, 160 + 800mg q12h; ciprofloxacin, 200–400mg q12h; ofloxacin, 200–400mg q12h; levofloxacin, 500mg q24h; gatifloxacin, 400mg q24h; gentamicin, 5mg per kg body weight q24h; ceftriaxone, 1–2g q24h; ampicillin, mezlocillin or piperacillin, 1–2g q6h; imipenem-cilastatin, 250–500mg q8h–q6h; meropenem, 1g q8h; ertapenem, 1g q24h ampicillin-sulbactam, 1.5–3g q6h; ticarcillin-clavulanate, 3.2g q8h–q6h; piperacillin-tazobactam, 3.375g q8h–q6h; aztreonam, 1g q12h–q8h

Antimicrobial regimen

Because urine culture and susceptibility testing takes several days to complete, the initial antimicrobial regimen for acute pyelonephritis is usually selected empirically (from among those agents that have suitable pharmacokinetic characteristics and a good 'track record' in pyelonephritis treatment trials) on the basis of the predicted susceptibility patterns of the expected organisms(s) (Table 69.2).[2] [5] [13] [43] [48] For all patients, activity against 'ordinary' Gram-negative bacilli is essential in the empiric regimen and, for patients who have complicated UTI or recent antimicrobial therapy, Gram-positive organisms and drug-resistant Gram-negative organisms must also be anticipated.

Suitable initial regimens are shown in Table 69.2 , which emphasizes aminoglycosides, fluoroquinolones, third-generation cephalosporins and ß-lactam-ß-lactamase inhibitor combination agents for parenteral use, and trimethoprim-sulfamethoxazole (TMP- SMX), fluoroquinolones and amoxicillin-clavulanate (co-amoxiclav) for oral use. Because of the high prevalence among uropathogens of resistance to ampicillin, other penicillins and first- or second-generation cephalosporins — as well as these agents' adverse pharmacokinetic properties and inconsistent performance in clinical trials[43] [48] — these drugs should be avoided as empiric monotherapy for even mild or uncomplicated pyelonephritis. Emerging resistance to TMP-SMX among uropathogens has diminished this drug's utility in the USA for empiric oral therapy of UTIs, particularly pyelonephritis, since in-vitro resistance is associated with clinical failure rates of more than 50%.[49] [55] Unfortunately, resistance to fluoroquinolones, which have traditionally been regarded as the 'fall-back' option for UTIs due to TMP-SMX-resistant Gram-negative uropathogens, is already quite prevalent in some places.[56] [57] How this will affect future recommendations for empiric therapy of pyelonephritis remains to be seen. Whether oral third-generation cephalosporins should have a role in the empiric therapy of pyelonephritis in outpatients has not been adequately studied.

Antimicrobial regimens can be simplified by using a single agent (there being little rationale for combination therapy except in patients who are thought to have both Gram-positive and Gram-negative pathogens)[58] and by using twice-daily dosing with ciprofloxacin, TMP-SMX and co-amoxiclar, or once-daily dosing with ceftriaxone, levofloxacin, gatifloxaci ertapenem and the aminoglycosides.

Conversion to oral therapy

Patients initially admitted to the hospital for intravenous therapy have traditionally been continued on parenteral therapy until susceptibility results are known. They are then placed on an oral agent selected on the basis of the susceptibility pattern of the urine organism, and are observed in the hospital for an additional 1–2 days to evaluate the success of oral therapy (Table 69.3). This approach leads to unnecessarily prolonged hospital stays in many patients.

TABLE 69-3 -- Criteria for conversion to oral therapy.

CRITERIA FOR CONVERSION TO ORAL THERAPY
Patient no longer severely ill or unstable
Patient taking fluids by mouth; no vomiting; adequate gut function
Suitable oral agent available:
• documented or predicted activity against causative organism(s)
• highly bioavailable
• good 'track record' in UTI therapy
• no contraindication to use (i.e. no history of previous adverse reaction), no drug-drug interactions, no fetal toxicity (pregnant women), no age-related toxicities (e.g. fluoroquinolones in children)

Conversion to oral therapy can be done safely as soon as the initial indications for parenteral therapy have resolved, as evidenced by the success of oral therapy for mildly ill ambulatory patients who have pyelonephritis. When the hospitalized patient is clinically ready for oral therapy before susceptibility results are available, an oral

regimen can be selected empirically, much as is done in the emergency department for patients treated with an oral agent from the outset.[43] [49] [50] In most locales in the USA, the fluoroquinolones are predictably active against *E. coli*. Thus, despite being slightly more expensive than TMP-SMX (which might be the preferred agent for a known susceptible organism), fluoroquinolones can yield a tremendous cost saving if they permit patients to be discharged sooner.

The practice of observing patients who have pyelonephritis in the hospital for 24 hours or longer on oral therapy before discharge is without empiric support. When examined retrospectively this approach was found to detect relapse in only 1% of patients and intolerance of the new oral agent in only 4%.[59] Thus, patients can usually be safely discharged once they have demonstrated tolerance of the first dose of an appropriate oral agent, whether the drug is selected empirically or on the basis of known susceptibility results.

Expected clinical course

Nearly all patients who have pyelonephritis and who will ultimately be cured by antimicrobial therapy alone experience substantial clinical improvement within the first 2 days of therapy, sometimes even after the first liter of intravenous rehydration fluid and before receiving any antimicrobial agent. Patients commonly continue to have fever and flank pain for several days on effective therapy but these manifestations should begin to wane and there should be improvement in the patient's energy level, appetite and sense of well-being. If after 48 hours there is no improvement in any of these parameters, aggressive re-evaluation is required.[2] [5] Possibilities to be considered include a mistaken diagnosis, a mismatch between the urine organism and the selected antimicrobial regimen, and an anatomic complication such as obstruction or abscess. A directed history and physical examination are indicated, as is repeated laboratory testing (including blood cultures and chemistries, urinalysis and urine culture plus Gram stain) and urinary tract imaging studies, beginning with enhanced abdominal CT. In some patients this evaluation will reveal a focal process in need of an invasive procedure, such as drainage of an abscess (see Fig. 69.8) or an obstructed collecting system; in some patients, continued medical therapy (with or without adjustment) will suffice (see Fig. 69.7). Consultation with an infectious diseases specialist and/or a urologic surgeon or interventional radiologist can be extremely helpful in problematic cases to ensure that all relevant options are considered and the appropriate procedures performed.

Complications

Supportive care for patients who develop septic shock, ARDS and multisystem organ failure during pyelonephritis, which is not specific to pyelonephritis, is discussed in Chapter 56 . When infection is present, obstruction to urine flow (e.g. by a stone or tumor) must be relieved, either by removal of the obstruction or by provision of alternative drainage. When possible, removal of urinary calculi from patients who have pyelonephritis is probably best delayed until the bacterial load can be reduced and the patient stabilized with medical therapy. Gas-forming UTIs have traditionally been managed surgically in most instances, often with nephrectomy in cases of emphysematous pyelonephritis (see Fig. 69.3).[60] However, reports of successful medical therapy of gas abscesses[31] and emphysematous pyelonephritis[61] indicate that even in these extreme situations therapy can be individualized.

Intrarenal (see Fig. 69.7) and perinephric (see Fig. 69.8) abscesses have also traditionally been managed with combined medical and surgical therapy.[9] [10] Recent experience with closed (catheter-assisted) drainage or medical therapy alone suggests the possibility of alternative approaches in this setting as well.[10] [62] Small abscesses, especially those occurring in otherwise intact hosts, are most likely to respond to medical therapy, whereas large collections, particularly in compromised hosts or in patients who have severe illness, are likely to require drainage. The cost and morbidity of a drainage procedure must be weighed against the cost and morbidity of the protracted antibiotic therapy that is usually required when abscesses are treated with antibiotics alone.[41] If an abscess is to be drained, the optimal method (open versus closed) depends in part on the anatomy, the host and local expertise. Perinephric abscesses (see Fig. 69.8) have been described as requiring a more aggressive interventional approach than intrarenal abscesses [9] but published experience suggests that drainage is not always needed even here.

Duration of therapy

The optimal duration of therapy for acute pyelonephritis, unlike that for acute cystitis, is largely undefined and remains a source of controversy. [58] As with other aspects of the management of pyelonephritis, because of the highly variable nature of the illness and the host substrate it is probably best to tailor duration of therapy to the individual patient. Clinical trial data demonstrate that 14 days of a traditional sequential regimen that includes an intravenous aminoglycoside initially, followed by oral TMP-SMX or ampicillin, eliminates the initial infection in 100% of women who have moderate or severe uncomplicated pyelonephritis, with no relapses at the 6-week follow-up visit. [63] Thus, courses of therapy longer than 14 days should be unnecessary when similarly potent regimens are used in comparable hosts. In other trials, approximately 90% of patients who had uncomplicated pyelonephritis and were treated for only 5 days with aminoglycosides, third-generation cephalosporins or fluoroquinolones were cured,[58] although some of the 10% failure rate was attributable to relapses with the initial pathogen.[64] Whether there is a real or clinically meaningful difference in success rates between 5–7 days and 10–14 days of therapy for uncomplicated pyelonephritis is unknown. Of note, a recent multicenter randomized clinical trial demonstrated that 7 days of oral ciprofloxacin (with or without an initial intravenous dose) was 96–99% effective for uncomplicated pyelonephritis of mild to moderate severity in ambulatory women.[49] Similarly, 14 days of oral TMP-SMX (with or without an initial intravenous dose of ceftriaxone) was 92–96% effective if the urine organism was susceptible to TMP-SMX.[49] However, these favorable findings are not necessarily applicable to women who have more severe uncomplicated infections or to patients who have complicating factors, for whom longer treatment duration may be preferable. Duration of therapy for abscesses must be individualized, taking into consideration

underlying host status, the nature of the abscess, adequacy of drainage (if undertaken) and response to therapy (both clinical and as revealed by serial imaging studies).

Follow-up

Routine repeat urine cultures are commonly performed during therapy for pyelonephritis to confirm sterilization of the urine but may add little beyond what is apparent from clinical evaluation and possibly from inspection of the urine for pyuria.[65] It is prudent to confirm at least by telephone that patients who are sent out from the emergency department with oral therapy are improving as expected. Whether routine post-therapy clinic visits, urine cultures and urinalyses contribute to favorable outcomes has not been studied. However, as it has been argued that in the setting of uncomplicated acute cystitis these measures are unnecessary,[66] it is possible that the same may be true with pyelonephritis, at least for uncomplicated cases in seemingly reliable and responsible patients. Post-therapy evaluations still are advisable in children, pregnant women[34] and probably also in other compromised hosts.

Urologic evaluation for predisposing conditions

In addition to the management of the acute pyelonephritis episode, in selected patients it is worth searching for an underlying urologic abnormality, as the surgical correction of such an abnormality might prevent future infections. The cost and morbidity of such a search must be weighted against the likelihood of finding a correctable abnormality, the morbidity of the possible corrective procedure itself and the infectious morbidity that can be averted by a successful procedure. In the absence of firm data, opinions differ as to the indications for imaging studies and corrective surgery after pyelonephritis.[66] One approach is to investigate all children and men who develop pyelonephritis, as they are the most likely to have an important correctable abnormality. Women probably should be studied if they have a second (same-strain) relapse of pyelonephritis despite an extended course of appropriate antimicrobial therapy for a first relapse. Whether women who have multiple episodes of pyelonephritis caused by diverse organisms will benefit from urologic investigation is unknown.

SUMMARY

Acute pyelonephritis is a diverse entity that challenges the clinician to intervene sufficiently but not excessively, and for which the management approach must be tailored to the individual patient. New developments in the field, such as the use of at-home oral therapy, shorter treatment courses, single-daily-dose intravenous aminoglycoside or ceftriaxone therapy and early hospital discharge provide opportunities for cost savings and enhanced patient convenience. Alertness is required to anticipate and detect complications in high-risk patients or in those who fail to respond to treatment as expected. Intrarenal and perinephric abscesses, gas-forming renal infections and infections superimposed on urinary obstruction are potentially lethal processes that require aggressive therapy, often including mechanical intervention.

Chapter 70 - Complicated Urinary Infection, Including Postsurgical and Catheter-related Infections

Lindsay E Nicolle

INTRODUCTION

The focus of this chapter is the group of urinary tract infections (UTIs) that is generally designated as 'complicated UTI'. This includes UTIs following urologic surgery. Infections associated with urinary catheterization, including intermittent catheterization and both short-term (<30 days) and long-term (>30 days) indwelling catheters, are also discussed.

EPIDEMIOLOGY

Urinary tract infection is the most common bacterial infection in adults. In the setting of structural or functional abnormalities of the genitourinary tract or after urologic interventions, its frequency may be exceptionally high (Table 70.1). For instance, for patients undergoing transurethral procedures with instrumentation or transurethral prostatectomy, the incidence of postintervention urinary infections is substantial for patients who do not receive antimicrobial prophylaxis.

Infection incidence on a population basis has not been reported. In a review of hospitalizations for acute pyelonephritis in Manitoba for 1989–92, [2] the total rate of admissions was 11 per 10,000 population for women and 3.3 per 10,000 for men. Of these, 34% of patients admitted to two tertiary care hospitals with pyelonephritis had complicating genitourinary factors. Of patients admitted to hospital for UTI other than pyelonephritis, 84% of subjects at one institution and 36% at a second had complicating factors.[7]

The urinary tract is also the most common source of infection in elderly individuals hospitalized with bacteremia and is responsible for about one-third of such bacteremic episodes. Most of these bacteremic elderly individuals have abnormalities of the urinary tract, primarily obstructing lesions and indwelling catheters.[8]

TABLE 70-1 -- Infection rates after genitourinary surgery, extracorporeal shock wave lithotripsy or catheterization.

INFECTION RATES AFTER GENITOURINARY SURGERY, EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY OR CATHETERIZATION	
Procedure	**Proportion infected postprocedure**
Genitourinary surgery	
Transurethral prostatectomy[1]	6–64%
Transurethral procedure with instrumentation for stone extraction [2]	25%
Extracorporeal shock wave lithotripsy (ESWL) [3]	
Negative urine culture before ESWL	1.5%
Positive urine culture before ESWL	21%
Sepsis	4.5%
Catheterization	
Urodynamic studies[4]	1.5–36%
Indwelling catheter[5]	5% per day
Intermittent catheterization[6]	4.06/100 patient days

Urinary tract infection is the most frequent hospital-acquired infection and is almost always associated with indwelling catheters. It accounts for 40% of all nosocomial infections and occurs at a rate of approximately 2 per 100 patient discharges. The catheterized urinary tract is the most frequent source of nosocomial Gram-negative rod bacteremia.[5] With short-term catheterization, acquisition of infection approaches 5% of exposed subjects per day.

Approximately 5% of individuals resident in long-term care facilities in North America have a chronic indwelling catheter. The prevalence of bacteriuria in these subjects is 100%.

Intermittent catheterization is also associated with a high frequency of infection. For individuals who have neurogenic bladders managed by intermittent catheterization, the reported rates of infection are 4.06 per 100 patient days[6] or 17.2 per patient year.[9]

Most catheter-associated infections are asymptomatic, but symptomatic infection, including bacteremia, sepsis syndrome and death, may occur. Although bacteremia occurs in only 2–4% of patients who have catheter-acquired UTI, the high frequency of indwelling catheter use means that the absolute number of episodes of bacteremia secondary to catheter-acquired UTI is high.

PATHOGENESIS

Risk factors

The normal genitourinary tract, apart from the distal urethra, is sterile. The usual colonizing flora of the distal urethra include *Staphylococcus epidermidis*, diphtheroids, streptococci and certain anaerobes. These organisms are rarely uropathogens. The sterility of the urine and genitourinary tract is primarily maintained through the flushing action of voiding of urine.

Obstruction to normal urine flow overwhelms all other factors in promoting infection. Other contributing factors to the development of UTI include the concentration and chemical composition of the urine, the bladder mucus layer and Tamm-Horsfall protein excreted from the kidneys. However, in complicated UTI, including postsurgical infection and catheter-related infections, the major factor contributing to the initiation and persistence of bacteriuria is an impaired ability to flush organisms from the urinary tract. This may be due to either:

- obstruction to urine flow with a pool of urine remaining in the urinary tract after voiding; or
- the presence of a protected environment, such as an infection stone or a bacterial biofilm on a catheter, from which organisms cannot be eradicated by usual antimicrobial therapy.

Many genitourinary abnormalities are associated with an increased incidence of UTI (Table 70.2). These are congenital or acquired functional, structural or metabolic abnormalities. The abnormality may be transient, for instance presence of a noninfected stone, a cystoscopy procedure or short-term catheterization. In this situation, the increased risk of UTI will resolve once the abnormality is corrected. If the abnormality cannot be corrected, as in a patient who has an ileal conduit or with a neurogenic bladder maintained on intermittent catheterization, there is a continued risk of recurrent UTI.

TABLE 70-2 -- Genitourinary abnormalities associated with an increased frequency of urinary tract infection.

GENITOURINARY ABNORMALITIES ASSOCIATED WITH AN INCREASED FREQUENCY OF UTI	
Type of lesion	**Examples**
Obstructing lesion	Tumor, stricture, urolithiasis, prostatic hypertrophy, diverticulum, pelvicalyceal junction obstruction, congenital abnormality, renal cysts
Foreign body	Indwelling catheter, ureteric stent, nephrostomy tube
Functional abnormality	Neurogenic bladder, vesicoureteral reflux
Metabolic illness	Diabetes mellitus, medullary sponge kidney, post renal transplantation
Urinary instrumentation and urologic surgery	Prostatectomy, cystoscopy
Urinary diversion	Ileal conduit

Where UTI occurs in a patient who has an indwelling urethral catheter, the organisms may have gained access to the bladder by two routes:

- ascending the mucous sheath from the periurethral area on the outside of the catheter; or
- intraluminally by ascension up the catheter.[10]

The intraluminal route appears to be more important in men than in women, in whom a shorter urethra probably facilitates extraluminal ascent.

When infection occurs in the presence of a foreign body in the genitourinary tract, such as a ureteral stent, nephrostomy tube or indwelling catheter, a bacterial biofilm usually forms on the inert material.[11] A biofilm is an adherent colony of organisms with individual organisms encased in copious extracellular matrix. This biofilm provides a relatively protected environment for the bacteria by interfering with the diffusion of antibiotics and host defenses and so contributing to relapsing infection.

Urinary tract infection may also be acquired in urologic practice as a result of organism transmission between patients on inappropriately cleaned diagnostic or therapeutic equipment.[12] In particular, contamination is a risk where instruments are not appropriately changed or cleaned between patients and where fluid is left standing for prolonged periods at room temperature. Multipatient use of urometers or urine collecting devices has also been repeatedly identified as a cause of nosocomial outbreaks of infection.[13]

MICROBIOLOGY

The spectrum of micro-organisms isolated from individuals who have complicated UTI is more varied than observed in patients who have uncomplicated UTI. Table 70.3 summarizes the organisms isolated in a number of studies of complicated UTI. Although *Escherichia coli* remains an important infecting organism, the frequency with which it is isolated is substantially lower than that reported for acute uncomplicated UTI. *Escherichia coli* has unique virulence characteristics, which promote symptomatic infection in the person with a normal genitourinary tract (see Chapter 67). Where abnormalities of the genitourinary tract bypass the important non-specific host resistance provided by complete voiding, organisms that do not possess unique virulence properties may also become important uropathogens. Therefore, there is a lower prevalence of genotypic or phenotypic expression of virulence factors by *E. coli* isolated from individuals who have complicated genitourinary infection than by *E. coli* isolated from acute uncomplicated UTI.[18]

TABLE 70-3 -- **Bacteria isolated in complicated urinary tract infection.** Shown is the frequency of isolation of different bacterial species.[14] [15] [16] [17]

BACTERIA ISOLATED IN COMPLICATED UTI	
Organism	**Proportion of total organisms isolated (%)**
Gram-negative organisms	
Escherichia coli	21–54
Klebsiella pneumoniae	1.9–17
Citrobacter spp.	4.7–6.1
Enterobacter spp.	1.9–10
Proteus mirabilis	0.9–10
Providencia spp.	1.9
Pseudomonas aeruginosa	2.0–19
Other Gram-negative organisms	6.1–23
Gram-positive organisms	
Enterococci	6.1–23
Coagulase-negative staphyloccoci	1.3–3.7
Staphylococcus aureus	0.9–2.0
Group B streptococci	1.2–3.5
Other Gram-positive organisms	1.9

A wide variety of bacterial species other than *E. coli* is isolated in UTI. The distribution of organisms is determined by factors such as:

- whether organisms are isolated from initial or recurrent infection;
- whether acquisition is nosocomial- or community-acquired; and
- previous antimicrobial exposure.

Common organisms include Enterobacteriaceae such as *Klebsiella, Citrobacter, Serratia, Proteus* and *Providencia* spp., other Gram-negative organisms such as *Pseudomonas aeruginosa* and other nonfermenters, and Gram-positive organisms such as *Enterococcus faecalis* and group B streptococci. Coagulase-negative staphylococci are frequently isolated, although rarely in symptomatic infection, and their pathogenicity is seldom clear. Yeasts, primarily *Candida* spp., may be isolated, usually in individuals who have had prolonged or repeated courses of antimicrobial drugs.[18A] Anaerobic organisms are isolated rarely, and then in the setting of highly complicated urologic abnormalities and abscess formation in the urinary tract.

The urease-producing organisms, principally *Proteus mirabilis, Providencia stuartii* and *Morganella morganii,* are important pathogens. Rarely, more unusual urease-producing organisms such as *Ureaplasma urealyticum* or *Corynebacterium* D2 may be isolated. These organisms maintain an alkaline environment, promoting persistence of infection and leading to the formation of struvite stones or catheter encrustation.

In addition to the much wider variety of infecting species in complicated UTI compared with uncomplicated UTI, there is also increased antimicrobial resistance among the infecting bacteria. Some of the infecting organisms, such as *P. aeruginosa*, are intrinsically more resistant to antimicrobials. Increased resistance is also promoted

by:

- repeated antimicrobial courses for previous UTI; and
- the high frequency of nosocomial infection.

PREVENTION

General measures

Urinary tract infection in the abnormal genitourinary tract occurs because of the presence of an underlying abnormality or intervention that breaches normal defenses and allows the introduction and persistence of micro-organisms. Therefore the most important interventions to prevent UTI are:

- to identify and, wherever possible, correct underlying abnormalities; and
- to avoid nonessential interventional procedures.

It is important to follow the appropriate aseptic technique for interventional procedures such as cystoscopy or urodynamic studies and for operative procedures. All fluids used in urologic procedures must be handled in a manner that ensures sterility. In particular, equipment must be disassembled after a procedure and reassembled using sterile components before the next procedure, and aseptic technique must be maintained. [12]

Institutions should establish and maintain appropriate infection surveillance programs to ensure that endemic infection rates are known and to facilitate early identification of potential outbreaks.

Catheter-acquired infection

The frequency of catheter-associated UTI in institutional settings has led to extensive study of specific interventions to prevent catheter-acquired infection (Table 70.4).[5] [10] The single most important practice in preventing infection in the catheterized patient is to maintain a closed urinary drainage system. In addition, use of an aseptic technique at insertion is important. Patients who have indwelling catheters who receive antimicrobial therapy have a decreased incidence of infection acquisition during the initial 4 days of catheterization compared with patients who do not receive antimicrobials. After the first 4 days, the infection rates are similar, but patients receiving antimicrobials develop infection with more resistant organisms. Therefore, antimicrobial therapy to prevent infection when an indwelling catheter is in situ is currently not recommended.

TABLE 70-4 -- Interventions to prevent catheter-acquired bacteriuria.[5] [10]

INTERVENTIONS TO PREVENT CATHETER-ACQUIRED BACTERIURIA	
Proven effective	Avoid use of catheter
	Limit duration of catheterization
	Aseptic insertion
	Maintain closed drainage system
	Antibiotics first 4 days (not recommended)
Possibly effective	Antibiotics last 48h of catheterization
	Antimicrobial decontamination of gut
Proven not effective	Daily meatal care with soap or antiseptic
	Disinfectant (formaldehyde, chlorhexidine, hydrogen peroxide) in drainage bag
	Silver-coated catheters
	Continuous antibiotic or antiseptic irrigation

TABLE 70-5 -- Prophylactic antimicrobial therapy in genitourinary surgery to prevent postoperative urinary tract infection.

PROPHYLACTIC ANTIMICROBIAL THERAPY IN GENITOURINARY SURGERY TO PREVENT POSTOPERATIVE UTI			
Procedure	**Regimen**	**Infection rate with prophylaxis (%)**	**Infection rate without prophylaxis (%)**
Transurethral instrumentation			
UTI with stone extraction[2]	Cefotaxime 1 g iv, one dose	8.5	25
Sepsis[20]	Cefotaxime 1 g iv, one dose	0	6.2
Prostatectomy			
Sterile urine preoperatively[22]	Various	3–22	6–70
Preoperative bacteriuria[22]	Various	35–41	65–92
Renal transplantation[23]	Trimethoprim-sulfamethoxazole 160mg–800mg daily for 4 months	8	35

Repeated evaluations of interventions using topical or local anti-infectives to prevent infection associated with indwelling catheters have consistently documented no benefit.[5] For instance, daily perineal cleansing with either soap or disinfectant does not decrease and may increase the rate of infection. Other measures that do not decrease the frequency of infection are the addition of disinfectants such as povidone-iodine or chlorhexidine to the drainage bag, the use of catheters impregnated with antimicrobial agents such as silver, and routine irrigation with normal saline. It is, in fact, remarkable how consistently local anti-infective measures have failed to modify the occurrence of catheter-acquired infection.

The use of antimicrobials for preventing infection in patients who have spinal cord injury and who are maintained on intermittent catheterization has also been controversial. Clinical studies report prevention of both asymptomatic and symptomatic infection in the early postinjury months, but at the cost of increased antimicrobial resistance when infection occurs. Prophylactic therapy in the long term is probably not effective. Therefore, prophylactic antimicrobials are currently not recommended for such patients.[19]

Postoperative infection

The perioperative use of antimicrobials encompasses two issues:

- treatment of pre-existing bacteriuria to prevent the complications of invasive infection; and
- prophylaxis to prevent postoperative infection in individuals without positive pre-intervention urine cultures.

Treatment of bacteriuria preoperatively in individuals undergoing genitourinary interventions is indicated to prevent postoperative bacteremia and sepsis. Postoperative

sepsis was reduced from 6.2% to zero in patients whose urine was infected preoperatively when appropriate antimicrobials were given 2–12 hours before operation.[20] The use of preoperative antimicrobials in this situation is most appropriately considered as therapy for UTI rather than prophylaxis, although it is prophylaxis for invasive infection. Antimicrobial therapy should be selected on the basis of the infecting organism and antimicrobial susceptibilities and initiated at least 1 hour before surgery.

There are some indications for the use of true prophylactic therapy in urologic surgery.[21] A summary of these indications is provided in Table 70.5 , with some reported rates of infection observed when selected prophylactic regimens are used. Most authorities[21] [22] now suggest that antimicrobial prophylaxis is appropriate for transurethral prostatectomy even if the pre-procedure urine culture is negative, although this recommendation was controversial in the past.[24]

There is no generally accepted 'standard' antimicrobial regimen for prophylaxis. Many different antimicrobials have been used.

Generally, an aminoglycoside, with or without a cephalosporin, or a fluoroquinolone is used. Studies have documented the efficacy of second- and third-generation cephalosporins, including cefotaxime, ceftriaxone, cefotetan, cefoxitin and ceftazidime, as well as fluoroquinolones. It is not clear, however, that these agents are superior to less costly alternatives such as aminoglycosides and trimethoprim-sulfamethoxazole.

The recommended dosing regimen is one dose 1–2 hours preoperatively. The appropriate duration of antimicrobial therapy has not been defined. If an indwelling catheter remains in situ postoperatively some authors recommend continuation of antibiotics until the catheter is removed. However, recent studies suggest that, at least for some agents, a single dose is as effective as multidose therapy.[25] [26] The shortest effective duration of therapy is preferred to limit cost, adverse effects and the emergence of antimicrobial-resistant organisms.

CLINICAL FEATURES

The clinical presentation of complicated UTI varies along a spectrum from asymptomatic bacteriuria without a measurable host response to septic shock and death.

In many clinical situations where chronic or recurring infection is anticipated, such as a patient with a chronic indwelling catheter or the individual who has a neurogenic bladder and is maintained on intermittent catheterization, asymptomatic bacteriuria is the most common presentation. When symptomatic infection occurs the clinical features are those usually observed with a lower UTI such as frequency, suprapubic discomfort, dysuria and urgency.

With renal infection the characteristic presentation of upper UTI infection, including fever and costovertebral angle tenderness, is observed.

Obstruction and trauma to the genitourinary mucosa at any site predispose to bacteremia and more severe infection. Other contributing factors in determining the clinical presentation for a given infectious episode have not been well studied.

Infection may occasionally present as a high fever without any localizing findings, particularly in individuals who have indwelling catheters or neurologic impairment. Therefore, the clinical presentation may suggest a urinary source of infection or be non-specific. A diagnosis of UTI in the febrile patient who has a positive urine culture and no localizing findings must, however, be viewed critically. In populations with a high prevalence of asymptomatic bacteriuria the majority of such episodes are not due to UTI.[27]

Infection may be localized to the bladder or may involve the upper tract or kidney. In addition, in males, bladder infection may be secondary to or lead to prostatic infection. Presenting clinical symptoms are generally unhelpful in localizing the site of infection unless renal or prostatic tenderness can be demonstrated. Infection may manifest with lower UTI irritative symptoms alone despite the presence of upper tract or renal infection. In individuals with uncomplicated UTI, fever is a reliable localizing symptom for upper UTI. This is not the case for complicated and postsurgical infection or infection in the presence of an indwelling catheter. In these cases trauma to the bladder mucosa can result in invasive infection and fever associated with lower UTI alone. In most cases, however, treatment decisions will not depend upon knowledge of the site of infection within the urinary tract.

Presentation in selected patient groups

Selected patient groups may demonstrate some variation in presentation.

For patients who have a spinal cord injury and a neurogenic bladder, the clinical presentation may differ from the usual irritative lower tract symptoms because of absent or altered sensation associated with the neurologic injury.[19] Signs and symptoms suggestive of UTI, in addition to fever, kidney pain or tenderness and bladder discomfort, may include a new onset of or increase in urinary incontinence, autonomic hyperreflexia, increased sweating, increased spasticity, cloudy or malodorous urine, and a general sense of being unwell.

In patients who have undergone renal transplantation, symptoms and signs may be absent or mild in the early post-transplant period, despite the presence of bacteremia. This lack of symptoms may be due to immunosuppressive therapy or uremia.

Occasionally, symptoms of the underlying genitourinary abnormality may be prominent. For instance, if a UTI occurs in the setting of a ureteral stone, symptoms of renal colic may predominate, and the bacteriuric patient who has diabetes mellitus and papillary necrosis may have prominent symptoms of renal colic. A man who has acute bacterial prostatitis may have prominent symptoms of urethral obstruction and even retention.

Presentation with specific infecting organisms

Infection by selected organisms may also produce a unique clinical presentation. *Corynebacterium* D2 infection is associated with the clinical syndrome of encrusted cystitis. This is encrustation of the bladder wall by struvite due to the urease production of the organism. Infections with Enterobacteriaceae, usually *E. coli* and *Klebsiella pneumoniae*, in patients who have diabetes mellitus and hyperglycemia and glycosuria may present as emphysematous cystitis or pyelonephritis. If a persistent fungal infection is identified, there may be a fungus ball in the bladder or kidney associated with obstruction.

Recurrent infection after antimicrobial therapy

Early recurrent infection after antimicrobial therapy is a characteristic clinical feature of individuals with persistent genitourinary abnormalities. It may be symptomatic or asymptomatic and may represent:

- relapse with recurrence of the pre-therapy infecting organism after therapy; or
- re-infection with a new organism.

Selected reports that document this high frequency of recurrent infection are summarized in Table 70.6 . Bacteriologic cure rates at 4–6 weeks (long-term follow-up) are consistently less than 50% (i.e. recurrent infection is the expected outcome). If the underlying abnormality

TABLE 70-6 -- Bacteriologic outcome after antimicrobial therapy of complicated urinary tract infection. NS, not stated.

BACTERIOLOGIC OUTCOME AFTER ANTIMICROBIAL THERAPY OF COMPLICATED UTI			
Regimen	**Follow-up after therapy**	**Cure (%)**	**Re-infection (%)**
Complicated urinary infection			
Lomefloxacin[15]	5–9 days	59	5.9
	4–6 weeks	43	19
Trimethoprim-sulfamethoxazole[15]	5–9 days	33	1.5
	4–6 weeks	28	9.2
UTI secondary to spinal cord injury			

Norfloxacin 14 days[28]	5–7 days	53	14
	8–12 weeks	16	NS
Varied 7–14 days[29]	1 week	47	NS
Varied =28 days[29]	1 week	41	NS

is transient or reversible, such as a single obstructing stone that is passed, permanent or long-term cure may, however, be achieved. If the underlying abnormality promoting infection cannot be corrected, recurrent infection with organisms of increasing antimicrobial resistance is a common outcome. Some patients may ultimately have infections for years with very resistant organisms such as *Pseudomonas* spp.

DIAGNOSIS

Clinical symptoms alone are not sufficient for a diagnosis of complicated UTI. For definitive diagnosis an appropriately collected urine specimen must be obtained for bacterial culture. The large variety of potential infecting organisms and the high likelihood of antimicrobial resistance in infecting organisms mean that a urine culture is essential for appropriate antimicrobial management of patients who have complicated UTI. The urine specimen must be collected before initiating antimicrobial therapy, using a urine collection method that limits contamination. A clean-catch voided specimen or, if a voided specimen cannot be obtained, a specimen obtained through in and out catheterization, is usually appropriate. For individuals who have indwelling catheters, urine is collected by aseptic aspiration from the catheter port. Specimens may also be obtained by ureteric catheterization or percutaneous aspiration of the renal pelvis but these invasive procedures are not recommended unless there is obstruction. There is no completely satisfactory way of collecting specimens for culture from people who have an ileal conduit. Specimens collected through the conduit will be contaminated with organisms colonizing the conduit.

Foreign material in the urinary tract, including indwelling urethral catheters, ureteric stents and nephrostomy tubes, are rapidly coated with a bacterial biofilm after insertion. Organisms isolated from urine specimens for culture obtained through such devices may be more representative of the microbiology of the biofilm on the inner surface of the catheter rather than of bladder urine. Therefore, it has been suggested that indwelling catheters should be changed before specimen collection and initiation of antimicrobial therapy.[10] The urine specimen is collected through the newly inserted catheter, which is free of biofilm, and is representative of bladder bacteriuria with a more reliable identification of the bacterial species responsible for symptoms.

Urine specimens should be forwarded promptly to the laboratory for semiquantitative culture and appropriate susceptibility testing. Blood cultures should also be obtained from patients who have evidence of sepsis, including fever, rigors, hypothermia and confusion, and from early post-transplant patients who may be significantly immunosuppressed.

TABLE 70-7 -- Quantitative bacteriology in the diagnosis of complicated urinary tract infection.

QUANTITATIVE BACTERIOLOGY IN THE DIAGNOSIS OF COMPLICATED UTI	
Clinical presentation	**Bacteriologic count**
Asymptomatic bacteriuria	=10^5 cfu/ml in two consecutive urine specimens
Symptomatic urinary infection	=10^4 cfu/ml in one specimen or =10^5 cfu/ml if collected by external catheter
Percutaneous aspiration in hydronephrosis	Any quantitative count
Diuresis, diuretic therapy, renal failure, selected infecting organisms (e.g. *Candida albicans*)	Lower quantitative counts (<10^5 /ml) may occur in these situations

Quantitative bacteriology

Current recommendations for quantitative bacteriology in the diagnosis of complicated UTI are provided in Table 70.7 . In the symptomatic patient, UTI may be diagnosed if the quantitative count of organisms in urine culture is 10^4 cfu/ml or more and there are symptoms consistent with genitourinary infection. For individuals who are asymptomatic, two specimens with a quantitative count of 10^5 cfu/ml or more with the same organism(s) isolated on two consecutive occasions are necessary for diagnosis. [30]

Infections usually involve a single infecting organism but there may be more than one bacterial species in the urine of patients who have frequent recurrent infections. In the patient who has a long-term indwelling catheter, isolation of two to five organisms is the norm.[5] In the presence of an indwelling catheter, small numbers of micro-organisms will usually increase to 10^5 cfu/ml or more in less than 24 hours and, therefore, any quantitative count may be significant.[31]

Rarely, less common organisms, such as yeast species, may not produce the usual quantitative counts. Unusual uropathogens such as *Mycoplasma hominis* or *Haemophilus influenzae*, which rarely cause infection, will not be isolated by routine laboratory methods for urine culture. Urine cultures may also be negative with symptomatic infection if the patient has had previous antimicrobial therapy or there is complete ureteric obstruction with infection localized proximal to the obstruction.

Pyuria

The presence of pyuria in a urine specimen may be useful in the diagnosis of UTI, but may be misleading. Pyuria reflects inflammation within the urinary tract, which is not necessarily caused by infection. Pyuria by itself is not sufficient to diagnose a UTI in the absence of a positive urine culture. Most UTIs have associated pyuria, but underlying abnormalities associated with complicated UTI, inflammation following a surgical procedure, or a chronic indwelling catheter may be associated with pyuria in the absence of infection. Pyuria does not discriminate between symptomatic and asymptomatic infection. Therefore, a dipstick test or urinalysis that shows evidence of pyuria is consistent with but not diagnostic of UTI.

MANAGEMENT

Essential elements in approaching the management of UTI in the setting of an abnormal genitourinary tract include:

- initial clinical evaluation and appropriate diagnostic specimen collection;
- initial antimicrobial therapy;
- appropriate supportive therapy;
- a review of urine bacteriology to ensure that the optimal antimicrobial regimen has been given; and
- an assessment of the need for genitourinary investigation and appropriate interventions to correct any abnormality.

Antimicrobial therapy

The empiric use of antimicrobials in this group of patients, who have a high likelihood of recurrent infection, will promote the emergence of organisms with increased antimicrobial resistance. Whenever possible, empiric therapy should be avoided and antimicrobial therapy should be specific for the infecting organism(s) identified in urine culture. This is frequently possible if the patient has mild symptoms. If the patient's symptoms are severe enough to warrant empiric therapy before the final culture results are available, a urine specimen for culture must be obtained before initiating therapy, and the antimicrobial therapy should be re-evaluated when the culture and susceptibility testing results are available, usually between 48 and 72 hours later.

TABLE 70-8 -- Oral therapeutic regimens for the treatment of complicated urinary tract infection.

ORAL THERAPEUTIC REGIMENS FOR THE TREATMENT OF COMPLICATED UTI	
Agent	**Dose**
Amoxicillin	500mg q8h
Amoxicillin-clavulanate	500mg q8h
Cephalexin	500mg q6h
Cefixime	500mg q24h
Nitrofurantoin	50mg q6h
Nitrofurantoin macrocrystals	100mg q6h
Norfloxacin	400mg q12h
Ciprofloxacin	250–500mg q12h
Ofloxacin	400mg/day or 200mg q12h
Lomefloxacin	400mg/day
Enoxacin	200mg q12h
Fleroxacin	400mg/day
Gatifloxacin	400mg q24h
Trimethoprim	100mg q12h
Trimethoprim-sulfamethoxazole	160mg trimethoprim-800mg sulfamethoxazole q12h

TABLE 70-9 -- Parenteral regimens for the treatment of complicated urinary tract infection.

PARENTERAL REGIMENS FOR THE TREATMENT OF COMPLICATED UTI	
Agent	**Dose**
Ampicillin	1g q6h
Piperacillin	3g q6h
Ticarcillin-clavulanate	3.1g q6h
Pipericillin-tazobactam	4g pipericillin-500mg tazobactam q8h
Cefazolin	1–2g q8h
Cefotaxime	1g q8h
Ceftriaxone	1g q24h
Ceftazidime	1g q8-12h
Imipenem	500mg q6h
Gentamicin	5mg/kg/day q12h or q24h
Tobramycin	5mg/kg/day q12h or q24h
Amikacin	15mg/kg/day q12h or q24h
Trimethoprim-sulfamethoxazole	160mg trimethoprim-800mg sulfamethoxazole q12h
Ciprofloxacin	400mg q12h
Ofloxacin	400mg q12h
Fleroxacin	400mg/day
Gatifloxacin	400mg/day

The antimicrobial agents appropriate for therapy are similar to those used in the treatment of acute uncomplicated UTI or acute nonobstructive pyelonephritis (Table 70.8 & Table 70.9). Initial parenteral therapy is preferred for individuals who have:

- hemodynamic instability;
- nausea and vomiting;
- questionable absorption of oral antimicrobials; or
- an infection by suspected resistant organisms for which oral therapy is not available.

In other situations, oral therapy can usually be initiated. The majority of patients can be managed without hospitalization or with a limited (24–72h) admission to a short stay unit for initial parenteral therapy. Oral therapy is then started as soon as the patient is stable, often when pre-therapy urine culture results are available to assist in selecting the appropriate medication.

The selection of a specific antimicrobial agent is based upon clinical presentation, the known or suspected infecting organism and its susceptibilities, patient tolerance, documented efficacy and, in some cases, cost. Comparative trials of different antimicrobials have not consistently reported that any one antimicrobial agent or class of antimicrobials is better than any other.[32] The selection of optimal antimicrobial therapy is further limited by a relative lack of relevant clinical trials. Although there are many published reports on the treatment of complicated UTI, few are useful in assisting with the selection of an antimicrobial in a specific clinical situation. One problem is the lack of an accepted 'standard' antimicrobial therapy with respect to agent, dose or duration to serve as a comparator for new agents.[30] In addition, studies have generally enrolled diverse and poorly characterized patient populations for whom different outcomes with therapy would be anticipated on the basis of underlying abnormalities. The severity of illness also varies, and subjects are enrolled into studies with clinical presentations ranging from an increase in incontinence or bladder spasms to a life-threatening illness with bacteremia.

In view of the very high frequency of relapse, therapeutic trials should provide both short-term (1 week post-therapy) and long-term (4–6 weeks post-therapy) outcomes.[30] Frequently, studies of therapy for complicated UTI have provided only short-term therapeutic outcomes. The many published studies therefore allow only a limited assessment of the comparative efficacy of different antimicrobials. They do, however, document the effectiveness of a wide variety of antimicrobial agents.

Oral therapy

For oral therapy, the quinolone antimicrobials in particular have been widely studied and promoted. Benefits of fluoroquinolones include a wide antibacterial spectrum and good patient tolerance. Problems include increasing antimicrobial resistance with widespread use of quinoline antimicrobials, and cost.

In studies of therapy for pyelonephritis, likely including some patients who had complicated infection, cell-wall-active agents such as amoxicillin or first-generation cephalosporins appear less effective than non-cell-wall-active agents such as trimethoprim-sulfamethoxazole or quinolones.[33] Appropriate comparative clinical trials have not shown whether these cell-wall-active agents have a lower efficacy for complicated UTI. For Gram-positive organisms such as group B streptococci and *Enterococcus* spp., amoxicillin orally or ampicillin parenterally would, of course, be the treatment of choice. Nitrofurantoin may be used for patients who have lower

tract symptoms. This agent should be avoided in subjects with renal impairment or pyelonephritis, and is not effective for *P. mirabilis* infection.

Parenteral therapy

For parenteral therapy, an aminoglycoside antimicrobial remains the treatment of choice because of the documented efficacy of this group of drugs over many years of use and the likelihood of effectiveness against more resistant organisms. The nephrotoxicity and ototoxicity of aminoglycosides are seldom a problem if the duration of therapy is limited, with an early switch to oral therapy. If *Enterococcus* spp. may be present, ampicillin should be added. The increasing prevalence of ampicillin resistance in *E. faecium* and *E. faecalis* in many institutions means that vancomycin may be necessary to treat nosocomial enterococcal infection. Empiric use of vancomycin is, however, to be discouraged because widespread empiric use will promote the emergence of vancomycin-resistant organisms.

Duration of therapy

Few reported studies have directly addressed the question of the appropriate duration of therapy. The usual recommended duration is

7–14 days.[30] There are selected clinical situations where alternative durations of therapy are appropriate:

- ¦ where relapsing infection is due to a prostate source, 6 or 12 weeks of antimicrobial therapy is appropriate;
- ¦ if symptomatic infection associated with an indwelling catheter is treated while the catheter remains in situ, it is recommended that the duration of therapy is as short as possible, usually 5–7 days, to limit the emergence of resistant organisms; and
- ¦ after successful extracorporeal shock wave lithotripsy for an infected struvite stone, antimicrobial therapy is continued for at least 4 weeks to prevent relapse and sterilize residual stone fragments.

Supportive therapy

This should be given as appropriate. It may include hemodynamic monitoring, parenteral fluids, measurement of urine output and antiemetic medication. If any obstruction in the urinary tract is suspected, urgent ultrasound or computerized tomography scan should be obtained. Immediate drainage may be necessary if an obstruction is identified. If a chronic indwelling catheter is present, catheter replacement prior to initiating antimicrobial therapy is associated with more rapid defervescence and a decreased frequency of symptomatic relapse[11] as well as providing a more accurate urine specimen for culture.

Renal failure

Patients who have abnormalities of the genitourinary tract are more likely to have impaired renal function. Renal function should be determined, if not already known, for patients who present with possible complicated UTI. If there is renal impairment:

- ¦ appropriate modifications in antimicrobial dose are necessary; and
- ¦ nitrofurantoin and tetracyclines other than doxycycline should be avoided.

Some quinolones have been shown to lead to a reversible increase in serum creatinine in renal transplant recipients receiving cyclosporin. Quinolones should be avoided, if possible, in these patients.

In renal failure, renal perfusion is decreased and antimicrobials may not reach infected renal tissue or achieve high urine levels. The aminoglycosides, in particular, may be less effective.[32] The fluoroquinolone antimicrobials, trimethoprim-sulfamethoxazole, trimethoprim and extended-spectrum ß-lactam antimicrobials appear, however, to be effective in treatment of UTI in the presence of significant renal failure. A more prolonged duration of antimicrobial therapy may also be necessary to cure UTI in patients who have renal failure.

An additional potential therapeutic problem is the patient who has normal measured renal function and satisfactory urinary antimicrobial levels but disparate kidney function.[32] If the function of one kidney is severely impaired relative to the other, blood flow is preferentially increased in the functioning kidney and, despite adequate bladder urine antibiotic levels, little antibiotic will be filtered by the poorly functioning kidney. Antimicrobial treatment may then not

TABLE 70-10 -- Treatment regimens for fungal urinary tract infection.[35]

TREATMENT REGIMENS FOR FUNGAL UTI		
Agent	**Dose**	**Cure rate (%)**
Amphotericin B: parenteral	0.3mg/kg single dose or 6mg/kg body weight total dose	75
Amphotericin B: bladder irrigation	Continuous, 50mg/l for 5 days	72–88
Fluconazole	50–400mg/day for 7 days	70–80
5-Flucytosine	50–150mg/kg/day q6h	70

eradicate infection localized to the poorly functioning kidney. This is one potential reason for relapsing infection.

Fungal infection

Treatment of asymptomatic funguria is not beneficial and is not recommended[34] .

Optimal treatment and expected outcomes for symptomatic fungal infection require further study.[35] The current treatment options and reported cure rates are listed in Table 70.10 . Currently recommended treatment for funguria is amphotericin B or fluconazole. Some non-albicans *Candida* spp., particularly *C. krusei* and *C. glabrata*, have decreased susceptibility or are resistant to fluconazole. Comparative trials of fluconazole and amphotericin B and, potentially, other azoles are necessary to understand the relative roles for different agents. Previously, bladder irrigation with amphotericin B has been recommended. This approach, however, is costly and time-consuming and is no longer considered optimal therapy.

If there is symptomatic fungal infection, the presence of a fungus ball in the bladder or kidneys should be excluded by ultrasound examination or other diagnostic imaging.

Suppressive therapy

Suppressive therapy is long-term antimicrobial therapy given to prevent recurrent symptomatic infection in individuals with underlying abnormalities that cannot be corrected (Fig. 70.1). [36] Long-term therapy, such as suppressive therapy, is infrequently indicated and should be used selectively because of the potential for inducing the development of resistant organisms.

Figure 70-1 Nephrocalcinosis complicated by relapsing *Pseudomonas aeruginosa* infection. Plain film of the abdomen showing multiple bilateral renal stones. This 31-year-old woman has had recurrent stone formation since the age of 18 despite dietary manipulation and repeated lithotripsy. Urinary infection with *P. aeruginosa* was identified at 24 years of age with subsequent recurrent episodes of symptomatic upper tract infection. She has been maintained on suppressive ciprofloxacin therapy for years with control of symptomatic infection.

TABLE 70-11 -- Indications for the treatment of asymptomatic bacteriuria.

INDICATIONS FOR THE TREATMENT OF ASYMPTOMATIC BACTERIURIA	
Definite	Before an invasive genitourinary procedure[20]
	Pregnancy[38]
	Infection stone[37]
	Renal transplant[23]
Not indicated	In the elderly[39]
	For a schoolgirl[40]
	Intermittent catheterization[19]
	Indwelling urinary catheter[5]

Suppressive therapy is recommended for the few individuals with a struvite (infection) stone that cannot be completely removed.[37] Prolonged suppressive therapy in this situation will usually prevent further stone enlargement and preserve renal function. If a patient who has an underlying abnormality that cannot be corrected experiences recurrent invasive infection suppressive therapy may prevent symptomatic episodes. Another situation where suppressive therapy may be appropriate is in men who have frequent recurrent episodes of symptomatic urinary infection from a prostatic source when prolonged antimicrobial therapy has failed to cure the infection.

Asymptomatic bacteriuria

Indications for the treatment of asymptomatic UTI remain controversial. Table 70.11 summarizes current recommendations with respect to the treatment of asymptomatic bacteriuria in different patient populations. These recommendations for treatment or nontreatment are based on published studies. Where treatment of asymptomatic bacteriuria is not indicated, therapy has not been shown to decrease morbidity but is associated with a greater frequency of negative outcomes, including the emergence of resistant organisms and adverse drug effects. Studies in children, in fact, suggest that the treatment of asymptomatic bacteriuria may increase the frequency of symptomatic infection. Asymptomatic bacteriuria should not be treated except where clinical studies have demonstrated a benefit. Following from this, screening for bacteriuria is not indicated except in those for whom treatment of asymptomatic bacteriuria is indicated.

INDICATIONS FOR INVESTIGATION

An important aspect of the management of UTIs is determining when to carry out urologic or imaging investigations to determine whether there are abnormalities in the genitourinary tract (see also Chapter 69). Single infections that respond promptly to antimicrobials are unlikely to be associated with significant underlying abnormalities. On other occasions the abnormality may be obvious, such as the presence of an indwelling catheter. In selected other patients, genitourinary investigation should be considered. These clinical scenarios include:

- delayed or incomplete response to appropriate antimicrobial therapy; and
- early recurrence of infection after therapy.

Patients presenting with sepsis and hemodynamic instability may require urgent investigation to identify an abscess or obstruction requiring immediate intervention. Studies that define the relative efficacy of and optimal approach to investigation in selected clinical scenarios are, however, necessary.

Chapter 71 - Tuberculosis of the Urogenital Tract

John David Hinze
Richard E Winn

The most common site for extrapulmonary tuberculosis (TB), next to lymphatic and pleural involvement, is the genitourinary tract.

EPIDEMIOLOGY

The incidence and prevalence of genitourinary TB are still uncertain. A large proportion of patients remain asymptomatic and symptoms that do arise are non-specific and easily attributable to other causes.[1] [2] The incidence of genitourinary TB has fallen over the past century, but at a slower rate than the decline of pulmonary TB. Extrapulmonary TB accounted for 22% of all TB cases in the USA in 1992.[3] When expressed as a proportion of extrapulmonary cases, genitourinary TB accounted for 18%.[4] Genitourinary TB varies from 1.3% of all TB cases in Europe[5] and less than 2% in the USA[6] to over 20% in developing countries.[6] [7] [8]

Most cases occur in sexually active adults aged 20–69 years. There is a male:female predominance of 2:1. The presence of TB at any site makes it mandatory to search for involvement at other sites.

PATHOGENESIS AND PATHOLOGY

Nearly all cases of genitourinary TB are caused by *Mycobacterium tuberculosis*. Renal infection with *M. tuberculosis* begins from hematogenous seeding of the renal cortex from a pulmonary source. Either primary or reactivated pulmonary TB infection, which may or may not be clinically apparent,[9] may seed the capillaries of the renal cortices. Other extrapulmonary sites should not, however, be excluded as potential sources. Infection has occurred in a native polycystic kidney after renal transplantation. [10] Given the high cardiac output delivered (20%) and therefore increased oxygen tension of the renal cortex, it is easy to understand the predilection of *M. tuberculosis* for the kidney among extrapulmonary sites. The vast majority of genitourinary TB cases involve the kidney bilaterally and may result in acute renal failure[11] but progression of disease is almost uniformly unilateral.

Once important, *Mycobacterium bovis* from cattle was transmitted via ingestion of infected cow's milk and caused gastrointestinal TB with the potential to spread to the genitourinary tract.

Mycobacterium kansasii and *M. avium-intracellulare* have been cultured from the urine of immunocompromised persons (i.e. AIDS patients), but these cases are rare. *Mycobacterium avium-intracellulare* in the urine is of uncertain clinical significance.

Once infected, host immune status determines the extent of destruction. Macrophages attracted to the site halt the progress of the tubercle bacilli, leading to necrosis and eventual granuloma formation. In an immunocompetent individual, tubercle bacilli are isolated and contained and may ultimately be killed by cellular enzymes. However, a less vigorous response by the host's immune system may not kill all the bacilli and these microscopic foci may remain dormant for decades. Later, if the host's cellular immunity becomes compromised secondary to age, malnutrition, diabetes mellitus, malignancy, corticosteroid use or chronic debilitating disease, reactivation TB may ensue. At this point, as infection spreads from the renal cortex, granuloma formation and subsequent necrosis advance with infection of the medulla and papilla (Fig. 71.1). As these foci coalesce, they form macroscopic cavitary lesions of caseation necrosis (Fig 71.2 and Fig 71.3).[6] [12] Infective debris can both infect and obstruct the calyces, ureters and bladder. Calyceal involvement by ulcerative and deforming lesions (Fig. 71.4) is responsible for many of the radiographic manifestations seen in genitourinary TB (Fig. 71.5). [6] If severe calyceal clubbing occurs with dilatation of the renal pelvis and ureters, then total destruction of the kidney ensues, termed 'autonephrectomy'.[13] Ureteral and bladder disease are secondary to renal involvement. During all stages of renal infection, tuberculous bacilluria is responsible for ureteral and bladder involvement, prostatitis and epididymitis. [14]

In men, urologic spread of renal foci will infect, in descending order of frequency, the prostate, seminal vesicles, epididymis and testes.[15] However, genital TB without renal involvement does occur, suggesting bacillemic spread. In addition, TB of the prostate, epididymis and glans penis can occur with conjugal contact. Primary TB of the glans penis is extremely rare, with about 150 cases reported[16] and, although transmission may be secondary to hematogenous dissemination, local direct sexual contact is most probable.

In women, as in men, genital TB is almost always hematogenous in origin. Direct spread from an intra-abdominal or intraperitoneal source is possible but genitourinary TB may also be part of a miliary process. The fallopian tubes are involved in 90% of cases[17] and chronic salpingitis is the most common manifestation. Fallopian TB is predominantly bilateral with a predilection for the ampullae.[18] From there the bacilli spread, in descending order, to the endometrium in 50–70% of cases, the ovaries in 30% and cervix in 5–15%; vaginal and vulvar disease are rare. [6] [19] [20]

In tuberculous endometritis, the typical lesion is the noncaseating granuloma formed by epithelial cells, lymphocytes and Langhans' giant cells.[18] Noncaseating granulomas are spread superficially and diffusely around the endometrium. Cases of vulvar or vaginal TB are usually secondary to hematogenous spread but, as in males, some may be sexually transmitted. Cases of sexually transmitted TB were reported at least as early as 1917 but remain uncommon.[21]

PREVENTION

The insidious nature of TB as well as the typical latency between onset of symptoms and medical therapy favors its communicability. Prevention of genitourinary TB mirrors that of pulmonary TB, involving identification of infected sources and institution of appropriate antimicrobial therapy. In addition, prevention of primary venereal transmission of TB should follow safe sex guidelines, as the true incidence, although small, is unknown. The Advisory Council for the Elimination of Tuberculosis in the USA recommends a national standard centered on three prevention strategies:

- identifying and treating patients who have active TB;
- screening contacts of active TB patients, determining whether they are infected and, if so, providing appropriate therapy; and

- screening high-risk populations and providing therapy to prevent progression to active TB.[20]

Figure 71-2 Chronic tuberculous nephritis with almost complete destruction of the kidney *Courtesy of Robert F Peterson*.

Figure 71-3 Diffuse acute tuberculous nephritis with abscess formation. *Courtesy of Robert F Peterson.*

Once at-risk contacts have been identified, the recommendations for chemoprophylaxis are the same as for pulmonary TB, especially for patients less than 35 years of age or in an 'at-risk' group.

CLINICAL FEATURES

It has long been known that 'generalized tuberculosis of the genitourinary tract may be present without the production of any grave symptoms'.[22] Genitourinary TB is a relentless destructive process that may lie dormant or clinically inapparent for decades. Many people who have pulmonary TB have coexistent asymptomatic genitourinary TB.[20] The most common clinical symptoms of genitourinary TB are:

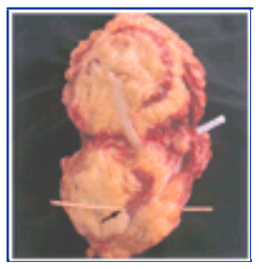

Figure 71-4 Chronic tuberculous nephritis with destruction of all landmarks and pelvic calculus. The arrow shows a fistulous tract delineated by the wooden probe. *Courtesy of Robert F Peterson.*

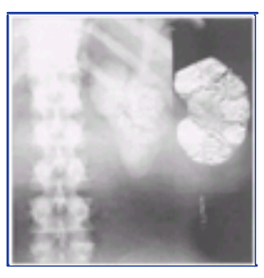

Figure 71-5 Intravenous pyelogram of left kidney with bivalved surgical pathology specimen.

- dysuria (including urinary frequency or urgency);
- recurrent urinary tract infections (UTIs); and
- pain (including back, flank, suprapubic and abdominal pain; Table 71.1).

TABLE 71-1 -- Symptom frequency in patients who have genitourinary tuberculosis.

SYMPTOM FREQUENCY IN PATIENTS WHO HAVE GENITOURINARY TB				
	Study of 160 patients[3]	**Study of 81 patients**[6]	**Study of 83 patients** [15]	**Study of 52 patients** [5]
Dysuria (with urgency and frequency included) (%)	52	65	46	31
Gross hematuria (%)	30	36	43	31
Frank pain/renal colic (%)	23	57	42	21
Fever (%)	12.5	35	23	ND
History of tuberculosis (%)	22.5	23.5	16	ND
ND, no data.				

Constitutional symptoms are generally uncommon but may be more frequent in patients who have advanced disease or those who are immunocompromised, and include fevers, chills, night sweats and weight loss. Hypertension is not generally a feature of tuberculous renal disease and its true prevalence is unknown, although case reports describe alleviation of hypertension after treatment of TB.[23]

In men, genital TB typically presents with a mildly tender or symptomless scrotal mass (epididymitis) and less commonly with prostatitis, orchitis or scrotal fistulas.

In women who have genital TB the most common presenting symptom is infertility[5] [13] [19] and it is estimated that 85% of patients have never been pregnant.[18] The next most common complaint is lower abdominal and pelvic pain, which occurs in 25–50% of patients. As the disease progresses, so does the intensity of the pain, which may be exacerbated by activity or coitus. The clinical presentation might mimic that of pelvic inflammatory disease unresponsive to usual therapy. The third most common complaint is abnormal menstrual bleeding.

DIAGNOSIS

A healthy clinical suspicion is mandatory to diagnose genitourinary TB early, given its insidious nature and the large proportion of patients who are asymptomatic. It should be considered in any patient who has unexplained fever. An evaluation for genitourinary TB is mandatory for any patient with a history of TB who develops dysuria or sterile pyuria from an unidentified cause. However, genitourinary TB may exist despite negative urine cultures. Historic queries regarding past exposure to TB, evening pyrexia, weight loss, asthenia, fatigue and past medical history are helpful. Physical examination findings are non-specific.

In over 50% of patients presenting with a UTI routine bacterial pathogens can be cultured from the urine, obscuring the underlying genitourinary TB. In men, a scrotal mass or nodular prostate may suggest TB. One study of 83 cases of genitourinary TB from Turkey revealed tenderness of the costovertebral angle in 55% of patients.[24]

After examination, initial laboratory investigation should include:

- renal function tests;
- at least three first-morning urine specimens for acid-fast bacillus (AFB) stain and culture; and
- tuberculin skin testing.

Positive AFB stains of urine are usually due to *M. tuberculosis* (R Wallace, personal communication). Of patients who have genitourinary TB, 77–92% will have positive urine cultures for *M. tuberculosis* [6] [7] [19] [24] and 90% will have positive tuberculin skin tests. [25]

Early in the course of genitourinary TB, radiologic manifestations are unremarkable. A chest radiograph should be obtained to assess for co-morbid pulmonary TB. Simple abdominal radiography is generally non-specific and commonly shows amorphous nephrocalcinosis or fine calcifications.

The 'gold standard' and most commonly used radiologic technique for evaluating the genitourinary system for *M. tuberculosis* remains the intravenous pyelogram (IVP) and excretory pyelogram.[26] The most valuable clue to renal TB is concurrent multiple abnormalities of both the upper and lower urinary tracts. Findings in progressive renal TB demonstrate abnormalities of the collecting system from the calyces to the bladder. Initially, an IVP may demonstrate irregular calyceal contours secondary to erosive inflammatory changes that later progress to delayed excretion, cavitation, 'moth-eaten' calyces or strictures with caliectasis. The characteristic finding of a 'phantom calyx' occurs when an IVP reveals an obstructed nonfunctioning calyx proximal to an infundibular stricture.[26] A 'hiked-up' renal pelvis is observed when the renal pelvis makes an acute angulation with the ureter, and is highly suggestive of renal TB. Another highly suggestive lesion is the 'putty kidney' consisting of a heavily calcified caseous mass surrounded by a thin parenchymal shell.[26] Autonephrectomy is the end result. Ureteral TB may manifest as different combinations of strictures and obstructions, giving the appearance of 'beading', 'corkscrewing', straight 'pipestems', focal calcification or hydronephrosis. Commonly, the bladder appears thickened and fibrotic with a small capacity.

In female genital TB, the hysterosalpingogram provides the most characteristic abnormalities, displaying a contracted deformed uterine cavity with associated intrauterine adhesions. The fallopian tubes may have ragged outlines and appear beaded or rigid.[18]

In the evaluation of genitourinary TB, ultrasound, computerized tomography (CT) and magnetic resonance imaging (MRI) are not usually necessary, although sometimes they have a role. A non-visualized kidney is best evaluated by ultrasound or CT.[26] Ultrasound has demonstrated small focal lesions in the kidneys in patients who have renal TB.[26] In women, ultrasonography may reveal predominantly solid adnexal masses containing small scattered calcifications bilaterally. Abdominal and vaginal ultrasound may have a role in delineating the features of tuberculous peritonitis.[26] In men, testicular ultrasound is a rapid and easy way for assessing scrotal contents; however, it is non-specific.[15] Transrectal ultrasound may also be helpful in delineating lower genitourinary tract pathology, but it is also non-specific. Sonography also has a use in providing a guide for fine-needle aspiration of genitourinary lesions.[19]

Computed tomography is superior to IVP and serial examination in delineating anatomic detail and may prove to be beneficial in contributing to therapeutic decisions.[24] Typical CT findings in genitourinary TB are caliectasis and focal cortical scarring (>80%).[26] Magnetic resonance imaging has also been used to describe tuberculous lesions because of its enhanced contrast resolution and multiplanar capabilities. Tuberculous foci appear hypointense on T2-weighted images.[26]

Although a positive purified protein derivative skin test with classic radiologic findings may be suggestive of genitourinary TB, diagnosis should only be made with bacteriologic or histologic evidence. If urine, menstrual blood or seminal fluid cultures are negative, then ultrasound- or CT-guided fine-needle aspiration or diagnostic laparoscopy can be used to provide appropriate tissue for bacteriohistologic diagnosis.

The use of diagnostic laparoscopy in women who have suspected genital TB may provide an earlier diagnosis (Fig. 71.6). The BACTEC system has reduced culture time to roughly 1 week. In addition, polymerase chain reaction (PCR) testing can, in just a few hours, detect

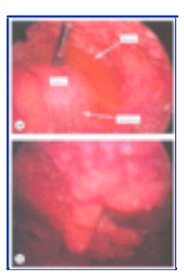

Figure 71-6 Laparoscopic views in genitourinary tuberculosis. (a) Free and loculated ascites and fine fibrous adhesions. (b) Miliary nodular exudate in the anterior wall.

the presence of *M. tuberculosis* in body fluids with exceedingly high specificity.[27]

Differential diagnosis

Differential diagnosis of genitourinary TB should include amebiasis as well as those entities that mimic granulomatous disease such as sarcoid, other mycobacterial disease (including leprosy), actinomycosis, histoplasmosis, tularemia, berylliosis, silicosis, foreign body reactions, malignancy and sexually transmitted diseases.[18] Other differential diagnoses include calyceal or diverticular stones, xanthogranulomatous pyelonephritis,[28] obstructive pyonephrosis and congenital multicystic dysplastic kidney.[17] The salpingitis and infertility of genital TB in women needs to be differentiated from that due to pelvic inflammatory disease.

MANAGEMENT (see also Chapter 37 and Chapter 202)

Many authors believe that there is little difference between the treatment decisions for extrapulmonary and pulmonary TB. Genitourinary TB should be easier to treat then pulmonary TB for several reasons:

- the lower bacillary load;
- the kidney's excellent blood supply;
- the high concentration of bactericidal medication in urine; and
- excellent drug penetration into closed cavities in lethal concentrations. [29]

Daily isoniazid, rifampin (rifampicin) and pyrazinamide for 2–3 months, followed by isoniazid and rifampin for the remainder of the therapeutic course have been used successfully (Table 71.2). If the patient comes from an area where drug resistance is common then a fourth drug, usually ethambutol, is added until drug susceptibility tests for *M. tuberculosis* have been completed.[19]

A 4-month regimen for genitourinary TB has been advocated, with excellent results.[30] However, a high incidence of surgical intervention was observed. A tailored regimen should be devised for each patient, based on susceptibility. The recommended treatment of

TABLE 71-2 -- Medications commonly used for renal tuberculosis, with dosages and common side effects.

MEDICATIONS COMMONLY USED FOR RENAL TB		
Medication	**Dose/day**	**Side effects**
Isoniazid	5–10mg/kg–300mg (max)	Hepatitis, peripheral neuropathy (pyridoxine may decrease the incidence), systemic lupus erythematosus, Dupuytren's contracture
Rifampin	10mg/kg–600mg po, single dose on empty stomach	Gastrointestinal irritation, abnormal liver function tests, stains body secretions orange, flu-like syndrome, multiple drug interactions
Ethambutol	25mg/kg for 2 months then 15mg/kg po	Optic neuritis manifested as changes in visual acuity and red-green color blindness, gastrointestinal discomfort
Pyrazinamide	25mg/kg to a maximum of 2.5g po	arthralgia, hyperuricemia
Streptomycin	15mg/kg im	Ototoxicity, nephrotoxicity
Capreomycin/amikacin	0.75/1.0g for 2–3 months then 1.0g 2–3 times a week	Low potassium, low magnesium

genitourinary TB, if sensitive, is a 9-month course of isoniazid and rifampin or, alternatively, a 6-month course with isoniazid, rifampin, pyrazinamide and ethambutol, as above. The mycobacterial burden is thought to be lower than in cavitary TB and short-course regimens are recommended for extrapulmonary disease in the same fashion.

A common problem in the management of genitourinary TB is the progression of nephroureteric disease despite appropriate antimicrobial therapy and negative sequential urine cultures. Obstructive fibrosis can occur anywhere along the urinary tract and is secondary to the healing process that begins after initiation of effective

chemotherapy.[23] Corticosteroids, endoscopic balloon dilatation and placement of stents for ureteral strictures have been advocated and may obviate the need for reconstructive or ablative surgery.

Prior to the advent of effective antimicrobial therapy, surgical resection of the 'more involved organ' was the standard of care.[31] Currently, nephrectomy should be restricted to patients who have intractable pain for longer than 1 year, uncontrollable or recalcitrant fever secondary to infection proximal to the stricture, life-threatening hematuria, uncontrollable hypertension secondary to renal TB and insurmountable drug resistance.[29] Surgical techniques vary, including laparoscopic, open and retroperitoneal approaches, and are usually employed for removal of nonfunctioning kidneys.[32] [33] [34] Occasionally percutaneous balloon stenting may be used to alleviate strictures.[35] It has been suggested that surgical intervention for pelvic TB is indicated for:

- recalcitrant disease;
- persistent pain;
- abnormal bleeding; and
- nonhealing fistulas.[17]

Re-evaluation of genitourinary TB should include urine cultures every 3 months; proof of cure must be documented by culture.[12] In addition, IVP or ultrasound should be considered every 6 months, to rule out obstructive uropathy, until the clinical regimen has been completed. Additionally, renal function should be assessed every 6 months for 2 years after therapy. No other specific intervention is necessary unless the patient experiences a recurrence of symptoms.

Chapter 72 - Practice Points

72.a Asymptomatic urinary infection in women with diabetes mellitus

George Zhanel
Allan R Ronald

A 40-year-old woman with a 26-year history of insulin-dependent diabetes mellitus consults you for moderate renal impairment (creatinine 290µmol/l (3.3mg/dl), urea 23.5mmol/l (66mg/dl)), proteinuria (3.5g in 24 hours) and pyuria (100 leukocytes per high-power field). The patient's diabetes has been stable on twice-daily insulin and no other therapeutic agents. She denies any urinary tract symptoms except for nocturia three times each night. A first morning void urine culture obtained on two occasions showed >10^5 cfu/ml of *Escherichia coli*, which was susceptible to all antimicrobial agents tested. The patient has no previous history of urinary infection and has had no pregnancies.

Background

Asymptomatic bacteriuria is common in women with diabetes, with a prevalence three times that of controls. Among patients with diabetes and asymptomatic bacteriuria, upper tract urinary infection is often present, with 'localization studies' demonstrating renal infection in 50–70% of women. Asymptomatic infection occasionally progresses to acute pyelonephritis with bacteremia. Among women with diabetes, acute urinary tract infections (UTIs) are the second most frequent reason for hospital admissions. In a recent populationbased study, the rate of hospitalization for acute pyelonephritis was 10 times greater among both men and women with diabetes than in the nondiabetic population. The determinants of asymptomatic bacteriuria and its complications among women with diabetes are mostly unsubstantiated. It is assumed that hyperglycemia and glycosuria with resulting impairment of leukocyte function and enhanced microbial metabolism, diabetic neuropathy with a neurogenic bladder, and renal microangiopathy each contribute to increased susceptibility to bacteriuria among women with diabetes. However, additional investigation is required to understand fully the factors that facilitate bacteriuria among women with diabetes.

No well-conducted prospective studies have shown that asymptomatic bacteriuria in diabetes contributes significantly to end-stage renal function; rather deterioration in renal function is almost always due to changes relating to progressive glomerulosclerosis.

Among patients with renal failure, regardless of the cause, asymptomatic bacteriuria is common. In most instances, these infections are presumably not due to the renal impairment but rather to multiple factors common in patients with renal failure, including prior urologic investigation, failure to achieve adequate antibacterial concentrations in renal tissue or in the urine, and altered host defenses. Few large cross-sectional studies have been carried out in patients with asymptomatic bacteriuria and renal impairment, and no definitive prospective studies are published. As a result, there is no information on the significance of asymptomatic bacteriuria in patients with renal failure, the importance of its treatment or its contribution to further loss of renal function.

Diabetes is now the most common cause of renal failure, accounting for about one-third of patients in developed countries, and asymptomatic infection in patients with diabetes and impaired renal function is exceedingly common. As a result, the clinical scenario of a woman with either type 1 or type 2 diabetes, impaired renal function and asymptomatic bacteriuria is often encountered.

What are the appropriate recommendations for the management of this patient? Should the patient have been screened for bacteriuria? Does the presence of pyuria have any prognostic significance? Once she is discovered to have bacteriuria, should she have further investigation or treatment? Without more data, therapeutic regimens are empiric and unproven, and decisions must be based on anectodal experience and personal opinion.

Specific issues

Diagnosis

The definitive diagnosis of asymptomatic UTI requires at least two urine cultures obtained as clean-voided midstream urine samples in order to have at least 95% assurance of bacteriuria. However, no studies have validated these criteria in patients with renal impairment. The presence of white blood cells provides credence to the diagnosis of asymptomatic bacteriuria. The microbial etiology of asymptomatic bacteriuria in diabetes is predominantly *E. coli*, with more resistant organisms in patients who have had hospital admissions or prior instrumentation. Some pathogens, particularly *Proteus mirabilis*, may more often be associated with complications, and some physicians would treat these pathogens regardless of symptoms because of their propensity to cause struvite calculi. In some studies, they have also been associated with an increased occurrence of acute pyelonephritis.

In patients with renal failure and complicated diabetes, clinical symptoms caused by 'asymptomatic bacteriuria' can be difficult to exclude. Does asymptomatic infection cause non-specific illness such as fatigue, irritability or malaise? Some patients after treatment of 'asymptomatic' infection relate improvement of symptoms that are not usually attributed to bacteriuria.

Imaging studies in these patients are problematic. Ultrasound studies lack sensitivity and specificity. Intravenous pyelography is contraindicated by the presence of renal failure and diabetes. A helical computerized tomography (CT) scan is the most effective means of excluding obstructing lesions (particularly calculi), evaluating renal size and identifying other abnormalities. The net marginal cost of obtaining a noncontrast helical CT scan may be less than that of ultrasonography, and it should usually be the imaging procedure of choice. Contrast should not be used unless absolutely essential and, when it is necessary, the patient should be well hydrated and a low ionic formulation should be prescribed. Imaging, preferably with a helical CT scan, is indicated in order to ensure that no remedial causes of renal impairment are present.

Treatment

In the presence of an intact urinary system and significant renal impairment presumed to be due to diabetes, how would we treat this asymptomatic infection? At present, no one can be dogmatic. We would choose treatment empirically in the hope that within several years clinical studies will have demonstrated the possible benefit of treatment or perhaps have identified a subset within this population in whom treatment is worthwhile. In treating such patients, we are hoping to prevent the complications of urinary infection that do occur with increased frequency in this population. However, there is no conclusive evidence that presumptive treatment prevents progression of renal impairment or acute complications, including acute pyelonephritis.

The choice of treatment is important. A therapeutic agent should be selected that will achieve reasonable levels in both renal tissue and urine despite impaired function. Renal tissue may be even further impaired regionally, owing to altered perfusion with variable antimicrobial levels. Also, an agent should be selected that is not known to be toxic to the kidney. There is no urgency to treat asymptomatic infection, and susceptibility tests can be used to identify one or more potential 'safe' agents.

In this instance, we would choose a fluoroquinolone or trimethoprim alone. Sulfonamides, aminoglycosides and tetracyclines should not be prescribed. The fluoroquinolones, including ciprofloxacin, and the newer agents levofloxacin, gatifloxacin and others, are well tolerated and diffuse widely in renal tissue. Nitrofurantoin should never be used in patients with impaired renal function because it does not achieve adequate urine or renal levels and because metabolites rapidly accumulate and produce serious neurologic toxicity.

We would prescribe the antibacterial agent for 14 days, obtain a urine culture on the last day of therapy to ensure temporary eradication of infection, and follow the patient. If the pathogen recurred within 2 weeks, after discussion with the patient we might prescribe a longer course of therapy on the basis that, in this 'normal

functioning' urinary tract, a cure of asymptomatic bacteriuria could be obtained and that this objective is worthwhile. However, if the patient continued to have recurrences, particularly with different organisms, and these remain asymptomatic, we would not pursue treatment or prescribe ongoing suppressive regimens or prophylaxis unless the patient appears to have clinical improvement in objective or subjective symptoms during the course of therapy.

In summary, this example illustrates our lack of knowledge in proper management strategies for patients with asymptomatic bacteriuria in the presence of diabetes or renal impairment. Careful clinical studies are necessary for a further understanding of the pathogenesis of UTIs in these patients and to enable bacteriuria to be managed on the basis of evidence rather than empiricism.

72.b Management of persistent symptoms of prostatitis

John N Krieger

Definition of the problem

A 40-year-old man is referred for persistent symptoms of prostatitis. The patient had an episode of acute urethritis when he was 20 that resolved during a course of antibiotics. He was well until 2 years ago when he experienced an acute onset of urinary frequency with perineal and penile discomfort radiating to his left hemiscrotum. This followed after a new heterosexual relationship. He has not responded to treatment with ciprofloxacin, doxycycline, trimethoprim-sulfamethoxazole and three other antibiotics whose names he cannot remember. The physical examination is unremarkable. Recent urinalysis and urine culture are negative and there are no additional laboratory studies.

Introduction

'Prostatitis' is the diagnosis given to men who present with varied complaints referable to the lower urogenital tract and perineum. By one estimate at least one-half of adult men experience symptoms of prostatitis at some time in their lives. The US National Health Center

data indicate that 76 of 1000 men each year seek a physician's opinion for genitourinary problems, and prostatitis accounts for approximately one-quarter of these visits. Patients may experience symptoms for prolonged periods. Management of patients who experience persistent symptoms following repeated courses of treatment is a challenge.

Pathogenesis

Most bacterial prostatic infections ascend through the urethra. The oblique courses of the ejaculatory and prostatic ducts may provide a mechanical defense. Other host defenses include the antimicrobial activity in the prostatic secretions, particularly a zinc-containing polypeptide known as prostatic antibacterial factor. The prostate has higher concentrations of zinc than any other organ and prostatic secretions from normal men contain high zinc levels. Men with chronic bacterial prostatitis have low prostatic fluid zinc concentrations, but their serum zinc levels are normal. Local immunoglobulin production by the prostate may also be an important host defense. Many patients with prostatitis have increased leukocyte numbers in their prostatic secretions or semen, but the role of cellular immunity in chronic prostatitis is uncertain.

Hematogenous dissemination may result in prostatic infection in patients with systemic infections, such as tuberculosis or other granulomatous infections. This route is especially common in patients who are immunosuppressed or who have HIV infection.

Microbiology

Uropathogenic bacteria

Bacteriuria is a hallmark of acute and chronic bacterial prostatitis. The agents are standard uropathogens associated with bacterial urinary tract infections. Recurrent infections caused by the same organism are the sine qua non of chronic bacterial prostatitis. Between episodes of bacteriuria these organisms may be 'localized' to the prostate as described below. Unfortunately, patients with well-documented acute and chronic bacterial prostatitis constitute less than 10% of patients presenting with prostatitis.

Other genitourinary pathogens

Other genitourinary pathogens have been implicated as causes of prostatitis. The best evidence supports a role for sexually transmitted pathogens. In the pre-antibiotic era, *Neisseria gonorrhoeae* was a recognized cause of prostatitis and the most common cause of prostatic abscess. However, in current practice *N. gonorrhoeae* is seldom implicated. Some studies suggest a role for the sexually transmitted pathogens *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Mycoplasma genitalium* and *Trichomonas vaginalis* but their role remains controversial.

Granulomatous infections

Granulomatous prostatitis is an uncommon syndrome with a characteristic histologic reaction. It is classified as 'specific' when associated with particular microbes such as *Mycobacterium tuberculosis*, atypical mycobacteria, BCG (after intravesical therapy for transitional cell carcinoma) and the deep mycoses. Causes of non-specific granulomatous prostatitis include acute bacterial prostatitis, prostatic surgery and connective tissue diseases.

Specific diagnostic studies are necessary to document pathogens in patients who may be at risk. Accurate diagnosis is a prerequisite for successful treatment.

Clinical features

Patients with prostatitis can be classified into four categories: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/ chronic pelvic pain syndrome, or asymptomatic prostatitis (Chapter 68 , see Table 68.1).

Acute bacterial prostatitis

This patient does not have acute bacterial prostatitis. The clinical features of acute bacterial prostatitis are readily apparent. Characteristic complaints include acute symptoms of urinary tract infection, including urgency, frequency and dysuria, and occasionally gross hematuria or acute urinary retention. Patients may also have systemic symptoms or a 'flu-like' syndrome, with fever, chills or other symptoms associated with bacteremia. Patients may experience bladder outflow obstruction due to acute edema of the prostate. The rectal examination is often impressive, with an exquisitely tender, tense prostate. Urinalysis reveals pyuria and cultures will be positive for uropathogenic bacteria. Leukocytosis is common, with increased numbers of segmented cells.

Chronic bacterial prostatitis

It is possible, although unlikely, that the patient may have chronic bacterial prostatitis. The characteristic clinical feature of chronic bacterial prostatitis is recurrent episodes of bacteriuria caused by the same organism. Patients may be totally asymptomatic or have only minimal symptoms between episodes. The infected prostate remains a focus of organisms causing relapsing infection. The prostate is usually normal on examination. Thus, absence of a documented urinary tract infection makes chronic bacterial prostatitis unlikely. With acute exacerbations, bladder bacteriuria may result from the prostatic focus. This is especially true among older men, who may have both prostatic obstruction and infection.

'Chronic prostatitis'

This is the largest group, representing more than 80% of patients presenting with symptoms, and is the most likely diagnosis in this case. Chronic prostatitis/chronic pelvic pain syndrome is the new National Institutes of Health consensus term for these patients. Chronic pelvic pain symptoms are the most common presentation, especially perineal, lower abdominal, testicular, penile and ejaculatory pain. Other genitourinary tract complaints include sexual dysfunction and voiding complaints. Some patients have objective evidence of inflammation in their prostatic secretions, post-prostate massage urine or semen (inflammatory subtype of chronic

prostatitis/chronic pelvic pain syndrome, formerly termed 'nonbacterial prostatitis'), while others have no evidence of inflammation (noninflammatory subtype of chronic prostatitis/chronic pelvic pain syndrome, formerly termed 'prostatodynia').

Asymptomatic prostatitis

Asymptomatic prostatitis may be diagnosed among men undergoing evaluation for other genitourinary tract problems. For example, some patients undergoing evaluation for infertility have increased concentrations of leukocytes in their seminal fluid. 'Chronic prostatitis' is also a common 'benign' diagnosis among men who undergo prostate biopsy for evaluation of elevated prostate-specific antigen levels and have inflammatory infiltrates on histology.

Investigations

The critical practice point is to distinguish patients with lower urinary tract complaints associated with bacteriuria from the larger number of men without bacteriuria. Urine culture is essential for men with acute lower urinary tract symptoms. Men with documented bacteriuria should undergo lower urinary tract localization studies (Table 72b.1). This investigation may document a prostatic focus of infection when the patient does not have a bacteriuria.

TABLE 72.b-1 -- Lower urinary tract localization study.

LOWER URINARY TRACT LOCALIZATION STUDY		
Specimen	**Abbreviation**	**Procedure**
Voided bladder 1	VB_1	Initial 5–10ml of urinary stream
Voided bladder 2	VB_2	Midstream specimen
Expressed prostatic secretions	EPS	Secretions expressed from prostate by digital massage after midstream specimen
Voided bladder 3	VB_3	First 5–10ml of urinary stream immediately after prostate massage
Unequivocal diagnosis of chronic bacterial prostatitis requires a 10-fold higher concentration of a uropathogen in the VB_3 of EPS specimen when compared with the VB_1 specimen. The organism is identical to organisms causing repeated episodes of bacteriuria.		

Documenting persistent prostatitis infection supports the need for continued antimicrobial therapy.

Unequivocal diagnosis of bacterial prostatitis requires that the colony count of a recognized uropathogen in postmassage (VB_3) urine exceed the colony count in the first-void urine (VB_1) by at least 10-fold. However, many men with chronic bacterial prostatitis harbor only small numbers of pathogenic bacteria in their prostates. Direct culture of the expressed prostatic secretions (EPS) is useful in this situation because colony counts in EPS are often one or two logs higher than comparable counts in the VB_3 . The hallmark of chronic bacterial prostatitis is that the uropathogen present in VB_3 or EPS may be isolated on multiple occasions and is identical to the organism causing episodes of bacteriuria.

Patients with risk factors for sexually transmitted disease (STD) pathogens should have appropriate testing for *N. gonorrhoeae* and *C. trachomatis*. Serologic testing is recommended for both syphilis and for HIV infection. Patients who have clinical findings suggesting granulomatous prostatitis should have appropriate studies for specific agents associated with this condition.

Document inflammation

Microscopic evaluation is important to identify EPS inflammation because this provides objective support for the diagnosis. We define inflammation based on chamber counts with >1000 leukocytes/mm^3 . There appears to be little value in counting EPS leukocytes in patients with urethral inflammation, especially among men at risk for STDs. Therefore, we examine a urethral smear before proceeding with a localization study.

Other investigations

Our standard approach is to recommend noninvasive uroflow and postvoid ultrasound residual testing. Patients with abnormal flow rates or significant postvoid residual urine have additional evaluation with a retrograde urethrogram to evaluate the possibility of urethral stricture and video urodynamics is reserved for patients with abnormal uroflow findings and negative urethrograms. Cystoscopy is recommended if carcinoma in situ or interstitial cystitis is considered likely (e.g. in older patients, those with hematuria, a history of chemical exposure or prominent painful voiding complaints). Urinary cytology is obtained if transitional cell carcinoma in situ is considered. Prostate-specific antigen testing is useful because occasional patients with carcinoma of the prostate present with symptoms of prostatitis. However, such testing is not recommended for patients with acute symptoms, since temporary elevation of prostate-specific antigen is common following acute episodes. Transrectal ultrasound evaluation may also be considered in selected patients to evaluate possible ejaculatory duct obstruction or complications such as prostatic abscess.

Management

Acute bacterial prostatitis

Appropriate therapy results in dramatic improvement. Many antimicrobials that do not penetrate the uninflamed prostate have proved effective. Thus, drugs appropriate for Enterobacteriaceae, *Pseudomonas aeruginosa* or enterococci should be started once cultures are obtained. For men who require hospitalization, conventional therapy is the combination of an aminoglycoside plus a ß-lactam drug. The fluoroquinolones or third-generation cephalosporins are attractive alternatives for monotherapy and the fluoroquinolones are the agents of choice for outpatient management.

Patients with acute urinary retention require bladder drainage. In this situation we prefer a suprapublic cystotomy tube as an indwelling transurethral catheter passes through and may obstruct drainage of the acutely infected prostate, increasing the risk for bacteremia and prostatic abscess.

Chronic bacterial prostatitis

Trimethoprim-sulfamethoxazole has been the 'gold standard'. Long-term therapy with trimethoprim (80mg) plus sulfamethoxazole (400mg) taken orally twice daily for 6–16 weeks is superior to shorter courses. Such therapy results in symptomatic and bacteriologic cure in approximately one-third of patients, symptomatic improvement during therapy in approximately one-third (who relapse after stopping treatment) and no improvement in the remaining patients.

During the past decade the fluoroquinolones have proved useful for treatment of chronic bacterial prostatitis. In contrast to the ß-lactams, concentrations of many fluoroquinolones are relatively high in prostatic fluid, prostatic tissue and seminal fluid as compared with plasma levels. Good results were reported for men with bacterial prostatitis, including patients who failed therapy with trimethoprim-sulfamethoxazole. Our first choice for curative therapy for chronic bacterial prostatitis is an appropriate fluoroquinolone, at full dose for at least 3 months.

Patients who are not cured may benefit from long-term suppressive treatment using low-dosage antimicrobial agents. Since patients may be asymptomatic between episodes of bacteriuria, the goal of suppressive therapy is to prevent symptoms of urinary infection. Very low doses of drugs can be remarkably effective. Available agents include tetracycline, cephalexin and trimethoprim-sulfamethoxazole. Although effective, we seldom recommend fluoroquinolones for chronic suppression, because of cost and the potential for development of resistance.

Chronic prostatitis/chronic pelvic pain syndrome

Therapy is often unsatisfactory because the etiology of chronic prostatitis/chronic pelvic pain syndrome remains unclear. As outlined above, an etiologic role has been suggested for many infectious agents. Prostaglandins, autoimmunity, psychologic abnormalities, neuromuscular dysfunction of the bladder neck or urogenital

diaphragm, allergy to environmental agents, stress and other psychologic factors have all been suggested as causes. Antimicrobial drugs are often prescribed. However, for men without evidence of infection by recognized pathogens, antimicrobial treatment usually fails. For these reasons, we prescribe antimicrobial agents only for patients with documented infections rather than recommending repeated courses of empiric therapy.

Other recommended treatments include a-blockers, prostate massage, anti-inflammatory drugs, anticholinergic drugs, allopurinol,

muscle relaxants, transurethral resection of the prostate, sitz baths, diathermy, exercises, physiotherapy and psychotherapy. Some clinicians recommend increased frequency of ejaculation to relieve 'congestion'. Others recommend abstinence and avoidance of alcohol, coffee, tea and spicy foods. Prospective studies are currently evaluating the efficacy of some of these recommendations. However, at present, there is no objective evidence that any of these measures change the natural history of the chronic prostatitis/chronic pelvic pain syndrome.

Conclusion

Patients with documented bacteriuria may have acute or chronic bacterial prostatitis. These conditions are rare in patients with no history of bacteriuria. Specific diagnostic studies will document uropathogens, STD agents or granulomatous infections in patients with prostatitis. Other diagnoses should be excluded in selected patients. Accurate diagnosis is the prerequisite for successful treatment.

72.c A positive urine culture with pyuria accompanied by bladder spasms in a 24-year-old woman who has spinal cord injury and an indwelling catheter

John Z Montgomerie
Kim Maeder

Introduction

Urinary tract infection (UTI) occurs in most patients who have spinal cord injury (SCI) during initial hospitalization and rehabilitation and may be a recurrent problem throughout their lives. Until methods of urinary drainage were improved, infections were the dominant cause of bacteremia and renal failure. These complications, with calculi and pyelonephritis, still occur and more frequently in patients who have indwelling urethral catheters. Indwelling catheters are used by more than 20% of patients with SCI in the USA.

Definition of the problem

A 24-year-old woman who has a 4-year-old spinal cord injury at T12 presents with increased leg spasms and feels generally unwell. She has had an indwelling Foley catheter since her injury. She has had these symptoms before and attributes them to recurrence of her urinary infection. She is on chronic trimethoprim-sulfamethoxazole for prophylaxis and suppression of urinary infection. Cultures from 6 weeks earlier grew both *Proteus mirabilis* and *Pseudomonas aeruginosa*.

Pathogenesis

The pathogenesis of UTI depends on the type of bladder drainage. Most patients immediately following SCI have an indwelling urethral catheter, which is always associated with bacteriuria. In most SCI centers the catheter is removed within a few days and intermittent catheterization is the preferred method of urine drainage.

Changes in the bladder associated with long-term use of the indwelling catheter include squamous metaplasia, thickening and fibrosis of the bladder wall, bladder contraction, diverticuli, calculi, alkaline encrusting cystitis with urease producing bacteria and squamous cell carcinoma of the bladder. In male patients, penile and scrotal fistulas, abscesses and epididymitis are other complications.

Microbiology

Studies of UTIs from different SCI centers have suggested that a wide range of micro-organisms infect the urine with different bacteria predominating at different centers. *Escherichia coli*, *Pseudomonas*, *Klebsiella* and *Enterococcus* spp. have been the predominant micro-organisms causing UTIs in patients who have SCI. Some centers have noted a high prevalence of *Proteus* spp.; this may relate to the more frequent use of indwelling catheters, which are also associated with multiple organisms. The presence of urease producers (*Proteus*, *Providencia* and *Morganella* spp.) raises concerns about calculus formation.

Indwelling, urethral and suprapubic catheters are associated with calculi and multiple organisms and multiresistant Gram-negative bacilli. The patient's sex and level of injury may affect the microbiology of bacteriuria and colonization. At our institution, male patients have had a high incidence of infection with *Klebsiella* and *Pseudomonas* spp. that relates to the use of external condom catheters and colonization of the perineum, urethra, bowel flora and urine in the urine drainage bags. In female patients with SCI receiving intermittent catheterization, *E. coli* and *Enterococcus* spp. accounted for 71% of infections. It has not been possible to alter significantly the colonization of the perineal skin through increased bathing, the use of antiperspirants or antiseptics to clean the skin.

There are few studies of the modes of transmission of these micro-organisms. Although the patient's body sites and drainage bags are the immediate source of such infections, transmission on the hands of health care personnel is the most likely means of transmission among patients.

Clinical features

Because of loss of sensation, patients with SCI do not usually have the common symptoms of UTI such as frequency, urgency and dysuria. The clinical features of UTI may include fever, pyuria and 'soft' symptoms and signs such as discomfort over the back or abdomen during urination, onset of incontinence, increased spasticity, autonomic hyperreflexia, malaise, lethargy or observation of cloudy urine with increased odor. The term 'soft' is used because increased spasticity (and other symptoms) may occur in patients

without obvious cause. The presence of a catheter by itself may induce spasms. Identification of the infecting organism by urine culture is important. Blood cultures should be obtained if patients have a high fever. Calculus formation may occur with the infection and small stones called 'gravel' may be present in the urine of patients with indwelling catheters.

Investigations

The exclusion of obstruction and other factors that might influence response to treatment is important. In those patients voiding reflexly it is important to determine the residual volume. Ultrasound and/or intravenous pyelogram may be important to confirm that there is no obstruction to urine flow and that there is adequate drainage from the kidneys and bladder. In patients with indwelling catheters it is important to change the catheter if there is any question of obstruction of the catheter.

Management

We should be concerned that a 24-year-old woman with SCI has chosen to use an indwelling urethral catheter rather than intermittent catheterization. However, this can be a rational choice for women since there are no reasonable external collection devices. As mentioned above, 20% of patients with SCI in the USA use indwelling catheters to drain the bladder. The choice is made if the patient is quadriplegic and cannot use her or his hands and an assistant is not available. Others, particularly busy people with full-time jobs or persons who travel, make this decision because of the inconvenience of the repeated catheterizations. They use the indwelling catheter to improve their quality of life despite the increased risks to their health.

Unfortunately there are few studies of the optimal methods of care of the patient with a long-term indwelling catheter. The recommendations from our own institution and our own observations are listed in Table 72c.1 . Urethral catheters need to be changed on a regular basis to prevent obstruction of the catheter, which occurs with encrustation that includes struvite and apatite crystals and bacterial biofilm. Changes every 2–4 weeks are almost always adequate to prevent catheter obstruction. Occasional patients need a more frequent change of catheter. Silicone catheters have not been demonstrated to have sufficient advantages to be used routinely.

Studies of patients with long-term indwelling catheters indicate surprisingly few episodes of fever. Most episodes are of low-grade fever lasting for less than 24 hours and resolve without antibiotics. Because patients with indwelling urethral catheters are colonized with three or more bacterial species that change frequently, no useful purpose is served by routine culture. Culture and sensitivity tests should be reserved for patients who are starting on antimicrobial

TABLE 72.c-1 -- Care of long-term indwelling catheters.

CARE OF LONG-TERM INDWELLING CATHETERS
• Use the smallest-sized catheter and balloon consistent with minimal leakage

• Change catheters regularly every 2–4 weeks
• Prevent trauma to the urethra
• Maintain at least 2L of fluid intake daily
• Use nonrestrictive clothing
• Daily perineal care with soap and water
• Urethral antisepsis and routine irrigations are not recommended

therapy. The laboratory should be notified that the urine was obtained from a patient with an indwelling catheter, otherwise the technicians may consider the multiple bacteria to be contaminants.

Because of lack of evidence that treating asymptomatic bacteriuria reduces symptomatic bacteriuria or influences the long-term function of the urinary tract or kidneys, bacteriuria in all patients with SCI should only be treated when symptoms or signs are present. In the patient with SCI and an indwelling catheter, a combination of factors makes us even more reluctant to use antibiotics. Antimicrobial agents rarely eradicate micro-organisms in the presence of the catheter or other foreign bodies and the bacteria in the urine may become resistant or may be replaced by resistant flora. A recent meta-analysis has confirmed that prophylactic antibiotics provide no advantage to patients with SCI.

In considering the patient who is the topic of this discussion, bacteriuria and pyuria are usually present in the SCI patient with a long-term indwelling catheter. Occasional bladder spasms are also common, particularly because of the physical presence of the catheter. By themselves, these symptoms and signs do not constitute evidence of a need to treat with antibiotics. Fever is the main indication for treatment but the catheterized patient sometimes has definite symptoms of UTI without fever. Patients who have had previous episodes of UTI with fever may recognize early symptoms such as increased bladder spasms or sudden onset of cloudiness of the urine or change of odor. At the first evidence of infection patients should increase their fluid intake. A catheter change should be considered. If the symptoms persist these patients will respond to oral antibiotics active in vitro. Appropriate duration of treatment has not been well studied in patients with indwelling catheters but they usually respond to relatively short courses of therapy (5–7 days). If there is evidence of renal infection longer courses may be indicated. In symptomatic patients with high fever, who may have bacteremia, broad coverage may be necessary until the results of the cultures are available because these patients are frequently colonized with resistant bacteria. Bacteremia in patients with SCI has usually been the result of bacteriuria associated with catheterization or other bladder manipulation. In those episodes, enterococci, *E. coli* and *Pseudomonas aeruginosa* were the organisms most frequently isolated from the blood.

The formation of stones in the bladder is a not uncommon problem associated with urease-producing bacteria (*Proteus*, *Providencia* and *Morganella* spp.). Attempts to clear small stones (gravel) can be made by increasing fluid intake or blocking urease production with acetohydroxamic acid. Cystoscopy may be necessary to remove the stones.

There are a number of gaps in our understanding of the management of patients with indwelling catheters and further study of the optimal care of the catheter is needed.

Chapter 73 - Epidemiology and Public Health Issues in Sexually Transmitted Infections

Michael Adler

WHY SEXUALLY TRANSMITTED INFECTIONS ARE IMPORTANT

Sexually transmitted infections (STIs) are a major public health problem and are among the commonest cause of illness, and even death, in the world today. They have far-reaching health, social and economic consequences, particularly in the developing world. The World Bank[1] estimated that for women aged 15–44 years, the STIs (excluding HIV infection) were the second commonest cause of healthy life lost after maternal morbidity (Fig. 73.1). Other studies have estimated that 5% of the total discounted healthy life years lost in sub-Saharan Africa are due to sexually transmitted diseases (STDs) excluding HIV infection, and that HIV infection alone accounts for 10% of healthy life years lost.[2] Also, the total days lost due to HIV, chlamydia and syphilis is similar to the number of days lost to malaria and measles.

The STIs are usually easy to diagnose and cheap to treat. However, many infections remain unrecognized and undiagnosed, resulting in considerable long-term morbidity which can be costly in both human and monetary terms. The complications of untreated infections are far-reaching and include cancer and reproductive and pregnancy-related problems (Table 73.1). It has been calculated that reproductive ill-health (death and disability related to pregnancy and childbirth, STIs, HIV/AIDS and reproductive cancers) account for 5–15% of the global burden of disease.[4] Data on the monetary costs of the complications of STIs are sparse, particularly for the developing world. American data gives estimates of total direct and indirect

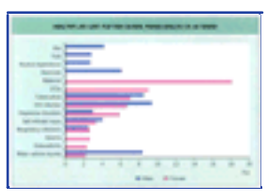

Figure 73-1 Healthy life lost — top ten causes in young adults aged 15–44 years.

costs attributable to STIs of US$ 9.9 billion annually, rising to US$16.6 billion if HIV infection and AIDS are included.[3] In the UK there are only limited data. For example, the prevention of unplanned pregnancy by National Health Service (NHS) contraception services probably saves over £2.5 billion per year, and the average lifetime treatment cost for an HIV-positive individual is £135,000–180,000 with a monetary value of preventing a single onward transmission of somewhere between £½ to 1 million in terms of individual health benefits and treatment costs.[5] Finally there are dramatic cost savings to be made by preventing infertility.

Few economic data exist in the developing world in relation to the consequences of STIs, which are considerable and personally devastating. Many women become infertile without even realising that they have suffered from pelvic inflammatory disease (PID). Estimates of the burden of infections for women in urban Africa have shown that chlamydial infection causes an average of 4.8 lost days of productive life, and syphilis 8.2 days per capita per year.[2] It has also been estimated that a high prevalence of syphilis among pregnant women, for example 10%, could result in up to 8% of all pregnancies carried beyond 12 week having an adverse outcome from syphilis.[6]

It is now recognized that there is a synergy between most STIs and HIV infection (particularly ulcerative and inflammatory conditions). STIs enhance infectivity in HIV-positive patients due to increased viral shedding and replication. STIs increase the possibility of HIV infection due to local trauma, ulceration and inflammation, and the increased presence and activation of cells receptive to HIV in the

presence of inflammation. The likelihood of risk per exposure to HIV in any sexual contact is in the order of 0.1%, which will increase considerably if an STI is present by the order of three to five. This synergy, and a realization that the control of STIs can have a profound effect on the incidence of HIV infection, has led to increased resources for STI control programs (see below). Clinical studies have

shown that HIV-positive patients with a urethral infection have an eightfold increase in HIV-1 RNA in semen and this falls following treatment.[7]

SIZE OF THE PROBLEM

The size of the global burden of STIs is uncertain because of the lack of effective control and notification systems in many countries. The

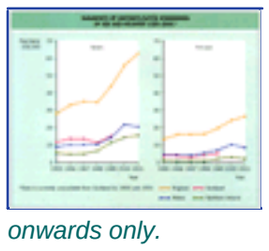

Figure 73-3 Diagnoses of uncomplicated gonorrhea by sex in England and Wales 1990–2000. ** Data for homosexually acquired infection in males available from 1994 onwards only.*

World Health Organization (WHO) has estimated a total of 340 million new cases of curable STIs in adults per year, mainly in South East Asia (151 million new cases per year), and sub-Saharan Africa (69 million) (Fig. 73.2 , Table 73.2). [8] In Eastern Europe and Central Asia the estimate is 22 million, and 17 million in Western Europe. The prevalence and incidence per million of the population varies regionally, for instance between sub-Saharan Africa and Western Europe, eight- and fourfold respectively (Table 73.3).

Gonorrhea

It is difficult to interpret differences between countries and even trends because of the variation in reporting practices and the provision of facilities. Rates of gonorrhea vary between countries in Europe. There was a peak in the number of cases of gonorrhea in most European countries during the early to mid 1970s. The subsequent advent of HIV and AIDS in the 1980s led to safer sexual practices and a reduction in the number of cases of gonorrhea, which has not been sustained in all countries. For example, recently there has been an increase in both male and female cases of gonorrhea in the United Kingdom between 1995 and 2001. In England there was a 128% increase in the number of cases in men from 6759 to 15,475, and in females a 95% increase from 3394 to 6641 (Fig. 73.3). The incidence of gonorrhea has increased since 1995 in homosexual men, particularly in those living in London, as have other sexually transmitted infections (Fig. 73.4). In 2000, 20% of gonorrhea diagnoses in males overall, and 24% of those in London, were homosexually acquired.

In Nordic countries, the annual incidence of gonorrhea declined very dramatically from over 100/100,000 of the population in most countries in the early 1980s to less than 10/100,000 by the late 1990s, but there have been recent slight increases. For example, in Sweden an all time low of 2.5/100,000 was achieved in 1996 but has risen again.

In the USA, the incidence of gonorrhea has declined, but there are marked differences between ethnic groups (Fig. 73.5). In 2000 there was a total of 358,995 reported cases, but the true number may be nearly double at 650,000 cases (Table 73.4).

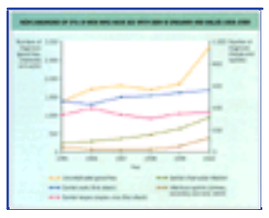

Figure 73-4 New diagnoses of selected STIs in men who have sex with men in England and Wales 1995–2000.

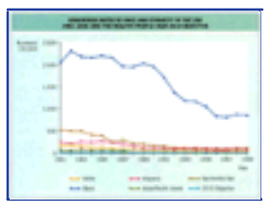

Figure 73-5 Gonorrhea rates by race and ethnicity in the USA 1981–2000 and the Healthy People Year 2010 objective. Nat Am/AK Nat, American Indian/Alaska Natives.

Eastern Europe, and particularly the newly independent states of the former Soviet Union have seen an epidemic of STIs, with high rates of gonorrhea in Estonia (166), Russia (138), Belarus (125) per 100,000 compared to France (18.5), Germany (5), and the Netherlands (8) per 100,000.

Syphilis

Syphilis is now rare in Western Europe and North America, largely due to the control of early acquired infectious syphilis in women and the screening of pregnant women for syphilis. In most Western European countries there has been a sustained decline in the incidence of syphilis to less than 5/100,000. As mentioned above, there has been an epidemic of most STIs in Eastern Europe with a recent epidemic of syphilis in all the newly independent states of the former Soviet Union. In 2000, the incidence of syphilis in these states ranged from 55 to 180/100,000 (Fig. 73.6). This epidemic is the vanguard of an HIV epidemic and already there have been outbreaks of HIV among intravenous drug users, particularly in Belarus, Russia and Ukraine. Likewise, syphilis is still a major clinical problem and cause of genital ulceration in the developing world. For

TABLE 73-4 -- Magnitude of the epidemics overall (USA).*

MAGNITUDE OF THE EPIDEMICS OVERALL (USA)		
STD	**Incidence Estimated number of new cases every year (millions)**	**Prevalence Estimated number of people currently infected (millions)**
Chlamydia	3	2
Gonorrhea	0.65	NA
Syphilis	0.7	NA
Herpes	1	45
Human papillomavirus	5.5	20
Hepatitis B	0.120	0.417
Trichomoniasis	5	NA
Bacterial vaginosis	NA	NA
NA, not available		

** From Cates 1999[9] .*

example, syphilis prevalence rates among pregnant women range from 17.4% (Cameroon) to 2.5% (Burkina Faso).

Chlamydia

In most of Europe and North America, chlamydia is still a major public health problem. In some countries, however, where widescale screening has been instituted, such as Sweden during the 1980s, the number of cases have declined dramatically. For example, in Sweden the number of cases in 1987 was 38,000 declining to 14,000 by 1997. In the UK no such trend has been seen, and *Chlamydia trachomatis* infection is now the commonest curable bacterial STI. There has been an increase in the number of cases since 1995 with females outnumbering males. In the year 2001, 71,055 people with chlamydial infections attended clinics: 30,725 males, 40,330 females. The condition is most commonly seen in young people; the peak age in men in 20–24 years and in women 16–19 years

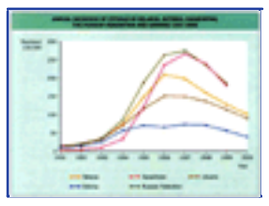

Figure 73-6 Annual incidence of syphilis in Belarus, Estonia, Kazakhstan, the Russian Federation and Ukraine 1991–2000.

(Fig. 73.7). Screening surveys carried outside normal STD clinic environments also show high levels in antenatal and gynecology clinics, general practice, family planning and termination of pregnancy clinics, prevalences ranging from 4.5 to 16%. Similar high rates have been seen in the USA. It should, however, be remembered that there has been increased availability of chlamydia testing and more sensitive detection tests, which to some extent account for the apparent increase in the number of cases seen.

Genital herpes and warts

In England and Wales, compared to gonorrhea and chlamydia, there has been a slowing down in the increase of both of these conditions in the past few years. It is estimated that the number of new cases of herpes per year in the USA is one million with a prevalence of approximately 45 million cases. For genital warts the number of new cases is 5.5 million with a prevalence of 20 million cases. Serologic surveys have shown an increase in prevalence of 17–21% in HSV-2 antibodies between 1976–1978 and 1988–1992 in population samples in the USA.[10]

It is often overlooked that high levels of herpes simplex virus (HSV) infection also exist in developing countries, for example in Mwanza, Tanzania, over 40% of teenage girls have serologic evidence of HSV infection. This becomes particularly important in relation to the increased risk of HIV acquisition.

Pelvic inflammatory disease

Pelvic inflammatory disease (PID) is one of the most serious complications of gonococcal and chlamydial infections and its prevalence is increasing in most countries. In western industrialized countries it is estimated that the annual incidence is 10/1000 women aged 15–39 years with a peak incidence of 20/1000 in age groups 15–24 years. Risk factors as well as STIs include the use of intrauterine devices and postpartum and puerperal infections. STIs cause most cases of PID, particularly in developing countries, and infertility as a result of PID is responsible for 50–80% of infertility among African women.[11]

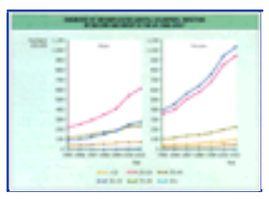

Figure 73-7 Diagnoses of uncomplicated genital chlamydial infection in genitourinary medicine clinics by sex and age group in the UK 1995–2000. *Data are currently unavailable from Scotland for 2000 and from Northern Ireland for 1996 and 1997. *Data from the PHLS and Scottish ISD(D)5 Collaborative Group (ISD, SCIEH and MSSVD).*

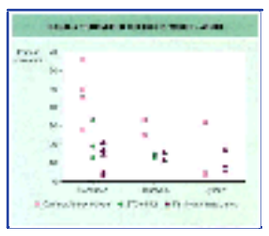

Figure 73-8 Sexually transmitted diseases in women in Africa.

Sexually transmitted infections in developing countries

STIs have a much higher incidence and prevalence in developing countries and are among the top five causes of consultation in general health services in many African countries. Routine and accurate surveillance data are often lacking, and an understanding of the burden of infection tends to come from ad hoc surveys, usually among high-risk groups. Particularly high rates of infections are seen in groups such as female prostitutes and their clients, and truck drivers. Prostitution continues to be an important factor in the transmission of STIs in developing countries. For example, in an urban Kenyan STD clinic, 60% of men with a diagnosis of gonorrhea or chancroid reported commercial sex exposure as the likely source of infection. Genital ulcer disease (syphilis, chancroid, lymphogranuloma venereum and granuloma inguinale) is more frequent than in developed countries. Fig. 73.8 illustrates the prevalence of three common STDs in women in an African setting taken from various surveys. In commercial sex workers, the prevalence of gonorrhea can reach nearly 50%, and the prevalence of syphilis ranges from 2–30% for acute or previous infection. Levels of chlamydia can be as high as 30%. The incidence of STI complications and their sequelae is much higher in developing countries due to lack of resources and adequate diagnosis and treatment. Particular complications that are seen relate to adverse pregnancy outcomes for both mother and the newborn, neonatal and infant infections, infertility in both sexes, ectopic pregnancy, urethral strictures in males, blindness in infants due to gonococcal and chlamydia ophthalmia neonatorum, and in adults due to gonococcal keratoconjunctivitis as well as genital cancers, particularly cancer of the cervix and penis.

CONTROL OF SEXUALLY TRANSMITTED INFECTIONS

Principles of effective STI control

The main principles of the control of STIs are to:

- prevent new infections;
- treat those with symptoms of infection and interrupt onward transmission — such treatment should prevent the development of disease complications and sequelae;
- identify and treat those without symptoms by screening and partner notification; and
- motivate health seeking behavior among those who may know they are infected but who delay or avoid seeking treatment.

Issues and problems in relation to control

Issues and problems in relation to control include:

- high rates of infection among young adults, adolescents and certain groups (e.g. commercial sex workers, truck drivers);
- asymptomatic infection;
- long-term morbidity, particularly in women;
- increased acquisition of HIV in transmission;
- disadvantaged and disempowered women;
- the complex mix of social, political, cultural, demographic and economic factors.

Approaches to prevention

It is theoretically possible to develop programs using the two approaches of primary and secondary prevention.

Primary prevention

The three basic elements of primary prevention are:

- health education,
- provision of condoms, and
- social, cultural and economic interventions.

Programs to promote safer sexual practices and increased condom use have been widely instituted throughout the developed and developing countries. Much of the cultural shift that has occurred in the past 20 years in relation to more explicit messages around sex and condom promotion have come with the advent of HIV infection and AIDS. Essentially, therefore, primary prevention should be concerned with entire communities and with efforts to prevent individuals from becoming infected. This approach requires a range of health promotion activities, both at national and local levels, to include sex education policies and programs, campaigns, and as mentioned previously, the promotion of condoms.

Encouraging the use of condoms has been a central part of many control programs, and is seen as particularly useful since their use reduces the acquisition and transmission of both STIs and HIV infection. There are now many examples in the literature of the effectiveness of condom use in both high-risk groups and the general population. For example, a 3-year program of condom promotion and STD control in Zaire saw an increase in consistent condom use from 11 to 68% among commercial sex workers.[12] This was associated with a decline in the incidence of HIV, gonorrhea, trichomoniasis and genital ulcer disease. Social marketing of condoms in Zaire saw sales increasing from 20,000 to 18 million in a period of 3 years. Multiple outlets were used, such as street traders, night clubs, commercial sex workers and pharmacists. More recent studies among commercial sex workers in the Côte d'Ivoire and Uganda confirm these earlier studies, namely that consistent use is related to a reduction in the prevalence of HIV infection and other STDs.[13] [14]

There are particularly problems in relation to the development of primary prevention initiatives. For example, even though initially health promotion and condom programs showed reductions of STIs and new HIV infections, for example in the UK and USA, the initial and profound changes of sexual behavior in homosexual men has not been universally sustained. This underlines the need for repeated reinforcement and continuation of health promotion programs. The particular problem in the developing world is the position of women, who are often poor and disempowered. To overcome this economic programs may be required that help reduce the necessity for women to work as commercial sex workers, and at the same time women need to be taught skills that help them negotiate safer sex with clients and their regular partners. Raising the status of women is a crucial factor in the effective control of STIs and HIV infection.

Secondary prevention

Health-seeking behavior

It is important to have a conceptual framework for the development of control programs to readily understand that not all those with infections seek care and are eventually treated successfully (Fig. 73.9). Thus, only half of those with an STD symptom recognize its significance, and only half of these present for treatment, of

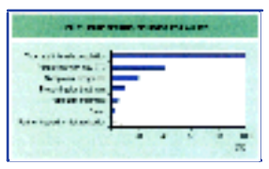

Figure 73-9 Health care-seeking behavior for an STD.

whom a further half receive adequate treatment. It is essential to encourage those with symptoms to seek treatment. It is therefore important to identify the large number of people who fail to obtain treatment or delay seeking treatment and may therefore continue to infect others and develop complications. The issue of health-seeking behavior is best addressed through public education, the provision of user-friendly services which do not stigmatize patients, and access to cheap confidential treatment.

Clinical services/case management

Once a patient attends for treatment, it is important that a correct diagnosis is made, effective treatment is instituted, compliance understood, risky behaviors discussed and partners notified. It is essential that services are nonjudgmental, sensitive, user friendly and easy to use.

Service models

Two types of approaches for control have been developed; vertical and integrated services:

- ¦ the vertical services model is the one that is usually developed in resource-rich countries and is based on etiologic diagnoses established by microscopy with laboratory back-up and run by specialist doctors;
- ¦ the integrated approach to services has been developed more in developing countries where services are run by nonspecialists using various facilities, for example outpatient clinics, primary health centers (PHCs), maternal and child health centers (MCHCs) and family planning clinics (FPCs) — in addition, private practitioners, pharmacists, traditional healers, unqualified practitioners and street vendors make a contribution to treatment.

Syndromic management

The WHO has put particular emphasis on integrated approaches and using the syndromic approach for patient management.[15] [16] Essentially this recognizes the limitation of resources for health care and of specialist trained medical personnel. It is used particularly in high prevalence areas where there are inadequate laboratory facilities, lack of trained staff, and large distances between rural primary health centers and specialist and laboratory facilities.

The syndromic approach is based on the use of algorithms developed for commonly presenting signs and symptoms, for example genital ulcers or urethral and vaginal discharge where laboratory support may or may not be present. One of the major advantages of this approach is that it can be integrated into other services such as MCHC, PHCs and FPCs. Unfortunately, not all the algorithms are

discriminatory and sensitive, for example that for vaginal discharge does not easily lend itself to making the distinction between vaginal infections and vaginal plus cervical infections. Work on improving this by incorporating risk assessment scores has been carried out in the last few years. The syndromic approach used in an integrated way received a considerable boost with the Mwanza Trial, which demonstrated the importance of an integrated STI program in rural communities on the incidence of HIV infection. [17] This trial showed that improved STI care integrated at PHC level resulted in a reduction of STI incidence of 42% over the 2-year period of the study.

Asymptomatic infection

Asymptomatic infection is a major issue in the control of STIs anywhere in the world. Strategies for dealing with asymptomatic infection are:

- ¦ encouraging check-ups for those at risk through mass media campaigns;
- ¦ promoting safer sex through health education and condom provision;
- ¦ screening and case finding, for example in antenatal clinics and FPCs;
- ¦ partner notification when a patient presents for care; and
- ¦ mass treatment.

The identification of asymptomatic infection by population screening requires an inexpensive and noninvasive, simple, available diagnostic test that can be widely used. Initial studies using the leukocyte esterase dipstick test in men on first-catch urine showed a low sensitivity. Newer tests using polymerase chain reaction techniques will help, but only if sensitive, specific and cheap.

Mass treatment

The attraction of mass treatment is the fact that a large number of asymptomatic and untreated infections can be eradicated and the Rakai Study carried out in Uganda showed the effectiveness of this approach.[18] In this study ciprofloxacin, azithromycin and metronidazole were used. The results showed that there was a failure to reduce the incidence of HIV infection despite good coverage of the study population. Considerable debate and analysis has ensued over this study, particularly since it contrasts with the Mwanza intervention. It is thought that the failure to have an impact on HIV infection was due to the fact that the HIV epidemic in Uganda was already mature and that STIs in such an epidemic are unlikely to have an important facilitatory role. On a more practical basis, even though it would appear that there was 80% coverage of the Rakai population, perhaps those at highest risk of infection, for example commercial sex workers and truck drivers, may not have been captured in the treatment intervention.

The principle disadvantages of mass treatment interventions are:

- ¦ the high cost of treating large numbers of people, many of whom do not require treatment;
- ¦ the potential danger of antibiotic resistance;
- ¦ the encouragement of unsafe sex in populations with lowered perception of risk;
- ¦ the danger of stigmatizing individuals or groups who are not diseased; and
- ¦ finally, ethical considerations of treating people who may not be infected and who may suffer ill effects from treatment.[19]

Interventions with core groups

Over and Piot have suggested that targeting core groups in relation to treatment would 'avert ten times as many cases of STIs as would have been averted by a policy directed at the non-core group'.[2] The rationale for this is that preventing STIs and HIV infection in individuals with high rates of partner change will avert many more infections than interventions among people with few partners. One of the stated disadvantages of this approach is the stigmatization of such groups. The approach of targeted interventions has been used, particularly in developing countries with commercial sex workers and their clients, and truck drivers. Evaluation of this approach is limited at this point in time.

Partner notification

Partner notification is an essential cornerstone of any control program, but is not always carried out. However, by offering treatment to sexual partners of patients whether they are symptomatic or not, reinfection can be halted and ongoing transmission curtailed. Partner notification can be carried out in a variety of ways:

- first, patient referral in which the index patient is encouraged to seek out his or her own sexual partners;
- second, provider referral in which the health team takes on the responsibility for identifying the partners; and
- finally, conditional referral — in this situation the health care workers of the index case obtain the names of the sexual partners but allow the patient a period of time to notify partners themselves — failure to do so in this time would result in the health care professionals taking on the responsibility for this mission.

CONCLUSION

STIs present a major public health problem throughout the world associated with significant morbidity and mortality rates. Well-designed control programs will help to reduce the incidence and prevalence of such diseases and reduce the morbidity, suffering and economic costs associated with them. Equally, eliminating STIs as a facilitatory factor in HIV transmission, and by contributing to behavioral changes towards safer sex, will play an important part in the prevention and control of HIV infection and AIDS.

Chapter 74 - Gonococcal, Chlamydial and *Mycoplasma* Urethritis

Kimberley K Fox
Myron S Cohen

Neisseria gonorrhoeae and *Chlamydia trachomatis* are the two major pathogens responsible for urethritis, a syndrome characterized by urethral discharge and dysuria. Urethritis is defined by its pathognomonic laboratory finding: an increased number of polymorphonuclear leukocytes (PMNs) on the Gram stain of a urethral smear. Urethritis has generally been classified as gonococcal urethritis or nongonococcal urethritis (NGU). Causes of NGU have only recently been elucidated; in addition to *C. trachomatis*, these include *Mycoplasma genitalium*, *Ureaplasma urealyticum*, other infectious agents and a variety of chemical and physical irritants.

EPIDEMIOLOGY

Neisseria gonorrhoeae and *C. trachomatis*, along with most other agents of urethritis, are sexually transmitted pathogens. Both pathogens have a worldwide distribution, although prevalences vary tremendously from region to region. In the USA, despite overall declines in the reported incidence of gonorrhea, rates remain high in adolescents and young adults (Fig. 74.1) and in minority groups. In 2000, rates among African-Americans were 30-fold higher than rates among non-Hispanic whites.[1] In addition, many cities in the USA have reported significant increases in gonorrhea among men who have sex with men (MSM) since the mid-1990s.[2]

Trends in chlamydial infection in the USA are less well documented because tests for *C. trachomatis* have only been widely available since the mid-1980s and only in 2000 was reporting of the infection mandatory in all 50 states. Chlamydial infection is probably several times more common than gonorrhea. However, currently reported rates of chlamydial infection (Fig. 74.2) reflect screening and reporting practices as much as they reflect the actual distribution of the disease. Testing for *C. trachomatis* in men has been especially limited. Specific testing for *M. genitalium* is not widely available, and so rates and trends for this infection have not yet been defined. Reported physician visits for NGU declined modestly during the 1990s.[1]

In Europe, gonorrhea rates declined during the 1980s and 1990s, reaching rates far lower than those in the USA. However, like the USA, many European countries saw increases in gonorrhea — especially among MSM — during the late 1990s. Chlamydial infection is still far more common than gonorrhea in most of Europe, as control programs were limited by the lack of sensitive diagnostic tests until the past decade.[3]

In the developing world, rates of gonococcal and chlamydial infection are less well known, but estimated incidence rates are several times higher than rates in many developed countries. The public health burden of these diseases is clearly tremendous. Complications such as pelvic inflammatory disease and its sequelae in women, urethral stricture in men and ophthalmia neonatorum in infants are common. [4]

Risk factors for urethritis are similar to those for other sexually transmitted diseases (STDs): multiple sexual partners, a recent new partner and other sexual behaviors that increase the likelihood of encountering a sexually transmitted pathogen. Young age, low socioeconomic status and minority race are recognized as risk markers for STDs, although these factors are more strongly associated with gonorrhea than with NGU.[5] [6] [7] Heterosexual men have higher rates of NGU and chlamydial infection than homosexual men, although rates of chlamydial infection among homosexual men may be increasing.[8] In addition, 10–30% of men with gonorrhea are co-infected with *C. trachomatis*. [9] [10]

PATHOGENESIS AND PATHOLOGY

The large majority of urethritis cases are caused by sexually transmitted infectious agents, most commonly *N. gonorrhoeae* and *C. trachomatis* (Table 74.1). For both pathogens, humans are the only natural host. *Neisseria gonorrhoeae* is a Gram-negative diplococcus that is highly adapted for growth on the mucosal membranes, infecting primarily columnar and cuboidal epithelium. Urethral infection requires that the organism first attach to the epithelium and then evade host defenses well enough to survive and multiply. The gonococcus uses a set of complex mechanisms to accomplish these goals (Fig. 74.3).[11] At least two outer membrane proteins, pilin and Opa, are important in adherence. Mechanisms for evading ingestion by PMNs appear to include production of the antioxidant catalase, competition for molecular oxygen and DNA repair mechanisms. Other mechanisms important in the evasion of host defenses include production of an IgA protease and blocking of antibody-mediated killing with sialylated lipo-oligosaccharide (LOS) or with blocking antibodies directed against reduction modifiable protein (Rmp). The purulent exudate characteristic of gonococcal infections is a result of the neutrophil response stimulated by LOS and other gonococcal antigens. Gonococci that cause disseminated infection have several unique characteristics, including particular nutritional requirements (arginine-, hypoxanthine- and uracil-requiring (AHU$^-$)), selected classes of the major outer membrane protein (IA serovars) and the ability to survive humoral defenses such as a complement-mediated bactericidal attack.[12]

Chlamydia trachomatis is the single most common cause of NGU, although it accounts for less than half of NGU cases in many populations. It is an obligate intracellular pathogen that primarily infects columnar epithelium. *Chlamydia trachomatis* serovars D–K cause ocular and genital disease; other serovars cause trachoma (A–C) and lymphogranuloma venereum (L1–L3). The pathogenesis of chlamydial infection is less well understood than that of gonorrhea. *Chlamydia trachomatis* has a unique life cycle involving an infectious stage, the elementary body; and a metabolically active stage, the reticulate body (Fig. 74.4). *Chlamydia trachomatis* evades host defenses by multiplying within a phagosome and preventing phagolysosomal fusion. Direct cytotoxicity and a host immune response to selected chlamydial antigens produce the clinical manifestations of infection. Repeated infection or chronic infection, with long-lived humoral and cell-mediated immune responses, are probably responsible for the complications of chlamydial infection such

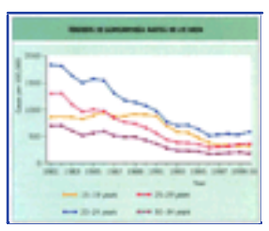

Figure 74-1 Trends in gonorrhea rates among men aged 15–34 years in the USA, 1981–2000. Rates are cases per 100,000 population. *Source: Sexually Transmitted Disease Surveillance, 2000.*[1]

Figure 74-2 Rates of chlamydial infection in the USA, 2000. Rates are cases per 100,000 population. *Source: Sexually Transmitted Disease Surveillance, 2000.*[1]

as Reiter's syndrome and tubal scarring leading to infertility. The immune response to a chlamydial 60kDa heat shock protein, which has substantial homology with human heat shock proteins, may be particularly important in producing these complications. [13]

Host factors involved in gonococcal and chlamydial infection are poorly understood. No racial and genetic factors predisposing to infection with these agents have been identified. Terminal complement deficiency predisposes to invasive, but not mucosal, gonococcal infections. Limited evidence supports the possibility of short-term, incomplete, strain-specific immunity to either agent. However, repeat infections with these agents argue against a longlived protective immune response after natural infection.

TABLE 74-1 -- Infectious and noninfectious causes of urethral discharge and dysuria.

INFECTIOUS AND NONINFECTIOUS CAUSES OF URETHRAL DISCHARGE AND DYSURIA		
Major infectious causes	**Other infectious causes**	**Noninfectious causes**
Neisseria gonorrhoeae	*Mycoplasma genitalium*	Chemical irritants (spermicides, bath products)
Chlamydia trachomatis	*Ureaplasma urealyticum*	Tumor
	Trichomonas vaginalis	Foreign body
	Herpes simplex virus	Stevens-Johnson syndrome
	Coliform bacteria	Wegener's granulomatosis

	Candida albicans	
	Treponema pallidum	
	Human papillomavirus	

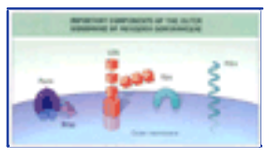

Figure 74-3 Important components of the outer membrane of *Neisseria gonorrhoeae*. Porin is the major outer membrane protein. Reduction modifiable protein (Rmp) is the target of blocking antibodies that prevent bactericidal antibodies from binding to porin. Pilin and opacity protein (Opa) are important in adhesion. Lipo-oligosaccharide (LOS) stimulates PMN response and, when sialylated, blocks antibody-mediated killing.

Nonchlamydial NGU is a group of syndromes caused by infectious and noninfectious agents. In the past decade, *M. genitalium* has been recognized as a relatively frequent cause of nonchlamydial NGU.[14] [15] [16] It exhibits strong adherence to eukaryotic cells and stimulates a neutrophil-dominated acute inflammatory response. The ability of *M. genitalium* to invade epithelial cells and persist in this environment may account for the association of this pathogen with persistent and recurrent urethritis.[14] [16] *Ureaplasma urealyticum* is found in 10–60% of all NGU cases, although its etiologic role has been controversial. It clearly causes symptomatic infection that responds to specific therapy in some men, but has also been found to colonize as many as 60% of men in STD clinic settings. [7] [15] *Mycoplasma hominis* is a frequent genital tract colonizer and was long suspected of causing urethritis, but studies have failed to confirm its role as a pathogen in men.

Approximately 10–20% of NGU cases are caused by agents other than *C. trachomatis*, *M. genitalium* and *U. urealyticum*. Herpes simplex virus can cause urethritis, usually in primary infection and in conjunction with external ulcerative lesions.[17] *Trichomonas vaginalis*

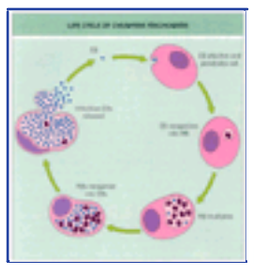

Figure 74-4 The life cycle of *Chlamydia trachomatis*. The elementary body (EB) invades the host cell and then reorganizes into the metabolically active reticulate body (RB) while in a phagosome. The reticulate body multiplies and the resultant reticulate bodies reorganize into elementary bodies, which are released by rupture of the host cell.

causes a variable proportion of NGU cases.[18] Coliform bacteria occasionally cause urethritis, especially if phimosis or urethral stricture is present or after urethral instrumentation. Distal urethritis may be caused by *Candida* spp. in association with yeast balanitis involving skin adjacent to the meatus. Urethral discharge without dysuria may be caused by an endourethral syphilitic chancre or by intraurethral condyloma acuminata. Limited evidence suggests that adenovirus, *Haemophilus influenzae*, *Clostridium difficile*, *Neisseria meningitidis* and *Bacteroides ureolyticus* may occasionally cause urethritis.

A small percentage of NGU cases do not have infectious causes. Spermicides and some bath products can cause a chemical urethritis. An endourethral tumor or intraurethral foreign body can cause a mucoid or bloody discharge and may become secondarily infected with local skin flora. Repeated vigorous urethral stripping (see Physical examination) may eventually cause the production of a clear urethral discharge. Heavy crystalluria or calculous gravel in the urine can produce dysuria and may have the appearance of a urethral discharge. Systemic illnesses such as Stevens-Johnson syndrome, Wegener's granulomatosis and Behçet's disease are occasionally associated with urethritis. Finally, the remnants of semen at the meatus or urinary incontinence may be misinterpreted by the patient as urethral discharge.

PREVENTION

The persistence of STDs such as urethritis in a community requires the spread of disease from each infected person to, on average, at least one other susceptible person. This concept is expressed in the equation, $R_0 = ßcD$, where the number of secondary infections arising from each case, or reproductive rate (R_0), depends on the efficiency of transmission (ß), the rate of sexual partner change (*c*) and the duration of infectiousness (*D*).[19] The value of each parameter varies by pathogen.

Gonococcal urethritis transmits infection with high efficiency, around 50–70% for a single act of vaginal intercourse.[20] Without treatment, gonococcal urethritis remains infectious for approximately 6 months, but most cases produce symptoms uncomfortable enough that men rapidly seek treatment, shortening the infectious period to several days. Given these parameters, the maintenance of gonorrhea in a community in which treatment is readily available requires an average partner change rate of 13 partners per year.[21]

Chlamydial urethritis is transmitted with less efficiency than gonorrhea — approximately 20–50% for a single contact or 70% for long-term partnerships.[22] Without treatment, chlamydial urethritis remains infectious for around 15 months and, because the majority of cases are asymptomatic, the infectious period remains long despite the ready availability of effective therapy. As a result of this long infectious period, the average partner change rate required to maintain chlamydial infection in a community is estimated at only four partners per year.[22] The transmission efficiency of *M. genitalium* urethritis has not been defined. Most persons with gonococcal or chlamydial infection in fact have lower rates of partner change; however, a small group of people — the core group — with higher rates of partner change are critical in maintaining the spread of infection.[23] This core group for chlamydial infection encompasses a broader population than that for gonorrhea because of the lower number of partners required.

Preventive measures targetting one or more of these key parameters can result in lowered rates of STDs (Table 74.2). Treatment of STDs reduces the duration of infectiousness, thereby limiting secondary spread of disease. Highly effective single-dose therapies are recommended for gonorrhea and single- or multiple-dose therapies for chlamydial infection (see Management). *Neisseria gonorrhoeae* is eliminated from the urethra within hours of oral or parenteral therapy;[24] elimination of *C. trachomatis* is slower. Treatment of the sexual partner is essential to prevent reinfection of the patient and spread to other individuals.

Screening, with prompt treatment of infected persons, is an important strategy to prevent secondary spread of asymptomatic or subclinical infections. Although the majority of gonococcal urethritis cases are symptomatic, men with asymptomatic infection contribute disproportionately to the spread of gonorrhea.[25] In addition, a large proportion of chlamydial urethritis cases are asymptomatic, and so screening of persons with high-risk behaviors is especially important in limiting the spread of this disease. A recent study of the general population in a major US urban center found that 7.9% of persons had untreated gonococcal or chlamydial infection.[26] Since chlamydial infection is highly prevalent in many areas, clinicians should have a low threshold for screening any sexually active person.

TABLE 74-2 -- Prevention of gonococcal and chlamydial infection.

PREVENTION OF GONOCOCCAL AND CHLAMYDIAL INFECTION	
Primary prevention	**Secondary prevention**
Male latex condoms	Screening of at-risk individuals
Sexual behavior change	Prompt treatment of infected individuals
Microbicides (under development)	Treatment of sexual partners
These preventive measures reduce the transmission effiency, the duration of infectiousness, or the rate of sexual partner change.	

Improving the accessibility and utilization of health care services to allow for prompt diagnosis and therapy can interrupt transmission and prevent complications of infection. Barriers to utilization include lack of awareness of STD symptoms, the cost of care, limited hours of service, lack of transportation and cultural differences between providers and patients.

Male latex condoms, when used correctly and consistently, are one of the most effective available tools for reducing the efficiency of transmission of gonorrhea and chlamydial infection.[27] The polyurethane female condom has been demonstrated to reduce transmission of trichomoniasis [28] and is being studied for its effectiveness in preventing transmission of other bacterial STDs. However, this product has had limited user acceptance in the USA.

Chemical barriers such as vaginal microbicides may have a future role in reducing the transmission efficiency of gonorrhea and chlamydia. The only currently available microbicide, nonoxynol-9 (also a spermicide), has poor efficacy against STDs and may increase the risk of HIV transmission.[29]

Finally, strategies to alter sexual behaviors to reduce the rate of partner change can decrease the spread of STDs. Changes in sexual behavior in the gay community were important in limiting the spread of HIV and other STDs in the 1980s[30] and recent relapses in risky sexual behaviors have been associated with increases in gonorrhea and syphilis in this population. [31] Effective strategies include enhanced risk reduction counseling for individuals or small groups and interventions that use peer opinion leaders to change community norms for sexual behaviors.

CLINICAL FEATURES

Urethritis classically produces urethral discharge accompanied by dysuria. The discharge may be scant or copious and may appear clear, white, yellow or green. Itching around the meatus is common. Frequency, urgency and hematuria are not generally part of this clinical syndrome and should lead to the consideration of alternative diagnoses.

The pattern of urethral symptoms and characteristics of the discharge can provide clues as to the etiologic diagnosis. In gonococcal urethritis, the incubation period is brief (2–6 days). The use of sub-curative doses of antibiotics during this time can prolong the incubation period. Symptom onset is abrupt. Gonococcal urethritis usually produces copious, purulent, often yellow-green discharge along with marked dysuria.[5] Inguinal lymphadenopathy is absent, although small nontender nodes, unrelated to the gonococcal infection, may be palpable in a majority of men. Up to 30% of men with gonorrhea are co-infected with *C. trachomatis*.[9] [10] The proportion of men with co-infection may be declining as dual treatment and, more recently, screening for *C. trachomatis* have become widely practiced.

Approximately 2–3% of men acquiring urethral gonococcal infection remain asymptomatic, especially those infected with strains that have selected serotypes and auxotypes.[32] [33] These infections may play a disproportionate role in the spread of *N. gonorrhoeae*, as they are identified only through partner notification or by the screening of high-risk populations. Symptomatic gonococcal urethritis becomes asymptomatic if left untreated over a period of months.[33]

Gonococcal urethritis and NGU can be accurately differentiated based on clinical grounds in three-quarters of patients.[5] Chlamydial urethritis has a longer incubation period (1–5 weeks) and produces more subtle symptoms than gonorrhea.[7] Onset of symptoms is subacute. The discharge is mucopurulent or mucoid and may be seen only after urethral stripping or in the morning before voiding. A small crust at the meatus may be the only visible discharge and may be associated with meatal itching. Dysuria is frequently present but may be less intense than in gonococcal infection. However, the presence of dysuria without urethral discharge is a very good (90%) predictor of NGU, including chlamydial infection.[5] As with gonorrhea, local lymphadenopathy is absent. One-quarter to one-half of men with chlamydial urethritis are asymptomatic.[7] The clinical manifestations of gonococcal and chlamydial urethritis appear to be similar in non-immunocompromised and immunocompromised patients, including those with HIV infection.

Urethritis caused by *M. genitalium*, *U. urealyticum* or *T. vaginalis* infection is clinically indistinguishable from chlamydial urethritis;[9] when available, laboratory testing for *T. vaginalis* may aid in diagnosis. Primary herpes simplex virus infection frequently results in urethritis accompanying external genital vesicle and ulcers.[17] Dysuria is severe and the mucoid discharge profuse; regional lymphadenopathy is common. Endourethral ulceration may result in localized tenderness along the urethra.

Several symptoms suggest diagnoses other than urethritis. Urinary frequency and urgency, with or without hematuria, suggest cystitis or upper urinary tract infection. Painless hematuria usually originates in the bladder or kidney from a variety of largely noninfectious causes. Hesitancy, dribbling and nocturia require evaluation for urologic and prostatic disorders. Prostate tenderness is not seen with simple urethritis, but may be found in the occasional case of prostatitis accompanying urethritis. Painful ejaculation without dysuria, blood in the ejaculate and pain radiating from the genitals to the pelvis or back are not seen in urethritis and mandate evaluation for other disorders.

Complications

Without treatment, gonococcal and chlamydial urethritis can lead to a variety of complications (Table 74.3). Epididymitis occurs in 1–2% of patients, with equal risk from *N. gonorrhoeae* and *C. trachomatis*. [7] [34] In this setting, epididymitis is unilateral and is caused by extension of the urethral infection via the vas deferens to the epididymis. Most cases of epididymitis in adult men under the age of 35 years can be attributed to *N. gonorrhoeae* and *C. trachomatis*. Homosexual men who practice and insertive intercourse may acquire urethritis and epididymitis caused by Gram-negative bacilli. Occasionally, epididymitis extends to the testis, producing epididymo-orchitis. Rapid differentiation of epididymitis and orchitis from testicular torsion is critical as the latter is a surgical emergency. Epididymitis and orchitis are discussed further in Chapter 68 .

Conjunctivitis, following accidental self-inoculation, complicates as many as 1–2% of cases of gonococcal or chlamydial urethritis.[34] In the pre-antibiotic era, prostatitis and urethral stricture often resulted from prolonged untreated gonococcal urethritis. Periurethral abscess occasionally complicates urethritis caused by coliform bacteria, especially if phimosis or pre-existing urethral stricture is present.

TABLE 74-3 -- Complications of urethritis caused by *Neisseria gonorrhoeae* and *Chlamydia trachomatis.*

COMPLICATIONS OF URETHRITIS CAUSED BY *NEISSERIA GONORRHOEAE* AND *CHLAMYDIA TRACHOMATIS*
Neisseria gonorrhoeae
Disseminated gonococcal infection (0.5–2%)
Prostatitis (very rare)
Chlamydia trachomatis
Reiter's syndrome (<1%)
N. gonorrhoeae* or *C. trachomatis
Epididymitis (1–2%)
Conjunctivitis (1–2%)
Urethral stricture (rare)
Enhanced transmission of HIV (risk increased 4- to 5-fold)
Approximate rates for each complication are provided in parentheses.

Fewer than 1% of patients who have chlamydial urethritis develop Reiter's syndrome, with the triad of urethritis, conjunctivitis or uveitis and arthritis. [35] Other clinical manifestations include painless erythema and ulceration of the glans (circinate balanitis), pustular or hyperkeratotic lesions of the soles of the feet (keratodermia blennorrhagica), nonarticular body pain and oral mucosal ulcerations. The majority of patients who have Reiter's syndrome have the HLA-B27 histocompatibility antigen. Pathogenesis is thought to involve an abnormal host response to antigens of *C. trachomatis*, which have been found in the synovium of affected joints. *Mycoplasma genitalium* has also been identified in the joints of patients with arthritis. [14] Reiter's syndrome also develops after infection with certain gastrointestinal pathogens (see Chapter 43).

Disseminated gonococcal infection (DGI) arises primarily from asymptomatic gonococcal urethritis caused by strains with particular serotypes (IA) and auxotypes (AHU^-).[12] Strains associated with disseminated gonococcal infection are also resistant to killing by normal human serum, presumably allowing invasion of the bloodstream and dissemination to distant sites. Terminal complement deficiency predisposes to invasive gonococcal infections, but the majority of patients who have DGI have normal complement levels. Signs and symptoms of DGI include small numbers (usually fewer than 30) of papular, petechial or pustular skin lesions, usually on the hands, wrists and feet, tenosynovitis of the hands or feet or asymmetric polyarthritis involving few joints, and fever. Culture of joint fluid from a patient who has this dermatitis-arthritis syndrome is usually negative, although blood culture may be positive. A frank septic arthritis caused by *N. gonorrhoeae* may develop; in such cases, joint fluid culture is often positive and blood culture negative. Overall, around one-half of patients who have DGI have positive blood or joint fluid cultures. In those with negative sterile body site cultures, urethral, pharyngeal or rectal cultures frequently produce *N. gonorrhoeae* and thus support the diagnosis.

Increasingly, the importance of classic STDs in facilitating the sexual transmission of HIV infection has been recognized. The relationship between STDs and HIV is bidirectional; the presence of STDs in an HIV-negative person appears to increase the risk of acquiring HIV infection, whereas the presence of STDs in an HIV-positive individual appears to increase the potential for transmission of HIV. Gonococcal and chlamydial infection are associated with a 4- to 5-fold increased risk of acquiring HIV infection independent of sexual behaviors and other factors. [36] Limited serologic data link *M. genitalium* with HIV transmission.[14] Community-wide treatment of STDs with effective therapies reduced the rate of new HIV infections in one large study.[37] Recent data provide biologic evidence supporting the concept of increased potential for HIV spread in persons dually infected with HIV and urethritis. HIV-infected men with gonococcal urethritis shed much larger quantities of HIV in their semen than those without gonorrhea; this shedding is reduced dramatically by treatment of the urethritis.[38]

Persistent urethritis

Persistent or recurrent urethritis develops in a small proportion of patients who have NGU. In many cases, this represent re-exposure to an untreated sexual partner or infection with tetracycline-resistant *U. urealyticum* or with *T. vaginalis*. Repeat therapy, in the case of re-exposure, or empiric therapy directed at *U. urealyticum* and *T. vaginalis* is appropriate; success of the therapy confirms the diagnosis. *Mycoplasma genitalium* has also been implicated in persistent urethritis and may respond to repeated or prolonged therapy with tetracyclines, macrolides or fluoroquinolones.[14] Accompanying prostatitis may be responsible for persistence or recurrence of urethritis until a long course of therapy (3–6 weeks) is provided.[39] Other less common agents, such as *Candida albicans*, genital warts and coliform bacteria, should be considered in cases of persistent or recurrent urethritis. Noninfectious causes may explain persistent symptoms despite antimicrobial therapy. Urologic evaluation, including urethroscopy to identify intraurethral lesions or foreign bodies, may be necessary in select cases.

Urethritis in women

Urethral infection with *N. gonorrhoeae* and *C. trachomatis* occurs commonly in women; however, the clinical manifestations of concomitant cervicitis usually overshadow signs and symptoms related to urethral infection. In fact, nucleic acid amplification techniques identify *C. trachomatis* in the first-voided portion of the urine from the vast majority of women with chlamydial cervicitis. In a small proportion of these women, careful examination may reveal urethral discharge.

The diagnosis of acute urethral syndrome is made in women with symptoms of cystitis and pyuria but fewer than 10^5 bacteria/ml urine. When low-level bacteriuria is present, the etiology is probably coliform organisms typical of cystitis; when bacteriuria is absent, *C. trachomatis* is often found and the symptoms respond to appropriate therapy.[40]

Dysuria in women is more commonly caused by cystitis and vulvovaginitis. Cystitis produces urgency, frequency and internal dysuria characterized by a deep burning sensation. Vulvovaginitis results in external dysuria caused by the irritant effect of urine contacting an inflamed perineum.

Physical examination

Examination of the man with urethritis symptoms begins with assessment for urethral discharge. Ideally, the patient should not urinate for at least 2 hours before examination, as this washes discharge from the urethra. The examiner should look for evidence of spontaneous discharge and note the color, quality and quantity of the discharge. The only evidence of mild discharge may be crusting at the meatus; meatal erythema should also be sought. If no discharge is found, the urethra should be stripped to bring discharge forward. Stripping is accomplished by applying pressure along the underside of the penis from the base to the meatus. In symptomatic men, stripping frequently produces a small amount of discharge. Urethral discharge should be collected on a swab and then rolled onto a glass slide for Gram staining (Fig. 74.5). If no discharge is produced, a urethral swab should be inserted 2–4cm into the urethra for collection of the specimen. Next, the inguinal lymph nodes should be palpated;

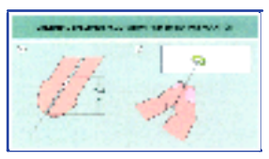

Figure 74-5 Procedure for obtaining a urethral specimen and preparing a smear for Gram stain. (a) If no discharge is present at the meatus, collect a specimen by inserting the urethral swab 2–4cm into the urethra and rotating for 5 seconds. (b) Roll the swab on a glass slide; rolling the swab preserves cell morphology.

small, mobile, nontender lymph nodes are commonly felt, but enlarged or tender lymph nodes suggest a diagnosis other than gonococcal or chlamydial urethritis. The scrotal contents should be evaluated for swelling, tenderness and warmth. Care should be taken to distinguish epididymitis and orchitis from testicular torsion, which requires prompt surgical attention (see Chapter 68).

Examination of the woman with urethritis symptoms should include a complete pelvic examination, during which cervical specimens may be obtained for diagnostic testing (see Chapter 62). In the absence of apparent cervical infection, a urethral specimen may be useful; urethral stripping may be accomplished by compressing the urethra against the symphysis pubis using a forward motion. A urethral swab should only be inserted into the most superficial part of the female urethra. However, the availability of diagnostic tests applied to urine (see Diagnosis) may obviate the need for urethral and cervical specimens in some settings.

DIAGNOSIS

Gram stain

Several laboratory studies are helpful in the diagnosis of urethritis. Once a specimen is obtained on a swab, the swab should be rolled on a slide for Gram staining (see Fig. 74.5). The presence of more than four PMNs per oil-immersion field averaged over five fields in the maximally dense part of the slide is considered objective evidence of urethritis (Fig. 74.6). Because recent urination washes away urethral discharge, fewer PMNs may be seen in this setting. In addition, variation in specimen collection technique and intraobserver variability in reading the smear mean that some men infected with agents of urethritis have fewer PMNs. As many as one-third of men with urethral chlamydial infection may not exhibit abnormal numbers of PMNs on the urethral smear.[7] The presence of Gram-negative intracellular diplococci (Fig. 74.7) indicates gonococcal urethritis with 95% sensitivity and 98% specificity and is adequate justification for therapy.[5] [20] However, sensitivity of the Gram-stained urethral smear may be lower in asymptomatic men and with specific

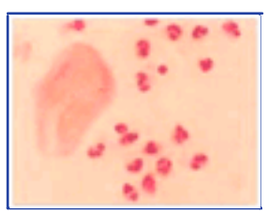

Figure 74-6 Nongonococcal urethritis. Gram-stained smear of urethral discharge containing many PMNs but no visible bacteria.

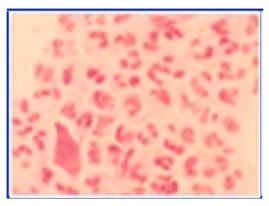

Figure 74-7 Gonorrhea. Gram-stained smear of urethral discharge containing numerous PMNs and Gram-negative intracellular diplococci consistent with *Neisseria gonorrhoeae*.

strains of *N. gonorrhoeae*.[41] Atypical intracellular or typical extracellular Gram-negative diplococci may represent other micro-organisms; gonorrhea cultures are positive in 20–30% of these cases. Other Gram-positive and Gram-negative organisms usually reflect colonization of the first centimeter of the urethra and are a normal finding.

Diagnostic tests for gonococcal urethritis and disseminated gonococcal infection

Gonorrhea culture or another test for gonorrhea should be performed if the Gram-stained smear is negative or equivocal. *Neisseria gonorrhoeae* is a fastidious organism, requiring specialized media and conditions for growth. Modified Thayer-Martin, Martin-Lewis or other media designed specifically for culturing *N. gonorrhoeae* should be used. Optimally, the specimen should be plated at the bedside and placed into a carbon dioxide incubator or candle jar immediately. Transportable culture systems using carbon dioxide-producing capsules have made culture possible in clinical settings when incubators are unavailable. Occasional strains sensitive to the concentrations of vancomycin used in the media result in false-negative cultures.

Culture has long been the gold standard for diagnosis of gonorrhea. However, the rigorous conditions necessary for successful culture have necessitated the development of new diagnostic methodologies (Table 74.4). The most important of these are the DNA probe and nucleic acid amplification assays. The DNA probe test for gonorrhea has a sensitivity of approximately 85% and specificity of 98–99%.[42] A DNA probe test is also available for *C. trachomatis*; a single swab can be submitted for both tests. Several nucleic acid amplification tests are available for the diagnosis of gonorrhea, including ligase chain reaction (LCR) and polymerase chain reaction (PCR). These techniques appear to offer no advantage over culture in terms of sensitivity and specificity for detection of urethral infection. [42] However, in situations in which optimal culture quality cannot be maintained, the DNA probe and nucleic acid amplification tests may be more sensitive than culture. In addition, nucleic acid amplification tests can be applied to the first-voided

TABLE 74-4 -- Diagnostic tests for *Neisseria gonorrhoeae.*

DIAGNOSTIC TESTS FOR *NEISSERIA GONORRHOEAE*			
Test	**Sensitivity (%)**	**Specificity (%)**	**Comment**
Gram stain*	95 (symptomatic) 60 (asymptomatic)	98	Results available immediately
Culture†	90–97	98–99	Requires careful handling and proper facilities
DNA probe†	85	98–99	Can test for *C. trachomatis* with same swab
DNA amplification (LCR, PCR, others)†	95	98–99	Can use first-voided portion of urine or urethral swab with equal performance, and test for *C. trachomatis* with same specimen
Sensitivity and specificity are given for the diagnosis of urethritis in men, using urethral specimens unless otherwise stated.

portion of urine or urethral specimens with equivalent performance. All nonculture tests have the disadvantage of not producing an isolate that can be used for antimicrobial susceptibility testing; this may become important in the near future if the prevalence of fluoroquinolone resistance increases.

The diagnosis of DGI generally depends on the constellation of clinical findings rather than on specific laboratory tests.[12] Patients suspected of having DGI should have genital, rectal and pharyngeal specimens cultured for *N. gonorrhoeae*. Joint fluid, if obtainable, should also be cultured. Blood cultures should be obtained for diagnosis and to exclude other infections associated with fever and petechial rash such as meningococcal sepsis. However, around 20% of patients who have DGI have no positive cultures. In the appropriate clinical setting, and with the exclusion of other bacterial infections of the joints or bloodstream, DGI is strongly suggested by the constellation of tenosynovitis, acral rash and fever.

Diagnostic tests for chlamydial urethritis

A wider variety of tests are available for the detection of *C. trachomatis* than for *N. gonorrhoeae* (Table 74.5). Although *C. trachomatis* can be cultured, the expense and complexity of this procedure have limited the clinical utility of culture as a diagnostic test. Several types of nonculture tests, including enzyme immunoassays (EIAs), direct fluorescent antibody tests (DFAs) and a DNA probe, have been widely used in chlamydial diagnostics; more recently, the nucleic acid amplification tests such as PCR and LCR have revolutionized the diagnosis of chlamydial infection by providing increased sensitivity and allowing the use of urine as a diagnostic specimen.

The EIAs and DFAs have sensitivities of 70–90% compared with culture and specificities of 95–99% when a confirmatory test is used. [43] Sensitivity in asymptomatic men is lower than that found in symptomatic men, presumably because of a lower organism burden. The DNA probe generally performs a little better than the EIA or DFA, with a higher sensitivity (86–93% compared with culture) and

TABLE 74-5 -- Diagnostic tests for *Chlamydia trachomatis.*

DIAGNOSTIC TESTS FOR *CHLAMYDIA TRACHOMATIS*			
Test	**Sensitivity (%)**	**Specificity (%)**	**Comment**
EIA*	70–90	95–99	Readily done in high volume
DFA*	70–95	95–99	Depends on skill of microscopist; not amenable to high volume
Culture†	65–80	>99	Requires expert laboratory
DNA probe†	85–93	98–99	Can test for *N. gonorrhoeae* with same swab
DNA amplification (LCR, PCR, others)†	94–99	98–99	Can use first-voided portion of urine or urethral swab with equal performance, and test for *N. gonorrhoeae* with same specimen
Sensitivity and specificity are given for the diagnosis of urethritis in men, using urethral specimens unless otherwise stated.			

* Compared with culture
† Compared with enhanced reference standard comprising DNA amplification plus culture or DFA test

high specificity.[44] The DNA probe test can be used to detect *N. gonorrhoeae* and *C. trachomatis* with the convenience of using a single swab. The performance of all of these tests is sensitive to the quality of specimen sampling and to the presence or absence of symptoms, as this may reflect organism burden. Rapid antigen detection tests that can detect *C. trachomatis* in less than 30 minutes and can be performed in the physician's office have been developed. However, until the sensitivity can be

improved from the current 50% (compared with culture), such tests will have very limited utility.

Comparisons of nucleic acid amplification tests with other tests for *C. trachomatis* suggest that the most sensitive test previously available, culture, detects only 65–80% of infections.[45] Nucleic acid amplification tests appear to detect 94–99% of urethral infections, based on a resolved gold standard.[45] [46] In addition to having higher sensitivities than any previously available test, nucleic acid amplification tests have very high specificities (98–99%) and can be performed using the first-voided portion of urine or urethral swabs with equivalent performance. All of the nonculture tests can detect nonviable organisms and accordingly should not be used within 2–3 weeks after treatment of chlamydial infection. A positive test for *C. trachomatis* using any of the above methodologies should be considered evidence of infection, although the clinician should recognize that even a highly specific test will yield some false-positive results, especially if the test is used to screen a low-prevalence population.

Other tests for urethritis

Tests for causes of urethritis other than *N. gonorrhoeae* and *C. trachomatis* have limited utility and are often not available to the clinician. Although *M. genitalium* is a frequent cause of urethritis, specific tests for this agent are not yet widely available. The role of *U. urealyticum* as a colonizer of the genital tract makes test results difficult to interpret; testing is also not widely available. *Trichomonas vaginalis* may rarely be seen in urethral Gram stains, but is better identified in a wet mount of the urethral specimen where motility can be appreciated (Fig. 74.8). However, most men infected with *T. vaginalis* have negative wet mounts. Culture and PCR for *T. vaginalis*, although not widely available, are much more sensitive than wet mount for urethral infection.[18] Reports of herpes simplex urethritis in the absence of external lesions suggest that testing for this virus in patients with NGU of unknown etiology may be useful. Despite use of all available diagnostic tests, 10–30% of NGU cases have no identified cause.

When the anatomic site of infection is in doubt, a urine sample can be used to distinguish urethritis from infection higher in the urinary tract. The presence of PMNs and mucous threads in the sediment of the first 10ml voided urine, while the remainder of the urine is clear, suggests urethritis;[47] equal numbers of PMNs in both parts suggests cystitis or pyelonephritis. The presence of at least 10 PMNs per high-power field in the sediment of first-voided urine is considered objective evidence of urethritis.

Figure 74-8 Trichomonal infection. Saline mount of *Trichomonas vaginalis* (arrow); characteristic ovoid shape and flagella can be seen.

Figure 74-9 A simplified approach to the diagnosis and management of symptomatic urethritis. hpf, high-power field; STS, serologic test for syphilis.

Diagnostic approach to symptomatic urethritis

An algorithm for the diagnosis and management of symptomatic urethritis is outlined in Figure 74.9 . The urethral smear classifies the patient as having gonococcal urethritis, NGU or no evidence of urethritis. The presence of typical intracellular Gram-negative diplococci is sufficient for the diagnosis of gonorrhea, requiring treatment for gonorrhea and possible co-infection with *C. trachomatis*. A test for *C. trachomatis* may be performed and partners should be treated. Since the presence of one STD increases the likelihood that another STD is present, a serologic test for syphilis is appropriate.

A patient who has a urethral smear showing five or more PMNs per high-power field, but no bacteria or only atypical diplococci, is treated for NGU. A test for *C. trachomatis* allows an etiologic diagnosis, but treatment should not be delayed pending test results. Gonorrhea testing should always be performed on patients thought to have NGU, as the Gram stain is less than 100% sensitive. As with all STDs, partners should be treated and a serologic test for syphilis performed.

If NGU persists or recurs after therapy, several possibilities should be considered. First, if the patient was noncompliant with therapy or was re-exposed to an infected partner, repeat therapy should be effective. Otherwise, empiric therapy directed at tetracycline-resistant *U. urealyticum* (erythromycin) and at *T. vaginalis* (metronidazole) is most likely to resolve the urethritis. Azithromycin may also be useful for *U. urealyticum* and for persistent or recurrent urethritis caused by *M. genitalium*. Less common causes of urethritis should also be considered at this time.

If four PMNs or fewer are seen per high-power field on the initial Gram stain, there is no objective evidence for urethritis. However, if a discharge is present, the patient should be managed as for NGU. Dysuria alone in a young sexually active man also suggests NGU; a single course of therapy directed at agents of NGU may be given before further evaluation. The presence of PMNs in first-voided urine supports the diagnosis of NGU. Whether or not treatment for NGU is given, testing for *N. gonorrhoeae* and *C. trachomatis* should be performed. If no discharge is present, and there are no PMNs in first-voided urine, then other diagnoses such as cystitis and prostatitis should be considered. Repeat examination after several hours without urination may also be helpful.

Screening for asymptomatic urethritis

A small percentage of men infected with *N. gonorrhoeae* and one-quarter to one-half of men infected with *C. trachomatis* are asymptomatic.[7] These men play a disproportionate role in spreading infection because they are unlikely to be identified and treated.[25] Attempts to improve identification of these men using leukocyte esterase testing of urine as a preliminary test have been unsatisfactory

TABLE 74-6 -- Therapeutic regimens for urethritis.[48]

THERAPEUTIC REGIMENS FOR URETHRITIS		
Gonorrhea	**Chlamydial infection**	**Nongonococcal urethritis (empiric therapy)**
Cefixime 400mg orally once*	Azithromycin 1g orally once*	Azithromycin 1g orally once
Ceftriaxone 125mg im once* †	Doxycycline 100mg orally q12h for 7 days	Doxycycline 100mg orally q12h for 7 days
Ciprofloxacin 500mg orally once† ‡	Ofloxacin 300mg orally q12h for 7 days	Ofloxacin 300mg orally q12h for 7 days
Ofloxacin 400mg orally once‡	Levofloxacin 500mg orally q24h for 7 days	Levofloxacin 500mg orally q24h for 7 days
Levofloxacin 250mg orally once‡	Erythromycin 500mg orally q6h for 7 days*	Erythromycin 500mg orally q6h for 7 days
Spectinomycin 2g im once*

** Safety in pregnancy not proved
† Preferred for coexisting pharyngeal gonorrhea
‡ Not recommended for gonorrhea acquired in Asia or the Pacific, including Hawaii

owing to the poor sensitivity of this test. Gram stain testing of a urethral smear identifies urethritis in high proportions of asymptomatic men at risk for STDs and has the advantage of identifying urethritis of any etiology. Nucleic acid amplification tests, which can be performed on urine, simplify screening for *C. trachomatis* and *N. gonorrhoeae*. Urine-based testing for these pathogens allows identification of asymptomatic infected men without the discomfort of a urethral swab and can be performed in settings in which clinicians or examination facilities are unavailable. Infection at other sites (e.g. throat, rectum) is not identified by urine or urethral testing and requires additional testing; nonculture methodologies have not been fully evaluated for use outside the genitourinary tract.

MANAGEMENT

Therapeutic regimens for the management of urethritis are outlined in Table 74.6 . Gonococcal urethritis is generally treated with single-dose therapy; a regimen active against *C. trachomatis* is added because of the high likelihood of co-infection. Nongonococcal urethritis or chlamydial urethritis is treated with a single-dose or multidose regimen. Recurrent or persistent urethritis may require more than one antibiotic or a long course of therapy. Sexual partners must also be treated, as the likelihood of infection is high. To avoid reinfection, abstinence is necessary until the patient and partner have completed therapy.

The presence of an STD is a marker for high-risk sexual behavior. Therefore, all persons with an STD should have a serologic test for syphilis and should be counseled about STD and HIV prevention. Patients without immunity to hepatitis B should be vaccinated. Urethritis in HIV-infected persons is managed no differently from urethritis in persons not infected with HIV. The management of epididymitis complicating urethritis is discussed in Chapter 68 .

Management of gonococcal urethritis and disseminated gonococcal infection

A variety of highly effective single-dose therapies are available for the management of gonococcal urethritis. Therapies recommended by the Centers for Disease Control and Prevention in 2002 include single doses of cefixime 400mg orally, ceftriaxone 125mg intramuscularly, ciprofloxacin 500mg orally, ofloxacin 400mg orally or levofloxacin 250mg orally.[48] These therapies produce greater than 95% cure rates for genital and rectal infection and the first three have been demonstrated to eliminate *N. gonorrhoeae* from the urethra within a few hours of administration.[24] The discomfort of ceftriaxone injections may be reduced by the use of a 1% lidocaine solution as a diluent. Cefixime has a lower therapeutic index (ratio of peak serum level to MIC) than ceftriaxone, but has the advantage of being orally administered. Several other cephalosporins have demonstrated efficacy in the treatment of gonorrhea, but have no advantages over the recommended therapies and experience with them is more limited. The cephalosporins are safe for use in pregnancy and in children.

The fluoroquinolones ciprofloxacin, ofloxacin and levofloxacin provide alternatives for patients who are allergic to ß-lactams, but they are contraindicated in pregnancy and in those under 18 years of age. In addition, resistance to these fluoroquinolones in *N. gonorrhoeae* has been prevalent in parts of Asia and the Pacific Islands for several years and has recently appeared in the USA.[49] A clinically important prevalence of resistance has been reached in Hawaii and parts of California. As the prevalence and geographic range of these strains are likely to increase, knowledge of local prevalence should guide the use of fluoroquinolones to treat gonorrhea. Doses lower than those recommended should not be used. Fluoroquinolones not specifically recommended for the treatment of gonorrhea may be less effective and should not be used. Cephalosporins are preferred for treatment of gonorrhea acquired in Asia, Pacific Islands (including Hawaii), or California. If the prevalence of fluoroquinolone resistance in the USA increases, it may be necessary to determine susceptibility when treating patients with these therapies.

An alternative to the recommended therapies for gonorrhea is spectinomycin 2g intramuscularly once, which can be used in patients intolerant of ß-lactams and in pregnancy, but is expensive, requires injection and is relatively ineffective against pharyngeal gonorrhea. Spectinomycin-resistant *N. gonorrhoeae* is rare in the USA, but is prevalent in some parts of the world where spectinomycin has been widely used. Penicillins and tetracyclines are no longer used to treat gonorrhea because of the high prevalence of resistant strains (around 30% of US isolates are resistant to one or both drugs).[49]

There are several additional considerations in managing the patient who has gonorrhea. First, treatment for gonorrhea should be accompanied by a regimen effective for possible co-infection with *C. trachomatis* (see below), unless a concurrent test for chlamydial infection is negative. Second, all patients with an STD should be screened for syphilis with a nontreponemal serologic test such as the rapid plasma reagin (RPR). Patients who have incubating syphilis, however, have negative serologic tests and are accordingly difficult to identify; ideally, therefore, treatment for gonorrhea would also cure incubating syphilis. The cephalosporins, but not the quinolones or spectinomycin, have activity against *Treponema pallidum*. Azithromycin and doxycycline also have activity against *T. pallidum* and azithromycin appeared to be effective in curing incubating syphilis in a small study.[50] Third, ceftriaxone and ciprofloxacin have been proved to be effective in the treatment of pharyngeal gonorrhea, with greater than 90% cure rates; data for other therapies are insufficient to recommend their use in pharyngeal gonorrhea. Follow-up is not necessary after treatment for uncomplicated gonorrhea because of the effectiveness of current therapies; however, all patients should be instructed to return if symptoms do not promptly resolve and follow-up is advised for those who acquired infection overseas or when the diagnosis is unsure.

Disseminated gonococcal infection requires at least 7 days of antibiotic therapy, beginning with parenteral therapy and switching to oral therapy after 24–48 hours of improvement. Recommended parenteral therapies are ceftriaxone 1g intramuscularly or intravenously q24h. Alternatives are cefotaxime 1g intravenously q8h, ceftizoxime 1g intravenously q8h, ciprofloxacin 400mg intravenously q12h, ofloxacin 400mg intravenously q12h, levofloxacin 250mg intravenously q24h or spectinomycin 2g intramuscularly q12h. Therapy may be completed with cefixime 400mg orally q12h, ciprofloxacin 500mg orally q12h, ofloxacin 400mg orally q12h or levofloxacin 500mg orally q24h. Concurrent therapy active against *C. trachomatis* should be provided unless the absence of chlamydial infection has been documented.

Management of chlamydial urethritis

Chlamydial urethritis should be treated with a single-dose regimen of azithromycin 1g orally or with a multiple-dose regimen of doxycycline 100mg orally q12h for 7 days. Other effective regimens are ofloxacin 300mg orally q12h for 7 days or levofloxacin 500mg orally each day for 7 days. Azithromycin has the advantage of a single-dose administration, but is more expensive than doxycycline. Clinical experience and limited data suggest that azithromycin is safe and effective in pregnancy.[51] Doxycycline, ofloxacin and levofloxacin are not recommended for use in pregnancy or in children. Ofloxacin and levofloxacin are expensive and have no dosing advantages over doxycycline.

An alternative regimen for chlamydial infection is erythromycin 500mg orally q6h for 7 days. Erythromycin is inexpensive, but gastrointestinal upset may limit compliance. Amoxicillin 500mg orally q8h for 7 days is useful in pregnant women unable to tolerate erythromycin.[51]

Patients who have satisfactory resolution of symptoms generally do not require follow-up testing for *C. trachomatis*. However, if erythromycin or amoxicillin are used, post-treatment testing is advised. Testing should be delayed until at least 3 weeks after completion of therapy, as dead organisms may produce false-positive results on nonculture tests performed sooner.

Management of nongonococcal urethritis

Treatment of NGU is directed at the likely etiologic agents, including *C. trachomatis, M. genitalium* and *U. urealyticum*. Symptoms resolve slowly, sometimes lasting for several days after the completion of therapy. Doxycycline 100mg orally q12h for 7 days and azithromycin 1g orally in a single dose are equivalent in curing NGU. Ofloxacin 300mg orally q12h for 7 days or levofloxacin 500mg orally daily for 7 days is effective, but more expensive than other regimens. Erythromycin 500mg orally q6h for 7 days may be used as an alternative. For NGU that fails to respond to initial therapy, several alternatives may be considered. Repeat treatment with the same drug may be used if noncompliance or re-exposure to an untreated sexual partner is suspected. However, some doxycycline failures may be attributable to tetracycline-resistant *U. urealyticum*, which may be successfully treated with a 7-day course of erythromycin, or to *T. vaginalis*, which may be cured with a single 2g oral dose of metronidazole. Some isolates of *U. urealyticum* are resistant to erythromycin but may respond to a 7-day course of ofloxacin 300mg orally q12h.[52] *Mycoplasma genitalium* has also been implicated in persistent or recurrent Nongonococcal urethritis and may require repeated or prolonged therapy for eradication.[14] Azithromycin may be the drug of choice for *M. genitalium* and may also be effective against *U. urealyticum*. Nongonococcal urethritis persisting after two courses of therapy requires consideration of other diagnoses such as cystitis and prostatitis. Urologic evaluation may include urine flow measurements and urethroscopy or urethrography to look for foreign bodies, strictures and periurethral abscesses. If no cause can be found, then a 3-to 6-week course of doxycycline or erythromycin can be tried,[39] although the long-term effectiveness of this is unknown.

Chapter 75 - Syphilis

George R Kinghorn

Syphilis is a chronic infectious disease caused by the spirochete *Treponema pallidum*, which is transmitted during sexual intercourse and other intimate contact; it may also be vertically transmitted by a pregnant woman to her fetus in utero or during birth.

The name of the disease was drawn from a poem, 'Syphilis sive morbus gallicus', written by Fracastoro of Verona in 1530, in which the mythical swineherd Syphilis refused to make sacrifices to Apollo and was smitten as a result. [1]

EPIDEMIOLOGY

An epidemic of sexually transmitted syphilis spread across Europe at the end of the 15th century. There are conflicting views about the origin of syphilis in Europe — some believe that it was brought back from the New World by Columbus, and others believe that it had been endemic throughout the Middle Ages and became sexually acquired at the time of the epidemic. The impact of syphilis in 16th century Europe was similar to the global impact of AIDS in the late 20th century. Syphilis had certainly become endemic in Europe by the 17th century, since when there have been several epidemic waves, notably during the Napoleonic wars and the period of industrialization in the 19th century, and during and after the two world wars of the 20th century.

In North America and the developed countries of northern Europe, syphilis had become predominately a disease of homosexual men by the 1970s. During the late 1980s, there were renewed outbreaks of heterosexual and congenital syphilis in North America in the wake of the HIV epidemic.[2] This resurgence was mainly observed in commercial sex workers, in whom it was often associated with selling sex for drugs (especially crack cocaine), and in other people of lower socioeconomic status. In 1994, there were 20,627 reported cases of primary and secondary syphilis in the USA (8.1 cases per 100,000 people, the rate being 60 times higher in non-Hispanic blacks than in Caucasians) compared with 304 cases in England (fewer than 0.6 cases per 100,000 people; Fig. 75.1).[3] Subsequently, incident syphilis cases have declined to fewer than 4 cases per 100,000[4] and syphilis is again being targeted for national elimination.[5]

Eastern Europe has experienced a 50-fold increase in reported syphilis cases between 1990 and 1997, with similar increases in the Ukraine, some central Asian countries, and the Baltic states. Neighbouring Scandinavian countries have witnessed an increase in imported cases.[6]

Although the overall incidence of syphilis in the UK was only 0.3 per 100,000 in 1998, there have since been outbreaks in several cities where there was previously a low prevalence.[7] The outbreaks have been characterized by rapid increases in sexual networks with high rates of partner change, travel or migration links with high incidence areas and an increasing predominance of homosexual transmission, with a high proportion of HIV co-infection among incident cases.

The annual incidence of congenital syphilis in infants aged less than 1 year in the USA increased from 3.0 per 100,000 live births in 1980 to a peak of 107.3 per 100,000 live births in 1990. The very large increase in reported cases has been artificially elevated by the introduction of a new reporting system,[8] [9] [10] which takes account of epidemiologic factors, especially maternal treatment status, in addition to cases showing characteristic clinical stigmata (Table 75.1). The annual incidence has since declined to 30.4 per 100,000 live births (in 1996).

The World Health Organization (WHO) estimates that the annual global incidence of syphilis is approximately 12.2 million cases, most of which occur in developing countries, where the disease has remained a prominent cause of genital ulcer disease in heterosexual men and women, of stillbirth, and of neonatal morbidity and mortality.[8] The prevalence of pregnant seropositive women is 0.1–0.6% in developed countries, but it may exceed 10% in many developing countries. In some parts of South Africa, seroconversion during pregnancy has been reported to occur in more than 2% of women.[11]

Transmission

The organism is transmitted from the early mucocutaneous lesions, and enters the body through small breaches in epithelial surfaces of genital, anorectal, oropharyngeal and other cutaneous sites.

Prenatal transmission is greatest in cases of maternal infection of short duration, but it may also occur during the latent stages of syphilis. Disease manifestations are unusual before 18 weeks in utero. Stillbirth caused by congenital syphilis has a maximum incidence at 6–8 months of gestation. Even when a previous pregnancy has resulted in an uninfected child, congenital syphilis may occur in subsequent offspring, and it may affect only one of twins. It is preventable with maternal treatment during pregnancy.

Syphilis is rarely transmitted during transfusion of blood or blood products or through needle sharing by intravenous drug abusers.

PATHOGENESIS AND PATHOLOGY

The causative spirochete of syphilis, *Treponema pallidum* subsp. *pallidum*, is microaerophilic with a unique wave-like cell body that is 6–15µm long and 0.15–0.20µm wide.[12] It contains a periplasmic flagellum and can be identified in darkfield microscopy by its characteristic morphology and movements, which typically include angling. The organism has evolved to become a highly invasive and persistent pathogen with little toxigenic activity and an inability to survive outside the mammalian host. It has extreme nutritional requirements, owing to deficiencies in biosynthetic pathways, and it has a narrow equilibrium between oxygen dependence and toxicity. It cannot be cultured on artificial media but it can be propagated in organ culture, such as rabbit testis. It has a slow growth rate, optimal at 91–95°F (33–35°C), with a doubling time of 30–36 hours. The organism is similar to and shares extensive DNA homology with three other pathogenic treponemes that cause yaws, bejel and pinta (see Chapter 230).

Analysis of the genome, which is contained on a single circular chromosome with 1,138,006 base pairs, shows that the organism

Figure 75-1 Diagnoses of syphilis in England and Wales. Primary, secondary and early latent infection seen in genitourinary medicine clinics. (a) 1931–2000 and (b) 1990–2000.

TABLE 75-1 -- Definitions of congenital syphilis.

DEFINITIONS OF CONGENITAL SYPHILIS	
Confirmed diagnosis	An infant in whom *Treponema pallidum* is identified by dark-field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, or autopsy material
Presumptive diagnosis	1. Any infant whose mother had untreated or inadequately treated syphilis at delivery, regardless of symptoms or signs in the infant
	2. Any infant or child who has a reactive specific treponemal test for syphilis and one of the following: evidence of congenital syphilis on physical examination evidence of congenital syphilis on long-bone X-ray reactive CSF VDRL elevated CSF cell count or protein (without other cause) reactive test for FTA-ABS-IgM using fractionated serum

lacks lipopolysaccharide and lipid biosynthesis mechanisms, as well as many metabolic pathways, including pathways for the tricarboxylic acid cycle, for components of oxidative phosphorylation, and for most amino acids and vitamins. It requires D-glucose, maltose and mannose but cannot utilize other sugars. It is able to use exogenously supplied amino acids and is dependent on serum components such as fatty acids.

Treponema pallidum initiates an inflammatory response at the site of inoculation and is disseminated during the primary infection. The organism has a surface-associated hyalouronidase enzyme, which may play a role in this process. Phagocytosis by cytokine-activated macrophages, as part of a predominant T-helper (Th)1-type early response, aids bacterial clearance and resolution of the primary lesion.[13] Virulent organisms promote adhesion of lymphocytes and monocytes to human vascular cells, and this is important in immunopathogenesis.[14] As with other organisms that cause chronic disease, *T. pallidum* has evolved mechanisms for evading immune responses. A Th1–Th2 switch occurs with macrophage suppression caused by prostaglandin E2 down-regulation; however, the molecular mechanisms remain poorly understood.[15] Depressed cell-mediated responses occur during the later stages of syphilis, and lowered $CD4^+$ lymphocyte counts have been reported.[16]

Relatively few genes are involved in pathogenesis.

It has been postulated that the immuno-evasiveness of *T. pallidum* is the result of the organism's unusual molecular architecture. The outer membrane lacks lipopolysaccharide and contains few poorly immunogenic transmembrane proteins; the highly immunogenic proteins are lipoproteins that are anchored predominately to the periplasmic leaflet of the cytoplasmic membrane.[17]

The dominant immunogen is a 47kDa membrane lipoprotein, which can induce synthesis of tumor necrosis factor-a. Immuno-blotting has also shown IgG responses to an antigen of 65kDa that is shared with nonpathogenic treponemes, and antigens of 44.5, 17 and 15.5kDa that are specific for *T. pallidum*.

Histologic appearances and pathology

Some manifestations of syphilis (e.g. neuropathy) are immune-complex mediated. In early lesions, perivascular infiltration by lymphocytes and plasma cells is accompanied by intimal proliferation in arteries and veins. This leads to ischemia and ulceration. Organisms are most numerous in the walls of capillaries and lymphatic vessels.

In late lesions, the characteristic lesion of mucocutanous surfaces is the syphilitic gumma. Granulation tissue forms with histiocytes, fibroblasts and epithelioid cells. Endarteritis obliterans and necrotic areas are pronounced. Gummas most often originate in subcutaneous tissues and spread in all directions. Spirochetes are not readily demonstrable in these lesions.

Heubner's arteritis occurs in cardiovascular and meningovascular syphilis. It is characterized by lymphocytic and plasma cell infiltration of the vasa vasorum and adventitia of large and medium-sized vessels. Occlusion of the vasa vasorum results in medial necrosis and fibroblast proliferation. There is associated subintimal proliferation, which leads to luminal occlusion and thrombosis.

PREVENTION

The risk factors for acquisition of syphilis mirror those of other sexually transmitted diseases (STDs), and primary prevention depends on similar methods, such as reducing the number of sexual partners and consistent use of condoms. Community outreach activities should target education at those who are at high risk.[18] Single-dose intramuscular benzathine penicillin G and oral azithromycin have been used as treatment for incubating syphilis.[19] Administration of treponemicidal antibiotics to treat other STDs, such as gonorrhea and chancroid, may also abort incubating concurrent syphilis. The development of a vaccine against syphilis has long been inhibited by the inability to grow the organism on artificial media, although the recent sequencing of the *T. pallidum* genome should advance new research efforts.

Secondary prevention by early diagnosis, treatment, partner notification, education and counseling remain the mainstay of prevention efforts. Access to prompt and appropriate services for infected persons is essential. In many developed countries, clinic-based specialist services have long been established. In developing countries, the WHO has recommended that STD management be integrated into basic health care and reproductive health services.

Serologic screening for syphilis remains a cost-effective measure for control. Congenital syphilis may be prevented by maternal screening and treatment during early pregnancy. In Europe, screening remains a

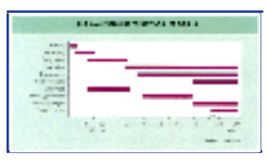

Figure 75-2 Clinical stages and presentation of syphilis.

routine part of antenatal care, usually at about 12 weeks of gestation. In developing countries, where congenital syphilis is more common, the disease occurs when there has been no maternal screening, when no treatment has been administered in response to positive tests or when primary infection occurs later in pregnancy. Repeat screening during the final trimester or at delivery is advocated in high prevalence regions. [20]

CLINICAL FEATURES

Incubation period

The time from transmission to the appearance of primary lesions averages 21 days (the range is 10–90 days); the incubation period varies inversely with the size of the spirochete inoculum.

The clinical presentation of syphilis is extremely diverse and may occur decades after initial infection. The time sequence of syphilis stages is shown in Figure 75.2 .

Primary syphilis

The primary chancre appears at the site of initial treponemal invasion of the dermis. It may occur on any skin or mucous membrane surface and is usually situated on the external genitalia (Fig. 75.3). Initial lesions are papular but rapidly ulcerate. They are usually single, but 'kissing' lesions may occur on opposing mucocutaneous

surfaces. Typically, the ulcers are nontender (unless there is coexisting infection) and indurated and have a clean base and raised edges (Fig. 75.4). There is often surrounding edema, especially with vulval lesions. [21] Chancres of the cervix, anorectum or oropharynx are commonly silent. Nontender, nonsuppurative, rubbery inguinal lymphadenopathy appears 1 week later and usually becomes bilateral after 2 weeks. The chancre usually heals spontaneously within 3–6 weeks but leaves a scar.

The differential diagnosis includes other sexually transmitted causes of genital ulcer disease (which may co-exist) such as chancroid, lymphogranuloma venereum, donovanosis and genital herpes, as well as traumatic ulceration, pyogenic lesions, aphthous ulceration and malignancy.[22]

Secondary syphilis

The manifestations of generalized treponemal dissemination first appear about 8 weeks after infection. Constitutional symptoms consist of fever, headache, and bone and joint pains. There is wide diversity in physical features.

Skin rashes are the commonest feature. They are initially macular and become papular by 3 months. Lesions appear initially on the upper trunk (Fig. 75.5), the palms and soles (Fig. 75.6), and flexural

Figure 75-6 Plantar syphilid in secondary syphilis. *From Kinghorn GR. Syphilis. Medicine 1995;24:64–8, with permission of The Medicine Group (Journals) Ltd.*

surfaces of the extremities.[23] The later papulosquamous eruptions typically have a coppery color and often follow skin cleavage lines, as in pityriasis rosea. Facial lesions follow the hairline of the temporal and frontal scalp (the so-called corona veneris) and cause split papules at the angles of the mouth (Fig. 75.7). There may be hypopigmented lesions on the lateral neck (collaris veneris). Lesions in hairy areas cause moth-eaten alopecia of the scalp, beard, eye-brows and eye-lashes. Atypical facial plaques or ulcerated nodules (lues maligna) are more common with co-existing HIV infection.[24] Condylomata lata are moist flat-topped papules that appear about 6 months after infection in the moist intertriginous areas around the genitalia, anus and axillae (Fig. 75.8) and beneath the breasts. On mucous membranes, especially of the mouth, erythematous macules evolve into asymptomatic, slightly elevated flat-topped lesions covered by a hyperkeratotic grayish membrane. These mucous patches may coalesce to form 'snail-track' ulcers.

Generalized lymphadenopathy occurs in 50% of cases of secondary syphilis. It has similar characteristics to the localized lymphadenopathy of primary infection. Other systemic features of secondary syphilis include panuveitis,[25] periostitis and joint effusions, glomerulonephritis, hepatitis, gastritis, myocarditis and aseptic meningitis.

The lesions of secondary syphilis resolve spontaneously in a variable time period and most patients enter the latency stage within the

Figure 75-8 Maculopapular rash extending into axilla in secondary syphilis. *From Kinghorn GR. Syphilis. Medicine 1995;24:64–8, with permission of The Medicine Group (Journals) Ltd.*

first year of infection. In some, especially the immunocompromised, primary or secondary lesions may recur.

The differential diagnosis is broad and includes exanthema associated with many infectious diseases, including primary HIV infection, dermatoses (e.g. pityriasis rosea and guttate psoriasis) and connective tissue disorders such as systemic lupus erythematosus. Condylomata lata must be differentiated from viral warts, scabies and lichen planus.

Latent syphilis

In latent syphilis there are no clinical stigmata of active disease, although disease remains detectable by positive serologic tests. In early latency, within 2 years of infection, vertical transmission of infection may still occur, but sexual transmission is less likely in the absence of mucocutaneous lesions. The late manifestations of syphilis arise, often decades later, in about 25% of those who have latent syphilis.

Tertiary gummatous syphilis

The characteristic lesions of tertiary syphilis appear 3–10 years after infection and consist of granulomas or gummas. The granulomas appear as cutaneous plaques or nodules of irregular shape and outline (Fig. 75.9) and are often single lesions on the arms, back and face. Gummas are areas of granulomatous tissue, often arising from subcutaneous structures. They have a tendency for central necrosis and ulceration and for peripheral healing with tissue-paper scarring. Punched-out lesions appear most commonly on the scalp, face and sternoclavicular areas of the chest and on the lateral calf (Fig. 75.10). Gummas can also cause palatal perforation; destruction of nasal cartilage, producing saddle-nose deformity; painless testicular swelling, which may mimic a tumor; portal hypertension and portosystemic anastomoses; and diffuse interstitial glossitis and subsequent malignant neoplasms of the tongue.

Cardiovascular syphilis

The typical lesion of cardiovascular syphilis is aortitis affecting the ascending aorta and appearing 10–30 years after infection. The aortitis may be asymptomatic and detected as dilatation of the ascending aorta on chest radiography, often accompanied by linear calcification of the aortic wall, or it may lead to stretching and incompetence of the aortic valve, to left ventricular failure or to aneurysm formation. Aneurysms may be associated with a variety of syndromes caused by pressure on adjacent structures in the mediastinum, and they may cause sudden death from rupture. Other symptoms include angina pectoris from associated coronary ostial stenosis. Cardiovascular syphilis is more commonly associated with neurosyphilis than with gummatous disease.

Figure 75-9 Cutaneous nodular gummas of upper arm in tertiary gummatous syphilis. The lesions have a serpiginous outline. *From Kinghorn GR. Syphilis. Medicine 1995;24:64–8, with permission of The Medicine Group (Journals) Ltd.*

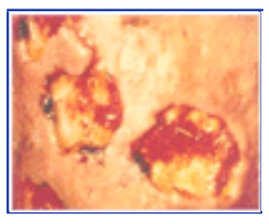

Figure 75-10 Multiple gummatous ulcers of lower leg in tertiary gummatous syphilis. The lesions have a punched-out appearance with 'wash-leather' slough overlying a base of granulation tissue. They show a tendency for peripheral healing with thin tissue-paper scars. *From Kinghorn GR. Syphilis. Medicine 1995;24:64–8, with permission of The Medicine Group (Journals) Ltd.*

The differential diagnosis of thoracic aortic aneurysm includes Behçet's disease, Tayakasu's arteritis, ankylosing spondylitis and atheromatous disease. Similar histologic lesions may appear in other large arteries.

Neurosyphilis

Neurosyphilis is characterized by a number of heterogeneous syndromes. The onset can occur weeks or decades after treponemal dissemination.[26]

Asymptomatic neurosyphilis precedes the development of clinically apparent disease and accounts for one-third of all neurosyphilis. It occurs in 10% of those with latent disease and has a peak

incidence at 12–18 months after infection. It reverts spontaneously in 70% of patients.

Meningeal neurosyphilis usually has its onset during secondary disease and is characterized by symptoms of headache, confusion, nausea and vomiting, neck stiffness and photophobia. There may be focal seizures, aphasia, delirium and papilledema. Cranial nerve palsies cause unilateral or bilateral facial weakness and sensorineural deafness.[27] Other manifestations include hydrocephalus, spinal pachymeningitis and spinal meningomyelitis.

Meningovascular syphilis occurs most frequenly between 4 and 7 years after infection. Symptoms usually begin abruptly, and focal neurologic signs are most common in the territory of the middle cerebral artery. Less commonly, focal ischemia affects the basilar or spinal arteries. The clinical features of hemiparesis, seizures and aphasia reflect multiple areas of infarction from diffuse arteritis.

Gummatous neurosyphilis is the least common syndrome. Lesions arise from the pia mater and subsequently invade the brain or spinal cord, resulting in features typical of a space-occupying lesion of these structures.

Parenchymatous syphilis appears later and has become rare in its classic forms in the antibiotic era. The peak incidence of general paralysis from parenchymatous disease of the brain used to be 10–20 years after infection. It was more common in males. The onset is insidious with subtle deterioration in cognitive function and psychiatric symptoms that mimic those of other mental disorders. As the disease progresses, neurologic signs develop, including pupillary abnormalities, hypotonia of the face and limbs, intention tremors and hyperreflexia. In late disease, there is progressive dementia, onset of seizures and increasing weakness leading to an incontinent bedfast state.

Tabetic neurosyphilis was the most common form of neurosyphilis before antibiotics were available. It has an onset 15–25 years after primary infection. The most characteristic symptom is of lightning pains — sudden paroxysms of lancinating pain affecting the lower limbs. Other early symptoms include paresthesia, progressive ataxia, and bowel and bladder dysfunction.

The clinical signs result from leptomeningeal infiltration of the preganglionic portion of the dorsal root ganglia, with subsequent atrophic change in the posterior columns of the spinal cord. The signs are hypotonia, areflexia, and impaired joint-position and vibration sense. Pupillary abnormalities are usual, and 50% of patients have the classic Argyll-Robertson pupil (small, irregular pupils that are unreactive to light but constrict normally to accommodation-convergence). Optic atrophy is also common.

Later features of tabes dorsalis include visceral crises in 10–15% of patients, characterized by recurrent episodes of epigastric pain and vomiting, mimicking an acute abdomen; acute urinary retention; progressive ataxia with a wide-based slapping gait; the appearance of neuropathic joints and perforating ulcers; and co-existing palsies of the third, sixth and seventh cranial nerves.

The differential diagosis of neurosyphilis covers the whole spectrum of neurologic and psychiatric conditions. Routine serologic screening tests for syphilis are indicated in patients that exhibit any of these features.

Congenital syphilis

Many infants with congenital syphilis are asymptomatic at birth. The placenta may show proliferative vascular changes and there may be acute inflammation of the umbilical cord (funisitis).[28] Early congenital syphilis manifests itself as rhinitis with serosanguinous nasal discharge, vesiculobulbous eruptions of the skin and oral mucous patches. Skin lesions on the lips, nostrils and anus heal with radiating scars (rhagades). In addition, there are often bone abnormalities, characterized by diaphyseal periostitis, osteochondritis and a positive

Figure 75-11 Typical facies in late congenital syphilis. There is frontal bossing, an underdeveloped maxilla, a prominent jaw and a depressed nasal bridge, with multiple gummatous ulcers of scalp. *From Kinghorn GR. Syphilis. Medicine 1995;24:64–8, with permission of The Medicine Group (Journals) Ltd.*

Wimberger's sign, which may present with limb pseudoparesis. Other features include chorioretinitis, visceral lesions causing pneumonia alba, hepatosplenomegaly associated with jaundice, and the nephrotic syndrome.

In late congenital syphilis (presenting after 2 years of age) there may be a variety of skeletal developmental defects, including a high-arched palate, a protruding mandible, frontal bossing of the skull and saddle-nose deformity resulting in a characteristic facies (Fig. 75.11); additionally, there can be bilateral hydroarthoses of the knees (Clutton's joints), sabre tibiae from osteoperiostitis, perforation of the palate and nasal septum, and sternoclavicular thickening. Dental abnormalities occur with peg-shaped permanent incisors (Hutchinson's teeth) and mulberry multicusped molars; together with interstitial keratitis and eighth nerve deafness, these dental abnormalities form Hutchinson's triad. Other features include hydrocephalus and mental retardation, as well as other typical lesions of gummatous syphilis and

neurosyphilis.

Syphilis and HIV infection

In most patients with early HIV infection, the clinical features, [29] serologic test results[30] and response to treatment are similar to those in non-HIV-infected people. With advancing immunosuppression, all of these may be significantly altered (Table 75.2).

DIAGNOSIS

Microscopic identification

Treponema pallidum can be identified from lesions of primary, secondary or early congenital syphilis by darkfield microscopy. The organism has a characteristic morphology and motility, with a sinusoidal profile with a wavelength and amplitude of 1.1µm and 0.4µm. Lesions are thoroughly cleansed with saline and scarified if necessary, and serum is allowed to collect for examination. Lymph node aspirates are also useful for microscopic examination in secondary syphilis.

The organism can also be identified by direct immunofluorescent antibody testing where no facilities for darkfield microscopy exist.

In biopsy specimens from late syphilis or in atypical early lesions, it may be possible to identify the organism by silver stains such as Warthin-Starry preparations or by direct immunofluorescent antibody testing.

Diagnosis using the polymerase chain reaction (PCR) has been based on primers and probes prepared from the 47kDa gene. After a

TABLE 75-2 -- Altered features of syphilis in HIV infection.

ALTERED FEATURES OF SYPHILIS IN HIV INFECTION	
Altered clinical features	Silent primary disease
	Presentation with secondary manifestations
	Persistence of primary lesions
	Lues maligna and atypical facial plaques
	Pneumonitis
	Accelerated course with early neurosyphilis
	Myelopathy, and auditory and ocular involvement
Altered serologic responses	Seronegative primary and secondary syphilis
	Increased incidence of prozone phenomenon
	Loss of reactivity to specific treponemal tests in previously treated disease
Altered therapeutic responses	Failure with benzathine penicillin treatment of early syphilis
	Relapse after iv penicillin G regimens for neurosyphilis

40-cycle series of denaturing, annealing and extension, the PCR products can be visualized by electrophoresis or Southern blot hybridization with a ^{32} P-labeled probe and then autoradiography. This technique should be of greatest value in detecting the low numbers of treponemal products in neurosyphilis; it should also be useful in congenital syphilis, in which the interpretation of serologic test results may be difficult.

Amplification of RNA is more sensitive than PCR, and positive results are indicative of living organisms. The reverse-trancriptase PCR uses the 16S ribosomal RNA of *T. pallidum* as the template.

Serologic testing

The serologic tests for syphilis[31] can be subdivided into two types: standard nontreponemal (reaginic) tests and the specific treponemal antibody tests (Table 75.3).

Standard nontreponemal tests

The nontreponemal tests detect IgM and IgG antibodies to lipoidal material released from damaged host cells and to lipoidal-like antigens of *T. pallidum*. There are four tests available that use the Venereal Disease Research Laboratory (VDRL) antigen (consisting of cardiolipin, cholesterol and lecithin) as the principal component. These tests are quantitative and are useful in assessing response to treatment. Reactivity to these tests does not develop until 1–4 weeks

TABLE 75-3 -- Serologic tests for syphilis.

SEROLOGIC TESTS FOR SYPHILIS					
	Sensitivity				Specificity
	Primary	Secondary	Latest	Late	
Non-specific reaginic tests					
VDRL	80	100	95	70	98
RPR	86	100	98	75	98
USR	80	100	94		98
TRUST	85	100	97		97
Specific treponemal antibody tests					
MHA-TP	76	100	96	95	99
FTA-ABS	84	100	100	96	97
FTA-ABS double-staining	80	100	100		98
The values for sensitivity are the mean values in CDC (Centers for Disease Control and Prevention) tests. The values for specificity are mean values in nonsyphilis populations in CDC tests.					

after the chancre appears in primary syphilis. Titers are highest in secondary syphilis. The prozone phenomenon occurs in 2% of sera; undiluted sera give negative results because of antibody excess or the presence of blocking antibodies, or both. The titer slowly declines after the 1- to 4-week period following the appearance of the chancre, and it may spontaneously become negative in some cases of late latent syphilis and neurosyphilis.

The VDRL Slide Test is widely used and requires the microscopic demonstration of antigen-antibody flocculations in heat-inactivated serum.

The unheated serum reagin (USR) test is similar to the VDRL test but does not require preheated serum, because the antigen has been stabilized.

The rapid plasma reagin (RPR) test and tuluidine red unheated serum test (TRUST) use either charcoal or red paint pigment added to the USR reagent to enhance visualization of the antigen-antibody flocculations. The flocculations are visible macroscopically.

Biologic false-positive reactions to these tests occur in a wide variety of conditions.[32] They can be subdivided into acute reactions, lasting for 6 months or less, and chronic reactions (Table 75.4).

Specific treponemal antibody tests

Specific treponemal antibody tests are used for confirmatory testing. They detect antibodies to antigenic determinants of treponemes. They are qualitative procedures and are not helpful in assessing treatment responses; once positive, they tend to remain positive for life, irrespective of treatment. They are used to differentiate true-positives from false-positives in the standard nontreponemal antibody tests.

The fluorescent treponemal antibody absorption (FTA-ABS) test and the FTA-ABS double-staining (FTA-ABS DS) test are both indirect immunofluorescent tests. The double stain test employs a fluorochrome-labeled counterstain for *T. pallidum* and an antihuman IgG conjugate labeled with tetramethyl rhodamine isothiocyanate to detect antibody in patient serum. False-positive results may occur in about 1% of sera; possible causes include technical error, Lyme borreliosis, pregnancy, genital herpes, alcoholic cirrhosis and connective tissue diseases such as systemic lupus erythematosus and scleroderma.

The microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP) detects passive hemagglutination of erythrocytes sensitized with ultrasonicated Nichol's strain *T. pallidum*. In many laboratories, the TPHA has been replaced by the similar *T. pallidum* particle agglutination (TPPA) test but uses gelatin particles rather than erythrocytes as the carrier. It is more sensitive than the FTA-ABS.

TABLE 75-4 -- Causes of biologic false-positive cardiolipin tests.

CAUSES OF BIOLOGIC FALSE-POSITIVE CARDIOLIPIN TESTS		
	Acute	**Chronic**
Physiologic	Pregnancy	Old age
Spirochete infections	Leptospirosis	
	Relapsing fever	
	Rat-bite fever	
	Lyme disease	
Other infections	Varicella zoster	Lepromatous leprosy
	Herpes simplex	Tuberculosis
	Infectious mononucleosis	Lymphogranuloma venereum
	Cytomegalovirus	Malaria
	Toxoplasmosis	Kala-azar
	Viral hepatitis	Trypanosomiasis
	HIV seroconversion illness	Tropical spastic paraparesis
	Mycoplasma infection	HIV or AIDS
	Malaria	
	Other acute viral or bacterial sepsis	
Vaccinations	Smallpox	
	Typhoid	
	Yellow fever	
Autoimmune diseases		Systemic lupus erythematosus
		Polyarteritis nodosa
		Rheumatoid arthritis
		Sjögren's syndrome
		Primary biliary cirrhosis
		Hashimoto's thyroiditis
		Autoimmune hemolyic anemia
		Idiopathic thrombocytopenic purpura
Other		Malignancy
		Malnutrition
		Injecting drug use

Treponemal enzyme immunoassay (EIA) commercial tests were initially designed as confirmatory tests for syphilis. Serum is added to microwells coated with a treponemal antigen. After incubation, an enzyme-labeled antihuman immunoglobulin conjugate and enzyme substrate are added to detect antigen-antibody reaction. The test can be modified to detect specific IgM antibody.

Treponema pallidum Western blot is available in some research laboratories and has similar sensitivity and specificity to those of the FTA-ABS test.[33] The presence of antibodies to the immunodeterminants with molecular weights 15.5, 17, 44.5 and 47kDa appears to be diagnostic for acquired syphilis. When an IgM-specific conjugate is used, the test has value in the diagnosis of congenital syphilis.

There are many commercial tests in any given format whose performance characteristics vary.

Guidelines for serologic screening

Guidelines have been developed for serologic screening for syphilis. [34] Recent studies suggest that a treponemal EIA used as a single test is an appropriate alternative to the combined VDRL-RPR and TPHA screen. It has a higher specificity than the FTA-ABS. The test also has advantages of automated or semiautomated processing and objective reading of results, and it can be interfaced with laboratory computer systems to allow electronic laboratory report generation.

Screening can be performed by either EIA or the combined VDRL-TPHA. Positive results are confirmed with a treponemal test of a different type. It is essential to

confirm the presumptive serologic diagnosis of syphilis on a second patient specimen.

Indications for examination of cerebrospinal fluid

Indications for examination of cerebrospinal fluid (CSF) in syphilis include:

- neurologic, ophthalmic or auditory symptoms and signs;
- other clinical evidence of active infection — aortitis, gumma, iritis;
- treatment failure;
- HIV infection;
- serum nontreponemal titer of more than 32 if duration of syphilis is more than 1 year; and
- non-penicillin-based treatment regimen planned.

The typical CSF findings of neurosyphilis consist of:

- moderate mononuclear pleocytosis (10–400 cells/ml),
- elevated total protein (0.46–2.0g/l), and
- positive CSFVDRL.

The CSFVDRL is highly specific, and false-positive results are rare in the absence of blood contamination. A negative CSFVDRL does not exclude neurosyphilis, although nontreponemal serologic tests usually remain positive in both serum and CSF in such cases.

Typical neuroimaging findings have been described for neurosyphilis. [35]

Evaluation of neonates for congenital syphilis

It is recommended that the following investigations be carried out in a child born to a seropositive mother if there has been no documented completion of treatment at least 4 weeks before delivery, if a nonpenicillin regimen was administered or if relapse or re-infection is suspected:

TABLE 75-5 -- Treatment of acquired syphilis.

TREATMENT OF ACQUIRED SYPHILIS			
Stage	**CDC-recommended regimens**	**Other penicillin regimens**	**Alternative regimens**
Early syphilis (primary, secondary, early latent of less than 2 years' duration)	Benzathine penicillin G 2.4 million units im single dose	Aqueous procaine penicillin 600,000–900,000 units im daily for 10 days	Tetracycline hydrochloride 500mg po q6h daily for 15 days
			Doxycycline 100mg po q12h for 15 days
			Erythromycin 500mg po q6h for 15 days
			Ceftriaxone 1g im daily for 10 days
Late syphilis (latent syphilis of more than 2 years' duration, cardiovascular, gummatous syphilis)	Benzathine penicillin G 2.4 million units im weekly for 3 weeks	Aqueous procaine penicillin 600,000–900,000 units im daily for 15 days	Tetracycline hydrochloride 500mg po q6h for 30 days
			Doxycycline 100mg po q12h for 30 days
Neurosyphilis	Aqueous crystalline penicillin G 3–4 million units iv q4h for 10 days	Aqueous procaine penicillin G 2.4 million units im daily for 10 days plus probenecid 500mg orally q6h for 10 days	No proven effective alternative — patients allergic to penicillin should be desensitized
	plus benzathine penicillin G 2.4 million units im weekly for 3 weeks	plus benzathine penicillin G 2.4 million units im weekly for 3 weeks	

- physical examination for stigmata of congenital syphilis,
- radiography of long bones for evidence of periostitis, and
- examination of the CSF.

Infection of the neonate is also suggested if the serum nontreponemal antibody titer is four or more times more than the mother's, or if specific IgM treponemal antibody tests are positive. Passively transferred maternal IgG antibody can persist in the infant's serum for up to 12 months.[36]

MANAGEMENT

Current treatment regimens are based on over 50 years of clinical experience with penicillin, expert opinion and open clinical studies rather than on randomized clinical trials.[37] [38] Many antibiotics, with the notable exceptions of the aminoglycosides and sulfonamides, have some treponemicidal activity, and their administration for other conditions may abort or modify the natural history of syphilis.[39]

Parenteral penicillin G is the preferred drug at all stages of syphilis. The preparations used, the dosage and the duration of treatment depend on the clinical stage and disease manifestations (Table 75.5). Adequate treatment requires the maintenance of serum concentrations in excess of 0.03 units/ml for at least 10 days.[40] A single intramuscular dose of 600,000 units of aqueous procaine penicillin gives an effective serum concentration for at least 24 hours; in comparison, a single intramuscular dose of 2,400,000 units of benzathine penicillin G maintains effective levels for about 2 weeks.

In patients who are hypersensitive to penicillin, regimens based on tetracycline, doxycycline, erythromycin, ceftriaxone and chloramphenicol have all been successfully used to treat syphilis; however, success is less assured than with penicillin. Azithromycin, given in dosages of 500mg daily for 7 days, has recently been successful but experience is limited.

Desensitization of penicillin-allergic patients is recommended for the treatment of pregnant women and neurosyphilis because parenteral penicillin G is the only treatment with documented efficacy in these situations.

Jarisch-Herxheimer reaction

The Jarisch-Herxheimer reaction is an acute febrile reaction that occurs in many patients within 24 hours of commencing treatment. It is mediated by cytokines. The fever may be accompanied by headache, myalgia, bone pains and an exacerbation of skin lesions. It must be differentiated from penicillin allergy. Patients should be advised that it may occur. Symptoms may be controlled by antipyretics.

In pregnant women the reaction may induce early labor or cause fetal distress. In late neurosyphilis and cardiovascular syphilis, the Jarisch-Herxheimer reaction can be more serious and may be associated with life-threatening sequelae. Many clinicians advocate a short course of corticosteroids to lessen its effects in these patients; one such regimen is to prescribe oral prednisone (prednisolone) 30–60mg daily for 3 days, beginning syphilis treatment on the third day, and then tailing off the

corticosteroid course by reducing the daily dosage by 10mg each day during the succeeding week.

Treatment of syphilis in HIV-seropositive patients

It is recommended that CSF examination be performed in all patients with syphilis who are seropositive for HIV and that a penicillin-based regimen appropriate for neurosyphilis, regardless of the stage of infection, be administered.[41] Because *T. pallidum* can persist in the central nervous system in spite of adequate antibiotic treatment, some clinicians have recommended that chronic maintenance treatment be administered after initial formal treatment. [42] Erythromycin has been reported to be ineffective. Close follow-up is essential, and CSF examination may be repeated after 6 months.

Treatment of congenital syphilis

The optimal treatment of congenital syphilis is unknown. Regimens that have been recommended for early congenital syphilis are intravenous crystalline penicillin G 50,000 units/kg every 8–12 hours for 10–14 days, or intravenous aqueous procaine penicillin G 50,000 units/kg once daily for 10–14 days. For infants with normal CSF findings, intravenous benzathine penicillin G 50,000 units/kg in a single dose has also been successful.[43] In children with late congenital syphilis presenting after 2 years of age, regimens should be the same as those recommended for late acquired disease.

Management of sexual contacts

It is recommended that attempts be made to identify, trace and offer further investigation to at-risk sexual contacts. In early syphilis, these are those contacts occurring within 3 months plus the duration

of symptoms for primary syphilis, within 6 months plus the duration of symptoms for secondary syphilis and within 1 year for early latent disease. All long-term partners of patients with late syphilis should be offered investigation.

Many clinicians recommend presumptive treatment of all sexual contacts within the 90-day period preceding patient presentation of early syphilis if serologic test results are not immediately available and if follow-up cannot be assured.

Follow-up

Follow-up for clinical and serologic assessment should be done at 3, 6 and 12 months after the completion of treatment in early syphilis. Recurrence is due more often to re-infection than to relapse.

In late latent or tertiary benign syphilis, a 2-year follow-up is adequate. Quantitative nontreponemal serologic testing are repeated at 3 and 6 months, and each 6 months after that. Follow-up of cardiovascular and clinical neurosyphilis should be for life.

Treatment failure is suggested by a 4-fold increase in titers, less than a 4-fold decrease in pretreatment titers within 12–24 months, and development of symptoms or signs attributable to syphilis. All treatment failures require CSF examination.

In neurosyphilis, it is usual to repeat the CSF examination every 6 months until the cell count has become normal. There is a slower response of the CSFVDRL and total protein. Retreatment should be considered if the cell count shows an inadequate response or if all of these parameters have not returned to normal by 2 years. In cases of serologic or clinical relapse, retreatment with double penicillin doses is recommended.

Prognosis

Cure rates with initial treatment of early syphilis are better than 95%. The long-term outcome of adequately treated cases is excellent. In late syphilis, infection can usually be arrested, although some treponemes may persist in less accessible sites (e.g. the eye and nervous system). As long as immune function is normal, this persistence of treponemes rarely has clinical sequelae. The outlook for HIV-positive and other immunocompromised patients appears to be less assured; however, long-term studies in these patients are needed.

Chapter 76 - Genital Herpes

Diane Goade

Genital herpes is one of the most common sexually transmitted diseases. Of these, the agents of genital herpes — herpes simplex virus (HSV) type 2 and, less commonly, HSV type 1 — are among the most frequently encountered human pathogens.[1] [2]

EPIDEMIOLOGY

Genital herpes infections are common, with estimates of 500,000–700,000 cases of symptomatic first episodes/year in the USA.[3] [4] [5] [6] [7] Humans are the natural reservoir for HSV and virtually all cases of genital herpes are sporadic, acquired via person-to-person transmission. There are no reported epidemics of genital herpes.[2]

Herpes simplex virus infections have a worldwide distribution, with seroprevalence to either HSV-1 or HSV-2 approaching 90% in some age and sex groups.[3] [4] [5] [6] [7] Herpes simplex virus-1 infection is common early in life, typically as orolabial 'cold sores' with antibodies appearing in childhood and prevalence increasing with age; HSV-2 antibodies increase in prevalence with increasing age after the onset of sexual activity. Approximately one in every 3–4 adults in the USA is seropositive for HSV-2.[3] [4] [5] [6] [7] Herpes simplex virus-2 seroprevalence rates in the USA differ for some racial, sex and ethnic groups. Women acquire HSV-2 infections more readily than men and overall have a higher seroprevalence rate.[6] [8] Other risk factors for genital herpes include lower socio-economic status, increased number of sexual partners, African-Caribbean race and Hispanic ethnicity.[4] [5] [6] [7] The highest prevalence of HSV-2 antibodies is among commercial sex workers and up to 70% of prostitutes in the USA have the infection. The lowest HSV-2 prevalence is in sexually abstinent groups, including nuns, where seroprevalence is 3% or lower.[4] [5] [6] [7]

The incidence of seroconversion is approximately 5–10%/year when discordant couples are followed longitudinally. Among HSV-naive females with male partners who have the infection, seroconversion is as high as 15–30%/year. However, when the female partner has the infection first, less than 5% of male partners seroconvert/year.[8]

After infection with an HSV, antibodies to HSV-1 and HSV-2 type common antigens provide partial protection to infection with the counterpart virus. In prospective studies, women who have HSV-1 infection have a 5–20%/year lower rate of seroconversion to HSV-2 than women who do not have HSV infection.[8] Seroconversion to HSV-1 during childhood has decreased, particularly in upper and middle class socio-economic groups in the Western developed countries, whereas symptomatic infection with HSV-2 during adulthood has increased and first visit for medical care of genital herpes remains on the rise.[4] [5]

PATHOGENESIS

Herpes simplex viruses are large enveloped DNA viruses with a diameter of approximately 150nm, a dsDNA core, an icosahedral capsid composed of 162 capsomers, an amorphous tegument layer and a lipid envelope. There are 11 different glycoproteins projecting from the envelope that are crucial for virion-cell surface attachment and cell-to-cell spread (Fig. 76.1 ; see also Chapter 215). [1] [9]

Herpes simplex viruses are spread by direct contact, including contact with infected secretions:

- HSV-1 is typically spread through close contact with infected oral secretions, and genital herpes due to HSV-1 is usually due to oral—genital contact; and
- HSV-2 is primarily spread through intimate contact with infected genital secretions and tissues.

Intact skin is fairly resistant to virus infection, but abraded skin or mucous membranes are more susceptible.

The virus attaches to the cell surface and the viral envelope fuses with the cell membrane using a specific cellular receptor. Virion—cell surface attachment and virus intracellular penetration are mediated by viral surface glycoproteins. The viral nucleocapsid is released into the cytoplasm where it is transported to the nuclear pores of the cell. Following viral DNA replication and gene expression in the cell nucleus, the replicated nucleocapsid is assembled and buds through the nuclear membrane, acquiring an envelope. The enveloped nucleocapsid is translocated across the cytoplasm and cell membrane, acquiring surface glycoproteins at both the nuclear membrane and cell surface.[1] [9]

Herpes simplex virus then infects and replicates in parabasal and intermediate skin cells. Replication results in lysis of the infected cell. Infection may spread locally by direct cell-to-cell invasion or to more distant sites via sensory nerve pathways. As virus replication spreads to involve the local autonomic and sensory nerve endings, retrograde transmission of virions (or possibly nucleocapsids) occurs with transport of virus particles to the regional sensory ganglia. Transient virus replication may occur in the ganglia at this point. From the sensory ganglia, antegrade virion migration along sensory nerves allows viral spread to other sites. By this method of spread, crops of herpetic lesions may arise at nonadjacent sites such as the thighs or buttocks. Virus replication is associated with cell lysis, cell destruction and local inflammation of all tissues except the sensory ganglia.[2] [10] [11]

Central nervous system disease may occur as an aseptic meningitis with primary HSV-2 or as a necrotic focal encephalitis with HSV-1 via spread through the cribriform plate to the temporal horns. Recurrent aseptic meningitis has been described, but is rare. Rarely, hematogenous dissemination may occur with visceral organ involvement, most commonly in immune compromised patients.[2]

Immune response

Both cellular and humoral host immune responses appear to be elicited by genital herpes infection.[9] [10] [11] [12] [13] [14] [15] [16] The lysis of infected epithelial cells results in local inflammation, macrophage recruitment and T-cell activation. In a murine model, there is induction of natural killer lymphocytes. Lymphocyte activation results in the appearance of antibodies, including virus-neutralizing antibodies and antibodies that provide passive protection against infection when given to animals who are then challenged with virus.[1] [9] T-cell responses, including cytotoxic T-cell responses, appear to be crucial in limiting

Figure 76-1 The herpes simplex virion. This consists of a dsDNA core surrounded by a capsid, an amorphous tegument layer and a lipid envelope with numerous glycoprotein spikes. The overall diameter is 150–200nm. Virus replication takes place within the nucleus of the infected cell. The envelope is gained as the virion passes through the nuclear membrane. Replication of virus within the host cell results in cell lysis and destruction. Latent virus do not cause neural cell lysis within ganglia.

and clearing disease.[13] Murine models also indicate that the degree of macrophage function at the site of local invasion may contribute to limiting the spread of infection.[1]

Cytokine induction is less well described. In cell culture models, HSV-infected cells express the cytokines interleukin-2, tumor necrosis factor a and interferon-?.[13] Peripheral blood mononuclear cells have been shown to produce interferon-a within hours of exposure to HSV virions.[11] Individuals with limited cellular immunity, including those at the extremes of life, patients with AIDS and bone marrow transplant recipients, tend to have prolonged severe disease with extensive tissue involvement and a higher rate of dissemination.[14]

Human humoral immune responses to HSV include the rapid generation of IgM antibodies following infection, with the appearance of detectable IgG and IgA antibodies approximately 10–14 days later. Antibodies appear first to certain structural proteins, and then sequentially to the various surface glycoproteins. Seroconversion to all virus antigenic determinants after infection may require months as measured by Western blot.[5] [12] [15] Lifelong virus neutralizing antibodies and antibody-dependent cellular cytotoxic antibodies are detectable approximately 1 month after infection. Lack of antibody-dependent cellular cytotoxic antibodies has been correlated with a poor clinical outcome and may be a factor in severe disease in the newborn.[1] [16] [17]

Histology

The characteristic lesion of HSV infection is an erythematous macular or papular lesion, which progresses to a thin-walled vesicle on an erythematous base. Histologically, HSV infection is characterized by edema, multinucleate giant cells and Cowdry type A intranuclear inclusions. The inflammatory reaction present within HSV lesions consists of a mononuclear cell infiltrate of predominantly $CD4^+$ T cells (Fig. 76.2).[18]

Latency

Lifelong latency is a unique property of the herpesviruses and is characterized by persistence of virus or viral DNA in aquiescent state in sensory and autonomic ganglia.[1] Viral transcription is limited to three latency-associated transcripts[1] and antiviral medications are unable to eradicate latent virus.[1] [2] [9]

Periodic recurrences of symptomatic disease are due to reactivation of latent virus. Latent virus begins to replicate and form active virus particles. The virus particles are transported by antegrade axonal flow from the ganglion to the epithelium in the genital tract. Following reactivation, fully infectious virus may be detected in cutaneous lesions at the site of recurrence.

Reactivation of latent virus tends to be site and virus specific. HSV-2 reactivates much more readily from the sacral ganglia than

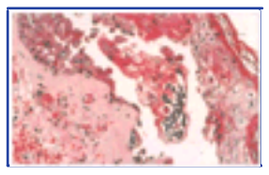

Figure 76-2 Histology. Section of human skin showing typical HSV virus effects: multinucleated giant cells (arrowhead) and intranuclear inclusion (arrow).

HSV-1 and HSV-1 reactivates more readily from the trigeminal ganglia.[2] [9] [19] How the virus remains latent within the ganglia and how reactivation occurs are not fully understood. In the epithelial cell, actively replicating virus DNA exists in a circular form. During latency the viral DNA assumes a linear configuration and latent viral DNA is episomal. Latency is not a wholly quiescent period, however, as some herpes simplex genes thought to be regulatory transcripts are expressed during this time.[1] [2] [9] Sequences within the herpes simplex genome specify 'latency-associated transcripts', which may be important in reactivation of virus replication. These sequences are highly divergent between HSV-1 and HSV-2 and may account for the preferential reactivation of virus type with its corresponding ganglion following latency.[2] [9] [19]

Virtually all recurrent genital herpes is due to reactivation of latent infection rather than to reinfection.[20] Several events may contribute to reactivation including trauma to the ganglia, immunosuppression, UV light, fever and possibly sexual activity.[2] [19]

PREVENTION

The only proven prevention strategy is avoidance of skin-to-skin contact when HSV is present in the genital tract. This includes avoidance of close physical contact during clinically symptomatic outbreaks when virus is present in high concentrations. Most patients can recognize symptomatic clinical outbreaks even when their symptoms are 'atypical' or mild and can avoid intimate contact during this time.

Frequent, intermittent aymptomatic or subclinical shedding of low titers of virus from the genital tract occurs in both men and women[21] and accounts for most cases of the transmission of genital herpes.[21] [22] [23] There is no current method to predict when asymptomatic virus shedding is occurring. It has been demonstrated that use of suppressive aciclovir decreases both the number of days of virus shedding and the quantity of virus shed.[24] Studies are under way to address the question of whether decreased shedding decreases transmission risk. Preliminary data indicate a 50% decrease in the amount of new disease among HSV discordant monogamous couples when the partner with HSV is on suppressive therapy (personal communication, L. Corey, 42nd ICAAC).

Vaccines

Protective vaccines may become important preventive options. The increasing incidence of genital herpes, the large number of HSV-2-seropositive individuals who are unaware of their infection status and the risk of disease transmission from asymptomatic shedding underscore the need for an effective vaccine.[22] [23]

In vaccine studies, various animal models, including a guinea-pig vaginal HSV-2 model and a mouse footpad inoculation or scarification model, indicate that certain vaccine candidates provide protection from acquiring infection or ameliorate disease.[25] [26] When studied in humans, these vaccine candidates have not been as effective as in the animal models. In a previous controlled trial in discordant couples, an inactivated HSV-2 glycoprotein vaccine failed to provide protection.[27] Recently, human trials have been completed or phase 3 trials are under way to evaluate recombinant surface glycoprotein vaccines.[28] [29] No vaccine for HSV-2 is currently licensed.

Barrier contraception

Barrier contraception such as latex condoms can reduce the risk of disease transmission by decreasing contact with the partner's infected skin or mucous membranes or infected secretions. Because herpesvirus may be present outside the portion of genital tract protected by barrier contraception, condom use is not infallible.

CLINICAL FEATURES

Genital herpes is a lifelong infection characterized by an initial infection followed by latency, and frequent recurrences. Infection may range from severe and symptomatic to asymptomatic. Herpes simplex virus disease is defined as:

- primary disease when a person lacking any antibodies to HSV acquires an infection with HSV-1 or HSV-2; and
- nonprimary first-episode disease when an individual with pre-existing antibodies to one serotype, typically HSV-1, acquires disease with the second type.

The presence of pre-existing type common antibodies and cell-mediated immune responses modifies the course of disease and so first-episode nonprimary disease is typically less severe than primary disease.[2] [9]

Genital herpes may recur from none to six or more times/year. Recurrent disease tends to be milder than symptomatic first-episode disease, with fewer vesicles, less discomfort and a shortened duration of symptoms.[2] [9]

Transmission of HSV-2 to a sexual partner or a neonate may be the first indication of the presence of genital herpes infection in an asymptomatic source partner.[23] [30] The time and source of disease acquisition are often difficult to prove conclusively because:

- genital herpes can have a prolonged asymptomatic phase after acquisition and may be transmitted via asymptomatic shedding; and
- clinically silent or unrecognized disease is common.

Primary first-episode genital herpes

Primary genital herpes is most often seen as a disease of sexually active teenagers and young adults. Following exposure, a clinically silent incubation period lasts for 2–7 days. Onset of clinically apparent disease may be heralded by fever, headache and local genital pain and burning. Patients may appear to be systemically ill. In general, females tend to have more severe disease than males, with estimates of urinary retention occurring in approximately 10% of females. Up to 25% of females manifest symptoms of aseptic meningitis.[2] [9]

The characteristic painful lesions in the genital area initially present as erythematous macules, which then progress to vesicles on an erythematous base, pustules, ulcers and finally to crusts (Fig. 76.3). Each crop of lesions takes an average of 8 days to heal completely, and successive crops of lesions may arise during the course of the disease. Untreated genital herpes may require weeks to resolve, averaging 3 weeks to cessation of lesions. Healing is usually complete, although particularly severe or large ulcers may result in scarring.[2]

Figure 76-3 Primary HSV. Multiple painful, erythematous, ulcerating lesions on shaft and head of penis. Exudative crust is visible over one lesion.

In the male, lesions typically appear on the penis and glans penis (Fig. 76.3). In females, lesions may be present throughout the genital tract including the perineum, vulva, labia, perianal regions and buttocks. The vesicles are typically distributed bilaterally in primary disease. Cervical involvement is usually present and may escape detection if limited external disease is present and a complete pelvic examination is not performed. A vaginal discharge may accompany cervical and, less commonly, vaginal herpes. In either sex, the perianal and rectal mucosa may be involved, especially if exposure was due to rectal intercourse. Tender bilateral inguinal adenopathy is generally present. Vesicles may also be present on the thighs.

If herpetic involvement of the urethra occurs, severe dysuria may result. Sacral radiculopathy may occur during the course of primary genital herpes, with urinary retention, neuralgias, dysesthesia and diminished rectal tone. Tenesmus and rectal pain may be present with rectal herpes.[2] [9]

In HSV-naive individuals, primary genital disease due to either HSV-1 or HSV-2 is clinically indistinguishable, making identification of infection by genital cultures and virus typing important for diagnosis. Atypical symptoms are quite common, with up to 30% of genital herpes presenting as paresthesias or urinary retention rather than the classically described vesicular genital lesions. [2] [9] [31]

Nonprimary first-episode disease

Nonprimary first-episode genital HSV-2 infection is typically intermediate in severity when compared with that of primary and recurrent genital herpes.[2] Untreated disease lasts for approximately 10–14 days, with fewer lesions and fewer crops of lesions than are typical for primary disease. Systemic symptoms, including fever, are less common than in primary genital herpes, and virus can be cultured less frequently from the cervix and genital tract.[2] [9]

Recurrent genital herpes

In approximately 50% of patients, a prodrome of symptoms heralds the onset of recurrent disease. Commonly reported prodromal symptoms include local burning and itching, tingling and dysesthesia. Patients may have their own recognizable cluster of symptoms. The prodromal symptoms may occur without the development of noticeable lesions or may be followed by the typical vesicular eruption lasting 6–10 days. In contrast to the widely distributed, bilateral lesions of primary genital herpes, the crop of vesicular lesions in recurrent disease tend to be localized and unilateral. Lesions are typically present on the vulva in women and the glans penis and penile shaft in men, although lesions may also present on the thigh or buttocks, in the rectum and at other sites. Paresthesia, dysesthesia, local edema, pain, regional adenopathy and local swelling may accompany recurrent cutaneous herpes.[2] [9]

Recurrence rates vary widely from none to six or more episodes/year, with some individuals having one or more recurrences each month. Recurrences may be triggered by sexual activity, with high rates of recurrent disease in commercial sex workers. Immunocompromised patients may experience frequent, prolonged and severe recurrences.[32] Genital herpes due to infection with HSV-2 reactivates much more readily than genital herpes due to HSV-1. Recurrent genital herpes has been reported in over 80% of individuals following primary genital HSV-2, whereas recurrence in patients who had HSV-1 primary genital herpes was less than 50%.[2] Recurrence of genital herpes averages 0.33/month with HSV-2 disease, but only 0.02/month for HSV-1 genital disease.[19]

Asymptomatic shedding

Landmark studies have demonstrated both by culture and by polymerase chain reaction (PCR) that herpesvirus is frequently present in the genital tract when lesions are absent and skin is intact, or when small or unrecognized lesions are present (Fig. 76.4). [33] [34] During periods of asymptomatic virus shedding, virus titers are typically lower than during a symptomatic acute outbreak. When detected by virus culture, asymptomatic shedding occurs on an average of 4% of days, whereas women with primary genital herpes may shed virus on up to 17% of days in the first few months following their primary outbreak. [21] [22]

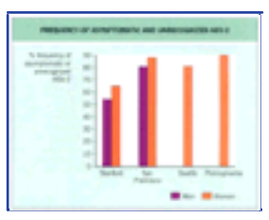

Figure 76-4 Frequency of asymptomatic and unrecognized HSV-2 in four major US cities.[4] [31] [37] [38] [39]

Uncommon sites of infection

Although the majority of herpes virus infections occur in the genital and orolabial regions, cutaneous disease may occur in virtually any site, causing localized to widespread disease. Genital herpes may present as:

- rectal herpes, with symptoms of proctitis, including rectal discharge, anal pain and pain on defecation;
- sacral paresthesia with urine retention; and
- painful anal fissures.

Males with rectal herpes may also present with impotence as a manifestation of neurologic involvement with HSV.[2] [9]

Neonatal herpes is a rare complication of genital herpes resulting from exposure of a newborn to HSV-2 from the maternal genital tract (see Chapter 65). Acquisition may occur during maternal primary genital disease via exposure to infectious virus in the birth canal during labor and delivery. Less commonly, the fetus acquires the infection during gestation. The incidence of neonatal herpes is approximately 1/3500 live births. An increased incidence is noted in preterm infants. Maternal acquisition of genital herpes during the third trimester of pregnancy increases the risk of neonatal transmission more than 10-fold compared with the risk of transmission from long-standing maternal HSV infection.[30] [35]

Disease in the immunocompromised host

Herpes simplex viruses may be significant pathogens in immunocompromised hosts (see Chapter 112 and Chapter 125). Patients who have HIV disease may have both frequent and increased duration of recurrences of HSV mucocutaneous disease (see Chapter 125). Delayed healing and continued virus replication lead to local spread and large, painful ulcers extending through the cutaneous and subcutaneous layers. In patients with $CD4^+$ lymphocyte count below 100 cells/mm^3 , treatment of

genital herpes may be complicated by emergence of aciclovir-resistant HSV strains.[2] [9] [32] [36]

DIAGNOSIS

Despite an overall increasing awareness of sexually transmitted diseases, recognition of genital herpes by both the patient and the health care provider is often limited, and the majority of infections are undiagnosed or unrecognized (Table 76.1).[4] [5] [31] Diagnosis of herpes simplex disease is important:

- to establish presence or absence of infection;
- to guide treatment considerations; and
- to allow the health care practitioner an opportunity to intervene in disease transmission.

Diagnosis may be accomplished by serologic and microbiologic methods.

Viral culture

Viral culture and typing is the preferred method for identifying infection, as it is the most accurate and most widely available diagnostic modality. It is recommended for all patients who have not had previous virologic confirmation of disease, including those with first-episode genital disease. Culture provides confirmation of the clinical diagnosis, and typing of virus predicts subsequent recurrence patterns. Culture of body fluids, vesicles and tissues from patients with symptomatic disease yields positive results in most cases when obtained early in the disease. Cervical cultures are positive in up to 90% of women with primary or first-episode genital herpes during the first week of symptoms, with decreasing rates of virus recovery during disease resolution. Virus may be recovered from mucocutaneous ulcers, cutaneous vesicles, CSF, rectum, urethra, urine and elsewhere in the genital tract. [2] [40]

In recurrent disease, virus may not be present in readily detectable quantities. Culture of multiple sites such as urethra, rectum and

TABLE 76-1 -- Differential diagnosis of genital herpes.

DIFFERENTIAL DIAGNOSIS OF GENITAL HERPES	
Disease	**Diagnostic clues**
Syphilis	Lesions usually single and painless; positive darkfield microscopy
Chancroid	Nonindurated ulcers, positive bacterial cultures for *Haemophilus ducreyi*
Lymphogranuloma venereum	Constitutional symptoms follow onset of lesions; responds to doxycycline
Genital warts	Chronicity of lesions: no vesiculation; minimal pain
Fixed drug eruption	History; viral culture negative
Contact dermatitis	History; lack of systemic symptoms; no adenopathy
Trauma	History; lack of systemic symptoms; no adenopathy
Psoriasis	Chronicity of lesions; lesions elsewhere on body

genital tract improves the chance of virus recovery. Growth and typing of virus requires less than 5 days, and modified culture techniques that detect herpes antigens (the shell-vial assays) yield preliminary results in 1–2 days.[33] [40]

Serologic assays

Type-specific serologic diagnosis is important:

- for serosurveys to gauge prevalence rates;
- for identification of asymptomatic patients;
- in situations where culture is not feasible or available; and
- for patient counselling in scenarios of sexually transmitted disease and other public health clinics.

Herpes simplex antibodies are readily detectable following infection, but it may take several months for complete antibody development to all antigenic determinants. Differentiating HSV-1 from HSV-2 antibodies is more problematic due to the antigenic similarity of the viruses.[1] [9] [15] Antibody responses in general are broadly crossr-eactive between HSV-1 and HSV-2.[40] Antibodies to glycoprotein G are type specific and antibodies to portions of glycoprotein B are type specific. [41] Recently developed tests using glycoprotein G-based serologic assays are now commercially available and include both ELISA and immunoblot formats. Sensitivities for HSV-2 using gG antibody development range from 80% to 98%, and perform worst in low-risk groups where false positives are more common. Specificity of gG assays is greater than 96%. Older assays do not discriminate between HSV type 1 and 2 and have little to no practical value.[41] [42]

Other diagnostic techniques

The advent of the PCR allows amplification and detection of HSV gene segments even when present in virus copy numbers too low for detection by culture. Assays based on PCR are rapid and sensitive, but strict control measures are necessary to avoid false-positive results. Detection of HSV by PCR is most useful for herpes meningitis, encephalitis and other central nervous system infections that are not readily diagnosed by cerebrospinal fluid culture or would other-wise require brain biopsy for diagnosis. The sensitivity of HSV PCR approaches that of biopsy for the diagnosis of herpes encephalitis. HSV-2 can be detected by PCR in a high proportion of people with recurrent aseptic meningitis.[1] [9] [43] [44]

Use of PCR to detect and quantify virus sequences on the skin and in the genital tract in the absence of lesions has provided important information about the duration and amount of asymptomatic virus shedding as the virus copy number is often below the threshold

of detection by culture.[21] Neonatal herpes infection may also be diagnosed by PCR amplification of HSV gene segments in the serum and CSF.

MANAGEMENT

Currently, the practitioner has a choice of effective, safe and well-tolerated medications (Table 76.2). Antiviral therapy is effective:

- in the treatment of primary and first-episode genital herpes;
- for episodic treatment of recurrences; and
- for suppression of frequent recurrences.

Continuous antiviral therapy has also been shown to decrease viral shedding. Antiviral therapy has not yet been shown to affect latency or 'cure' genital herpes. Preliminary data are encouraging that continuous antiviral therapy may decrease, but not eliminate, the risk of transmission.

Pharmacologic agents (see also Chapter 205)

Aciclovir is the acyclic analogue of the nucleoside guanosine. In order to be active, it must first be phosphorylated by the virus-encoded

TABLE 76-2 -- Antiviral therapy.

ANTIVIRAL THERAPY

Medication	Indication	Dose, route	Side-effects
Aciclovir	Primary genital herpes	200mg po five times daily or 400mg po q8h for 10 days	Nausea
	Recurrent genital herpes	200mg po five times daily or 400mg q8h for 5 days	Nausea
	Suppression of frequent recurrences	400mg po q12h or 200mg po q8h	Nausea
	Severe or disseminated disease	5mg/kg slow iv q8h for 10 days	Reversible crystalline nephropathy, tremors
	Encephalitis	10mg/kg slow iv q8h for 10 days	Reversible crystalline nephropathy, tremors
Valaciclovir	Primary genital herpes	1g q12h for 10 days	Nausea
	Recurrent genital herpes	500mg q12h for 5 days	
	Suppression of frequent recurrences	500mg q12h or 1g daily	
Famciclovir	Primary genital herpes	250mg po q8h for 10 days	Nausea
	Recurrent genital herpes	125mg po q12h for 5 days	
	Suppression of frequent	250mg po q12h	
Foscarnet	Aciclovir-resistant herpes simplex virus	60mg/kg q8h, infuse over 2 hours for 10 days	Azotemia, seizures, hypo- or hyperkalemia and hypo- or hyperphosphatemia
Note that the topical aciclovir 5% ointment available in the USA is of little value in the treatment of genital herpes and is not recommended as effective therapy. Valaciclovir 1g daily and 500mg daily are both approved for chronic suppressive therapy, but the authors recommend 500mg q12h.			

enzyme, thymidine kinase, to aciclovir monophosphate. The monophosphorylated form is then further phosphorylated by cellular enzymes to the di- and triphosphate form. The active form, aciclovir triphosphate, inhibits the HSV-specific DNA polymerase and terminates the replicating DNA chain by competing with its analogue deoxyguanosine triphosphate. Aciclovir lacks the 3'-hydroxyl group necessary for subsequent phosphodiester linkages, so that extension of the replicating DNA chain is no longer possible.[34]

Aciclovir has proved to be a well-tolerated and effective medication with a wide margin of safety. Its safety and specificity result from the relative inability of cellular kinases to phosphorylate aciclovir to its active form and from the more potent inhibition of HSV DNA polymerase than human DNA polymerase by aciclovir triphosphate. Resistance to aciclovir occurs when HSV strains develop that lack thymidine kinase or, less commonly, by strains with an altered thymidine kinase or DNA polymerase.[34]

Aciclovir is currently available as an oral, topical and intravenous agent. Clearance is via the kidney, with approximately 90% of the drug excreted unchanged in the urine.[34] Side-effects for the oral and topical forms are minimal. Topical aciclovir may cause burning and is not approved for use on mucous membranes.[45] Oral aciclovir may cause nausea, especially with high doses. These symptoms are generally mild and resolve over time with continued use of the drug.[46] Intravenous aciclovir may cause local pain and phlebitis if drug extravasates during administration.[34] The most common significant side effect of intravenous aciclovir is a reversible nephropathy secondary to crystallization of aciclovir in the renal tubules. Administration of intravenous doses slowly over 1 hour decreases the incidence of nephropathy. Aciclovir nephropathy is rarely seen in normal adults, but is more common in the elderly and in those with underlying renal dysfunction. Intravenous aciclovir may rarely cause neurologic complications, including lethargy, delirium and tremors.[34]

Other therapeutic agents

Antiviral medications that have recently become available include valaciclovir, penciclovir and famciclovir.

Valaciclovir

Oral bio-availability of aciclovir is limited, with only 15–20% of the oral dose absorbed. Valaciclovir, a prodrug of aciclovir, was developed to increase the oral bio-availability and is absorbed at levels 3–5 times greater than those for aciclovir. Following absorption, valaciclovir is then hydrolyzed to aciclovir. Oral administration of valaciclovir can lead to serum levels of aciclovir approaching those following intravenous administration of aciclovir.[47]

Penciclovir

Penciclovir is also an acyclic nucleoside analogue and is available in oral and topical forms. Topical penciclovir is a treatment option for orolabial HSV-1 but has not been approved for use in genital herpes. Like aciclovir, the drug must first be phosphorylated by the HSV-encoded thymidine kinase to penciclovir monophosphate. Cellular kinases then phosphorylate the compound to the di- and triphosphate forms. Like aciclovir triphosphate, penciclovir triphosphate is an inhibitor of HSV DNA polymerase. Although penciclovir is phosphorylated by thymidine kinase much more readily than aciclovir, this benefit is offset by reduced activity against the viral polymerase compared with that of aciclovir. DNA chain termination is not a significant property of penciclovir triphosphate. The intracellular half-life of penciclovir triphosphate is much longer than that of aciclovir triphosphate. It is unclear still whether these differences have an effect on the effectiveness or safety of penciclovir compared with those of aciclovir.[48] [49]

Famciclovir

Famciclovir is an oral prodrug of penciclovir. Similar to valaciclovir, famciclovir was developed in an effort to increase oral bioavailability. Following ingestion, famciclovir is rapidly converted by deacetylation to penciclovir. Approximately 60–70% of the dose is excreted in the urine as penciclovir.[50]

Foscarnet

Foscarnet is a pyrophosphate analogue that inhibits viral DNA polymerase.[51] Because it does not require phosphorylation to become active, its efficacy is not dependent on the presence of HSV-specific thymidine kinases. As such, foscarnet is one of the few drugs available for the treatment of aciclovir-resistant herpes simplex due to thymidine kinase or thymidine kinase-altered strains. Foscarnet is only available as an intravenous preparation. The most common side-effects include nephrotoxicity, electrolyte abnormalities, seizures and penile ulcers. Saline hydration decreases the renal toxicity and is recommended to diminish the risk of azotemia. Foscarnet-resistant HSV strains have occasionally developed in immunosuppressed hosts.[52]

Cidofovir or (S)-9-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine

Cidofovir is an acyclic nucleoside phosphonate antiviral agent currently used in the treatment of cytomegalovirus retinitis. Cidofovir is active *in vitro* against HSV and has activity against thymidine kinase-negative and thymidine kinase-altered HSV strains. Trials

TABLE 76-3 -- Drug comparison trials.

DRUG COMPARISON TRIALS				
Medications	**Indication**	**Authors**	**Results**	**Conclusions**

Aciclovir 200mg po five times daily for 10 days versus placebo	First-episode genital herpes	Corey *et al.*[58]	With po or iv aciclovir, pain decreased by 4 days, viral shedding decreased by 7 days, time to healing reduced by 7 days, 60% fewer new lesions; topical aciclovir of limited value	Oral aciclovir significantly effective in treatment of first-episode genital herpes
Famciclovir various doses po q8h versus aciclovir 200mg po five times daily	First-episode genital herpes	Loveless *et al.*[60]	Famciclovir 125, 250 or 500mg q8h equal to aciclovir 200mg five times daily each given for 10 days; famciclovir 250, 500 or 750mg q8h equal to aciclovir 200mg five times daily each given for 5 days	Famciclovir equal in efficacy to standard dose aciclovir and required less frequent dosing interval
Valaciclovir 1g po q12h po versus aciclovir 200mg five times daily po	First-episode genital herpes	File *et al.*[73]	Valaciclovir q12h doses as effective as aciclovir five times daily	Valaciclovir as effective as aciclovir, but required less frequent dosing interval
Valaciclovir 1g q12h po versus aciclovir 200mg five times daily po versus placebo	Recurrent genital herpes	Smiley *et al.*[65]	Time to healing equivalent for valaciclovir and aciclovir (115–116 hours) and shorter than with placebo (144 hours); duration of viral shedding also decreased in treated group	Treatment with valaciclovir or aciclovir significantly more effective than with placebo, and no difference between the two drug treatments (valaciclovir 500mg q12h now shown to be as effective as 1g q12h in a separate study)
Famciclovir 125, 250 or 500mg q12h po compared with placebo	Recurrent genital herpes	Sacks *et al.*[74]	Time to healing reduced by 1.1 days in treated group; significant reduction in shedding	Famciclovir effective in treatment of recurrent genital herpes
Aciclovir 400mg q12h po versus placebo	Suppression of frequent recurrences	Mertz *et al.*[69]	Mean number of recurrences 11.4/year for placebo group, 1.8/year for treated group; number free from recurrences for 1 year: 2% for placebo group, 44% for treated group	Aciclovir highly effective at suppressing recurrences; minimal side-effects, frequent high patient compliance and satisfaction with treatment
Famciclovir various doses po versus placebo	Suppression of frequent recurrences	Mertz *et al.*[75]	Time to first recurrence 82 days for placebo, greater than 120 days for treatment; 250mg q12h most effective and 78% of patients with no recurrences at 120 days versus 42% of those treated with placebo	Famciclovir 250mg q12h effective for suppressing frequent recurrences
Aciclovir 400mg q12h po versus placebo	Suppression of asymptomatic viral shedding	Wald *et al.*[24]	Five of 34 treated shed virus during therapy compared with 25 of 34 in placebo group; days shed were 6.9% with placebo, 0.3% with aciclovir	Aciclovir dramatically decreases asymptomatic viral shedding

of cidofovir in humans for the treatment of resistant genital herpes have not been completed. The primary toxicity of cidofovir at doses used to treat cytomegalovirus is nephrotoxicity. The doses of cidofovir necessary to treat aciclovir-resistant genital herpes have not been established.[53] [54]

Ineffective therapies

Ineffective therapies include BCG vaccination, topical betadine, topical vidarabine, topical idoxuridine and gammaglobulin. Topical therapy with foscarnet has been disappointing, with recent studies of treatment of recurrent genital herpes showing little to no benefit.[55] Lysine is a popular over-the-counter supplement purported to decrease the symptoms of genital herpes. Well-controlled clinical trials of lysine, including a double-blinded cross-over study, have failed to demonstrate efficacy.[56] ,57

General treatment guidelines

Antiviral therapy decreases both the duration of symptoms and viral shedding in genital herpes. Maximum benefit occurs when antiviral therapy is initiated promptly, ideally with the first prodromal symptoms with recurrent genital herpes. With the wide margin of safety of the oral antiviral medications and the need to initiate therapy promptly, it is appropriate to begin medication before receiving culture results or other confirmatory test results.

Aciclovir, famciclovir or valaciclovir are all appropriate agents for the treatment of genital herpes. For some indications, valaciclovir and famciclovir offer more convenient dosing regimens. However,

for many health care providers, generic aciclovir remains the drug of choice for the treatment of genital herpes due to the extensive clinical experience with the drug, its excellent safety and efficacy profiles, wide availability and lower cost (Table 76.3).

Treatment of primary genital herpes

Antiviral therapy is clearly of benefit in the treatment of primary genital herpes. When compared with placebo it has been shown to reduce median:

- duration of viral shedding by 7 days;
- duration of pain by 4 days; and
- time to healing by 7 days.[58]

Antiviral therapy does not prevent the establishment of latency or affect the likelihood and frequency of recurrences when compared with placebo.[59] Higher than recommended doses of antiviral medications are no more effective in the treatment of genital herpes and may be associated with an increased risk of nausea. [46] Treatment for longer than 10 days in the normal host does not improve outcome when compared with the standard regimen.

Primary or first-episode genital herpes may be adequately treated with a variety of oral regimens including aciclovir at doses of 200mg five times daily or 400mg q8h for 10 days. Alternatively, valaciclovir 1g q12h for 7 days or famciclovir 250mg q8h for 7–10 days is also effective treatment for primary genital herpes.[57] [60]

Individuals with severe disease or who are unable to take oral medications should be treated with intravenous aciclovir at doses of 5mg/kg administered over 1 hour q8h. Topical aciclovir is of little value in the treatment of primary disease.[58] The combination of oral and topical aciclovir offers no therapeutic advantage.[57] [61]

Oral famciclovir and oral valaciclovir have been compared with oral aciclovir for the treatment of first-episode genital herpes in recent clinical studies. Oral famciclovir in doses of 125,250 or 500mg q8h for 10 days has been shown to be as effective as aciclovir 200mg five times daily for 10 days.[57] [62] Valaciclovir 1g q12h was also as effective as aciclovir 200mg five times daily in the treatment of first-episode genital herpes. [57] [63] Neither famciclovir nor valaciclovir appears any more effective than aciclovir.

Episodic treatment of recurrent genital herpes

Recurrent genital herpes is generally milder and of shorter duration than primary disease, so the expected benefits of treating individual episodes with antiviral therapy are not as profound as those seen in primary disease. Episodic treatment of recurrent genital herpes with antiviral therapy results in only a modest decrease in disease severity, with a mean decrease in the duration of symptoms of 1 day or less.[62]

Aciclovir at a dose of 200mg five times daily or 400mg q8h for 5 days remains the recommended therapy.[64] Patient-initiated therapy at the time of onset of prodromal symptoms has been shown to be of significantly greater benefit than therapy delayed to initial lesion onset.[62]

Both valaciclovir and famciclovir have been evaluated for effectiveness in the treatment of recurrent genital herpes. Recent clinical trials comparing valaciclovir (1g

q12h) with either aciclovir (200mg five times daily) or placebo showed the following in both treatment arms when compared with placebo:

- decreased time to lesion healing;
- decreased duration of pain; and
- reduced duration of viral shedding.[65]

Oral famciclovir at doses of 125, 250 or 500mg q12h reduced viral shedding and duration of symptoms and reduced time to healing when compared with placebo.[66] The lowest effective dose, 125mg q12h for 5 days, is the currently approved treatment dose. Neither famciclovir nor valaciclovir appears to offer any therapeutic advantage over aciclovir.

The 5% topical aciclovir ointment available in the USA is not effective at reducing viral shedding, symptoms or time to healing, and is not licensed or recommended for treatment of recurrent genital herpes.[67] A different preparation available in Europe, a 5% topical aciclovir cream, has been shown to be effective and may be an appropriate alternative to oral therapy if available to the patient.[68]

Suppression of frequently recurring genital herpes

Chronic antiviral therapy has proven to be a safe and well-tolerated mechanism for suppressing symptomatic recurrences in patients with moderate to frequently (more than five episodes per year) recurring genital herpes.

Aciclovir

Aciclovir was the first antiviral agent evaluated for effectiveness in suppressing recurrent disease. In one study, patients with frequent recurrences had a reduction of recurrences from more than 12/year to an average of 1/year when treated with aciclovir 400mg q12h.[69]

Suppressive therapy is safe and well tolerated, with no long-term effects on sperm motility, no noted laboratory abnormalities and minimal side-effects. [69] [70]

Aciclovir has now been used for suppressive therapy for up to 10 years and has not been associated with development of tolerance or with any significant development of resistant strains in the normal host.[69] [71] [72] However, interruption of therapy at 1- or 2-year intervals is suggested to assess the frequency of episodes and need for suppressive therapy. It has recently been shown that suppressive therapy with aciclovir decreases the frequency of asymptomatic viral shedding in women.[24]

Famciclovir

Famciclovir is now licensed in the USA for suppressive therapy at a dose of 250mg q12h, the most effective dose tested in a dose-ranging study of famciclovir compared with placebo for suppression of frequently recurring genital herpes in women.[75] In this trial, once-daily dosing regimens were not as effective as the q12h dosing regimens at equal or higher cumulative daily doses. A subsequent 1-year trial in men and women also found that the 250mg q12h dosage was effective and well tolerated. At present, there are no results available of trials comparing the efficacy of suppressive therapy with famciclovir to therapy with valaciclovir or aciclovir.

Valaciclovir

Valaciclovir has also been used for suppression of genital herpes and has recently been licensed in the USA at a dose of 500mg or 1g orally daily for suppression of genital herpes in the normal host. The 500mg daily dose appears to be effective in persons with a history of 6–10 episodes/year. This regimen appears to be less effective than aciclovir 400mg orally q12h or valaciclovir 1g daily or 250mg q12h in patients with very frequent recurrences (10 or more episodes a year). Once-daily dosing with valaciclovir 1g appears to have acceptable efficacy in the normal host, but should not be used in the immunocompromised host because there is evidence of reduced efficacy in people who have HIV infection. Valaciclovir 1g daily or 250mg q12h and aciclovir 400mg q12h appeared equivalent in efficacy, even among people with frequent recurrences. For maximum efficacy, we prefer to use valaciclovir at a dose of 500mg q12h for suppression. This dose was found to be safe and was also significantly more effective than valaciclovir 1g orally daily in suppressing genital herpes in people who have HIV infection and a median $CD4^+$ lymphocyte count of 320 cells/mm^3 .[76]

Summary

In summary, there are no data at present suggesting that suppressive therapy with either famciclovir or valaciclovir at the licensed doses is more effective than suppressive therapy with aciclovir 400mg q12h. In addition, cost comparisons favor the use of generic aciclovir rather than the newer agents.

CONCLUSION

Genital herpes is one of the most commonly encountered sexually transmitted diseases. Its management requires:

- recognition of disease;
- patient education about the unique features of the disease, including latency and virus shedding; and
- judicious use of antiviral medications.

Chapter 77 - Papillomavirus Infections

Sten H Vermund
Madhav P Bhatta

INTRODUCTION

Human papillomavirus (HPV) is probably the most common sexually transmitted viral infection in humans. Infected persons are usually asymptomatic. Mild disease includes genital warts, verruga or cytologically evident dysplasia of the cervix or anus. Persistent anogenital infection is associated with advanced cervical neoplastic disease and invasive carcinoma of the anogenital region, most notably the cervix.[1] High-risk genotypes of HPV are likely to be responsible for a high proportion of carcinomas of the cervix, vagina, vulva, anus and penis worldwide.[2] Other types of HPV are associated with lower grade squamous lesions such as low-grade neoplasia and abnormal squamous cells of unknown significance.[3]

Nongenital types of HPV cause benign epithelial warts of the hands, feet and elsewhere, as well as a number of other dermatologic conditions not reviewed in this chapter (see Chapter 216). Infection with HPV may be a risk factor for squamous cell carcinoma of the head and neck.[4] [5] However, further research is needed to elucidate the full role of HPV in the development of nongenital tract cancers. 'Low-risk types' such as HPV-11 can nonetheless cause severe non-neoplastic disease including juvenile laryngeal papillomatosis characterized by laryngeal warts in children. While benign from an oncologist's viewpoint (hence the term 'low risk'), juvenile laryngeal papillomatosis can compromise the respiratory integrity of a child and may require repetitive surgical intervention. The focus of this chapter is diagnostic, epidemiologic, molecular and therapeutic issues in anogenital disease.

Human papillomaviruses

Human papillomavirus represents a family of DNA viruses with more than 142 related genetic types of which more than 90 have been fully sequenced (Table 77.1).[6] The genome consists of a circular double-stranded DNA about 8000 base pairs long and is encapsidated in an icosahedral protein coat with no membrane envelope.[7] Most HPV genotypes have a similar organization consisting of:

- a transcription and replication control region;
- an early region encoding proteins for replication, regulation and modification of the host cytoplasm and nucleus; and
- a late region encoding capsid proteins.[6]

While HPV is related to other nonhuman papillomaviruses, there is considerable virus-to-species specificity among other vertebrates, including mammals, birds, amphibians and reptiles. [7]

EPIDEMIOLOGY, PATHOGENESIS AND PATHOLOGY

Epidemiology

Human papillomavirus is a common infection among sexually active adults and adolescents.[8] Incidence and prevalence estimates for HPV infection are imprecise due to diagnostic limitations, subclinical cases, repeated and multiple infections and the phenomenon of inconsistent HPV types noted at separate clinical encounters. In the latter circumstance, one cannot be sure whether a new viral type

TABLE 77-1 -- Human papillomavirus types and associated diseases.[6] [7]

HPV TYPES AND HPV-ASSOCIATED DISEASES	
HPV-associated diseases	**HPV types**
Skin warts	1,2,3,4,7,10,26,27,28,29,41,48,57,60,63,65,75,76,77,78
Epidermodysplasia verruciformis benign lesions	3,5,8,9,12,14,15,17,19,20,21,22,23,24,25,36,47,49,50
Epidermodysplasia verruciformis squamous cell carcinoma	5,8,14,17,20,47
Periungual squamous cell carcinoma	16,34,35
Laryngeal papillomas	6,11
Oral focal epithelial hyperplasia	13,32
Squamous cell carcinoma (tonsil)	16,33
Anogenital warts	6,11,40,42,43,44,54,55,74
Low-grade anogenital intraepithelial neoplasia	6,11,16,18,30,31,33,34,35,39,40,45,51,52,56,57,58,59,61,64,66,67,68,70,71,72,73,74
High-grade anogenital intraepithelial neoplasia	16,18,31,33,34,35,39,45,51,52,56,58,59,68
Squamous cell carcinoma (cervix mostly)	16,18,31,33,35,39,45,51,52,56,58,59,68
Adenocarcinoma (cervix mostly)	16,18

has been acquired or whether it was missed at a prior diagnosis. The estimates of prevalence based on visible warts will grossly underreport prevalence, while estimates based on molecular evidence of infection (presence of HPV DNA in exfoliated genital tract cells) show the highest rates (to 20% in a general or to 75% in a very high-risk population of women or adolescents). However, it is estimated that more than 50% of sexually active adult females show serologic evidence of prior infection with one or more genital HPV types.[8] The rate of active HPV infection decreases with age; sexually active women under age 25 years consistently show the highest rates. Both acquired genital tract immunity and diminishing behavioral risk with age may be responsible for this strong inverse prevalence-age relationship. A longitudinal study of HPV infection in a cohort of college women in the USA found an average annual incidence of 14% and about 60% of the women were infected with HPV at some time during the 3-year follow-up period.[9] Similar results were also observed in a slightly older cohort (mean age 32 years) of women with a cumulative incidence of 54% after 3 years.[10]

Age remains a significant predictor for HPV infection even adjusting for other factors such as number of sexual partners. Other risk factors associated with HPV infections include number of recent and lifetime sexual partners, frequency of sexual intercourse, immune status and characteristics of the sex partner, including genital warts

and the number of lifetime sex partners.[8] Estimates based on HPV DNA detection methods suggest that the prevalence of HPV in men may be similar to that found in women.[11] However, penile and urethral data on men are quite limited, due in large part to inadequate cell sampling modalities.

Infection with HPV in women is typically transient, with a 70% clearance rate in 12 months and greater than 90% clearance rate in 2 years.[9] [12] [13] [14] [15] Persistence of type-specific HPV infection is an important risk factor for cervical cancer development and progression.[16] [17] [18] Factors associated with persistence of infection include higher number of lifetime sexual partners, older age of the women, infection with multiple types of HPV, high-risk HPV type, higher HPV virus load and infection with multiple HPV types.[9] [10] Note that while both prevalence and incidence of HPV are higher among younger women, it is older women who seem to be at higher risk of persistent HPV infection.

Human papillomavirus infection and cervical cancer

Cervical HPV infection is the single most important risk factor for squamous intraepithelial lesions (SILs) of the cervix.[1] The association between cervical cancer and a sexually transmitted etiologic agent was hypothesized long before identification of genital HPV infection. For several decades, cervical cancer risk has been recognized in association with early onset of sexual activity and multiple sexual partners either of the woman herself or of her male sexual partner. Although most women with cervical cancer are over 45 years of age when diagnosed, HPV infection and disease pathogenesis are known to begin at the onset of sexual activity.[19] Early signs of cervical intraepithelial neoplasia (CIN) are detectable through cervical cytology screening programs that provide periodic Papanicolaou-type cervical cell examination testing (Pap smear). An overwhelming majority of cervical cancer cases occur in women receiving suboptimal cervical screening and treatment regimens. Hence, cervical cancer cases reflect failures in public health and preventive gynecology. Older women and women from ethnic or racial minorities are more likely to be diagnosed with advanced-stage disease as a direct consequence of fewer cervical testing opportunities. [20]

Cervical cancer is the second most common cancer among women worldwide. Globally, an estimated 468,000 new cases and 233,000 deaths occurred in the year 2000, with developing countries accounting for 80% of the cases.[21] In the absence of screening programs, 85% of the women with cervical cancer will die given the advanced stage of the disease at the time of diagnosis.[22]

Despite widespread screening in the USA, it is estimated that about 13,000 new cases and 4100 deaths from invasive cervical carcinoma were reported in the USA in 2002.[23] In 1997, the estimated cervical cancer prevalence in the USA was over 200,000 women, suggesting the long duration and under-recognition of most cervical cancers. In the USA, about 35% of invasive cervical cancers and 57% of deaths occur in women over 55 years of age. [20] Data from the Surveillance Epidemiology End Results (SEER) program indicate an overall age-adjusted incidence rate for invasive cervical cancer in the USA of 7.7/100,000 women during 1994–98. The lifetime risk for acquiring invasive cervical cancer in the USA is 0.85% and that for dying from it is 0.30%. However, black women are 61% more likely to develop invasive disease and have about twice the risk (0.56% vs 0.27%) of dying from invasive cervical cancer than white women in the USA.[20] The racial disparity in the incidence of cervical cancer becomes more prominent among women over the age of 40 years. Cytologic screening in the USA results in the treatment of at least 750,000 women each year for cellular abnormalities suspected to represent possible cancer precursor lesions.[24]

Oncogenesis

Molecular studies demonstrate that HPV has a direct mechanistic role in oncogenesis.[25] [26] The integration of viral DNA is critical for malignant transformation while continued expression of HPV proteins is necessary for maintenance of the transformed state. In benign warts and in preneoplastic lesions, the HPV genome is maintained in a circular non-integrated form, whereas in cervical cancer cells the previously circular viral DNA is often found integrated into the linear host cell genome.[27] Proteins from both HPV and endogenous origins can deregulate cell cycles and enable carcinogenesis to occur. The expression of some of the 'early' genes (E6/E7) of high-risk HPVs (16, 18 and others) seems to be an essential factor for malignant conversion of the cervical epithelium. The viral DNA will integrate into the host DNA within the E1/E2 open reading frame of the viral genome.[28] Because the E2 region of the viral DNA normally represses the transcription of the E6 and E7 early viral genes, HPV integration causes overexpression of the E6 and E7 proteins of high-risk HPV types.[28] Transformation can occur when these expressed E6 and E7 proteins bind the products of tumor suppressor genes p53 and *pRb*-1, respectively. This modifies or inactivates their normal cell-regulating functions, namely the transcription of genes involved in cell cycle control.[25] The E6/p53 and E7/*pRb*-1 interactions cause genomic instability, resulting in the accumulation of chromosomal abnormalities followed by clonal expansion of malignant cells.[6]

Gene mutations in the p53 region have been seen with high frequency in cervical and vulvar cancer specimens, although there is some uncertainty as to how central p53 is to the carcinogenic pathway.[6] The affinity of these transforming viral proteins for the products of the tumor suppressor genes differs depending upon the oncogenic potential of a given HPV type. E6 and E7 proteins derived from high-risk HPV bind to p53 and *pRb* with high affinity, whereas the E6 and E7 gene products of low-risk HPV bind with low affinity.[27] The weight of both the epidemiologic and molecular evidence suggests HPV as the primary carcinogenic initiator of cervical neoplasia. Additional cofactors and mutational events may be important through chromosomal rearrangements, proto-oncogene activation and other viruses acting as modulators. [28] Metastases and recurrences from cervical cancer usually have the same viral types that were present in the primary tumor unless clonal diversity existed at the primary site.

Cofactors for oncogenesis

Human papillomavirus DNA from oncogenic viral types is found in nearly all cervical cancer cells (99.7% in one study using polymerase chain reaction (PCR) for detection).[29] [30] Previously, it was thought that only squamous cell tumors were associated with HPV. However, low-risk HPV types do not appear to cause cancer. A study of cervical cancer samples from patients around the world identified HPV-16 as the most commonly found viral type (50%), followed by HPV-18 (15%), HPV-45 (8%) and HPV-31 (5%).[29] The remaining 20% of the samples in this global survey contained other high-risk HPV types. HPV-16 was predominant everywhere except Indonesia, where HPV-18 was more common. HPV-45 was noted more often in Western Africa, whereas HPV-39 and HPV-59 were comparatively common in Central and South America. In squamous cell tumors, HPV-16 was found in 51%, whereas HPV-18 predominated in adenocarcinomas (56%) and adenosquamous tumors (39%). The more extensive the geographic and molecular research effort in clinical studies, the more diversity and complexity are noted.[31] Since high-risk HPV type infection is common in women with normal cervical cytology and only a fraction of HPV-infected women develop cervical cancer, HPV infection is a necessary but not sufficient cause of cervical and many other anogenital cancers.

Carcinogenic risk is enhanced by factors for which detailed explication is beyond the scope of this brief chapter. These cofactors include viral pathogenicity, host immunogenetic factors, host immunosuppression, host sexual behavior, acquired mucosal immunity and health care access.[24] Women who are infected with more than one HPV type or have higher viral loads[32] [33] are probably at higher risk for progression of HPV infection to high-grade CIN or cancer. Persistence of HPV interacts with other key cofactors (e.g. HPV type, immunosuppression, multiple sexual partners) and may be the major factor mediating carcinogenesis.[16] [17] [18] Other genital tract infections such as herpes simplex virus type 2 have been implicated as cofactors in disease pathogenesis.[34] Douching and resultant bacterial vaginosis with high amine production, high vaginal pH and altered microbial ecology may increase HPV risk.[35] High parity is associated with higher risk of squamous cell carcinoma among HPV-infected women.[36] Those women with seven or more full-term pregnancies are four times more likely than nulliparous women, and two times more likely than women with 1–2 full-term pregnancies, to develop squamous cell carcinoma. Parity, however, is not associated with the risk of adenocarcinoma or adenosquamous carcinoma.[36]

Local inflammation from infectious or other causes may stimulate cytokine responses that impact on HPV expression.[34] Keratinocyte growth factor is a cytokine that downregulates HPV-16 expression and stimulates squamous epithelial growth. In contrast, a number of inflammatory cytokines may have a dysfunctional role by upregulating HPV expression. When inflammatory cytokines are present in high concentration associated with other sexually transmitted infections, increased HPV expression may ensue. Local inflammation from infectious or other causes may stimulate cytokine responses that impact on HPV expression. Vascular adhesion molecules may enable local recruitment of inflammatory cells.[37] Inflammatory cytokines from bacterial vaginosis or sexually transmitted infections may increase HPV expression.[34] [38]

The prevalence of HPV declines with age, perhaps due to reduced risk behavior and/or to increased acquired immunity at the systemic and mucosal level over time. Women who do not clear their virus at these older ages may not have successfully developed acquired immunity. Women at highest risk are those in whom HPV is persistent, suggesting the potential utility of therapeutic vaccine or immunotherapies if they could help the mucosal immune system to clear the HPV infection.

Smoking, diet and drugs

Smoking may be an independent risk factor for cervical cancer. [24] Toxic cigarette smoke components can be found in high concentrations in cervical mucus. A putative carcinogenic impact of smoking could be formation of DNA adduct mutations in the host cells.[39]

Protection of the integrity of mucosal immunology and structure may require selected nutritional factors. Retinoids such as ß-carotene, antioxidants such as vitamin C and methylation agents such as folic acid have been implicated in cervical disease.[40] Chemicals and drugs may also affect cervical risk. Corticosteroids may increase oncogenic risk, presumably through immunosuppression and facilitation of HPV persistence.[24] Long-term use of oral contraceptive hormones appears associated with

an increase in the risk of cervical cancer in HPV-infected women.[41] Whether parity and oral contraceptive use are fully independent risk factors is uncertain, however, since their association with cervical disease may be confounded by multiple sexual partners.

Host genetics and immunosuppression

A current research challenge is to investigate the role of host genetics in HPV acquisition, retention and disease pathogenesis. Theoretically, HLA type or other host cell receptor genetic profiles may affect the degree of host cell susceptibility, efficiency of viral replication, nature of host immune responses and likelihood that infection will persist.[3] Molecular techniques have improved the precision and affordability of immunogenetic assessments within epidemiologic and clinical studies.[25] Recent studies have suggested a role of HLA class II polymorphisms in genetic susceptibility to HPV infection and/or cervical cancer in various populations.[42] [43] [44] [45] [46] [47] [48] [49]

Impaired immunity increases susceptibility to many infections and malignancies; HPV and anogenital cancers are no exceptions. Immunosuppressed persons, including those with low $CD4^+$ T-cell counts due to HIV infection, cancer chemotherapy recipients, renal transplant patients or rheumatology patients on immunosuppressive drugs, may have an impaired ability to clear HPV, permitting longer duration of infection and increased likelihood of oncogenic integration of HPV into the host genome. Immunosuppression can exacerbate the severity of epithelial warts and facilitates the persistence, pathogenicity and progression of HPV-induced neoplasia.[50] [51]

Cervical and anal HPV infection and neoplastic changes are more common in HIV-infected persons than among persons with comparable behavioral risk who are not infected with HIV.[52] [53] [54] [55] [56] [57] In many (but not all) studies, the magnitude of increased risk is proportionate to the severity of immunosuppression.[10] [58] [59] [60] [61] Cervical intraepithelial neoplasia progresses more rapidly and recurs more often after ablative therapy in HIV-infected women than in other women. Human papillomavirus may also infect the vulva and the anus, especially in association with immunosuppression.[62] Cervical cytology is now deemed an adequate screening tool for CIN in HIV-positive women, but the high recurrence rate and multifocal nature of this disease reinforce the need for regular screening at least once a year.[55] [63] Among HIV-infected persons, it is plausible that the short-term risk of HPV-related 'opportunistic malignancies' will decline due to immune reconstitution from highly active antiviral therapies, but that later viral resistance resulting in drug failures as well as a longer duration of life in a relatively immunosuppressed state will result eventually in an increased cancer incidence. Hence, it remains most urgent that routine screening be maintained among at-risk persons.

Male cofactors and sexual behavior

A 'male factor' is apparent in increased cervical cancer risk to women. Women married to men whose first wives died of cervical cancer, monogamous women married to seafarers or travelling sales-men who frequently are away from home, and female sexual partners of men with penile cancer all have a higher than expected cervical cancer risk.[24] Lack of male circumcision is associated with higher penile HPV infection rates and increased risk of cervical cancer in their female sex partners.[64]

That the risk for cervical cancer can be influenced by characteristics of a woman's sexual partner is certainly consistent with its sexual form of transmission. Commercial sex workers with exceedingly high numbers of sexual partners have a very high cervical cancer risk, while celibate women such as nuns and virgins have a very low risk. While a history of multiple sexual partners is clearly associated with increased cervical cancer risk, early age of first coitus, early age of first pregnancy and a history of sexually transmitted diseases may also contribute. Unlike with other sexually transmitted pathogens, condom use is neither strongly nor consistently associated with HPV prevention, perhaps indicating higher infectiousness per contact of HPV or the possibility of genital transmission from perineal or other noncoital sexual contact. Sexual couples can be discordant in HPV infection status or type, demonstrating the transient nature of infection in many persons, its low level in at least one partner and/or resistance to HPV by the uninfected partner through local immune or genetic factors.[65] HPV-related genital

cancers can cluster in families due, perhaps, to shared risk factors and/or host immunogenetics.[66]

Transmission from mother to child

Human papilomavirus transmission can occur intrapartum due to vaginal delivery.[24] Conjunctival papillomas present during infancy may occur and mothers of infants with conjunctival papillomas should be examined for HPV infection.[67] Viral load in cervical and vaginal cells may be an important determinant for the risk of perinatal HPV transmission.[68] Whether acquisition of HPV during the perinatal period predisposes to an increased risk of CIN among female infants in later life is unclear as the evidence for high-risk HPV transmission and persistent infection throughout childhood is uncertain.[69] [70] Juvenile laryngeal papillomatosis can cause aphonia or severe respiratory obstruction; it is probable that vertical transmission results in laryngeal HPV-11 infection that manifests in warts years later. Genital warts in children, in contrast, do not seem to occur from perinatal transmission and are typically the consequence of child sexual abuse when seen in immunocompetent children.

Other genitourinary cancers

Anal cancers in women and men are strongly associated with HPV. A high level of HPV infection may be important for development of anal intraepithelial neoplasia.[71] Men and women who practice receptive anal intercourse have higher anal cancer rates, but anal disease in women can occur even without anal intercourse, presumably through perineal HPV spread. Prior to the era of highly active antiretroviral combination chemotherapies, the HIV epidemic was associated with a huge rise in anal cancer rates affecting both men and women. [72] Cytologic screening for anal disease with a Pap smear-type anal swab is advocated for high-risk persons, especially for sexually active homosexual men; the utility of HPV for anal disease screening is not established.

Invasive squamous carcinoma is not common in the vulva or vagina. When cancer does occur in these genital tissues, HPV infections of the same types as seen in cervical disease are often detected. Squamous carcinoma represents 74% of invasive vulvar malignancies and 71% of invasive vaginal malignancies.[73] Both HPV types 16 and 18 are associated with vulvar squamous cell carcinoma,[74] although the prevalence of HPV-16 is less than in cervical carcinoma.

Primary squamous cell carcinoma of the ovary is rare; most cases represent malignant transformation of ovarian teratomas and are not HPV related. [74] Oncogenic HPV types can be detected very often in carcinoma of the penis and urethra.[11] Other urologic malignancies (e.g. prostate and bladder) may not have an HPV etiology although this continues to be studied. It has been suggested, but not clearly demonstrated, that HPV can act as an oncogenic agent in persons who are already predisposed to bladder cancer for other reasons.[75]

PREVENTION

Primary prevention for HPV is similar to that for any sexually transmitted infection. This includes encouraging abstinence among sexual inexperienced youth, mutual monogamy, condom use (although good evidence of condom protection against HPV is lacking) and other sexual risk reduction strategies. However laudable primary prevention is, measurable successes in reducing the incidence of cervical cancer have actually been achieved in industrialized nations through secondary prevention, namely screening by cervical cytology (Pap smear) followed by clinical treatment when indicated. In countries where screening has been extensive, the mortality rate from cervical cancer has fallen markedly since the 1950s. Detection and treatment of cancer precursors and identification of invasive cancer at an earlier, more curable stage can save many lives. The number of abnormal Pap smears and the number of women receiving preventive medical intervention are orders of magnitude higher than the number of cervical cancer cases in industrialized countries. These health care screening, diagnosis and treatment costs are not borne easily by developing countries where cervical cancer rates are often extraordinarily high compared with rates in industrialized nations. This is most tragic since tens of thousands of women lose their lives yearly in resource-limited nations as a direct consequence of failure to use Pap smear screening. [76] [77] [78]

While the importance of the Pap smear needs no further validation, its complexity is also substantial. A proper Pap smear requires a pelvic examination, an adequate sample of cells including those from the transformation zone (the squamo-columnar junction), proper fixing of the cells, excellence in cytopathologic processing and assessment, and adequacy of the clinical response to the results (both definitive diagnosis with colposcopically directed biopsy and therapeutic intervention when indicated). This complexity, combined with the Pap smear's only moderate sensitivity and reasonably high specificity, has motivated a search for improved cervical cancer screening approaches. Human papillomavirus screening is now feasible to consider as a screening tool, with a commercial product in its second generation that virtually eliminates interlaboratory variation as a problem (Hybrid Capture II™, Digene Corporation, Gaithersburg, MD). Whether HPV has value as a stand-alone screening tool, can complement cytology screening or is too costly for use has been the subject of intense investigation. Screening for HPV to help with the management of ambiguous repeated Pap smears and for cytologic quality control has been recommended since the early 1990s.[79]

Current screening guidelines

In 2001 and 2002, results from an historic National Institutes of Health-sponsored, multicenter, clinical trial called the Atypical Squamous Cells of Undetermined

Significance (ASCUS) Low-grade Squamous Intraepithelial Lesion (LSIL) Triage Study (ALTS), a consensus report crafting revised guidelines for reporting cervical cytologies ('2001 Bethesda System'), another consensus report for management of women with abnormal cervical cytology and two cost-effectiveness models suggested logical roles for HPV testing in cervical cancer screening programs.[80] [81] [82] [83] [84] [85] [86] [87] [88] [89] Based on the ALTS results, the 2001 Bethesda System subdivides the previous ASCUS cytopathologic category into two: 'atypical squamous cells of undetermined significance' (ASCUS) and 'atypical squamous cells, cannot exclude high grade SIL' (ASC-H). The 2001 Consensus Guidelines for Cervical Cytological Abnormalities highlight the fact that liquid cytologic assessment makes possible retention of the Pap test specimen for subsequent HPV screening. Thus, a valuable role for HPV testing is use of the Pap test using the liquid cytology method and testing of the remaining sample should the cytology demonstrate ASCUS. Note that another visit and examination is not needed with this approach.

A decision analysis model from Georgetown University investigators developing cost-efficiency judgments on cervical screening strategies looked at three screening regimens: Pap test alone, HPV by hybrid capture technique alone, or a Pap test plus an HPV test. The combined approach was superior in quality-adjusted life-years saved using an every-2-years screening approach. Cervical cancer could be reduced by an additional 59% over either modality alone, according to the model. [88] The second decision analysis model looked at the cost efficiency of different approaches to managing women with an ASCUS cytologic screening result:

- immediate colposcopy,
- repeat Pap testing,
- an HPV DNA test on a subsequent visit,

- an HPV test done on the same cellular specimen as the original Pap test ('reflex' HPV test), and
- routine care ignoring the ASCUS result.

The 'reflex' HPV DNA test, in which the HPV test is done on the same specimen taken for the original Pap test, was judged superior in that the same or greater life expectancy was obtained as with other options but at lower cost.[89] The investigators suggested that every-other-year liquid-based Pap tests with 'reflex' HPV tested would save billions of dollars in an American or European setting compared to conventional yearly Pap testing with repeat visits for Pap smears and colposcopically directed biopsies since these would be eliminated for HPV-uninfected women. While much additional modeling work is needed, these studies suggest for the first time a cost-effective algorithm using HPV testing for cervical cancer screening.

Lower-income women may have higher sexual risk profiles, the lowest Pap smear screening rates, the highest cervical cancer rates and the poorest access to health care services, resulting in cervical cancer death rates that are orders of magnitude greater than that seen among women from higher socio-economic groups. More efforts and research are needed to increase overall screening rates among the indigent and the isolated. Application of 'reflex' HPV screening may be most helpful in such populations. Fiscal difficulties, challenges in health care organization and women's health traditions that emphasize health of others (children and men) rather than themselves have inhibited effective Pap smear screening programs both in developing countries and in selected poverty pockets of industrialized nations. [90]

Vaccines

A high public health priority is the development of HPV vaccines, especially those targeting HPV-16 and HPV-18.[12] Both preventive (for HPV-uninfected women) and therapeutic (for HPV-infected women) vaccine approaches look promising. Vaccines have been successful in several animal models. Safety and immunogenicity of a live recombinant vaccinia virus expressing the E6 and E7 proteins of HPV-16 and HPV-18 (TA-HPV) have been evaluated in a phase 1 human clinical trial.[91] Studies to investigate the use of TA-HPV for immunotherapy of cervical cancer are underway.[92] Vaccines proposed as immunomodulators or therapeutic adjuncts to radiation therapy are termed therapeutic vaccines. Among the most promising vaccine approaches for prevention of sustained HPV infection (preventive or prophylactic vaccines) is the use of recombinant virus-like particles.[93] Virus-like particles are highly antigenic, protective in animal models and lack potentially carcinogenic viral DNA. Recently published results of a controlled clinical trial of HPV-16 L1 virus-like-particle found a very high efficacy (100%) in preventing HPV-16-related cervical e.g. intraepithelial neoplasia in 18 months of follow-up. [94] Immunization with HPV peptides of tumor origin will be tested both for therapy and prophylaxis with a goal of tumor regression or prevention.[95]

CLINICAL FEATURES

Human papillomavirus infection may be asymptomatic or may be manifested in various benign or malignant lesions on cutaneous and mucosal surfaces. Genital warts can be flat (condyloma lata), as is common in the cervix, or more papillary (condyloma acuminata), as is typical in the vulva, vagina or anus. Human papillomavirus is present in a wide variety of clinical circumstances — subclinical latent infection, clinically apparent warts, neoplasia or carcinoma — with normal or abnormal genital cytology.[96] Condyloma acuminata and condyloma lata are often caused by low-risk HPV types 6, 11 or related types. Most tend to regress naturally and are rarely associated with malignant progression. They are often multifocal, can be large and have a high rate of recurrence after treatment.[3]

Cervical intraepithelial neoplasia that exhibits nuclear atypia possesses potential for progression to invasive carcinoma if not removed. The transformation zone (squamo-columnar junction) of the cervix has neither the protective qualities of the keratinized squamous cells nor the vascular and immunologic milieu of the columnar epithelia and is particularly susceptible to HPV infection and subsequent neoplastic transformation. The usual cervical lesion is flat with warty colposcopic and cytopathic features and may be visualized when painted with 5% acetic acid to reveal aceto-white thickening. Both CIN I and II may precede CIN III and carcinoma in situ, and a small proportion progress to invasive carcinoma.[97] The majority of lower grade CIN regresses to normal. The trend in cytopathology and gynecologic pathology is to use full descriptions of biopsy results, acknowledging the limitations of the CIN system that may not capture the complexity of a given cervical specimen. In addition, the 2001 Bethesda System for cytology results (Table 77.2) merges CIN II and III, as did the older system, since interobserver reliability in distinguishing these is poor.[85] [98]

High-risk HPV types have been associated with all grades of CIN, whereas low-risk HPV types have segregated primarily in condylomata and CIN I. However, discrepancies between HPV type and morphology do exist, and cytology and histology provide variable and at times conflicting information.[97] Cells with inflammatory changes but no neoplastic characteristics are termed abnormal squamous cells or atypical cells (Fig. 77.2) and their management was the topic of the clinical trial (ALTS) described above.[99]

Human papillomavirus infections occasionally are clinically recognized by the characteristic raised appearance of the accompanying warts. Aceto-whitening (whitened color after application of 5% acetic acid) is helpful to clinicians examining the cervix, vagina, vulva, anus or penis, especially under magnification (colposcopy). This is done commonly following an abnormal cytology result in order to identify lesions requiring biopsy. A valid reference standard for grading HPV-related anogenital pathology remains elusive, as clinical and pathologic results are prone to observer interpretation and misclassification (Fig 77.3 , Fig 77.4 , Fig 77.5 , Fig 77.6 , Fig 77.7). [3]

On microscopic examination of a Pap test or biopsy, the diagnosis of HPV infection can sometimes be made by finding neoplasia or dysplasia. The term 'koilocytotic dysplasia', coined by Koss in the 1950s, is still used widely if cells pathognomonic for HPV infection are seen. Koilocytes are large cells with a clear enlarged cytoplasmic space. The nucleus is hyperchromatic, often irregular and larger than normal. It may appear smaller than normal but it is not, because the

TABLE 77-2 -- The 2001 Bethesda System terminology for reporting results of cervical cytology. [85] [98]

THE 2001 BETHESDA SYSTEM TERMINOLOGY FOR REPORTING RESULTS OF CERVICAL CYTOLOGY
SPECIMEN TYPE: *Indicate conventional smear (Pap smear) vs liquid based vs other*
SPECIMEN ADEQUACY

• Satisfactory for evaluation (*describe presence or absence of endocervical/transformation zone component and any other quality indicators, e.g. partially obscuring blood, inflammation, etc.*)
• Unsatisfactory for evaluation ... (*specify reason*)
• Specimen rejected/not processed (*specify reason*)
• Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of ... (*specify reason*)
GENERAL CATEGORIZATION (*optional*)
• Negative for intraepithelial lesion or malignancy
• Epithelial cell abnormality: see Interpretation/Result (*specify 'squamous' or 'glandular' as appropriate*)
• Other: see Interpretation/Result (*e.g. endometrial cells in a woman 40 years of age*)
AUTOMATED REVIEW
If case examined by automated device, specify device and result.
ANCILLARY TESTING
Provide a brief description of the test methods and report the result so that it is easily understood by the clinician.
INTERPRETATION/RESULT
Negative for intraepithelial lesion or malignancy (*when there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other non-neoplastic findings*)
ORGANISMS:
• *Trichomonas vaginalis*
• Fungal organisms morphologically consistent with *Candida* spp.
• Shift in flora suggestive of bacterial vaginosis
• Bacteria morphologically consistent with *Actinomyces* spp.
• Cellular changes consistent with herpes simplex virus
OTHER NON-NEOPLASTIC FINDINGS (*optional to report; list not inclusive*):
• Reactive cellular changes associated with:
• inflammation (includes typical repair)
• radiation
• intrauterine contraceptive device
• Glandular cells status post-hysterectomy
• Atrophy
Other
• Endometrial cells (*in a woman 40 years of age*) (*Specify if 'negative for squamous intraepithelial lesion*)
Epithelial cell abnormalities
SQUAMOUS CELL
• Atypical squamous cells
• of undetermined significance (ASCUS)
• cannot exclude HSIL (ASC-H)
• Low-grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN I
• High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN II and CIN III
• with features suspicious for invasion (*if invasion is suspected*)
• Squamous cell carcinoma
GLANDULAR CELL
• Atypical
• endocervical cells (NOS *or specify in comments*)
• endometrial cells (NOS *or specify in comments*)
• glandular cells (NOS *or specify in comments*)
• Atypical
• endocervical cells, favor neoplastic
• glandular cells, favor neoplastic
• Endocervical adenocarcinoma in situ
• Adenocarcinoma
• endocervical
• endometrial
• extrauterine
• not otherwise specified (NOS)
Other malignant neoplasms (*specify*)
EDUCATIONAL NOTES AND SUGGESTIONS (*optional*)
Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included)

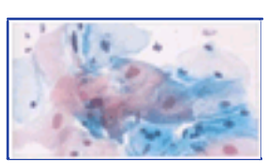

Figure 77-2 Atypical squamous cells of undetermined significance. Here the cells are slightly enlarged and irregular relative to the cells in Figure 77.1 and contain perinuclear clear areas suggestive, but not diagnostic, of HPV infection. *Courtesy of Dr William H Rogers (Pap stain).*

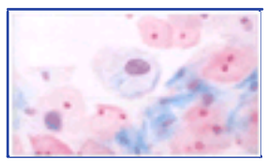

Figure 77-3 Low-grade squamous intraepithelial lesion. In this case, the lesion would classically be called a mild dysplasia; the cell in the center of the photograph has a nucleus that is enlarged more than four times the size of the surrounding normal squamous cells. In addition, the nucleus has irregular nuclear outlines and hyperchromasia. *Courtesy of Dr William H Rogers (Pap stain).*

nucleus is within a larger than normal cell and cytoplasmic space.[3] A cytologic or pathologic description of koilocytotic atypia alone implies that no dysplasia is seen, but the 2001 Bethesda System demands more detailed reporting to establish the proper classification.

DIAGNOSIS

Human papillomavirus cannot yet be grown in culture. Using molecular techniques, more than 90 HPV genetic types have been sequenced and more are certain to be identified in the future. Oncogenic, high-risk HPV types are found in a large majority of squamous cell cervical cancers. Genital tract HPV types include 6, 11, 16, 18, 31, 33, 35, 39, 40, 42, 43, 44, 45, 51, 52, 53, 54, 55, 56, 57, 58, 59, 61, 66, 68 and 70. High-risk types of major public health significance include 16, 18, 31, 33, 35, 39, 45, 51, 52, 54, 56, 58, 68 and 70.[6]

The sensitivity of PCR can result in DNA detection in a very large proportion of sexually active women (often 20–60%). Although it is the most sensitive technique for identifying HPV, a loss of specificity for predicting cervical disease means that the appropriate use of PCR in clinical screening remains to be determined. Older methods for molecular detection of HPV measure the presence of HPV DNA directly without PCR amplification, including Southern blot, in-situ

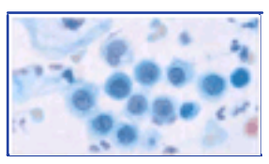

Figure 77-4 High-grade squamous intraepithelial lesion. This contains small cells with an increased nuclear to cytoplasmic ratio and marked nuclear hyperchromasia; in the classic terminology, this would be considered a severe dysplasia or CIN III. *Courtesy of Dr William H Rogers (Pap stain).*

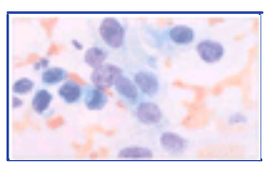

Figure 77-5 Carcinoma in situ. The abnormal hyperchromatic cells have indistinct cell borders and form a pseudosyncytial arrangement. *Courtesy of Dr William H Rogers (Pap stain).*

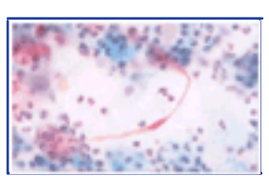

Figure 77-6 Squamous cell carcinoma. This shows highly atypical, enlarged, abnormal keratinized cells. *Courtesy of Dr William H Rogers (Pap stain).*

hybridization, filter in-situ hybridization and dot blot hybridization. These are hard to standardize across laboratories and are now used less commonly due to low sensitivity.[100]

Hybrid capture is a nonradioactive, rapid method of direct detection of HPV DNA. The technique allows semiquantitative assessment of major HPV types and can be used with a variety of cervical specimen collection methods. A second-generation hybrid capture technology

Figure 77-7 Genital HPV infection. (a) Vulvovaginal HPV infection. (b) Penile HPV infection.

Figure 77-8 Cervigrams. (a) Normal cervix. (b) Cervix with ectopy. (c) Cervix with microglandular hyperplasia.

uses an enzyme-linked immunosorbent assay (ELISA)-type plate to enable lower cost and greater test volume without any loss in the sensitivity or high specificity of the test.[101] Hybrid capture is more reproducible across laboratories than PCR. Paradoxically, lower sensitivity of hybrid capture compared with PCR may be helpful in clinical screening by only detecting infections above a given quantitative threshold. It is probable that the 18 genotypes (including the 13 high risk) that the second-generation hybrid capture system can detect are associated with about 95% of HPV-related cancers.[102]

Cell sampling strategies include scrape, swab, brush, cervicovaginal lavage, home lavage performed by women themselves and even sampling from vaginal tampons. In many epidemiologic and clinical investigations, high sensitivity of HPV assessment is desired to avoid false-negative assessments. In such circumstances, use of the cervicovaginal lavage increases sensitivity method related directly to cellular yield.[103] In routine cervical screening, the Pap test-style approach of cervical scrape and swab, using DNA-based diagnostics, seems sufficiently sensitive for clinical purposes.

Serology may become a tool to evaluate treatment success, but it is not yet an adequate clinical diagnostic tool due to its suboptimal sensitivity and specificity and given the ubiquitous yet transient nature of HPV infection. Seroepidemiologic studies have assessed antibody response to HPV-16 and HPV-18, and HPV-6 and HPV-11 for most part. A variety of test formats have been employed, including ELISA, Western blot, radio-immunoprecipitation assays and IgG and IgA levels in serum and in cervical secretions.[3]

Innovative diagnostic approaches include infrared spectroscopy of cervicovaginal lavage fluid, automated PCR-ELISA-based techniques, laser-induced cervical fluorescence and semiquantitative techniques.[103] It is uncertain whether these technologies will reach the mainstream of clinical testing. Liquid-based cytology (Thin Prep™ Pap smear) is now the test of choice of many clinicians and laboratories for cervical cytology due to its relative ease of standardization

and sensitivity.[104] The role of cervicography, high-resolution photography of the cervix (Fig. 77.8), is unclear given its high cost and failure to demonstrate superiority to the currently recommended approaches.[86]

MANAGEMENT

An accurate diagnosis and appropriate treatment plan can help eliminate the long-term sequelae of HPV disease. Current forms of treatment attempt to ablate the

pathologic lesions and eliminate HPV. The first goal is realistic in a large majority of patients, whereas the second is elusive given multifocal infection and the ease of reinfection with HPV.

Ablation of frank warts or pathologic lesions identified visually or by biopsy can be achieved by topical application of chemicals, cold (cryosurgery), heat (loop electrosurgery, laser) or surgery (cone biopsy, hysterectomy). Topically applied chemicals and medications include salicylic acid, cantharidin, podophyllin liquid, podophilox gel, trichloroacetic acid and topical 5-fluorouracil.[105] Success in treating condylomata can be increased if the area is first soaked with 5% acetic acid to show the extent of the local infection more clearly. Topical therapies are more efficacious when applied on warts occurring on moist mucosal surfaces than on lesions found on heavily keratinized epithelia. Cryosurgery applies liquid nitrogen with a swab, freezing superficial squamous epithelium and killing many of the HPV inhabiting the cells that are killed.[106] Loop electrosurgical excision procedure (LEEP) is currently a popular option, especially for cervical lesions, due to the relatively high rates of cervical disease compared with other anogenital sites.[52] Warts of the vagina, urethral meatus, anus and oral mucosa are often treated with cryotherapy initially, while topical agents may be used to treat warts of the vagina, vulva, anus and urethral meatus, and penis in men, when the evidence implicates low-risk HPV types. Recurrence rates associated with all modalities are high because these methods often fail to eradicate the subclinical or latent reservoir of HPV remaining in adjacent epithelial cells and mucous membranes.[95] Invasive treatment modalities such as carbon dioxide laser and surgery are reserved for patients with either extensive or refractory lesions.[107]

During pregnancy, removal of visible warts is often advisable due to their propensity to proliferate and become friable. Similarly, high-grade CIN may need intervention even during pregnancy. In contrast, treatment for subclinical genital HPV infection and lower grade CIN during pregnancy is not recommended as spontaneous improvement postpartum is common.

Immunologic therapy with interferons can be directed against all sites of infection, including clinical, subclinical and latent disease. Interferons have been used successfully as monotherapy or in combination with traditional modalities to treat anogenital condyloma acuminata.[95] They function as cytokines, intercellular signaling proteins that help regulate cell proliferation, differentiation and immune function. Interferons indirectly perform their diverse biologic activities by binding tightly to specific cellular receptors, resulting in transmembrane signaling and synthesis of effector proteins. Cost and side-effects inhibit the widespread use of interferon for therapy. Persons with severe or recurrent disease are far more likely to receive interferon therapy in combination with other therapeutic modalities than monotherapy alone.[95]

In the absence of HIV co-infection, currently available therapeutic methods (all modalities) are moderately successful in the treatment of frank genital warts, with recurrence rates of 25% within 3 months, and in clearing HPV. Fortunately, cytologic successes are higher than HPV clearance rates. Patient follow-up is based on colposcopy and cytology, while the use of HPV diagnostic use for posttherapeutic prognosis and management remains to be defined.[108] All screening and therapeutic contacts with patients or their partners should emphasize the importance of primary prevention (i.e. health care providers should counsel on how to reduce sexual risk taking).[108]

Chemoprevention

Chemoprevention is the use of agents to prevent or retard neoplastic progression. The desired effect for chemopreventive agents is complete regression or at least the prevention of progression. However, spontaneous high regression rates, the subjective nature of CIN diagnosis, the impact of biopsy on regression and the low threshold for ablative intervention complicate evaluation of such approaches. [109]

Several processes in the HPV infection cycle are appropriate targets for the development of antiviral and/or antineoplastic agents. The development of chemical compounds active against HPV could prevent the benign and malignant diseases associated with HPV infection.[110] Use of retinoids such as dietary vitamin A (retinol) and carotenoids is being studied early in the neoplastic process (either systemically or locally) to maintain normal cervical cell function and inhibit the disease progression. Retinoids do not seem to inhibit proliferation of HPV-immortalized cervical cells via effects on HPV E6 and E7, but they may act to inhibit cervical proliferation by suppressing the activity of epidermal growth factor and insulin-like growth factor signaling pathways. Combined interferon-retinoid therapy might provide enhanced anticancer benefits due to the fact that each agent inhibits cervical cell proliferation.[111]

CONCLUSION

Human papillomavirus is a ubiquitous, often transient infection that can cause anogenital carcinoma under conditions favoring persistence of high-risk genotypes. Our understanding of viral pathogenesis has improved markedly in the past three decades. Diagnosis, therapy, screening policies and vaccine development are all evolving at a rapid pace. However, immediate progress in control of HPV-mediated genital tract cancers depends on expanded screening and neoplasia treatment programs both for high-risk populations in the industrialized world and for persons in developing countries.

Chapter 78 - Lymphogranuloma Venereum, Chancroid and Granuloma Inguinale

Virginia R Roth
D William Cameron

Cutaneous lesions are common on the external genitalia.[1] [2] [3] Such lesions may be restricted to the genital region, part of a generalized skin eruption or a local manifestation of a systemic disorder (see Table 78.1). Genital lesions are often a source of great anxiety, although many are benign or inconsequential. This chapter focuses on penile lesions. Vulvar lesions are discussed in Chapter 62 .

A thorough medical history often provides the key to correctly diagnosing genital lesions. A history of multiple sexual partners, a recent new sexual contact or contact with commercial sex workers increases the likelihood of venereal disease. HIV infection also increases the risk of sexually transmissible genital ulcer diseases; conversely, genital ulcers are associated with a higher rate of HIV transmission. HIV-infected persons may present with genital Kaposi's sarcoma or Norwegian scabies or with an atypical presentation of a common disease such as herpes genitalis (due to herpes simplex virus, HSV).

A history of recent drug intake or systemic illness is useful in diagnosing fixed drug eruption or erythema multiforme. Although almost any drug can be implicated, antibiotics and antivirals are common causes of such reactions. A lesion that recurs at the same location upon reintroduction of the causative drug is characteristic of a fixed drug eruption. A history of trauma, such as a 'zipper accident', or genital manipulation may suggest traumatic ulcers. Trauma may also precipitate psoriasis or recurrent HSV and a history of trauma or inflammation helps to distinguish the white lesions of postinflammatory hypopigmentation from those of vitiligo. History of an autoimmune disorder or vitiligo elsewhere may confirm vitiligo. Minor trauma, such as shaving or scratching, can provide portals of entry for molluscum contagiosum and other infections. Contact dermatitis is usually accompanied by a history of contact with an irritant or allergen. These can include soaps, antiseptics, urine, feces, topical medications, lotions, lubricants, condoms or spermicides. In some cases, a history of contact is not obvious if the irritant was inadvertently transferred to the genital region by the hands (e.g. poison ivy). A history of pruritus may be obtained with contact dermatitis, scabies, lichen planus or lichen sclerosis. Local tingling or paresthesia may precede the appearance of recurrent HSV lesions. A history of systemic involvement should be sought, although genital lesions are rarely the sole manifestation of systemic disorders such as Reiter's syndrome, Behçet's syndrome and Crohn's disease.

The chronicity of a genital lesion may indicate a noninfectious cause such as malignancy. Occasionally the age of onset may guide the diagnosis, as certain lesions are more likely to appear in adolescence (e.g. hidradenitis suppurativa, pearly penile papules), after puberty (e.g. Fordyce spots, Beçet's syndrome, psoriasis), in middle age (e.g. lichen planus) or in the elderly (e.g. seborrheic keratosis, malignancy). A family history is rarely helpful, although up to 10% of patients with lichen planus may have a positive family history.

On physical examination, genital lesions can be broadly categorized as raised, flat or ulcerative (see Table 78.1). Raised lesions such as condylomata lata, pearly penile papules or molluscum contagiosum may be mistaken for genital warts. Hyperpigmented lesions, though usually benign, should be biopsied to rule out squamous cell carcinoma, Kaposi's sarcoma or malignant melanoma. Flat hypopigmented lesions that are not morphologically characteristic of vitiligo or postinflammatory hypopigmentation also should undergo biopsy to seek a diagnosis of lichen sclerosis or lichen planus. Ulcerative lesions may be classified as painful or painless. Painful ulcers include chancroid, HSV, aphthous ulcers and Behçet's syndrome. Syphilis and granuloma inguinale are typically painless, unless complicated. A general physical examination may provide diagnostic clues to a systemic disorder. Reiter's syndrome classically involves a triad of urethritis, conjunctivitis and asymmetrical polyarticular arthritis. Behçet's syndrome may manifest with oral ulcers, panuveitis, large joint arthritis, erythema nodosum or chronic meningoencephalitis.

The management of cutaneous genital lesions generally depends on making an accurate diagnosis. However, a syndromic approach to the management of venereal diseases has proved both feasible and useful in light of the cost and logistics required to make a definitive microbiological diagnosis in resource-limited settings.[4] The management of syphilis and HSV is discussed elsewhere in this text. The remainder of this chapter will deal with lymphogranuloma venereum, chancroid and granuloma inguinale.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by three serovars of *Chlamydia trachomatis*: L1, L2 and L3.

EPIDEMIOLOGY

Lymphogranuloma venereum is endemic in parts of Africa, India, Asia, South America and the Caribbean. It occurs sporadically in North America and Europe, usually in returning travelers or military personnel. Missed diagnosis and underreporting of LGV are thought to be common. Men are six times more likely than women to have a clinically evident infection, and are only infectious until the primary ulcer heals. In contrast, women may harbor persistent asymptomatic cervical lesions that serve as reservoirs of infection.

PATHOGENESIS AND PATHOLOGY

Lymphogranuloma venereum is acquired sexually, but transmission through direct contact with infected tissues or fomites has been documented. After exposure, epithelial abrasions allow the organism to penetrate the mucosal barrier. Replication within the macrophages is followed by spread via the lymphatic system. The histopathological changes on biopsy resemble those of other bacterial infections.

CLINICAL FEATURES

Lymphogranuloma venereum begins in the genital region and spreads through the lymphatics. Clinical disease occurs in three stages. The

transient primary lesion is a small, painless genital ulcer or papule. It appears 3–21 days after inoculation and generally goes unnoticed. It usually occurs on the coronal sulcus in men and on the cervix, posterior vaginal wall or vulva in women. Urethral involvement may cause urethritis.

The second stage occurs days to weeks after the primary infection. It is characterized by painful regional lymphadenopathy and systemic symptoms. In men, the inguinal lymph nodes are affected and node enlargement on either side of the inguinal ligament produces the characteristic 'groove sign'. In women, lymph drainage from the rectum and vagina results in pelvic lymphadenopathy. Involvement of these deep nodes causes lower abdominal and back pain. Initially, the lymph nodes are mobile and discrete, but with progressive inflammation they become fixed and suppurative with bubo formation. Buboes may spontaneously rupture or form chronically draining sinuses. Subsequent scarring and fibrosis results in lymphatic obstruction and genital edema (Fig. 78.1). Regional spread of LGV to the pelvis may cause salpingitis, pelvic adhesions and infertility. Hematogenous dissemination has been documented by the recovery of organisms from the blood and cerebrospinal fluid. Such patients experience nonspecific constitutional symptoms or, less commonly, present with meningoencephalitis, pneumonitis, arthritis or hepatitis. Skin lesions such as erythema nodosum classically follow surgical manipulation of infected tissue.

The tertiary or anorectal stage is predominantly seen in women and homosexual men. Rectal infection may result from anal intercourse, lymphatic spread or spread from vaginal secretions. Patients present with fever, rectal pain and mucopurulent or bloody discharge. The appearance on sigmoidoscopy resembles that of inflammatory bowel disease with mucosal ulceration and friable granulation tissue. Fibrosis can cause rectal strictures and bowel obstruction.

Conjunctival or oropharyngeal infection may be a result of autoinoculation or orogenital sex. The regional mandibular and cervical lymph nodes are involved and subsequent spread to supraclavicular and mediastinal nodes has been reported to cause pericarditis.

DIAGNOSIS

When LGV is suspected clinically, other causes of genital ulcer disease should be excluded. Growth of the organism in cell culture is the most specific diagnostic test but it is labour intensive, with a recovery rate of only 50%.[5]

Serology has been the mainstay for the diagnosis of LGV. Complement fixation is currently the most sensitive and widely used test and a titer of 1:64 or greater in the appropriate clinical setting is considered diagnostic. Other *Chlamydia* infections may result in a positive complement fixation test, but a titer of less than 1:16

Figure 78-1 Lymphogranuloma venereum causing unilateral vulvar lymphedema and inguinal buboes.

essentially excludes acute LGV. Microimmunofluorescence is more specific but less sensitive than complement fixation. More recently, enzyme-linked immunosorbent assay (ELISA) and direct fluorescein-conjugated antibody tests have become available. Polymerase chain reaction (PCR), though highly sensitive and specific, is costly and not routinely available.

MANAGEMENT

Although LGV infections resolve spontaneously, this occurs over several weeks and may be complicated by fibrosis, stricture formation or superinfection. Antimicrobial therapy decreases the incidence of complications, but has not been shown to affect the rate of healing. The recommended therapy is oral doxycycline 100mg twice daily for 3 weeks. Alternative regimens are oral erythromycin 500mg four times daily or oral trimethoprim-sulfamethoxazole (TMP-SMX; cotrimoxazole) twice daily.[4] [6] Asymptomatic sexual partners should also be treated. Patients should be followed to document clinical resolution. Repeated aspiration of buboes may be necessary to relieve pain and prevent rupture. Surgical intervention may be required for fistula or stricture or for management of chronic local edema, genital elephantiasis.

CHANCROID

Chancroid is a classic sexually transmitted genital ulcer disease. The etiologic agent is *Haemophilus ducreyi*, a fastidious Gramnegative coccobacillus.

EPIDEMIOLOGY

Chancroid occurs worldwide. It is endemic in tropical climates and has been the commonest cause of clinically presenting genital ulcer disease in many developing countries. It is much less frequent in North America and Europe where it occurs in sporadic outbreaks associated with prostitution, illicit drug use, travel and returning military personnel. The prevalence is much higher in men than women, reflecting its association with prostitution. Uncircumcised men are apparently more susceptible to infection. A low clinical suspicion and a lack of readily available diagnostic tests have resulted in underreporting of the disease, particularly where the disease is uncommon.

Outbreaks of chancroid are related to frequent sexual partner change and the number of sexual partners of an infected person, as occurs in prostitution, which consistently appears to be the main reservoir of infection. Women are often asymptomatic and commercial sexual activity may continue despite active infection and ulceration. Also, PCR testing on cervical specimens from high-risk women without genital ulcers has confirmed that asymptomatic carriage of *H. ducreyi* does occur.[7]

Chancroid and other genital ulcer diseases are significantly associated with an increased rate of HIV transmission.[8] [9] Conversely, the presence of HIV is also associated with an increased risk of genital ulcer and chancroid in some populations. The significance of epidemiological synergy between chancroid and HIV, which is the result of these complex bidirectional clinical and ecological interactions, was emphasized in an epidemiologic study that estimated that genital ulcer disease increases the risk of HIV transmission per sexual exposure by 10–300-fold.[10]

PATHOGENESIS AND PATHOLOGY

Haemophilus ducreyi is a bipolar-staining, pleomorphic Gramnegative coccobacillus. In the past, three distinct histological zones have been described on biopsy of the chancroid ulcer. The superficial

zone, in which the organism is most readily seen, contains necrotic debris, fibrin and degenerated neutrophils. The middle zone is characterized by edematous inflammatory tissue with neovascularization, and the deep zone exhibits a dense cellular infiltrate. This inflammatory infiltrate contains $CD4^+$ lymphocytes and macrophages, which HIV-target cells may contribute to the facilitation of HIV transmission.[11]

Chancroid is transmitted from person to person by direct contact. A break in the skin may allow the organism to penetrate, establish infection and evoke humoral and cellular immune responses. Despite the host immune response, reinfection and serial autoinfection can occur. Virulence factors have not been well defined. Pili have been demonstrated, but their role in cellular adhesion is unknown. The production of lipo-oligosaccharides, heat shock proteins and cytotoxins may contribute to tissue damage and ulceration. Evasion of bacterial killing by phagocytosis and of other immune defences may be mediated in part through lipo-oligosaccharide, cytotoxins and outer membrane proteins. Virulence factors and studies of inducible immunity are sought in *in vivo* models of animal and human experimental infection.

PREVENTION AND CONTROL

The role of chancroid in HIV transmission makes it a great public health concern and its proven potential control an opportunity for HIV control. Thus, treatment of infected persons and their sexual contacts and the examination and treatment of commercial sex workers in targeted medical health care are important public health control measures. In certain settings, effective treatment of sexually transmitted diseases (STDs) can decrease the population incidence of HIV.[12] The future development of vaccines for prevention of genital ulcer diseases including chancroid may also be highly effective in reducing the spread of HIV. Global chancroid eradication is gaining recognition as a feasible and worthwhile effort for preventing HIV transmission.[4] [13]

CLINICAL FEATURES

Patients who have chancroid generally present with painful genital ulcers within 4–7 days of exposure. An initial painless papule, usually unnoticed, develops into a pustule and progresses to form a painful ulcer about 1–2cm in size (Fig. 78.2). The ulcer margins are raised, irregular and sharply demarcated. Because the ulcer edge is not indurated, it is known as 'soft chancre'. The friable, granular base is often covered with a necrotic exudate. Approximately one-third of patients develop multiple lesions, which may coalesce to form giant ulcers. Autoinoculation may result in 'kissing lesions' on opposing surfaces.

The clinical picture varies with gender and men are more symptomatic than women. In men, the ulcer is usually located on the prepuce, coronal sulcus, penile shaft, glans or urethral meatus (Fig. 78.3). The scrotum and perineum are less frequently involved. In women, the clinical presentation may be atypical, with symptoms of dyspareunia or dysuria. Ulcers in women are more likely to be painless and are found on the forchette, labia, perineum, perianal region and the medial aspect of the thigh. Involvement of the vagina and cervix is rare. The ulcers may resemble those of syphilis, genital herpes or granuloma inguinale (GI). Co-infection with herpes simplex or syphilis commonly occurs, in as many as 10%.

Inguinal lymphadenitis is seen in about 50% of men and 35% of women and may be bilateral. Lymph nodes progressively enlarge to become necrotic and fluctuant (buboes). Systemic symptoms are characteristically absent. Extragenital ulcers are rare, but have been described in the mouth, fingers and breasts. Co-infection with HIV

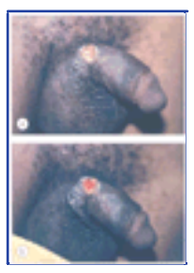

Figure 78-2 Chancroid ulcer. (a) Before and (b) after the performance of a swab, demonstrating the friability of the ulcer base.

Figure 78-3 Typical chancroid ulcer. Unilateral lymphadenitis and demonstration of the aspiration of a bubo.

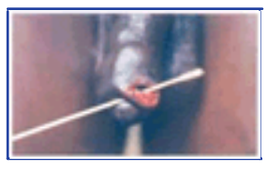

Figure 78-4 Phagedenic chancroid with extensive tissue destruction.

may alter the clinical presentation, as these patients are more likely to have multiple genital lesions, to develop extragenital ulcerations and may experience a delayed or reduced response to treatment. However, disseminated infection does not occur even in the immunocompromised. Although untreated ulcers usually heal spontaneously, they can be complicated by secondary bacterial infection, tissue destruction, scarring, fistula and stricture formation (Fig 78.4 , Fig 78.5).

DIAGNOSIS

Laboratory methods for the identification of *H. ducreyi* have developed rapidly over recent years.[14] Because the accuracy of clinical diagnosis may be as low as 33%,[14] laboratory confirmation of

Figure 78-5 Healed inguinal bubo with scar formation from previous chancroid infection.

infection should be obtained when possible. In addition, all patients who have suspected chancroid should be tested for HIV and for other or co-existing causes of genital ulcer disease.

Specimens are collected by swabbing the ulcer base. Bacterial contamination reduces the accuracy of the Gram stain and its overall sensitivity and specificity are less than 50%. Before the development of nucleic acid testing methods, culture of the organism was the standard diagnostic test. *H. ducreyi* is a fastidious, temperature-sensitive organism requiring an experienced laboratory and specific culture methods to achieve a sensitivity of 70–80%. A variety of culture media have been used (most commonly Mueller-Hinton or gonococcal agar base) and recovery rates can be improved by using more than one type of medium concurrently. Specimens should be inoculated onto culture plates within 1 hour of collection or stored in an enriched medium and refrigerated for up to 1 week. Culture plates are incubated at 91.4°F (33°C) in maximal humidity and high CO_2 . Growth is usually seen within 72 hours, but plates should be kept for 5 days before being reported negative. Colonies are raised; they are nonmucoid, yellow-gray in color and very cohesive. A positive culture may be confirmed by demonstrating the presence of nitrate reductase, cytochrome oxidase, alkaline phosphatase and the requirement for heme.

PCR techniques have become the preferred diagnostic test, with a sensitivity of 83–96% and a specificity of 100%.[14] A commercially available multiplex PCR assay for the simultaneous detection of *H. ducreyi, Treponema pallidum* and herpes simplex viruses simplifies the diagnosis and management of genital ulcer disease. Antigen detection techniques are of little clinical use. Serologic tests are available, but are primarily useful in epidemiologic studies.

MANAGEMENT

The treatment of chancroid has been complicated by antimicrobial resistance and HIV co-infection. There are wide regional variations in antimicrobial susceptibilities, but increasing global resistance to tetracycline, aminoglycosides, sulfonamides and amoxicillin-clavulanic acid has been documented.

Current recommendations for treatment include oral azithromycin 1g in a single dose, intramuscular ceftriaxone 250mg in a single dose, oral ciprofloxacin 500mg twice daily for 3 days or oral erythromycin base 500mg four times daily for 7 days.[4] Ease of administration and compliance make single-dose therapies preferable and there is good evidence that single-dose ciprofloxacin 500mg orally is effective regardless of HIV serostatus.[15] Intramuscular spectinomycin 2g is an alternative regimen. Response to treatment is characterized by a decrease in pain within 48 hours and complete ulcer healing may take approximately 10 days, depending on the size of the ulcer. The development of fluctuant buboes may occur on treatment and these should be aspirated by needle or drained by incision.

GRANULOMA INGUINALE

Granuloma inguinale (or donovanosis) is caused by the Gramnegative bacterium *Calymmatobacterium granulomatis*. It is a fastidious organism that is difficult to culture and thus continues to evade taxonomic classification and definition of its biochemical characteristics.

EPIDEMIOLOGY

Granuloma inguinale is endemic in tropical and subtropical regions such as Papua New Guinea and India. It can also be found in South East Asia, parts of Africa, the Caribbean, central Australia and South America. Granuloma inguinale is rare in North America and Europe. Underreporting probably occurs in nonendemic areas because of a low clinical suspicion and diagnostic difficulties.

The prevalence is highest among adults aged 20–40 years, although it does occur in children and in the elderly. The male to female ratio is about 2.5:1. Affected individuals are usually sexually active and may have a history of multiple sexual partners or contact with prostitutes. A significant association between granuloma inguinale and HIV seropositivity has been documented, particularly in men with genital ulcers of long duration.[16]

PATHOGENESIS AND PATHOLOGY

The exact mode of transmission is not known. However, it is widely believed to be sexually transmitted because of its predominance in sexually active persons, its predilection for the genital region, the high incidence of co-infection with other STDs and the association of anal lesions in men with receptive anal intercourse. The possibility of nonsexual transmissibility has been inferred from its occurrence in persons such as children presumed sexually inactive.

On histopathology, large mononuclear cells containing inclusion bodies (Donovan bodies) are characteristic. The associated epithelial changes include ulceration, microabscesses, acanthosis, irregular elongation of the rete pegs and pseudoepitheliomatous hyperplasia. Untreated lesions may become hyperkeratotic. The dermal layer exhibits inflammatory changes, with a dense cellular infiltrate and varying degrees of fibrosis and edema.

PREVENTION

Serious morbidity is best prevented by early diagnosis and treatment. Sexual contacts should be examined, as the rate of infection in this group is as high as 50%. It has been suggested that annual screening may reduce the incidence of GI in endemic areas and that condom use may decrease sexual transmission. As with other genital ulcer diseases, reducing the incidence of GI may be important in controlling the spread of HIV.[17]

CLINICAL FEATURES

Granuloma inguinale is a chronically progressive, ulcerative disease with no systemic symptoms. The incubation period appears to range from 3 to 90 days. Patients usually present with a nonsuppurative genital lesion. Less common presentations include vaginal bleeding or discharge, hematochezia, hematuria, pelvic inflammatory disease or a pelvic mass. The initial lesion is a small firm papule at the site of infection, which erodes to form a painless ulcer (Fig. 78.6). The ulcer is granulomatous and 'beefy-red' with a nonpurulent base. Multiple lesions may develop on opposing surface

Figure 78-6 Granuloma inguinale. The chronic, granulomatous, beefy-red ulcer without suppuration is typical. *Photo kindly supplied by J K Maniar.*

Figure 78-7 Granuloma inguinale. Lack of treatment has permitted progressive destruction of the scrotum. *Photo kindly supplied by J K Maniar.*

or along skinfolds. Lesions are usually found in the genital, perianal and inguinal regions. In women, cervical lesions may mimic dysplasia. Less frequently, extragenital sites such as the mouth, face or neck are involved. Abscess formation in the groin mimics lymphadenitis (pseudobuboes), but the lymph nodes themselves are rarely involved. This typical clinical picture may be altered if the genital lesions become secondarily infected, resulting in pain, purulent exudate and tender lymphadenopathy.

Without treatment, GI is slowly progressive, often resulting in soft tissue destruction and extensive scarring (Fig. 78.7). Possible sequelae include genital adhesions, stenosis of the urethral, vaginal or anal orifices, rectovaginal fistulas and lymphatic obstruction with genital pseudoelephantiasis. Contiguous pelvic spread may result in a 'frozen pelvis' or in hydronephrosis. Rarely, hematogenous spread to the bones or liver may occur. Even with treatment, there is a tendency for recurrence.

Granuloma inguinale may be confused with other causes of genital ulceration. Co-infection with other STDs is common. Carcinoma of the penis and vulva may occur simultaneously with GI or in areas of previously healed ulcers. It should be recognized that ulcers that do not respond to treatment or which appear recurrent may represent a malignancy. During pregnancy, GI is often more aggressive, with a higher rate of dissemination and a slower response to treatment. Perinatal infection is rare, but prophylactic antibiotics should be administered to the infant.

DIAGNOSIS

In nonendemic areas, a high index of suspicion is required to make a diagnosis of GI. Alternative or concomitant diagnoses must be ruled out. Clinical suspicion is confirmed by the demonstration of Donovan bodies on smear or biopsy. Reliable culture techniques and serologic tests are not available. To obtain a smear for diagnosis, the ulcer is scraped and the granulomatous tissue is spread directly onto a slide. The slide is air dried and stained with Wright or Giemsa stain. Donovan bodies are seen as darkly staining, ovoid organisms with or without a capsule. In the appropriate clinical setting, the 1-minute 'Quick test', in which the specimen is stained with eosin and thiazine dyes, is diagnostic.[18]

The smear is more likely to be negative if the lesion is early, sclerotic or secondarily infected. In such cases, a histological diagnosis should be sought. The diagnosis may also be established using transmission electron microscopy to identify Donovan bodies. PCR techniques, including a colorimetric detection system, have been developed recently but are not yet routinely available.[19]

MANAGEMENT

Treatment regimens are empiric, as *in vitro* susceptibility testing is not available. Currently recommended regimens include oral azithromycin 1g followed by 500mg daily, oral doxycycline 100mg twice daily, a double-strength tablet of TMP-SMX twice daily, oral ciprofloxacin 750mg twice daily or erythromycin 500mg four times daily.[4] [6] Clindamycin, the newer fluoroquinolones, chloramphenicol and aminoglycosides are also effective. Clinical resistance to tetracycline, ampicillin, TMP-SMX and streptomycin have been reported. The rapid clinical response achieved with azithromycin has made this drug the treatment of choice.[4] [20] Intravenous or intramuscular gentamicin may be added briefly in treatment for lesions that resolve slowly, and for HIV-infected persons. Combination therapy is used in more severe

disease. Response to treatment is usually seen within 1 week but antibiotics should be continued until all the lesions have resolved, which may take months in advanced disease.

Relapses are common and may occur up to 2 years after apparently successful treatment, requiring an additional course of antibiotics. Complications such as strictures, sinus formation, extensive superinfection or disfiguration may require surgical intervention.

TABLE 78-1 -- Differential diagnosis of cutaneous genital lesions.

DIFFERENTIAL DIAGNOSIS OF CUTANEOUS GENITAL LESIONS				
Category		**Lesion**	**Usual morphology**	**Comments**
Flat lesions	Erythematous	Contact dermatitis	Red edematous patch, may be vesicular	Recent contact with an irritant or allergen
		Seborrheic dermatitis	Ill-defined, erythematous, scaly patches or plaques with crusting	Idiopathic inflammation of the sebaceous glands
		Tinea cruris (dermatophytosis)	Well-demarcated scaling plaques, with an erythematous border, over the inner thighs	See Chapter 240
		Psoriasis	Well-demarcated erythematous plaques with scales on keratinized skin, and without scales on nonkeratinized skin	Typically involves the scalp, elbows, knees, back and buttocks
		Candidal balanitis	Red papules or plaques on penile shaft	See Chapter 237
		Plasma cell (Zoon's) balanitis	Glistening, moist, erythematous patch over the glans penis or coronal sulcus	Benign, chronic balanitis
	Hyperpigmented	Pigmented nevi	Well-demarcated lesions with regular borders and homogeneous pigmentation	Biopsy to rule out malignant melanoma
	Hypopigmented	Lichen sclerosis	Hypopigmented plaques of atrophic skin with progressive scarring over the vulva or penis (balanitis xerotica obliterans)	Benign chronic dystrophic disease, more common in postmenopausal women
		Lichen planus	Reticulated, white branching striae on nonkeratinized skin	Presents as inflammatory papules on keratinized skin
		Vitiligo	Depigmented well-demarcated patches with no skin surface changes	Absence of melanocytes, possibly autoimmune
		Postinflammatory hypopigmentation	Flat ill-defined demarcated patches with partial or total loss of pigment	Follows healing of some inflammatory lesions
Raised lesions	Normal pigmentation	Genital warts	Cauliflower-like (condylomata acuminata), flat-topped or rounded papules	See Chapter 77
		Secondary syphilis	Moist, hypertrophic, flat-topped papules (condylomata lata)	May also be ulcerative See Chapter 75
		Molluscum contagiosum	Smooth, firm, shiny umbilicated nodules	See Chapter 218
		Pearly penile papules	Crownlike arrangement of dome-shaped papules around the corona of the penis	Benign angiofibromas usually appearing in adolescence
		Prominent sebaceous (Tyson's) glands	Clustered pale papules on the corona and inner surface of prepuce	Aberrant sebaceous glands, normal anatomic variant
		Cysts	Dome-shaped nodules or papules	Common, benign growths
		Fordyce spots	Purplish or reddish telangiectatic papules on scrotum, penis or vulva	Occurs in late puberty, normal anatomic variant
		Sclerosing lymphangitis	Firm translucent cord encircling the penis proximal to the corona	Result of trauma or friction
	Erythematous	Scabies	Elongated papules (female's burrow) with surrounding excoriation	Look for corresponding lesions on wrists or in fingerwebs; see Chapter 11
		Hidradenitis suppurativa	Tender inflamed nodules at base of hair follicles	Recurrent abscesses of apocrine glands
		Pyogenic granulomas	Pedunculated vascular masses usually on the scrotum	Benign tumors
	Hyperpigmented	Seborrheic keratosis	Brown, keratotic, verrucous lesions	Benign lesions usually occurring after age 40
		Lichen planus	Pruritic, flat-topped violaceous papules on keratinized skin	Idiopathic, inflammatory eruption, often associated with oral lesions
		Squamous cell carcinoma in situ (3 forms)	Large, red-brown scaly or crusted verrucous lesion, usually solitary	Bowen's disease
			Smaller, flat verrucous lesions, usually multifocal	Bowenoid papulosis
			Erythematous, raised, irregular plaques	Erythroplasia of Queyrat
		Kaposi's sarcoma	Violaceous indurated plaques or nodules	See Chapter 132

Ulcerative lesions	Nonvenereal diseases	Aphthous ulcers	Painful irregular ulcers with erythematous borders and a white fibrin base	Commonly associated with oral ulcers
		Behçet's syndrome	Painful, shallow, irregular ulcers with erythematous borders and a white fibrin base on the glans penis or labia minora	Associated with oral ulcers, uveitis, arthritis, vasculitis or chronic meningoencephalitis
		Reiter's syndrome	Painless, serpiginous, shallow erosions of the penis with raised, erythematous borders (circinate balanitis)	Typically associated with urethritis, arthritis or conjunctivitis
		Erythema multiforme	Superficial vulvar, vaginal or penile erosions	Associated with stomatitis or bullous eruption over palms and soles
		Fixed drug eruption	Well-demarcated dusky red shallow erosion	History of drug intake
		Erosive lichen planus	Non-specific shallow ulcerations	Commonly associated with oral lesions
		Trauma	Variable morphology	History of recent trauma
		Crohn's disease	Ulcerative perineal granulomas; may form scars, sinuses or fistulas	Inflammatory bowel disease, anal fissures may be present
		Squamous cell carcinoma	Irregular, friable ulceration	Elderly patients with an indolent nonhealing ulcer
	Venereal diseases	Primary syphilis	Single painless ulcer with indurated edges and clean base	See Chapter 75
		Secondary syphilis	Multiple painless shallow ulcers	See Chapter 75
		Herpes simplex virus	Painful shallow ulcers, may be crusted	See Chapter 76
		Chancroid	Painful irregular, nonindurated ulcer with necrotic base; may have multiple ulcers	Commonly associated with inguinal buboes
		Granuloma inguinale	Painless nonindurated, 'beefy-red' ulcer with a clean base; may have multiple ulcers	May develop groin abscesses (pseudobuboes)
		Lymphogranuloma venereum	Primary lesion usually unnoticed but may present as a small painless ulcer or papule	Usually presents with painful inguinal lymphadenopathy

Chapter 79 - Practice Points

79.a Persistent/recurrent vaginal discharge

Jonathan M Zenilman

Introduction

Vaginal discharge is one of the cardinal symptoms of lower tract gynecologic exudative infections. These disorders are classified by anatomic site of origin. For example, gonorrhea and chlamydial infections are cervical infections; bacterial vaginosis (BV), trichomoniasis and vaginal yeast infections are vaginal disorders. Herpes simplex and human papillomavirus can cause epithelial lesions on the external genitalia, but they can also cause cervicitis with discharge (see Chapter 62).

Initial steps

The first step in assessing a complaint of recurrent vaginal discharge is to differentiate between a normal physiologic discharge, a vaginal discharge, and cervical infections. Many women have a small amount of vaginal discharge (physiologic leukorrhea), which is clear or white, does not have an odor, and is composed predominantly of squamous epithelial cells; this may vary with the menstrual cycle.

Patients do not differentiate from cervical and vaginal disorders, but often report 'vaginal discharge', which may represent either cervical or vaginal pathology. Therefore, initial evaluation of a patient who has recurrent or persistent discharge should include assessment for cervical infection. 'Recurrent' chlamydial and gonococcal infection is most often due to either patient noncompliance with treatment regimens, re-exposure to an untreated sexual partner, or re-exposure (i.e. new-incident infection). New-incident gonococcal and chlamydial infection is particularly common among adolescents.

Assuming that gonococcal and chlamydial infection have been ruled out and that the problem has been localized to the vagina, the next step in managing recurrent vaginal discharge is to determine the specific etiology of the vaginitis. This involves taking a careful history, with attention to recent douching, antimicrobial use (including use of over-the-counter antifungal medications) and reproductive history, followed by a clinical examination, which should include microscopic evaluation of vaginal discharge and determination of vaginal pH. The differential algorithm proposed by Sobel (see Further reading) is the standard in clinical assessment. The clinical and microscopic evaluation of recurrent vaginitis is shown in Figure 79a.1).

Recurrent vaginitis due to infection

Recurrent trichomoniasis

Recurrent infection with *Trichomonas* spp. is most commonly due to re-infection from an untreated male partner or to re-exposure. Trichomoniasis in men is usually asymptomatic, and it is therefore imperative that all male partners of women who have trichomoniasis be treated with metronidazole, 2g orally, as a single dose.

Metronidazole-resistant trichomoniasis is rare (<1% of clinical isolates) and should be considered only after re-infection has been ruled out and the patient has failed two courses of therapy. In these patients, metronidazole resistance should be confirmed, and they will respond frequently to a prolonged course of metronidazole (2–4g daily for 10–14 days).

Recurrent candidal vaginitis

Candidal vaginitis is extremely common, and recurrences occur frequently, in up to 45–50% of cases in some studies. Recurrent candidiasis is found more frequently in women who are taking antimicrobial agents and in those who have uncontrolled diabetes mellitus. Immunosuppressed patients, such as persons who have advanced HIV disease, are also at higher risk of recurrent candidiasis as well as recurrent BV (see below).

After potential precipitating factors have been considered, there remains a subset of women who continue to get frequent recurrences. Careful microbiologic evaluation, with identification of the fungal species, may occasionally reveal a yeast that is resistant to the commonly used imidazole therapies, such as *Candida glabrata* or *Candida tropicalis*. These investigations are expensive and should be reserved for use only after the clinical and epidemiologic risks have been identified. Persons who have chronic, recurrent candidiasis that is known to be caused by *Candida albicans* often benefit from a course of long-term prophylaxis with fluconazole, 100–200mg weekly (see also Chapter 62).

Recurrent bacterial vaginosis

Bacterial vaginosis is a disorder due to ecologic disturbances among the vaginal flora. Bacterial vaginosis is particularly prone to relapse. As above, the management of recurrent BV should account for the following:

¦ assurance that appropriate antimicrobial treatment was given initially — for example, many practitioners currently use a single dose regimen of metronidazole (2g orally), and this has a treatment failure rate of up to 20%; persons who have suspected recurrence should be treated with a full multiday regimen, of metronidazole 500mg orally q12h, or metronidazole vaginal gel (0.75%) 5g q12h for 5 days, or 2% clindamycin cream 5g q12h for 7 days;

¦ removal of exogenous factors that contribute to the pathogenesis of BV, including douching or long-term antimicrobials — douching is particularly associated with the development of BV because of the disruption of the local mucosal surfaces and flora and women who use spermicides are at higher risk for BV and must balance the risk and benefits of their use;
¦ ruling out the presence of cervical infection — infections in the lower genital tract induce an inflammatory response, which in turn causes BV, for example, therefore, as above, ruling out cervical gonococcal and chlamydial infection is important early in the evaluation of persons who have recurrent BV.

Figure 79.a-1 Clinical and microscopic evaluation of recurrent vaginitis.

There is a large population of women who have primary BV (i.e. BV without an identifiable cause). Primary BV resolves with treatment, but BV recurs frequently in these patients. Recurrence rates are as high as 20–30% 1 month after treatment. In these cases, long-term treatment with metronidazole should be considered. In nonpregnant women, treatment should take into account the impact of symptoms on the patient's lifestyle. In pregnant women, because of the potential for perinatal complications, periodic evaluation and treatment for recurrences is recommended.

Other causes of recurrent vaginitis

Bacterial vaginosis and yeast vaginitis are the most common types of recurrent vaginitis. Uncommon causes include hypersensitivity vaginitis, especially to latex, which is managed by avoiding latex exposure. This is one situation in which natural membrane condoms may be appropriate. Desquamative interstitial vaginitis is an uncommon disorder that is diagnosed by a high vaginal pH, a negative amine test, the absence of clue cells and the presence of polymorphonuclear leukocytes. These patients may respond to intravaginal 2% clindamycin cream, 5g q12h for 1 week; however, they are prone to frequent recurrence.

Use of biologic remedies

Women who have frequently recurrent vaginitis occasionally turn to biologic remedies obtained from health food shops or over the internet. These have included (among others) yoghurt douches, lactobacilli for vaginal instillation and prescriptions for eating large quantities of yoghurt. Controlled studies to date have failed to demonstrate any benefits of these remedies.

Patient counseling

By the time they see a medical specialist, patients who have recurrent vaginal discharge have typically been seen by many medical care providers with limited results, and they are therefore often frustrated. Counseling on the etiology and pathogenesis of the disorder with frank explanation of the expected impact of therapy is a critical component of management. Issues of sexuality should also be explored, because patients may find intercourse either uncomfortable or embarrassing.

Summary

Important points to remember are:

- take a complete history,
- account for exogenous factors,
- account for systemic diseases,
- rule out cervical sexually transmitted diseases,
- perform a complete evaluation including microscopy,
- consider episodic management and suppressive management, and
- counsel the patients intensively.

79.b A couple with difficulty conceiving: is it due to previous sexually transmitted diseases?

John W Sellors
John A Collins

Definition of the problem

Pelvic infection and epididymo-orchitis are serious consequences of sexually transmitted disease (STD) that have known effects in the female on the function of the fallopian tubes (Chapter 63) and in the male on the ability to produce an adequate ejaculate. Although not all cases of STD have such clearly damaging outcomes, silent injury to the relevant tissues can occur, and the worry about fertility is a legitimate concern.

It has been estimated, from longitudinal studies among Swedish women, that about 8% of women develop laparoscopically proven salpingitis after infection caused by either *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. Less than 30% of cases of acute pelvic inflammatory disease have been proven to be due to *C. trachomatis* (by tubal specimens or serology), and a much smaller percentage has been linked to *N. gonorrhoeae*. The risk of tubal infertility in women is directly related to the number and severity of the episodes of pelvic inflammatory disease. Serologic studies in North American women have shown that at least half of the cases of tubal infertility and ectopic pregnancy are attributable to *C. trachomatis* infection.

Chlamydial and gonococcal infections frequently cause urethritis in young men. Spread into the upper genital tract can cause epididymo-orchitis, particularly in those who do not receive effective treatment. Epididymo-orchitis is invariably accompanied by pain with tenderness and swelling of the structures involved, while urethritis and other infections in men may be asymptomatic and may not lead to overt clinical manifestations in the infertile male partner. Although a link between epididymo-orchitis and infertility would be logical, a causal association has not yet been established. In epidemiologic studies, chlamydial serology was more often positive among infertile men but (with one exception — anti-chlamydial IgA in semen) the differences were not significant. A recent review found that studies linking prior STD infections and semen parameters among infertile men were methodologically flawed, and found a need for further research to demonstrate a link between STD and male infertility.

Typical case

A couple in their late twenties have not conceived after 2 years of coitus during which they did not use contraception. The history reveals no contributory information other than the concern that both partners had a history of STD as adolescents. They wish to know about any possible relationship between their infertility and STD and request further investigation and management.

Their question is not uncommon. In the average Western country, up to 10% of married couples are infertile. In those under 30 years of age, the prevalences of *C. trachomatis* and *N. gonorrhoeae* infections are approximately 7% and less than 1%, respectively, in asymptomatic women. The reported rates in men are less than one-sixth of these levels. In less developed countries, prevalence rates of these infections are generally higher and so too are the attributable fractions of infertility due to these preventable causes.

Diagnosis

The diagnostic assessment of infertility is designed to evaluate the couple for the presence of defects in ovulation, seminal or tubal function or the presence of endometriosis. These diagnostic categories (Fig. 79b.1) occur with the following approximate frequencies: ovulation defect 25%, seminal defect 25%, tubal defect 20% and endometriosis 5%. The remaining 25% have no apparent abnormality and are categorized as unexplained infertility. Of the 20% with a tubal defect, total tubal obstruction accounts for only one-quarter, and of the 25% with a seminal defect, azoospermia accounts for only one-fifth. Although oligospermia may occur in men who have a history of STD and infertile men who do not have such a history, it also occurs among fertile men. Even in the presence of an apparent deficiency such as oligospermia, however, it is possible that some other undetectable defect is the true cause of infertility.

Infertile couples should be managed together and both should undergo the testing that is deemed necessary in a given case. Initial testing includes general health screens in both partners, and cervical cytology and rubella antibody in the female partner. The investigation of infertility in the female partner includes a menstrual history and a midluteal progesterone assay to confirm ovulation. Follicle stimulating hormone (FSH), thyroid stimulating hormone (TSH) and prolactin should be evaluated if the woman has amenorrhea. Semen analysis is necessary for the male partner and the semen analysis will be within normal limits in the majority of infertile male partners with a history of STD infection. If there is azoospermia, the FSH level should be estimated. Normal FSH levels are typical with obstructive azoospermia, which may be due to epididymo-orchitis or a related infection, while elevated FSH levels are common with non-obstructive azoospermia, which may be due to testicular failure.

For the evaluation of tubal disease, most clinicians prefer a hysterosalpingogram because it is a visual test that distinguishes between total and partial tubal obstruction. A laparoscopy is indicated as a primary procedure if there is a high risk of tubal disease or endometriosis and also whenever the hysterosalpingogram is abnormal. More than 50% of women who have tubal infertility have no history of pelvic inflammatory disease, however, and would not appear to be at high risk for tubal disease. The characteristic findings with either silent or manifest tubal disease include visible changes (adhesions, loss of fimbriae, tubal occlusion and hydrosalpinx) and microscopic changes, which range from minor impairment of the cilia to complete loss of epithelial function with evidence of chronic infection. When combined with laparoscopy, salpingoscopy allows an assessment of endotubal morphology.

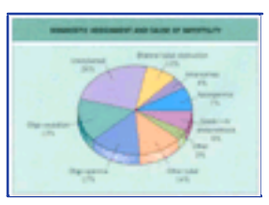

Figure 79.b-1 Diagnostic assignment and cause of infertility.

Genital culture should be carried out as a screening test before invasive testing. The most accurate tests for *C. trachomatis* are amplified nucleic acid assays (based on the polymerase chain reaction or the ligase chain reaction). *Neisseria gonorrhoeae* is best isolated by routine culture. Endocervical and urethral swab specimens are advisable to rule out infection in the woman and either urethral or first void urine specimens are acceptable in men. Chlamydial and gonorrheal serologic studies are not helpful in the investigation of infertility in either gender. Cultures for *Mycoplasma* spp. have no proven clinical use. Testing for antibodies to HIV may sometimes be warranted but there is a duty to provide counseling to the couple both before and after HIV testing.

Management options

Notwithstanding the diagnostic test findings, three characteristics of infertile couples are associated with a good prognosis:

- shorter duration of infertility;
- a previous pregnancy in the partnership (secondary infertility); and
- a younger female partner.

On average, untreated couples with only 2 years of primary infertility have a 22% likelihood of having a conception within 12 months that will lead to live birth. The rate

per month is just over 2% in the first 6 months.

If chlamydial, gonorrheal or trichomonal infections are found, the couple should be adequately treated with the appropriate antimicrobials. There is no evidence that presumptive treatment (of unproven infection) is an effective intervention for infertility. Similarly, the use of empiric antimicrobial therapy if leukocytospermia or endocervical leukocytosis is detected, in the absence of any defined pathogen, is of no proven benefit to the couple. For men who have oligospermia with or without a history of STD, empiric treatments such as clomiphene and antibiotics have not been demonstrated to be effective. In the presence of a varicocele, surgical repair is not an effective treatment for infertility. Intrauterine insemination of prepared sperm is associated with a small but statistically significant improvement in pregnancy rate, compared with intracervical insemination or timed intercourse. Intracytoplasmic sperm injection (ICSI) in an in-vitro fertilization (IVF) cycle is an effective but costly treatment for severe male infertility achieving pregnancy rates in excess of 25% per cycle. When the male partner has azoospermia, donor insemination is the most common treatment. Typical couples experience pregnancy rates as high as 15% per cycle of insemination. With obstructive azoospermia, sperm may be retrieved from the epididymis or the testis and even small numbers are sufficient for ICSI.

Many infertile women who have a history of STD have no evidence of tubal disease, but there may be either unilateral or bilateral occlusion and a variable extent of adhesions. When one fallopian tube is patent, the treatments include ovulation stimulation and intrauterine insemination, surgery and IVF. Bilateral tubal occlusion is optimally treated by IVF achieving pregnancy rates in excess of 25% per cycle, while microsurgery is associated with pregnancy rates of 15–20%.

Conclusions

Only 40–50% of infertile couples are successful in having a child and only 1–2% undergo IVF with or without ICSI, which is the most effective treatment for tubal infertility, severe male infertility or persistent infertility after the failure of conventional treatment. Not all couples choose to continue through every available investigation and treatment and therefore it is helpful for the physician to consider the wishes of the couple. Optimal infertility treatment decisions blend evidence from medical care research with the patients' preferences.

Jonathan Cohen
Steven M Opal

Chapter 80 - Pathogenesis of Fever

Aric L Gregson
Philip A Mackowiak

HISTORICAL CONSIDERATIONS

Akkadian cuneiform inscriptions confirm that fever has been recognized as a sign of disease since at least the 6th century BC. [1] Although various theories to explain the source of fever were advanced over the centuries, it was not until the 1850s that Claude Bernard correctly attributed the source of fever to metabolic processes within the body itself.

Our ability to measure body temperature progressed more quickly than our understanding of its source and regulation. Early devices used the expansion property of air to measure temperature, probably first in the 2nd century BC. In 1592, Sanctoria Sanctoria, a colleague of Galileo's at Padua, employed such a device in clinical studies, leading him to hypothesize the existence of a 'normal' body temperature. These early devices were prone to changes in barometric pressure until a closed thermometer employing alcohol was invented by Cornelius Drebbel in 1608. Some of the earliest closed liquid thermometers used scales based upon the freezing point of water and the oral temperature of a healthy human.[2] It was not until the early 18th century that Gabriel Daniel Fahrenheit popularized a reliable mercury-based thermometer with a scale based on the freezing and boiling points of water.

In spite of these advances, clinical thermometry was not fully integrated into medical practice until Carl Reinhold August Wunderlich published his sentinel work, *Das Verhalten der Eigenwärme in Krankenheiten* (The course of temperature in diseases) in 1868. In it, he reportedly examined some 25,000 patients from whom he obtained nearly 1 million individual measurements. These observations led him to propose 98.6°F (37°C) as the 'normal' body temperature and temperatures of 100.4°F (38°C) or above as fever.[3] [4] Despite the fact that these observations were made more than 130 years ago, were based on axillary temperatures and were obtained using thermometers calibrated 2.6–4.0°F (1.4–2.2°C) higher than contemporary thermometers, many clinicians continue to regard Wunderlich's observations as definitive.[5]

FEVER VERSUS HYPERTHERMIA

Fever is defined as 'a state of elevated core temperature, which is often, but not necessarily, part of the defensive responses of multicellular organisms (host) to the invasion of live (micro-organisms) or inanimate matter recognized as pathogenic or alien by the host'.[6] More simply, fever is a regulated rise in core temperature in response to a physiologic threat to the host. The febrile response, of which fever is a component, is characterized by a cytokine-mediated rise in core temperature, accompanied by increases in acute-phase reactants and a host of other immunologic, endocrinologic, neurologic and physiologic changes.

Fever and the febrile response should be differentiated from hyperthermia, which involves an unregulated increase in core temperature in which inflammatory cytokines play only a minor role. Hyperthermia is characterized by a sustained elevation of core temperature lacking the diurnal fluctuations characteristic of both fever and normal body temperature, and does not respond to antipyretic drug therapy.[7] [8]

Heat stroke, a cause of hyperthermia, often occurs in association with exertion and drugs, such as phenothiazines, anticholinergics or cocaine, that alter the body's ability to regulate heat. Classic heat stroke is most often seen in individuals at the extremes of age with co-morbid conditions. It is associated with a lack of sweating, moderate rhabdomyolysis and lactic acidosis, and rarely causes renal failure. In the exertional form of heat stroke, sweating is marked, making its detection more difficult. Rhabdomyolysis may be severe in exertional heat stroke, and, along with marked lactic acidosis, leads to a significant risk of renal failure. Common to both types of heat stroke is extreme hyperthermia, in which core temperatures may exceed 106°F (41.1°C).

Malignant hyperthermia, induced by general anesthetics in predisposed persons, and the closely related neuroleptic malignant syndrome are other types of hyperthermia. Malignant hyperthermia is a rare autosomal dominant disorder, usually triggered by inhalational anesthetic agents, which manifests as elevated core temperature, acidosis and muscular rigidity. Muscular rigidity appears to follow the development of hyperthermia in a majority of cases, suggesting that, at least initially, the increased core temperature is due to increased metabolism, not muscle contraction. Temperature increases rapidly, approximately 1.8°F (1°C) each minute. Core temperatures reaching 114.8°F (46°C) have been reported.[9] Hyperthyroid storm can also lead to hyperthermia, although in such cases temperatures rarely exceed 104°F (40°C).

CLINICAL THERMOMETRY

In clinical practice, fever is defined as a core temperature above the normal range. Presently, no physical examination is considered complete without a measurement of body temperature. Nevertheless, when interpreting the significance of such measurements, clinicians frequently disregard important variables such as the anatomic site at which the measurement is obtained, the time of day it is taken and the type of instrument used to obtain the temperature recording. Thermometers must be tested periodically according to the manufacturer's recommendations to ensure proper calibration.[10] [11] When measurements are taken, thermometers must be allowed adequate time to equilibrate with the test site. For example, when mercury-in-glass thermometers are used, rectal measurements require 1–5 minutes for optimal readings, whereas axillary and oral measurements require up to 11 minutes.[12] [13] Newer thermistor-based electronic thermometers have shorter equilibration times than traditional mercury-in-glass thermometers. Tympanic membrane thermometers equilibrate in seconds and are extremely convenient to use. Unfortunately, their results are inconsistent and correlate poorly with concurrent rectal and oral measurements.[2]

Core temperature is an amalgam of temperatures derived from the various internal organs, all having different metabolic rates. Under normal physiologic conditions such differences are small. However,

during shock or in the face of extreme thermal stresses, regional and organ-specific differences in temperature can be marked.[14] Because core temperature readings

are difficult to obtain, peripheral temperature measurements are used to approximate core temperature. Studies of the effect of anatomic site, oral stimulation and body position on estimates of core temperature have shown that mean rectal temperatures exceed oral by 0.8°F (0.4°C) and tympanic membrane temperatures by 1.6°F (0.8°C).[15] [16] During shock, rectal temperature may underestimate an elevated core temperature because of poor rectal perfusion.[17] Moreover, rectal measurements are associated with a small but significant risk of infection due to cross-contamination.[18] Oral temperature measurements have long been standard in clinical practice, largely because of accessibility but also because oral temperatures change quickly in response to changes in core temperature. Mastication and smoking both increase oral temperature. Ice-water ingestion decreases oral temperature, although only for a brief period.[16] Two recent studies of the effect of tachypnea and openmouth breathing on oral temperature found that open mouth breathing, but not tachypnea *per se*, lowers oral temperature.[19] [20] Because oral measurements require the subject's cooperation, they are difficult to obtain in critically ill and uncooperative patients.

NORMAL BODY TEMPERATURE

Despite the widespread application of thermometry in clinical medicine for over a century and a half, the definition of normal body temperature is still debated. A temperature of 98.6°F (37°C) is regarded as normal by most physicians and health care professionals, in all probability because of Wunderlich's work mentioned above. 'Normal body temperature', however, is not a specific temperature but a range of temperatures, the parameters of which vary from one person to another, as well as according to anatomic site and all those other factors noted above.[21] One of the largest studies of oral temperature in healthy subjects yielded a mean temperature of 98.2°F (36.8°C)[21] . Only 8% of the temperatures recorded were 98.6°F (37°C). In the subjects examined, the mean temperature varied diurnally, with a nadir at 0600h and a peak between 1600h and 1800h, a mean amplitude of variability of 0.9°F (0.5°C), and a range of 0.1–2.4°F (0.05–1.3°C). Women had slightly higher mean temperatures than men — 98.4°F (36.9°C) versus 98.1°F (36.7°C), $p < 0.001$ — but did not have greater diurnal variability. In this study population, 98.6°F (37°C) had no special significance with regard to normal body temperature (Fig. 80.1). The upper limit of normal temperature (i.e. greater than the 99th percentile), varied according to the time of day from an early morning low of 99.0°F (37.2°C) to an evening peak of 100°F (37.8°C).

THERMOREGULATION

Mammals employ various thermogenic mechanisms to increase heat production during episodes of cold exposure and during the initiation of fever. Shivering is a principal thermogenic mechanism, except in neonates. Nonshivering thermogenesis is most closely linked to brown adipose tissue, so named because of its brown color, which is due to a profuse vascular supply and a high concentration of mitochondria. Brown adipose tissue is most prominent near the shoulder blades, neck, adrenals and deep blood vessels. Noradrenaline (norepinephrine) induces enzymatic hydrolysis of triglycerides to glycerol and free fatty acids in brown adipose tissue. These free fatty acids are the primary substrate oxidized by mitochondria to produce adenosine triphosphate (ATP) and heat. They also act as a signal to uncouple oxidative phosphorylation, thereby generating excess heat.

In the resting state, approximately 72% of basal metabolic heat is produced by vital organs. Heat is distributed throughout the body

Figure 80-1 Distribution of baseline oral temperatures in healthy men and women. Frequency distribution of 700 baseline oral temperatures obtained during two consecutive days of observation in 148 healthy young volunteers. Arrow indicates location of 98.6°F (37°C). *With permission from Mackowiak et al.[21] Copyright 1992, American Medical Association.*

via the circulatory system. Variations in cutaneous blood flow determine the amount of heat lost at the skin surface by radiation, evaporation, convection and conduction. [22] When environmental temperature exceeds body temperature, evaporation is the most effective means of heat dissipation. The balance between heat production and heat loss, largely under control of the autonomic nervous system, is the means by which body temperature is maintained near the hypothalamic set-point of 98.2°F (36.8°C). When it is necessary to decrease core temperature, blood flow is preferentially directed to the skin and sweating mechanisms are activated. In cold environments or when fever dictates an increase in core temperature, blood flow is directed away from the surface towards the internal vital organs to minimize heat transfer to the environment.

More than 60 years of investigation have suggested that no single, central location is responsible for temperature regulation. Rather, a series of hierarchical structures appear to control body temperature (Fig. 80.2). This hierarchical system includes a continuum of structures from the hypothalamus and limbic system extending through the brain stem, reticular formation, spinal cord and sympathetic ganglia. The rostral hypothalamus, referred to as the 'preoptic' region, is actually composed of the medial and lateral aspects of the preoptic area, the anterior hypothalamus and the septum. This preoptic region plays a pivotal role in thermoregulation and appears to have greater thermosensitivity than other structures, which allows it to detect subtle changes in body temperature. The preoptic region orchestrates thermoregulatory responses in other effector areas via signals transmitted through the median forebrain bundle, a bidirectional pathway within the lateral hypothalamus.[23] Indeed, the median forebrain bundle has been shown to manage efferent signals controlling shivering and cutaneous blood flow.[24] Afferent signals ascend to the brain stem reticular formation via the lateral spinothalamic tract. The preoptic region of the hypothalamus, in turn, receives this information and integrates afferent and efferent signals to maintain the appropriate body temperature.

The rostral hypothalamus coordinates thermoregulation via a subset of temperature-sensitive preoptic neurons. There are three basic types of such neuron, which differ according to their responses to temperature changes. So called 'warm-sensitive neurons', accounting

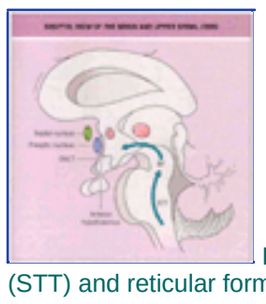

Figure 80-2 Sagittal view of the brain and upper spinal cord. The figure shows the multisynaptic pathway of skin and spinal thermoreceptors through the spinothalamic tract (STT) and reticular formation (RF) to the anterior hypothalamus, the preoptic region and the septum. *Redrawn with permission from Mackowiak.[1]*

for approximately 30% of the preoptic neuronal population, increase their firing rates in response to increases in preoptic temperature. Their efferent output initiates heat loss responses proportional to increases in body temperature over a certain threshold. A smaller number of 'cold-sensitive neurons' present in the preoptic region comprise less than 5% of total neurons. These neurons increase their firing rates as body temperature decreases. Cold-sensitive neurons are under synaptic inhibition from warm-sensitive neurons and, as the firing rates of warm-sensitive neurons decrease, so does the synaptic inhibition on cold-sensitive neurons. The net result is an increase in the firing rates of the cold-sensitive neurons[23] (Fig. 80.3). It may be that only the warm-sensitive neurons are truly thermosensitive and that thermoregulation is accomplished through their inhibitory and excitatory signals.[25] [26] [27] The majority of preoptic neurons do not demonstrate changes in firing rates in response to changes in preoptic temperature.

Pyrogens

Although peripheral neuronal input is of paramount importance during normal homeostatic thermoregulation, soluble 'endogenous pyrogens' (pyrogenic cytokines) exert a pronounced effect on temperature regulation during fever. These pyrogens are thought to mediate fever by elevating the hypothalamic set-point temperature (see also Chapter 2).

Pyrogens are artificially divided into 'endogenous' and 'exogenous' varieties. Pyrogenic cytokines are endogenous immunoregulatory polypeptides, such as interleukin (IL)-1ß, IL-6 and tumor necrosis factor (TNF)-a. They are primarily derived from stimulated mononuclear phagocytes and are capable of direct interaction with the anterior hypothalamus to elevate the core temperature set-point. Exogenous pyrogens are the usual stimuli that induce mononuclear cells to produce and release pyrogenic cytokines. They include substances such as lipopolysaccharide (LPS), peptidoglycan, lipopeptides

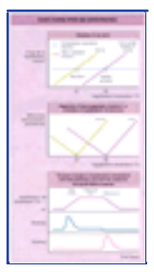

Figure 80-3 Events during fever and defervescence. When pyrogens are present in the preoptic region the whole body and neuronal responses are as shown by the purple lines. Upper: Normally the firing rates of warm-sensitive and temperature-insensitive neurons functionally overlap at 98.6°F (37°C), the set-point of thermoregulatory neurons. During pyrogen inhibition of warm-sensitive neurons this overlap occurs at the raised set-point of 102.2°F (39°C). Center: During fever, heat production is initially great but, as body temperature rises towards 102.2°F, heat production diminishes and should cease at 102.2°F. Lower: During fever initiation, shivering causes an increase in hypothalamic temperature and then ceases as the temperature reaches 102.2°F. During defervescence the hypothalamus activates heat loss responses such as sweating. *Adapted with permission from Boulant.*[23]

and numerous other microbial products. The distinction between endogenous and exogenous pyrogens and their ability to initiate fever is artificial, since some endogenous molecules can themselves induce the production of pyrogenic cytokines.

Figure 80-4 Production of fever. Microbial agents, inflammatory agents and some cytokines induce the synthesis and release of pyrogenic cytokines from a variety of cells. These cytokines, in turn, trigger specialized endothelial cells of the hypothalamic vascular organs, which release PGE_2 . Elevated PGE_2 then brings about increases in cyclic adenosine monophosphate (cAMP) monoamines and calcium in the thermoregulatory center of the anterior hypothalamus, resulting in a resetting of the thermostatic temperature from normothermia to febrile levels. These neurotransmitters then activate the vasomotor center, which brings about vasoconstriction (heat conservation) and increased heat production, both resulting in an increase in blood temperature (fever). Regardless of the cause of fever, antipyretics inhibit this pathway by preventing the increase in cytokine-mediated PGE_2 production in the hypothalamus. IFN, interferon.

Antigen- antibody complexes, complement, inflammatory bile acids and androgenic steroid metabolites are examples. Pyrogenic cytokines have numerous activities other than pyrogenesis, including autocrine, paracrine and endocrine functions that determine the character of the febrile response. Finally, the recent recognition that Toll-like receptors (TLRs) are expressed in the organum vasculosum laminae terminalis (OVLT) means that it is likely that exogenous pyrogens can induce fever directly, independently of proinflammatory cytokines.

Current concepts maintain that fever is initiated by exogenous pyrogens, such as LPS which exert their pyrogenic effect by increasing circulating pyrogenic cytokines, thereby elevating the thermal set-point of the thermoregulatory center in the preoptic region of the anterior hypothalamus (Fig. 80.4). However, being large, hydrophilic molecules, pyrogenic cytokines do not easily cross the blood-brain barrier, and it is unclear how they interact with central regions in the brain. One way in which they might gain access to thermoregulatory sites within the brain is through the relatively leaky blood-brain barrier associated with the OVLT. However, even in this region, and with the assistance of active transport, passage of pyrogenic cytokines across the blood-brain barrier is too slow and modest to account for the initial rapid onset of fever seen following the intravenous administration of LPS, IL-1 or IL-6.[28] Endothelial and microglial cells at the blood-brain barrier have IL-1 receptors and, in response to IL-1 and LPS, synthesize TNF-a, IL-1ß and IL-6, as well as cyclo-oxygenase (COX)-2 mRNA.[26] [29] Interaction of pyrogenic cytokines with cells at the OVLT might also induce responses that route the febrile signal inward toward the preoptic area via secondary cytokine production, phospholipase A_2 /COX-2 activity, a nitric oxide secondary messenger, or via direct neural input to the preoptic region.[30] Prostaglandin $(PG)E_2$, on the other hand, is able to cross the blood-brain barrier. Moreover, inhibiting PGE_2 synthesis blocks cytokine-induced fever, supporting its primary role in the pathogenesis of fever. Nitric oxide is generated by endothelial cells in the blood-brain barrier in response to IL-1 and IL-6. However, its role as a secondary messenger of the fever response is uncertain. [31]

It is more than likely that there are alternative mechanisms for activating the OVLT. In certain experimental models, circulating levels of IL-1 do not correlate with the initial fever peak, although IL-6 may correspond to subsequent peaks.[26] [32] Such observations suggest that IL-1 and TNF-a are paracrine modulators and IL-6 an endocrine modulator.[33] Yet other models suggest that bacterial superantigens, such as staphylococcal enterotoxin B, induce cell-associated cytokines that activate endothelial and microglial cells at the OVLT in the absence of high levels of circulating, cell-free cytokines.[34] Moreover, hepatic vagal fibers, stimulated by PGE_2 produced by Kupffer cells, appear to induce fever through neural input to the preoptic area.[28] Thus, it is possible that different combinations of mechanisms control fever in different situations.[34]

Acute-phase response

Fever is just one component of the febrile response, which also encompasses a host of other physiologic alterations collectively referred to as the 'acute-phase response'. Often fever and the acute-phase response are linked, as in trauma or infection. However, they can also exist independently, suggesting that, although pyrogenic cytokines have the capacity to elicit both responses, fever and the acute-phase response are, nevertheless, independently regulated entities (see also Chapter 2).

A wide array of physiologic and endocrinologic alterations occur during the febrile response. These include anorexia and sleepiness, and altered synthesis of glucagon, insulin, adrenocorticotropic hormone, cortisol, catecholamines, growth hormone, thyroid stimulating hormone, thyroxine, aldosterone and arginine vasopressin. Inhibition of bone formation, negative nitrogen balance, gluconeogenesis and altered lipid metabolism also occur. Serum levels of zinc and iron fall, whereas copper levels rise. Decreased erythropoiesis, in part responsible for 'anemia of chronic disease' (or, more appropriately 'anemia of chronic inflammation'), thrombocytosis and leukocytosis are additional features.[35]

Like fever, the acute-phase response is a tightly regulated response activated by a variety of stimuli (e.g. surgery, trauma, infection, cancer, burns). It is further characterized by production of an array of acute-phase proteins. These proteins are designated 'positive' or 'negative', depending on whether their levels rise or fall during the acute-phase response (Table 80.1). Those belonging to the former category are substantially more prominent than those belonging to the latter. The major positive acute-phase proteins are C-reactive protein (CRP) and serum amyloid A. Negative acute-phase proteins include albumin, pre-albumin (transthyretin) and transferrin. C-reactive protein and serum amyloid A normally exist in only minute concentrations but increase more than 1000-fold during the acute-phase response. C-reactive protein enhances phagocytosis by binding phosphocholine, present on foreign pathogens and damaged host cells, and activates complement. In

TABLE 80-1 -- Acute phase proteins.[‡]

ACUTE PHASE PROTEINS	
Positive acute-phase proteins[*]	
CRP	Ferritin
Serum amyloid A	Phospholipase A_2
Haptoglobin	Plasminogen activator inhibitor-1
a_1 -Acid glycoprotein	Fibronectin
a_1 -Protease inhibitor	Hemopexin
Fibrinogen	Pancreatic secretory trypsin inhibitor
Ceruloplasmin	Inter-alpha protease inhibitor

Complement (C3 and C4)	Mannose binding protein
C-1 esterase inhibitor	LPS binding protein
C4b binding protein	
a_2 -Macroglobulin	
Negative acute-phase proteins†	
Albumin	Transferrin
Transthyretin	a_2 -HS glycoprotein

† Proteins exhibiting decreased plasma concentrations during the acute-phase response.

certain situations, CRP stimulates thrombosis and promotes inflammatory cytokine production and the release of tissue factor by monocytes. Nevertheless, considerable evidence suggests that, in vivo, CRP functions primarily as an anti-inflammatory mediator.[37] Serum amyloid A enhances phagocyte adhesion and chemotaxis. Complement components, another group of acute-phase proteins, influence chemotaxis, opsonization and vascular permeability. The antioxidants and anti-inflammatory molecules haptoglobin and ceruloplasmin also appear to function as both positive acute-phase proteins and modulators of the inflammatory response. The thrombocytosis, decrease in iron and zinc levels and other features of the acute-phase response all appear to be important components of the defense against bacterial pathogens. [38]

Cryogens

Core temperature rarely if ever reaches, far less exceeds, 106.0°F (41.1°C) during fever. This suggests that fever has a thermal ceiling designed to protect the host against the deleterious effects of temperatures higher than 106.0°F (41.1°C).[32] Indeed, the warm-sensitive neurons in the preoptic region reach their peak firing rates and the cold-sensitive neurons in the same region are maximally suppressed at 107.6°F (42°C), suggesting that the anterior hypothalamus is incapable of thermoregulation at temperatures higher than 107.6°F (42°C).[39] Various mechanisms, including pyrogen tolerance, circulating cryogens and modification of effector synthesis, appear to work to prevent core temperature from rising to 107.6°F (42°C). The pyrogenic effects of IL-1 and TNF-a are attenuated after repeated or prolonged exposures. Moreover, an important feature of tolerance to LPS is a decrease in pyrogenic cytokine production by macrophages.[32] [40]

The best characterized endogenous cryogens are a-melanocyte stimulating hormone (aMSH), arginine vasopressin (AVP), lipocortin-1, glucocorticoids and IL-10.[41] [42] [43] IL-10 has been shown to prevent LPS-induced fever by attenuating the production of TNF-a, IL-6 and IL-1 and increasing release of soluble IL-1-receptor antagonist, and through direct interaction with microglial cells in the central nervous system.[44] Arginine vasopressin appears to exert its cryogenic effects as a neurotransmitter of specialized neurons projecting into the ventroseptal area. Firing of such neurons increases during fever.[45] Moreover, neutralization of AVP during experimental fever is associated with increases in both the height and the duration of fever, all of which suggest a cryogenic role for AVP.[43] The melanocortin aMSH is a neurotransmitter of neurons with projections to the hypothalamic paraventricular nucleus, the integrative output nucleus for fever and numerous autonomic stress responses. Under experimental conditions, peripheral and intracerebral administration of aMSH blocks IL-1- and LPS-induced fever. Centrally administered aMSH-receptor blockers inhibit the cryogenic effect of aMSH.[46]

Arachidonic acid liberated from cell membranes by the action of phospholipase can be metabolized either by COX to pyrogenic PGE_2 or via an alternative cytochrome-p450-mediated pathway to cryogenic eicosanoids (epoxyeicosanoids). Induction of cytochrome p450 shifts arachidonic acid metabolism away from COX and toward the cytochrome p450 pathway, thereby reducing core temperature through a combination of diminished PGE_2 production and an increase in production of cryogenic epoxyeicosanoids.[47]

ANTIPYRETICS

Aspirin and acetaminophen (paracetamol) have been a mainstay of antipyretic drug therapy since the turn of the 20th century. Release of the fenamates in the 1950s and indomethacin in 1963 was followed by introduction of a host of nonsteroidal anti-inflammatory drugs (NSAIDs), all with antipyretic properties. Despite the popularity of these drugs among both health care workers and the general public, it is still not clear that reducing core body temperature benefits febrile patients. Although antipyretic therapy assumes that fever is, at least in part, noxious and that suppression of fever will eliminate or reduce its noxious effects, neither assumption has been validated experimentally. Consequently, rational guidelines for suppressing fever have been slow in coming.

Fever creates a number of potential metabolic challenges for the host. During the chill or ascending phase of fever, activation of the sympathetic nervous system causes peripheral vasoconstriction and an associated increase in mean arterial pressure.[48] Oxygen consumption increases, as does carbon dioxide production.[49] External cooling can attenuate these effects, but only if shivering is prevented.[50] If shivering is not prevented, external cooling reduces skin temperature faster than core temperature and initiates vasoconstriction and shivering, which can paradoxically increase core temperature, oxygen consumption and the respiratory quotient. Importantly, external cooling can also cause vasospasm of diseased coronary arteries.[51] Unfortunately, certain antipyretic drugs also cause coronary vasoconstriction in patients who have coronary artery disease. Friedman *et al*. [52] observed significant increases in mean arterial pressure, coronary vascular resistance and myocardial arteriovenous oxygen difference after administration of intravenous indomethacin (0.5mg/kg) in such patients. Mean coronary blood flow decreased simultaneously from 181 ± 29 to 111 ± 14ml/min ($p < 0.05$). Thus, in this investigation, myocardial oxygen demand increased in the face of a fall in coronary blood flow following indomethacin administration.

Aspirin, acetaminophen and the NSAIDs all inhibit COX-mediated synthesis of inflammatory thromboxanes and prostaglandins from arachidonic acid. Cyclo-oxygenase has central and peripheral forms, as well as at least two distinct isoforms, COX-1 and COX-2. Cyclo-oxygenase-1 is expressed constitutively by cells and is involved in various housekeeping functions. Cyclo-oxygenase-2 is an inducible enzyme produced by a variety of cell lines, including macrophages, synoviocytes and endothelial cells. Pyrogenic cytokines and LPS induce COX-2 expression. Prostaglandin E_2 formed by COX-2 in microvascular endothelial cells is responsible for hypothalamus-mediated fever.

The distinctive affinities of the various categories of antipyretic drug for the different COX variants are thought to determine their

relative antipyretic and analgesic potencies. Acetaminophen and aspirin, for example, are equally potent inhibitors of central COX but only 10% as potent in this regard as indomethacin. Acetaminophen is only 0.02% as potent an inhibitor of peripheral COX as indomethacin. Its relatively poor activity against peripheral COX is thought to explain acetaminophen's weak systemic anti-inflammatory activity.[53] Only aspirin irreversibly inhibits COX and does so via acetylation within the active site of the enzyme. Other NSAIDs and acetaminophen inhibit COX reversibly.

Recent studies have shown that aspirin and the NSAIDs have COX-independent antipyretic activity. Aspirin induces cytochrome p450, which might augment its antipyretic effect by shifting arachidonic acid metabolism toward cytochrome-p450-mediated production of cryogenic epoxyeicosanoids. Additionally, acetylation of COX-2 by aspirin increases the production of 15R-hydroxyeicosatetraenoic acid, which neutrophils use to form aspirin triggered lipoxins (ATL). These lipoxins have potent anti-inflammatory activity, independent of aspirin. Heat shock proteins have been shown to reduce transcription of IL-1ß in vitro, and therapeutic doses of aspirin and certain NSAIDs increase heat shock factor-1 concentration in vitro. These same drugs also diminish the activity of transcriptional activator nuclear factor-?B.[54] The latter is involved in the transcription of pyrogenic cytokines, adhesion molecules, inducible nitric oxide synthase and COX-2 in certain cell lines. Production of adenosine, an anti-inflammatory mediator produced by leukocytes, is enhanced by aspirin and NSAIDs. The clinical implications of these alternative antipyretic pathways remain to be determined.

Antipyretic therapy is commonly administered to enhance patient comfort. General experience with antipyretic drugs, which are for the most part also analgesic agents, seems to support this rationale. However, carefully controlled efficacy studies have never quantified the degree to which antipyretic therapy enhances the comfort of patients who have fever. Moreover, the relative cost of such symptomatic relief, in terms of drug toxicity and adverse effects of the antipyretic agents on the course of the illness responsible for the fever, has never been determined. The importance of these negative drug effects is underscored by studies that demonstrated prolonged time to crusting of varicella skin lesions in children,[55] increased rhinovirus shedding and decreased neutralizing antibody formation following acetaminophen use in adults.[56] [57] Paracetamol use has been reported to prolong parasite clearance time in children infected with *Plasmodium falciparum*, presumably by decreasing

production of TNF and oxygen radicals.[58] The risks of antipyretic drug therapy, including direct and indirect drug toxicity, increased morbidity from infection and the masking of a possible underlying infection, must be weighed against any possible benefit.

Antipyretic therapy has not yet proved effective in preventing febrile seizures.[59] Camfield *et al*.[60] conducted a randomized double-blind study comparing single daily-dose phenobarbital plus antipyretic instruction with placebo plus antipyretic instruction in preventing recurrent febrile seizures following an initial simple febrile seizure. In children treated with phenobarbital and antipyretics, the febrile seizure recurrence rate was 5%, whereas in those receiving placebo and antipyretics the rate was 25%, suggesting that a single daily dose of phenobarbital is more effective than counseling parents about antipyretic therapy in preventing recurrent febrile seizures. More recent studies in children have shown that, whether given in moderate doses or in relatively high doses, both acetaminophen[61] and ibuprofen[62] fail to reduce the rate of recurrence of febrile seizures.

Finally, there has been considerable recent interest in the use of antipyretic drugs to modulate the activity of pyrogenic cytokines during bacterial sepsis.[63] In certain animal models, antipyretic drugs that inhibit COX confer protection when given soon after bacterial challenge, presumably by blunting the adverse effects of TNF-a and IL-1. In a recent large clinical trial, Bernard *et al*.[64] reported that 48 hours of intravenous therapy with the COX inhibitor, ibuprofen, lowered core temperature, heart rate, oxygen consumption and blood levels of lactic acid but did not decrease the incidence of organ failure or 30-day mortality rate in patients who have sepsis. Despite promising results in some experimental models, ibuprofen has not yet been shown to be of clinical value in treating bacterial sepsis.

Although clinicians have used various forms of antipyretic therapy since time immemorial, there is a dearth of data concerning the benefits and relative risks of such treatments. Nevertheless, several tentative conclusions regarding antipyretic therapy seem justified in light of the limited data available. It is clear, for instance, that short courses of approved doses of standard antipyretic drugs carry a low risk of toxicity. Most antipyretic drugs have analgesic as well as antipyretic properties. Therefore, if not otherwise contraindicated (as is, for instance, aspirin in young children because of the risk of Reye syndrome), such drugs can be used to provide symptomatic relief in patients who have fever, to reduce the metabolic demands of fever in chronically debilitated patients and possibly to prevent or alleviate fever-associated mental dysfunction in the elderly. To minimize antipyretic-induced fluctuations in temperature and the risk of recurrent shivering and its increased metabolic demands, antipyretic agents should be administered to patients who have fever at regular intervals to preclude abrupt recurrences, rather than as needed for temperatures above some arbitrary level. When prescribing such medication, physicians must recognize that each carries its own risk of toxicity and may prolong the course of at least some infections. It should be noted further that there is no compelling evidence that a response to antipyretic medications is useful diagnostically in distinguishing serious from self-limited illnesses, nor is there evidence that such medications are effective in suppressing febrile seizures, even if given prophylactically.

In view of the capacity of external cooling measures to induce a cold pressor response, it is questionable whether this form of antipyretic therapy should ever be administered to patients who have fever. If external cooling is used to treat fever, care must be taken to prevent shivering because of its associated increase in oxygen consumption. Unfortunately, even if shivering is prevented, there is no guarantee that a cold pressor response will be averted. In view of indomethacin's capacity to cause coronary vasoconstriction in patients who have coronary artery disease, NSAIDs should be used with caution, if at all, to suppress fever in such patients.

Chapter 81 - Clinical Approach to the Acutely Febrile Patient

Harold Lambert

Fever is one of the most frequent symptoms that leads to consultation with a health professional. Vast numbers of febrile illnesses are of short duration and benign outlook, and few of these are diagnosed. However, in the midst of this mass of minor illness are patients whose illness is serious or likely to become so. Some of these serious illnesses also present a danger to others, and thus have a significance beyond that of the individual patient. This is the challenge of acute fever: to distinguish the threatening from the trivial in acute illnesses in which fever is a main feature.

In some cases, of course, the fever becomes prolonged and this topic of more longlasting fever (fever of unknown origin; FUO) is discussed in Chapter 82 . The distinction between fevers of short and those of longer duration is important in considering diagnostic possibilities. Many acute and short-lived fevers are of viral origin, and conversely viral fevers without particular diagnostic features rarely last longer than 1 or 2 weeks; thus, prolonged fever without distinguishing features is rarely caused by a virus, at least in immunologically normal patients.

HISTORY

As with any other medical problem, the history is the most productive component of the initial encounter. Hypotheses are generated from the patient's account and the physician's observations, and are successively pursued or rejected in the light of emerging data. In the case of acute fever, however, a few special features of the history stand out. One of these is the common difficulty in reaching agreement on the meaning of words and phrases used in this context. It is rare for the phrase 'I have a fever' to mean that the body temperature has been measured by a reliable method. More often, the phrase means that the patient has a subjective sensation of warmth, or a feeling of chilliness or undue sweating. 'Flu' is another word in common use and usually describes aching muscles, chills and shivering, but sometimes is used to denote upper respiratory symptoms such as a runny nose or scratchy throat, and sometimes to indicate a fever. And, of course, different meanings are attached to these and other words in different cultures and languages.

A second distinctive point when taking the history of a patient with acute fever relates to the time-honored 'systems review'. This is usually employed, if at all, at the end of a history taking, but often has so little to contribute that it is discarded. In the case of acute fever, however, because the range of possibilities is so much wider than for many presenting symptoms, the systems enquiry is useful early in the history taking; it often reveals the only relevant localizing evidence, as patients may have forgotten or thought insignificant symptoms that provide valuable clues. Among the apparently minor clues that may emerge on direct enquiry are minor respiratory, abdominal or urinary symptoms, a transient rash or previous episodes of illness of a similar nature. Apparent localizing features that are actually symptoms of the raised temperature may, however, give false leads. Thus, dark urine in a febrile patient may simply denote dehydration, and some patients, especially women, experience burning and discomfort passing urine when they are febrile. Muscle and joint pains are also hard to interpret during fever: severe pains suggest viral infections such as influenza or dengue, but they are also a feature of some enteroviral infections (Bornholm disease) and of leptospirosis. Neurologic features are especially difficult. Some patients regularly experience headache when febrile, and many children and some older patients become delirious with a high fever; whether such clinical features indicate a specifically neurologic involvement obviously needs careful observation.

A history of medication may be important in acute febrile disease. A large number of drugs may themselves cause fever, often without a rash or other clear indicators. Among antimicrobial agents, penicillins, cephalosporins and sulfonamides are especially notable, but many others may be implicated. Anti-infective agents may suppress or modify infections, and so confound a diagnosis, and antipyretic agents may greatly modify the pattern of fever in an infection.

Travel history

As rapid movements of vast numbers of people throughout the world have been made possible in the era of air travel, so have the possibilities of an infection developing in one country when it was acquired in another. A travel history must never be omitted in a patient who has fever and many tragic deaths from *Plasmodium falciparum* malaria testify to its importance. Acute fever and respiratory symptoms after a recent trip to Southern China may point to a diagnosis of the newly recognized severe acute respiratory syndrome (SARS). The history should be accurate as to time and place. The name of a country is not enough; a stay in a four-star hotel in a capital city presents different risks from those of a camping trek in rural areas of the same country. Timing is especially helpful, even though many infections have a wide range of recorded incubation periods. For example, an illness beginning more than about 10 days after return is unlikely to be one of the common acute respiratory infections, with the exception of *Mycoplasma pneumoniae* and perhaps Q fever; dengue, too, and other arbovirus infections would have developed by this time. An incubation period of more than 3 weeks excludes the hemorrhagic virus infections, such as Lassa fever, and almost excludes typhoid. On the other hand, longer periods still leave open the possibility of viral hepatitis, Katayama fever (acute schistosomiasis) and primary HIV infection. As to malaria, the incubation period of *P. falciparum* infection may be as little as 1 week, but after 6 or 8 weeks a first presentation of this form of malaria becomes uncommon. *Plasmodium vivax* and *Plasmodium malariae* infections may develop months or years after travel to a malarial area.

Other important aspects of the travel history are the immunization record and an account of medications, with special emphasis on antimalarial prophylaxis.

It is sometimes necessary to begin treatment before a definite diagnosis has been made, or when the causal organism but not its antibiotic susceptibility is known. The travel history is important here too, as the pattern of antibiotic resistance in many pathogens

varies greatly from country to country, and will determine an appropriate choice of therapy. Notable examples are the differences in drug resistance in malaria in different countries, the spread of multi-resistant typhoid and shigellosis and the erratic distribution of pneumococcal resistance to penicillin. In each of these examples, the area in which infection was acquired may limit the options available for chemotherapy.

Every physician who sees a febrile traveler cannot be expected to have an up-to-date knowledge of the precise infective risks, let alone the antibiotic resistance patterns of possible pathogens, and therefore early communication with a Tropical and Infectious Diseases Unit and with one of the specialized information services that deals with travel medicine, which are available in many countries, is essential.

What are the actual causes of acute fever in returning travelers? (As this chapter focuses on illnesses with a large element of fever, primarily diarrheal diseases, or sexually transmitted diseases with mainly local symptoms and signs, and many other health risks of travel are not discussed here, see Chapter 145 .) Contrary to popular myth, the 'classic' tropical diseases are rarely acquired by short-term travelers, with the vital exceptio of malaria. This ranks first among diagnoses of acute fever in returning travelers, followed by a large group of short-lived fevers for which no etiology is ever established. Other diagnoses obviously vary in their frequency with the pattern of travel to and from a particular country. As the traveler is exposed not only to exotic pathogens, but also to a changing ecologic background of widely distributed pathogens, it is not surprising that ordinary respiratory infections, ranging from colds to pneumonia, are common. So too are initially febrile presentations of diarrheal diseases and prodromes of hepatitis. Urinary infection, as one of the most common causes of fever in women not always accompanied by localizing symptoms, must also be remembered. Some diagnoses encountered with widely variable frequency in different units are listed in Table 81.1 .

Contact history

Contact history may be relevant in travelers and in people staying at home. Information about local endemic or epidemic infections is to be sought. Most frequent of all, especially in the winter months, is a history of contact with acute respiratory infection, which is possibly relevant because so many respiratory infections begin with 1 or 2 days of indeterminate fever, but the very frequency of such infections

TABLE 81-1 -- Diagnoses made in travelers returning from tropical countries with fever as a principal symptom.

FEVER IN RETURNING TRAVELERS
Common
Malaria
No diagnosis made
Respiratory infection
Diarrheal disease (fever before or accompanying gut symptoms)
Urinary tract infection
Viral hepatitis; febrile prodrome
Uncommon
Dengue
Typhoid
Tuberculosis

Acute HIV infection
Acute schistosomiasis
Rickettsial infections
Amebiasis

makes this aspect of the history difficult to interpret. Even in places with high uptakes of routine immunization, measles is encountered, and tends then to be missed because of its low prevalence and because it may occur in older subjects in highly immunized populations. Measles is especially important when the patient, or a contact, is immunosuppressed. Rubella, a more difficult and uncertain clinical diagnosis, is clearly of the greatest import if the patient or a contact is pregnant. Known contact with meningococcal disease obviously demands immediate attention, although, owing to the vagaries of meningococcal carriage and immunity, few patients who have this disease have a direct contact history. A story of 'food poisoning' or diarrheal disease in contacts may be relevant because shigellosis, salmonellosis and *Campylobacter jejuni* infections may all begin with a febrile phase, while ingestion of raw milk and some cheeses raises the possibilities of brucellosis and listerial infection. The long incubation periods of most forms of viral hepatitis should be remembered in exploring possible contact history. Of those most commonly associated with travel, the incubation period of hepatitis A is 2–6 weeks and that of hepatitis B from 4 weeks to many months.

Occupational history

Many occupational exposures are not particularly relevant to acute febrile presentations, but many of the points about contact history just discussed are especially applicable to health workers and to those involved in child care. Other specific risks arising from occupation that may present as an acute fever include leptospirosis in sewage workers and fish farmers, and the many infective risks in veterinary and abattoir work, including brucellosis and *Streptococcus suis* infection. Fever may be the first clinical manifestation of tuberculosis relevant to health professionals, especially those involved with the care of patients who have HIV, and to carers of the homeless (see Chapter 90).

Some fevers associated with occupation are not infective. Fever and chills may be caused by inhalation of metal fumes or breakdown products of polymers. Many occupational lung diseases manifest with primarily respiratory features, but in extrinsic allergic alveolitis fever and influenza-like symptoms may dominate the picture. These conditions are characterized by recurrent episodes related to the particular exposure.

Bioterrorism and fever

Several agents that might be involved in bioterrorism are likely to cause non-specific fever as their initial manifestation (Table 81.2). In smallpox, after the incubation period of 12 days, there is nearly always a period of 2 or 3 days of fever and chills, perhaps rigors, headache and backache before the focal rash begins to emerge. In the most severe forms, hemorragic manifestations appear and the patient

TABLE 81-2 -- Bioterrorism and fever.

BIOTERRORISM AND FEVER	
Agent	**Main early features**
Smallpox	Non-specific fever for 2–3 days followed by rash slowly progressing to vesicles or pustules OR hemorrhages, system failure and death within a few days
Pulmonary anthrax	Rapidly progressive systemic illness with fever, dyspnea, sometimes wide mediastinum and pleural effusions
Pneumonic plague	Rapidly progressive systemic illness with respiratory features prominent from the second day. Extensive, often bilateral, pneumonia

Figure 81-1 The early focal rash of smallpox. This is the fifth day of the fever and the third day since the rash began to appear.

dies without ever developing the focal rash. An early focal rash is illustrated in Figure 81.1 . The onset of plague is also very acute, with chills, rigors, headache and generalized pains. Signs of system failure including generalized hemorrhage become apparent early in the septicemic form, but are also often seen together with enlarged nodes in bubonic plague. Pulmonary anthrax usually has a very acute onset, with early respiratory and systemic symptoms, but less acute presentations are now known to occur. Chest radiography may show mediastinal widening. (For a further discussion of bioterrorism see Chapter 6 .)

PHYSICAL EXAMINATION

Temperature

Depending on the duration of the illness, few temperature measurements may be available for evaluation. Recorded temperatures of higher than 102.2°F (39.0°C) are more likely to be caused by a significant infection than are lesser degrees of fever, but very high fever must raise suspicion of a noninfectious cause such as heat stroke or substance abuse. The pattern of fever is much less valuable than is commonly supposed. This aspect is discussed more fully in Chapter 82 , but a few points relevant to short-term fevers may be mentioned. A dramatic fever with wild swings between readings is suggestive of pyogenic infection and especially of abscess formation, and of acute pyelonephritis, but may also be seen in other conditions, including malaria and disseminated tuberculosis, also in Still's disease and occasionally in drug fever. Perhaps the most common reason for this kind of chart, however, is the use of antipyretics in a febrile patient, which often gives rise to this feature.

The most important caveats relate to malaria, and they cannot be emphasized enough. The temperature pattern in *P. falciparum* infections is often quite erratic, and this diagnosis must be considered in all febrile and some nonfebrile patients coming from a malarial area. Regular tertian or quartan fevers (meaning every other day and every third day, respectively) are not found in the early stages of malaria, and are a feature of relapse rather than initial infection. On the other hand, when present they are very characteristic of malaria.

Rashes

Many acute febrile illnesses are accompanied by a rash, which aids greatly in establishing a diagnosis. A few, notably those of meningococcal sepsis, are of vital importance in determining the need for urgent treatment or the protection of contacts (Fig 81.2 , Fig 81.3). Some are pathognomonic, others only indicative (Fig 81.4 , Fig 81.5), and the features of the rash must be placed in context with other features of the illness. In hand, foot and mouth disease the distribution is pathognomonic. Table 81.3 Table 81.4 Table 81.5 provide information about rashes associated with acute fevers, including those encountered in

Figure 81-2 Fully developed, almost pathognomonic hemorrhagic rash of meningococcal sepsis.

Figure 81-3 Very early rash of meningococcal sepsis. A few petechiae only, but meningococcal sepsis nonetheless. It can progress to the appearance of Figure 81.2 within minutes or hours. This is the window of opportunity for early treatment.

Figure 81-4 Hand, foot and mouth disease. This shows the scanty lax vesicles found at these sites. There is often a maculopapular rash too, especially on the buttocks.

Figure 81-5 Purpuric skin lesions in staphylococcal endocarditis.

returning travelers, but a few specific points are worth emphasizing. In measles, easily forgotten in well-immunized populations but by the same token important to remember in older age groups, fever precedes the Koplik spots and the exanthem by 2 or 3 days, but sometimes by as much as 1 week, although respiratory features are prominent for most of this time. In rubella and in enteroviral infections, general symptoms only rarely precede the rash, and then only by 1 day or so. In dengue, the rash characteristically appears in the second phase of the biphasic illness. Conditions associated with pathognomonic or at least characteristic rashes may, however, also occur with nonspecific rashes; the early rash of meningococcal sepsis may be macular or maculopapular, and Lyme disease may exhibit nonspecific rashes in addition to erythema migrans.

TABLE 81-3 -- Rashes associated with acute viral infections.

RASHES ASSOCIATED WITH ACUTE VIRAL INFECTIONS		
Virus	**Syndrome**	**Comment**
Measles	Measles	Maculopapular followed by staining
Rubella	Rubella/German measles	Macular, often general facial flush
Herpesvirus 6	Roseola infantum	Macular or maculopapular after several days of fever
Parvovirus B19	Erythema infectiosum	Slapped cheeks, lacy on trunk and limbs, often rubelliform or hemorrhagic
Varicella-zoster	Chickenpox	Vesicular, rarely hemorrhagic
	Shingles	Neurologic distribution, premonitary pain, erythema
Herpes simplex	Disseminated herpes	
	Eczema herpeticum	
Epstein-Barr virus		Occasionally macular rash; severe rashes usually ampicillin-induced
Enteroviruses		Usually macular or maculopapular; sometimes hemorrhagic and/or vesicular (hand, foot and mouth disease; see Fig. 81.4)
Primary HIV	Mononucleosis-like illness	(Maculopapular rashes in chronic HIV infection; see Chapter 122)
Viral hemorrhagic fevers	(See Chapter 183)	Purpura, ecchymoses

TABLE 81-4 -- Rashes associated with acute bacterial infections.

RASHES ASSOCIATED WITH ACUTE BACTERIAL INFECTIONS		
Agent	**Rashes**	**Comment**
Neisseria meningitidis	Petechial/purpuric	Also non-hemorrhagic early rashes
Neisseria gonorrhoeae	Hemorrhagic vesicles, pustules	
Staphylococcus aureus	Pyogenic skin lesions	
	Scalded skin syndrome	
	Peripheral purpura	In staphylococcal endocarditis
	Erythema	In toxic shock syndrome
Streptococcus pyogenes	Erysipelas	Local erythema, bullae
	Erythema	In toxic shock syndrome
Salmonella typhi	Rose spots	
Pseudomonas aeruginosa	Ecthyma gangrenosum Cellulitis ± blebs	Also in *Aeromonas* and other Gram-negative bacillary infections
Haemophilus aegyptius	Brazilian purpuric fever	

TABLE 81-5 -- Rashes associated with acute spirochetal and rickettsial infections.

RASHES ASSOCIATED WITH ACUTE SPIROCHETAL AND RICKETTSIAL INFECTIONS		
Agent	**Rashes**	**Comments**
Leptospirosis	Hemorrhages	Weil's disease
	Also other rashes	
Borrelia recurrentis (relapsing fever)	Petechiae	Often no rash; sometimes severe hemorrhages
Borrelia burgdorferi (Lyme disease)	Erythema migrans	Sometimes secondary annular or nonspecific rashes
Spirillum minus (rat-bite fever)	Blotchy macular, papular and urticarial rashes, beginning near the bite and spreading	Rashes also in the *Streptobacillus moniliformis* form of rat-bite fever
Rickettsial infections	Macular, papular petechial	Primary eschar (*tache noir*) in some syndromes

Mouth

The mouth may show useful signs in a febrile patient (Table 81.6 , Fig. 81.6). Especially in infancy and childhood, the tongue and mouth give some indication of dehydration, although mouth breathing and tachypnea often produce a similar appearance. The tongue is notably raw and red in scarlatina, in Kawasaki disease and in toxic shock syndrome. Vesicles are found, especially on the soft palate and anterior fauces, in some enteroviral infections (hand, foot and mouth disease). Palatal petechiae are fairly non-specific, but are common in infectious mononucleosis and rubella. Many important signs in HIV infection are to be found in the mouth and these are discussed in Chapter 132 .

Eyes

Some degree of conjunctival suffusion is common in people with a high temperature. This is often prominent in measles, rubella, some

TABLE 81-6 -- Oral signs in acute fever.

ORAL SIGNS IN ACUTE FEVER	
Sign	**Diagnosis**
Dehydration	Any fever
Herpes simplex	Common in meningococcal and pneumococcal infection
Raw tongue	Scarlatina
	Kawasaki disease
	Toxic shock syndrome
Ulcers, vesicles	Varicella
	Herpes simplex
	Enteroviruses (herpangina, hand, foot and mouth disease)
	Aphthous stomatitis
	Secondary syphilis
	Erythema multiforme
Palatal petechiae	Non-specific, but common in infectious mononucleosis and rubella

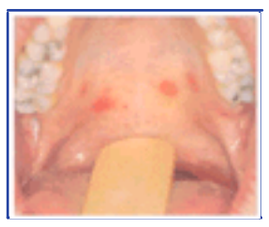

Figure 81-6 Oral signs in hand, foot and mouth disease.

adenovirus infections and in leptospirosis. In infections with a hemorrhagic rash, conjunctival hemorrhages may be present in addition to skin petechiae or purpura; this is especially helpful in patients with dark skin, when petechiae are difficult to see. Other ocular signs that may be important in acute febrile illness are uveitis in acute sarcoid (although many patients who have acute sarcoid do not show ocular involvement) and in Still's disease. Choroiditis occurs in histoplasmosis and in toxoplasmosis. Although choroidoretinitis in toxoplasmosis is most frequently a late marker of congenital infection, it is now clear that a few patients with acute acquired toxoplasmosis (and not HIV-infected) do have acute choroiditis. Miliary tuberculosis, with or without tuberculous meningitis, sometimes manifests as fever and general ill health; the diagnosis is immediately established if choroidal tubercles are seen.

Lymph nodes

Generalized node enlargement is relatively uncommon in acute febrile illness. Among the common infections of children and young adults, rubella, Epstein-Barr virus mononucleosis and cytomegalovirus infection are notable causes, to which must be added cat-scratch disease and, in those at risk, secondary syphilis and primary HIV infection. These latter infections are especially important to remember in returning travelers. General node enlargement is also seen in some more specifically tropical diseases, of which dengue is the most likely to affect a short-term traveler. Acute histoplasmosis is another possibility after a first visit to an endemic area.

Focal nodes must direct a careful search of the relevant drainage area. For example, tender enlarged inguinal nodes may be more prominent than the source of infection, which may be insignificant looking streptococcal lesions of the feet, perhaps superimposed on insect bites or fungal infection. Acquired toxoplasmosis in the immunocompetent host, although usually subclinical, manifests as a febrile illness with localized lymphadenopathy, most often in one or other cervical group but sometimes in nodes elsewhere. The persistent fallacy that toxoplasmosis is a cause of a 'glandular fever' syndrome must be firmly laid to rest. It is rare for the lymphadenopathy of acquired toxoplasmosis to be generalized, and atypical mononuclear leukocytes, if found at all on the blood film, are few in number.

Spleen

Acute and longer-term febrile illnesses make an interesting contrast here. Splenomegaly is found in so many of the infections and other conditions that can cause FUO that it is of little diagnostic value. By contrast, splenomegaly in a patient who has fever of a few days' duration certainly merits further attention. It may indicate a particular infection, such as infectious mononucleosis, rubella, a hepatitis prodrome, in which splenomegaly is especially common in children, or, in a returning traveler, malaria. Splenomegaly may be attributable to an underlying hematologic condition, perhaps a hemolytic anemia or a lymphoma, itself the cause of the fever or a reason for increased susceptibility to infection.

MAKING A DECISION

Some specific factors in the history and examination suggest the need for a plan of management that goes beyond symptom relief. This may mean repeated observation, investigation or investigation combined with provisional treatment. The factors are:

- recent travel, especially to a malaria-risk country (see Chapter 166);
- chills and rigors;
- height of fever;
- fever and rash;
- extremes of age;
- any known or suspected immunosuppression;
- neurologic features;
- dehydration;
- parental or partner concern; and
- physician's impression.

Chills are common enough at the onset of respiratory infections, particularly at the onset of influenza. Nevertheless, the rapid rise in body temperature that they denote is also common in some more serious infections, and this caution applies with greater force if the patient has rigors. A temperature of more than 102.2°F (39°C) is

common enough in the early stage of an ultimately minor infection, but higher temperatures sustained for more than a short time are more likely to be associated with serious infections.

The combination of fever and any kind of hemorrhagic rash, be it only a few petechiae, is especially important.

Many patients on immunosuppressive therapy are living and working normally in the community but are at increased risk of infection. In some conditions, notably asplenia from any cause,

infection may take a fulminant course and any fever demands very prompt attention (see Chapter 109). In addition, some forms of immunosuppression may initially manifest with a febrile illness, and the possibility of a first presentation of HIV infection is especially to be borne in mind.

Depression of consciousness, meningism or localizing neurologic signs are clearly important. Children with high fever may exhibit mild confusion and experience hallucinations; this is seen less commonly at older ages. Whether such clinical features denote specific neurologic involvement needs careful assessment.

Children and the elderly are at greater risk of dehydration, but patients of any age with fever, especially in warm conditions and if anorexic or vomiting, may become fluid deficient.

Whatever the level of anxiety in patient or carer, someone close to the patient may well have an accurate notion of whether the illness is out of the ordinary, and their opinions should be carefully considered.

The physician may form the impression that the illness is unusual, or serious, or likely to become serious. This is so common an issue as to merit more detailed discussion.

Is the patient ill?

Even after the most meticulous history taking, physical examination and attention to the issues just discussed, there are large numbers of patients with fever of short duration in whom no particular warning features are present. Fortunately, most patients who have fever of a few hours or a few days duration recover uneventfully without sequelae and without a diagnosis other than a meaningless attribution to 'viral infection'. How should one judge, in the home, in the health center or practice premises, or in the hospital emergency room, which of these patients should be further investigated, or investigated and given provisional empiric treatment? This must be one of the most frequent decisions that has to be made by clinicians all over the world and yet it is ignored in books about diagnosis. Decision theory is largely silent in this context because the elements of the decision involve multiple factors, usually heuristic in character, few of which can be assigned a numeric value.

It seems that the most common factor affecting the physician's decision is the impression that the patient has an infection with systemic and potentially hazardous features — for which the word 'toxic' is often used as shorthand — and this is the main determinant of further investigation and treatment in patients who have acute febrile illness. Indeed, algorithms on this problem often begin with the question 'Is the patient toxic?'

Attempts to analyze the physician's impression of illness have been more often pursued in children than in adults; this work had its origin in the increased use of blood culture in infants and children, most of whom did not look ill, taken to 'walk-in' clinics or hospital emergency rooms in the USA. Positive blood cultures were found in 2.8–8% of these infants. In most places the main organisms were *Streptococcus pneumoniae, Neisseria meningitidis* and, before general immunization against this organism, *Haemophilus influenzae*. A few of these children, perhaps 4–7%, went on to develop meningitis or other focal infections.[1] These findings spawned a vast amount of work on the early detection of potentially serious illness in febrile infants and on developing management plans for their care. Observations which commonly raise concern in doctors and parents about the possibility of serious illness are the child's reaction to handling and to social overtures, the skin color and state of hydration,[2] while in one recent study, the most sensitive predictors of serious illness were poor feeding and restlessness. [3] A qualitative study of 83 cases of meningococcal disease seen in general practice in South Wales showed how, even in the absence of a rash, clinical and contextual features helped to differentiate these patients from the many with acute self-limiting febrile illnesses.[4] Many of the patients showed 'features not normally expected in children with acute self-limiting illnesses'; these included lethargy, poor eye contact, altered mental state and abnormal cry.

Assessments attempting to systematize what experienced physicians do without conscious thought have thus confirmed the value of clinical judgment in predicting or excluding a high risk of serious disease in older infants and children and it seems impossible to dispense with the elusive but crucial clinical impression of illness, although even this may deceive in either direction. One reason for disasters associated with *P. falciparum* malaria is the apparently good condition of the patient that may precede a rapid decline, whereas, conversely, patients may look much more ill than they are after an exhausting long journey or a lively party. When, as so often, there is doubt about the assessment, a total leukocyte count of greater than 15×10^9 /l has been valuable in some but not all studies, in indicating an increased post-test probability of bacteremia. It is also sensible, if further investigations are decided upon, to include urine microscopy at this stage. Assessment is particularly difficult in infants younger than 3 months, and this problem is not addressed here.

Beyond the basic need for time and care in clinical assessment, a confident relationship between patient and physician and easy access for further consultation are perhaps the most important factors in ensuring that major illness is not missed.

A decision tree for the management of acute febrile illness is given in Figure 81.7 .

LABORATORY INVESTIGATIONS

With few exceptions, among them the classic infectious diseases such as measles and varicella, most acute and short-lived infections have no specific features that enable a clinical diagnosis to be made. Few of these illnesses are investigated. Facilities to do so are not available in most of the world and, when they are available, are unnecessary in patients who have mild and self-limiting illnesses. It follows that most of these infections remain undiagnosed, although a specific diagnosis can be assigned to a substantial number of them in research projects in which full virologic investigations are undertaken. This is the case especially in acute infections in children, who may experience a remarkably large number of infections, most of them viral, in the course of a year.

Investigations are certainly indicated when any of the 'danger points' just described are present, and in any febrile patient whose general condition gives concern. The precise range of investigations chosen will obviously vary depending on the facilities available and on the vagaries of the clinical situation, but even a small and frequently accessible range of investigations (Table 81.7) greatly increases the possibility of establishing a diagnosis. When the features of the illness give no specific direction, the most useful investigations are a routine blood count together with careful examination of a stained blood film, blood culture, urine examination, and posteroanterior and lateral radiograph of the chest. When blood is taken, a serum specimen should be saved for later study.

Initial investigations are often, of course, much more extensive depending as they do on available resources and initial clinical clues. These will most commonly include liver function tests, stool microscopy and culture, antigen detection and serologic tests for particular pathogens, and relevant imaging especially abdominal ultrasound scanning and computed tomography or magnetic resonance imaging. The more extensive range of investigations is fully discussed in the context of FUO (see Chapter 82).

Figure 81-7 Decision pathway for the management of acute febrile illness.

Total and differential leukocyte count

Modest degrees of neutrophilia, up to about 15×10^9 /l are of little help. More definite neutrophilia is principally found in pyogenic bacterial infections, but also in amebiasis, leptospirosis and in many noninfectious conditions such as thromboembolism, rheumatic fever, Still's disease, exacerbations of chronic liver damage and mechanical tissue damage (Table 81.8).

Neutropenia is common in many viral infections, including rubella and influenza, and, among infections of travelers, is often found in malaria, typhoid, brucellosis, rickettsial diseases and visceral leishmaniasis. Leukopenia is also a feature of severe and overwhelming sepsis, but the serious condition of patients who show this feature is

TABLE 81-7 -- Basic laboratory investigations in patients who have acute fever.

BASIC INVESTIGATIONS IN ACUTE FEVER
• Routine blood count
• Stained blood film
• Urine microscopy and culture
• Chest radiograph
• Save serum

TABLE 81-8 -- Value of total and differential leukocyte count in acute fever.

VALUE OF LEUKOCYTE COUNT IN ACUTE FEVER	
Neutrophilia	**Neutropenia**
Sepsis	Severe sepsis
Abscess	Malaria
Amebiasis (usually)	Typhoid
Leptospirosis (usually)	Brucellosis
Still's disease	Visceral leishmaniasis
Lymphoma (uncommon)	Rickettsial infections
Atypical mononuclear cells	**Eosinophilia**
Epstein-Barr virus	Schistosomiasis (Katayama fever)
Cytomegalovirus	Visceral larva migrans (toxocariasis, etc.)
This table concerns acute illnesses in which fever is a principal feature; it does not include conditions such as tropical eosinophilia in which respiratory features are dominant.	

usually only too evident. Thrombocytopenia is a very frequent feature of the blood film in malaria and in sepsis.

A substantial number of atypical mononuclear cells is found most commonly in acute Epstein-Barr virus and cytomegalovirus infections, whereas eosinophilia points to the tissue-invasive stage of many parasitic infections.

Specific diagnoses from the blood film

Malaria is by far the most important finding from examination of the blood in those at risk, but other diagnoses that can sometimes be made in this way are listed in Table 81.9 . In addition to examination of the blood, a diagnosis may occasionally be aided by direct examination of material from a skin lesion, for example in meningococcal sepsis.

TABLE 81-9 -- Specific diagnoses from the blood film.

DIAGNOSES FROM BLOOD FILM
• Malaria
• Babesiosis
• Trypanosomiasis
• Filariasis
• Leptospirosis (dark field)
• Relapsing fever (dark field or staining)
• Bartonellosis
• Ehrlichiosis
• Meningococcemia
• Histoplasmosis, candidemia
Etiologies of acute fever are sometimes established by examination of the blood film.

Figure 81-8 Chest radiograph of a patient with *Mycoplasma* pneumonia. Respiratory symptoms are often scanty or absent in the first few days of the illness.

Urine examination

Small degrees of proteinuria are of no significance in febrile patients. Dipsticks can be used to detect Gram-negative infections and pyuria, but should not be used alone in the diagnosis of fever because of the high false-negative rate of the nitrate test for bacteriuria. Urinary infection is best diagnosed by direct microscopy of a drop of urine with the finding of heavy pyuria, often some hematuria and visible organisms. The presence of organisms in association with pyuria in a freshly obtained specimen indicates significant bacteriuria and a Gram stain can help in distinguishing positive cocci from negative bacilli. Urinary infection is one of the most common infections that sometimes manifests as a febrile illness with no localizing symptoms or signs.

Chest radiograph

The most important findings in a febrile but previously healthy patient are areas of consolidation, since general symptoms and fever may precede respiratory symptoms and signs by several days and radiographic changes may be surprisingly prominent in patients with few or no respiratory symptoms. This is especially likely in 'atypical' pneumonia, such as that associated with Q fever or *Mycoplasma pneumoniae* infection (Fig. 81.7). The other crucial finding is that of pulmonary tuberculosis, in some communities to be suspected throughout the population, and in others more especially in the indigent and those with HIV infection. Other diagnoses may also be made, such as *Pneumocystis carinii* infection in HIV infection before respiratory features become evident, allergic pneumonias, visceral larva migrans and pulmonary emboli.

Blood culture

The importance of blood culture in febrile patients thought ill enough to need investigation is evident but, important as it is, the information gained is necessarily delayed and thus irrelevant to the immediate management decisions.

Serum

It is always sensible, if blood is drawn, to save a serum sample, especially for later comparative tests if the illness proves to be prolonged and remains undiagnosed.

ISOLATION

A few patients who have infections present a risk to other people. Because the diagnosis is often obscure at the time of admission to hospital of an acutely febrile patient, isolation is often advisable initially, if facilities are available. Sometimes, as for example in suspected Lassa fever, more elaborate measures involving the control-of-infection team in liaison with the public health authorities are indicated. Similar levels of precautions may be indicated for newly described and highly transmissible pathogens such as the SARS epidemic in Southern China and other regions in Asia. These aspects of the management of infection are discussed in Chapter 87 .

MANAGEMENT

Symptomatic treatment

Drug therapy is unnecessary in many acute fevers, but discomfort can be alleviated by agents such as aspirin, paracetamol and nonsteroidal anti-inflammatory agents, which act as cyclo-oxygenase inhibitors. There is little to choose between their effect on fever, but aspirin is avoided in infants because of its association with Reye's syndrome, and in many older patients because of its effects on the gastric mucosa.

The effectiveness of antipyretics in reducing fever does not seem to correlate with its cause. In a study of 1559 children with a temperature of more than 101°F (38.4°C) on arrival at the emergency room, reductions of temperature 1 and 2 hours after a single dose of paracetamol (acetaminophen) were slightly greater in patients who had a serious bacterial infection than in those who did not,[5] although it had been thought that fever with a serious cause might be less responsive to an antipyretic.

Sponging is still sometimes used as a method of reducing fever. It certainly does this, but it is often very uncomfortable, particularly if done with iced rather than tepid water. The vasoconstriction and shivering causing distress do not, however, produce a rise of core temperature. Combining paracetamol (acetaminophen) with sponging gives a slightly greater reduction of temperature than sponging alone. [6]

It is useful to know the timing of antipyretic action, especially if the aim is to reduce the likelihood of febrile convulsions. Both antipyretic drugs and sponging show an appreciable effect within about 30 minutes and have their maximal effects in 2–3 hours.

Corticosteroids are effective antipyretics but should be used only for specific indications in conjunction with appropriate anti-infective therapy for the known or presumed cause of the fever.

Maintaining hydration is important and not always easy in a warm climate as patients who have fever are often anorexic and sometimes vomiting.

Empiric treatment

One of the most taxing and common decisions that has to be taken in acute febrile illness is whether to start empiric treatment based on one or more hypotheses about the diagnosis. On one side is the fear of rapid and perhaps irreversible deterioration, especially in *P. falciparum* malaria and in septic shock. On the other are the confounding effects of possibly inappropriate treatment, and the added problem of adverse drug reactions. If immediate treatment is given, it is nearly always possible to take blood before starting and this can be used for diagnostic tests.

TABLE 81-10 -- Some dangerous features in patients who have acute fever.

DANGER POINTS IN ACUTE FEVER
• Petechial/purpuric rash
• Travel involving risk of malaria
• Chills and rigors
• Extremes of age
• Neurologic signs
• Asplenia
• Hypogammaglobulinemia
• Post bone marrow transplant

Some indications for immediate treatment (Table 81.10) in acutely febrile patients can be firmly stated; others are contingent and depend on the precise details of the clinical and epidemiologic situation. The most urgent are the possibility of meningococcal sepsis and that of serious infection in asplenic subjects. Next in urgency are indications pointing toward streptococcal sepsis and, in returning travelers, the possibility of *P. falciparum* malaria with clinical deterioration. Immediate treatment should also be seriously considered if there is evidence of any immunologic disorder and, more generally, if other indicators of severe illness such as those already discussed are present. Table 81.11 gives some recommendations for action in these circumstances. The antibiotic choice, as always, must take account of local susceptibility patterns, and for this reason, more than one option is given. For example, penicillin is no longer the agent of first choice in many places for serious pneumococcal infection, and the spread of meningococcal resistance to penicillin may make future changes necessary in the national policy in the UK for immediate treatment of suspected meningococcal sepsis.[7]

TABLE 81-11 -- Suggested empiric regimens for use when urgent treatment is indicated in patients who have acute fever.

EMPIRIC TREATMENT IN ACUTE FEVER	
Presumed diagnosis	**Action**
Meningococcal sepsis	1. Blood culture if possible
	2. Penicillin G (benzylpenicillin)
Septic shock in asplenia	1. Blood culture if possible
	2. Penicillin G (benzylpenicillin) or cephalosporin*
Streptococcal sepsis	1. Blood culture if possible
	2. Local lesion, Gram stain and culture if possible
	3. Penicillin G (benzylpenicillin) +/- clindamycin
Staphylococcal sepsis	1. Blood culture if possible
	2. Local lesion, Gram stain and culture if possible
	3. Flucloxacillin or similar agent*
Severe malaria	1. Blood films
	2. Quinine (or artemether or artesunate; see Chapter 166)
Lassa fever	1. Strict isolation
	2. Tribavirin (ribavirin)
	3. Inform public health authorities

* Knowledge of local resistance patterns and antibiotic policy needed

It has been written (by Garrison) that Wunderlich, the founder of clinical thermometry, 'found fever a disease and left it a symptom'. This chapter shows that fever remains an important and challenging symptom that demands meticulous analysis so as to achieve the best prospects for accurate diagnosis and treatment.

Chapter 82 - Fever of Unknown Origin in the General Population and in HIV-infected Persons

Wendy Armstrong
Powel Kazanjian

INTRODUCTION

Fever of unknown origin (FUO) is one of the most challenging tests of the clinical acumen of the physician. The clinical characteristics of 1315 cumulative cases of FUO in the general population have been published in 15 selected reports that span 77 years, from 1930 to 1997 (Table 82.1).[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] Since the early case series from the USA on FUO were published,[1] [2] [3] [4] [5] [6] important sociologic and technologic changes have occurred; for example, new microbiologic techniques[16] and radiographic diagnostic tools[17] have become routinely available, a growing number of people use intravenous drugs[18] or have implanted prostheses,[19] and patterns of immigration and travel destinations have expanded.[20] The incidence of newly described diseases such as AIDS[21] and Lyme disease[22] has risen. In developed countries, certain 'older' diseases such as rheumatic fever remain uncommon,[23] yet the frequency of tuberculosis has risen again after a decline during the 30 years preceding 1985.[24]

The Petersdorf and Beeson criteria for FUO, which standardized its definition in 1961,[7] are:

- a body temperature of more than 101°F (38.3°C) for at least 3 weeks; and
- failure to establish a diagnosis after 1 week of investigation.

These criteria were designed to eliminate self-limited diseases that might have been represented in the five series on FUO reported before 1961.[1] [2] [3] [4] [5] [6] Each of the eight subsequent published case series on FUO[8] [9] [10] [11] [12] [13] [14] [15] used the classic Petersdorf and Beeson criteria. Some of the recent series[13] [14] use a revised Petersdorf definition of FUO[25] [26] that permits the investigation to take place in the ambulatory setting as well as in hospital, the setting originally specified. Furthermore, a subclassification of HIV-associated FUO has been added to the classification of FUO in the general population to incorporate this new disease.[27] Fever of unknown origin associated with HIV infection has now been reviewed in several series. Five selected series are detailed totalling 257 cases;[28] [29] [30] [31] [32] HIV-associated FUO has been defined as fever that lasts more than 4 weeks in outpatients or 3 days in hospitalized patients and remains unexplained despite investigation. These series are reviewed later in this chapter.

CLASSIC FEVER OF UNKNOWN ORIGIN

Disease categories

An etiology of FUO is identified in the majority of cases in each published series on FUO (average 73%, range 30–93% of cases). In early reports, the individual diseases causing FUO were limited to a small number of predominantly infectious diseases.[1] [2] [3] [4] [5] In contrast, recent series show that the diseases responsible for FUO are much more extensive, involving over 100 disorders.[12] [13] [14] [15] Consequently, recent case series use disease categories rather than enumerating individual diseases to describe the clinical spectrum of FUO. The principal disease categories include infection, neoplasms and collagen diseases. For the sake of simplicity, the remaining diverse range of cases can be grouped together as 'miscellaneous' (see Table 82.1).

Certain changes in disease categories have occurred since the original description of FUO. Infections remain the most common cause of FUO in all but three series. Overall, 30% (range 6–70%) of cases of FUO are due to an infection. Neoplasms are responsible for 18% (range 7–34%) of cases, and the proportion of cases due to malignancy has remained constant. In contrast, there has been an increase in cases caused by collagen disorders. Although the overall percentage of cases in this category of diseases is only 12% (range 0–22%), series published within the past 10 years indicate an increase in the number of cases caused by collagen diseases. Diseases falling into the category of miscellaneous disorders have been identified in 14% of cases (range 0–28%). The individual diseases represented by these categories are discussed below.

Infections

The major infections represented in older papers — tuberculosis, endocarditis and abdominal abscesses — continue to make up a significant proportion of FUO in recent series — 5%, 5% and 10% respectively.[13] [14] However, compared with earlier series, the types of infection causing FUO have become more diverse.[11] [12] [13] [14] [15] Recently described infections, including HIV infection and Lyme disease; immunodeficiency-related infections such as *Pneumocystis carinii* pneumonia and atypical mycobacterial infection; and diseases such as typhoid fever and amebiasis in patients who have resided in developing countries were described for the first time in series reported within the past decade.[12] [13] [14] [15] In addition, these reports describe infections involving critically ill patients whose lives have been prolonged in an intensive care setting and who have developed superinfections with *Candida* spp. Other infections that make up a small percentage of FUOs include pyelonephritis, perinephric abscess, toxoplasmosis in the immunocompetent host and mononucleosis caused by Epstein-Barr virus or cytomegalovirus (CMV).

There are several reasons why tuberculosis, abdominal abscesses and infectious endocarditis make up the majority of the infectious causes of FUO. For example, tuberculosis continues to be prevalent in Africa and South East Asia and afflicts intravenous drug users, the elderly and HIV-infected persons.[20] [21] [22] Furthermore, the increase in the numbers of people who have prosthetic heart valves[19] [23] has affected the number of cases of FUO caused by infectious endocarditis.[15] In addition, advances in microbiologic techniques permit the identification of fastidious organisms that cause valvular vegetations.[33] Finally, modern radiologic studies permit the detection of abdominal abscesses in cryptic locations such as the spleen.[34]

The first appearance of newly discovered diseases such as HIV infection[21] and Lyme disease[22] as causes of FUO reflects the increased recognition of these diseases. The increase in the number of immunocompromised persons reflects the increase in the incidence of opportunistic infections, such as *P. carinii* pneumonia, *Mycobacterium avium* and disseminated candidiasis, as causes of FUO.[35]

Neoplasia

Hodgkin's and non-Hodgkin's lymphoma have remained the most common neoplastic diseases responsible for FUO, and lymphoma is the most common individual disease causing FUO.[12] [13] [14] [15] Its ability to present in an insidious and protean fashion may explain why lymphoma continues to account for a sizable number of cases despite new diagnostic modalities.[36] For example, fever in some cases persists for months before a gland may become enlarged. In addition, it may be difficult to locate an involved lymph node on physical examination when the axilla is involved, and it is impossible when the retroperitoneal nodes or bone marrow are the only site of disease. Furthermore, a directed percutaneous needle biopsy of an involved gland or bone marrow may contain insufficient material to reveal diagnostic histopathology.[37] Thus, lymphoma may elude clinical detection for a long time. Malignant histiocytosis, [38] angio-immunoblastic lymphadenopathy with dysproteinemia [39] and Kikuchi's disease,[40] although uncommon, are causes of FUO with lymphadenopathy that were first recognized within the past 15 years.

Other neoplasms and solid tumors are less common causes of FUO than lymphoma.[12] [13] [14] [15] The peripheral blood smear of certain leukemias and myelodysplastic syndromes may reveal no definitive findings (aleukemic leukemia); establishing the diagnosis requires bone marrow examination. Renal cell carcinoma may present with prolonged fevers and no other symptoms in a minority of cases.[41] Metastatic adenocarcinoma in the liver, regardless of the primary site, may also cause FUO.[41] In most situations, but not all, there is elevated hepatic alkaline phosphatase, hepatomegaly or both. Other solid tumors that can cause FUO include leiomyosarcomas of the gastrointestinal tract, sarcomas and atrial myxomas.[42]

Rheumatologic disorders

Adult Still's disease, for which there is no definitive laboratory test, remains the most common rheumatologic cause of FUO.[43] The typical clinical features are myalgias, leukocytosis, lymph node enlargement, splenomegaly and an evanescent rash that appears with febrile episodes; other causes of this clinical presentation must be excluded.

Temporal arteritis, with or without polymyalgia rheumatica,[44] should be considered in those aged over 50 years; the erythrocyte sedimentation rate (ESR) is nearly always elevated. The classic presentation of temporal arteritis — headache, jaw claudication, visual loss — or a palpable temporal artery may be absent in one-third of patients who have temporal arteritis.

Other less common rheumatologic causes of FUO include Wegener's granulomatosis and cryoglobulinemia; polyarteritis nodosa should be considered if there is mononeuritis multiplex, myalgias, skin lesions, abdominal pain (which is due to small intestinal ischemia) and azotemia.[45]

Miscellaneous

A diverse array of conditions, including granulomatous diseases, inflammatory illnesses and drug-related fevers, are classified as miscellaneous. Crohn's disease, sarcoidosis and granulomatous hepatitis are examples of granulomatous diseases.[46] Patients who have granulomatous hepatitis require a biopsy of involved tissue and exclusion of other causes of this histologic pattern, such as infections with *Mycobacterium* spp., fungi or bacteria (e.g. brucellosis, tularemia, cat-scratch disease), and lymphoma.

Other conditions that must be considered include alcoholic hepatitis, [47] pulmonary emboli,[48] subacute thyroiditis, Sweet's syndrome and familial Mediterranean fever.[49] Leukocytosis may occur with these conditions but it is often especially prominent in alcoholic hepatitis and familial Mediterranean fever.[48] Fever most often resolves within a few days following anticoagulation in patients who have pulmonary emboli, but it may take longer in certain instances.[48] Familial Mediterranean fever causes recurrent fever, peritonitis and leukocytosis. Subacute thyroiditis may be difficult to diagnose because there are usually no systemic features of thyrotoxicosis and the thyroid function tests are usually normal. The thyroid gland may be nontender; however, it is commonly diffusely enlarged.[49] Schnitzler syndrome (hyperostosis, lymph node enlargement and monoclonal IgM gammopathy) is a rare cause of FUO.[49] In children, a new syndrome, PFAPA (periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis), has been described.[50] This syndrome can be difficult to distinguish from familial Mediterranean fever but lacks serositis and episodes respond to steroids.

Hematomas and drug fever may cause FUO.[51] Hematomas causing FUO may occur as a result of hemorrhages into the abdominal

TABLE 82-2 -- Drugs associated with fever of unknown origin.

DRUGS ASSOCIATED WITH FUO	
Common	**Less common**
Atropine	Allopurinol
Amphotericin	Hydralazine
Penicillins	Isoniazid
Cephalosporins	Rifampin (rifampicin)
Phenytoin	Macrolides
Procainamide	Clindamycin
Quinidine	Vancomycin
Sulfonamides	Aminoglycosides
Interleukin-2, interferon	

cavity or retroperitoneal space, but bleeding within the wall of an aneurysm or dissection of the thoracic or abdominal aorta has also been reported as being responsible.[51] In these cases, persistent fever and anemia typically follow an episode of chest, back or abdominal pain that spontaneously resolves.[51] Trauma may predispose to the formation of hematomas in extravascular spaces.

Drug fever can occur with virtually any medication, even those administered for long periods without previous problems (Table 82.2).[52] There may be no eosinophilia.[52] There are no distinctive clinical features associated with drug fever that help to distinguish it from the other causes of fever mentioned above.

Other miscellaneous causes of FUO are rare. Endocrinologic causes of FUO include hyperthyroidism and adrenocortical insufficiency.[49] Factitious fever does not always follow a specific pattern of a characteristic patient population, although many have the features of Munchausen syndrome.[53] In order to provide objective evidence of fever, some patients may warm the thermometer when the health care worker is not in attendance. Others may subject themselves to mutilation through such maneuvers as injecting themselves with specimens contaminated with micro-organisms.

Undiagnosed fever of unknown origin

Between 7% and 30% of cases remain undiagnosed despite intensive evaluations.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] The long-term follow-up, available in two FUO series, shows that fever resolves in the majority of these patients within a short time.[54] In one series, follow-up was available for eight cases in whom no diagnosis was established.[14] Fever resolved within 3 weeks of the period of FUO in 87% of cases and within 4 months in all patients. The other series investigated the long-term follow-up of 49 cases of undiagnosed FUOs taken from a larger cohort of 199 cases.[54] Fever resolved within a few weeks of discharge in 31 of the 49 cases (63%) and within 2 years of discharge in 83%. In the remaining eight patients (17%), fever recurred and required repeated courses of nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids. Despite the lack of diagnosis in these patients, the mortality rate 5 years after discharge was small — only 3%. Thus, in most of these patients the fever abated without treatment, and rarely did a serious disorder emerge later. [14] [54]

FEVER OF UNKNOWN ORIGIN IN OTHER GEOGRAPHIC REGIONS

Table 82.1 details several large studies characterizing the spectrum of FUO as defined by strict inclusion criteria. All these studies, however, were performed in the USA or in northern Europe. The spectrum of disease in developing countries differs from that in the developed world. However, the literature on FUO in developing countries is limited. Several series have been published that characterize the specific diagnoses associated with prolonged fevers in other countries. Few of these series meet the revised Petersdorf and Beeson criteria requiring absence of a diagnosis despite an initial work-up. Several constraints have been identified that limit application of strict inclusion criteria to these studies.[55] These include presentation of the patient late in disease, limited access to diagnostic tests, including accurate blood culture methods, limited treatment facilities and poor patient follow-up. Accurate diagnosis can be further complicated by the presence of endemic disease that may not be the etiology of the prolonged fever under investigation. For example, typhoid fever is often diagnosed by serologic methods (the Widal test). However, in endemic areas, 12–29% of patients may have a positive titer at baseline. Convalescent titers are difficult to obtain because of poor follow-up, and misinterpretations of these tests frequently occur.[55]

Two large series have been published in the developing world that selected patients based on Petersdorf and Beeson criteria.[56] [57] The first, with 159 patients from Bangladesh, noted infectious diagnoses in 63% of patients, while the second with 233 patients in India reported infectious etiologies in 46%, suggesting a greater contribution of infectious causes when compared with the series in Table 82.1 . In each series, two of the three leading infectious diagnoses were typhoid fever and tuberculosis. In addition, malaria and chloroquine-responsive fever were common. Other diagnoses included visceral leishmaniasis, amebiasis, syphilis, leprosy and filariasis. In addition, conditions seen commonly in the developed world such as endocarditis and intra-abdominal abscesses were present. The suggestion that infectious diagnoses comprise a greater proportion of cases of FUO in developing countries is supported in other series as well.[55] [58] [59]

The clinician must consider diseases more common in specific geographic regions when evaluating patients from these areas. For example, a compilation of all FUO series in Spain over 25 years, including 914 patients, demonstrated that brucellosis accounted for 16% of infectious diagnoses and that 8% were due to parasitic causes, including hydatid disease, leishmaniasis and *Fasciola* infection.[60] Studies conducted in hospitalized patients who had fever in India and in Nigeria reported a *Brucella abortus* seroprevalence of 0.8–5.2%, leading the authors to speculate that brucellosis might account for a percentage of cases of undiagnosed FUO in these regions as well.[61] [62] Studies of prolonged fever in Egypt note that 16% of cases were diagnosed with a parasitic infection.[63] In addition to typhoid fever and tuberculosis, melioidosis has been reported as a common cause of FUO in South East Asia.[64] [65] HIV infection is an important consideration throughout the developing and developed world. Specific diagnoses to consider in the HIV-infected patient who has fever are discussed below.

GENERAL APPROACH TO DIAGNOSIS

Although some disorders may be associated with a distinct pattern of fever (Table 82.3), the charted fever curve is rarely helpful in establishing an individual diagnosis. The following approaches should be pursued, because most disorders that cause FUO do not have a specific fever pattern.

Routine noninvasive tests

Recent series have shown that a growing number of cases of FUO are being identified by a variety of noninvasive tests.[12] [13] [14] [15] Several factors may explain this observation. The number of diseases diagnosed by microbiologic methods has risen, possibly because of advances in diagnostic capabilities. [16] For example, blood

TABLE 82-3 -- Diseases associated with distinct patterns of fever.

DISEASES ASSOCIATED WITH DISTINCT PATTERNS OF FEVER		
Term	**Description**	**Disease**
Intermittent	Temperature elevation returns to normal at least once during most days	Abscesses, falciparum malaria, Still's disease
Remittent	Fevers do not return to normal each day	Tuberculosis, endocarditis, typhoid fever
Relapsing	Recurrent over days or weeks	Relapsing fever, brucellosis, malaria (tertian or quartan fever pattern), lymphoma (Pel-Ebstein fever pattern)
Biphasic	Recurs only once	Leptospirosis, dengue, Colorado tick fever, lymphocytic choriomeningitis
Continuous	Fever varies less than 1.8°F (1°C) over several days	Encephalitis, drug fever, salmonella, factitious fever

cultures using the lysis-centrifugation technique may identify *Mycobacterium* spp. and obviate the need for bone marrow aspiration.[66] The practice of incubating blood cultures in a carbon-dioxide-enhanced environment and subculturing broth even in the absence of turbidity has led to the detection of infectious endocarditis caused by fastidious organisms.[33] In other instances, the available serologic techniques have supplanted the need for pathologic analyses of surgically obtained tissue;[28] for example, elevated antibody titers to *Entamoeba histolytica* in patients who have hepatic masses seen on computerized tomography (CT) scans supports the diagnosis of amebiasis and avoids the need for invasive procedures.[14] Advances in serologic testing are relevant for 'older' diseases as well; for example, systemic lupus erythematosus can now be detected in a person who is negative for antinuclear antibody.[14] Also, newly described diseases that have made their first appearance as causes of FUO, such as Lyme disease or HIV infection, can be diagnosed by serologic methods.

The number of cases of FUO diagnosed by noninvasive techniques is likely to increase in the future as noninvasive diagnostic testing improves. Blood culture with use of the lysis-centrifugation technique is a sensitive method of detecting common mycobacterial and fungal infections that cause prolonged fever in patients who have AIDS.[66] The development of assays such as the polymerase chain reaction (PCR) for disseminated *M. avium* infection may further reduce the need for invasive procedures by identifying the organism far in advance of the time that is required to isolate it from blood cultures. The application of the PCR for diagnosis of other infections, such as acute HIV infection[67] or *Legionella* infection, could also avoid the need for an invasive procedure in selected circumstances. Finally, advances in obtaining expectorated sputum and analyzing it for the presence of *P. carinii* will drastically reduce the need for bronchoscopy for the diagnosis of *P. carinii* pneumonia in persons who have AIDS and have had prolonged fevers.

Testing guided by abnormal findings

In most instances of FUO, diagnostic testing is guided by notable findings on the physical examination or by abnormal values in a routine laboratory test.[68] The careful evaluation of patients necessary to reach a diagnosis cannot be replaced by the early use of new diagnostic tests such as transesophageal echocardiography and magnetic resonance imaging (MRI) in an effort to hasten a diagnosis.

A uniform diagnostic algorithm is not useful because studies are most helpful when performed in a guided fashion determined by each individual case. One study has identified the amount of time and resources required to establish the diagnosis.[14] This study showed that diagnosis required a mean time of 19 days (range 1 day to 8

months), including 11 days of hospitalization (range 3 days to 5 weeks) and four outpatient visits (range: 0–11). A substantial part of the evaluation should take place in an outpatient setting[69] if the patient's condition allows.

The approach to FUO is influenced by whether abnormal findings are present in the early or later stages of FUO. Several studies have reaffirmed the paramount importance of repeated evaluation of patients who have FUO in whom no abnormal findings are present in the early stages of the illness.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [68] Repeated histories and physical examinations are crucial for detecting new developments. If no group of findings occur early in the febrile course, then prolonged and meticulous observation is the most successful approach to discovering the cause of FUO. This approach yields crucial findings that do not become evident until a late stage of the illness. In one series, repetition of the physical examination, selected laboratory tests or observation after specific therapeutic intervention led to a diagnosis in 28 of the 86 cases.[14]

This study has also shown that the late appearance of abnormalities on physical examination helps to direct further diagnostic testing.[14] In this report, excisional biopsy of a skin lesion that appeared late in the course of the fever in two patients showed polyarteritis nodosa in one and Sweet's syndrome in the other. In addition, the visual appearance of keratoderma blenorrhagicum was diagnostic of a case of Reiter syndrome. In other situations, neither the gross nor the microscopic appearance was specific, but the diagnosis of Still's disease, systemic lupus erythematosus, POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes) syndrome and essential mixed cryoglobulinemia was aided by the late appearance of a skin eruption. In some cases of lymphoma and in one case of angioimmunoblastic lymphadenopathy, fever persisted for months before a lymph gland became enlarged.

One case series has also demonstrated that the etiology of FUO may be established when diagnostic laboratory results first appear in the later stages. [14] Examples of cases diagnosed in this fashion include viral infections that were identified by a significant rise in serologic titers for CMV, Epstein-Barr virus or HIV. Blood cultures facilitated a diagnosis of infectious endocarditis caused by *Actinobacillus actinomycetemcomitans* and *Enterococcus faecium* and of abdominal abscesses caused by *Listeria monocytogenes*. Eosinophilic pneumonia, bronchial adenoma and cranial subdural empyema were diagnosed by evolution of findings on radiographic studies.

One series showed that abnormal findings may be present in the early stage of the febrile illness.[14] In these cases, the abnormal findings were discovered by the initial examining physician, who decided to initiate treatment for the most likely condition before testing for the presence of less likely diseases. When fever persisted, cessation of therapy and investigation for alternative explanations of the original clinical pattern proved to be an effective clinical approach. Examples of diagnoses established in this fashion included tuberculosis in a person who had pulmonary infiltrates that did not respond to empiric antibiotics. In another case, an open thoracotomy with pleural and lung biopsy was performed when fever persisted despite antimycobacterial therapy in a man who had a bloody lymphocytic exudate and a reactive tuberculin skin test. Histopathologic stains of tissue revealed lymphomatoid granulomatosis. In these cases, the true disease process was identified only when fever persisted despite initiation of therapy for the most likely cause of the condition. It is conceivable that diagnostic riddles solved by this approach may not be considered true FUOs in the future. Rapid

diagnostic tests may become available and lead to a prompt identification of the illnesses considered in the differential diagnosis prior to the initiation of treatment.

The laborious process of investigating FUOs is difficult to accomplish in today's medical environment; carefully listening to and examining a patient, contemplating the problem in a quiet environment and collaborating with others is an arduous task. Frustration, weariness and impatience intervene when a diagnosis is not promptly reached, and they render the physician vulnerable to over-looking the appearance of a valuable new finding. The physician must expect to devote a large amount of time to pacifying impatient relatives of the patient and justifying the length of stay to insurers and administrators who would prefer a quicker solution.

Blind testing in absence of abnormal findings

Although previous series and reviews have stressed the fact that tests that are not guided by abnormalities found on physical examination or laboratory testing have a low diagnostic yield, one series showed that diagnoses were established by such tests in 10% of cases.[14] An example from this series is a biopsy of a temporal artery that revealed temporal arteritis in an elderly woman who had an elevated ESR but no localizing symptoms for that disorder. In addition, abdominal CT scanning led to a specific diagnosis in 6% of total cases; for example, one such CT scan showed extensive liver metastases in a man who had stomach cancer but no liver enlargement and normal liver function tests. In other cases, abdominal CT scans identified retroperitoneal lymphadenopathy despite the absence of abnormalities detected on physical examination; specific diagnoses were established by biopsies of the enlarged nodes.

Of note, percutaneous CT-guided techniques are useful for obtaining diagnostic specimens in patients who have abnormalities identified by abdominal CT scan.[70] The quantity of the material obtained by these procedures may be inadequate to demonstrate the characteristic histopathologic changes of neoplasms[26] but it is often sufficient for microbiologic analysis to be able to establish the diagnosis of an infectious process. One series showed that the yield of these procedures is high for infection but low for tumor.[14] Biopsies of tissue that are found to be abnormal by physical examination (e.g. lymph node) or diagnostic imaging techniques (e.g. lung) have been shown to have a higher yield (38%) than routine biopsies of bone marrow or liver (see below).

In contrast, 'blind' serologic and biopsy procedures are often fruitless at best and may actually prove misleading, resulting in unnecessary diagnostic procedures. For example, serologic testing for zoonotic infections such as tularemia, Lyme disease or Rocky Mountain spotted fever should be performed only if the patient has been exposed to a relevant animal or tick; similarly, review of serial blood smears for malaria or serologic testing for conditions such as amebiasis or leishmaniasis should be undertaken only if the patient has been in an endemic region (Table 82.4).

The yield of routine bone marrow examination and liver biopsy has been mentioned in several case series.[12] [13] [14] The diagnostic yield of bone marrow examination varies but is low in most series, ranging from 0% to 14%.[12] [14] Liver biopsy has been commented upon as being useful in several series[71] [72] but these series do not list the diagnostic yield. For example, Petersdorf's two series state that needle biopsy of the liver is of particular value in certain cases, even when hepatomegaly or jaundice are absent, because of the frequent involvement of this organ in systemic disease.[7] [12] More recent series[13] report that the diagnostic yield of liver biopsy is 14%.

The previously useful diagnostic 'blind' laparotomy has been supplanted by the abdominal CT scan[14] and recent studies suggest that there is no longer an indication for routine exploratory laparotomy in the evaluation of FUO.[73] In contrast, exploratory laparotomy continues

TABLE 82-4 -- Evaluation of fever of unknown origin in patients with recent travel, occupational or recreational exposure.

EVALUATION OF FUO IN PATIENTS WITH RECENT TRAVEL, OCCUPATIONAL OR RECREATIONAL EXPOSURE.		
Exposure	**Disease**	**Method of evaluation**
Recent residence in or travel to an endemic region	Tuberculosis	Skin test, sputum smear
	Malaria	Blood smear
	Brucellosis	Serology, blood culture
	Hepatitis A, hepatitis E	Serology
	Typhoid fever	Blood culture
	Dengue	Serology
	Leptospirosis	Serology, urine culture
	Amebiasis	Serology, smears
Tick exposure	Relapsing fever	Blood smear
	Rocky Mountain spotted fever	Serology
	Lyme disease	Serology
	Tularemia	Serology, blood culture

Animal contact	Tularemia	Serology, blood culture
	Leptospirosis	Serology, blood culture
	Brucellosis	Serology, blood culture
	Q fever	Serology
	Psittacosis	Serology
	Murine typhus	Serology
All the conditions that are endemic in a particular region have their own unique geographic distribution. All the conditions associated with animal contact are caused by a unique pattern of animal exposure.		

TABLE 82-5 -- Distribution of causes of fever of unknown origin in the elderly.

DISTRIBUTION OF CAUSES OF FUO IN THE ELDERLY	
Cause	**Percentage of cases**
Infection (e.g. abdominal abscess, bacterial endocarditis, tuberculosis)	25–35
Connective tissue disorders (e.g. giant cell arteritis, polymyalgia rheumatica)	25–31
Neoplasia (e.g. lymphoma, carcinoma)	12–23
Unknown	9–16

to be a useful method for characterizing known lesions when percutaneous procedures are not feasible or are nondiagnostic.

The yield from biopsy of the temporal artery in elderly patients who have an ESR above 40mm/h is not available in any case series. However, reports on temporal arteritis estimate that up to 30% of patients who have this illness do not have the classic localizing symptoms. Moreover, several series comment that biopsy of the temporal artery should be performed early in the evaluation of an elderly patient who has an ESR above 40mm/h, because giant cell arteritis is a common cause of FUO in this age group and also because early recognition and treatment of giant cell arteritis can prevent the sudden blindness that it sometimes causes. Table 82.5 lists the distribution of conditions causing FUO in elderly patients. [74]

The usefulness of screening with radionuclide scans in patients who have FUO remains unestablished.[75] [76] [77] Several reports suggest that the value of these scans in FUO has been over-rated and that the overall value of the test has been disappointing and potentially misleading. In one large series, approximately 14% of gallium-67 scans were helpful in providing a diagnosis but false-positive results that were potentially misleading and led to unnecessary testing occurred in 21% of patients.[12] This series was performed before the

widespread use of abdominal CT scanning. Because abdominal CT scanning has proved to be of value in the evaluation of FUO, it may further reduce the value of gallium-67 scans in this setting. The diagnostic yield of indium-labeled leukocyte scanning, [76] technetium-labeled antigranulocyte antibody and indium-labeled polyclonal IgG[77] has not been systematically evaluated. Indium scans may be even less useful than gallium scans because tumors may not take up indium-labeled leukocytes. More recently, the value of positron emission tomography using 2-(^{18} F) fluoro-2-deoxy-D-glucose (FDG-PET scanning) has been evaluated in patients who had FUO, with inconsistent results. Although one study noted that 41% of scans aided in establishing a diagnosis, 48% of abnormal scans were noncontributory and potentially misleading.[78] In contrast, in another study, 11 of 12 abnormal scans led to the diagnosis.[79] PET scanning may prove to be more useful than other radionuclide scans. At present, however, because radionuclide scans may give misleading results, they should not be part of the standard evaluation of FUO. Because of false-positive test results, physicians should be cautious in interpreting the findings and should not recommend invasive procedures solely on the basis of positive radionuclide scans.

Drug-related fevers

When a drug-related fever should be considered, necessary drugs can be changed to alternatives of a different class. After stopping the agent that is responsible for the fever, the fever will usually resolve within 3 days, although it may take as long as 2 weeks. Persistence of fever beyond this should direct the clinician to investigate an alternate source. If the fever remits, the clinician can definitively confirm the diagnosis by re-instituting the agent, which characteristically elicits fever again within a few hours. This procedure is safe unless drug-induced organ damage, such as interstitial nephritis or hepatitis, has occurred.

THERAPEUTIC INTERVENTIONS

In most instances therapeutic trials should be discouraged in the early course of FUOs. The purpose of such trials is to establish a diagnosis by noticing an abatement of fever following the use of a therapeutic agent such as an antibiotic, a corticosteroid or a NSAID. The empiric use of agents such as these may be misleading for several reasons:

- medical intervention makes it difficult to determine whether a new finding has resulted from the treatment or the underlying disease;
- fall of temperature may be fortuitous or it may result from the antipyretic effects of corticosteroids or NSAIDs; and
- improper use of antibiotics may lead to a false sense of therapeutic and diagnostic security and interfere with finding a diagnosis.

The spontaneous resolution of fever in stable patients is another argument against the empiric use of therapeutic trials. Employing empiric antibiotics except in the most urgent situations ultimately creates more frustration, confusion and despair for the physician and the patient.

Prolonged empiric therapy may have multiple deleterious consequences beyond unnecessary expense and inconvenience for the patient. When fever in a patient who has a self-limited illness coincidentally abates while the patient is receiving treatment for an unproven diagnosis (e.g. antibiotics for possible culture-negative endocarditis, antimycobacterial therapy for possible tuberculosis or corticosteroid therapy for a collagen disorder) the patient may be exposed to unnecessary iatrogenic complications resulting from the treatment. In addition, complications resulting from unnecessary interventions may confuse further diagnostic strategies based on abnormalities on physical examination or laboratory findings. For these reasons, therapeutic interventions should be discouraged in stable patients. Nevertheless, there are occasional circumstances in which a patient has a rapidly progressive, potentially fatal illness in which empiric therapy becomes unavoidable. In such cases, for instance a fulminant vasculitis and even, rarely, tuberculosis, high-dose corticosteroid therapy can be life-saving.

FEVER OF UNKNOWN ORIGIN IN HIV-INFECTED PERSONS

Fevers of unknown origin are not infrequent in the late stage of HIV infection[27] (see Chapter 124 , Chapter 125 , Chapter 126 , Chapter 127 , Chapter 128 , Chapter 129 , Chapter 130 , Chapter 131 , Chapter 132 , Chapter 133). One prospective study showed that fever occurred in 46% of patients who had advanced HIV infection.[28] The number of FUO cases caused by AIDS-related diseases is likely to increase as HIV infection becomes more prevalent.

Several HIV-associated illnesses may present with fever before the onset of specific organ-related symptoms.[28] [29] [30] [31] [32] [80] [81] [82] [83] Examples include lymphoma, *P. carinii* pneumonia, leishmaniasis and infections due to CMV, *Cryptococcus neoformans*, *Toxoplasma gondii* and *Mycobacterium tuberculosis*. Other illness, such as disseminated *Mycobacterium avium* infection and histoplasmosis, may present with constitutional symptoms alone in the absence of specific symptoms of organ involvement. Five large series of FUO in HIV-infected persons, with a total of 257 cumulative patients, are summarized in Table 82.6 . The mean $CD4^+$ lymphocyte counts, reported in four of the five series, were 58, 71, 94 and 98. Thus, in HIV-infected persons, FUO tends to occur in the late stage of HIV infection. A modified criteria for FUO was used in four of the five series: a fever in excess of 101°F (38.3°C) that persists for more than 4 weeks as an outpatient or 4 days as an inpatient and that has no obvious source.

Infections are the most common cause of FUO in HIV-infected persons, accounting for more than 70% of cases (see Table 82.6). Mycobacterial infections, both *M. tuberculosis* and *M. avium*, account for the majority of these cases. The remaining infections are due to pyogenic infections and to infections caused by *T. gondii*, *P. carinii*, *C. neoformans* and *Leishmania* spp. Cytomegalovirus and HIV itself account for a small percentage of FUO. The cause of FUO was attributed to HIV alone

when the diagnostic evaluation did not reveal a specific etiology and when the fever abated following antiretroviral therapy. Tumors, principally lymphomas, are responsible for 7% of cases. Miscellaneous causes, including drug fever, adenoviral pneumonia and bleomycin lung toxicity, account for 13% of cases. The diagnosis remains unestablished in approximately 15% of cases. In 20% of cases there was found to be more than one disease causing the unexplained fever.

As with classic FUO, the spectrum of infections causing HIV-associated FUO differs according to geographic location. In the USA, the most common cause of HIV-associated FUO is disseminated *M. avium* infection. In contrast, outside the USA, tuberculosis accounts for the majority of cases of FUO.[32] Leishmaniasis is a common cause of FUO in series from outside the USA, and salmonellosis and cryptococcosis are more common in some non-US series.[31] [32] Histoplasmosis and Chagas' disease are prevalent in Central and South America and infection with *Penicillium marneffei* has been reported from South East Asia.[32]

Diagnosis

The utility of the available tests for FUO has not been determined from direct studies. Nevertheless, indirect information on their usefulness may be derived from studies that establish their sensitivity for the specific opportunistic infections that are responsible for causing FUO. The diagnostic modalities and the studies that establish

In some cases, HIV itself as a cause of FUO was defined as a response to antiretroviral therapy. Included in the category of 'other diagnosis' are factitious fever, zidovudine toxicity, *Isospora belli* enteritis, *Candida* sepsis, aspergillosis, varicella-zoster encephalitis, drug fever, bleomycin pneumonitis, hepatitis B, malaria, disseminated histoplasmosis, pulmonary nocardiosis, disseminated *Penicillium marneffei* infection, disseminated cryptosporidiosis, Kaposi's sarcoma, Castleman's disease, hepatitis C, adenovirus pneumonia and herpes simplex esophagitis.

their usefulness in the evaluation of HIV-associated FUO are discussed below.

Noninvasive tests

Blood cultures for bacteria, *Mycobacterium* spp. and fungi are valuable diagnostic tests in the evaluation of FUO. In one report, blood cultures had a sensitivity of 75% for disseminated *M. avium* infection; other reports suggest a sensitivity of 64–85% for *Mycobacterium* spp.[29] Available systems include Bactec, Dupont Isolator and lysis-centrifugation systems; the comparative yield for each of these systems for FUO in HIV-infected persons is unknown. *Histoplasma capsulatum* has been grown from lysis-centrifugation system when it failed to grow in the routine biphasic blood culture system. In rare instances, other organisms may be recovered from isolator blood cultures, such as *Nocardia* spp. Buffy-coat culture for CMV infections has not been proved to be a useful test in establishing the diagnosis of disseminated CMV infection, both because patients may be viremic without having disease due to CMV infection and because fewer than 50% of patients who have documented CMV disease are viremic.[84]

Serum and urine antigen techniques are useful in identifying certain fungal and viral infections. Serum cryptococcal antigen is sensitive and specific for detecting dissemination with *C. neoformans*; it is therefore a useful test for this purpose.[85] Recent reports suggest that serum antigen for CMV and molecular testing to detect CMV DNA are sensitive for detecting dissemination due to CMV disease.[86] [87] Antibodies for CMV are not helpful in establishing a diagnosis because 90% of HIV-positive patients have antibodies to CMV. Diagnosis of CMV esophagitis, colitis, gastritis or encephalitis requires pathologic evidence of the effects of the virus; retinitis may be diagnosed by funduscopic examination. *Histoplasma* antigen in urine or serum is a very sensitive and specific finding for the diagnosis of disseminated histoplasmosis; [88] serial antigen assessment has also been found to be useful in monitoring the response to therapy.

For the diagnosis of *P. carinii* pneumonia, expectorated sputum is rarely diagnostic, because in most cases the cough is not productive. Nebulizer-induced sputum is a technique that is available in the ambulatory setting and is diagnostic in many cases because of the high number of organisms that are present in the alveoli. Published studies show that the sensitivity of the test for evaluating *P. carinii* pneumonia is 75–90%.[89] [90] The technique involves centrifugation of liquified sputum and staining the specimen with a direct fluorescent monoclonal antibody that reacts with the cyst wall. This test may establish the diagnosis of *P. carinii* pneumonia in a noninvasive fashion and avoid the need for bronchoscopy.

Invasive procedures

The introduction of sensitive noninvasive tests for diagnosing many conditions responsible for FUO in HIV-infected persons has reduced the need for invasive procedures. However, invasive procedures, such as biopsies of bone marrow, liver and abnormal lymph nodes, continue to have a role in evaluating FUO, especially when patients remain febrile despite a prolonged noninvasive evaluation.

The yield of bone marrow examination for FUO in HIV-infected persons has been investigated in several series and has ranged from 13% to 42%.[91] [92] [93] One series showed that, in 86% of patients in whom a cause of the fever was identified by bone marrow examination, the same diagnosis had been established by a noninvasive diagnostic modality.[93] This series also showed that in 53% of patients the diagnosis was made by bone marrow examination as rapidly as or sooner than it was by other modalities and that in 16% of patients the diagnosis was made exclusively by bone marrow examination. The authors concluded that bone marrow examination is indicated when a diagnosis is urgently sought or when an evaluation by other diagnostic modalities has been unsuccessful.[93]

The usefulness of liver and lymph node biopsy has been evaluated in several studies.[94] [95] [96] [97] The yield from liver biopsy in evaluating FUO in HIV infected persons has varied between 40% and 58%. Biopsy of enlarged lymph nodes has been reported to have a high yield. [98] [99] [100] In a population at high risk for HIV, the yield of lymph node biopsy for tuberculosis was 57%. Fine-needle aspiration was also reported in one study to have a high diagnostic yield.[100]

Approach to the diagnosis

An initial approach in the evaluation of FUO in HIV-infected persons should be to discontinue medication, especially antiviral agents and sulfonamides. The clinical features associated with opportunistic infections that cause prolonged fever often overlap with those associated with drug reactions (e.g. cytopenia and elevation of liver enzyme tests). If there is no response after 3 days, blood culture using the lysis-centrifugation technique is a sensitive method of identifying intracellular organisms that cause disseminated infections (e.g. *H. capsulatum, C. neoformans, M. avium*). However, because the mean time for cultures to turn positive is 18–25 days for *M. avium*, [83] other noninvasive tests should be performed simultaneously. Induced sputum for *P. carinii* and *M. tuberculosis* should be obtained because prolonged fevers may precede the onset of respiratory symptoms in both *P. carinii* pneumonia and tuberculosis. Tuberculin skin testing and antigen testing for *H. capsulatum* in serum and urine also should be performed. If the serum cryptococcal antigen is reactive at a titer of less than 1:16, a lumbar puncture should be performed, even if the patient does not complain of headache or demonstrate nuchal rigidity.[85] A dilated ophthalmologic examination should be performed to investigate retinitis due to CMV.

If the initial approach does not yield a specific diagnosis, the subsequent evaluation should include repeated physical examinations and routine laboratory work. Because abnormal findings of diagnostic importance (e.g. skin nodules, asymmetric and enlarging lymphadenopathy, and rapid and significant rise in serum alkaline phosphatase levels) may make their first appearance long after the onset of fever, abnormal organs should be biopsied and organisms looked for using special stains.

Other invasive procedures should not be performed while waiting for an organism to be isolated from lysis-centrifugation cultures if the patient remains stable, because cultures of material aspirated from bone marrow or lymph nodes or biopsied from the liver are no more sensitive than isolator blood cultures. If cultures of blood are still negative after 3 weeks, a bone marrow examination should be performed, even if the patient is stable, because the bone marrow examination has been shown to be the sole method of identifying an illness in approximately 5% of patients in whom all noninvasive tests have been unrevealing.[92] [93] Outside the USA, bone marrow examination may be considered earlier in the diagnostic evaluation, given the enhanced prevalence of leishmaniasis and tuberculosis in other countries.

In the evaluation of prolonged, unexplained fevers, the patient's previous exposures, stage of HIV infection and present epidemiologic setting often provide important clues. For example, tuberculosis should be suspected in anyone who has HIV infection and has been exposed to an infected person or who has resided in an endemic region. Similarly, histoplasmosis or coccidioidomycosis may occur in persons who have been in an endemic region.[82] Leishmaniasis should be considered in people who have been in South America or the Mediterranean area. Infections caused by *P. marneffei* should be considered in people who have lived in southern Asia. Extrapulmonary *P. carinii* infections may be identified in patients in the late stages of HIV infection who have been receiving aerosolized pentamidine.[81] Infections due to *Bartonella henselae* should be considered in people who have had exposure to cats; the organism may be identified by serology or by isolator blood cultures. Lymphoma should be considered in patients who have no specific exposure history. Finally, patients who have very low $CD4^+$ counts and have recently commenced highly active antiretroviral therapy who experience marked immunologic improvement are at risk for immune reconstitution disease. Unusual presentations of opportunistic infections should be considered in these persons; for example, *M. avium* or cryptococcal lymphadenitis can occur in the absence of disseminated disease and with a low burden of organism on biopsy specimens. Immune reconstitution illness also occurs in patients who have recently started antiretroviral therapy who are also being treated for an active opportunistic infection. Fever in this setting does not represent progression of the opportunistic infection and does not indicate a need for change of antimicrobial therapy. Rather patients should be treated with anti-inflammatory agents and, if necessary, corticosteroids.

When the initial and subsequent evaluation for FUO has been unrevealing, abdominal CT scan occasionally proves to be a useful diagnostic tool. Occasionally, peritoneal masses or a group of enlarged retroperitoneal lymph nodes may be identified on the scan; a directed CT-guided biopsy of these abnormal areas on CT scan may reveal the cause of fevers. Gallium scans and indium-labeled leukocyte scans are frequently performed in the setting of prolonged unexplained fevers but the tests are rarely of diagnostic value and are potentially misleading. Another test of uncertain significance is the buffy-coat culture of blood for CMV, because viremia may occur without symptoms and the test is insensitive for the detection of CMV disease.[86] A thorough evaluation of FUO as outlined above yields a diagnosis in approximately 85% of cases. Multiple causes for FUO will be identified in up to 20% of cases — the feature that distinguishes FUO in HIV-infected persons from those who are not infected with HIV.[32]

CONCLUSION

Since its original description in 1930, case series have shown that a careful, organized approach to the problem on the part of the physician remains of pre-eminent importance in identifying the cause of FUO. This remains true even though new diagnostic modalities that are useful in the evaluation of FUO have been introduced and the number of illnesses that are responsible for FUO has expanded. How to employ the available diagnostic tools must be individualized for each patient and remains a challenge for the physician. The role of exploratory laparotomy is limited to characterization of known lesions that remain undiagnosed after percutaneous procedures and of those that are not accessible by the percutaneous approach. Because blood culture with the use of the lysis-centrifugation technique is a sensitive method of detecting many of the infectious causes of HIV-associated FUO, invasive procedures may be avoided if the patient remains stable. Despite the introduction of new diagnostic modalities, the investigation of FUO in the general population or in HIV-infected persons remains one of the most challenging tasks for the clinician.

Chapter 83 - Health Care-associated Infections

Didier Pittet
Hugo Sax

EPIDEMIOLOGY

Trends and complexity in health care

Health care-associated infections (HAIs), whether acquired during home, ambulatory, institutional or hospital care, constitute one of the greatest challenges of modern medicine. According to the Institute of Medicine, Washington DC, USA, preventable hospital-related adverse events in the USA, including nosocomial infections, are responsible for 44,000–98,000 deaths annually and represent a cost of $17–29 billion. Among these, nosocomial infections now affect 5–15/100 hospitalized patients and can lead to complications in 25–50% of those admitted to intensive care units (ICUs). Costs for nosocomial infections related to hospital stay were estimated at $4.5 billion in 1992, which translates to $7.5 billion in 2001 using the Consumer Price Inflator.[1] In the UK, hospital-acquired infections cost around £1 billion a year. Importantly, these estimates only concern infections acquired in acute care hospitals and ignore those resulting from ambulatory care or acquired in other settings.

Infection characteristics and risks are strongly related to changes in health care. Whereas the hospital has traditionally been the center of health care systems, it only constitutes one piece of the jigsaw today. Similarly, while physicians and nurses have generally been considered as the primary health care workers (HCWs), they have been progressively assisted and even replaced in some instances by other health care providers, professionals or technicians. The economic pressures on health care are important drivers of such a splinter effect. One of the main results is the shift of patient care from acute care hospitals to other facilities or systems. Two main avenues can be identified:

- long-term care facilities (LTCFs), mainly due to the increasing elderly population; and
- different forms of ambulatory care (Fig. 83.1).

In the USA, around 1.5 million persons reside in approximately 17,000 nursing homes and 40% of those over 65 years of age will spend some time in a nursing home before dying.[2] Because of frailty and the closed environment, HAI rates in this setting probably equal those in acute care.[3] In 1985, they were estimated at 1.5 million annual infections,[4] or an annual incidence of five to six infections per 1000 resident days.[5]

Over the past two decades, a spectacular increase in specialized ambulatory clinics has been observed. In 1980, approximately 15% of all surgical interventions were carried out on an outpatient basis. Today, outpatient surgery represents almost three-quarters of all procedures. Similarly, there has been an increase of nearly 200% in the number of outpatient surgical procedures being performed in ambulatory care centers over the past decade.[6] Experts agree that this trend is likely to continue with a parallel economic impact on hospitals.

Major changes have occurred in the way in which health care is delivered and financed over the past few years. The patient demand for health care services has also substantially increased. In 1999 for example, 82.5% of the entire USA population had paid at least one visit to a physician's office, an emergency department or a clinic, or had received care at home. In 2000 in the USA, 31.7 million hospital discharges stood against 83.3 million outpatient department visits.[7] [8] Patient care is moving from hospital, to outpatient clinic, ambulatory care and finally home care. Some patients are not treated by physicians or even nurses for their conditions, and there has been a greater emphasis on providing quality health care at a low cost.

Health care-associated infections are becoming increasingly important as a result of multiple converging trends. Shortening of hospital stay has become an issue of survival for hospitals, especially under capitation, leading to an aggregation of the sicker patients who must remain in acute care hospitals,[9] and to the risk of early discharge of patients to sometimes poorly prepared health care settings or structures. Technical and scientific progress introduce more risk for acquiring infection, such as by the increase in device use, care complexity, immunosuppressive therapy and organ transplantation. This is shown by the data of repeated prevalence studies in a large tertiary care center over 10 years (Fig. 83.2).[10] As illustrated, while average length of stay decreased over time, patient case-mix and device use rates increased, resulting in an increased risk of device-associated infections despite stable overall infection rates. Aging of the population increases the problem further and treatments are increasingly aggressive, even in the elderly; for example, advanced age is no longer an exclusion factor for ICU admission.

Spiralling health costs fuel these changes, leading to early patient discharge and downsizing in staff number and expertise. There is no reason why this trend should be reversed in the near future. The various components of the health care system remain less separated than previously and overlap because of accelerating patient transfer activity. Of note, transferred patients have been found to be infected four times more frequently than new admissions from the community.[11]

Not all of this evolution has been anticipated and the necessary adaptations of very basic structures such as patient data update have not been made or lag behind in progress. This applies also for infection prevention.

Leading infections in different health care settings

The traditional focus for nosocomial infection is the acute care setting. Of equal importance is infection in lower level care institutions such as LCTFs. The increasing recourse to ambulatory care would suggest that this setting has an important potential for infection, but very few data exist on this topic. We discuss below the most common types of HAIs.

In contrast to acute care, LTCFs feature a higher proportion of soft tissue and urinary tract infections, but have less bloodstream and surgical site infections (Fig. 83.3). Note the considerable proportion of respiratory infections in all settings. Importantly, although infection rates were higher in critical care, they were no higher in acute-than in long- or intermediate-care beds, stressing the need to implement infection prevention strategies in all health care settings.

Bloodstream infections are the most easily defined because they are mostly related to the very specific event of a positive blood culture. The majority of these are due to intravascular device use.

Figure 83-1 Complexity of modern health care systems.

Although these events are rare in the long-term setting, they may be important and under-recognized in the outpatient setting among patients with long-term intravascular catheters, such as those with cancer or osteomyelitis. Bloodstream infection is associated with an increased mortality rate, an increased hospital and ICU

stay, and resource use. Attributable mortality rate averages 25%, and additional costs range from $10,000 to $45,000 in acute care settings. However, such data remain unknown for infections acquired in LTCFs or in the ambulatory or outpatient setting.

Infections at the surgical site complicate 1–10% of operations. They are associated with substantial morbidity and mortality rates, double the duration of hospitalization, and increase the cost of health care. Importantly, over 50% of these infections become manifest only after hospital discharge. Again, infection rates associated with ambulatory practices remain unknown; outbreaks of infections have been reported, however, further stressing the need for closer surveillance and control outside the hospital setting.

Pneumonia is the leading infection in the critical care setting, but its importance in the nonacute setting is often underestimated. In the ICU, it is mostly related to invasive respiratory support and associated with high crude and attributable mortality rates, and significant extra costs. In LTCFs, respiratory tract infections are associated with multiple risk factors and mostly treated with broad-spectrum antibiotics because of the high prevalence of antimicrobial resistance. [12] In this setting, mortality rates have been estimated to be up to 20%.[13]

Overall, there is a lack of comprehensive statistical data on infections acquired in the outpatient setting or during home therapy, but the literature abounds with reports of health care-associated events, in particular, infections. For example, a cluster of hepatitis B transmission at a physician's office, bloodstream infections associated with home infusion therapy, HIV transmission from a dentist to his clients, and transmission of tuberculosis in an ambulatory waiting room.

Trends in microbial pathogens and resistance

In contrast to the acute care hospital, data are scarce on trends in pathogens for HAIs outside this setting. Table 83.1 provides an overview of the importance of different multiresistant pathogens in different health care institutions.

Antimicrobial resistance is mostly the product of health care intervention and has become a worldwide problem. Together with globalization, issues related to resistance in one continent become relevant in almost any other. Similar trends in health care development (risk factors, antibiotic use) and spread due to increased travel activity might be the major determinants for this evolution. As an example, the proportion of methicillin resistance among *Staphylococcus aureus* infections is increasing globally, and identical strains are found at distant places at short intervals.

International air traffic has increased from 2 million passengers per year in the 1950s to over 1.4 billion in 2000. Over half of all European adults travel abroad during the same year, a large proportion to developing countries. This constant population movement facilitates global dissemination of infectious diseases, and carriage of micro-organisms from one corner of the earth to another occurs in a matter of hours. Asymptomatic carriers disseminate antimicrobial resistance. As an example, some major hospital outbreaks of methicillin-resistant *S. aureus* (MRSA) infection in Canada could be traced to a small village in North India.[14]

There are striking differences in the epidemiology of multiresistant pathogens between different continents, countries or hospitals. Antimicrobial prescription outside the hospital also dramatically differs from country to country (Fig. 83.4). Infection control practices such as the use of alcohol-based hand disinfection and barrier precautions have an effect on the transmission of nosocomial pathogens. Unfortunately, compliance with recommendations varies greatly, both among individual care-givers and institutions, and even among different countries.

Impact of health care-associated infections

Medicine was an art for over 3000 years, a science for the past 100 years, and has become a business for 30 years. Economic concerns have taken on increasing importance in health care over the past three decades. There is a major interest in determining the financial impact of HAIs to better tailor and target prevention efforts under current resource restraints. In acute care hospitals, the impact concerns mortality rates and morbidity, mostly expressed in additional length of stay and direct costs. The impact of infections on the health care system or the society must also be considered, but has been poorly studied so far. Although infections acquired in chronic care facilities or in the ambulatory or home care setting might be associated with fatal outcome in rare instances, they mostly impact on patient morbidity and extra costs to the society. For example, following ambulatory surgery, surgical infection may prolong patient absence from work. Furthermore, costs associated with extra help at home to take care of the family when a parent is sick need to be considered. Most of these costs are not 'billed' to the health care system, but certainly have an effect on other areas of society.

Another unique currency in which the costs of HAI can be expressed is the emergence of antimicrobial resistance, again further increasing hospital costs, as well as ambulatory and home care. The financial implications of antibiotic resistance in the hospital setting have been discussed in two review articles, which summarized examples of studies on the economic impact of transmission of antibiotic-resistant organisms.[16] [17] Direct medical costs of antibiotic resistance include, but are not limited to, the cost of more expensive

Figure 83-2 Trends in average length of hospital stay, patient case-mix, and nosocomial infection; Yale-New Haven Hospital, 1988–1995. (a) Trends showing the decrease in average length of hospital stay and the increase in the mean diagnosis-related group case-mix index. During the study period, there was a significant decrease in the mean length of stay, from 7.3 to 6.0 days (p = 0.01), and a concomitant increase in the mean diagnosis-related group case-mix index, from 1.03 to 1.24 (p = 0.001). (b) Nosocomial infection rates, assessed by repeated prevalence surveys, remained unchanged (p = 0.43) over the study period, but rates of nosocomial bloodstream infection increased (p = 0.05) corresponding to increased medical device use (p = 0.001, not shown). *From Weinstein et al.[10] , with permission.*

antibiotics, labor costs, laboratory costs, the cost of extra hospital days because of failure of initial therapies, and the cost of isolation and other infection control measures.[13] Accordingly, the annual direct cost of infections caused by antibiotic-resistant organisms in the USA are estimated to be $4–5 billion.[16]

PATHOGENESIS

Infection results from an interaction between host, micro-organism and health care setting-related factors (Fig. 83.5). A prerequisite is the presence of a microbial pathogen, be it from an endogenous patient colonizer or an exogenous source. Whereas some microbial pathogens are intrinsically virulent, others infect as a result of previous host colonization and a break in host vigilance, thus seizing the chance to multiply after disruption of physiologic flora or a break in the anatomic barrier. Pathogens are undesirable either because of their special virulence to the exposed population or because of their resistance pattern. Examples of breakdown in host defenses include a break in the skin barrier, the bypass of mucosal defense mechanisms and introduction of foreign bodies. The immune system may be hampered by immunosuppressive agents, pre-existing health conditions or simply by age.

To fully acknowledge possible risk factors, patient care must be seen in its larger sense, including:

- the patient environment (air and water quality, architecture, device sterilization);
- technical aspects of care (engineered solutions, device material, design);
- organizational structures (bed occupancy, transport of patients and material, ward exchange rate of patients and personnel); and
- health care worker and patient behavior toward procedures of care and health in general (Table 83.2).

Whereas procedures and quality of care are more closely attributable to individual patients, environment and, even more so, organizational factors are rather associated with the health care system and thus are common to an entire group of patients. Since therapeutic interventions such as immunosuppressive therapy or the nature and quality of surgical technique are a prerequisite to potential infection, they may be regarded as quality issues from the angle of infection outcome. Once preventive interventions are known, they become part of quality of care or departure from it (antibiotic prophylaxis in surgery to prevent surgical site infection, restriction in sedatives in elderly patients to prevent aspiration pneumonia, and skin care to prevent soft tissue infections). Importantly, even when procedure, environmental and organizational related parameters are optimal, patient or health care personnel behavior might interfere with patient safety.

IMPORTANCE OF MULTIRESISTANT PATHOGENS IN DIFFERENT HEALTH CARE SETTINGS				
	Intensive care unit	**Acute care**	**Long-term care facility**	**Outpatient**
Methicillin-resistant *Staphylococcus aureus*	+++	++	+++	+
Vancomycin-resistant *Enterococcus* spp.	+++	++	++	-/+
Penicillin-resistant *Streptococcus pneumoniae*	-	+	?	++
Gram-negative rods with extended spectrum ß-lactamase	+++	++	+	-
Multiresistant *Pseudomonas* spp.	+++	++	+	-
-, no problem; +, small problem; ++, intermediate problem; +++, important problem.				

PREVENTION

History

Although many historic examples could be used to recall the milestones of HAI prevention, only two are cited here.

In 1846, the Hungarian physician Ignaz Philipp Semmelweis observed, at the Lying-In Women's Hospital of the General Hospital in Vienna, that women whose babies were delivered by students and physicians consistently had a higher mortality rate than those whose babies were delivered by midwives. He also noted that physicians and medical students who went directly from the autopsy room to the obstetrics ward had a disagreeable odor on their hands despite washing them with soap and water upon entering the delivery room. After thorough investigation, he postulated that the high rate of puerperal fever was caused by cadaverous particles transmitted from the autopsy to the delivery room via the hands of students and physicians. As of 15 May 1847, Semmelweis insisted that students and physicians scrubbed their hands in a chlorinated lime solution before every patient contact. The maternal mortality rate subsequently dropped dramatically and remained low thereafter. This intervention by Semmelweis represents the first evidence suggesting that cleansing hands with an antiseptic agent between patient contacts may reduce cross-transmission of infectious agents. Semmelweis' difficulties in modifying hand hygiene behavior among his peers and colleagues can be considered as the first step of the crusade of most hospital epidemiologists whose objective is to improve compliance with infection control practices.

Florence Nightingale, considered to be the first nurse-epidemiologist, published in 1863 the third edition of her book, *Notes on Hospitals*, which had a major impact on health care in Great Britain. She reported mortality rates for the country's main hospitals, concluding that 'most unhealthy hospitals are those situated within the vast circuit of the metropolis' and also made the statement that 'in all probability a poor sufferer would have much better chance of recovery if treated at home'. This famous book also contains arguments for a direct relationship between sanitary conditions and postoperative complications, such as gangrene and pyemia, as well as a detailed description for ward construction and the concept of air control. Furthermore, information is provided on an observed higher mortality rate among hospital personnel (matrons, sisters, nurses) compared to the female population of London, and possibly resulting from contagious conditions. Nightingale was also the first person to suggest that nurses could survey hospital-acquired infection. Together with William Farr, the Registrar General and premier British health statistician, she showed that contagious diseases and crowding could explain the excess mortality rate among soldiers in the Crimea, and pleaded for improved general hygiene practices.

Figure 83-4 Outpatient antibiotic use in different developed countries. *From Harbarth et al., [15] with permission.*

Figure 83-5 The essential causes of infection.

Structure, process and outcome

Infection prevention relies on measuring parameters integrated in the health care structure, process or outcome as categorized by Donabedian.[18] Once faults are recognized, action may be directed at improving structure- or process-related issues. For the latter, infection prevention should include influence on health care partner and patient behavior to achieve optimal outcome.

Semmelweis chose an outcome-based approach, measuring maternal mortality rate from puerperal sepsis. By modifying the process of care through the implementation of an intervention (system change), he changed HCW hand hygiene behavior with a subsequent impact on the outcome measure. Florence Nightingale worked on both issues — improvement of: the structure of hospitals and wards by modifying the architecture and introducing patient charts; and the process by collecting outcome data to justify the implemented changes.

As a very comprehensive approach, the seminal SENIC study for infection control in hospitals[19] (see Chapter 87) issued quality standards regarding structure (personnel) and process (feedback of surveillance results) based on outcome measurement.

Attempts to ameliorate process quality range from guidelines to improve device use and care, to water and air quality controls. For their efficient implementation, behavior control plays a strategic role but also represents the most challenging and important element because it may interfere with any prevention strategy.

Outcome measurement is typically considered the gold standard and motivates the major investment in infection surveillance. Yet, because of the rarity of some infectious outcomes or technical difficulty associated with assessing these events, structure or process measurement may often be more adequate to guide prevention. In this case, pre-existing knowledge must be available about the relation between structure or process and the outcome. The following serves as an illustration. An ever-increasing number of gastrointestinal and pulmonary endoscopic procedures are being carried out in physicians' consulting rooms and outpatient clinics.

Numerous outbreaks of infections associated with the improper use or cleansing of endoscopes have been reported. Reusable accessories that break the mucosal barrier should be cleaned and sterilized or submitted to high-level disinfection between each patient. Personnel assigned to reprocess endoscopes must receive device-specific reprocessing instructions and training to ensure proper management and patient safety. Competency testing of such personnel is not conducted on a regular basis among most private practice physicians and there are no regulations governing this issue. Appropriate control of endoscopic procedures in private practice would be an example of patient safety promotion outside the hospital; process control in this case would certainly be more effective than outcome-based surveillance, which is extremely difficult and time-consuming in this setting.

The art of intervention: two examples

By the following two examples, we attempt to explain the way interventions might be performed successfully. We believe that the fundamental elements will not change according to the health care setting.

Catheter-associated infection: implementation of evidence-based guidelines

Despite continued technologic progress, infection related to the use of intravascular catheters remains a major concern. It has recently been estimated that the annual cost of intravenous catheter-related

TABLE 83-2 -- Summary of risk factors by category and selected examples.

SUMMARY OF RISK FACTORS BY CATEGORY AND SELECTED EXAMPLES					
Category	**Issues**	**Examples**			
		Acute care	**Chronic care**	**Outpatient**	**Home care**
Host associated	Genetic background	HLA type, leukocyte function, polymorphisms of immune response genes, etc.			
	Real-life experience	Lacking immunity due to pathogen exposure or vaccination, poor living conditions, homeless, lack of adequate insurance coverage			
	Chronic health conditions	Diabetes, cirrhosis, renal insufficiency, immunosuppressive medication	Pressure ulcers, incontinence, dependency, age, poly-medication	Smoking, alcohol or intravenous drug use	Poor nutritional state, negligence
	Acute health condition	Acute physiologic imbalance, severe trauma, extensive burn, acute hyperglycemia	Reduced alertness after stroke	Viral respiratory infection	Falls
Microbial associated	Pathogen virulence	Multiplication rate, invasion strategies, adhesion, intracellular survival, colonization advantage			
	Pathogen transmission route	Airborne transmission route, environmental survival			
Environment associated	Space concept	Poor operating theater ventilation, deficient hospital architecture, lack of space between patients	Poor compromise between conviviality and hygiene needs	Poor waiting room concept, lack of workspace, attending day care center	Poor room adaption, impractical hygiene installation
	Inanimate environment treatment	Poor cleansing, disinfection, sterilization and dust removal	Like acute care	Uncontrolled instrument reprocessing	Poor hygiene conditions
	Air and water treatment	Lacking filter maintenance, uncontrolled water quality	Lacking negative pressure rooms for tuberculosis patients	Lacking aeration	
Procedure and care associated	Indication for procedure	Overuse of vascular access devices	Overuse of urinary catheters	Overuse of invasive diagnostic procedures	Prolonged use of vascular access
	Device and procedure design/technique	Lack in justified application of minimal invasive surgery, intravenous catheter coating, tunneled catheter, noninvasive ventilation	Open urinary drainage systems	Poor endoscope design	
	Operator performance	Prolonged surgical intervention time, poor antisepsis in catheter placement	Poor antisepsis in urinary catheter placement	Poor antisepsis in joint puncture	Poor compliance with hand hygiene between patients
Health care system organization	Staffing	Excessive workload, lacking expertise, training, inadequate nurse-to-patient ratio	Shortage in trained staff	Lack in basic training in endoscope reprocessing	Lack in basic training in infection prevention issues
	Patient allocation	Overcrowding, early transfer, wrong specialty attribution, highly specialized wards lacking experience in basic care outside of expertise	Mistaken transfer from and to acute care	Wrong specialty attribution	Missed hospitalization
	Guidelines	Missing written guidelines, no antibiotic use policy	Antibiotic use guidelines not adapted to local resistance or to patients' specificity	Lacking guidelines for 'standard precautions'	No guidelines
	Communication	Lack of surveillance scheme for legionellosis between public health and hospitals	Lack of communication of multiresistant organism carriage at patient transferral	Lack of access to patient record at time of consultation	Lack of stop order for intravascular device
Behavior	Patient behavior	Noncompliance with prescriptions	Mental impairment	Unhealthy lifestyle	Noncompliance with peritoneal dialysis procedure
	Health care personnel behavior	Noncompliance with vaccination guidelines, hand hygiene practice, lack of motivation			

bloodstream infections in USA ICUs is between $296 million and $2.3 billion and that approximately 2400–20,000 patients die annually of this infection (see Chapter 84).[20] Intravascular access is, however, essential for patient care and the search for effective preventive measures is an active field of clinical research.

Device-related infections can be reduced by specific prevention strategies and improved guidelines for their use. Strategies are multiple and include not only those dealing with catheter insertion and maintenance but also the choice of device material. According to recent studies, education and reinforcement strategies are of paramount importance. Physician-in-training education has been proven to decrease the risk of catheter infection.[21] A 1-day course on infection control practices and on procedures of vascular access insertion was shown to reduce the infection rate by 73%.[21] A multiple-approach prevention program to decrease vascular access infection was used in a medical ICU;[22] 3154 critically ill patients were included in a cohort study with longitudinal evaluation of an overall catheter-care policy

associated with an educational program including detailed information on clinical pathways for vascular access insertion, and device maintenance and use, based on previously identified risk factors. Following the intervention, the incidence of exit-site catheter infection and that of bloodstream infection decreased by more than 60%. Overall, the incidence of all infections acquired in the ICU was reduced by 35%.[22] Although infection rates before the intervention were within the accepted limits, the results of this study confirm that a large proportion of infections related to extrinsic factors are still preventable and that interventions targeted at vascular access can have a significant effect on the overall incidence of infections. The impact in terms of reduction of nosocomial infections in these two studies[21] [22] was impressive. Sherertz *et al.*[21] estimated that their program was associated with cost savings of at least $63,000 and may have exceeded $800,000. Using conservative estimates, the savings associated with the global strategy described[22] would correspond to the annual salary of three to six full-time infection control nurses. One of the important implications of the results is the possibility of extending the designed strategy outside the critical care arena, and including all patients with vascular access in health care settings. The program's cost-effectiveness would allow its generalization.

Hand hygiene: applied behavior science

Hand hygiene is the most effective measure to prevent cross-transmission and reduce the spread of antimicrobial resistance. Despite considerable evidence of its importance, compliance with hand hygiene by HCWs is unacceptably low. Factors predicting noncompliance have been extensively studied and include, among others, excessive workload. Reasons for noncompliance with recommendations at individual, group and institutional levels should be considered. Easy access to hand hygiene in a timely fashion is mandatory for appropriate hand hygiene behavior. In particular, in high-demand situations, in high-stress working conditions, and at times of overcrowding or understaffing, handrub with an alcohol-based solution appears to be the only alternative to allow decent compliance. Alcohol-based handrub is superior to traditional handwashing with (un)medicated soap, because it requires less time, acts faster and irritates hands less often. Furthermore, it was used in the only program that reported a sustained improvement in hand hygiene compliance associated with decreased infection rates. [23] The availability of alcohol-based handrub is, however, not sufficient to obtain sustained improvement with hand hygiene practices. Promotion strategies should be multimodal and multidisciplinary, and easy access to fast-acting hand hygiene agents should be viewed as the main tool of the strategy. Time constraint is the leading factor for noncompliance, but also the easiest to modify. System change must be addressed in most health care settings where waterless hand disinfection has not become a standard of care. In addition, HCW education and motivation are obviously important and must be part of multimodal strategies to enhance compliance during patient care. Successful promotion and behavioral changes will result in reduced infection rates and antimicrobial resistance spread, and enhance patient safety.

Guidelines for hand hygiene in health care settings were recently developed (www.cdc.gov/handhygiene/). They are not limited to indications for hand hygiene and technical recommendations, selection of hand hygiene agents and HCW skin care, but equally contain strategies for motivational programs, administrative measures and recommended outcome or process measurements. Importantly, administrative measures include:

- making improved hand hygiene adherence an institutional priority;
- providing appropriate administrative support and financial resources; and
- implementing a multidisciplinary program that includes a readily accessible waterless antiseptic agent.

Although the guideline has been prepared for hospitals, the majority of its content is valid for any health care setting; private physicians, home care nurses as well as those working in LTCFs will benefit from it.

CLINICAL FEATURES

Microbiologic phenomena are of widespread epidemiologic importance and demonstrate the complexities associated with new trends in health care. As examples, we have chosen the epidemiology and control of vancomycin-resistant enterococci (VRE), MRSA, penicillin-resistant *Streptococcus pneumoniae* (PRSP) and legionellosis. Table 83.3 summarizes the linkage between different health care settings and the emergence and dissemination of pathogens. These pathogens are discussed in detail in the following chapter on ICU infections (see Chapter 84).

Vancomycin-resistant enterococci

In the USA, VRE are among the feared multiresistant pathogens produced by acute care hospitals. The problem was detected in the late 1980s, and by 2000 28% of ICU-acquired enterococcal infections were caused by resistant strains. [24] The healthy population without contact with the health care system is not usually colonized. Vancomycin-resistant enterococci were initially transmitted in high-risk units such as ICUs and hemodialysis, hematology and transplant units, but then spread to the entire hospital and, consequently, to the community. This makes it a typical hospital-generated problem pathogen that is similar to MRSA in its reservoir (high-risk patients) and risk factors for transmission (the hands of HCWs and possibly the environment).[25]

In Europe, the situation is quite the opposite. There is a high prevalence of stool carriage of VRE in the healthy community who have no previous contact with the health care system. In contrast with this, VRE cause only singular outbreaks in hospitals, and have never reached threatening levels of appearance in HAIs. By indirect proof, it has become clear that this widespread colonization is introduced by the food chain.[26] Avoparcin, a glycopeptide antibiotic, was introduced in livestock as a growth promoter and has induced high-level intestinal colonization. Livestock is therefore the main reservoir for VRE in Europe; outbreaks only occur when colonized patients are exposed to antibiotic selection pressure and shed a high amount of pathogen, which is then transmitted within the hospital to other patients.

After the ban of avoparcin in various European countries in the mid-1990s, resistance in the animal and human population decreased.[27]

Decreasing genetic variability in VRE over time in US inpatients [28] leads to the assumption that the first VRE may have been imported from Europe at around 1990. Additional support for this hypothesis

TABLE 83-3 -- Interlinkage health care system components by a selection of indicator pathogens.

INTERLINKAGE HEALTH CARE SYSTEM COMPONENTS BY A SELECTION OF INDICATOR PATHOGENS				
	Origin	**Reservoir**	**Transmission**	**Effect**
Methicillin-resistant *Staphylococcus aureus*	Acute care hospitals (wards, ICU); patient-to-patient transmission, antibiotic pressure	Acute care hospitals, LTCF; patients Secondary: community; discharged patients	Acute care hospitals dialysis units, (physician's office, community?); hands of HCWs, (devices, environment)	Endemic, outbreaks in acute care hospitals, LTCF, dialysis units
Vancomycin-resistant *Enterococcus* spp. (USA)	Acute care hospitals; patient-to-patient transmission, vancomycin and cephalosporin overuse	Acute care hospitals; patients, devices, (environment)	Acute care hospitals, dialysis units, (physician's office, community?); hands of health care workers, devices, environment	Endemic, outbreaks in acute care hospitals, LTCF, dialysis units
Vancomycin-resistant *Enterococcus* spp. (Europe)	Avoparcin in livestock husbandry	Livestock, human gut	Food chain, (acute care hospitals)	Sporadic outbreaks in acute care hospitals
Penicillin-resistant *Streptococcus pneumoniae*	Pediatric and adult outpatient office; penicillin overuse	Community; children, adults	Community (schools, kindergarten); interhuman spread	Acute care hospital; community-acquired pneumonia
***Legionella* spp.**	Ubiquitous; man-made water systems	Ubiquitous; man-made water systems	Hospital, (community); exposure of lower respiratory tract with contaminated water	Acute care hospitals, LTCF; community and nosocomial pneumonia

comes from the fact that European VRE have similar resistance patterns as animal VRE and are polyclonal, whereas USA VRE are monoclonal.[29] Vancomycin-resistant enterococci serve as a good example of interaction between different conditions in separated areas of health care with global linkage of HAI problems spinning off from antibiotic abuse in agriculture. Control seems only possible when these interactions are revealed and intervention is multiorganizational.

Methicillin-resistant *Staphylococcus aureus*

Staphylococcus aureus is one of the leading causes of community-and hospital-acquired infection. Methicillin-resistance acquisition and spread is one of the most typical results of recent trends and the complexity of health care. Since its initial detection in Europe in 1960, MRSA has become a leading cause of HAI worldwide. According to molecular typing techniques, five MRSA clones account for almost 70% of over 3000 MRSA isolates recovered in hospitals in southern and eastern Europe, South America and the USA. These five pandemic clones have evolved from only two distinct ancestral genetic backgrounds, one of which can be traced back to the very first European MRSA isolates and also to related methicillin-susceptible *S. aureus* isolates identified in Danish hospitals in the mid-1950s. Isolates close to the epidemic MRSA 16 (EMRSA-16) were also detected in the early Danish isolates. EMRSA-15 and EMRSA-16 are currently responsible for the dramatic increase in the rate of nosocomial infections, in particular bacteremia, observed in the UK. Several MRSA clones are widespread worldwide. Methicillin-resistant *S. aureus* is highly endemic in most hospitals and LTCFs in the USA, the latter being considered major reservoirs of the burden of infection. High endemicity is associated with an increased nosocomial infection rate, increased use of glycopeptides with subsequent risk of suboptimal treatment and emergence of resistance in Gram-positive bacteria, and higher health care costs. Furthermore, since the first clinical isolate of *S. aureus* with intermediate susceptibility to vancomycin (VISA) was reported from Japan in 1996 and subsequently from four different continents, the first case of vancomycin-resistant *S. aureus* (VRSA) infection was confirmed in July 2002 in a patient in the USA.[30]

Patients who require hospitalization in today's modern health care industry tend to be very ill. Not surprisingly, the accumulation of critically ill patients increases the risk for MRSA infections because host factors are undoubtedly serving as indirect markers of frequent patient-staff contact (i.e. risk of transmission of MRSA by hands of personnel). Increased workload, understaffing and overcrowding have been associated with an increased risk for cross-transmission, and MRSA acquisition in particular. The inconsistent application of infection control guidelines, in particular hand hygiene, by hospital personnel largely accounts for the dissemination of MRSA in most institutions, whether acute, chronic or long-term care facilities.

Epidemic MRSA strains imported by unrecognized carriers from one geographic region to another have been repeatedly documented. On-admission screening of high-risk patients and implementation of barrier precautions pending results ('modified quarantine') is practiced systematically in countries where MRSA has been eradicated (e.g. The Netherlands). It is also practiced in certain endemic hospitals and is a cost-effective strategy for controlling transmission; the critical risk factor is direct or indirect exposure to a health care system.

Finally, MRSA has become an incipient community pathogen in many geographic regions with reports from Canada, Australia, the USA and Europe. Thus, unfortunately, after being considered for 40 years as a typical hospital problem, MRSA is now challenging the entire worldwide health care system. To combat this, an urgent need exists for international strategies for MRSA control to be applied by all partners of health care systems.

Penicillin-resistant pneumococci

Resistance of *S. pneumoniae* to penicillin is a widespread and increasing problem and illustrates the individual and community-level effects of antibiotic use on the spread of antimicrobial resistance. Studies of the association between antibiotic use and resistance in pneumococci vary in design, setting and quality.[31] Nevertheless, present evidence suggests that:

- ¦ although recent antibiotic treatment by itself, in particular with ß-lactams or cephalosporins, is not associated with an increased risk for PRSP infection in the individual patient, it makes carriage of these strains more likely than that of susceptible strains; and
- ¦ treatment of carriers of susceptible organisms reduces their infectiveness and carriage duration, but increases the carriage of resistant strains.

In other words, antibiotic treatment indirectly promotes cross-transmission of resistant organisms in the community by reducing the carriage of susceptible strains.

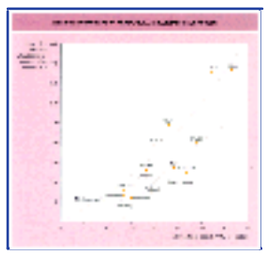

Figure 83-6 Relationship between antibiotic consumption and penicillin-resistant pneumococci. Total use of antibiotics (in daily defined dose (DDD) per 1000 population) is indicated (horizontal axis) and percent of penicillin-resistant *Streptococcus. pneumoniae* isolates. *Data aggregated from several studies and kindly provided by Dr S Harbarth. From Harbarth et al.,[15] with permission.*

Figure 83.6 illustrates the relation between the overall use of antibiotics in different countries and the reported proportion of low-level penicillin-resistant strains among *S. pneumoniae* isolates. This figure cumulates results from aggregated and cross-sectional data from different sources and illustrates the impact of antimicrobial use on resistance acquisition and spread at the population-level.[15] In countries with a significant proportion of PRSP, treatment with broad-spectrum antibiotics, such as oral third-generation cephalosporins, has been used extensively. [32] These drugs, considered as 'reserve drugs' for hospital use only a few years ago, are now recommended for the empiric treatment of community-acquired pneumonia by many experts.[33] Thus, overuse of antibiotics in the community has been the driving force for a major change in prescribing practices at all levels of the health care system, further accelerating the vicious cycle of antibiotic resistance.

Legionella spp.

The ubiquitous nature of *Legionella* spp. in natural aquatic environments, the intracellular survival in protozoa within biofilm, and their multiplication in a wide temperature range around 98.6°F (37°C) make them ideal invaders of water systems.[34] From these reservoirs, pulmonary exposure to aerosols and microaspiration from contaminated water sources constitute the main routes of transmission. Impaired cough and deficient immune function are the major patient-related risk factors, which explains why lower density of water contamination will have a major impact within hospitals, particularly in transplant and ICU patients.[34]

Because of the possibility of a low incidence of cases over a prolonged time related to the same source,[35] legionella surveillance must be active and prospective. On an inter-regional, statewide or international level, this requires an important, rapid and accurate flow of information to detect the common source of seemingly sporadic cases. An international effort has been made in Europe by the EWGLI (European Working Group for Legionella Infections) to detect sources of travel-associated cases (http://www.ewgli.org).

Importantly, as the length of hospital stay decreases, even in the domain of transplantation, high-risk patients are increasingly subject to immunosuppressive treatment at home. Control of the home environment may have to be revised together with other preventive aspects.[36] Surveillance and control of *Legionella* spp. as purely environmental pathogens challenges the linkage between the health care system and public health.

DIAGNOSIS

Surveillance — diagnosing health care defaults

Surveillance for nosocomial infections has been the foundation of infection control in the USA since the 1960s, whereas in Europe and elsewhere it has only been introduced over the past two decades. In the USA, surveillance has become such an integral part of infection control that professionals have to be reminded of its original primary purpose (i.e. to measure the outcome of interest, nosocomial infection), and to design and control interventions targeted at its reduction. [32] In Europe, infection control has been oriented since its inception toward intervention and procedure quality, sometimes on unfounded grounds.

Outpatient infection surveillance is very challenging because of the need to monitor multiple health care systems. Even if infected patients could be traced, denominator data are entirely lacking.[37] Construction of outpatient infection surveillance is only possible

after evaluation of the risk factors and applicability of infection definitions. [38] Novel approaches must be sought that include data already available on public health databases.

Data collection of infection rates always implies comparison. On a microepidemiologic level, this implies comparison of endemic rates over time within the same population before and after an intervention or system change or outbreak detection. Over the past few years, interinstitutional comparison, or 'benchmarking' as it is termed in analogy with industrial quality efforts, is on the rise. Two challenges emerge with benchmarking: case-mix adjustment and standardization of the method.

Health care-associated infections are considered to be one of the most accurate indicators of the quality of patient care. Interhospital benchmarking of nosocomial infection rates is being performed with the aim of improving the effectiveness of health care and promoting patient safety. Similar comparisons might soon be made between different health care settings. However, benchmarking among health care structures requires meticulous adjustment for case-mix. In a recent nationwide study, higher crude infection rates in larger compared with small hospitals suggested a health care quality problem.[39] Further analysis revealed this difference to be due to case-mix; hospital size turned out to be a surrogate marker, but not a risk factor for nosocomial infections. Failure to adjust adequately for infection-associated factors will erroneously punish commitment to more challenging medical tasks and, thus, hinder quality improvement. Hence, it is increasingly vital to have adjustment at hand for comparing infection rates between different health care structures and procedures. This is a field of intense research and expanding knowledge.

Standardization of surveillance method is a second challenge that must be addressed in order to make comparison possible. This obviously clashes with the will to improve and adapt definitions to medical progress and local specificities. Currently, even if standard definitions are applied, it is difficult to compare results due to methodologic variations.[40]

Adjustment should be implemented according to variations in the use of microbiologic investigation within the different health care settings and type of diagnostic techniques applied. Diagnostic power and accuracy largely impact on infection rates. This holds especially true for LTCFs because of budgetary constraints and for private practices because of the use of independent laboratories of uncertain standardization and quality assurance. This concern increasingly includes hospitals because of the trend to outsource microbiologic laboratory tasks.

Voluntary participation in a surveillance network, confidentiality and adequate feedback of the results are the prerequisites for health care settings' adherence to the method and dedication to data quality. Exchange of successful strategies in implementing quality initiatives based on surveillance data are often shared among participants in national networks, and this may represent the major impact of surveillance on infection rates.

MANAGEMENT

The understanding of infection as an indicator of flaws in patient safety and as being an often preventable event concerning all components of the health care system raises the issue of new organizational structures. It is not yet clear how this challenge will be met. Two conceptually different solutions are possible:

- ¦ expanding current duties and activities of hospital-based infection control teams (Fig. 83.7) regarded as centers of excellence to the remainder components of the health care system; or
- ¦ revising the structure entirely and creating government-associated infection prevention units.

However, any combination between these two scenarios can be imagined.

Exporting the product 'infection prevention and control' from hospitals considered as centers of excellence has several attractive aspects. A longstanding experience has accumulated within these services through exposure to everyday problems and the successful implementation of interventional strategies in real life conditions. The entire range of necessary efforts has been met, such as surveillance, outbreak investigation, procedure revision and standardization, and counseling in process and structure design, and has been shown to be cost-effective.

Furthermore, some issues might only be resolved in the controlled environment of the hospital. As an example, assessment of outcome as the gold standard of quality measurement might not be possible beyond this setting for a prolonged period because of the lack of reliable data sources and standardization. However, evidence about the linkage between structure, procedure and infection as the outcome of interest could be substituted by what was learned in the hospital setting. Still, central governmental-funded structures are necessary to ensure co-ordination, communication and guidance as much on a national as on an international level.

Some solutions for out-of-hospital surveillance have been driven by the need to meet the inter-regional, if not global, threat of bioterrorism. There is a parallel between these needs and the expanding interlinkage of the health care system over state and national boundaries. A report describes the use of a commercially available medical record system used by many large medical practice groups in the USA (Epicare; Epic Systems Corporation, Madison, Wisconsin). This system provides real-time data about each outpatient medical contact of a large group of people, which make it suitable as an online bioterrorism alert if a given clinical picture were to appear more frequently.[41] Payment information, which is more readily available in outpatient clinics and physician's offices than in hospitals, represents a further valuable data source for infection follow-up.

In the hospital, the development of computerized patient record systems featuring a standardized data structure provides valuable data more close to the patient (e.g. information on individualized medication, clinical signs and symptoms, nonmedical prescriptions and workload). Eventually, this technical support will be available for the entire health care system. Exploitation of these very heterogeneous data in an even more heterogeneous health care setting calls for powerful tools in data compilation and analysis. Whereas multinational enterprises already make use of more advanced techniques such as data mining, their value for infection control are only just being discovered.[42]

On the front of antibiotic resistance management, a new horizon will open with genetic diagnosis on the pathogen level as much as the host level. Microarray technology, once price and specificity issues are resolved, will provide instant data on carrier state and antibiotic resistance patterns of each subject in contact with the health care system to determine tailored measures for transmission precautions and infection prevention. To cut down on price, modeling will single out the population at risk to be screened. Widespread use of these techniques will deliver more accurate information about microepidemiology and local resistance patterns.

The CDC is planning a new HCW safety network to ultimately include noninfectious adverse events such as medication errors and patient falls. After almost a decade of discussion, this development could finally formalize widespread expansion of infection control beyond its traditional mandate. The aim of the CDC is to promote health care quality in a wide variety of health care settings with the vision to create a web-based knowledge system for accumulating, exchanging and integrating relevant information and resources among private and public stakeholders that support local efforts to

Figure 83-7 Current and future structure of infection prevention programs.

protect patients and promote health care safety. Users are from different types of health care settings, including clinics, health plans and consumers of care. The ultimate goal is to improve patient and HCW safety by providing protocols for monitoring adverse events associated with devices, procedures and medications. Performance improvement will be promoted by providing performance feedback and a free access to prevention tools, lessons learned and best practices. In our opinion, however, such a system would still need infection control practitioners to support care-givers at the bedside in their daily challenge to prevent HAI in today's increasingly complex health care delivery system.

To conclude, events on a local, micro-environmental level determine the evolution of HAIs in a much wider area. Although bacterial resistance is a global problem, its origins can be traced to local events. As René Jules Dubos declared, 'Think globally — act locally'.[43]

Chapter 84 - Prevention of Infection in ICU Patients

Robert A Weinstein
Dennis G Maki

Intensive care units (ICUs) are synonymous with cutting-edge, high-tech medicine; mechanical ventilatory support; hemodynamic monitoring; total parenteral nutrition; hemodialysis; intracranial pressure monitoring; innovative forms of surgery; and a huge arsenal of drugs, especially anti-infectives of every genre. They have improved the care and outcome of patients with trauma, shock states and other life-threatening conditions. However, the complexities of ICU care and the fragile condition of many ICU patients yield rates of hospital-acquired (nosocomial) infection that are 3–5 times higher than rates in other hospital wards. Infection, usually nosocomial, is the most common cause of death, directly or indirectly, of patients who survive major trauma or full-thickness burns and it is the most commonly identified cause of multiple organ dysfunction syndrome.[1]

In the past 15–20 years, we have learned a great deal about the epidemiology of nosocomial infections acquired in the ICU.[2] [3] Evidence-based guidelines for prevention are now available (e.g. at www.cdc.gov/ncidod/hip/GUIDE/guide.htm) and, if applied consistently, these guidelines can reduce the risk of nosocomial infection, in some estimates by over a third. In this chapter, we review the epidemiology, prevention and control of ICU infections in general and the features of three areas of special concern: vascular access-related infections, ventilator-associated pneumonia and antibiotic resistance (Chapter 189). Additional site-specific infection topics and programmatic infection control issues (Chapter 87) and Employee Health Service concerns (see Chapter 83 , Chapter 88) are covered in other chapters.

EPIDEMIOLOGY

Nosocomial infections are estimated to affect more than 2 million patients in US hospitals annually, are a factor in more than 88,000 hospital deaths each year and, in 1992, cost more than $5 billion in excess health care costs. Considering that nosocomial infections acquired by ICU patients account for nearly half of all infections in most US hospitals — and more than half of all nosocomial epidemics now occur among the 10% of hospitalized patients confined to an ICU — progress in reducing the incidence of infection acquired within ICUs could produce substantial economic benefits. The epidemiology of ICU infections and its economic consequences is remarkably similar in many European countries and developed countries in Asia. The situation in ICUs in developing countries is less well characterized and likely to be highly variable depending on the nature of the patient population and access to potentially costly infection control techniques (disposable needles, syringes, gloves, medical devices, hand wash basins, etc.).

The US Centers for Disease Control and Prevention (CDC) has published widely recognized definitions for the purpose of surveillance of nosocomial infection, [4] [5] although for research purposes more stringent definitions are often used, especially for pneumonia. The incidence of nosocomial infection is most commonly expressed as the number of infections per 100 patients hospitalized and is highest in burn, surgical and neonatal ICUs (5–30%), intermediate in medical and pediatric ICUs (5–7%) and lowest in coronary care units (1–2%).[1] [2] [3]

Since the risk of nosocomial infection is heavily influenced by patients' lengths of stay and to facilitate interhospital comparisons, the CDC has advocated the use of infection rates expressed per 1000 patient-days.[3] Because the majority of infections acquired in ICUs are related directly to the use of invasive devices, the CDC has further recommended specific surveillance of device-associated nosocomial infections, reported as infections per 1000 device-days. [3] [6] [7] [8] Representative rates of ICU device-associated nosocomial infection in US hospitals that are members of the CDC's National Nosocomial Infection Surveillance System (NNIS); (Table 84.1) can be used for interhospital comparisons. Such comparisons are an increasing focus of attention from hospital accrediting organizations and third party payers.

Nosocomial infection site-pathogen tropisms in ICUs are well recognized (Table 84.2). Approximately 50% of nosocomial infections in the ICU are caused by aerobic Gram-negative bacilli, especially *Pseudomonas aeruginosa, Enterobacter* spp. or *Serratia marcescens*; 20% are caused by Gram-positive cocci, most commonly coagulase-negative staphylococci, *Staphylococcus aureus* or enterococci; 5–10% are caused by *Candida* spp.; and filamentous fungi such as *Aspergillus* and *Zygomycetes* spp. are being seen increasingly in patients with hematologic malignancy or those who received solid organ transplants. Viruses such as respiratory syncytial virus (RSV) and rotaviruses are important pathogens in pediatric ICUs. *Legionella* spp. now account for up to 10% of nosocomial pneumonias in some centers.

PATHOGENESIS

Patients admitted to ICUs are usually more susceptible to infection because of underlying diseases or conditions associated with impaired immunity, such as cancer, trauma or advanced age, or because of immunosuppression associated with malnutrition or therapy with corticosteroids, cancer chemotherapeutic agents or immunosuppressive drugs. Broad-spectrum antimicrobial agents — administered to the majority of ICU patients for treatment of community-acquired or prophylaxis or treatment of nosocomial infections — increase the likelihood of subsequent colonization or infection by antibiotic-resistant pathogens.[9] Even transfusion therapy may produce immunosuppression and increase the risk of nosocomial infection.[10]

In most cases, colonization is the first step in the progression to nosocomial infection. Understanding the reservoirs and modes of transmission of pathogens and colonization and infection risk factors (see Table 84.2) is essential to developing effective prevention strategies. In the ICU, the major reservoir of nosocomial organisms is the infected or colonized patient and these organisms, most often, are spread on the hands of medical personnel. A few pathogens, most notably *Mycobacterium tuberculosis* and varicella, can be spread by the airborne route.[11] Occasionally, ICU outbreaks result from the

TABLE 84-1 -- Rates of device-related nosocomial infection in US hospital intensive care units, expressed per 1000 device-days.†

RATES OF DEVICE-RELATED NOSOCOMIAL INFECTION IN US HOSPITAL ICUs, EXPRESSED PER 1000 DEVICE-DAYS*			
Type of infection	**Type of ICU**	**Rate (no. of cases per 1000 device-days)**	
		Median	**Range for 10th–90th percentile of hospitals**
Catheter-associated urinary tract infection	PICUs	4.9	0.9–11.1
	MICUs	6.8	1.9–12.2
	SICUs	4.9	1.1–9.3
Ventilator-associated pneumonia	PICUs	4.0	0–11.4
	MICUs	7.4	1.8–15.5
	SICUs	12.3	5.4–25.1
Central line-associated bloodstream infection	PICUs	7.1	1.7–12.8
	MICUs	5.4	1.5–10.2
	SICUs	4.9	1.3–9.8
MICU, medical ICU; PICU, pediatric ICU; SICU, surgical ICU.			

† *Adapted from Alonso-Echanove and Gaynes.*[3]
* *From the CDC's NNIS, January 1992-October 1998; the data include 62 PICUs, 125 MICUs and 146 SICUs.*

TABLE 84-2 -- Profile of common nosocomial infections in the intensive care unit.†

PROFILE OF COMMON NOSOCOMIAL INFECTIONS IN THE ICU		
Infection (% by site*)	**Major pathogens (% within site)**	**Common colonization and infection risk factors**
Urinary tract (17–35)	*Pseudomonas aeruginosa* (7–13) and *Escherichia coli* (14–28)	Urinary catheter
	Klebsiella (6) and *Enterobacter* spp. (5)	Monitoring of urine output
	Enterococci (14)	Other urologic manipulation or bladder irrigations
	Staphylococcus epidermidis	Renal transplantation
	Candida albicans (6–21)	Diabetes
		Female > male

Pneumonia (24–39)	*P. aeruginosa* (14–22)	Tracheostomy
	Klebsiella (7) and *Enterobacter* spp. (2–13)	Endotracheal tube, reintubation
	Serratia marcescens (1–4)	Nasogastric tube
	Acinetobacter spp. (3–6)	Intracranial pressure monitoring
	Staphylococcus aureus (17–21)	Stress ulcer prophylaxis with H_2 blocker or antacids
	Oral anaerobes	Immunosuppression, granulocytopenia
Postsurgical wound or intra-abdominal (5–13)	*S. aureus*	Trauma, especially penetrating abdominal injury
	Escherichia coli and other Gram-negative bacilli	Gastrointestinal or radical gynecologic surgery
	Enterococci	Prolonged operation
	Bacteroides fragilis and other bowel anaerobes	Immunosuppressive therapy
Bloodstream (14–19)		
Catheter related	Coagulase-negative staphylococci (37)	Heavy colonization of insertion site skin
	S. aureus (9–24)	Hemodynamic monitoring
	Candida albicans (3–6)	Exposure of catheter to remote-source bacteremia
Contaminated infusate	*Enterobacter* spp.	Intrinsic (i.e. manufacturer) or extrinsic (i.e. in use) contamination
	Serratia marcescens	
	Citrobacter spp.	
	Pseudomonas cepacia or *Stenotrophomonas maltophilia*	

† *Adapted from Maki and Weinstein[1] and Alonso-Echanove and Gaynes.[3]*
* *Site and pathogen percents are presented, where available, from the CDC's NNIS data[3] ; ranges represent data from pediatric, medical, surgical and coronary ICU.*

presence of a health care provider who is a carrier of an epidemic strain, usually *S. aureus* or group A streptococcus.

Many nosocomial infections acquired in the ICU derive from resistant enteric organisms carried by patients at the time of ICU admission. This explains the failure of conventional infection control practices that are directed at preventing extrinsically acquired infection.[12] Food and even enteral feeding preparations are often heavily contaminated by micro-organisms but studies have only rarely linked such contamination to disease.[13] Nosocomial organisms originating from colonized or infected patients are readily perpetuated and spread in contaminated medical equipment or devices, such as urine collection receptacles, respiratory therapy equipment, chamber domes or transducers used for hemodynamic monitoring, dialysis machines and fiberoptic bronchoscopes. [1]

PREVENTION AND INFECTION CONTROL

Infection control programs (Table 84.3)

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) in the USA and similar regulatory agencies in many other countries mandate that every hospital have an active program for surveillance, prevention and control of hospital-acquired infections. Surveillance of nosocomial infections is the cornerstone of an effective control program. Many hospitals focus their surveillance activities on infections that are associated with high morbidity (e.g. nosocomial pneumonia), that greatly increase health care costs (e.g. postcardiac surgery sternotomy infections), that are caused by antibiotic-resistant organisms with potential for spread (e.g. *C. difficile* colitis) or that are highly preventable (e.g. intravascular device-related bloodstream infections). American hospitals are also regulated by the Occupational Safety and Health Administration (OSHA) in terms of institutional standards and programs to protect health care workers from blood-borne pathogens and tuberculosis; the Environmental Protection Agency provides regulations for disposing and tracking medical waste, only a small fraction of which is truly biohazardous.

TABLE 84-3 -- Aspects of hospital infection control programs that impact intensive care units.[*]

ASPECTS OF HOSPITAL INFECTION CONTROL PROGRAMS THAT IMPACT ICUs
✚ Active Infection Control Committee, with representation from major departments and services, including the ICU(s)
✚ Surveillance of nosocomial infections, especially in each ICU
✚ Comprehensive and regularly updated institutional policies and procedures for:
¦ surveillance of nosocomial infections
¦ isolation precautions
¦ sterilization and disinfection
¦ indications for and management of invasive procedures and devices:
• all types of intravascular catheters
• hemodynamic monitoring
• tracheostomy and endotracheal intubation
• mechanical ventilation and other respiratory therapy
• bronchoscopy and gastrointestinal endoscopy
• anesthesia and the operating room
• hemodialysis
• intra-aortic balloon pumps
• cardiopulmonary bypass
• intracranial pressure monitoring
¦ investigation of an epidemic
✚ Guidelines for use of antibiotics, including ongoing utilization review
✚ Strong liaison with clinical microbiology laboratory:
¦ representation on the Infection Control Committee
¦ laboratory-based surveillance
¦ monitoring and reporting of trends in antimicrobial susceptibility

¦ saving of important isolates
¦ microbiologic support of all infection control activities
¦ subtyping of isolates for investigations or studies
✚ Educational programs for new employees and periodic updates dealing with nosocomial infection control
✚ Active employee health department:
¦ free immunizations (hepatitis B, influenza A, measles, mumps, rubella, varicella)
¦ tuberculin screening
¦ postexposure protocols
✚ Quality assurance review of implementation of infection control policies and practices

** Adapted from Maki and Weinstein.*[1]

All health care personnel working in an ICU must receive training in the epidemiology and control of nosocomial infections. This may be most important for trainees in teaching hospitals, who often have only a rudimentary knowledge of asepsis but have hands-on contact with many patients each day.[14] Caregivers in ICUs must be especially familiar with their hospital's protocols for management of invasive devices, such as intravascular lines, urinary catheters, endotracheal tubes, tracheostomies and external ventricular drains.

Health care workers

Health care workers in general, but especially those working in ICUs who are exposed daily to critically ill patients, many of whom have contagious but undiagnosed infections, are at increased risk of acquiring occupationally related infections. These include tuberculosis, herpetic whitlow, varicella-zoster virus infection, hepatitis A or B, HIV infection, influenza A infection, measles, rubella and viral conjunctivitis. Essential components of employee health activities for ICU staff include pre-exposure vaccination (e.g. for hepatitis B, influenza, measles, mumps, rubella and varicella), postexposure prophylaxis (e.g. for HIV or tuberculosis) where indicated, and education about hand hygiene and isolation precautions (see Chapter 87 for detailed discussion).

Environmental issues

Although the hospital's inanimate environment (e.g. surfaces and walls) does not contribute measurably to the occurrence of most nosocomial infections, some infections, such as those caused by airborne *Aspergillus* spp. and other filamentous fungi in seriously immunocompromised patients, may derive from environmental contamination. Moreover, in ICUs, where virtually all patients are heavily exposed to invasive devices and have a very high risk of infection, the inanimate environment may be a reservoir of resistant nosocomial organisms, such as methicillin-resistant *S. aureus* (MRSA), *Clostridium difficile* and vancomycin-resistant enterococci (VRE).[1] Although the ICU environment cannot be made microbe free, certain architectural and environmental issues warrant attention.[1] [15]

¦ ICUs should be located in areas that limit traffic flow to essential ICU personnel.
¦ Single-patient rooms theoretically may increase the likelihood of hand hygiene being practiced and may improve adherence to isolation practices, reducing the risk of cross-infection.
¦ Because of the large amount of equipment required for the care of many patients, it has been recommended that each cubicle or room should provide a minimum of $11 m^2$ per bed.[16]
¦ A centralized, filtered air-handling system that provides at least six room air exchanges per hour has been recommended.
¦ There must be an adequate number of sinks and dispensers of sinkless alcohol degermer for convenient hand hygiene by all entering personnel who will have or have had contact with the patient or the immediate environment.[17]
¦ Separate areas and sinks should be used for cleaning, for storage and for reprocessing contaminated equipment.
¦ All ICUs should have airborne infection isolation room(s) (i.e. negative pressure and 100% exhaust or HEPA filtration for any recirculated air) for patients with tuberculosis or other airborne infections, such as varicella or measles.
¦ For ICUs that house bone marrow transplant patients or other patients with prolonged severe granulocytopenia, positive-pressure isolation rooms using HEPA filters should be available.
¦ All surfaces contiguous to the ICU patient should be wiped down with the general hospital disinfectant at least daily and urine measuring devices, a frequent reservoir of antibiotic-resistant Gram-negative bacilli, should be rinsed with a disinfectant after each use.

¦ Each ICU patient should have a dedicated stethoscope and sphygmomanometer.
¦ The use of electronic measuring devices on multiple patients in an ICU needs re-evaluation, unless stringent efforts are made to decontaminate the devices after each use.

Disinfection and sterilization

Policies and procedures for disinfection and sterilization are a mundane but essential and often breached component of ICU infection prevention. [18] [19] Numerous epidemics of Gram-negative infection have stemmed from failure of a chemical disinfectant to disinfect reusable medical apparatus, such as respiratory therapy equipment, or failure of an antiseptic to disinfect the skin before insertion of invasive devices. In many outbreaks, the epidemic organisms were cultured from a working solution of the germicide. Most of these outbreaks were traced to use of dilute aqueous solutions of chlorhexidine, quaternary ammonium or phenolic germicides. Even iodophors such as povidone-iodine, in the past the most widely used antiseptics for cutaneous degerming in US hospitals and clinics, have been implicated in epidemics of nosocomial infection due to *Pseudomonas* organisms that contaminated the product in the manufacturer's plant.[20] Numerous epidemics have been traced to contaminated bronchoscopes or endoscopes[21] that were not reliably decontaminated after clinical use, usually because of the use of an unreliable chemical disinfectant, design flaws of automated endoscope washing machines or lack of attention to detail by personnel processing the scopes.

Hand hygiene

The role of hand hygiene in ICU infection prevention must be stressed at all times.[17] Handwashing rates are abysmally low (<30–50%) because of the personnel time required — up to 90 minutes per shift when handwashing is performed by ICU nurses as often as recommended by the CDC — and because of perceived and real damage to the skin of health care workers as a result of repeated soap and water washing. A potential solution, and an opportunity to fulfill the infection control 'prime directive' — use technologic advances to improve behavior — is the use of alcohol-based sinkless hand rubs. Studied extensively in Europe, alcohol-based hand rubs are highly effective degermers that can reduce the time spent on hand hygiene up to 4-fold and can improve the condition of health care workers' hands, thus overcoming the two major barriers to adequate hand hygiene.[17] Although alcohol, when used for handwashing or scrubbing, is perceived by health care workers as causing dry skin, use of alcohol hand rubs without rinsing is beneficial to skin condition, most likely because the protective oils are left in place on the hands when the alcohol dries and because of emollients and moisturizers in the products. In comparisons of alcohol hand rub and medicated soap and water handwashing, health care workers found that the hand rub caused less skin dryness and was readily accessible and convenient to use.

Aggressive hand hygiene campaigns, with adherence monitoring and feedback of ward and individual results, may achieve compliance rates as high as 70%. For some situations (e.g. when there is a large, endemic antibiotic resistance problem and extensive patient colonization by antibiotic-resistant bacteria[9] [12] [22]), these levels of adherence may not be sufficient to control cross-infection. A response to this problem has been to consider use of 'universal gloving', in addition to use of alcohol-based hand rubs (a 'belt-and-suspender' approach), to bridge the gap that is left by incomplete attention to hand hygiene even in the best of circumstances. Use of universal gloving has been successful in controlling spread of aminoglycoside-resistant Gram-negative bacilli in ICUs and *C. difficile*-related diarrhea.[22] Because patients' intact skin and the environment in patient rooms may be a source of resistant bacteria such as VRE, we recommend that disposable examination gloves be worn for all contact with ICU patients or their environment. Because gloves are not a complete barrier, they must be removed and hands disinfected by an alcohol hand rub between patient contacts.

Hand hygiene adherence rates, especially for nursing personnel, decrease as provider-to-patient ratios increase (e.g. when individual nurses are required to care for

two or more critically ill patients).[17] To improve nursing care and the likelihood of hand hygiene adherence, ICUs must have an adequate number of staff. Although the optimal nurse-to-patient ratio in an ICU is not known, one-to-one nursing may reduce risks of cross-infection considerably.

Isolation precautions

Isolation precautions for patients colonized or infected with problem pathogens are used to curtail cross-infections. The CDC's *Guideline for isolation practices in hospitals*[23] separated precautions into 'standard precautions', designed for the care of all patients in hospitals, regardless of their diagnosis or presumed infection status; and additional 'transmission-based precautions', designed for the care of specified patients who are known or suspected to be infected with highly transmissible or epidemiologically important pathogens. Standard precautions are designed to reduce the risk of transmission of micro-organisms from patient to patient and from patient to health care worker, from both recognized and unrecognized sources of infection in the hospital. Transmission-based precautions are divided into three subgroups, based on the mode of transmission: contact precautions, droplet precautions and airborne precautions. Contact precautions are recommended with multidrug-resistant bacteria that can be acquired by contact with the colonized patient or environmental surfaces or objects. Droplet precautions provide additional measures for preventing transmission by large-particle droplets, such as use of face masks by personnel during suctioning or bronchoscopy. Airborne precautions are added to standard precautions for care of patients with tuberculosis and other micro-organisms transmitted by the airborne route.

To contain the spread of certain resistant organisms in the ICU (e.g. MRSA, VRE), 'cohort nursing' is strongly recommended based on empiric evidence and on mathematical models of spread of infection in ICUs.[22] In cohort nursing, the care of patients known to be infected (or determined by surveillance cultures to be colonized) by problem organism(s) is provided by nurses and respiratory therapists who will not provide care during that shift for noninfected patients, and the nursing care of noninfected patients is restricted to personnel who will not have contact with infected patients, except in an emergency.

CLINICAL FEATURES

Vascular catheter-related infection

Intravascular devices are a major source of iatrogenic disease in ICUs, especially bloodstream infections originating from colonization of the device or, less often, from contamination of infusate. Vascular catheter-related bacteremia or candidemia in hospitalized patients is associated with two to three times increased attributable mortality. Most epidemics of nosocomial bloodstream infection derive from vascular access in some form. Probably more than any other nosocomial infection, intravascular device-related bloodstream infection is preventable.[1] [24] [25] [26] [27]

One of the most serious forms of intravascular device-related infection occurs when a thrombus surrounding the catheter becomes infected, creating a septic (suppurative) thrombophlebitis, which often produces overwhelming sepsis with high-grade bacteremia or

fungemia that characteristically persists despite removal of the device. The catheter insertion site is devoid of signs of inflammation more than half the time. The micro-organisms most commonly implicated are the same organisms that cause uncomplicated catheter-related bloodstream infection, namely *S. aureus*, enterococci, nosocomial Gram-negative bacilli and *Candida* spp.

Certain clinical, epidemiologic and microbiologic findings point toward an intravascular device as the source of a bloodstream infection.[1]

- A patient without significant underlying diseases, who is an unlikely candidate for sepsis.
- Lack of another source of infection to account for the picture of sepsis.
- Local inflammation, especially purulence, at the catheter insertion site.
- Abrupt onset, associated with fulminant shock, suggestive of heavily contaminated infusate.
- Sepsis refractory to antimicrobial therapy or dramatic improvement with removal of the device or discontinuation of the infusion.
- Nosocomial bloodstream infection caused by skin flora (e.g. staphylococci, especially coagulase-negative; *Corynebacterium*, especially JK, or *Bacillus* spp.) or by certain fungi (e.g. *Candida, Fusarium, Trichophyton* or *Malassezia* spp.). In contrast, bacteremia caused by streptococci, aerobic Gram-negative bacilli (especially *P. aeruginosa*) or anaerobes is less likely to have originated from infected intravascular devices.
- Bacteremia caused by strains that grow well in infusates — members of the tribe Klebsielleae (e.g. *Enterobacter cloacae* or especially *Enterobacter agglomerans*), non-*aeruginosa* pseudomonads (particularly *Pseudomonas (Burkholderia) cepacia* or *Pseudomonas pickettii*), *Stenotrophomonas maltophilia* or *Flavobacterium* or *Citrobacter* spp. — suggests the possibility of contaminated intravascular fluids. A cluster of cases mandates full-scale investigation, which may include culturing in-use infusions and informing the local, state and federal public health authorities.
- Primary (i.e. no source site identified) nosocomial bacteremia caused by psychrophilic (cold-growing) organisms, such as non-*aeruginosa* pseudomonads, *Achromobacter, Flavobacterium, Enterobacter, Serratia, Salmonella* or *Yersinia* spp., should raise suspicion of a contaminated infusion that is stored at refrigerator temperature, such as a blood product.

TABLE 84-4 -- Rates and risk factors for intravascular catheter-related infections.‡

RATES AND RISK FACTORS FOR INTRAVASCULAR CATHETER-RELATED INFECTIONS			
Type of catheter	**Mean no. of bloodstream infections/100 catheters (95% CI)**	**Risk factors for catheter infection**	**Approximate magnitude of increased risk***
Peripheral iv	0.2 (0.1–0.3)	Cutaneous colonization of site > 10^2 cfu	3.9
		Contamination of catheter hub	3.8
		Moisture on site, under dressing	2.5
		Placement > 3 days	1.8
		Systemic antimicrobial therapy	0.5
Arterial	1.5 (0.9–2.4)	Cutaneous colonization of site > 10^2 cfu	10.0
		Second catheter in site, placed over guide wire	-†
Central venous	3.3 (3.3–4.0)	Exposure of catheter to unrelated bacteremia	9.4
		Cutaneous colonization of site > 10^2 cfu	9.2
		Placement >4 days	-†
Swan-Ganz pulmonary artery	1.9 (1.1–2.5)	Cutaneous colonization of site > 10^3 cfu	5.5
		Internal jugular vein cannulation	4.3
		Duration > 3 days	3.1
		Placement in operating room under less stringent barrier precautions	2.1
cfu, colony-forming units.

* Relative risk or odds ratio
† Indeterminate

Culturing a catheter segment semiquantitatively on solid media or quantitatively in liquid media by removing organisms by sonication provides a strong correlation between high colony counts and catheter-related bloodstream infections.[24] Direct Gram or acridine orange stains of intravascular segments of removed catheters also show excellent correlation with quantitative techniques for culturing catheters and can permit rapid diagnosis of catheter-related infection. Diagnosing infection caused

by contaminated infusate requires that a sample of fluid is aspirated from the line and cultured quantitatively.

Blood cultures are essential to the diagnosis of device-related bloodstream infection and, in any patient suspected of infusion-related sepsis, two blood cultures should be drawn, ideally from peripheral veins by separate venepunctures. If available, quantitative blood cultures drawn by venepuncture from a peripheral vein and concomitantly through the device, that show a =10-fold step-up, can permit the diagnosis of central venous device-related bacteremia or fungemia to be made with sensitivity and specificity in the region of 90%. A shorter incubation time to positivity for blood cultures drawn via the contaminated vascular device versus a simultaneous venepuncture blood sample using automated blood culture systems can also be used as a diagnostic clue to a vascular catheter-related infection.[24]

The intravascular device associated with the greatest risk of bloodstream infection today is the central venous catheter (Table 84.4). These catheters have been shown to be the single most important risk factor for nosocomial candidemia, exceeding serious underlying disease, and 80–90% of intravascular device-related bloodstream infections originate from them.

Considerable evidence suggests that the largest proportion of catheter-related bloodstream infections derives in some fashion from the cutaneous microflora of the insertion site. Hubs of central

venous catheters also are frequently contaminated, particularly by coagulase-negative staphylococci, and can cause catheter-related bacteremia. However, contaminated hubs do not appear to be as important in the pathogenesis of catheter-related sepsis with short-term, non-cuffed catheters as micro-organisms from the skin that invade the intracutaneous catheter tract.[1] [25] [26] With long-term, surgically implanted, cuffed Hickman or Broviac catheters, micro-organisms colonizing the hub and lumen may be the most important source of bloodstream infection deriving from these devices.

Although most catheter-related bloodstream infections originate from infection of the percutaneous catheter tract or contamination of the catheter hub, contamination of infusate is the most common cause of epidemic device-related bloodstream infection and of

TABLE 84-5 -- General recommendations for the prevention of intravascular device-related (IVDR) bloodstream infections (BSIs).†

GENERAL RECOMMENDATIONS FOR THE PREVENTION OF INTRAVASCULAR DEVICE-RELATED BLOODSTREAM INFECTIONS	
Recommendation	**Strength of evidence***
General measures	
Educate all health care workers involved with vascular access regarding indications for use, proper insertion technique and maintenance of IVDs	**IA**
Surveillance	
Routinely monitor ICU rates of IVDR BSI	IA
Determine rates of CVC-related BSI, using standardized definitions and denominators, expressed per 1000 CVC-days	IB
At insertion	
Use aseptic technique	
Observe proper hand hygiene before insertion or manipulation of any IVD	IA
Wear clean or sterile gloves during insertion or manipulation of non-central IVD	IC
Use maximal barrier precautions (mask, cap, long-sleeved sterile gown, sterile gloves and large sterile sheet drape) during insertion of CVCs	**IA**
Use cutaneous antisepsis (chlorhexidine is preferred; however, tincture of iodine, an iodophor or 70% alcohol can be used)	**IA**
Use sterile gauze or a sterile semipermeable polyurethane film dressing to cover the catheter insertion site	IA
Do not use prophylactic systemic antibiotics before insertion or during catheter use to prevent catheter colonization or infection	IA
Maintenance	
Designate trained personnel for insertion and maintenance of IVDs	IA
Remove IVDs as soon as their use is no longer essential	**IA**
Monitor the IVD site on a regular basis, at least daily	IB
Change dressing of CVC insertion site at least weekly	II
Do not use topical antibiotics at insertion sites (except for dialysis catheters)	IA (II)
Clean injection ports with 70% alcohol or an iodophor before accessing the system	IA
Cap all stopcocks when not in use	IB
Replace PIVCs every 72–96 hours in adults	IB
Replace administration sets no more often than every 72 hours (unless lipid-containing admixture or blood products given, in which case administration sets should be replaced within 24 hours)	IA (IB)
Technology	
No recommendation can be made for use of chlorhexidine-impregnated sponge dressing (but do not use in neonates)	NR (II)
If, after consistent application of comprehensive infection control precautions, the institutional rate of CVC-related BSI is above the goal set based on benchmark rates[24] and local factors, use a CVC coated with an anti-infective agent (i.e. chlorhexidine-silver sulfadiazine or minocycline-rifampin) in adults whose catheter is expected to remain in place > 5 days	IB
Do not routinely use antibiotic lock solutions to prevent IVDR BSIs. For individual patients with long-term IVDs in place who have had recurrent IVDR BSIs, despite consistent application of infection control practices, consider the use of a prophylactic antibiotic lock solution (e.g. heparin with vancomycin (25 µg/ml) with or without ciprofloxacin (2 µg/ml))	II
CVC, central venous catheter; PIVC, peripheral iv catheter. Performance indicators that individual institutions should use to monitor their progress in implementing, and the impact of, these recommendations are shown in bold print.	

† *Adapted from CDC.*[24]
* IA, strongly recommended for implementation and strongly supported by well-designed experimental, clinical or epidemiological studies; IB, strongly recommended for implementation and supported by some experimental, clinical or epidemiologic studies and a strong theoretical rationale; IC, required by state or federal regulations, rules or standards; II, suggested for implementation and supported by suggestive clinical or epidemiologic studies or theoretical rationale; NR, no recommendation for or against use at this times.

approximately half of the endemic bloodstream infections caused by arterial infusions used for hemodynamic monitoring. Arterial set-ups may be particularly at risk because their infusions consist of a stagnant column of fluid subjected to frequent manipulations, especially entries for drawing blood specimens.

Prevention of vascular catheter- and infusion-related infections must be a primary focus of ICUs. Recommended, evidence-based measures from the CDC's Healthcare Infection Control Practices Advisory Committee (HICPAC) and from other expert groups[24] [25] [26] [27] should inform these efforts (Table 84.5). The HICPAC has recommended that hospitals use four specific 'performance indicators' (highlighted in Table 84.5) tom monitor their success in implementing the vascular catheter prevention guidelines. [24]

Ventilator-associated pneumonia

Nosocomial pneumonia in ICU patients is largely ventilator associated (VAP), although aspiration pneumonia related to surgery or other procedures in nonventilator patients may occur occasionally. The diagnostic criteria and tests for VAP include clinical criteria; qualitative and quantitative endobronchial cultures; bronchoalveolar lavage (BAL) or culture of protected specimen brush samples obtained by bronchoscopic techniques; and specimens, including bronchial washings, mini-BAL and protected specimen brush samples, obtained by blind nonbronchoscopic procedures.[1] [28] [29] Clinical criteria (e.g. fever, leukocytosis, purulent secretions, new or changing radiographic infiltrate) have high sensitivity but relatively low specificity. They are most useful for initial screening for VAP and for selecting patients for invasive procedures, such as BAL, that have sensitivities and specificities in the region of 80%.

Rates of VAP in NNIS hospital ICUs, based largely on clinical diagnostic criteria, range from 0.7 cases per 1000 ventilator-days in coronary care units to 26 cases per 1000 ventilator-days in trauma units.[30] [31] It has been estimated that nosocomial lower respiratory tract infections, which largely represent VAP, prolong hospital stay for an average of 6 days and increase hospital costs by approximately $6000, based on 1992 dollars. Although mortality rates in patients who have VAP are 20–50%, the attributable mortality rates are in the range 6–14%, suggesting that a patient's risk of dying from VAP is affected greatly by other factors, most importantly comorbid conditions, inadequate antimicrobial therapy and specific nosocomial pathogens (particularly *P. aeruginosa* and *Acinetobacter* spp.). Of note, most interventions that have been effective in reducing VAP rates have not decreased ICU mortality, further suggesting that patients who die during the course of VAP may be dying with, rather than because of, the pneumonia.[1] [28] Nevertheless, VAP is associated with more nosocomial deaths than is infection at any other body site.

Based on clinical diagnosis, the most common pathogens isolated from pneumonia in patients in ICUs are *S. aureus, P. aeruginosa, Enterobacter* spp. and *Klebsiella pneumoniae*, with varying prevalences depending on the type of ICU.[30] [31] Early-onset VAP, which manifests within the first 4 days of hospitalization, is more often caused by community-acquired pathogens, such as *S. pneumoniae* and *Haemophilus* spp. When invasive techniques are used to diagnose VAP, the frequency of recovery of enteric Gram-negative bacilli decreases from 50–70% of isolates to 35–45%. Ventilator-associated pneumonia is polymicrobial in as many as 20–40% of cases. The role of anaerobic bacteria in VAP is not well defined.

Pathogens that cause VAP fall into two broad categories: endogenous and exogenous organisms. Endogenous organisms, largely Gram-negative bacilli and typical community-acquired pulmonary pathogens such as *S. pneumoniae* and *Haemophilus* spp., colonize the oropharyngeal mucosa. The role of the 'gastro-pulmonary' axis in causation of VAP has been controversial. In general, it appears that oropharyngeal bacteria, rather than gastric bacteria, are the major source of pathogens in VAP. Exogenous organisms are brought to patients mostly on inadequately disinfected hands of health care workers, who transmit bacteria and fungi between patients. Other potential exogenous sources include inadequately disinfected or sterilized respiratory therapy equipment, contaminated multidose medication vials and inadequately disinfected nebulizers or other devices or equipment that may be shared among patients. Risk factors for the development of VAP include those events that increase the risk of colonization by potential pathogens, that heighten the possibility of aspiration of oropharyngeal contents into the lower respiratory tract and that reduce the host defense mechanisms in the lung and permit overgrowth of aspirated pathogens.[1] [28] [29]

TABLE 84-6 -- Recommendations for the nonpharmacologic prevention of ventilator-associated pneumonia.[?]

RECOMMENDATIONS FOR THE NONPHARMACOLOGIC PREVENTION OF VAP			
Prevention strategy	**Recommended for clinical use**	**Grade***	**Recommended by CDC†**
Effective strategies			
Removal of nasogastric or endotracheal tube as soon as clinically feasible	Yes	C	Yes
Use of a formal infection control program	Yes	C	Yes
Proper hand hygiene between patient contacts	Yes	B	Yes
Semirecumbent positioning of the patient	Yes	B	Yes
Avoidance of unnecessary reintubation	Yes	C	NSA
Provision of adequate nutritional support	Yes	C	NSA
Avoidance of gastric overdistention	Yes	B	Yes
Oral (non-nasal) intubation	Yes	D	No
Scheduled drainage of condensate from ventilator circuits	Yes	C	Yes
Continuous subglottic suctioning	Yes‡	A	No
Maintenance of adequate pressure in endotracheal tube cuff	Yes	C	Yes
Ineffective strategies			
Routine changes of ventilator circuit	No	A	No

† NSA, not specifically addressed. CDC recommendations are described in reference. [29]
§ This strategy is recommended for specific groups of patients described in the studies cited.

are aimed at reducing rates of colonization by potential pathogens, such as by use of selective digestive decontamination, have been relatively problematic. For example, selective decontamination has reduced rates of VAP caused by Gram-negative bacilli, without consistently altering mortality rates in ICUs. Use of sucralfate, rather than histamine type 2 blockers or proton pump inhibitors, for stress ulcer prophylaxis, with a goal of maintaining gastric pH and thereby suppressing gastric colonization by potential VAP pathogens, initially appeared to be a promising preventive strategy but this was not effective in a large, multicenter, randomized trial.[28] [29] Preventive measures aimed at reducing the risk of aspiration, particularly by semirecumbent positioning of patients, have been among the more successful and less costly strategies.

Antibiotic resistance and control

There is a global crisis in antibiotic resistance that reflects in large measure the heavy use of systemic antibiotics worldwide over the past 30 years.[9] [22] [32] Antimicrobial therapy has its greatest ecologic impact in the close confines of the ICU. Antibiotic pressure, which promotes the exchange of genes encoding drug resistance by a variety of transfer mechanisms, has been shown to be the single most important factor predisposing patients to nosocomial infection with resistant organisms. [32] Modern-day ICUs are the breeding grounds for MRSA, VRE and *Enterobacter, Serratia, Citrobacter, Proteus-Providencia* spp. and *P. aeruginosa* that are resistant to aminoglycosides, fluoroquinolones or extended-spectrum ß-lactams. Broad-spectrum antimicrobial therapy is the root cause of antibiotic-associated diarrhea and colitis caused by *C. difficile*. The recent report of a clinical isolate of a fully vancomycin-resistant MRSA should be a wake-up call for even the most complacent physicians. The ICU component of the CDC's NNIS system demonstrates the major rates of bacterial resistance in ICUs (Fig. 84.1).

In epidemiologic and clinical studies of antibiotic resistance, there are a proportion of patients in whom resistance emerges without exposure to the problem antibiotic. These patients usually have other important risk factors, such as increased severity of underlying disease, extremes of age, presence of invasive devices, recent surgery or proximity to patients who are infected or colonized with antibiotic-resistant bacteria. In these cases, the presence of antibiotic-resistant strains is most often attributed to indirect patient-to-patient spread, usually on contaminated hands of health care workers; occasionally, spread results from a contaminated common source, such as an inadequately cleaned piece of equipment or a colonized worker.[1] [9] [22] [32]

Stemming the tide of antimicrobial resistance requires a multifaceted approach (Table 84.8), especially in ICUs, where antibiotic pressures, lapses in hospital hygiene and the close proximity of high-risk patients are usually greatest.

CONCLUSION

It is clear that nosocomial infection is one of the most important causes of iatrogenic morbidity and mortality in patients who require prolonged life support care in an ICU. Strategies to increase adherence to hand hygiene, to prevent patient colonization and to prevent infection once colonization has already occurred should be a major focus of ICU staff attention and a research priority. The importance of hand carriage of pathogens by hospital personnel, the role of airborne transmission in the ICU and the relevance of contamination of the inanimate hospital environment by resistant pathogens need to be better delineated. Larger and more sophisticated studies, using multivariate techniques of statistical analysis to define risk factors and attributable morbidity and mortality for the major *endemic* nosocomial infections and pathogens in the ICU, are needed to guide allocation of infection control resources and to target future research efforts. More effective ways to communicate essential information on nosocomial infection control to hospital personnel, especially with regard to hand hygiene, aseptic use of devices and antibiotic therapy, and to apply control measures more consistently in all hospitals would have vast immediate benefits.

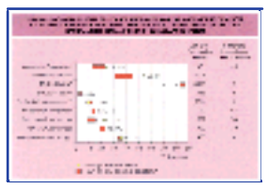

Figure 84-1 Antimicrobial resistance. Summary of antimicrobial resistance among common pathogens identified from ICU patients with nosocomial infections in hospitals participating in the CDC's NNIS. *From: http://www.cdc.gov/ncidod/hip/NNIS/ar_surv99.pdf*

TABLE 84-8 -- Multifaceted approach to control of nosocomial antimicrobial resistance.*

MULTIFACETED APPROACH TO CONTROL OF NOSOCOMIAL ANTIMICROBIAL RESISTANCE
✚ Active surveillance for resistance
✚ Molecular typing (e.g. pulsed-field gel electrophoresis) of resistant bacteria if rates increase
✚ Aggressive campaigns to improve hand hygiene
¦ Alcohol hand rub between patient (or environmental) contacts
¦ Universal gloving; gloves must be changed between patients (an adjunct and not a substitute for hand hygiene)
¦ Monitor adherence and give ward and health care worker-specific feedback of adherence rates
✚ Prevention of device-related infections (see Table 84.3 , Table 84.5 , Table 84.6 , Table 84.7)
✚ Stewardship of antimicrobial use
¦ Clinical guidelines for therapy of common infections
¦ Monitor appropriateness and need for continuation of therapy; give concurrent feedback
¦ Antibiotic restriction program
¦ Computer-based provider order entry
¦ Consider antibiotic cycling for ICUs (for control of specific resistance problems)
¦ Monitor adherence; give feedback
✚ For continued, increasing or difficult-to-control resistance
¦ Routine surveillance cultures to detect colonized patients (the 'resistance iceberg')
¦ Contact precautions for colonized and infected patients
¦ Cohort nursing for colonized and infected patients if contact precautions do not control spread

Chapter 85 - Infection in Burn Patients

David J Barillo
Albert T McManus

EPIDEMIOLOGY

Thermal burns are less common than other forms of trauma but are unique in the production of the most severe physiologic stresses seen in any form of traumatic injury. It is estimated that 2 million people are burned annually in the USA, resulting in the need for 500,000 emergency department visits, 74,000 hospital admissions and 20,000 admissions to specialized burn treatment facilities.[1] Approximately 6500 people die each year from burns or exposure to fire in the USA.

Burn trauma is classified by depth of injury, extent of body surface area involvement and associated injuries:

- first-degree burns involve only the epidermal layer of skin, usually heal without medical intervention and normally do not become infected — they are not included in estimations of burn size for the purposes of determining triage, need for fluid resuscitation or for survival estimates;
- second-degree (partial thickness) burns involve varying layers of the dermis, and whether they heal without operative intervention depends upon depth of injury; and
- third-degree (full thickness) burns involve the full thickness of dermis and normally require operative debridement followed by split thickness skin grafting or other techniques to achieve wound closure.

The mortality rate of burn injury is proportional to the age of the patient and the size of the cutaneous second- and third-degree burn. Burn injury is poorly tolerated in the young, the elderly and in those with pre-existing chronic medical illness. For example, a burn sustained by an elderly diabetic while soaking a neuropathic foot in hot water may represent less than 3% total body surface area but can easily evolve into a limb-threatening or life-threatening injury if treatment is inadequate or delayed.

The mortality rate from burn injury has decreased significantly over the past half century, primarily because of improved control of burn wound infection through the use of topical antimicrobial agents and aggressive surgical debridement. The LA_{50} (percentage body surface burned associated with a 50% mortality rate) now exceeds 80% in selected age groups. The combined effects of burn size and age on predicted mortality rate are demonstrated in Figure 85.1 .

Infection remains the most frequent cause of morbidity and death in burn patients.[2] Although the incidence of invasive burn wound infection has significantly decreased, other infections, particularly pneumonia, remain a problem. Injury to the lungs from exposure to smoke is a significant co-morbid factor, and predisposes the patient to nosocomial pneumonia.[3]

The American Burn Association has established criteria for the referral of patients who have thermal injury to specialized care facilities (Table 85.1). These criteria, endorsed by the Advanced Trauma Life Support and Advanced Burn Life Support programs,[4] [5] represent the standard of care in developed countries. The infectious disease specialist is often the first consultant to see the burn patient in a community hospital setting. Referral to a designated burn center may be the optimal approach in this situation.

PATHOGENESIS AND PATHOLOGY

Burn injury produces profound alterations in homeostasis, which are proportional to the size of the cutaneous injury. Virtually every organ system is affected, and changes in the cardiovascular and immunologic systems are particularly pertinent.

Thermal injury results in a significant and sustained hypermetabolic response. The causes of post-burn hypermetabolism are poorly understood but may be related to a centrally mediated release of catecholamines, glucagon and cortisol. [2] Severe burn injury can result in resting metabolic rates that are twice normal levels, causing nutritional depletion if sufficient exogenous calories are not supplied. Burn hypermetabolism persists until the burn wounds are closed,[2] a process that may require several weeks.

The initial cardiovascular response to burn injury is a decrease in cardiac output along with an increase in systemic vascular resistance secondary to hypovolemia. With appropriate fluid resuscitation cardiac output returns to a normal level within 24 hours of injury. During the second 24 hours, the patient becomes hypermetabolic and cardiac output increases to supernormal (2–2.5 times predicted normal) levels. The elevation of cardiac output is accompanied by a reciprocal drop in systemic vascular resistance to 40–80% of normal levels.[6] Cardiac output remains elevated until the burn wounds are closed.[2] The stress on the cardiovascular system may precipitate myocardial infarction, particularly at the peak of the hypermetabolic response (1 week post-burn).[2] It cannot be overemphasized that the pattern of elevated cardiac output and decreased systemic vascular resistance is a normal response to thermal injury, and is not, of itself, indicative of sepsis.

The hypermetabolism of burn injury results in increased heat production, elevation of core temperature and a central upregulation of the thermoregulatory set point. Fever in the burn patient is thus often physiologic and not related to infection. Burn patients have poor temperature autoregulation while their wounds are still open. Loss of skin integrity results in high heat losses to the environment. Despite the hypermetabolic and thermogenic nature of burn injury, such patients may become hypothermic if the ambient temperature is not increased to compensate for these losses. The evaluation of hypothermia in the burn patient should start with consideration of an environmental cause.

A final consequence of burn hypermetabolism is the increased clearance of many medications, including antibiotics and anticonvulsants. Patients treated with standard doses of medications pre-injury cannot be assumed to retain therapeutic levels on the same doses post-injury. Drug dosing should be based upon repeated serum measurements if these are available. Likewise, administration of therapeutic antibiotics at dosages effective for nonburn populations will often result in subtherapeutic levels in burn patients. Antibiotic administration, particularly of aminoglycosides and vancomycin, must be guided by frequent measurements of peak and trough serum levels.

Thermal injury suppresses cell-mediated immunity. One benefit of this immunosuppression is the ability to use allogeneic skin grafts (cadaver skin) as a temporary skin substitute without fear of early

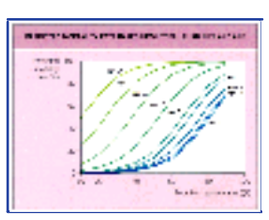

Figure 85-1 Predicted mortality rate based upon total burn size and age.

TABLE 85-1 -- American burn association criteria for referral to a burn center.[4] [5]

AMERICAN BURN ASSOCIATION CRITERIA FOR REFERRAL TO A BURN CENTER
Second- and third-degree burns >10% body surface area (BSA)
Third-degree burns of any size
Second- and third-degree burns involving face, eyes, ears, hands, feet, genitalia, perineum, or overlying major joints
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with pre-existing medical conditions that could complicate management, prolong recovery or affect mortality rate
Burn injury with associated trauma
Burn injury in patients with special social, emotional or rehabilitative needs, including suspected child abuse or neglect

graft rejection.[2] The multiple immunologic consequences of burn injury are well described[2] [7] [8] [9] [10] [11] and are summarized in Table 85.2 . An important point is that leukocyte counts in the range of 14,000–18,000 cells/ml or higher may be seen in burn patients in the absence of infection. The trend of white blood cell elevation rather than an isolated white blood cell elevation should alert the clinician to the possibility of infection.

A final immunologic consequence is the need for multiple transfusions of blood products. Transfusion is known to produce immunosuppression and may serve as a source of blood-borne pathogens. A study of 594 burn patients with a burn size over 10% body surface area surviving for more than 10 days showed an average transfusion rate of 19.7 units of packed red cells per patient.[12] A significant association exists between infectious morbidity and number of transfusions, independent of burn size or patient age.

In summary, a variety of metabolic events conspire to make the timely diagnosis of infection difficult in the burn patient. Hyperthermia, hypothermia, leukocytosis, tachypnea, tachycardia, disorientation, glucose intolerance and positive wound surface cultures are all seen in the absence or the presence of infectious processes, and are not sufficient to diagnose burn wound infection.[2]

TABLE 85-2 -- **The impact of thermal injury on the immune system.**

THE IMPACT OF THERMAL INJURY ON THE IMMUNE SYSTEM		
Circulating	IL-1	Initial increase in serum levels followed by decreased production
		Increased local production at sites of inflammation
	IL-2	Suppressed production
	TNF-a	Increased serum levels in severely infected burn patients
	IL-6	Increased serum levels in severely infected burn patients, increased local production at sites of inflammation
	Neopterin	Serum levels increased (non-specific marker of macrophage stimulation)
	Immunoglobulins	Decreased serum levels in first week
	Prostaglandin E_2	Increased serum levels
	Thromboxane B_2	Increased serum levels
	Activation/depletion of alternative complement pathway	
	Secondary elevation of fibronectin levels	
	Reduction in serum opsonic activity	
Cellular	Initial leukopenia (margination) followed by leukocytosis	
	Generalized activation of circulating granulocytes by multiple pathways	
	Depression of neutrophil chemotaxis, phagocytosis and bactericidal activity	
	Depression of helper T cells	
	Generation of suppressor inducer T cells in animal studies	
	Increased production of suppressor effector T cells in animal studies	
	Suppression of IL-2 production by lymphocytes	
	Activation of macrophages	
Other	Loss of cutaneous skin barrier to infection	
	Smoke inhalation — increased risk of pneumonia (impaired mucociliary clearance mechanisms, defective alveolar macrophage function, distal airway obstruction, alveolar collapse, segmental atelectasis, increased requirements for airway intubation and mechanical ventilation)	
	Requirement for long-term intubation of bladder and vascular system	
	Nutritional deficits	
	Impairment of reticuloendothelial system function	
	Multiple blood transfusions	
IL, interleukin; TNF, tumor necrosis factor.		

PREVENTION

Several steps may be taken to reduce the risk of infectious complications in the burn population. As with any intensive care unit patient, infectious complications are reduced by:

- the prompt extubation of respiratory, cardiovascular and genitourinary systems when clinical condition allows;
- the provision of adequate nutrition; and
- the timely mobilization of the patient to prevent pressure sores and atelectasis.

The use of single-room isolation for burn patients delays the onset of colonization with *Pseudomonas aeruginosa* and reduces the incidence

of wound infection, bacteremia and pneumonia associated with this pathogen.[13] Topical use of mafenide acetate in association with the avoidance of any pressure on the external ear reduces the incidence of suppurative chondritis.[14] The incidence of suppurative thrombophlebitis is decreased by the regular rotation of intravenous cannulation sites. At burn centers all indwelling venous lines should be replaced at the time of admission (if started outside the burn center) and every 3 days thereafter by fresh venipuncture.[15] Line changes over guidewires are not performed. The incidence of nosocomial pneumonia is decreased by the use of high-frequency percussive ventilation, which facilitates the removal of endobronchial secretions and allows adequate ventilation at lower airway pressures than conventional techniques.[15] [16] A bronchopneumonia incidence of 29.3% was reported in burn patients treated with high-frequency percussive ventilation compared with 52.3% in a

matched cohort treated with volume-cycled ventilation.[16]

Burn patients are prone to stress ulcers of the gastrointestinal system, and this process can be minimized by treatment with antacids and H_2 -blocking agents. In one study nosocomial Gram-negative pneumonia occurred more frequently in patients requiring mechanical ventilation who received antacids and H_2 -blocking agents than in a similar cohort receiving sucralfate.[17] Gram-negative colonization of the stomach secondary to elevation of gastric pH was a postulated mechanism. The study group was predominantly patients who had nontraumatic illness. A second study by Cioffi and associates was limited to burn patients.[18] Antacid and H_2 -blocker therapy was prospectively compared with sucralfate. No differences in rate of colonization of the respiratory or gastrointestinal tracts were observed, but a higher incidence of nosocomial pneumonia and upper gastrointestinal bleeding occurred in the sucralfate group.[18] A drug that could prevent gastric ulceration while maintaining a sufficiently low gastric pH to prevent colonization would be ideal for the prophylaxis of stress ulceration in burn patients. At present, a drug with these characteristics remains to be developed.

CLINICAL FEATURES

Organisms causing infections

The history of burn wound infection has been largely influenced by therapeutic and environmental factors. Before the development of antimicrobial agents and the use of fluids to resuscitate the burn patient, essentially all those with serious burns died within a short period from the consequences of hypovolemic (burn) shock. Those patients who remained in hospital after the initial shock period were subject to streptococcal infection. It is this group of organisms that was targeted by Lister and others for topical protection for open burns with antiseptics. With the recognition of the requirement for resuscitation, patients who have severe burns began to survive the initial post-burn period. This new patient population with large wounds that remained open for months led to the development of specialized burn centers, which were established at large hospitals and by the military. The traditional hospital open-ward design was adapted for burn care and little could be done to prevent cross-contamination. The situation of general ward care, large open wounds and the introduction of expanding generations of antimicrobial agents often resulted in wound infection by antimicrobial-resistant microbial pathogens. By the 1960s burn centers worldwide experienced infections from *P. aeruginosa* and other opportunists with intrinsic resistance to many antibiotics and with the capacity to acquire and propagate resistance mechanisms against newer generations of antimicrobials. Burn centers often gained notoriety for having a high incidence of infection and antimicrobial resistance.

With the recognition of the significance of cross-contamination and the necessity to improve patient isolation, the design of most

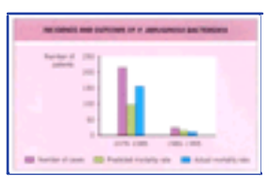

Figure 85-2 Incidence and outcome of *Pseudomonas aeruginosa* bacteremia over a 20-year period.

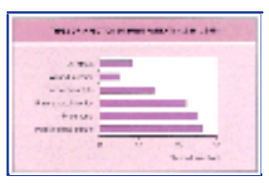

Figure 85-3 Types of infections in burn patients (1986–1995).

modern burn centers has changed to single rooms for the intensive phase of burn care. This change occurred at our burn center in 1983 and markedly changed the incidence, etiology and outcome of burn wound infections.[13] [19]

In subsequent reviews the continued prevention of previously common infections with multiply resistant organisms and improved survival has been documented. [20] An example of such change is presented in Figure 85.2 . These data document the incidence and outcome of *P. aeruginosa* bacteremia during the past two decades. In the first decade, the incidence of this infection was 9.4% and the mortality rate in bacteremic patients was 73%. When this mortality rate is compared with that predicted for severity of injury alone, an excess attributable mortality rate of 61% is realized.[13] During the current decade, the incidence of this infection has dropped to 1.2% of admissions and the mortality rate noted is not different from that predicted based on severity alone.[20]

The review of infections and their causes in the past decade is presented in Figure 85.3 and Figure 85.4 . As can be seen, wound invasion, the hallmark of burn infections for many decades, has been reduced to 5% of infections.

Coincident with a decline in bacterial wound infection, an increase in the incidence of fungal infection has been seen. A histopathologic review of all burn autopsy data at our institution between the years 1960 and 1969 showed a 10-fold increase in the incidence of wound infections caused by *Phycomycetes* and *Aspergillus* spp. coincident

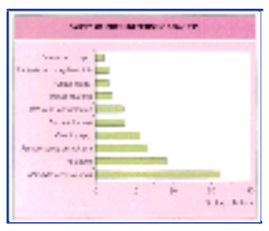

Figure 85-4 Causes of infection.

with the introduction of mafenide acetate burn cream in 1964.[21] More recent experience between the years 1979 and 1989 demonstrates a marked decrease in the incidence of bacterial wound infection, attributable to patient isolation, topical chemotherapy and surgical wound excision.[22] Interestingly, the incidence of fungal wound infection did not change during the same period. Bacterial and fungal wound infections were associated with large body surface area burns (mean 62.4% total body surface area (TBSA) burn for fungal infection and 54.4% TBSA for bacterial infection) and an increased incidence of smoke inhalation injury (74.5% of patients with fungal infection vs 70.6% of patients with bacterial infections). The immunosuppression of burn injury may predispose patients to fungal infection, which is difficult to prevent given the ubiquitous nature of fungi in the environment.[22] Indiscriminate use of systemic antibacterial agents in the absence of documented infection may suppress normal bacterial flora and result in fungal superinfection.

The burn wound

An understanding of the burn wound is key to an understanding of the burn patient. The physiologic, metabolic and immunologic changes seen in burn injury are proportional to the size of the cutaneous wound and do not return to normal until the burn wound is successfully closed. The burn wound is the first site to examine when sepsis is suspected.

The thick leathery nonviable coating of a burn is termed eschar. Burn eschar is warm, protein rich, moist and avascular, and represents an excellent culture medium that is unaffected by parenterally administered antibiotics or by circulating elements of the immune system.[2] [15] For this reason, the eschar of full thickness burns should be surgically excised as quickly as possible. Burn eschar normally becomes colonized with the patient's own flora (Gram-positive bacteria) within 3–5 days of injury.[9] This initial colonization is subsequently replaced by Gram-negative flora present in the hospital unit over a variable interval. The principal concern is eventual colonization of the subeschar space. When bacterial densities at the interface of eschar and underlying viable tissue reaches a level of 1×10^5 /g of tissue, wound infection with systemic microbial spread is likely.[2] The goals of burn wound management are to contain microbial colonization to a manageable level with topical agents pending surgical debridement and wound closure with skin autografts or other modalities.[2]

Figure 85-5 Contact plate used for wound surveillance cultures. The culture media is lifted out of the Petri dish by the attached sterile gauze, placed in contact with the burn wound, and then returned to the Petri dish for incubation.

Because the presence of bacteria in the burn wound per se is not a pathologic finding, a number of specialized procedures and terms have been developed to quantify the potential for wound infection. Burn wound colonization is the term given to the presence of microorganisms within the eschar. As the eschar is avascular, colonization 'does not imply an unavoidable and active local or systemic infection'. [9] Burn wound invasion occurs when micro-organisms invade viable tissue adjacent to the burn eschar. True invasive burn wound infection is rarely seen in most burn centers when topical antimicrobial agents are properly and promptly employed. Invasion accompanied by a positive blood culture or by distant spread of micro-organisms or toxic products is termed burn wound septicemia.[9]

Diagnostic modalities include swab or plate cultures of the burn wound surface, cultures of debrided tissue, quantitative wound cultures and histologic examination of the burn wound. Cultures of the burn surface or of debrided tissue are useful for epidemiologic purposes to document resident flora in the event of true infection.[2] [7] Surface cultures should be performed with contact plates (Fig. 85.5) rather than with swabs in order to sample a larger and more representative area and to avoid errors relating to prolonged incubation of the swab in transport media.[23] Quantitative wound cultures[24] or counts of colony forming units (cfu) per gram of tissue have limited the diagnostic modality in burn wound care. A negative quantitative culture (bacterial density $<10^5$ cfu) correlates well (96.1% negative predictive power) with absence of invasive infection on histopathologic tissue evaluation; however, the agreement between positive cultures and positive histologic examination is only 35.7% (positive predictive power).[25] Thus, only a negative quantitative culture has clinical significance.

The *sine qua non* of wound evaluation is histopathologic examination of a biopsy specimen to determine the presence of micro-organisms in viable tissue.[2] This is performed as a bedside procedure under local anesthesia. A 500mg sample of eschar (ellipse measuring 1–2cm) is excised to include the underlying viable tissue and submitted for microbial and pathologic analysis.[2] [23] Using a frozen section technique, results are available in 30 minutes.[26] The frozen section technique has a 3.6% false-negative rate, and should be confirmed by examination of permanent sections.[23] [26] A rapid section technique that produces permanent sections in 4 hours has been described. [27] Results with either technique are communicated to the clinician using standardized nomenclature (Table 85.3).

TABLE 85-3 -- Histologic classification of burn wound colonization and infection.

HISTOLOGIC CLASSIFICATION OF BURN WOUND INFECTION		
Class 1 - Colonization	1A Superficial	Superficial bacterial colonization of the wound
		Micro-organisms present on wound surface
	1B Penetration	Penetration of the eschar by bacteria in variable thickness of eschar
	1C Proliferation	Multiplication of micro-organisms present in the subeschar space
Class 2 - Invasion	2A Microinvasion	Micro-organisms present in viable tissue immediately subjacent to subeschar space
	2B Generalized	Multifocal or widespread penetration of micro-organisms deep into viable tissue
	2C Microvascular	Involvement of small vessels and lymphatics

The use of effective topical antimicrobial agents has decreased the incidence of true invasive wound infection. The percentages of infection-related deaths attributed to wound infection has decreased from 25.5% in 1979 to as low as 5.1% between 1987 and 1991.[15] [28]

Pneumonia

As the incidence of wound infection decreases, pneumonia has emerged as the most frequent septic complication of burn injury.[15] With better microbial control of the burn wound, the route of pulmonary infection has changed from hematogenous to airborne, and the predominant radiographic pattern has changed from nodular infiltrates to bronchopneumonia.[15] Smoke inhalation injury results in mucociliary dysfunction, atelectasis, ventilation-perfusion mismatch and impairment of polymorphonuclear leukocyte function. These defects in pulmonary function increase the risk of pneumonia nearly 5-fold.[2] [7] The effects of inhalation injury and pneumonia on predicted mortality rate in burn injury are independent and additive: inhalation injury increases expected mortality rate by up to 20%; pneumonia increases mortality rate by up to 40%; and the combination of inhalation injury and pneumonia increases mortality rate by up to 60%.[3] For this reason, prevention of pneumonia has become a prime concern in patients who have smoke inhalation injury. As discussed earlier, the use of single-room isolation, volume diffusive ventilation techniques and certain stress ulcer prophylaxis regimens may be associated with a lower risk of nosocomial pneumonia.

Criteria used at our burn center for the diagnosis of pneumonia in the burn patient are presented in Table 85.4 . Cases that meet criteria for diagnosis but lack radiographic evidence of an infiltrate are termed tracheobronchitis. Surveillance sputum cultures obtained three times per week provide an indication of the predominant organism when pneumonia or tracheobronchitis is diagnosed, allowing timely administration of an appropriate antibiotic. Pathogens commonly associated with bronchopneumonia in burn patients include *P. aeruginosa* and *Staphylococcus aureus*. The emergence of Gram-positive organisms as the predominant cause of bronchopneumonia has been a recent trend in many burn centers.[15] Staphylococcal pneumonia usually responds well to vancomycin. Our

TABLE 85-4 -- Diagnostic criteria for pneumonia or tracheobronchitis.

DIAGNOSTIC CRITERIA FOR PULMONARY INFECTION	
Pneumonia	1) Clinical findings consistent with pneumonia (i.e. pleuritic chest pain, fever, purulent sputum or other signs of sepsis)
	2) More than 25 polymorphonuclear leukocytes on methylene blue stain of endotracheal secretions with less than 25 squamous epithelial cells per 100× field
	3) Radiographic findings consistent with pneumonia
	4) Positive sputum cultures (confirmatory but not essential for diagnosis)
Tracheobronchitis	As above without radiographic evidence of infiltrate

Figure 85-6 Clinical appearance of suppurative chondritis.

preference is to treat Gram-negative pneumonia with double antibiotic coverage, usually an aminoglycoside along with a broad-spectrum ß-lactam antibiotic (see Chapter 35).

Suppurative chondritis

Burns to the ears may result in secondary infection of the cartilage. This process, termed suppurative chondritis, occurs in partial and full thickness burns, has a peak incidence between 3 and 5 weeks post-burn, and may occur after skin healing is completed.[14] Before the widespread use of mafenide acetate, chondritis occurred in

20–25% of patients who had ear burns.[14] [29] This incidence has decreased to 0–3.3% when burned ears are treated with this agent.[14] Silver sulfadiazine does not penetrate eschar well and is not as effective in the prevention of chondritis.

Suppurative chondritis has a rapid onset, manifesting as a throbbing ear pain poorly relieved by narcotics.[29] Over several hours the external ear becomes edematous with loss of the normal surface features of the antihelix and scapha (Fig. 85.6). Edema may create the appearance of the external ear being more prominent or anterior displaced compared with the contralateral side. The pathogens responsible may be polymicrobial, with *Pseudomonas* spp. involved in 83–95% of cases and *Staphylococcus* spp. involved in 55%.[14] Intravenous antibiotics are ineffective because the ear cartilage does not have an intrinsic blood supply and diffusion from the perichondrium is impaired by edema. Treatment of chondritis is surgical.

Figure 85-7 Bivalve excision of infected cartilage.

Figure 85-8 Vein resection for suppurative thrombophlebitis.

Early cases may respond to local debridement, whereas established chondritis often requires a disfiguring bivalve incision with removal of a majority of the ear cartilage (Fig. 85.7). Wounds are packed open with fine mesh gauze soaked in an antimicrobial solution, then allowed to close by granulation.

Suppurative thrombophlebitis

Suppurative thrombophlebitis occurs in up to 1.4–4.2% of burn patients.[30] Although the overall incidence is low, burn patients are at particular risk secondary to the need for long-term intravenous cannulation and to skin colonization with burn pathogens. The diagnosis is suggested by a positive blood culture in the absence of any obvious source. Clinical examination of current and previous intravenous cannulation sites is undertaken, although local signs of infection, including cellulitis, are present in only 35% of patients who have infected vessels. When the diagnosis is in doubt, surgical exploration is indicated. Infection is most frequently found at the vein site adjacent to the catheter tip; however, proximal migration and skip lesions are common, and the suspected vein should be excised proximally to the point at which the vessel becomes a tributary of the next larger order of veins (Fig. 85.8). In selected patients, resection may be terminated at a point at which the vein appears normal, has a lumen free of clot or intimal thickening and demonstrates brisk bleeding. The resected vessel should be sent for histologic and micro-biologic analysis (Fig. 85.9). Failure to clear bacteremia after vein

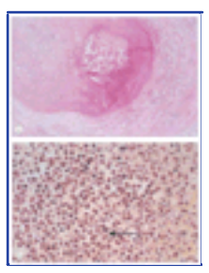

Figure 85-9 Suppurative thrombophlebitis. (a) Histologic section of excised vein demonstrating thrombus. (b) Micro-organisms (Gram-positive cocci) present within the thrombus (arrow).

excision should prompt consideration of exploration of other vessels. Septic thrombophlebitis of central vessels is usually treated with systemic anticoagulation and intravenous antibiotics because surgical excision is impractical.

Other infections

Sinusitis is a concern in burn patients because of the need for prolonged intubation of one or both nostrils. Nasotracheal intubation is the preferred airway access in burn patients for reasons of comfort and safety,[31] and nasojejunal tube feeding remains the method of choice for delivery of nutrients. The presence of sinusitis is suggested by headache, facial pain or purulent nasal discharge, although the diagnostic accuracy of clinical examination has been estimated to be only 60%. Plain film radiographs of the sinuses, particularly when taken with portable equipment, are difficult to interpret and add only 10% diagnostic accuracy to the clinical examination; for this reason the preferred diagnostic modality is computerized tomography scan of the sinuses. Treatment of sinusitis is removal of nasal tubes and administration of decongestants and culture-specific antibiotics. Antral puncture is infrequently required and should be reserved for patients who do not respond to conventional treatment (see Chapter 32 for further discussion on sinusitis).

Acute infective endocarditis is diagnosed in 1.3% of burn patients. [15] The right side of the heart is more commonly affected than the left; the offending organism is usually *S. aureus*. Heart murmurs are difficult to hear in burn patients, who are normally hyperdynamic, tachycardiac and frequently have their chest covered with dressings.

The diagnosis is usually made with transesophageal echocardiography. Intravenous antibiotics are instituted and continued for 6 weeks after the last positive blood culture. The management of endocarditis is reviewed in detail in Chapter 59 .

MANAGEMENT

Burn patients are prone to infection by virtue of loss of immune function and skin integrity. The daily care of burn patients requires meticulous infection control practices to avoid nosocomial infection. A microbial surveillance system is important to allow timely and exact diagnosis of infection and to guide antibiotic use. Because of the danger of superinfection from antibiotic-resistant organisms, the administration of antibiotics should strictly follow established protocols. The empiric administration of systemic antibiotics for fever, leukocytosis or non-specific 'sepsis' in the absence of a known infectious source should be strongly discouraged. [15]

The nursing care of burn patients requires adherence to barrier precautions and reverse isolation techniques appropriate for the immunosuppressed. The use of an open dressing technique (application of topical antimicrobial to the burn without overlying dressings) allows earlier identification of potential wound infection and is the standard of practice at many burn centers. The use of open dressings or the changing of closed dressings requires all personnel entering the patient's room to wear gowns, head covers and gloves.[13] Barrier precautions have the added benefit of protecting the staff from occupational exposure to blood-borne pathogens. Medical supplies and equipment should not be moved from room to room, and stethoscopes are provided in each room to avoid cross-contamination.

The use of single-bed isolation for burn patients is desirable. Compared with open-ward housing, single-bed isolation significantly delays the onset of colonization with *P. aeruginosa* by 10 days and decreases the incidence of bacteremia, pneumonia and burn wound invasion.[13] A delay in colonization may decrease morbidity and the mortality rate because the patient may be more likely to resist infection later in their hospital stay as wound healing progresses.

Resistance isolation is used when a patient is identified as harboring a bacterial organism with multiple antibiotic resistance or when a patient is transferred after being

an inpatient in another hospital for 7 days or more. Under resistance isolation, nursing staff are assigned to the same patient every day and normally do not enter the room of any other patient. Supplies are arranged to maximize patient care with minimal traffic in and out of the room, and physician care proceeds from non-isolated to resistance-isolated areas as the patient condition allows. Personnel providing resistance-isolation care must change all garments, including scrub clothing, before entering other areas of the hospital. Under optimal conditions, nurses providing resistance-isolation care are not reassigned to other patients until 48 hours after exposure to the isolated patient.

The microbial surveillance system in use at this and certain other burn centers[9] consists of thrice weekly cultures of sputum, wound surfaces and urine of all patients. The surveillance system allows timely identification of patterns of antibiotic resistance, identifies nosocomial spread of flora and facilitates the rational choice of antibiotic when infection is identified. In general, the antibiotic sensitivities of flora seen in the burn center are different from similar species isolated from other nursing care units, and the regular hospital antibiogram should not be relied upon when choosing antibiotics. If a full burn surveillance system cannot be established, an alternative is to produce an antibiogram specific for isolates from the burn treatment unit.

Care of the burn wound centers on debridement of nonviable tissue and prevention of infection. Wounds are cleansed twice daily with chlorhexidine gluconate solution and then placed in 'alternating agents' consisting of mafenide acetate cream during the day and silver sulfadiazine cream at night. The combination of mafenide and silver sulfadiazine reduces the incidence of complications and drug resistance compared with that seen when either agent is used alone. Mafenide acetate provides the best penetration into nonviable eschar and may be employed as a single agent when the wound is obviously full thickness or when invasive infection is suspected. The advantages and disadvantages of this and other topical antimicrobial agents are summarized in Table 85.5 .

The entire wound surface must be inspected at least daily for signs of infection.[2] Wound care should be provided in the individual patient's room to avoid cross-contamination between patients. Hydrotherapy or wound debridement in a Hubbard tank is no longer performed at most burn centers.

The ultimate goal of burn care is permanent wound closure. To this end, surgical excision of full thickness and deep partial thickness wounds commences 3–5 days after the burn injury and continues on a frequent basis until the entire burn is excised. Split thickness autografts harvested from unburned skin surfaces are used to cover the excised area. When donor sites are insufficient, temporary wound closure is performed with cadaver allograft or biosynthetic dressings. Donor sites may generally be reharvested every 10–14 days, allowing eventual replacement of temporary coverage with the patient's own skin.

Special considerations

Surgical prophylaxis

Topical antimicrobial agents such as silver sulfadiazine and mafenide acetate do not sterilize the burn wound and are intended only to keep microbial colonization of the burn eschar to manageable levels. Surgical excision and grafting therefore involves manipulation of colonized tissue, and perioperative antibiotic coverage would seem prudent. Despite this, there is little agreement among burn practitioners regarding the need for surgical prophylaxis or choice of agent, and few recent studies upon which to base recommendations.

A survey of 51% of all USA burn centers (*n*=68) conducted by Worrell *et al.* demonstrated that 46% use surgical prophylaxis in all patients and 20% do not use prophylaxis for any patient. [32] The remaining 34% base selective prophylactic decisions on factors such as cellulitis, suspected soft tissue infection or type of surgical procedure. Cefazolin as a single agent is the most common antibiotic used for prophylaxis. This drug provides poor coverage of the flora commonly present in the burn eschar. Burn excision and grafting procedures commonly result in significant blood loss, requiring intraoperative transfusion of multiple units of blood products. Despite this, only 20% of respondents re-dose antibiotics intraoperatively based upon length of procedure, and 2% re-dose based upon blood loss.

Studies in the 1970s demonstrated that the incidence of bacteremia following burn excision and grafting procedures ranged from 20.6 to 46%.[33] [34] The surgical management of burns has changed considerably since the time of these studies. More recently, Mozingo *et al.*[35] prospectively studied the incidence of bacteremia during burn wound care and during surgical excision procedures. The incidence of new bacteremia following wound cleansing and wound excision was 9.5 and 15.8%, respectively. No bacteremia occurred in any patient with total burn size under 40% of total body surface area when excision was undertaken within the first 10 days post-burn.

Clinically, there is no question that burn wound excision and grafting procedures may result in postoperative circulatory instability and a 'septic' picture in certain patients, even when appropriate perioperative antibiotics are used. On this basis, we advocate perioperative coverage with antibiotics based upon specific culture results of the patient in question or upon surveillance cultures or burn center

TABLE 85-5 -- Topical antimicrobial therapy of the burn wound.

TOPICAL ANTIMICROBIAL THERAPY OF THE BURN WOUND		
Agent	**Advantages**	**Disadvantages**
Mafenide acetate 11.1% cream	Best eschar penetration, most widely studied agent; broad spectrum, bacteriostatic against Gram-positive and Gram-negative, especially effective against *Pseudomonas aeruginosa* and *Clostridia* spp.; no Gram-negative resistance	Painful to apply on partial thickness burns; metabolic acidosis from carbonic anhydrase inhibition; accentuates hyperventilation; minimal coverage of yeasts; poor coverage of *Providencia* spp.; most effective when utilized with open dressing technique
Mafenide acetate 5% aqueous solution	Good eschar penetration; useful in wet dressings to facilitate debridement; especially effective on wound bed after eschar removal; effective dressing for open granulating wounds or over meshed autografts	Requires wet dressings; may contribute to hypothermia; not Food and Drug Administration approved in USA
Silver sulfadiazine 1% cream	Painless on application; good Gram-negative and yeast coverage; infrequent hypersensitivity; may be used with open or closed dressings; may be combined with nystatin to increase yeast coverage	Poor eschar penetration; transient leukopenia; poor or no coverage of *Enterobacter, Klebsiella, Clostridia* and some *Pseudomonas* spp.; plasmid-mediated resistance to this agent may extend to other antimicrobials
Silver nitrate 0.5% solution	Bacteriostatic against a broad spectrum of Gram-positive, Gram-negative and yeast-like organisms; effective for patients with toxic epidermal necrosis syndrome or burn patients allergic to sulfa drugs	Little to no eschar penetration; precipitates on tissue contact; works best on minimally colonized or debrided tissue; stains tissue, clothing and bedlinens; causes hyponatremia, hypokalemia and hypocalcemia; wet dressings may contribute to hypothermia; poor coverage of *Klebsiella* and *Providencia* spp.
Sodium hypochlorite 0.025% solution	Bactericidal against a broad spectrum of Gram-positive and Gram-negative organisms; inexpensive	Must be freshly compounded; requires wet dressings, which may contribute to hypothermia
Gentamicin sulfate 0.1% cream	Broad spectrum	Rapid emergence of resistant organisms; no longer in common use
Nitrofurazone 0.2% cream	Effective against *Staphylococcus* spp. (including methillin-resistant *Staphylococcus aureus* (MRSA)) and nonpseudomonad Gram-negative organisms	Poor coverage of *Pseudomonas* spp.
Mupirocin 2% cream	Effective against Gram-positive organisms, including MRSA; effective against some Gram-negative enteric organisms; useful for graft infection secondary to *Staphylococcus* spp.	Expensive; not a first-line therapy
Nystatin 100,000 units/g	Effective against *Candida* spp. and most true fungi	No antibacterial coverage
Clotrimazole 1% cream	Broad-spectrum antifungal effective against *Candida, Trichophyton* and *Microsporum* spp.; minimal systemic absorption from topical use	No antibacterial coverage; poorly absorbed through normal skin; eschar penetration unknown

antibiogram indicating the flora and sensitivities likely to be present. In our current practice, perioperative antibiotic coverage is usually undertaken with vancomycin added to an appropriate aminoglycoside.

Use of vancomycin in the burn center

The emergence of Gram-positive pathogens that are resistant to vancomycin is a growing concern. As a result, many institutions have instituted special methicillin-resistant *S. aureus* (MRSA) isolation procedures or restricted the prescription of vancomycin. Neither policy is necessary nor desirable in the burn center. In most cases, antibiotic use in the burn center is both selective and conservative, and in most burn centers effective isolation procedures are already in place. In addition, the methicillin sensitivity of *S. aureus* recovered from burn patients does not impact on outcome. Furthermore, at least one study (see discussion below) has demonstrated that the appropriate use of vancomycin in a burn center is not associated with the emergence of significant bacterial resistance to this drug.

Burn patients are immunosuppressed and at increased risk of infection secondary to large open wounds. For this reason, most burn care providers take exceptional care with infection control measures. Effective isolation and barrier techniques have been used in burn centers for over 50 years, both preceding and exceeding those mandated by universal precautions, body substance isolation or MRSA isolation. As an example, the resistant organism isolation techniques elsewhere mentioned in this chapter are instituted when a patient is transferred to the burn center following hospitalization in another facility. These additional infection control measures are continued until surveillance cultures demonstrate absence of pathogens that are multiple-drug resistant.

The significance of MRSA colonization and infection was examined in 1100 consecutively admitted, seriously burned patients in whom vancomycin was used to treat all staphylococcal infections.[36] Colonization with *S. aureus* was identified in 658 patients, including 319 patients with MRSA. Infection with *S. aureus* was documented in 178 patients, including 58 with MRSA. Survival of either group was the same as predicted solely on basis of age and burn size; there was no increase in mortality rate attributed to MRSA infection. On this basis, the study questioned the economic or clinical usefulness of added infection control practices for MRSA.

The long-term use of vancomycin in burn patients is not associated with the development of significant resistance of either *S. aureus* or *Enterococcus* spp. strains. McManus *et al.*[37] reported resistance patterns in burn patients from the USA Army Institute of Surgical Research/Burn Center at Brooke Army Medical Center. As part of a microbial surveillance program, all patients are cultured three times a week, including wounds, sputum, urine and gastrointestinal aspirate or stool. In a study of 2266 consecutive admissions between 1986 and 1995, there were 15,125 Gram-positive isolates, including 957 enterococci. Vancomycin resistance was found in only six of the 15,125 isolates, including three isolates positive for vancomycin-resistant

enterococci, two *Corynebacterium* and one *Lactobacillus* spp. Vancomycin was not used in three of these patients and none of the vancomycin-resistant organisms was associated with infection. In the absence of routine surveillance cultures, none of these organisms would have been clinically apparent. The lack of vancomycin resistance in this population is more remarkable for the fact that vancomycin had been used in this burn center for virtually every Gram-positive infection and most surgical prophylaxis since 1978.

Vancomycin remains a first-line antibiotic in the burn center. In view of the fact that methicillin sensitivity of *S. aureus* infection in burn patients does not appear to impact upon outcome, and because burn isolation techniques are routinely used for all patients, the usefulness of the term 'MRSA' in contemporary burn practice is questionable.

Diagnostic investigation of the potentially septic burn patient

As previously mentioned, the presence of fever, leukocytosis, elevated cardiac output, low systemic vascular resistance and positive wound surface cultures all represent 'normal' physiology in the burn patient. These clinical features may exist in the absence of sepsis, and thus are not diagnostic per se of infection. Nevertheless, given the fact that infection remains the major source of burn morbidity and death, careful and repeated examination for septic foci is indicated in this population.

Acute infection may be suggested by the presence of any of the above findings, or more commonly by a change in hemodynamic status, body temperature or clinical condition. Increased need for ventilatory support or the new onset of ileus, glycosuria or glucose intolerance also indicates the need for a 'septic workup'. We do not consider acute burn patients to be febrile until core (rectal or pulmonary artery catheter thermistor) temperature exceeds 102.5°F (39.2°C) and do not perform 'fever workups' below this level. An exception is the patient with nearly closed burn wounds who has previously returned to a 'normal' (98.6°F/37°C) body temperature; such patients are considered febrile by the usual criteria.

A 'septic workup' starts with a complete physical examination. In addition to the usual examination of the ears, oropharynx, sinuses, lungs and abdomen, specific attention should be directed at the burn wound (see below) and to any current or previous site of intravenous cannulation. Rectal examination should be performed to rule out prostatitis in males and perirectal disease in both sexes. Cultures of blood, sputum and urine are obtained, along with a chest radiograph. A time frame of initial presentation of infection by site is presented in Figure 85.10 .

Intra-abdominal processes producing sepsis include acalculous cholecystitis, bowel ischemia or necrosis, pancreatitis and, rarely, perforation of a gastric or duodenal ulcer. Pancreatitis or cholecystitis is evaluated by abdominal ultrasound. Triple contrast (nasogastric/rectal and intravenous) computerized tomography scan of the abdomen may be useful. We have found diagnostic peritoneal lavage, as normally performed for acute abdominal trauma, to have a sensitivity of 0.86, a specificity of 1.00 and an overall accuracy of 94% in the diagnosis of intraperitoneal infection in burn patients;[38] this technique remains our primary diagnostic modality for the abdomen.

Children may develop idiopathic fevers in the 103°F (39.5°C) range early in the course of burn care. The fever usually resolves without a source being identified; however, all febrile burned children should be carefully examined with particular attention paid to the middle ears, oropharynx and urinary system. Asymptomatic colonization of the pediatric oropharynx with Lancefield Group A ß-hemolytic streptococci is a theoretic concern because spread of streptococci to the burn wound can result in a rapidly spreading cellulitis

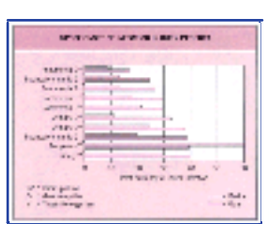

Figure 85-10 Day of onset of infection in burn patients.

or loss of previously placed autograft. Some advocate the prophylactic administration of penicillin to pediatric[39] or 'most' (pediatric and adult) burn patients.[40] Given the low incidence of ß-hemolytic streptococcal infection in burn patients, such routine prophylaxis is probably unjustified.[41] [42] A middle course is to obtain pediatric throat cultures or antigen tests at the time of admission, and to administer penicillin to only those children for whom group A streptococci are isolated.[29]

Electrical injury is a special category of burn trauma where extensive muscle necrosis may occur along the route of current passage. Because the external position of the skin allows rapid heat dissipation, it is common to encounter necrotic muscle covered by entirely normal appearing skin. The investigation of fever or sepsis in the electrical injury patient should include prompt surgical exploration of body regions known or suspected to be involved if another septic source is not immediately apparent.

Positive blood cultures in the absence of wound infection should prompt examination of intravenous cannulation sites and consideration of endocarditis. When a single positive blood culture is inconsistent with the clinical picture, treatment may be deferred pending repeat culture results.[2] Two blood cultures positive for the same organism that are uncontaminated by passage through the burn wound should be treated with systemic antibiotics even in the absence of systemic signs.[2] Gram-negative bacteremia, but not Gram-positive bacteremia, in burn patients is significantly associated with an increased mortality rate.[43] The association of fungemia with an increased mortality rate is equivocal.[43]

Radionucleotide studies such as indium or tagged leukocyte scans, in general, are of little use in the burn patient. Areas of open burn wound or skin donor sites will frequently concentrate isotope, making interpretation difficult.

Evaluation and treatment of the burn wound as a possible source of sepsis

The burn wound should be examined on a daily basis at least and at the first sign of systemic infection. Cellulitis is diagnosed by the presence of expanding erythema at the margins of the burn wound. Erythema surrounding second- or third-degree burn injury that does not increase in size may also represent areas of first-degree burn. Burn wound cellulitis usually responds well to a penicillin. [2]

True burn wound infection is suspected based upon signs such as early eschar separation, conversion of partial thickness to full thickness

Figure 85-11 Invasive pseudomonal burn wound infection, stage 2C.

injury, subeschar hemorrhage, degeneration of granulation tissue, dark red, brown or black discoloration of eschar (Fig. 85.11), violaceous discoloration of the unburned skin at the wound margins or ecthyma gangrenosum (green discoloration of subcutaneous fat due to pseudomonas infection).[2] [7] Diagnosis of invasive wound infection is confirmed by wound biopsy and histologic examination. When invasive bacterial infection (stage 2A, 2B or 2C) is diagnosed, the wound should be continuously covered with mafenide acetate cream and all other agents discontinued.[7] Systemic antibiotics are then instituted based upon the predominant organism in the biopsy specimen or on surveillance cultures; Gram-negative organisms are most frequently implicated.[2] The wound should be surgically excised as soon as possible.[7] Subeschar injection of systemic antibiotics (clysis) is a useful adjunct and should be performed upon diagnosis and repeated both 6 hours prior to and immediately prior to surgical excision of the burn eschar.[2] [44] One half of the daily dose of a semisynthetic penicillin (piperacillin or carbenicillin) may be mixed in sufficient diluent (1 liter of normal saline) for injection through a 20-gauge spinal needle.[7] [44] Clysis may be repeated twice a day for patients too unstable to tolerate surgical excision.[2] [44]

Fungal infection

Aspergillus, Candida, Mucor and *Rhizopus* spp. are the most common fungal infections of the burn wound. Wound colonization involving *Candida* spp. is commonly treated with topical nystatin or clotrimazole although few studies have addressed the effectiveness of these agents in burn care.[2] [22] *Aspergillus* spp. characteristically produce superficial colonization or infection amenable to local surgical excision.[2] *Mucor* spp. may produce a rapidly spreading fascial infection with early microvascular involvement. [2] Radical surgical debridement or amputation may be required to control this type of infection.[2]

We reserve the use of systemic antifungal therapy for cases where disseminated or systemic fungal infection is known or suspected, or when wound biopsies are positive at a 2C level.[22]

Chapter 86 - Infectious Complications Following Surgery and Trauma

Philip S Barie
Soumitra R Eachempati

Whether inflicted by accident, with malevolence, or as a consequence of treatment, tissue injury substantially increases the risk of infection for several reasons. The host response to injury is immunosuppressive — transgression of natural epithelial barriers (e.g. skin, respiratory mucosa, gut mucosa) creates a portal of entry for invasion by potential pathogens; tissue injury and ischemia provide optimal conditions for bacterial proliferation, especially if cofactors such as blood or a foreign body are present; well-intentioned therapies can have adverse consequences; and lapses of infection control often occur under emergency conditions. These risks can be apportioned as patient-derived risks, environment-derived risks or treatment-derived risks. Owing to the multiplicities and complexities of trauma and critical surgical illness, it can be appreciated that these risks are additive and that the danger for patients is high.

Some infective complications are unique to surgery (e.g. surgical site infections (SSIs), infection of traumatic wounds and burns, postoperative intra-abdominal infections), whereas others potentially affect all patients, although especially so in the surgical setting (e.g. nosocomial pneumonia (NP)). The approaches to diagnosis and management reflect the general principles described throughout this book; what is different in the surgical environment is, first, that it can be particularly difficult in surgical patients to distinguish sterile inflammation with or without bacterial colonization from invasive infection, and, second, that prevention of infection is of particular importance, especially after trauma and before high-risk elective surgery.

The incidence of infection following surgery or trauma is context-sensitive. The incidence of SSI following minor, clean, elective surgery is approximately 2%, and that of other infectious complications is practically nil.[1] In contrast, the overall incidence of infection following major trauma is about 25%.[1] [2] Infection is common, and the leading cause of late deaths after injury (i.e. among patients who die neither from exsanguination nor massive central nervous system injury) is the development of multiple organ dysfunction syndrome (MODS).[3] [4] [5] It is generally estimated that the development of nosocomial infection, especially with a multidrug-resistant pathogen, increases the risk of death 3- to 5-fold,[5] but the attribution of mortality to infection is controversial and not universally accepted.[6] In short, do critically ill or injured surgical patients die *of* infection or *with* it? Is nosocomial infection possibly just a marker of host immunosuppression and organ dysfunction?

PATIENT-DERIVED RISK FACTORS

Risk factors that result from intrinsic attributes of the host are listed in Table 86.1 . Among these factors are age, chronic medical conditions (especially diabetes mellitus) and hypocholesterolemia. The contribution of age to infection risk is increasingly being recognized.[7] [8] In a multicenter, preoperative risk assessment for the development of postoperative pneumonia, age was found to be the most powerful independent predictor of risk.[7] Substantial evidence indicates that perioperative hyperglycemia increases the risk of infection,[9] [10] [11] even if mild or transient. Failure to maintain euglycemia during open heart surgery triples the risk of sternal wound infection, [9] whereas a serum glucose concentration over 220mg/dl (12.2mmol/l) at any point on the first postoperative day quadruples the risk of SSI after major non-cardiac surgery.[10] A randomized study of critically ill surgical patients demonstrated that tight control of blood glucose (<120mg/dl (6.6mmol/l) vs 180–220mg/dl (10–12.2mmol/l)) reduced mortality by nearly 50%.[11] Hypocholesterolemia is rapid and dramatic after surgical stress,[12] and it has been associated with an increased risk of SSI and pneumonia[13] and independently with an increased risk of death in critically ill patients with systemic inflammatory response syndrome (SIRS).[14] The possible mechanisms underlying this risk are several, including dysfunction of lipid-laden macrophages or decreased binding of endotoxin by apolipoproteins.

The surgical stress response

Surgical stress is associated with a stereotypical response.[15] The stress hormone response to surgical stress or tissue injury augments cardiovascular function through the sympathetic nervous system, enhances glycogenolysis, mobilizes peripheral lean tissue and fat for use as fuel, enhances coagulation to limit hemorrhage, and stimulates a proinflammatory cytokine response to begin the process of tissue repair. Cellular immunity is depressed in large part by the actions of cortisol. Three major events characterize the initial inflammatory response:

- activation of coagulation;
- increased microvascular endothelial permeability with tissue edema formation; and
- chemotaxis, margination and transvascular migration of neutrophils.

The first step in the process is recognition of a foreign antigen, either by elements of the adaptive immune system (e.g. T cells, preformed antibodies) or by innate immune elements (e.g. phagocytic cells, alternative pathway of complement, coagulation). The development of inflammation is then amplified in a complex process regulated by cytokines, plasma enzymes (e.g. complement, coagulation, kinin and fibrinolytic pathways), lipid mediators (e.g. prostaglandins, leukotrienes) and mediators derived from mast cells and platelets. Fast-acting mediators, such as vasoactive amines and bradykinin, modulate the immediate response. Several hours later, mediators such as leukotrienes, chemokines and platelet-activating factor are involved in the accumulation and activation of phagocytes. Once neutrophils have arrived at a site of inflammation, they release mediators that, in turn, control the later accumulation and activation of monocytes and macrophages.

The acute-phase response is a dynamic homeostatic process that involves all of the major systems of the body, notably the immune, cardiovascular and central nervous systems.[16] Normally, the acute-phase response lasts only a few days. Two physiologic responses are closely associated with acute inflammation. The first involves the alteration of the temperature set point in the hypothalamus and the generation of fever. The second involves alterations in metabolism and gene expression in the liver. Interleukin (IL)-1, IL-6 and tumor necrosis factor-a regulate the febrile response through the induction of

TABLE 86-1 -- Host factors that contribute to the development of nosocomial infection.

HOST FACTORS THAT CONTRIBUTE TO THE DEVELOPMENT OF NOSOCOMIAL INFECTION
Ascites
Chronic inflammation
Corticosteroid therapy (controversial)
Obesity
Diabetes mellitus
Extremes of age
Hypocholesterolemia
Hypoxemia
Peripheral vascular disease (especially for lower extremity surgery)
Postoperative anemia
Prior site irradiation
Recent operation
Remote infection
Skin carriage of staphylococci
Undernutrition

prostaglandin E2, possibly as a protective mechanism against bacterial infection (see Chapter 80). At the same time, IL-1 and IL-6 act on the hypothalamic-pituitary-adrenal axis to generate corticotropin and stimulate cortisol production. This provides a negative feedback loop, because corticosteroids inhibit cytokine gene expression.

The second important aspect of the acute-phase response is altered hepatic protein synthesis. Normally, the liver synthesizes numerous plasma proteins at steady state concentrations. In the acute phase of tissue injury or inflammation, production of several proteins is upregulated, whereas synthesis of others is suppressed. Acute-phase reactants (APRs) thus may be 'positive' or 'negative'. Most positive APRs are induced several-fold over normal concentrations. This group includes, among others, fibrinogen, clotting elements, protease inhibitors, complement components, serum amyloid A and C-reactive protein. Negative APRs (e.g. albumin) are decreased in plasma concentration during the acute phase response to allow an increase in the capacity of the liver to synthesize the induced APRs. Although most APRs are synthesized by hepatocytes, some are produced by other cell types such as myeloid cells, endothelial cells, fibroblasts or adipocytes.

Acute-phase reactants contribute to host defense in several ways, including direct neutralization of inflammatory mediators, thereby minimizing tissue damage and facilitating tissue repair. For example, increased synthesis of complement proteins mobilizes neutrophils and macrophages. Fibrinogen plays an essential role in hemostasis and the promotion of wound healing. Protease inhibitors (e.g. a_1 -antitrypsin) neutralize the lysosomal proteases released following the infiltration of activated neutrophils and macrophages, thus mitigating the activity of the proinflammatory enzyme cascades. Increased plasma concentrations of metalloproteases help to prevent iron loss during infection and injury, minimize the amount of heme iron available for bacterial metabolism, and scavenge reactive oxygen species. There is evidence that elderly patients have a blunted acute-phase response,[16] and that minimally invasive surgery attenuates the response (see Chapter 2).[17]

PATHOGENESIS OF INFLAMMATION AND ORGAN DYSFUNCTION

The acute response to injury is characterized by a syndrome of:

- fever (=100.4°F (38°C)) or hypothermia (=96.8°F (36°C));
- leukocytosis (>12,000/µl), leukopenia (<4000/µl) and excess bands (>10% immature neutrophils);

¦ increased heart rate (<90 beats/minute); and
¦ increased respiratory rate (>24/minute) or, if mechanically ventilated, $P_a CO_2$ <32mmHg.

Figure 86-1 Conditions associated with systemic inflammatory response syndrome. The complex, overlapping relationship between infection and inflammation.

Systemic inflammatory response syndrome[18] is the name given to this constellation if at least two of the parameters are present. Among surgical patients, there are many causes of tissue injury-induced inflammation (e.g. trauma, burns, pancreatitis) (Fig. 86.1) that have no relation to infection on initial presentation. Recovery from general anesthesia can produce symptoms indistinguishable from true SIRS, but the effect is transitory. Although SIRS has been derided conceptually as being too non-specific, in the surgical setting the presence and especially the persistence of SIRS is important prognostically. The presence and magnitude of SIRS in the trauma bay has been associated with increased risk of nosocomial infection.[19] Moreover, among critically ill surgical patients, persistent SIRS was associated with prolonged stay in intensive care units (ICU), worsening SIRS was associated with higher mortality, and a greater magnitude of SIRS was associated with both a higher incidence and greater degree of MODS (see also Chapter 56).[20]

The proinflammatory response can be incited by tissue injury or infection. Inflammation is modulated by a complex inter-relationship of activation of the coagulation, kinin, complement and other systems, generating numerous already-known and probably yet-to-be-discovered mediators, including prostaglandins, leukotrienes, reactive oxygen and nitrogen species, lipid peroxides, coagulation factors, adhesion molecules and cytokines. Consequently, phagocytic cells, platelets and endothelial cells are activated, in part to contain the inflammatory response (e.g. to localize and eradicate a nascent infection). Containment is also the likely role of the counter-regulatory anti-inflammatory response, downregulating the proinflammatory response so that the patient will not be immolated on the pyre of inflammation. The anti-inflammatory response is mediated by cortisol, IL-4, IL-10, myeloid colony stimulating factors, transforming growth factors and other mediators. The counter-regulatory response results in the activation of genetic programs ('suicide' genes) that cause phagocytic cells to undergo apoptosis (i.e. programmed cell death). Apoptosis causes inflammation to subside, whereas several adverse clinical events such as hypoxemia[21] or blood transfusions[22]

may delay apoptosis, promote inflammation and lead to adverse outcomes. None of the putative anti-inflammatory mediators are measured with ease or regularity by the modern clinical chemistry laboratory. Therefore, the anti-inflammatory response is difficult to quantify at the bedside, and the clinically relevant relationships between proinflammatory and anti-inflammatory responses are hypothetical.[23]

Do nosocomial infection and organ dysfunction result from exuberant inflammation unchecked by an inadequate or even normal anti-inflammatory response? Does the anti-inflammatory response overwhelm the proinflammatory response (which is a necessary component, for example, of normal tissue repair), or does it supplant inflammation as it subsides as part of an inflammatory ebb and flow (Fig. 86.2). There is substantial experimental evidence that an accentuated neutrophil proinflammatory response occurs by neutrophils that are first 'primed' by an inflammatory stimulus, and then respond in an exaggerated, deleterious manner in response to a second insult.[24] Examples of a primary insult include a period of hypoxia[21] or blood transfusion,[22] or the initial injury (e.g. a femur fracture), whereas an example of a second insult would be a postoperative nosocomial pneumonia. The exaggerated proinflammatory response results in release of mediators that, among other effects, induce adherence of neutrophils and platelets to microvascular endothelium; entrap microthrombi of fibrin, platelets, neutrophils and cellular debris; and cause tissue hypoperfusion, ischemia and edema as a result of loss of microvascular integrity.[25] Resuscitation and natural fibrinolysis may restore microvascular flow before tissue necrosis occurs, but re-introduction of molecular oxygen to the ischemic bed may result in the generation of reactive oxygen species. These highly toxic mediators have innumerable deleterious effects, including the ability to oxidize lipid components of cell membranes.

The splanchnic bed is especially susceptible to ischemia, and ischemia and reperfusion of the gut may be central to the pathogenesis of inflammation and organ dysfunction.[26] The intestine is an immunologically active organ that serves to protect the host from ingested bacteria as well as the potentially lethal bacterial inoculum contained in feces. Ischemic reperfused intestine becomes dysfunctional, with ileus and the ensuing putative release of mediators, bacterial toxins (e.g. endotoxin) or live bacteria ('bacterial translocation'). Although the existence of bacterial translocation is unproved in humans, it is plausible that the gut is the source of a proinflammatory stimulus and that under catabolic

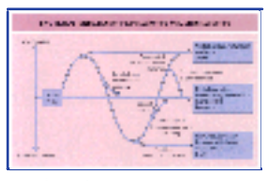

Figure 86-2 Hypothetical interactions of proinflammatory and anti-inflammatory responses. Pathogenesis of immunosuppression, nosocomial infection, organ dysfunction and outcome.

conditions the dysfunctional gut no longer provides trophic support of hepatic function, if indeed gut-derived mediators and toxins are the cause of the disrupted hepatocyte-Kupffer cell interactions that can no longer maintain hepatic reticuloendothelial host defense function.

Interleukin-1 and IL-6 are important regulators of the hepatic acute-phase response, bile secretion and (with other cytokines) the intercellular signaling that maintains normal hepatocyte-Kupffer cell interactions. When Kupffer cells (fixed tissue macrophages that are the critical component of hepatic host defenses) become dysfunctional, clearance of circulating particulates is decreased and other microcirculatory beds, notably the pulmonary microcirculation, become susceptible to microembolization and tissue injury.

The clinical manifestations of MODS are protean (see Fig. 86.2) and the consequences are grave. No longer conceptualized as an 'all-or-nothing' phenomenon in which organ 'failure' is recognized after a threshold of dysfunction is reached, MODS can affect several organs to varying degrees, and the effects are cumulative. Several methods exist for quantifying organ dysfunction; one of these methods, that of Marshall *et al.*,[27] correlates in magnitude with severity of illness on admission to the ICU, length of ICU stay and mortality.[4] As many as 50% of critically ill surgical patients and nearly 100% of critically ill nonsurvivors develop some degree of MODS. The development of MODS prolongs ICU stay even among patients who develop only minimal organ dysfunction, and it increases mortality exponentially as it manifests itself fully.

ENVIRONMENT-DERIVED RISK FACTORS

The importance of colonization with bacteria or active remote infection as a risk factor for subsequent infection cannot be over-emphasized. Patients who are chronic carriers of staphylococci and streptococci are at increased risk of SSIs after elective surgery,[28] as are patients with active soft tissue infections at tissue sites remote from the surgical wound. In hospitalized patients, colonization of the skin, lower airway and gut with pathogenic bacteria and fungi is common and occurs rapidly even among immunocompetent hosts. Aided and abetted by many standard health care practices (or lack thereof, in the case of breaks in infection control), these colonists wait for vulnerable hosts or their care providers to facilitate invasion and the establishment of infection. The risk of SSI[29] or failure of management of intra-abdominal infection[30] is increased by prolonged

pre-event hospitalization. Nosocomial pneumonia is promoted by pre-existing nosocomial sinusitis[31] or colonization of the lower airway by the same pathogen.[32] The same can be said for invasive fungal infections of surgical patients, which are often preceded by multiple-site colonization.[33] Numerous studies indicate that invasive infection with vancomycin-resistant enterococci is associated with prolonged hospitalization, repetitive ICU admission and prior exposure to antibiotics such as vancomycin and third-generation cephalosporins among debilitated, immunosuppressed patients.[34] Although bacterial colonization of hospitalized patients can occur regardless of exposure to antibiotics, there is no doubt that antibiotic selection pressure leads to nosocomial infections with multidrug-resistant bacteria, which are a threat to vulnerable patients.

TREATMENT-DERIVED RISK FACTORS

Modern therapy is often invasive and disruptive of homeostasis even as treatment tries to restore it (Table 86.2). Clinicians must be cognizant of and vigilant for the adverse consequences of therapies that may impair host defenses or disrupt commensal flora, increasing the risk of nosocomial infection. Among several factors of importance are the control of the serum glucose concentration, the avoidance of blood transfusion, maintenance of normoxia and normothermia, minimized duration of mechanical ventilation, and rational antibiotic prophylaxis and therapy. Also crucial are maintenance of the operating room environment and adherence to the principles of infection control and universal precautions. There are published guidelines for the prevention of SSI[35] (see also Chapter 84 and Chapter 87) and vascular catheter-related infection (see also Chapter 57);[36] the US Centers for Disease Control and Prevention produces updates and new guidelines.

Blood transfusion

Evidence is substantial and increasing that allogenic transfusion of red blood cell concentrates is immunosuppressive and increases the risk of nosocomial infection. Transfusion requirements are understandable in the trauma and surgery environment, and alternatives are few. Nonetheless, optional transfusions can be avoided safely,[37] and they should be avoided, especially in hemodynamically stable patients who are not bleeding.

Protection of the hypoxic wound

A fresh surgical incision is a hypoxic, ischemic environment. Blood vessels are divided at the wound margins, and use of electrocautery leaves a surrounding margin of coagulation necrosis. Maneuvers to support the oxygenation and perfusion of the incision have demonstrated benefit. Hypothermia (body temperature under 94.1°F (34.5°C)) leads to MODS and increased mortality after elective abdominal aortic aneurysm repair[38] and to an increased incidence of

TABLE 86-2 -- Examples of clinical interventions and potential deleterious effects upon host immunity.

EXAMPLES OF CLINICAL INTERVENTIONS AND POTENTIAL DELETERIOUS EFFECTS UPON HOST IMMUNITY	
Incisions	Drain pus but create portal of entry
Catheters	Help in the monitoring of the patient but create portal of entry and an artificial surface for colonization by bacteria
Transfusions	Improve oxygen transport but promote immunosuppression and increased risk of nosocomial infection and organ dysfunction
Nutrition	Encourages wound healing but promotes immunosuppression (parenteral nutrition) and carries a risk of aspiration (enteral feedings)
Antibiotics	Kill bacteria but disrupt host commensal flora

SSI after elective colon surgery.[39] Intraoperative hypothermia should be avoided at all costs. Avoidance can be challenging in trauma surgery, where operations are often prolonged, a large skin surface area may require exposure and open body cavities induce prodigious heat loss (especially if multiple, as in a thoracoabdominal incision). Avoidance should be absolute during elective surgery with the use of fluid warmers, forced-air blankets and the like.

ANTIBIOTIC PROPHYLAXIS AND THE RISK OF SURGICAL SITE INFECTION

The administration of antibiotics before surgery is commonplace and of proven benefit for the minimization of postoperative SSI. However, it is only the surgical incision that is afforded protection, and antibiotics are not a panacea. If not administered properly, antibiotic prophylaxis will not be effective and may be harmful (see also Chapter 190).

Selection of patients for antibiotic prophylaxis

Most commonly, the risk of SSI, as categorized by the National Nosocomial Infections Surveillance program, is defined by three risk factors:[1]

- a contaminated or dirty wound,
- poor overall medical condition of the patient, and
- a prolonged operative time (longer than the 75th percentile for operations of the type).

Surgical incisions are classified as clean (class I), clean-contaminated (class II), contaminated (class III) or dirty (class IV). A poor overall medical condition of the patient is categorized by an American Society of Anesthesiologists score of more than 2 (Table 86.3). Prolonged surgery has implications for the degree of tissue injury, antibiotic pharmacokinetics and intraoperative repeat dosing, and it provides a prolonged opportunity for wound inoculation. An increased risk of SSI occurs with an increasing degree of wound contamination (e.g. clean wounds have less risk than contaminated wounds), regardless of other risk factors (Table 86.4), [40] and as the number of risk factors increases for a given type of operation (Table 86.5).

TABLE 86-3 -- ASA physical status score.

ASA PHYSICAL STATUS SCORE		
Score	**Description**	**Examples**
ASA 1	A normal healthy patient	
ASA 2	A patient with a mild to moderate systemic disturbance that results in no functional limitations	Hypertension, diabetes mellitus, chronic bronchitis, morbid obesity, extremes of age
ASA 3	A patient with a severe systemic disturbance that results in functional limitations	Poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris, prior myocardial infarction, pulmonary disease that limits activity
ASA 4	A patient with a severe systemic disturbance that is life-threatening with or without the planned procedure	Congestive heart failure, unstable angina pectoris, advanced pulmonary, renal or hepatic dysfunction
ASA 5	A moribund patient not expected to survive with or without the operative procedure	Ruptured abdominal aortic aneurysm, pulmonary embolism, head injury with increased intracranial pressure
E	Any patient in whom the procedure is an emergency	

TABLE 86-4 -- Incidence of surgical site infection as a function of wound classification.

INCIDENCE OF SURGICAL SITE INFECTION AS A FUNCTION OF WOUND CLASSIFICATION					
	NNIS risk index				
Traditional class	0	1	2	3	All
Clean	1.0%	2.3%	5.4%	NA	2.1%
Clean-contaminated	2.1%	4.0%	9.5%	NA	3.3%
Contaminated	NA	3.4%	6.6%	13.2%	6.4%
Dirty	NA	3.1%	8.1%	12.8%	7.1%
All	1.5%	2.9%	6.8%	13.0%	2.8%
NNIS, National Nosocomial Infections Surveillance Program; NA, not applicable (by definition, because the traditional wound classification is one of the risk factors, patients with clean wounds cannot have three risk factors, nor can those with dirty wounds have no risk factors)

TABLE 86-5 -- SSI percentage rates for selected procedures.

SSI PERCENTAGE RATES FOR SELECTED PROCEDURES					
Procedure	**Time cutpoint (hours)**	**Number of risk factors**			
		0	**1**	**2**	**3**
Coronary artery bypass graft (chest or leg)*	5	1.20	3.57	5.68	9.63
Laparotomy	2	1.71	3.29	5.16	7.77
Open reduction and internal fixation of fractures†	2	0.73	1.35	2.51	4.85
From National Nosocomial Infections Surveillance System[1]					

* Pooled incidence of surgical site infection for both incisions
† Overall incidence

Antibiotic prophylaxis is indicated clearly for most clean-contaminated and contaminated (or potentially contaminated) operations. Dirty operations are those in which surgery and antibiotics represent treatment for an infection, not prophylaxis against it. An example of a potentially contaminated operation is lysis of adhesions for mechanical small bowel obstruction — intestinal ischemia cannot be predicted accurately before surgery, and the possibility exists of an enterotomy during adhesiolysis, which increases the risk of SSI 2-fold. An example of a clean-contaminated operation in

TABLE 86-6 -- Risk of the development of surgical site infection relative to the timing of antibiotic prophylaxis.

RISK OF THE DEVELOPMENT OF SSI RELATIVE TO THE TIMING OF ANTIBIOTIC PROPHYLAXIS				
Timing	**No. patients**	**No. (%) infections**	**RR (95% CI)**	**OR (95% CI)**
Early	369	14 (3.8)*	6.7* (2.9–14.7)	4.3* (1.8–10.4)
Preoperative	1708	10 (0.59)	1.0	
Perioperative	282	4 (1.4)	2.4 (0.9–7.9)	2.1 (0.6–7.4)
Postoperative	488	16 (3.3)*	5.8* (2.6–12.3)	5.8* (2.4–13.8)
All	2847	44 (1.5)		
Early, administration more than 2 hours preoperatively; Preoperative, administration during the recommended interval (=2 hours before skin incision); Perioperative, administration within 2 hours after the skin incision; Postoperative, administration more than 2 hours after the skin incision				
From Classen et al.[45]				

* $p<0.0001$ compared with preoperative group

which antibiotic prophylaxis is not always indicated is elective cholecystectomy. Antibiotic prophylaxis is indicated only for high-risk biliary surgery; patients at high risk include those over the age of 70 years, diabetic patients and patients whose biliary tract has recently been instrumented (e.g. during biliary stenting). [41] The vast majority of patients who undergo laparoscopic cholecystectomy do not require antibiotic prophylaxis.[42] Laparoscopic clean-contaminated operations are generally at decreased risk of infection. [1] The potential reasons are several, including a diminished surgical stress response, decreased tissue injury and smaller incisions.

Antibiotic prophylaxis of clean surgery is controversial. When bone is incised (e.g. in a craniotomy or sternotomy) or a prosthesis is inserted, antibiotic prophylaxis is generally indicated. The controversy exists in the case of clean surgery of soft tissues (e.g. breast, hernia). A randomized prospective trial has shown some benefit of prophylaxis,[43] but the results are confounded by higher than expected infection rates in the control group.

Choice of antibiotic

Most SSIs are caused by Gram-positive cocci. Most common is *Staphyloccoccus aureus*, followed by *Staphylococcus epidermidis*, *Enterococcus faecalis* and *Escherichia coli*, the latter two of which are common pathogens after clean-contaminated surgery. The antibiotic chosen should be directed against staphylococci for clean cases and high-risk clean-contaminated elective surgery of the biliary and upper gastrointestinal tracts. A first-generation cephalosporin is the preferred agent for most patients, with clindamycin preferred for patients with a history of anaphylaxis to penicillin. Although methicillin-resistant *S. aureus* (MRSA) has been isolated in the community from never-hospitalized patients, vancomycin prophylaxis is appropriate only in institutions where the incidence of MRSA is high.

Elective colon surgery is a special circumstance, and one in which practices are in evolution. Mechanical bowel preparation to reduce bulk feces made colon surgery safe for the first time. Antibiotic bowel preparation, standardized in the 1970s by the oral administration of nonabsorbable neomycin and erythromycin base, reduced the risk of SSI further to its present rate of approximately 4–8%, depending on the number of risk factors. Although outpatient mechanical preparation is now the norm, three doses of oral antibiotics are still given to most patients at approximately 18, 17 and 10 hours preoperatively so that fecal bacterial counts are minimal at the time of surgery. A dose of parenteral second-generation cephalosporin (or a quinolone or monobactam plus metronidazole for the penicillin-allergic patient) is given before skin incision, and the benefit appears to be additive.[44] Moreover, there is less reticence to operate on the less-than-perfectly-prepared colon, extrapolating from good results from primary repair of penetrating colon injuries.

Timing and duration of parenteral antibiotics

When should parenteral antibiotics be given for optimum effect? It is firmly established that the optimal time to give cephalosporin prophylaxis is within 2 hours before the time the incision is made (Table 86.6).[45] Antibiotics given sooner (except possibly for longer half-life agents such as quinolones and metronidazole) are not effective, or are agents that are given after the incision is closed. Antibiotics with short half-lives should be re-dosed during surgery if the operation is prolonged or bloody,[46] and there is still some benefit if the initial antibiotic dose is given intraoperatively.

Considering the exigencies of surgical hemostasis, and that the fresh surgical incision is ischemic, the postoperative administration of antibiotics is questionable owing to hypoperfusion that results from divided vessels. Single-dose prophylaxis should be standard, with intraoperative dosing as noted above, but excessively prolonged usage is pervasive. A 24-hour regimen is often standard for orthopedic and cardiac or vascular surgery, owing in part to a lack of randomized, prospective studies. Other than in solid-organ transplant surgery, in which therapeutic immunosuppression has made 48-hour regimens standard, there is no indication for prolonged antibiotic prophylaxis. In particular, antibiotics should not be administered to cover indwelling drains or catheters or to mitigate operative technical shortcomings.

Topical antiseptics and antibiotics may also help prevent SSI. A preoperative shower with an antiseptic soap (e.g. povidone-iodine) is a mainstay of perioperative preparation. Topical mupirocin ointment applied to the nares of patients who are chronic carriers of *S. aureus* reduces the increased incidence of SSI that is characteristic of chronic staphylococcal carriage. [28] [47]

Prolongation of antibiotic prophylaxis beyond 24 hours not only provides no benefit, but can also be associated with a number of complications. *Clostridium difficile*-associated disease (CDAD) has been associated with disruption of the normal balance of gut flora and overgrowth of the enterotoxin-producing *C. difficile*. The incidence and possibly the severity of nosocomial CDAD is increasing.[48] The spectrum of disease is broad, ranging from asymptomatic to life-threatening pancolitis with infarction or perforation. Although virtually every antibiotic has been implicated in the pathogenesis of CDAD, even after administration of a single dose, prolonged antibiotic prophylaxis clearly increases the risk. Prolonged prophylaxis also increases the risk of later nosocomial infections unrelated to the surgical site, and the emergence of multidrug-resistant pathogens. Both pneumonia and catheter-related infections have been associated with prolonged antibiotic prophylaxis,[49] [50] as has

the emergence of SSI caused by MRSA. [50]

ANTIBIOTIC PROPHYLAXIS OF TRAUMA-RELATED INFECTIONS

Traumatic injury is profoundly immunosuppressive, and injured patients are at very high risk of infection. The overall incidence of infection after trauma is approximately 25%,[51] with infection of a wound (or an incision made as treatment) and nosocomial infection equally likely. Certain patterns of injury are independently associated with infectious morbidity in particular, including hemorrhagic shock, the need for blood transfusion, heavy wound contamination, central nervous system injury, colon injury, combined thoracoabdominal injuries, four or more organs injured, and increasing injury severity.[3] Co-morbid factors of importance include hyperglycemia, hypothermia and hypoxemia.

Certain characteristics of trauma make the situation more complex. Antibiotics are administered after injury, but there is a period when injured tissues may be vulnerable before antibiotics are administered. Trauma patients may be hypotensive and vasoconstricted owing to shock, and tissue penetration may be decreased. Ongoing blood loss may result in ongoing antibiotic loss, especially if the agent is highly protein-bound and tissue redistribution is slow, or if the antibiotic is administered before major hemorrhage is controlled. Postinjury fluid shifts and hypoalbuminemia can cause major fluctuations in volume of distribution that can be difficult to estimate. As a result, it has been postulated that higher doses of antibiotics should be administered for the prophylaxis of post-traumatic infection. Although older work with aminoglycosides suggest that this theory may be correct,[52] aminoglycosides are now seldom used except for the prophylaxis of high-grade open fractures, and the few studies performed more recently suggest otherwise.

Despite the high risk, the basic principles of antibiotic prophylaxis still apply — use a safe, narrow-spectrum agent for a defined brief period (no more than 24 hours), preferably one that has a limited role in the therapy of infection (e.g. a first- or second-generation cephalosporin).[3] Multiple studies indicate unequivocally that 24 hours of prophylaxis with a second-generation cephalosporin is all that is necessary following penetrating abdominal trauma, even in the presence of a colon injury and shock.[51] Other injuries in which appropriate antibiotic prophylaxis is beneficial include high-grade open fractures,[53] animal bites[54] and, possibly, chest injuries when an emergency tube thoracostomy is required.[55] Following a human bite, the risk of infection is so high that 7–10 days of therapy with an agent effective against oral anaerobic flora is commonplace.[56] Injuries in which there is demonstrated to be no benefit of antibiotic prophylaxis include clean lacerations (even if primary repair is delayed)[57] and skull fracture with or without leakage of cerebrospinal fluid.[58]

Tetanus prophylaxis is administered almost routinely despite widespread shortages of tetanus toxoid and despite the fact that most wounds are not tetanus-prone. Certainly, tetanus prophylaxis should be administered for true high-risk wounds, such as soft tissue wounds with fecal contamination (e.g. injury caused by farm implements), but if the injury truly poses a high risk then administration of tetanus toxoid will be insufficient and tetanus immune globulin should be co-administered (see Chapter 232).

Prophylaxis of postsplenectomy sepsis is another special circumstance, albeit an increasingly rare one owing to the development of successful protocols for the nonoperative management of blunt splenic injuries. Postsplenectomy sepsis can be fulminating and lethal, and is most commonly caused by encapsulated organisms such as *Streptococcus pneumoniae* (see Chapter 109).[59] The incidence is sufficiently low in adults (<1%) for long-term antibiotic prophylaxis not to be indicated. Children have a higher incidence, and daily oral penicillin prophylaxis until the age of 18 years is a standard recommendation. Polyvalent pneumococcal vaccine is administered both to adults and to children, usually postoperatively, although the asplenic host has a blunted immune response to vaccination; moreover, the optimal timing of administration is unknown, and whether booster immunization is ever required is also unknown. Although there is no evidence that vaccination of these patients against *Haemophilus influenzae* or *Neisseria meningiditis* is beneficial, many clinicians choose to vaccinate for these pathogens because of the safety and probable effectiveness of these vaccines. There is no evidence that patients with splenic injury who are managed nonoperatively need to be vaccinated (see Chapter 109).

THE POSTOPERATIVE PERIOD

Several circumstances conspire to make fever the most common postoperative complication. A proinflammatory response follows tissue injury. Pulmonary defense mechanisms are impaired during anesthesia and recovery, and small-volume pulmonary aspiration of

gastric contents unquestionably occurs. Wound hematoma is one of many known noninfections causes of fever,[60] and other potential postoperative complications, including venous thromboembolic disease, pancreatitis, myocardial infarction, visceral ischemia and atelectasis, can also cause fever in the absence of infection. In this milieu it is challenging, but crucial, to distinguish inflammation from infection so as to treat patients appropriately. Confounding the evaluation of patients further is that hospitalized patients become colonized rapidly with potential pathogens.[61] Colonization is known to precede invasive infection. However, the high incidence of colonization, especially of the upper aerodigestive tract, makes it imposible to equate the mere isolation of a pathogen with the diagnosis of nosocomial infection, especially in critically ill patients.

Postoperative prophylaxis of infection

Surgical patients are at especially high risk of nosocomial infection. Judicious preoperative antibiotic prophylaxis decreases the risk of infection, but this prophylaxis in the absence of other techniques will not accomplish much. Proper infection control practice cannot be emphasized enough. Handwashing is the most effective infection control practice of all, yet studies continue to demonstrate poor compliance.[62] The use of fast-drying alcohol gels for hand disinfection improves compliance, can be used in the operating room [63] and should be used at the bedside.[64]

Surgery is invasive and surgical patients are often immunosuppressed owing to illness or injury; the surgical stress response augments the immunosuppression. Many standard interventions impair host defenses (see Table 86.2). Surgical care must minimize the possibility of iatrogenic infection, while supporting the patient until host defenses can recover.

Catheters and drains should be removed as soon as possible. Each time a natural epithelial barrier to infection (e.g. skin, respiratory tract mucosa, gut mucosa) is breached, a portal is created for potential invasion of the host by pathogens. Prolongation of the time that drains and catheters are in place increases the risk of infection and is a factor that is controllable, to a degree, by the surgeon. Subcutaneous drains increase the risk of SSI.[65] Prolonged central venous catheterization increases the risk of bacteremia.[36] Prolonged intubation and mechanical ventilation increase the risk of pneumonia. [66] If prolonged catheterization is essential, silver-impregnated urinary drainage catheters,[67] antibiotic-coated central venous catheters[68] and aspiration of subglottic secretions via an endotracheal tube with an extra lumen [19] can all decrease the risk of nosocomial infection (see Chapter 83).

Although cumbersome and therefore not popular, topical antiseptics and antibiotics appear to decrease the risk of nosocomial infection in seriously ill, high-risk patients. Data demonstrate that topical 0.12% chlorhexidine mouthwash (a bactericidal, viricidal and fungicidal antiseptic), applied to the oropharynx and the exposed surface of the endotracheal tube, decreases the incidence of postoperative pneumonia. Selective digestive decontamination, described in various forms nearly two decades ago, utilizes an oral paste of multiple antibiotics, enteral administration of the same antimicrobial agents by gavage, and sometimes a short course of intravenous antibiotics. Infection rates are reduced unequivocally,[69] but critics point out the possibility of the development of resistance and also that the mortality rate is sometimes not reduced. At this point, it cannot be recommended universally, but it may be appropriate in high-risk situations.[70] [71]

Prophylaxis of fungal infections is controversial. Although surgical patients are immunosuppressed and are frequently exposed to antibiotics, invasive fungal infections are unusual. Although *Candida* is a frequent isolate from the peritoneal fluid of patients with peritonitis, specific antifungal therapy is generally not indicated unless *Candida* is isolated in pure culture from blood, from peritoneal fluid or from an abscess. Fungemia can be associated with indwelling central venous catheters (see below), but on the rare occasions where fungemia complicates surgery (solid-organ transplant patients excepted), the patient is usually debilitated and in the throes of a protracted serious illness and has already been exposed to multiple courses of antibiotics. Most surgical patients who are potential candidates for antifungal prophylaxis, apart from commonplace administration as part of organ transplant protocols, are those who become colonized with yeast at two or more sites (e.g. skin and urine). Colonization does precede invasive infection when it does occur in the absence of a gastrointestinal tract perforation, and therefore some have advocated prophylaxis with fluconazole as a means of decreasing the risk of invasive infection.[20] However, disciplined antibiotic prescribing may also be effective.[72] Fluconazole has numerous drug interactions (e.g. cyclosporine, macrolides, quinolones) and widespread use of fluconazole has been associated with the emergence of fluconazole-resistant strains of *Candida*.[73]

Blood transfusion

In surgery and trauma, blood transfusions are given commonly and may be life-saving; alternatives to transfusions in the acute setting are few, but for hemodynamically stable postoperative patients hemoglobin concentrations >7g/dl are well tolerated.[37] Erythropoietin administration may decrease transfusion

requirements of the 'chronically critically ill' patient. An expanding body of evidence suggests that blood transfusion should be avoided, if possible. The immunosuppressive effects of allogeneic blood transfusions have been demonstrated in both solid-organ transplant recipients (in whom graft survival has been prolonged) and colon cancer surgery patients (in whom survival is decreased).

Observations that blood transfusions are associated with increased rates of nosocomial infection are numerous. Blood transfusions have been associated with an increased risk of infection following penetrating abdominal trauma independent of related factors such as shock or acute blood loss,[74] and they have been related to increasing injury severity and increasing transfusion volume in unselected trauma patients.[75] Data suggest that blood transfusion therapy of 6–20 units in the first 12 hours following multiple trauma is associated with an increased risk of nosocomial infection. [76] The risk of infection increased as the total transfusion volume increased, especially when units were transfused after more than 14 days of storage.[76] The postulated 'storage lesion' is complex but includes changes in oxygen affinity, red blood cell deformability, shortened circulation time, and the biologic consequences of cytokine generation and release. Recently, observational studies have suggested that transfusion of critically ill patients increases the risk of nosocomial infection,[77] and may worsen MODS and increases mortality.[78]

Hyperglycemia and control of blood sugar

Hyperglycemia has several deleterous effects on host immune function, most notably impaired function of neutrophils and mononuclear phagocytes. It is possible also that hyperglycemia is a marker of the catabolism and insulin resistance associated with the surgical stress response, and that exogenous insulin administration may ameliorate the catabolic state. Increasing evidence indicates that poor control of blood glucose during surgery and in the perioperative period increases the risk of infection and worsens outcome from sepsis. Diabetic patients have a higher risk of infection of both the sternal incision and the vein harvest incisions on the lower extremities.[9] Tight control of blood glucose by the anesthesiologist during surgery must be accomplished to decrease the risk, and that control must extend into the immediate postoperative period as well. Moderate hyperglycemia (>200mg/dl (>11mmol/l)) at any time on

the first postoperative day increases the risk of SSI after noncardiac surgery.[10] Hyperglycemia during the immediate phase of trauma resuscitation increases the risk of nosocomial infection and death after trauma. Exogenous insulin administration to keep blood glucose concentrations under 120mg/dl (6.7mmol/l) was associated with a 40% decrease of mortality among critically ill surgical patients with sepsis[11] (see Chapter 56).

The need to manage carbohydrate metabolism carefully has important implications for the nutritional management of surgical patients. Gastrointestinal surgery may render the gastrointestinal tract unusable as a route for feeding, sometimes for prolonged periods. Ileus is common in surgical ICUs, whether from traumatic brain injury, narcotic analgesia, prolonged bed rest, inflammation in proximity to the peritoneal envelope (lower lobe pneumonia, retroperitoneal hematoma, fractures of the thoracolumbar spine, pelvis, or hip) or other causes. Parenteral nutrition is relied on for feeding, despite evidence of a lack of efficacy[79] and the possibility of hepatic dysfunction; hyperglycemia may be an important complication as well. Every effort should be made to provide enteral feeding, including the use of promotility agents such as erythromycin.[80] Substantial evidence indicates that enteral feeding reduces the risk of nosocomial infection by nearly one-half among critically ill and injured patients.[81]

The diagnosis of postoperative infection

The evaluation of a patient for possible infection usually begins with the report of a fever. The clinical response is too often the reflexive ordering of multiple cultures of various body fluids, even at times when the likelihood of infection and therefore the yield of the cultures is low.[82] The only intervention mandated by new-onset fever is a history and physical examination. [60] All additional evaluations, whether radiologic or microbiologic, should be dictated by the findings of the evaluation at the bedside. [83] Fever related to infection in the immediate postoperative period (<48–72 hours after the operation) is rare unless the patient has been operated on to treat a febrile illness. The exception is necrotizing SSI caused by *Streptococcus pyogenes* or *Clostridium* spp., for which inspection of the incision is mandatory. The yield of blood cultures is known to be very low in the immediate postoperative period,[74] and obtaining cultures to evaluate fever less than 72 hours postoperatively is not recommended.[60] After 72 hours, the possibility of nosocomial infection increases, but even then there is still the possibility that fever may be due to a noninfectious cause (e.g. venous thromboembolic disease, wound hematoma), and diagnostic rigor must be maintained. Overall, postoperative fever may be due to a noninfectious cause in as many as one-half of circumstances.[75]

Intra-abdominal infection

Intra-abdominal infection is a recognized complication following abdominal surgery, but it can, rarely, occur after other types of surgery as well. In contrast, nosocomial intra-abdominal infection is rare in medical and pediatric ICUs. Better patient selection and preparation before high-risk elective surgery, appropriate resuscitation, early nutritional support and prophylaxis of stress-related gastric mucosal hemorrhage have all contributed to improved outcomes (see also Chapter 47).

After an abdominal operation, infection may persist or recur. Potential causes include severe illness, inadequate antibiotic dosing, resistant pathogens, inadequate source control, technical shortcomings, tissue ischemia and complete failure of intra-abdominal host defenses. Most patients with community-acquired intra-abdominal infections (e.g. secondary peritonitis from, for instance, appendicitis or diverticulitis) are infected by sensitive Enterobacteriaceae and anaerobic Gram-negative bacilli such as *Bacteroides fragilis*. Such patients rarely harbor multidrug-resistant pathogens; if surgery is required for a good-risk patient and is performed properly, the patient will usually recover regardless of which of several appropriate antibiotic regimens may be chosen.[84]

Source control is an emerging concept in the management of intra-abdominal infection.[85] Simply stated, adequate source control is the correct operation performed at the correct time in the correct manner. In practice, though, it is much more difficult to define. Whereas the surgical management of complicated appendicitis has relatively few permutations, this is not the case for complex entities such as perforated diverticulitis. Issues surrounding whether to resect, perform an anastomosis or a colostomy, or place drains make it impossible to declare that there is one 'correct' surgical approach, but it may be possible to describe management attributes that are clearly not appropriate. Studies suggest that source control is inadequate in approximately 10% of cases of complicated intra-abdominal infection; therefore, failure of source control is more likely as a cause of failure of treatment of intra-abdominal infection than any shortcoming of the antibiotic regimen.

With nosocomial infections (e.g. fecal peritonitis after dehiscence of a colon anastomosis), antibiotic selection is more crucial in addition to the corrective surgical procedure, because organisms such as *Enterococcus* spp., *Pseudomonas aeruginosa* and sometimes *Candida* spp. may be encountered. In circumstances in which involvement of the peritoneal cavity is generalized and at least one source control procedure has failed to control a nosocomial intra-abdominal infection, the patient may be considered to have tertiary peritonitis.[86] Diffuse peritonitis, infected serosanguinous fluid rather than pus, poorly localized collections and isolation of enterococci, coagulase-negative staphylococci, yeast and *P. aeruginosa* are characteristic. Local peritoneal host defenses are nonfunctional. The management of tertiary peritonitis is controversial. Some experts believe that the peritoneal cavity is colonized rather than infected, and that peritoneal toilet should be provided by daily saline lavage with the abdomen left open,[87] but randomized studies are nonexistent. What is clear, however, is that the typical mortality rate of about 30% is more than 10-fold higher than that usually reported for secondary peritonitis.

Ischemic enteropathies (e.g. acute pancreatitis, acalculous cholecystitis, ischemic colitis, ischemic hepatitis) can complicate the management of critical surgical illness. Patients have usually sustained a period of splanchnic hypoperfusion, and the consequences can be devastating. Such patients usually manifest SIRS owing to tissue ischemia, and whether the patient is infected or becomes infected at some point can be very difficult to discern. Acute pancreatitis can complicate cardiopulmonary bypass or upper abdominal surgery (e.g. gastrectomy, splenectomy); most patients do not become infected and the administration of prophylactic antibiotics to patients with acute pancreatitis is controversial.[88]

Outcomes of postoperative pancreatitis vary widely, depending on the severity of the attack. Acute acalculous cholecystitis has been reported as complicating virtually any operation but has a predilection for patients with trauma, burns, shock and emergency cardiac and peripheral vascular surgery.[89] The diagnosis is made most efficiently by bedside ultrasonography, and the treatment of choice is evolving to percutaneous cholecystostomy. The mortality rate of acute acalculous cholecystitis is approximately 30%.

Ischemic colitis is the most dangerous of these entities. The distribution and severity vary widely; sometimes, the presentation can be as subtle as occult blood in the stool or an unexplained fever. When it does manifest itself, it usually does so within 72 hours of the insult that puts the patient at risk. The diagnosis is made most frequently by flexible lower gastrointestinal endoscopy but, because only the mucosa is inspected, endoscopy is not quantitative. Mild cases are probably noninfectious - there are no data to demonstrate that antibiotic therapy alters the course of mild ischemic colitis. Transmural

colitis can lead to perforation; at worst, when severe ischemic colitis necessitates an emergency colectomy in the context of critical illness, the mortality rate may be as high as 80%.[90]

Computerized tomography (CT) is probably the most useful modality for imaging the abdomen of seriously ill patients, particularly when there is substantial uncertainty as to the precise diagnosis, but it is not a panacea. The benefits of imaging must be weighed against the formidable logistics and inherent risk of transporting a critically ill patient within the hospital for an imaging study. Moreover, it is possible to image the abdomen too soon (before about 7 days postoperatively) and thereby achieve a false-negative result. Fewer than one-half of abdominal-pelvic CT studies performed on critically ill patients yield meaningful information about diagnoses that are amenable to further intervention.

Sinusitis

Nosocomial sinusitis is a closed-space, often occult infection that is recognized increasingly as a major cause of morbidity and mortality among critically ill patients.[18] Major risk factors include prolonged nasotracheal intubation (30–35% incidence after 1 week), nasogastric intubation, facial fractures, prolonged recumbency and corticosteroid administration. Maxillary sinusitis is the most recognized type (and the most treatable, by a drainage procedure), but infection can also involve the ethmoid or sphenoid sinuses. The pathogenesis is believed to be related to poor natural drainage in recumbency, combined with obstruction of sinus ostia by transnasal tubes. Outcomes can be adverse because the diagnosis must be sought specifically. An occasional patient will present with purulent or foul-smelling nasal drainage, but most cases of sinusitis are found in the context of evaluation for an occult source of fever. Considering that clinical manifestations are usually non-specific, it is important to remember the diagnosis when faced with a patient who has persistent fever with an elusive source.

The diagnosis of sinusitis is best made by CT of the facial bones, looking for thickened mucosa, an air-fluid level within the sinus or opacification. If any of those criteria are found in a maxillary sinus, the sinus should be punctured by needle, aspirated for culture and irrigated with saline.[91] Sinus fluid can be accessed easily via the alveolar ridge or the bicuspid ostium, but attention to disinfection before aspiration is crucial lest the sample be contaminated by pathogens colonizing the oral mucosa.

The potential list of pathogens is long,[18] but among surgical patients the most likely pathogens are *P. aeruginosa* and *S. aureus*. Fungal sinusitis has been reported. Most antibiotics achieve high concentrations in sinus fluid, so the choice of antibiotic therapy may be guided by the microbiology. Most episodes will respond to the initial course of drainage and antibiotics, but the possibility exists that the sinus may need to be aspirated again to achieve cure. In rare circumstances, formal surgical drainage either by endoscopy or by an open procedure may be necessary (see Chapter 32).

Although not a prerequisite, sinusitis is a recognized risk factor for the development of nosocomial pneumonia.[18] Microbiologic concordance between sinus cultures and subsequent sputum cultures is high, and a common pathogenesis has been postulated (notably prolonged endotracheal intubation and a large inoculum of potential pathogens in the upper airway waiting to be aspirated).

Pneumonia

Although SSI is probably the nosocomial infection most closely associated with surgery, nosocomial pneumonia (NP) is probably more common and certainly more dangerous. Long-term observational studies suggest that NP is more common than SSI among surgical patients, and indicate clearly that the incidence of NP is higher in surgical ICUs than in medical or pediatric ICUs.[1] In surgical subspecialty

TABLE 86-7 -- Incidence of ventilator-associated pneumonia.

INCIDENCE OF VENTILATOR-ASSOCIATED PNEUMONIA			
Type of ICU	**Ventilator utilization**	**Pooled mean**	**Median**
Medical	0.49	7.3	6.0
Pediatric	0.45	4.9	3.9
Surgical	0.47	13.2	11.6
Cardiothoracic	0.47	10.5	9.5
Neurosurgical	0.38	14.9	11.9
Trauma	0.58	16.2	15.3
Burn	0.33	15.9	
Utilization, number of ventilator days per number of patient days; rates are per each 1000 days of indwelling artificial airway (e.g. endotracheal tube, tracheostomy tube)			
From National Nosocomial Infections Surveillance System[1]			

units (e.g. burns units, trauma units, neurosurgical units, cardiothoracic units), the incidence of NP exceeds 15 cases/1000 days of mechanical ventilation (Table 86.7).[1] The increased incidence of NP among surgical patients occurs despite comparable rates of mechanical ventilation in the ICU, which may reflect that intraoperative mechanical ventilation is not captured in ICU statistics if the patient is extubated early after surgery. However, surgical patients are at increased risk with respect to airway reflexes (because of anesthesia, analgesia and sedation), hypoventilation and atelectasis (because of the above factors plus painful chest or upper abdominal incisions), gastric intubation, ileus and numerous other factors. Trauma patients are at especially increased risk if they sustain a head or chest injury (e.g. pulmonary contusion, rib fractures) or are intoxicated with drugs or alcohol. The risk of NP is increased by aspiration during endotracheal intubation, high severity of injury, blood transfusions, hyperglycemia, prolonged mechanical ventilation and the acute respiratory distress syndrome.

Elective surgical patients are at risk of pneumonia as well, with an estimated incidence of approximately 3%. Observational study has identified preoperative risk factors among elective surgical patients and allowed the development of a validated prediction model. Patients at highest risk include those over the age of 70 years and those who are to undergo thoracic surgery, upper abdominal surgery or aortic surgery.[7]

If increased risk can be defined, then effective targeted prevention strategies should be utilized to the fullest extent possible. Meticulous infection control to minimize the spread of pathogens around the unit, minimized sedation, daily sedation 'holidays', keeping the head of the patient's bed at an angle of 30° at all times, antiseptic or antibiotic decontamination of the oropharynx, endotracheal extubation at the earliest possible opportunity, early tracheostomy if extubation cannot occur promptly, early enteral nutrition and meticulous pulmonary toilet, including continuous aspiration of subglottic secretions, can all be part of a comprehensive program for the prevention of pneumonia (see Chapter 35 , Chapter 84 and Chapter 87).[92]

The diagnosis of NP can be challenging, especially if the patient is receiving mechanical ventilation and the diagnosis of ventilator-associated pneumonia (VAP) is being pursued. The clinical constellation of fever, leukocytosis, purulent sputum and a new or changed chest radiographic infiltrate is unreliable for the accurate diagnosis of NP-VAP,[93] considering that numerous noninfectious process can produce fever or pulmonary infiltrates, or both. Studies indicate that both clinical acumen[94] and chest radiography are non-specific for the diagnosis of VAP. Sputum cultures obtained by routine endotracheal suctioning without quantitative microbiology are often contaminated

by upper airway colonists, and the diagnosis may be made in error on the basis of such false-positive cultures. Such patients are often treated when they need not be, without the possibility of benefit but with the potential for the adverse consequences of antibiotic therapy. Methods to improve the accuracy of the diagnosis of NP-VAP have been developed to reduce the likelihood that the sputum specimen is contaminated in the collection process. Quantitative sputum cultures increase diagnostic specificity. However, the methods of 'high-technology' diagnosis of NP remains controversial (i.e. protected-specimen brush or bronchoalveolar lavage, or not; with or without quantitative microbiology; with or without bronchoscopy), owing to limited data that better diagnoses translate into better outcomes. Studies performed in surgical patients indicate that routine suctioning for sputum collection results in numerous false-positive cultures, and that sputum Gram stain is unreliable.[95] Because of the prevalence of SIRS and the substantial proportion of noninfectious febrile episodes among surgical patients, bronchoscopic bronchoalveolar lavage is employed increasingly in surgical critical care practice. Although imperfect, diagnostic accuracy is increased from about 50% to about 80%. If the diagnostic threshold to consider quantitative cultures to be positive is not reached ($>10^3$ cfu/ml of a predominant organism by protected-specimen brush, 10^4 cfu/ml for bronchoalveolar lavage), empiric antibiotic can be discontinued. One international multicenter trial of suspected VAP that included substantial numbers of surgical patients has shown that management according to bronchoscopic quantitative microbiology, as opposed to routine care, reduced mortality, exposure to antibiotics and the emergence of *Candida* spp.[72]

Bloodstream infection

Bacteremia is an unusual complication of most surgical infections. Bacteremia accompanies only 8% of intra-abdominal infections overall, although less common infections such as cholangitis are characterized by positive blood cultures in about 90% of cases. Clostridial bacteremia can complicate emphysematous cholecystitis or occult perforation or neoplasm of the gastrointestinal tract.[96] Surgical site infections have been described as potential sources of staphylococcal [97] or enterococcal bacteremias, and staphylococcal or pseudomonal bacteremia can complicate pneumonia caused by those organisms. Suppurative phlebitis, a bacteremic complication of infected vascular access sites, usually a peripheral intravenous site, is rare but dangerous.[98]

Catheter-related bloodstream infection is relatively uncommon in surgical units compared with medical or pediatric units, despite the high reliance on central venous access and monitoring (Table 86.8).[1] However,

TABLE 86-8 -- Incidence of central line-associated blood stream infections, National Nosocomial Infections Surveillance System, 1995–2001.

INCIDENCE OF CENTRAL LINE-ASSOCIATED BLOOD STREAM INFECTIONS			
Type of ICU	**Central line utilization**	**Pooled mean**	**Median**
Medical	0.51	5.9	5.2
Pediatric	0.46	7.6	6.8
Surgical	0.66	5.3	4.9
Cardiothoracic	0.79	2.9	2.4
Neurosurgical	0.44	4.7	4.5
Trauma	0.63	7.9	7.0
Burn	0.49	9.7	
Utilization, number of central venous catheter days per number of patient days; rates are per 1000 days of indwelling catheter			
From National Nosocomial Infections Surveillance System[1]			

the threat is high and the danger is real for surgical patients, and therefore strict adherence to principles of infection control for central venous catheter insertion and care must be observed. According to the US Centers for Disease Control and Prevention, the operator must wear a cap, mask and sterile gown and gloves for all insertion procedures, and the operative field must be draped widely.[36] Central venous catheter insertion under emergency conditions (e.g. trauma resuscitation, cardiac arrest) almost always has lapses of infection control, and therefore catheters inserted under such conditions should be removed (and replaced at a different site, if needed) as soon as the patient has been stabilized. Ironically, the area of the hospital where these principles are most often overlooked is the operating room.

The most common organisms causing catheter-related bloodstream infections are *S. epidermidis, S. aureus* and *E. faecalis*, implying that the skin is the source for most of the bacteria. Unfortunately, *S. epidermidis* is also the most common contaminant of false-positive blood cultures as well as being the major pathogen for infection of prosthetic implants such as joint prostheses and synthetic vascular grafts. A blood culture that is positive for *S. epidermidis* in only one bottle is most likely contaminated, and antibiotics can be withheld safely with close observation in most cases when there is neither a prosthetic implant nor an implanted vascular access device. When such a device is present, prudence often dictates a course of therapy, usually with vancomycin[99] (see Chapter 57 and Chapter 84).

PRINCIPLES OF ANTIBIOTIC THERAPY

Although the decision to start empiric antibiotic therapy is a clinical one, it is important for the decision to be an informed one. An occasional patient will develop an early infection, but when it occurs it is usually the delayed manifestation of a community-acquired infection that was occult at the time of admission. In the case of pneumonia that develops within 3 days after surgery, the clinician must be alert to the possibility of a pneumococcal pneumonia. However, 'atypical' pneumonia is almost unheard of in surgical practice unless the patient is profoundly immunosuppressed, and so there is seldom a consideration to administer a macrolide antibiotic for that indication.

It can be useful to distinguish NP as 'early-onset' NP or 'late-onset' NP (within 5 days of hospitalization, or in the case of VAP, of endotracheal intubation) with respect to likely pathogens and appropriate initial empiric therapy.[100] Early-onset pneumonia is more likely to be caused by antibiotic susceptible strains of *S. aureus*, *H. influenzae*, *E. coli*, and *Klebsiella pneumoniae*, whereas late-onset pneumonia is more likely to be caused by multidrug-resistant pathogens such as MRSA, *P. aeruginosa*, *Acinetobacter* spp. and others. Considering that *S. aureus* and *P. aeruginosa* are the two most common health care-associated pneumonia pathogens, initial empiric antibiotic therapy must account for both pathogens, meaning two-drug anti-MRSA and anti-pseudomonal treatment in institutions with a high prevalance of MRSA, until data have been generated by the microbiology laboratory to inform the prolongation of therapy.

The decision to truncate a course of antibiotics once it has been started or to narrow the spectrum of coverage is crucial. Although there are few data regarding the appropriate duration of therapy for NP-VAP, or for any other nosocomial infection for that matter, the typical decision to continue antibiotics until some time after the patient becomes afebrile and the leukocytosis has resolved may not be appropriate in every circumstance. Because the consequences of overtreatment (primarily later nosocomial infections with multidrug-resistant bacteria, or opportunistic pathogens such as fungi) can be as severe as undertreatment, ongoing antimicrobial therapy should be reviewed every day in every patient with a bias to stopping treatment as soon as the patient improves. It may be possible to withhold

or truncate antibiotic therapy by the use of a propensity score, such as the Clinical Pulmonary Infection Score.[101] [102]

The pharmacokinetics of antimicrobial agent dosing can be challenging in surgical patients. Shock and hypoperfusion, blood loss, hypoalbuminema and marked changes in volume of distribution owing to 'third-space' fluid shifts to the extravascular interstitial space are important but unpredictable factors. If anything, these factors conspire to cause antibiotic underdosing, which must be taken into consideration. It is unknown, for the most part, whether novel antibiotic administration strategies such as single-daily-dose aminoglycoside administration or continuous-infusion ß-lactam antibiotic administration have utility in the surgical setting.[103] It is also unknown whether high-dose, short-course antibiotic regimens might be better than the conventional-dose, prolonged (e.g. for 10–14 days) regimens that are commonplace.[104]

It has been hypothesized that 'antibiotic heterogeneity' — changing the pattern of antibiotic use either randomly (as may occur when choice is unfettered), by computerized decision support or by scheduled change of antibiotic class (e.g. antibiotic 'rotation' or 'cycling' programs) — may be a valid alternative to antibiotic control or restriction programs to prevent the emergence of multi-drug-resistant bacteria. Initial data in surgical patients provide support for the 'cycling' hypothesis. Quarterly cycling of cefepime, ciprofloxacin, imipenem-cilastatin and piperacillin-tazobactam resulted in decreased use of aminoglycosides, vancomycin and antifungal agents.[105] Moreover, infections caused by resistant bacteria were reduced, and so was mortality. It is not known which attribute or attributes (drug, order of administration, duration of cycle, omission of other drugs for potential empiric use) contribute to the effect.

Chapter 87 - Hospital Infection Control

Marc J Struelens
Baudouin Byl

EPIDEMIOLOGY

Definitions of hospital infections

Hospital infection, also known as nosocomial infection, encompasses all types of infections acquired by patients while being cared for in an acute care institution, and those acquired by health care personnel and visitors. The rationale for categorizing these infections separately lies in our ability to prevent them through adequate organization of patient care in the hospital setting.

To study the epidemiology of hospital infection and to evaluate the efficacy of prevention strategies, hospital epidemiologists must use standardized definitions. An extensive set of criteria that are widely used internationally for the detection and classification of hospital infection has been published by the Centers for Disease Control and Prevention (CDC; Table 87.1).[1] [2] These definitions include a combination of clinical criteria and, when available, documentation by laboratory test results, pathologic findings and imaging data. Although these standard case definitions provide a useful basis for recording hospital infections, their application inevitably entails some degree of interobserver bias and variability, because several criteria (e.g. visual detection of purulence) are based on subjective clinical judgment whereas others (microbiologic findings) rely on laboratory test usage and performance.

Incidence and public health impact

Hospital infections are an important public health problem because of their frequency, attributable morbidity and mortality, and cost. In the USA and in Europe, approximately 5–10% of hospitalized patients develop an infection during their hospital stay.[3] [4] [5] Higher incidence rates are reported in hospitals in developing countries.[6] [7] The risk of infection varies by type of patient population and clinical area of care. For example, among critically ill patients the prevalence of hospital infection can reach 50% in intensive care units where patients stay for prolonged periods and undergo invasive therapeutic support, such as mechanical ventilation.[8] Incidence rates of hospital infection are higher in larger and tertiary care hospitals, where patients are more severely ill and are exposed to more intensive care. The most common types of hospital infection include (in order of decreasing frequency) urinary tract infection, surgical site infection, pneumonia and bacteremia. Record trends indicate that the incidence density rates of some hospital infections have increased over the years, as illustrated by the rise of bacteremia incidence rates reported in Belgian hospitals in the past decade (Fig. 87.1), whereas other risks appear to be better controlled, as shown by a decrease in adjusted incidence rates of device-associated infections in critically ill patients in the USA (Fig. 87.2). [9] [10] [11] [12] [13]

Although the majority of hospital infections are minor, there is a wide range in the severity of clinical illnesses they cause; some have serious consequences, as in patients with infections of implanted prostheses who develop permanent disability or who need reoperation. The hospital length of stay is prolonged in infected patients, on average by 5–10 days.[11] The risk of death approximately doubles in patients who acquire hospital infection. [11] [14] The mortality rates attributable to bloodstream infection and pneumonia are 25–50% and 7–27%, respectively, depending on the etiologic agent and underlying disease.[10] [14] [15] [16] Estimates of direct and indirect costs associated with hospital infection vary widely according to differences in epidemiologic and econometric cost measures, patient population and health financing system. However, all studies consistently show that hospital-acquired infections are very expensive and contribute significantly to the escalating costs of health care.[16] [17] It has been argued that, even if moderately effective, a hospital infection control program is one of the most cost-effective and cost-beneficial preventive medical interventions currently available.[17] [18]

Modes of acquisition of hospital infections

Infection can be acquired in the hospital by either endogenous or exogenous routes. The relative contributions of these routes can be determined by epidemiologic investigation coupled with intensive microbiologic surveillance and molecular typing (see below). It is of key importance to identify the major routes of colonization and infection for the design of effective control strategies. A majority of hospital infections (approximately 80%) are acquired by the endogenous route through translocation of micro-organisms from the patient's mucocutaneous flora (Fig. 87.3). This autoinfection occurs as a result of predisposing host conditions (Table 87.2) and by exposure to invasive diagnostic and therapeutic procedures that lead to disruption of mucocutaneous barriers (Table 87.3 ; Fig 87.4 and Fig 87.5). These factors interfere with the normal balance between host defenses and the invasive properties of the commensal microflora. Examples of endogenous translocation leading to common hospital infections include *Escherichia coli* urinary tract infection in a patient who has an indwelling bladder catheter and *Staphylococcus epidermidis* bacteremia in a patient who has a percutaneously inserted intravenous catheter. The micro-organisms will migrate from their mucosal or skin habitat along the external surface of the catheter and across the meatal or skin barrier to gain access to the site of infection. In addition, the commensal microflora changes during hospitalization because of mucosal modifications (pH, expression of surface receptors, etc.) and the selective pressure of antibiotics, favoring the multiplication of resistant organisms.

The second mechanism of acquisition of hospital infection is by the exogenous route, from a microbial reservoir in the hospital. This includes other patients, hospital staff or the inanimate environment. The most common route is cross-infection or cross-colonization, for which the reservoir is the microbial flora of other patients. This flora is frequently transmitted by the hands of health care workers (see Fig. 87.3). Cross-infection may account for approximately 10–20% of hospital infections. This proportion can reach 40% in the intensive care unit where there is frequent interaction between health care workers and patients who have altered host defenses. [19] Contact spread is a mode of nosocomial transmission of environmentally sturdy micro-organisms that can be difficult to control, such as *Clostridium difficile* and *Candida*. [20] [21] Examples of pathogens

TABLE 87-1 -- Keypoints in Centers for Disease Control and Prevention Surveillance definitions of major nosocomial infections in adult patients.*

KEYPOINTS IN CDC SURVEILLANCE DEFINITIONS OF MAJOR NOSOCOMIAL INFECTIONS IN ADULT PATIENTS
Surgical site infection (SSI)
Infection affecting the surgical site and occurring within 30 days of the operative procedure, or within 1 year after implant surgery
Superficial incisional SSI
At least one of the following:
• Purulent drainage from the skin or subcutaneous tissue above fascia layer
• Organism isolated from aseptically collected fluid or tissue from the superficial incision closed primarily
• Surgeon deliberately opens the superficial incision, unless the culture is negative
• Diagnosis by the surgeon or attending physician
Deep incisional SSI
At least one of the following:

• Purulent discharge from the deep incision (i.e. fascia and muscle)
• Deep incision that spontaneously dehisces or is deliberately opened by the surgeon when the patient has fever and/or localized pain or tenderness, unless culture is negative
• Abscess or other evidence of infection of deep incision seen on direct examination, during reoperation or by histopathologic or radiologic examination
• Diagnosis by the surgeon or attending physician
Organ/space SSI
Infection of any organ/space located below the incision and opened or manipulated during the operative procedure, which meets at least one of the following:
• Purulent drainage from a drain that is placed through a stab wound into the organ/space
• Organism isolated from an aseptically obtained culture of fluid or tissue from organ/space
• Abscess or other evidence of infection of the organ/space seen on direct examination, during reoperation or by histopathologic or radiologic examination
• Diagnosis by the surgeon or attending physician
Bloodstream infection (BSI)
Laboratory-confirmed BSI infection was not present or incubating at time of admission and occurred during or after hospital stay, which meets one of the following:
• Recognized pathogen(s) isolated from blood culture and pathogen is not related to infection at another site or is related to an intravascular device (primary BSI) or related to nosocomial infection at another site (secondary BSI)
• Fever, chills or hypotension and isolation of a common skin contaminant from two blood cultures or from a single blood culture in a patient with an intravascular device if physician institutes appropriate antibiotic therapy, or positive antigen test on blood
Urinary tract infection (UTI)
Symptomatic UTI
Infection not present or incubating at the time of hospital admission that meets one of the following:
• Fever, urgency, frequency, dysuria or suprapubic tenderness and urine culture with $=10^5$ colonies/ml with no more than two organism species
• Two of the preceding symptoms and pyuria, or positive leukocyte esterase or nitrate test, or positive Gram stain, or two urine cultures with repeated isolation of organism with $=10^2$ colonies/ml, or one urine culture with $=10^5$ colonies/ml if physician institutes appropriate antimicrobial therapy, or diagnosis or appropriate therapy by physician
Asymptomatic bacteriuria
One of the following:
• Urine culture with $=10^5$ colonies/ml with no more than two organism species in a patient with an indwelling catheter and no symptoms
• Two urine cultures with $=10^5$ colonies/ml of the same organism in a patient who had no indwelling catheter in previous 7 days and no symptoms
Pneumonia
Infection not present or incubating on admission, which meets one of the following:
• Rales or dullness on chest percussion and new onset of purulent sputum, or pathogen isolated from blood, transtracheal specimen, bronchial brushing or biopsy
• New lung infiltrate, consolidation, cavitation or pleural effusion on chest radiograph and one of above criteria, or positive direct or serologic diagnostic test for respiratory pathogen, or histopathologic diagnosis of pneumonia

** Adapted from Garner[1] and Horan.[2]*

spread by this route are given in Table 87.4 . In fact, most micro-organisms that cause endogenous hospital infection have been shown to transiently contaminate the hands of hospital staff and to be disseminated in this way. Vehicles of cross-infection also include contaminated medical devices (such as inadequately disinfected endoscopes,[22] thermometers, electrodes or respirators), infected blood products or organ transplants (see Table 87.4).

Person-to-person spread of pathogens can also follow the fecal-oral route, secretion droplet route and airborne route (see Table 87.4). Pathogens transmitted from person to person in the hospital include community-acquired infectious agents, such as viruses (e.g. varicella-zoster virus, respiratory syncytial virus (RSV), influenza virus, herpes simplex virus, hepatitis A virus, rotavirus, adenovirus), bacteria (e.g. *Staphylococcus aureus, Neisseria meningitidis, Haemophilus influenzae, Mycobacterium tuberculosis*) and parasites (e.g. *Cryptosporidium* spp.). The risk of transmission of these pathogens in the hospital can vary depending upon the age and immune status of hospitalized patients, the staff-to-patient ratio, the number of patients sharing a room, the availability of handwashing facilities and geographic location of the health care facility. Seasonal and environmental changes may affect the prevalence of locally endemic infections in the community. Because many of these pathogens are virulent for normal, nonimmune hosts, these hospital outbreaks can involve infection of hospital personnel and visitors as well as patients.

Occasionally, healthy carriers or infected individuals among hospital personnel may be the source of outbreaks of nosocomial infections (see Table 87.4). Well-documented examples include operating room personnel who are mucosal or skin carriers of *Streptococcus pyogenes, Staph. aureus* or *Staph. epidermidis* and become the source of epidemics of surgical site infection.[23] [24] [25] Certain conditions, such as upper respiratory tract infection or dermatitis, appear to predispose individuals to become efficient airborne disseminators of these organisms.[26] Nosocomial outbreaks of adenovirus keratoconjunctivitis, of RSV and of influenza pneumonia have also been linked to infected health care workers.

Environmental acquisition is an uncommon route of hospital-acquired infection, accounting for less than 5% of cases. Common-source outbreaks can result from exposure of susceptible patients to

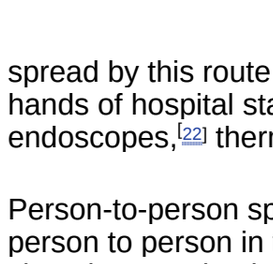

Figure 87-1 Record trend, 1992–2001, in bloodstream infection in Belgian hospitals by pathogen group.

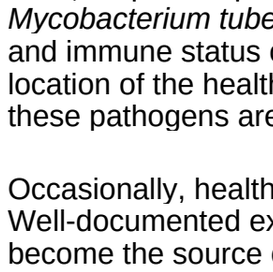

Figure 87-2 Trends in bloodstream infection rates by intensive care unit type and year. National Nosocomial Infection Surveillance System, USA, 1990–99.[13]

air, water, food, medication, disinfectant or medical devices contaminated with micro-organisms originating from environmental reservoirs inside or outside the hospital (see Fig. 87.3 and Table 87.4). Airborne pathogens include *Legionella* spp., *Aspergillus* spp. and other filamentous fungi[27] and *Nocardia* spp. These organisms represent a particular hazard to immunocompromised patients, especially those with cancer and transplant recipients. Waterborne outbreaks of infections in hospitals have been linked to patient bathing in hydrotherapy pools or enteral feeding with water contaminated with *Pseudomonas aeruginosa*, *Acinetobacter* spp. or *Legionella*

spp. Foodborne outbreaks are most frequently caused by *Salmonella* spp. Enteric feeds contaminated with *Enterobacter* spp., can be a source of sepsis. Contamination of intravenous fluids, medications, antiseptics, blood products or medical devices with a variety of aquatic

Figure 87-3 Endogenous and exogenous sources of hospital infection. Hospital infection can originate from an endogenous source or from an exogenous route. Endogenous infection may occur by translocation of resident microflora secondary to a breach in host defense (top). Exogenous infection may result from transmission from patient to patient or from health care worker to patient. It can also occur after exposure of a susceptible patient to a contaminated environmental source, such as inadequately disinfected medical devices (bottom).

micro-organisms, such as *Serratia* spp., *Enterobacter* spp., *Acinetobacter* spp., *Pseudomonas* spp. and *Mycobacterium chelonae*, have caused hospital outbreaks of bacteremia, wound infection and pneumonia.[22] [28] Extrinsic contamination occurs during hospital handling of medications and can lead to a local outbreak[29] or, less commonly, intrinsic contamination takes place during manufacturing of the product, often triggering multi-hospital epidemics.[30] A wide spectrum of agents cause hospital outbreaks, as reported in 228 investigations published from 1997 to June 2002 and identified by Medline searching (Fig. 87.6).

TABLE 87-2 -- Host factors predisposing to hospital infection.

HOST FACTORS PREDISPOSING TO HOSPITAL INFECTION	
Factor	**Example**
Age	Neonates; elderly patients
Underlying disease	System or organ failure (e.g. liver cirrhosis, diabetes mellitus, chronic obstructive pulmonary disease, renal failure), cancer, neutropenia
Immunodeficiency	Congenital or acquired (e.g. AIDS, immunosuppressive therapy, malnutrition)
Specific immunity	Susceptibility to viral infections
Breach of mucocutaneous barriers	Trauma, burns, surgery, endoscopy, indwelling devices
	Mucosal and skin diseases
Anesthesia, sedation	Suppression of cough and peristalsis, hypoventilation
Antibiotics, antacids	Alterations of resident microflora and decrease of resistance to colonization by hospital flora
	Selection of antibiotic-resistant mutants and naturally resistant bacteria and yeasts
Colonizing flora	Carriage of opportunistic bacteria and fungi
Latent infection	Latent infection with intracellular pathogens reactivated by immunosuppression
A variety of factors can alter host defenses and predispose hospitalized patients to infection.	

TABLE 87-3 -- Infections associated with invasive devices and procedures.

INFECTIONS ASSOCIATED WITH INVASIVE DEVICES AND PROCEDURES	
Device/procedure	**Type of infection**
Intravascular catheter	Bacteremia; catheter site infection
Bladder catheter	Urinary tract infection
Mechanical ventilation	Pneumonia; sinusitis
Stents	Pyelonephritis; cholangitis; meningitis
Surgery	Surgical site infection; pneumonia
Endoscopy	Bacteremia; pneumonia; gastroenteritis and cholangitis
Blood transfusion	Bacteremia and fungemia; viral infections
Examples of important hospital infections that are directly related to the use of invasive diagnostic and therapeutic devices and procedures.	

Figure 87-4 Catheter exit site infection in a patient with central venous catheterization through the jugular vein. *Courtesy of Dr F Jacobs.*

ETIOLOGIC AGENTS

A selection of important nosocomial pathogens and their major reservoirs and sources is presented in Table 87.4 . The majority of infections are caused by commensal bacteria, with *E. coli* and *Staph. aureus* being the most common.[7] [8] [9] [10] Micro-organisms isolated from patients who have nosocomial bacteremia and surgical infection reported by the National Nosocomial Surveillance of Hospital Infection in Belgian hospitals are illustrated in Figure 87.7 . The pattern of agents causing hospital infection can vary greatly according to the site of infection, the age and underlying conditions of the patients, and their exposure to medical procedures, invasive devices and antimicrobials.

The spectrum of hospital pathogens has changed over the past decades, reflecting the evolution of medicine. In the pre-antibiotic era, most infections were caused by *Strep. pyogenes* and *Staph. aureus*. Gram-negative bacteria emerged as leading pathogens in the 1960s and 1970s in response to the increased use of antistaphylococcal antibiotics. In the 1980s and 1990s, the massive use of broad-spectrum antimicrobials, the improved survival of critically ill patients, the growing population of compromised patients and the increased use of indwelling medical devices all contributed to the current emergence of multiple antimicrobial-resistant nosocomial pathogens. Well-known examples are methicillin-resistant *Staph. aureus* (MRSA)[31] and *Staph. epidermidis*,[9] multiply resistant *Enterococcus faecium*[32] [33] and *Enterobacter* spp.,[34] *Candida* spp.[9] and *Clostridium difficile*. [20] These changes are illustrated by the modification of the rates of antimicrobial resistance among pathogens identified from intensive care unit patients with nosocomial infections (Fig. 87.8).[35] A dramatic example of the resurgence of a major pathogen is the occurrence of outbreaks of multiply resistant *M. tuberculosis* in hospitals caring for HIV-infected patients and in which adequate diagnostic and patient isolation facilities were not available.[36]

The increasing prevalence of antibiotic-resistant bacteria as agents of hospital infection has reached alarming proportions.[37] [38] Occasional strains of organisms such as *E. faecium*, *P. aeruginosa* or *Acinetobacter baumannii*, that are resistant to all available antimicrobials with established clinical efficacy, cause infections that leave few therapeutic options. Patients infected with resistant pathogens are more likely to receive ineffective therapy, require hospital care, stay in for a longer time, develop complications and die of the infection.[39] The cost of care is also increased for such patients, due to the need for second-line drugs, longer duration of hospital stay, increased need for intensive care and diagnostic testing, and expenses of isolation precautions.

To provide a sound basis for the control of this problem, research efforts have focused on determining the respective roles of selection by antibiotic treatment of naturally resistant micro-organisms from the endogenous flora, selection and transfer of resistant mutants and of mobile genetic determinants, such as transposons and plasmids, and dissemination of resistant clones between hospitalized patients. [40] A number of recent studies, performed in intensive care units in which antibiotic-resistant bacteria were frequent and clinically significant, showed that these various determinants generally interact in a multifactorial fashion. [33] [41] [42] [43] [44] [45] [46] Although variations are observed between bacterial strains and different hospitals, general trends in the relative contributions of these mechanisms can be recognized as typical of each resistant pathogen (Table 87.5). Clonal dissemination from patient to patient is a predominant mechanism of increased prevalence for the majority of resistant nosocomial pathogens. Transmission occurs most commonly via the contaminated hands of health care personnel and, less commonly, by contaminated equipment. Risk factors for colonization (which generally precedes infection) or infection with

Figure 87-5 Severe clinical conditions are often associated with invasive life-support devices (a) causing multiple disruptions of mucocutaneous barriers. (b) Oropharyngeal and nasogastric tubes; (c) wound drainage; (d) urinary indwelling catheter; (e) central venous catheter.

resistant bacteria include the local 'colonization pressure' (or the proportion of colonized patients on admission to the unit), the severity of underlying disease, the duration of stay in intensive care and in the hospital, and the intensity of exposure (number and duration) to broad-spectrum antimicrobial drugs and invasive devices such as intravascular and urinary catheters.[33] [41] [42] [43] [44] [45] [46] Cost containment in hospital management has led to increased patient turnover and transfer between institutions as well as to chronic understaffing, both of which are factors that enhance nosocomial transmission of antibiotic-resistant bacteria.

CONTROL STRATEGIES

Before we examine the different components of an effective infection control program, it is worth considering exactly what the targets and objectives of the prevention strategies are, based on our

TABLE 87-4 -- Modes of transmission of nosocomial pathogens.

MODES OF TRANSMISSION OF NOSOCOMIAL PATHOGENS		
Mode of transmission	**Reservoir/source**	**Examples of pathogens**
Contact	Patients/health care workers, fomites, medical devices	*Staphylococcus aureus*
		Enterococcus spp.
		Enterobacteriaceae
		Clostridium difficile
		Respiratory syncytial virus
		Rotavirus
		Adenovirus
		Candida spp.
Droplet spread	Health care workers, patients	*Staphylococcus aureus*
		Respiratory syncytial virus
		Influenza virus
Device-related	Water/respiratory equipment, endoscopes	*Pseudomonas aeruginosa*
		Acinetobacter spp.
		Stenotrophomonas maltophilia
Medication-related	Water/iv fluids, disinfectants	*Burkholderia cepacia*
		Acinetobacter spp.
		Serratia marcescens
Transfusion, needlestick	Patients/blood	Hepatitis B virus, hepatitis C virus, HIV, etc.
Transplantation	Patients/donor tissue	Cytomegalovirus
		Toxoplasma gondii
		Creutzfeldt-Jacob agent
Airborne	Patients	*Mycobacterium tuberculosis*
	Hot water/showers	*Legionella* spp.
	Soil/dust	*Aspergillus* spp.
Food-borne	Animals/food products	*Salmonella* spp.
	Water/enteral feeding	*Enterobacter* spp.
		Pseudomonas aeruginosa
Modes of transmission and examples of sources of infection for selected nosocomial pathogens.		

understanding of the pathogenesis and epidemiology of hospital infection (Table 87.6). This classification is of course somewhat simplistic, as a single strategy may meet several objectives. For example, perioperative antibiotic prophylaxis reduces not only the bacterial inoculum released from the patient's own flora but also the bacteria released into the operative site from the surgical team's flora. However, this approach underlines the fact that further research into the mechanisms of acquisition of hospital infection is needed to design optimal prevention methods.

Functions and organization of the hospital infection control program

Major differences among countries in their health care resources and organization and different medical cultures explain the diversity of approaches to the organization of hospital hygiene and infection control in hospitals around the world. The best known approach is the paradigm of hospital epidemiology developed in the USA.[47] In the hospitals of industrialized countries today, the co-ordination of infection control typically operates on two levels: an executive body — the infection control team — and an advisory body to the hospital management — the infection control committee — which adopts the 'legislative' role of policy making. The functions of these

bodies are to design, revise and recommend policies and procedures; foster good hygienic practices through continuing education of and interaction with health care personnel; to perform epidemiologic surveillance and outbreak management; and to monitor and advise on the utilization of

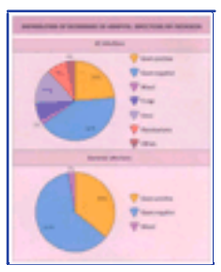

Figure 87-6 Distribution of outbreaks of hospital infection by pathogen. Distribution of outbreaks of hospital infection identified by Medline search from 1997 to June 2002, by category of pathogen. Bacteria caused 65% of outbreaks, of which 61% were Gram negative, 36% Gram positive and 3% mixed bacterial pathogens.

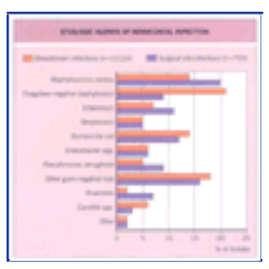

Figure 87-7 Etiologic agents of nosocomial bloodstream and surgical site infections in Belgian hospitals. National Program for the Surveillance of Infection in Hospitals, 1992–95.

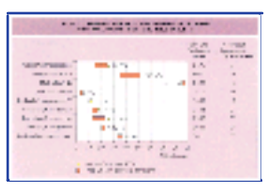

Figure 87-8 Selected antimicrobial resistant pathogens associated with nosocomial infections in intensive care unit patients. Comparison of resistance rates from January-December 2000 with 1995–99, NNIS Surveillance. CNS, coagulase-negative staphylococci; 3rd ceph, resistance to 3rd generation cephalosporins.

antimicrobial agents, safety of new medical devices, sterilization, disinfection, waste management and housekeeping in the institution. Evaluation of the program must ensure institutional compliance with policies, recommendations, regulations and accrediting requirements.

To achieve these broad missions cost-effectively, the infection control program requires adequate human and material resources proportional to the size and sophistication of the health care institution and the vulnerability of the patient population. In general, the team should include at least one or more physician and nurse specially trained in infectious diseases, microbiology, epidemiology and infection control. The hospital infection control physician may be an infectious diseases specialist or a clinical micro-biologist. Beyond the availability of infection control professionals, an extensive infrastructure is required, including microbiology laboratory support and access to integrated computing systems linking administrative, laboratory and clinical data.[48] Expert system software integrated in the microbiology laboratory information system can provide early warning of outbreaks by identifying the abnormal occurrence of clusters of patients colonized or infected with similar micro-organisms. Access to all sources of useful outcome data needs

TABLE 87-5 -- Relative importance of mechanisms that contribute to the increasing frequency of antimicrobial resistance of selected nosocomial pathogens.

MECHANISMS OF INCREASED ANTIMICROBIAL RESISTANCE OF NOSOCOMIAL PATHOGENS								
Pathogen	**Resistance pattern**	**Selection of mutation**	**Gene spread**	**Clonal spread**	**Reservoir**		**Transmission**	
					Human	**Environment**	**Direct**	**Indirect**
Staphylococcus aureus (MRSA)	ß-Lactam, multiple	+	+	+++	+++	+	+++	+
Enterococci	Glycopeptides, multiple	+	++	++	+++	+	+++	++
Klebsiella spp.	Extended spectrum ß-lactamase	+	++	+++	+++	-	+++	-
Enterobacter cloacae	Derepressed chromosomal ß-lactamase	+++	-	+	+++	-	+	-
Enterobacter aerogenes	Multiple	++	+	++	++	+	++	+
Acinetobacter baumannii	Multiple	++	+	+++	++	++	++	++
Pseudomonas aeruginosa	Multiple	+++	+	+	++	+	+	++

to be developed such as, for example, results of post-mortem examination to detect cases of nosocomial aspergillosis.

The landmark Study on the Efficacy of Nosocomial Infection Control, conducted in the 1970s in US hospitals, showed that the incidence of infection could be reduced by 32% in hospitals with an adequately staffed infection control team (defined as one physician per 1000 beds and one nurse per 250 beds) and performing active surveillance activities, compared with hospitals without such programs.[4] The infection control committee is typically composed of the physician hospital epidemiologist, hospital manager, hospital infection control practitioners (often nurses), medical and nursing directors, leading medical and nursing representatives of clinical departments, and representatives of other departments such as the microbiology laboratory, pharmacy, sterilization services, employee health clinic and safety committee. This advisory body develops and regularly updates infection control policies and reviews the progress achieved toward the institution's objectives in this field. Policies are designed based on national regulations, the published data documenting prevention strategies, guidelines and standards provided by national advisory committees and consensus conferences, and the local epidemiologic data and patient care resources. Extensive and detailed guidelines

TABLE 87-6 -- A rational classification of hospital infection prevention strategies.

A RATIONAL CLASSIFICATION OF HOSPITAL INFECTION PREVENTION STRATEGIES		
Target	**Objective**	**Example of strategy**
Endogenous infection	To prevent or neutralize the translocation of commensal flora	• Antibiotic prophylaxis in surgery
		• Skin antisepsis before surgery
		• Antiseptic-bound iv catheter
		• Intestinal decontamination of neutropenic patients
		• Pneumococcal immunization before splenectomy

Exogenous infection	To prevent cross-infection	• Hand hygiene for patient care procedures
		• Isolation and decolonization of carriers of transmissible pathogens
		• Sterilization or disinfection of invasive devices
		• Cleaning and disinfection of fomites
		• Outbreak detection and molecular epidemiologic studies to determine the mode and vehicles of spread
	To prevent common-source infection	• Ultra-clean air for prosthesis surgery or bone marrow transplant recipients
		• Disinfection of *Legionella* spp. in water systems
		• Environmental, water and food hygiene
		• Sterile parenteral drugs and implantable material
		• Outbreak detection and molecular epidemiologic studies to identify the source
Antimicrobial resistance	To prevent the emergence, and spread of resistance genes	• Restricted usage of broad-spectrum antimicrobial agents
		• Optimized anti-infectious therapy (agents, dosage and duration)
	To prevent the spread of resistant strains of micro-organisms	• Detection, monitoring and timely reporting of antimicrobial resistance
		• Isolation precautions and treatment of carriers of transmissible resistant strains
		• Molecular epidemiologic studies to distinguish between mutant selection, gene or clone dissemination

TABLE 87-7 -- Aims of hospital infection surveillance.

AIMS OF HOSPITAL INFECTION SURVEILLANCE
• To identify high-risk patients and procedures and assign infection control priorities
• To monitor trends over time of incidence and patterns of infection
• To detect outbreaks of hospital infection
• To evaluate the efficacy of prevention and control interventions
• To evaluate quality assurance programs
• To educate and motivate heath care providers and decision makers

have been published by the CDC and the Hospital Infection Control Practice Advisory Committee (HICPAC). The latest version of these recommendations is available at: www.cdc.gov/ncidod/hip/HICPAC. Each recommendation is categorized according to supporting scientific evidence, theoretical rationale and applicability.

TABLE 87-8 -- **Surveillance methods for the evaluation of infection control program outcomes and processes.**

SURVEILLANCE METHODS FOR THE EVALUATION OF INFECTION CONTROL PROGRAM OUTCOMES AND PROCESSES		
Scope	**Objective, indicators and method of data collection**	
Outbreak warning	Objective	Detection and cluster analysis of transmissible organisms
	Indicators	Numerator: colonization or infection by specific micro-organism
	Case-finding	Laboratory-based
Prevalence of hospital infection	Objective	Periodic assessment of prevalence of infection: hospital-wide or selective
	Indicators	Numerator: infection by site, ward, procedure or device
		Denominator: patient census on day of survey, procedures or devices
	Case-finding	Laboratory and/or ward liaison, chart review, computerized patient record
Incidence of hospital infection	Objective	Continuous monitoring of incidence of infection: hospital-wide or selective
	Indicators	Numerator: infection by site, ward, procedure or device
		Denominator: patient admissions, hospital-days, procedures, device-days
	Case-finding	Laboratory and/or ward liaison, chart review, computerized patient record
Antibiotic usage	Objective	Continuous monitoring and quality assessment of antibiotic utilization patterns
	Indicators	Numerator: type of antimicrobial cures, doses and duration used for prophylaxis and treatment
		Denominator: surgical interventions, documented infections (e.g. bacteremia), patient admissions
	Case-finding	Pharmacy records, operating room record, medical and nursing records, chart review, computerized patient record
Hygiene practices	Objective	Monitoring of compliance with, and quality assessment of, hygiene practices
	Indicators	Numerator: patient care procedures performed with appropriate hygiene precautions
		Denominator: procedures requiring standard hygiene precaution, patient census, density of care index
	Case-finding	Ward observations, pharmacy and central supply records (gloves, disinfectants, etc.)
Surveillance methods can vary in scope and objectives. The choice of indicators and case-finding methods will depend on the surveillance strategy selected.		

As a result of ongoing re-engineering of health care systems to improve cost-effectiveness, acute care hospitals increasingly operate as partners of larger consortia of health care programs including long-term care facilities, day-care surgery, outpatient clinics and home care. Likewise, infection control programs must increasingly assess and manage risk through these various levels of care. Furthermore, as nosocomial epidemics easily spread with transfer of

patients between acute and long-care facilities, and as the development of evidence-based control strategies requires substantial investment and data sample size, communication and co-ordination at regional and national levels has become an important part of infection control programs. The increasing demand for public accountability of health care providers also means that validated process and outcome indicators must be determined for performance assessment of the infection prevention.[11]

Surveillance

Epidemiologic surveillance is a systematic, ongoing process of data collection, analysis, interpretation and reporting, which is performed to monitor the temporal trends in disease frequency and associated risk factors in a population. The basic principle of its application to hospital infection surveillance is to measure the reduction of risk of infection as an outcome indicator of the effectiveness of the prevention efforts. Some of the objectives that can be assigned to surveillance activities are described in Table 87.7 . As a tool to evaluate the quality of care, outcome surveillance (i.e. monitoring the risk of hospital infection) can be coupled with the auditing of processes regulated by the infection control program, such as compliance with standards of antimicrobial usage and hygienic care practice.

A key element to the usefulness of any surveillance system is to achieve a consensus with the patient care providers on what will be its objectives, indicators and methods of case-finding and validation. Likewise, the involvement of clinical staff in data collection and interpretation of results is necessary for ensuring the credibility of the surveillance data as a guide to optimal care practices.

Because surveillance is a costly and time-consuming activity, each hospital must carefully tailor its system to its priorities and resources. Except in some US hospitals, staffing levels of infection control teams do not allow for comprehensive, hospital-wide surveillance of incidence rates of all infection types. Therefore, selective surveillance must be targeted to high-risk populations or procedures, particularly if specific control interventions are implemented. Haley provided a scheme to select surveillance objectives by site of infection based on the avoidable costs and morbidity associated with each infection type.[49]

Depending on the scope and objectives of the surveillance activities, different indicators and data collection methods can be used (Table 87.8). Outbreak warning can be largely accomplished by time-and-place cluster analysis of numerator laboratory data. This analysis will focus on patients colonized or infected by micro-organisms known to be transmissible by cross-infection or common-source acquisition, such as *C. difficile*, MRSA or *Legionella* spp. (alert organisms).

For the monitoring of overall infection risk, repeated prevalence surveys are more cost-effective than continuous incidence surveillance and can be used successfully to evaluate the efficacy of control measures.[50] [51] Data sources and collection methods used for the detection of patients who have hospital-acquired infection vary in their efficiency (i.e. the balance between accuracy and workload). A comparative evaluation of selective surveillance methods in a UK hospital reported a sensitivity of 76% for a time of 6.4 hours per 100 beds per week by using a laboratory-based and ward liaison method. [52] This method consists of daily review of case records of patients who have a positive microbiology report and of patients reported by nursing staff to have an infection. The reference method, based on exhaustive record review and staff interview, required 18.1 hours per 100 beds per week. In that study, laboratory-based detection had a sensitivity of 51% for a time requirement of only 3.1 hours per 100 beds per week. In US or Belgian hospitals this method achieved a sensitivity of 80–84%,[53] whereas it had only a 20% sensitivity in a Brazilian hospital.[54] These discrepancies illustrate the fact that the efficiency of a surveillance method will depend on local factors, such as the rate of utilization of microbiology tests. Other case detection methods based on review of temperature and drug prescription charts or on patient risk factors also appear to be efficient.[52] Ideally, the sensitivity, specificity and interobserver repeatability should be evaluated by comparison with an exhaustive case-finding reference method to validate the method used.

The efficiency of hospital infection surveillance and quality assessment of antimicrobial prescription can be greatly enhanced by the development of computerized patient records and integrated hospital information systems that link clinical information, laboratory, radiology and pharmacy records into a single database.[55] [56] Standardization of criteria for codification of risk factors, interventions and definitions of hospital infection is a first step toward inter-hospital comparison of rates.[57] [58] National surveillance systems can provide baseline data for hospitals willing to compare the rate of infection in their institution with risk-adjusted rates in similar institutions. However, methodologic issues remain unsettled on how best to adjust for confounding factors and to define similar institutions. National surveillance networks can also be set up to monitor the rate of nosocomial transmission of major pathogens, such as the incidence of MRSA acquisition in hospitals in which co-ordinated control policies have been implemented.[58]

When surveillance is used to assess the effectiveness of infection control interventions, a quantitative assessment of compliance with the recommended methods is a valuable component of the policy evaluation (see Table 87.7). Direct methods of practice auditing (e.g. observation of patient care procedure such as glove use, hand disinfection or reprocessing of flexible endoscopes) are preferred for data collection but require significant staffing resources. Indirect methods, for example measuring the rate of material usage (e.g. gloves, disinfectant, isolation facilities), are more efficient but provide only partial and crude indicators of patient care practices.

Outbreak management

An epidemic or outbreak can be defined as a significant temporal increase in the prevalence of infection above the expected baseline prevalence in a given population. The early detection and prompt management of outbreaks of hospital infection are important because of the frequent occurrence, clinical impact and preventable nature of epidemic infections.[59] The prevalence of outbreaks has been reported at approximately 1 per 10,000 admissions and the etiologic fraction can be estimated to account for 5–10% of all hospital-acquired infections. [59] [60] In addition, even small clusters of infection that do not cross the threshold of statistical significance can be worth investigating, because identification of the mode of transmission can lead to effective prevention. The true magnitude of small-scale clustering caused by cross-infection remains to be defined. In a study employing molecular subtyping [19] 38% of episodes of nosocomial infections detected in patients admitted to intensive care units were found to be cross-transmitted. Although many outbreaks resolve spontaneously, delay in the detection and control of an outbreak may be associated with considerable excess morbidity, mortality or costs.[61] The steps involved in the investigation and control of outbreaks have been well defined (Table 87.9).[59]

A pseudo-epidemic associated with extrinsic contamination of clinical samples during collection or processing should be ruled out, as well as any spurious rise in incidence due to observation bias, such as improvement in diagnostic sensitivity by change in laboratory methods. The first step to confirm the suspected epidemic event is the elaboration of a case definition on the basis of which additional epidemic cases should be sought. The definition is based on clinical signs, etiologic agents or both. As many nosocomial epidemics involve transmission of bacteria from asymptomatic

TABLE 87-9 -- Steps in the investigation and control of outbreaks.*

STEPS IN THE INVESTIGATION AND CONTROL OF OUTBREAKS
1. Establish a case definition and define the population at risk
2. Confirm existence of a true outbreak
• rule out pseudo-outbreaks (contamination of cultures during clinical sample collection or processing)
• rule out surveillance artefacts (increase in laboratory utilization, or improved laboratory or surveillance methods)
• determine space-time clustering and/or significant increase of incidence rate versus baseline period in exposed cohort
3. Determine clinical severity of infections and number of patients affected to define the degree of emergency; allocate time and resources for further investigation accordingly
4. Complete case-finding retrospectively and prospectively; ensure accurate microbiologic sampling and processing for optimal ascertainment of etiology; ensure storage and plan the typing of clinical isolates
5. Review the literature about risk factors and potential sources and compare with host and exposure factors revealed by reviewing the medical charts of infected patients
6. On the basis of descriptive epidemiology of epidemic cases in time, place, patient characteristics, and common exposure to devices, treatments and procedures, formulate tentative hypotheses about host factors, hospital exposure factors, reservoirs, source and mode(s) of transmission
7. Reinforce standard hygiene precautions and initiate temporary control measures based on hypotheses defined in step 6; follow-up impact on rate of transmission
8. If necessary, test hypotheses defined in step 6 by case-control, cohort and/or intervention studies and by epidemiologic typing of representative isolates
9. If necessary, initiate targeted culture surveys from potential reservoirs/sources (patients, personnel, environment, as appropriate); confirm the suspect epidemiologic link by comparative typing of isolates
10. Review results of the investigation with all concerned authorities and staff; report to the Infection Control Committee
11. Conduct follow-up surveillance to evaluate efficacy of control measures; update control measures if necessary; follow-up evaluation reports for the Infection Control Committee and all staff concerned

* *Adapted from Wendt and Herwaldt.*[59]

carriers, it may be useful to include both infected and colonized patients in the epidemic case definition. The epidemic is confirmed by comparing the incidence of cases during the outbreak period with the expected incidence using historic controls in the same population. Some rare and clinically severe nosocomial infections such as pneumonia caused by *Legionella* or *Aspergillus* surgical site infection should trigger immediate investigation and corrective action after a single case is detected. More generally, at the initial phase of epidemic investigation, it will be useful to reinforce standard hygiene procedures as insidious decline in compliance with these often

contributes to outbreaks.

The distribution of cases over time (the epidemic curve) may be suggestive of the mode of acquisition of the infection. The collection of data on demographic characteristics of cases, underlying disease, exposure to invasive procedures and devices is essential to complete the descriptive analysis and to formulate hypotheses of transmission. When needed, these hypotheses should be tested by performing analytic studies, often of case-control design, to identify the risk factors for transmission. Microbiologic investigations, including culture surveys and molecular typing, may be required to identify

TABLE 87-10 -- Role of the clinical laboratory in the investigation of hospital infection outbreaks.[*]

ROLE OF THE CLINICAL LABORATORY IN THE INVESTIGATION OF HOSPITAL INFECTION OUTBREAKS		
Investigation step	**Laboratory method**	**Aim**
Outbreak detection	Identification and susceptibility testing of clinical isolates	Case finding, cluster detection
Outbreak confirmation and descriptive epidemiology	Epidemiologic typing of clinical isolates	Delineation of clonal spread
Identification of reservoirs and mode of transmission	Culture surveys of reservoirs and vehicles	Documentation of reservoir of epidemic clone(s)
	Typing of environmental isolates	Test of transmission hypotheses
Follow-up of efficacy of control measures	Typing of clinical isolates, as part of post-outbreak surveillance	Test of interruption of transmission hypothesis

** Adapted from Struelens.*[60]

the reservoirs of the epidemic micro-organism and confirm the routes of transmission. The rapid evolution of medical technology results in the continuous introduction of new medical devices and modification of diagnostic and therapeutic procedures. Because the infection control team is often incompletely informed of these modifications, discussion with clinical staff and direct observation of patient care practices is useful for the detection of violation of infection control standards or problems with inadequate product design, maintenance or utilization.

After an outbreak is controlled and at regular intervals for endemic transmissible pathogens such as MRSA, the infection team should provide a report on the outbreak management to the infection control committee and local health authorities. Moreover, it is essential to provide feedback to all concerned clinical staff to consolidate compliance with the recommended procedures and trust in the infection control team (see also Chapter 50a).

Role of the clinical microbiology laboratory

The microbiology laboratory plays a key role in the detection, investigation and control of outbreaks of nosocomial infections (Table 87.10). This role includes accurate detection, species identification and susceptibility testing of micro-organisms causing hospital infection; archival and ongoing epidemiologic analysis of clinical test results; performing targeted microbiologic surveys of the hospital environment; and storage and epidemiologic typing of microbial isolates to support outbreak investigations.[60] [62]

Rapid laboratory detection and reporting of 'alert' organisms known for their potential to cause outbreaks, for example *C. difficile*, MRSA or multidrug-resistant *M. tuberculosis* (see Table 87.8), lead to the timely implementation of specific infection control precautions to reduce the risk of secondary spread.[60] In the past decade, 63% of outbreaks were detected in our institution by prospective or retrospective reviews of laboratory data. Certain types of epidemics are difficult to identify, like those caused by organisms that are also common causes of endemic infections or those caused by multiple strains. This type of epidemic can follow a break in disinfection technique, as observed in an outbreak of postendoscopy biliary sepsis in which only molecular typing could distinguish multiple strain cross-infection from endogenous infections.[22]

Epidemiologic typing

Epidemiologic typing is used for discrimination between unrelated isolates of the same microbial species and related isolates, derived by clonal descent from the same ancestor cell, as part of a common chain of transmission.[63] [64] This can be achieved by scoring appropriate phenotypic or genotypic markers that exhibit sufficient intraspecies diversity.[65] Typing systems can be used for different purposes, including to delineate the extent and patterns of dissemination of epidemic clone(s); to test hypotheses about the reservoirs, sources and vehicles of transmission; and to verify the interruption of transmission by application of control measures.[63]

A rapidly expanding number of laboratory techniques are available for the epidemiologic analysis of nosocomial pathogens. Table 87.11 gives an overview of the underlying principles and performance of selected typing methods. For the evaluation of performance, several criteria are used, including typeability, reproducibility, stability, discriminatory power and versatility:

- *typeability* refers to the proportion of isolates that can be assigned a type, ideally all isolates;
- *reproducibility* is the ability of the system to assign the same type on repeat testing of the same strain;
- *stability* is the probability that clonally derived isolates express the same type over time;
- *discriminatory power*, or the ability to distinguish epidemiologically unrelated isolates, is particularly important because it conditions the probability that isolates sharing the same type or clonal group of types are epidemiologically linked; and
- the *versatility* of a typing method, or its ability to type different pathogens, given minor technical modifications, is an important additional practical advantage for clinical laboratories involved in the study of nosocomial infections.

TABLE 87-11 -- Conventional and molecular typing systems for the epidemiologic analysis of nosocomial pathogens.

CONVENTIONAL AND MOLECULAR TYPING SYSTEMS FOR THE EPIDEMIOLOGIC ANALYSIS OF NOSOCOMIAL PATHOGENS						
Typing system	**Principle**	**Versatility**	**Typeability**	**Discrimination**	**Reproducibility**	**Stability**
Antibiogram	Susceptibility profile to a panel of antimicrobials	Broad	Excellent	Variable	Good	Variable
Biotype	Phenotypic characteristics (e.g. biochemical reaction profile)	Narrow	Excellent	Variable	Good	Good
Serotype	Pattern of surface antigens, defined by a set of specific antibodies	Narrow	Good	Moderate	Good	Good
Phage type	Lysis susceptibility pattern to a panel of specific bacteriophages	Narrow	Moderate	Good	Moderate	Moderate
Immunoblotting	Molecular weight patterns of protein antigens, separated by PAGE and identified with labeled antibodies	Narrow	Excellent	Good	Good	Moderate
Plasmid RFLP analysis	Pattern of restriction fragments of plasmid DNA by agarose electrophoresis	Moderate	Variable	Variable	Good	Moderate
Ribotyping	Pattern of restriction fragments of genomic DNA by Southern blot analysis with ribosomal RNA (or ribosomal DNA)-labeled probe	Broad	Excellent	Moderate	Excellent	Excellent
Southern blot RFLP analysis of genomic DNA	Pattern of genomic DNA restriction fragments by Southern blot analysis with specific DNA-labeled probe (e.g. insertion sequence element, structural gene sequence)	Narrow	Excellent	Variable	Excellent	Excellent
PFGE of macrorestriction fragments of genomic DNA (PFGE analysis)	Pattern of large genomic DNA restriction fragments generated by rarely cleaving endonucleases and resolved by PFGE	Broad	Excellent	Excellent	Good	Good

PCR-mediated gene RFLP analysis	Pattern of restriction fragments of PCR-amplified polymorphic gene region (e.g. variable size tandem repeats)	Narrow	Excellent	Variable	Excellent	Excellent
AP-PCR and randomly amplified polymorphic DNA analysis	Pattern of low-stringency PCR-amplified genomic DNA segments lying between motifs partly homologous to short, arbitrary sequence primers	Broad	Excellent	Good	Moderate	Good
Inter-repetitive element spacer length polymorphism analysis (rep-PCR analysis)	Pattern of high-stringency PCR-amplified genomic DNA segments lying between repeat motifs (e.g. insertion sequence elements, ERIC sequences) by using outwardly oriented primers	Variable	Variable	Good	Good	Good
AFLP analysis	Pattern of high-stringency PCR-amplified segments of adaptor-tagged genomic DNA restriction fragments	Broad	Excellent	Excellent	Excellent	Excellent
Nucleotide sequence analysis	Determination of DNA sequence of variable genomic regions	Universal	Excellent	Excellent	Excellent	Good
A tentative assessment of the performance characteristics of the methods is proposed. Many methods are still under evaluation and their performance may vary according to the pathogen analyzed.						

As yet there is no universally applicable, optimally discriminating, well-standardized and easily interpretable system. It is recommended that a combination of typing systems be applied to confidently assess microbial relatedness. In contrast to most phenotypic typing systems, many methods based on the analysis of genomic DNA polymorphism have broad applicability. Similar reagents (e.g. restriction enzymes) and equipment (e.g. electrophoresis systems and pattern recognition software) can be used for typing different micro-organisms. The majority of these methods provide results within 1–3 days (i.e. rapidly enough to be useful in outbreak management). In general, molecular typing systems are more discriminating than

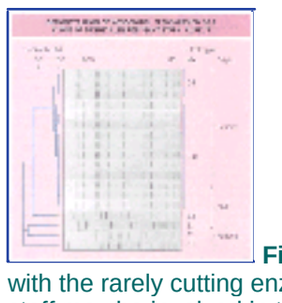

Figure 87-9 Demonstration of nosocomial transmission of a clone of methicillin-resistant *Staphylococcus aureus.* PFGE pattern of macrorestriction fragments cleaved with the rarely cutting enzyme *Sma I* of genomic DNA from MRSA. The same genotype (type D4) is found in isolates from 12 patients and 2 colonized health care staff, indicating that some members of staff may be involved in transmission in an intensive care unit department. Unrelated genotypes are also observed (B2–G1). Size marker, kb: kilobase pairs.

phenotypic methods (Table 87.11), but the results produced, typically as an electrophoretic pattern of DNA fragments (Fig. 87.9), can be complex and difficult to interpret. Guidelines have been proposed for definitions of commonly used terms, such as strain and clone, and of criteria for epidemiologic relatedness, based on the results from some DNA typing systems, such as pulsed-field gel electrophoresis (PFGE) analysis.[63] [66] Molecular typing systems have contributed greatly to our understanding of the mechanisms of acquisition of hospital infections. Pathogens that are difficult to type such as *Enterococcus faecalis* and *Candida albicans*, that were until recently believed to arise solely from an endogenous origin, have been shown to cause common-source or cross-infection outbreaks in hospitals by molecular epidemiologic studies.

Commonly used conventional and molecular methods are outlined below and their advantages and limitations are briefly reviewed. It should be stressed that adequate comparative evaluations of these methods are not available for many of the newer methods or less well-studied pathogens, making any comparative overview indicative only.

Phenotyping methods

Antibiogram

This conventional phenotypic method, particularly if it provides quantitative susceptibility data, is a useful and routinely available first-line technique used to recognize outbreaks of hospital infection with resistant bacteria, including *Staph. aureus*[67] and *A. baumannii*.[68] However, as phenotypic characters that influence fitness undergo periodic selection, unrelated clones of nosocomial pathogens exposed to the selective pressure of antimicrobials can display evolutionary convergence to the same advantageous resistance phenotype through mutations and multiple genetic exchanges. The level of discrimination of antibiogram varies according to the battery of test drugs used and the prevalence of acquired resistance traits in the study population.

Biotyping

This is based on diversity of colonial morphology, biochemical activity and other phenotypic characters, which tend to be unstable and poorly reproducible, unless highly specialized biotyping schemes are used.

Serotyping

Surface antigens are characterized using a panel of species-specific polyclonal or monoclonal antibodies. It is a moderately discriminating tool used for strain delineation of several hospital pathogens, including *Legionella* spp., *P. aeruginosa* and *C. difficile*. For a number of reasons, surface antigens are not, however, reliable markers of population structure. Clonally related strains may show antigenic variation, as occurs, for example, among highly genomically related *Legionella pneumophila* strains isolated from an outbreak of legionellosis.[69]

Phage typing

This highly specialized technique is based on susceptibility to cell lysis by a defined set of bacteriophages. Although very useful in past investigations and still used in some reference laboratories for typing important pathogens such as *Salmonella* spp. and *Staph. aureus*, it is being gradually supplanted by molecular techniques because of incomplete typeability, poor reproducibility and difficulties in pattern interpretation. [60] [70]

Immunoblot analysis

Also known as Western blot analysis, this technique involves the separation of bacterial proteins using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and their subsequent transfer onto a membrane and reaction with labeled, broad-spectrum antibodies. It has been applied successfully to different bacterial pathogens, including *C. difficile*,[20] *Staph. aureus* and *A. baumannii*, [70] [71] but is now supplanted by genotypic methods. Immunoblotting shows good discrimination, but interpretation of pattern differences is not well defined. Other phenotypic methods that can be valuable for epidemiologic typing, such as multilocus enzyme electrophoresis and pyrolysis mass spectrometry, are less widely used.

Genotyping methods

Plasmid profile analysis

The first DNA-based typing method available for epidemiologic studies, plasmid typing has now largely been replaced by methods that determine chromosomal DNA polymorphism because of technical variability and biologic limitations. Restriction endonuclease analysis of plasmid DNA improves reproducibility and discrimination and is useful for strain differentiation of important pathogens such as *Staph. aureus*.[70] However, plasmids can be lost or acquired by conjugation and can recombine internally or into the chromosome by transposition. The in-vivo instability of plasmids must be taken into account when interpreting typing results.[72] Plasmid analysis is essential for the epidemiologic analysis of hospital infections with multiple antibiotic-resistant organisms and for tracing dissemination of mobile antibiotic resistance

genes.

Restriction fragment length polymorphism analysis

Genotyping can be performed by cleavage of chromosomal DNA with restriction endonucleases and electrophoretic separation of DNA fragments (Fig. 87.10). Restriction endonucleases that have frequent recognition sites produce complex fragment patterns by agarose or PAGE separation. The number and length of restriction fragments are affected by sequence variations that create or delete

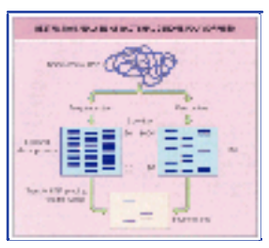

Figure 87-10 Restriction analysis of bacterial genome polymorphism. Chromosomal DNA is released after lysis of the bacterial cells. Restriction endonucleases that recognize commonly occurring sites will cut DNA in many small fragments. After conventional electrophoresis, these fragments are transferred onto a membrane and revealed by hybridization with labeled probes (Southern blot analysis). Alternatively, DNA can be restricted by endonucleases that recognize only rarely occurring sites. The few large, or macrorestriction, fragments are then separated by PFGE analysis.

recognition sites and by recombinational events that occur at or between restriction sites. To improve the resolution and facilitate the interpretation of genomic restriction fragment length polymorphism (RFLP) analysis, two approaches are used:

- transfer of restriction fragments onto membranes, followed by Southern blot hybridization with DNA probes, and
- use of endonucleases that have infrequent (<30) recognition sites in the chromosome, followed by separation of these macrorestriction fragments by PFGE (see Fig. 87.9).

Genome RFLP analysis by Southern blot hybridization

This can be applied by using different types of nucleic acid probes, including randomly cloned chromosomal fragments;[69] structural gene sequences;[73] insertion sequences and transposons;[74] and ribosomal RNA or cloned ribosomal DNA sequences, also called ribotyping.[75] The performance of these systems depends on the organism and DNA probe. Probe sequence, restriction endonucleases, electrophoresis and hybridization conditions must be optimized for each species. In general, these RFLP typing techniques are less discriminating than other genotyping systems such as PFGE and arbitrarily primed polymerase chain reaction (AP-PCR), described below.

Ribotyping

This is the most versatile and the most widely used RFLP typing strategy. The evolutionary conservation of ribosomal RNA makes *E. coli* ribosomal RNA applicable as a universal bacterial probe. Most bacteria have more than five ribosomal operons per chromosome and produce ribotype patterns of 5–15 bands. An automated ribotyping system is commercially available. Ribotyping exhibits excellent reproducibility and stability, but only moderate discriminatory power.[75] In addition, no consensus has been achieved on an optimal procedure and rules for pattern interpretation.

Genome macrorestriction analysis resolved by PFGE analysis

This method is currently preferred for molecular typing of most nosocomial pathogens.[60] [66] Low-frequency cleaving enzymes cut the bacterial chromosome into fewer than 30 fragments, typically 10–700kb in size. Periodic change in the orientation of electric field during agarose electrophoresis, or Pulsed Field Gel Electrophoresis (PFGE), allows separation and size determination of these macrorestriction fragments (see Fig. 87.10). It can be applied to any bacteria or yeasts, with minor technical modifications. In comparison with other typing methods, PFGE analysis shows equal or greater discriminatory power. Consensus rules for interpretation of PFGE patterns in outbreak investigation are available.[66]

PCR-based strategies

In PCR-mediated gene RFLP typing, a polymorphic DNA target sequence is PCR-amplified at high stringency, cut with restriction endonucleases, separated by electrophoresis and isolates are compared by RFLP pattern. Careful identification of polymorphic gene sequences and selection of discriminant enzymes must be performed for each species. Polymerase chain reaction-RFLP typing is a rapid, simple and reproducible technique, but it gives only moderate discrimination

Arbitrarily primed PCR typing and similar methods such as random amplified polymorphic DNA (RAPD) analysis are based on low-stringency PCR amplification and use a single primer of arbitrary sequence. In the early cycles of the PCR, the primer anneals to multiple sequences with partial homology and segments of DNA lying between closely spaced annealing sites are amplified to produce a strain-specific array of DNA fragments. This simple and rapid technique can be used for strain typing of bacteria, fungi and protozoans.[76] The discriminatory power varies according to the number and sequence of arbitrary primers and amplification conditions. Arbitrarily primed PCR typing is, however, limited by problems in reproducibility and the lack of consensus rules for interpretation of pattern differences. It is best used as a first-pass, efficient screening method to assess the genomic similarity of organisms during outbreak investigations.

Repetitive element PCR (rep-PCR) typing consists of high-stringency PCR amplification of spacer fragments lying between repeat motifs of the genome by the use of two outwardly directed primers. Targets for rep-PCR analysis include the repetitive extragenic palindromes, the enterobacterial repetitive intergenic consensus (ERIC) sequences, insertion sequences and other species-specific repeat elements.[77] Repetitive element-PCR typing shows moderate discriminatory power but a better reproducibility than does AP-PCR analysis.

The amplified fragment length polymorphism (AFLP) analysis has high resolution and excellent reproducibility.[78] A restriction-ligation reaction produces restricted genomic DNA fragments tagged with specially designed adapters. Primers complementary to these adapters and adjacent nucleotides are used to amplify various parts of the tagged restriction fragments.

Binary probe typing

Binary probe typing systems detect polymorphic genomic regions by solid-phase hybridization with a reference panel of sequence-variant specific probes. The resulting binary types are highly reproducible and portable. A validated binary type system is commercially available for *Staph. aureus*. [79] This approach is currently being developed based on DNA microarray technology.

Determination of nucleotide sequence

This is the most accurate method for comparing strains based on localized genomic polymorphism. It is completely portable between laboratories. This method is important in the investigation of transmission

of viruses, such as hepatitis C virus.[80] Sequence analysis of polymorphic loci is also applicable to bacterial pathogens, such as allelic variants of the protein A gene of *Staph. aureus*. Multilocus sequence typing (MLST) of bacteria consists of direct analysis of the nucleotide sequences of internal fragments of seven housekeeping genes following the concept of multiallele scoring established by multilocus enzyme electrophoresis (MLEE).[81] It is a phylogenetically robust and precise method that indexes genomic polymorphism at representative, evolutionary neutral loci. The sequence type data are relevant for population genetics, evolutionary genetics and

global epidemiology. This method is validated for *Staph. aureus*. Direct MLST database sharing between laboratories is possible over the Internet (www.mlst.net). Progress in the efficiency of automated sequence analysis systems will enlarge the application of this approach.

Interpretation of typing results

Molecular typing systems are used to determine whether isolates are clonally derived and thus likely to belong to the same chain of transmission. The level of genomic similarity that can be used to define clonally or epidemiologically related organisms depends on the resolving power of the typing system used, the genomic plasticity of the organism and the time scale of the study.[63] Rules for interpretation of differences in PFGE patterns, as applied to outbreak investigations, correlate increase in the number of restriction fragment mismatches with increasing number of genetic differences and with decreasing probability of epidemiologic relatedness.[66] Restriction pattern similarity coefficients are also useful for interpretation, particularly for large-scale studies and surveillance data.

Implementing molecular typing systems

Given the diversity of nosocomial pathogens, broad-range typing systems are to be preferred for hospital epidemiology. Confident assessment of clonality often requires the use of two or three methods in combination. The methods used should be highly discriminatory and give reproducible results, at least within the laboratory. Use of standard, 'library typing' systems is recommended for surveillance programs, especially if interlaboratory data comparisons or pooling for multicenter surveillance is the aim.[82] The methods currently best suited for hospital epidemiology, especially outbreak investigation, are the antibiogram and, when appropriate, serotyping, followed by PFGE analysis and/or PCR-based methods, particularly AFLP. Methods used for surveillance typing also include binary probe typing, MLST and other sequence-based analytic methods. Whatever method is chosen, typing should always be undertaken with a clear purpose in mind. Specific hypotheses to be tested by typing will guide the selection of the appropriate method(s) and sample of isolates. Interpretation of results requires careful comparison of clinical, epidemiologic and typing data.

Ideally, molecular typing services should be integrated into the clinical laboratory to ensure a close dialogue between the infection control team and the microbiologist. This joint approach is important to define the questions asked, to ensure the appropriate selection of isolates for typing and to interpret the results. Another option is to refer isolates for typing to a central reference laboratory. Although this may delay the availability of results, it will offer the advantage that standard 'library typing' methods are more often available to such centers and therefore the results refer to a surveillance database. Quality assurance is essential to ensure reproducibility and discrimination of typing methods. External proficiency surveys through networks of laboratories are one of the means to achieve this goal. Establishing a molecular typing service linked to the infection control and antimicrobial resistance surveillance programs appears to be cost-effective and cost-saving by contributing to a significant reduction in the incidence of nosocomial infection.[83] Additional benefits to consider include the sparing of unnecessary investigation when a suspected outbreak is not confirmed by typing and the local identification of multiresistant bacteria that need special isolation precautions.

STERILIZATION AND DISINFECTION

To minimize the risk of transmission of micro-organisms during invasive procedures that involve penetration of mucosa or skin, complete or nearly complete removal of micro-organisms from invasive devices must be achieved by sterilization or disinfection. In addition, skin antisepsis is essential for reducing the risk of autoinfection in surgery and for preventing cross-colonization between patients via contaminated hands of health care personnel.

Sterilization is the process of removing or destroying all viable micro-organisms from an object. Disinfection consists of eliminating or killing the majority of potentially pathogenic micro-organisms from a contaminated item. [84] These processes can be accomplished by using a variety of physical, chemical or physicochemical methods that denature proteins and nucleic acids (Table 87.12). Sterilization is most commonly performed by using steam heated under pressure (autoclaving), ethylene oxide gas, plasma sterilization or prolonged immersion in liquid sterilizing chemicals. Disinfection is usually achieved by using liquid chemicals for a shorter contact time. Different types of micro-organisms show varying levels of susceptibility to disinfectants. The most resistant forms are bacterial spores followed by (in decreasing order of resistance) mycobacteria, nonlipid viruses, fungi, vegetative bacteria and lipid viruses.[85] Medical devices can be classified according to the level of invasiveness of their intended use and are processed accordingly to ensure safe procedures. For example, critical devices that enter sterile tissues, such as surgical instruments or implants, require sterilization. Semicritical devices that come into contact with mucous membranes, such as endoscopes and rectal thermometers, must undergo high-level disinfection. This process should kill all micro-organisms, except for high levels of bacterial spores, and is achieved by using chemical or thermochemical methods (see Table 87.12). Noncritical items and surfaces that come in contact with intact skin, such as stethoscopes, can be submitted to low-level disinfection procedures to kill the majority of pathogenic micro-organisms, with the exception of mycobacteria and bacterial spores.

Sterilization and disinfection must be preceded by meticulous cleaning to eliminate organic material from the device and to reduce the biologic burden. A number of technical factors are important to ensure adequate sterilization and disinfection of medical material: the type and load of contaminating micro-organisms, the nature and physical configuration of the object, the concentration of chemical agent used, and the temperature and pH of the process.[85] To provide effective processing, it is preferable that high-level disinfection and sterilization are performed by specialized personnel in adequately centralized facilities. To monitor effectiveness, initial validation and regular quality control must be performed. Physical and chemical monitoring of each process cycle is necessary. Additional quality assurance can be achieved by periodically incorporating biologic indicators, generally a known inoculum of bacterial spores, and by testing their nonviability by culture after processing. Flexible fiberoptic endoscopes are especially difficult to clean internally and disinfect adequately and specific reprocessing guidelines must be followed.[86]

In recent years, new disinfection and sterilization technologies have been developed.[87] Ortho-phtalaldehyde, a new aldehyde compound, has several advantages compared with glutaraldehyde as it requires no activation, is less irritating to the eyes and nasal passage,

TABLE 87-12 -- Sterilization and disinfection techniques commonly used in hospital practice.

STERILIZATION AND DISINFECTION TECHNIQUES COMMONLY USED IN HOSPITAL PRACTICE			
Objective	**Method**	**Principle of microbial inactivation**	**Example of use**
Sterilization	Steam autoclaving	Thermal denaturation	Metallic surgical instruments
	Ethylene oxide	Thermochemical denaturation	Heat-labile surgical instruments
	Gamma-irradiation	Ionizing denaturation	Implantable medical devices (catheters, protheses)
	Gas plasma	Generated free radical induced denaturation	Heat-labile instruments
Disinfection	Chlorine	Chemical denaturation	Water disinfection
	Alcohols	Chemical denaturation	Skin antisepsis
	Iodophors	Chemical denaturation	Skin and mucosae antisepsis
	Aldehydes	Chemical denaturation	Flexible endoscopes
	Peracetic acid	Chemical denaturation	Flexible endoscopes

has excellent stability, does not require exposure monitoring and has a barely perceptible odor. In the field of sterilization, hydrogen peroxide gas plasma sterilization was recently cleared by the US Food and Drug Administration.

The most important and unresolved problem remains the effective disinfection and sterilization of material contaminated with unconventional agents such as prions. Prions indeed exhibit unusual resistance to conventional chemical and physical decontamination methods. Decontamination of medical devices must take into account a determination of the risk related to the patient (e.g. those with known or suspected Creutzfeldt-Jakob disease (CJD)) and the nature of the tissue in contact with the instrument, separated into high risk (e.g. brain, eyes), low risk (e.g. CSF, kidney, liver, spleen) and no documented risk (e.g. blood, serum, skeletal tissue).[88] Specific disinfection and sterilization procedures have been recommended for decontamination of these unconventional agents.[88] The infectivity of tissue remains controversial and, in particular, the new variant form of CJD may differ from sporadic and familial forms in terms of tissue infectivity.[89] [90] In Europe, strict recommendations have been made considering the potential risk associated with the emergence of this new variant form of CJD.[91] [92]

HAND HYGIENE AND ISOLATION PRECAUTIONS

To prevent transmission of potentially infectious micro-organisms from colonized or infected patients to other hospitalized patients, visitors or health care personnel, systematic hand hygiene precautions must be taken during patient care. In addition, patients who have certain conditions must be placed in special isolation to prevent transmission of pathogens by other routes. Isolation methods include special room requirements and the use of protective equipment, generally worn by patient care personnel.

Between 1970 and 1996, the CDC formalized a series of guidelines to implement isolation precautions. Category-specific precautions are based on the classification of infectious diseases into six categories according to their route of transmission: strict, contact, respiratory, tuberculosis, enteric and drainage-secretion precautions.[93] Disease-specific isolation is tailored according to the mechanism of transmission of each infectious disease. Although logical, these strategies are complex to implement. They tend to be difficult to apply to newly admitted patients who present with an undiagnosed, presumably infectious, syndrome.

In the face of the HIV pandemic, universal precautions were proposed to complement the disease-specific isolation precautions.[93] The goal was to protect health care workers from infection with blood-borne viruses such as HIV. Universal precautions required the use of gloves and other barrier precautions to avoid contact with blood, internal body fluids and genital secretions. To reduce the risk of percutaneous exposure to blood and body fluids, minimal handling of needles and sharp instruments and their safe disposal was recommended. At the same time, a simplified system, called body substance isolation, was proposed as an attempt to merge the objectives of contact isolation and universal precautions. [94] This system is based on the premise that any contact with tissue, body fluids, wounds, mucous membranes and secretions is potentially contaminating and a source of transmission of infectious agents to health care workers and other patients. The systematic use of gloves, and other barrier precautions when necessary, was advocated for any contact described above with all patients. The latest CDC guidelines incorporate this strategy with the additional need for handwashing after removing gloves, which was shown to recontaminate hands, as 'standard precautions' (Table 87.13). [95] These systematic precautions are supplemented by patient-specific isolation precautions, grouped into three categories, for preventing contact, droplet and airborne transmission of specific pathogens. In addition to physical isolation in a private room and use of barriers such as gloves and gowns, cohort nursing can contribute to effective isolation, as shown for the prevention of nosocomial RSV infection.[96]

The growing importance of nosocomial transmission of multiple antibiotic-resistant pathogens has led national advisory bodies to issue specific guidelines for the early detection, isolation and decolonization of patients with infection or colonization with MRSA,[31] [97] vancomycin-resistant enterococci,[98] vancomycin-resistant *Staph. aureus*[99] and extended-spectrum ß-lactamase producing Enterobacteriaceae.[100]

Since the seminal intervention studies of Semmelweis 150 years ago, it has been known that adequate hand hygiene is the most effective measure to reduce cross-infection resulting from patient care. The optimal methods of hand hygiene in hospital practice remain under debate.[101] This relates to major problems with health care

TABLE 87-13 -- Key points in the 1996 Centers for Disease Control and Prevention guidelines for isolation precautions in hospitals.*

KEY POINTS IN THE 1996 CDC GUIDELINE FOR ISOLATION PRECAUTIONS IN HOSPITALS				
Feature	**Standard precautions**	**Contact precautions**	**Droplet precautions**	**Airborne precautions**
Patient room	Standard	Private	Private	Private; door closed; well ventilated (minimum 6 air changes per hour; negative pressure)
Gloves	Contact with blood, body fluids, mucous membranes, secretions, excretions or broken skin	Before entering room	Standard	Standard
Handwashing	After glove removal; between patients	Standard; with antiseptic soap	Standard	Standard
Gown	Before procedure likely to generate projections of blood, body fluids, secretions or excretions	Contact with patient; if patient has diarrhea or open drainage of wounds or secretions	Standard	Standard
Mask	Before procedure likely to generate projections of blood, body fluids, secretions or excretions	Standard	If within 3 feet of patient	Before entering room
Examples of conditions	All patients	• Multidrug-resistant bacteria of special clinical and epidemiologic significance (e.g. MRSA, VRE)	• Meningitis	• Tuberculosis, or suspected tuberculosis
		• Major abscess, cellulitis or decubiti	• Diphtheria	• Measles
		• *Clostridium difficile* infection	• Pertussis	• Varicella, disseminated zoster
		• Acute diarrhea, in an incontinent or diapered patient	• Influenza	
		• RSV infections, bronchiolitis and croup in young infants	• Mumps	
			• Rubella	
			• Streptococcal pharyngitis, pneumonia or scarlet fever in young children	

* *Adapted from Garner.*[95] Refer to the original guideline for complete information.

worker compliance and tolerance with traditional handwashing. The latter is generally practiced only about 30–50% of the time it should be.[102] With the increasing use of gloves to prevent soiling of hands during contaminating procedures, greater emphasis is placed today on hand antisepsis, particularly in Europe. Handrub with alcohol-based disinfectants, such as 70% isopropyl-alcohol, is more effective, faster, easier to use and better tolerated compared with handwashing and medicated soap antisepsis (Table 87.14). Promoting hand cleansing with an alcohol-based handrub solution by multimodal educational programs that include observation of health care workers' hand hygiene practices and regular feedback of compliance rates can improve these practices and should be encouraged.[103]

TABLE 87-14 -- Hand hygiene methods.

HAND HYGIENE METHODS			
Feature	**Handwashing**	**Hand alcohol antisepsis**	**Gloves**
Advantages	• Removes soiling	• High efficacy for removal of transient microflora (3–4 log)	• Prevents soiling
	• Low cost	• Low cost	• Protects health care worker
		• Fast and easy to use	
Disadvantages	• Low efficacy for removal of transient microflora (2 log)	• Efficacy decreased on soiled hands	• Contamination during removal
	• Time consuming	• Skin intolerance	• Skin intolerance
	• Skin intolerance		• Cost
The use of gloves to prevent hand soiling and to reduce hand contamination can be combined with alcohol antisepsis after glove removal. Frequent handwashing with plain soap and water or with disinfectant/detergent and water leads to considerable problems of skin intolerance.			

CONTROL OF ANTIBIOTIC RESISTANCE

Learned societies have published guidelines for optimizing antibiotic use and controlling antibiotic resistance in hospitals by multimodal strategies. [104] [105] Action plans based on similar approaches have been formulated by public health agencies. [37] Important components of these guidelines include better medical training; education and regulation of prescribers by consultant specialists; multidisciplinary co-operation between hospital management, clinicians, infectious diseases specialists, infection control team, microbiologists and hospital pharmacists; formulary-based guidelines on anti-infective therapy and prophylaxis; monitoring and auditing drug use; surveillance

of resistance in the hospital flora; early detection and investigation of outbreaks by molecular typing; detection and notification of patients colonized with transmissible resistant bacteria for patient isolation and/or decolonization; and promotion of standard precautions and hand hygiene. These guidelines are mostly based on limited evidence from analytic studies and uncontrolled intervention studies. Few strategies have been tested for cost-effectiveness.[106] The applicability of guidelines may be limited by the ecologic heterogeneity in health care organizations. Because each hospital has its own ecosystem that evolves rapidly, effective solutions should be tailored to local needs and resources. Mathematical modelling can contribute to the prediction of the most effective interventions based on local ecology and epidemiology.[46] [107] On the other hand, regional co-ordination can lead to successful control of emerging antibiotic-resistant nosocomial pathogens.[108]

Antibiotic policies, including restriction, substitution and cycling, can help contain the prevalence of resistance in hospitals, particularly in outbreak settings. Selective antibiotic restriction has been followed by decreased transmission of resistant nosocomial pathogens, such as *C. difficile* [109] and *Klebsiella pneumoniae*. [110] Controlling the antimicrobial usage by restriction based on antibiotic formularies has been met with mixed success in the long term. [111] Studies linking antibiotic control to lower prevalence of resistance are difficult to interpret because of methodologic problems. [111] [112] [113] Computer-assisted support to prescribing antibiotics, based on locally defined consensus guidelines, can improve antibiotic use, reduce drug costs and limit the rise of antibiotic-resistant pathogens.[114] As antibiotic prescribers, physicians in all disciplines contribute to antimicrobial resistance and must strive for prudent antibiotic use. Innovative strategies are needed to improve the control of antibiotic-resistant nosocomial infections.

Chapter 88 - Employee Health Service

Kent A Sepkowitz

An active hospital employee health service (EHS) or occupational health service is crucial to control of nosocomial infection. This is accomplished in several ways:

- identification and vaccination of workers susceptible to vaccine-preventable diseases;
- active surveillance for diseases such as tuberculosis (TB); and
- prompt diagnosis of transmissible illnesses such as respiratory syncytial virus (RSV) or hepatitis A virus infection in symptomatic workers.

Several reviews address specific infectious disease problems frequently encountered by an EHS.[1] [2] [3] [4]

ORGANIZATION OF EMPLOYEE HEALTH SERVICE

The organization of the EHS varies according to the size and administrative structure of a hospital. At larger hospitals, the EHS is staffed by full-time nurses and physicians, as well as by clerical staff. The model at smaller hospitals is characterized by fewer staff, limited hours and more limited capabilities (Fig. 88.1). The administrative reporting mechanisms for the EHS also vary considerably from hospital to hospital. The employee health service may be part of infection control, the Department of Nursing, or may report primarily to a senior hospital administrator.

Few studies have defined the scope of EHS activity.[5] [6] [7] In one analysis of 21,886 annual visits:

- 25% were for preventive services, such as vaccination and routine examinations;
- 25% were for occupationally related illnesses, including infectious diseases, stress and accidents; and
- 15% were for administrative procedures, such as prescription renewal, requests for letters and completion of forms.[5]

Another study reviewing 3000 annual visits found 30% of visits to the EHS were for occupationally related illness or injury, and of these less than 3% were for fever. [6]

ROUTINE TESTS FOR NEW EMPLOYEES

The medical evaluation of new employees is a fundamental job for the EHS. In general, all new employees should have tests performed to evaluate for immunity to various potentially transmissible diseases (Table 88.1). These include serologic tests and a tuberculin skin test for TB. Routine chest radiography should be reserved only for those employees with known pulmonary problems, a previously abnormal chest radiograph, or a positive tuberculin skin test. Recent concern about potential bioterrorism has resulted in some EHSs requesting information about previous vaccinia vaccination as well.

Serologic testing for numerous potential pathogens is essential, both for the safety of the health care worker and for patient safety. The Centers for Disease Control and Prevention (CDC) has published recommendations on immunization of health care workers[8] and infection control in hospital personnel.[9]

Since 1992 the US Occupational Safety and Health Administration has required demonstration of seropositivity to hepatitis B virus (HBV) for all health care workers with occupational exposure to blood or body fluids.[10] Seronegative health care workers must either receive vaccine or formally decline the three-vaccine series, which is offered free of charge. The rates of vaccination have subsequently increased, but remain low, at about 50%.[10] The observed decrease in HBV-associated morbidity and mortality among health care workers is attributed to improved vaccine coverage.[11] Varicella-zoster virus (VZV) antibody status should also be determined. In some countries (e.g. the USA) vaccination of susceptible employees is recommended but not required.[12] Specific countries and regions may require evidence of immunity to other pathogens, such as measles, mumps and rubella.

Few hospitals track pneumococcal vaccine status of employees and none mandate or even suggest routine vaccination of health care workers. However, reports have appeared of outbreaks of pneumococcal disease,[13] including those caused by penicillin-resistant strains.[14] Although pneumococcus has not been firmly established as a nosocomial pathogen, additional reports of possible nosocomial spread may force a careful reconsideration of the issue. Finally, as new vaccines eventually become available for such illnesses as RSV and cytomegalovirus (CMV), the EHS will be charged with assuring vaccine program implementation and delivery (Table 88.2).

Because of the USA cases of intentionally spread anthrax, concern has grown about other agents, especially smallpox. The potential role of vaccinia vaccine to prevent an outbreak of smallpox is being actively discussed. At issue is the risk of rapid spread of smallpox throughout a hospital, as has been described, versus the risk of the vaccine itself which is estimated to cause a fatal reaction in one per million persons and various other adverse events less commonly. Should the decision be made to vaccinate health care workers, the EHS will be entrusted with identifying, educating, and vaccinating the employees, as well as monitoring them for adverse events.

REGULAR FOLLOW-UP TESTING AND REVACCINATION

Routine surveillance to exclude infectious diseases is required for only a few illnesses, of which TB is a classic example. With the sudden rise in TB cases in many USA cities in the late 1980s and with the recognition of several dramatic nosocomial outbreaks of the disease, hospitals scrambled to implement effective TB control programs. These were plagued by poor or absent baseline data, nonspecific boosting as a result of frequent skin testing of employees, and concerns about the lack of effective prophylaxis against multidrug-resistant TB (MDR-TB). Because of this experience, effective tuberculosis control measures were developed. Control programs have waned in recent years in many developed nations, coincident with the national decrease in numbers of cases of TB. Of looming concern is development of an approach to protecting workers in less developed nations, where tuberculosis is much more common and resources are much more scarce.

Figure 88-1 Example of organization and interdisciplinary roles in an EHS.

TABLE 88-1 -- Immunizations recommended for hospital workers.*

IMMUNIZATIONS RECOMMENDED FOR HOSPITAL WORKERS			
Immunization against:	**Indications**	**Vaccine dose and schedule**	**Contraindications**
Hepatitis A virus	Employees working in high-risk areas (e.g. food service, neonatal intensive care unit) without serologic evidence of previous hepatitis A virus infection	1.0ml im at 0 and 6–12 months	Known hypersensitivity to any component of the vaccine.
Hepatitis B virus	All employees at risk for occupational exposure to blood or body fluids	1.0ml im (deltoid) at 0, 1 and 6 months	Hypersensitivity to yeast
Influenza	All hospital employees	0.5ml im annually	History of anaphylactic reaction to eggs
Measles	Employees with no history of physician-diagnosed measles or no laboratory evidence of immunity	0.5ml subcutaneously of trivalent measles, mumps and rubella vaccine	Pregnancy, history of anaphylactic reaction to eggs or neomycin, severe febrile illness, immunosuppression, recent receipt of iv immunoglobulin
Mumps	Employees without a history of physician-diagnosed mumps, laboratory evidence of immunity, or proof of vaccination on or after their first birthday	As for measles (above)	As for measles (above)

Pneumococcus	Employees over 65 years of age or with underlying cardiac, pulmonary, liver, renal or immunocompromising disease	0.5ml subcutaneously or im; booster dose every 6–10 years	Safety in pregnancy unknown
Rubella	Employees without verification of live vaccine delivery on or after their first birthday or proof of laboratory immunity	As for measles (above)	As for measles (above)
Tetanus-diphtheria	Employees who have not completed their initial series or who have not received a booster dose within 10 years	Initial series: 0.5ml im at 0.1 and 6–12 months; booster dose for immunized employees: 0.5ml im every 10 years	History of neurologic or hypersensitivity reaction following a previous dose; first trimester of pregnancy
Varicella	Employees with patient contact who have no history of chickenpox and negative varicella titer	0.5ml at 0 and 4–8 weeks	Hypersensitivity to vaccine, gelatin, neomycin; immunosuppression or immunodeficiency; active tuberculosis; febrile illness; pregnancy

** Data from Diekema and Doebbeling, 1995.*[4]

The best approach is to maintain an effective ongoing TB control program, both during outbreaks and, as importantly, when no outbreaks are occurring. [15] Such a program should test all tuberculin-negative employees every year. Consideration should be given to 'two-step' testing of new employees, especially those who have received bacille Calmette-Guérin (BCG) vaccination or are older than 40–50 years. This minimizes the potential effect of the booster phenomenon, which is particularly seen in these groups (in serial skin tests the reaction may be 'boosted' in subsequent tests). The CDC has recently updated recommendations and advises that hospitals with a modest rate of tuberculosis annually (six cases or less) may decide to test only new employees and as needed for outbreak investigation; routine annual testing in this circumstance is no longer recommended.[15]

Chemoprophylaxis with isoniazid should then be offered according to standard guidelines.[16] Chemoprophylaxis for health care workers exposed to patients with isoniazid-resistant MDR-TB is complex and not standardized. This topic is discussed in detail in Chapter 37 .

In the USA, the EHS plays a central role in the annual drive to revaccinate against influenza. Many countries in Europe do not routinely vaccinate workers against influenza. In the USA, experts feel that an adequate number of studies have demonstrated benefit to both health care workers and to patients; despite this, acceptance rates for influenza vaccination among healthcare workers in the USA remain poor, generally well below 50%.[17] Compliance rates for vaccinations

TABLE 88-2 -- Other potential health care worker vaccines: controversies and needs.

OTHER POTENTIAL HEALTH CARE WORKER VACCINES: CONTROVERSIES AND NEEDS	
Controversies Vaccine	**Issue**
BCG	Lack of proven efficacy in preventing pulmonary disease
	Compromise of the specificity of the purified protein derivative (tuberculin) test
Vaccinia	Threat of smallpox unknown but probably quite low
	Adverse reaction in 1/100,000; fatal reaction in 1/million
Meningococcus	Immunity not long-lived so protection from occupational exposure is unlikely
	Does not protect against several strains
Anthrax	Vaccine must be given yearly and requires multiple injections to establish immunity
	Risk for nosocomial spread (e.g. from patient clothes) very low
Needs Vaccine	**Issue**
HIV	Occupational risk remains
	Hospitals spend substantial funds on 'safer needle' systems and management of exposures
Hepatitis C	Treatment of disease not established
	Hospitals spend substantial funds on 'safer needle' systems and management of exposures
RSV	May cause significant morbidity and mortality rates among transplant recipients
	Symptoms non-specific in adults and cannot be distinguished from common cold
CMV	Would allay fears of CMV-seronegative workers
Norwalk virus	Rapid spread may affect up to 90% of those exposed, potentially interfering with a hospital's ability to care for patients

given during identified outbreaks, such as of measles or pertussis, are much higher.

Measles outbreaks in the early 1990s among previously vaccinated persons led to the recognition of waning vaccine-induced immunity and gave rise to the new recommendation that an additional measles vaccine was necessary before or during teenage years.[18] Evidence that the new requirement is in fact effective is lacking, although there have been no outbreaks of measles in USA hospitals in over 20 years.

Because of the issue of waning vaccine-induced measles immunity, many have wondered about the durability of vaccine-induced immunity to infections such as varicella, pertussis and HBV. At present, in the USA there is no recommendation extant for routine follow-up surveillance to determine immunity to these vaccine-preventable diseases. In many European countries, a booster dose of HBV vaccine is given to workers at risk every 5–10 years. However, should outbreaks of diseases continue to occur in well-vaccinated populations, as has been described with pertussis,[19] routine follow-up surveillance to demonstrate immunity may be advisable.[20] With measles programs, repeat serologic testing with targeted revaccination is significantly cheaper than simply vaccinating all workers.[21]

OUTBREAKS CAUSED BY HEALTH CARE WORKERS WHO ARE CARRIERS

Health care workers who are carriers may be responsible for the spread of infections to other health care workers and to patients (Table 88.3).

Reports have documented the spread of HBV[22] and hepatitis C virus (HCV)[23] from health care workers to patients. This emphasizes the need for careful guidelines for the potentially infectious health care worker[33] that do not interfere with that person's individual rights.[34] These thorny issues surfaced in the USA in the early 1990s, when the possibility of mandatory testing for HIV of all health care workers was considered by the CDC.[35]

Spread of HBV from an occupationally infected surgical resident has been well documented by routine and molecular epidemiologic

TABLE 88-3 -- Infections spread by health care workers to patients or other health care workers.

INFECTIONS SPREAD BY HEALTH CARE WORKERS TO PATIENTS OR OTHER HEALTH CARE WORKERS	
Infection	**Comment**
Hepatitis B virus[22]	e-Antigen positivity and high level of viremia associated with transmission

Hepatitis C virus[23]	Surgeon resumed work following medical control of his hepatitis C infection
Methicillin-resistant *Staphylococcus aureus* [24] [25]	'Cloud adult' and chronic sinusitis may facilitate spread
Group A streptococci[26]	Carriers may harbor the organism in throat, vagina, rectum or skin
Salmonella[27] [28]	Routine surveillance for dietary workers of unproven benefit
Tuberculosis[29] [30]	Health care workers may spread disease through hospitals
Measles, rubella[31] [32]	Unvaccinated medical students are source of many outbreaks

methods.[22] In one report, 19 (13%) of 144 susceptible persons became infected after receiving surgery from a surface- and e-antigen-positive thoracic surgery resident. Molecular analysis of 13 available strains showed identity with the surgeon's strain. A semiquantitative polymerase chain reaction test of the surgeon's serum revealed more than one billion infectious particles per milliliter, suggesting viral load may be an important factor determining transmissibility. More importantly from the EHS perspective, the index case had chosen to decline HBV vaccine 2 years before he himself became infected via occupational exposure. Thus the entire episode may have been averted with a more persuasive HBV vaccination program.

Probable transmission of HCV from a cardiac surgeon to at least five patients who underwent valve replacement was reported from

Spain.[23] In this study, molecular analysis showed significant homology between the surgeon's and the patients' virus. The surgeon was treated with interferon-a2b and ribavirin until his HCV RNA level, as measured by polymerase chain reaction, became undetectable. At that point, he was allowed to resume performing surgery.

Nasal carriage of *Staphylococcus aureus*, which is found in 20–90% of health care workers, has been associated with outbreaks of infection, often in intensive care units. Poor handwashing by workers is frequently revealed as the cause. Chronic sinusitis may also contribute.[24] An additional means of transmission — the 'cloud adult' — has also been described.[25] This refers to the occurrence of a viral upper respiratory infection in a patient with established nasal carriage of *S. aureus*. The associated sneezing results in aerosolization of the resistant bacteria, hence the term. In one study, a single 'cloud adult' surgeon was associated with spread of methicillin-resistant *S. aureus* to eight of 43 persons in an intensive care unit. The amount of bacteria aerosolized was significantly decreased when the surgeon wore a mask.[25] Nasal carriage can often be eradicated by local application of mupirocin ointment combined with oral ciprofloxacin and rifampin (rifampicin). Early recurrences are seen with this regimen, however, as has occurred with other regimens that have been used through the years. Selective screening of health care workers during nosocomial outbreaks of *S. aureus* infections is recommended. [36]

Outbreaks of group A streptococci traced to a health care worker have frequently been reported.[3] In many circumstances the health care worker is asymptomatic, but cultures of throat, vagina, rectum, or skin yields group A streptococci. When investigating a possible outbreak, it is essential to culture all potential sites routinely. The mode of spread may be by direct contact, via droplet transmission, or, in one report, through infected food. [26]

Dietary workers who are salmonella carriers have spread infection via the hospital kitchen, as may occur in restaurants.[31] [32] In one study routine surveillance of all dietary staff failed to prevent a nosocomial outbreak, bringing into question the value of surveillance.[27] Interruption of another outbreak required treatment of all dietary staff with trimethoprim-sulfamethoxazole (co-trimoxazole). [28]

OUTBREAKS DUE TO HEALTH CARE WORKERS WHO ARE ILL

A significant problem is the health care worker who continues to work despite feeling ill and thus spreads disease to patients and other staff. Younger doctors may be particularly likely to be associated with outbreaks of vaccine-preventable infections, such as measles and rubella.[31] In one study, 12% of all health departments had reported that medical students or interns were probably the source case of a nosocomial outbreak of measles or rubella.[32]

Varicella may also be spread by health care workers. In one report, a susceptible pediatric resident failed to report an exposure and continued to work until he himself developed chickenpox.[37] This resulted in exposure of 250 patients or workers and a cost of about $US10,000. No secondary cases of varicella occurred. The CDC and the Advisory Committee on Immunization Practices have recommended but not required varicella vaccination for health care workers.[12] Other methods of decreasing the likelihood of transmission of varicella from health care worker to patient, including wearing masks during the potentially infectious days and taking aciclovir pre-emptively, have also been suggested.[38]

Tuberculosis has been transmitted from staff to patients and to other staff.[29] [30] In one report eight health care workers developed active TB, and tuberculin conversion rates ranged from 30 to 48% on wards housing patients with TB.[29] On one ward, transmission from health care worker to health care worker was strongly implicated by molecular fingerprint analysis. Distinction between community and occupational transmission may be difficult in health care workers who also socialize together.[30] Although older reports suggest that compliance with isoniazid prophylaxis in health care workers, particularly physicians, is poor, one study showed that more than half of eligible health care workers completed the recommended course of therapy.[39] Furthermore, rates of completion were higher among physicians (74%) than among nonphysicians (48%). The occurrence of several cases of TB among health care workers at this medical center might have resulted in higher compliance rates.

The well-publicized case of a Florida dentist who apparently spread HIV to at least four patients became the subject of a national debate regarding patients' right to know the health status of their physicians and dentists.[40] Numerous thorough 'look-back' studies of surgeons, other dentists and other practitioners, however, failed to demonstrate transmission.[26] In France, a probable case of transmission from an infected orthopedic surgeon to a patient has forced a re-evaluation of this issue.[41]

OCCUPATIONALLY ACQUIRED INFECTIONS IN HEALTH CARE WORKERS

Similar to many other occupations, health care workers are at risk for a wide variety of occupationally acquired illnesses (Table 88.4).[38] [42] Three relatively simple interventions have been shown through the years to ensure the safety of workers. These include handwashing, vaccination and appropriate isolation of persons with known or suspected infectious diseases. More detailed consideration of this topic has been published.[38] [42]

Blood-borne transmission

Transmission of blood-borne infection has been the subject of intense scrutiny. Studies have demonstrated that HIV is transmitted in about 0.3% of exposures overall.[43] [44] To date, at least 57 health care workers have developed occupationally-acquired HIV and another 137 have probably developed disease from an occupational exposure. [45] Five confirmed cases have been transmitted through mucocutaneous exposure, whereas the others have involved a percutaneous injury. [45]

A retrospective case-control study determined that zidovudine prophylaxis reduced transmission by about 80% compared with placebo.[46] Factors associated with increased risk of transmission included a deep (intramuscular) injury [adjusted odds ratio (OR) 15], visible blood on the sharp device (OR 6.2), injury from a needle that had been used to enter a blood vessel (OR 4.3) and a source patient who has terminal AIDS (OR 5.6). New US Public Health Service recommendations have suggested that therapy be tailored to the likelihood of transmission and that a two- or three-drug combination be selected and given for 1 month (Table 88.5).[47] The recommended drugs include zidovudine, lamivudine and indinavir. This regimen costs about $US1000 for medications and monitoring.[48] Side-effects resulting in changes or discontinuation of the regimen are common (57%), but seldom severe (see also Chapter 117).[49]

The risks and rates of occupationally acquired HBV infection are even more disturbing. The CDC estimates that 120–195 health care workers die each year in the USA as a result of occupationally acquired HBV.[50] The rate of transmission is determined by the e-antigen status of the source case (about 3% for an e-antigen-negative and 30% for an e-antigen-positive source case). [51] A more recent estimate has suggested that the annual number of deaths among health care workers is decreasing as vaccine coverage increases.[11]

The morbidity and mortality rates of occupationally-acquired HCV infection are not yet well defined. Transmission occurs in about 3% of percutaneous exposures.[42] [52] The rate of progression of HCV

TABLE 88-4 -- Infectious diseases transmitted from patient to health care worker.[*]

INFECTIOUS DISEASES TRANSMITTED FROM PATIENT TO HEALTH CARE WORKER			
Infection		**Transmission rate**	**Comment**
Blood-borne	HIV	0.3%	New recommendations include up to three-drug therapy for needlestick injuries
	Hepatitis B virus	e-Antigen negative: 3%	More than 100 health care workers die annually from hepatitis B virus complications
		e-Antigen positive: 30%	Vaccination rates improving
	Hepatitis C virus	3%	No known therapy or prophylaxis though interferon appears promising for acute disease
	Cylomegalovirus	Very low	Studies do not demonstrate transmission risk to health care workers
	Ebola	Very high	Health care workers account for >30% of cases in recent outbreaks
Air-borne	Tuberculosis	20–50% in outbreaks	Several deaths from occupationally acquired multidrug-resistant tuberculosis and treatment
	Varicella	5–15%	New vaccine should decrease rates
	Measles	Very high	Physicians and nurses account for majority of occupational cases
	Rubella	13%	Some affected health care workers have opted to terminate pregnancy
	Parvovirus B19	>25%	Spread is less dramatic than in schools
	Respiratory syncytial virus	>40%	Infection control interventions decreased spread to patients but not to health care workers
	Adenovirus	>20%	May be spread more efficiently if source case intubated
	Pertussis	43%	Spread in one outbreak to 87 health care workers (2% of all health care workers)
Enteric	Hepatitis A virus	20%	Vaccine now available
	Salmonella	5–20%	May spread to health care worker from food, excretions or from patient
	Helicobacter pylori	Unknown	Implications of higher seroprevalence among endoscopists unknown
	Norwalk virus	>50%	Extremely high rates of spread for nursing assistants
	Cryptosporidia	>30%	Animal handlers at particular risk
	Clostridium difficile	Unknown	One health care worker died of apparent occupationally acquired *Clostridium difficile* infection

** Data from Septkowitz, 1996.*[36] [42]

TABLE 88-5 -- Recommended HIV postexposure prophylaxis for percutaneous injuries.[£]

RECOMMENDED HIV POSTEXPOSURE PROPHYLAXIS FOR PERCUTANEOUS INJURIES					
Exposure type	**Infection status of source**		**Source of unknown HIV status[†]**	**Unknown source[§]**	**HIV-negative**
	HIV-positive class 1[*]	**HIV-positive class 2[*]**			
Less severe[¶]	Recommend basic two-drug PEP	Recommend expanded three-drug PEP	Generally, no PEP warranted; however, consider basic two-drug PEP[?] for source with HIV risk factors[‡]	Generally, no PEP warranted; however, consider basic 2-drug PEP[?] in settings where exposure to HIV-infected persons is likely	No PEP warranted
More severe[¢]	Recommend expanded 3-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP[?] for source with HIV risk factors[‡]	Generally, no PEP warranted; however, consider basic 2-drug PEP[?] in settings where exposure to HIV-infected persons is likely	No PEP warranted

£ From CDC.[47]

† Source of unknown HIV status (e.g. deceased source person with no samples available for HIV testing).

§ Unknown source (e.g. a needle from a sharps disposal container).

* HIV-positive class 1 — asymptomatic HIV infection or known low viral load (e.g, <1500 RNA copies/ml); HIV-positive class 2 — symptomatic HIV infection, AIDS, acute seroconversion or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

¶ Less severe (e.g. solid needle and superficial injury).

? The designation 'consider PEP' indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.

‡ If PEP is offered and taken and the source is later determined to be HIV-negative, PEP should be discontinued.

¢ More severe (e.g. needle, deep puncture, visible blood on device, or needle used in patient's artery or vein).

to chronic liver disease, including cirrhosis, appears in excess of 80% for all patients. [53] The lack of an effective vaccine, therapy or prophylaxis makes this disease of increasing concern for health care workers.[54] A recent study examined the effectiveness of interferon in treating acute symptomatic HCV infection.[55] Included in the study were 14 health care workers who acquired the disease by needlestick. The authors demonstrated a rate of disappearance of detectable virus in the bloodstream of more than 95%. The fact that all patients were symptomatic was an extremely unusual feature of this study and may make generalization of the findings difficult. Evaluation of any percutaneous injury should be thorough and systematic, with attention to the injury and the source (Table 88.6 Table 88.7 Table 88.8).

Outbreaks of various viral hemorrhagic fevers, including Ebola virus, typically affect large numbers of health care workers in the treating hospitals. [42] Cytomegalovirus is a concern to pregnant health care workers, but studies have not demonstrated an increased rate of disease transmission to pediatric nurses or to other health care workers.[9] [42] The CDC does not recommend that any CMV seronegative worker avoids work among patients with high rates of CMV disease, such as those with AIDS or bone marrow transplant recipients. Rather, adherence to universal precautions is sufficient to protect the worker.[9]

B virus (simian herpes B virus) is a risk for researchers who work with old world monkeys, such as macaques and rhesus monkeys. At

TABLE 88-6 -- Recommendations for the contents of the occupational exposure report.[*]

RECOMMENDATIONS FOR THE CONTENTS OF THE OCCUPATIONAL EXPOSURE REPORT
Date and time of exposure
Details of the procedure being performed, including where and how the exposure occurred; if related to a sharp device, the type and brand of device and how and when in the course of handling the device the exposure occurred
Details of the exposure, including the type and amount of fluid or material and the severity of the exposure (e.g. for a percutaneous exposure, depth of injury and whether fluid was injected; for a skin or mucous membrane exposure, the estimated volume of material and the condition of the skin, for example chapped, abraded, intact)
Details about the exposure source (e.g. whether the source material contained HBV, HCV, or HIV; if the source is HIV-infected, the stage of disease, history of antiretroviral therapy, viral load, and antiretroviral resistance information, if known)
Details about the exposed person (e.g. hepatitis B vaccination and vaccine-response status)

Details about counseling, postexposure management and follow-up

** From CDC.*[47]

TABLE 88-7 -- Factors to consider in assessing the need for follow-up of occupational exposures.*

FACTORS TO CONSIDER IN ASSESSING THE NEED FOR FOLLOW-UP OF OCCUPATIONAL EXPOSURES
Type of exposure
Percutaneous injury
Mucous membrane exposure
Nonintact skin exposure
Bites resulting in blood exposure to either person involved
Type and amount of fluid/tissue
Blood
Fluids containing blood
Potentially infectious fluid or tissue (semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial and amniotic fluids)
Direct contact with concentrated virus
Infectious status of source
Presence of HBsAg
Presence of HCV antibody
Presence of HIV antibody
Susceptibility of exposed person
Hepatitis B vaccine and vaccine response status
HBV, HCV, and HIV immune status

** From CDC.*[47]

least 40 cases have occurred from occupational exposure (usually bites) and many have died of progressive encephalomyelitis.[56] The CDC has established guidelines for prevention and management, including serologic screening of all imported monkeys.[57] Cases should be treated with an active agent, such as aciclovir. Lifelong suppression may be necessary because relapse has occurred even after prolonged courses.

Air-borne transmission

The risk of caring for patients with TB was demonstrated in the USA during several large hospital-based outbreaks of MDR-TB.[58] In these outbreaks at least 20 health care workers developed clinical MDR-TB,[59] whereas hundreds of others became latently infected and will remain at risk for re-activation disease during the decades ahead. At least one health care worker has died because of drug toxicity from

TABLE 88-8 -- Evaluation of occupational exposure sources.*

EVALUATION OF OCCUPATIONAL EXPOSURE SOURCES
Known sources
Test known sources for HBsAg, anti-HCV, and HIV antibody
Direct virus assays for routine screening of source patients are *not* recommended
Consider using a rapid HIV-antibody test
If the source person is *not* infected with a blood-borne pathogen, baseline testing or further follow-up of the exposed person is *not* necessary
For sources whose infection status remains unknown (e.g., the source person refuses testing), consider medical diagnoses, clinical symptoms, and history of risk behaviors
Do not test discarded needles for blood-borne pathogens
Unknown sources
For unknown sources, evaluate the likelihood of exposure to a source at high risk for infection
Consider likelihood of blood-borne pathogen infection among patients in the exposure setting

** From CDC.*[47]

a second-line regimen given for her MDR-TB[60] and several others have died of MDR-TB itself.[59] Recommendations for preventing transmission of TB in hospitals stress the need to place suspected cases into effective isolation immediately.[9] [15]

The introduction of the varicella vaccine has changed the infection control strategy for containing VZV infection at many hospitals.[2] [12] Transmission rates are poorly defined, but the incidence of new cases among susceptible individuals may exceed 10% per year if no precautions are taken.[2] [38] In addition, the problem of a potentially infectious health care worker is discussed above.

Measles virus may enter a hospital from the community or spread to the community from a hospital-based outbreak. Attack rates among susceptible individuals are high, vaccine failures occur, and physicians and nurses are at highest risk. Outbreaks of rubella[61] and parvovirus B19 [62] are of particular concern to pregnant employees because both infections may affect fetal development. Some health care workers in rubella outbreaks have opted to terminate pregnancies.[61] Transmission of RSV, adenovirus and pertussis to health care workers has been well-documented and probably occurs much more frequently than has been reported.[38]

Fecal-oral transmission

Nosocomial outbreaks of hepatitis A virus with spread to health care workers have occasionally been reported, often from neonatal intensive care units. One report described an outbreak traced to a child with an immune defect that prevented a detectable antibody response to hepatitis A virus.[63] This delayed serodiagnosis resulted in spread to 15% of the staff, a rate similar to that in other outbreaks.

Salmonella may spread in hospitals in numerous ways:

- from a point source, such as contaminated food;
- from patient to health care worker; and
- from contact with contaminated excretions.

As noted above, routine surveillance of hospital dietary employees may not be effective. [27] [28] In addition to nurses, laundry workers appear at increased risk.[64]

Other common enteric infections such as Norwalk virus and cryptosporidiosis may spread to workers.[42] Norwalk virus, a small round structured virus, is particularly contagious, and may affect more than 90% of health care workers in close contact. The clinical implications of elevated seroprevalence to *Helicobacter pylori* among persons who perform endoscopy are unknown.[42]

Chapter 89 - Recreational Infections

Alastair Miller

INTRODUCTION

Although the arrival of the 21st century does not seem to have produced the predicted 'Age of Leisure' people continue to spend their leisure time in more adventurous and imaginative ways. This chapter examines how these activities expose them to increased risks of infection and disease. As with many other factors that predispose to clinical infection, recreational behavior may either expose the host to infective organisms or modify the host's immune response, thereby increasing susceptibility to infection and disease. Recreational infection can be classified by recreational activity or according to the particular infections (or systems infected — Fig. 89.1) Inevitably there is considerable overlap with other sections of this book, such as geographic and travel medicine (see Chapter 142 , Chapter 143 , Chapter 144 , Chapter 145 , Chapter 146 , Chapter 147 , Chapter 148 , Chapter 149 , Chapter 150 , Chapter 151 , Chapter 152 , Chapter 153 , Chapter 154 , Chapter 155 , Chapter 156 , Chapter 157 , Chapter 158 , Chapter 159 , Chapter 160 , Chapter 161 , Chapter 162 , Chapter 163 , Chapter 164 , Chapter 165 , Chapter 166 , Chapter 167 , Chapter 168 , Chapter 169 , Chapter 170 , Chapter 171 , Chapter 172 , Chapter 173 , Chapter 174 , Chapter 175 , Chapter 176 , Chapter 177 , Chapter 178 , Chapter 179 , Chapter 180 , Chapter 181 , Chapter 182 , Chapter 183 , Chapter 184 , Chapter 185 , Chapter 186), sexually transmitted diseases (see Chapter 73 , Chapter 74 , Chapter 75 , Chapter 76 , Chapter 77 , Chapter 78 , Chapter 79) and zoonotic infections (Chapter 222).

TRAVEL

Travel is a common recreational activity either as an end in itself or in order to participate in other recreations. Travelers may be exposed to infection either during the journey or at their destination. During travel there may be exposure to gastrointestinal pathogens in mass-produced food or exposure to respiratory pathogens from air-conditioning units and fellow travelers. In addition the general fatigue of long-distance travel may perhaps lower resistance to infection in a nonspecific manner.

Outbreaks of food poisoning from airline food occur frequently and are well described,[1] and even cholera has been transmitted in this way.[2] An estimated 4.5 million North Americans travel on cruise ships each year and a recent review has drawn attention to the incidence of respiratory and gastrointestinal infection associated with this activity.[3] Outbreaks of gastrointestinal illness have been caused by contaminated food and water,[4] and in addition there have been descriptions of more prolonged outbreaks of infection associated with the possibility of person-to-person transmission and environmental contamination. This type of outbreak is usually thought to be due to viral infection with organisms such as Norwalk agent or small round structured viruses.[5] [6] Historically a number of bacterial infections, including cholera and typhoid, have been associated with shipborne spread.[3]

Respiratory infection, including multidrug-resistant pulmonary tuberculosis, has also been transmitted during aircraft flight,[7] [8] and there is a well-recognized association between outbreaks of *Legionella* infection and air-conditioning systems in holiday hotels.[9]

Western travelers are increasingly seeking more exotic destinations where, as a result of poverty and poor infrastructure in the local population, they may be at risk of infection with common pathogens (particularly of the gastrointestinal and respiratory tracts). They may also be at risk of more exotic infections that do not exist in their own country (e.g. malaria). By the nature of the travel, the patient with infection often may not have access to the level of diagnostic and therapeutic interventions that would be regarded as standard in the developed world, so empiric treatment of presumed infections is often required. These risks are discussed in detail in Chapter 143 .

ZOONOSES

Zoonoses are infections of animals that can be transmitted to humans, who may act either as a dead-end host or may propagate the infection further. The resulting infection may or may not be clinically apparent. This topic is addressed in Chapter 164 , Chapter 174 , Chapter 175 , Chapter 176 , Chapter 177 , Chapter 178 , Chapter 179 , Chapter 180 , Chapter 181 , Chapter 182 , Chapter 183 , Chapter 184 , Chapter 185 , Chapter 219 and Chapter 222 , but issues specifically related to recreation are discussed here. Many leisure activities increase the opportunity for contact between humans and animals, with consequent increased risk of infection.

Hiking and camping (particularly light-weight backpacking) increase the risk of zoonoses. People may hike in a temperate climate or, increasingly, may choose to trek in a tropical or developing country. These activities increase the potential for contact with infected animals. Infection can then be transmitted by a number of possible routes such as:

- inhalation (e.g. Q fever, anthrax);
- ingestion of contaminated food or water (e.g. infections with *Salmonella* and *Brucella* spp.);
- animal bites (e.g. rabies, skin infections);
- exposure of skin to contaminated water (e.g. leptospirosis, schistosomiasis); and
- arthropod vectors (e.g. arboviruses, Lyme disease).

Zoonotic infection acquired by inhalation

Inhaled zoonoses that can be acquired by the intrepid outdoor explorer include Q fever (caused by *Coxiella burnetii*) and brucellosis (more commonly acquired by ingestion). Rarer problems include plague, anthrax, tularemia and psittacosis.[10]

Zoonotic infection acquired by ingestion

Many of the common 'food poisoning' organisms are zoonoses, and these are discussed in detail in Chapter 43 , Chapter 144 , Chapter 161 , Chapter 163 and Chapter 164 . Certain recreational activities particularly expose participants to increased risks of ingesting pathogenic organisms (which are often zoonotic, although they may be exclusively human parasites). Backpackers drinking inadequately boiled or purified water may become infected with *Cryptosporidium* spp., *Giardia* spp., hepatitis A, *Aeromonas* spp., and *Salmonella* spp. Barbecues are particularly notorious for leading to the ingestion of inadequately cooked meat (or fish) and consequent infection with *Salmonella* spp.,[11] *Campylobacter* spp.,[12] and other more exotic organisms such as *Trichinella* spp. There have been well-documented outbreaks of cryptosporidial infection in children enjoying recreational visits to farm open days.[13] [14]

Arthropod-borne zoonoses

Viruses that must spend some of their life cycle in a blood-sucking arthropod are known as arboviruses (see Chapter 222). Over 200 such viruses have been identified and over 70 have been reported as affecting humans. In 1994, 100 cases of presumed or confirmed arboviral disease were reported from 20 states of the USA.[15] These

TABLE 89-1 -- Recreational activities associated with risk of infection.

RECREATIONAL ACTIVITIES ASSOCIATED WITH RISKS OF INFECTION	
Activity	**Risk**
Travel	Infection during travel: gastrointestinal respiratory pathogens
	Geographic (tropical) infection
'Outdoor' recreation: hiking, backpacking, trekking, barbecues, etc.	Zoonoses: ingestion, inhalation, inoculation, arthropod spread
Water contact: jacuzzi, bathing, nonbathing water activity (wind surfing, canoeing, sailing, etc.)	Inhalation, inoculation, ingestion (see Table 89.2)
Contact sport: rugby, football, etc.	Skin infections, blood-borne pathogens
Strenuous exercise	Upper respiratory infection (possibly; see Table 89.3)

were all encephalitis viruses (mainly Californian and St Louis encephalitis), principally spread by mosquitoes. In 2001 there was a large outbreak of West Nile virus in the Eastern US with 48 human cases and numerous infections of birds (principally crows). [16] By 2002, the outbreak had spread to most of the contiguous United States, with several thousand human cases, and over 100 deaths (see Chapter 4). Yellow fever is a life-threatening mosquito-borne, zoonotic viral infection and the illness remains a risk for travelers and residents during outdoor activities in endemic regions in Africa and South America. In Europe, tick-borne encephalitis is regularly reported from Austria and southern Germany.[17] A major risk factor is outdoor recreation (in particular, walking through long grass while wearing short trousers). An inactivated vaccine against tick-borne encephalitis virus is available.

Tick-borne rickettsiae (see Chapter 14 , Chapter 179 and Chapter 235) are also potential pathogens among those who enjoy 'the great outdoors'.[18] They are mainly of the spotted fever group. In southern Europe, Africa and India, the disease is called tick typhus or boutonneuse fever and is caused by *Rickettsia conorii*. In the USA, it is Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*. New rickettsioses identified during the past decade include Japanese spotted

TABLE 89-2 -- Infections spread by recreational contact with water.

INFECTIONS SPREAD BY RECREATIONAL CONTACT WITH WATER				
Mode of spread	**Organisms**			
	Bacteria	**Viruses**	**Protozoa**	**Helminths**
Fecal-oral spread (accidental ingestion)	*Vibrio* spp. *Salmonella* spp. *Campylobacter* spp. *Aeromonas* spp. *Escherichia coli* *Shigella* spp.	Enteroviruses (including polio) Hepatitis A Small round structured viruses	*Cryptosporidia* *Giardia*	
Spread by direct inoculation	*Pseudomonas* spp. *Aeromonas* spp. *Vibrio* spp. *Mycobacterium marinum* *Leptospira* spp.		*Acanthamoeba* *Naegleria*	*Schistosoma*
Spread by aerosol or aspiration	*Legionella* spp. *Pseudomonas* spp.	Adenoviruses		

fever, Astrakhan fever, Flinders Island spotted fever, California flea typhus, African tick-site fever and *Rickettsia slovaca* infections in central France.

Scrub typhus may affect the trekker in eastern Asia. The infective organism is *Rickettsia tsutsugamushi*. The reservoir is rodents and the vector is the larva (chigger) of the trombiculid mite. Clinically the disease resembles other rickettsial infections, and prevention and treatment strategies are similar.

Lyme disease (see Chapter 54), caused by infection with *Borrelia burgdorferi*, is another condition that may be acquired by recreational exposure. The reservoir consists of mammals such as rodents and deer, with infection being spread by hard ticks (the *Ixodes ricinus* complex).

INFECTIONS CAUSED BY EXPOSURE TO WATER

A large number of infections can be caused by exposure to water (Table 89.2), and some of these have already been discussed in the section on zoonoses. Exposure to water can take place in a variety of recreational contexts. Trekkers and fishermen may wade through infected water, people may bathe in fresh water or sea water, and people may undertake other non-bathing recreational activities in water (e.g. water skiing, sailing, canoeing). There is also an increasing popularity of spa baths, whirlpool baths and jacuzzis.

As with arthropod-borne infections, infections related to water may be acquired by a number of routes, including ingestion, aspiration, inhalation of aerosols, and penetration of skin or mucous membranes by invasive organisms. A variety of clinical infections, including gastrointestinal infection, hepatitis, conjunctivitis, pneumonia, skin and soft tissue infection, may result, and numerous diverse organisms have been implicated.

Pathogenic organisms may enter the water from exogenous sources such as human contamination (e.g. sewage), animal and bird contamination, and farm effluent. Organisms may also come directly from aquatic animals or protozoa or be free living in the water supply.

Infection associated with whirlpools

Jacuzzis, whirlpool baths, and spa baths, which are increasingly found in leisure resorts, are all based on the principle of being bathed in warm water through which jets of water and bubbles of air are blown in order to produce feelings of relaxation and pleasure. They therefore share the potential for the transmission of cutaneous,

mucosal and respiratory infection. The main pathogens implicated in these infections are *Pseudomonas aeruginosa* and *Legionella pneumophila*. *Pseudomonas* infections of the skin were initially described in the early 1980s.[19] The first reports were of folliculitis, but infection of wounds, eyes, ears and urinary tract have now been described.[20] Fatal *Pseudomonas* pneumonia in an immunocompetent male has been associated with jacuzzi exposure.[21]

Legionella spp. (mainly *L. pneumophila*, but other species are also implicated) cause two distinct syndromes:

- legionnaires' disease (or legionnaires' pneumonia), which is usually a severe pneumonic illness requiring appropriate antibiotic treatment; and
- Pontiac fever, which is generally a more benign self-limiting illness causing myalgia, fever and headache.

The latter syndrome has frequently been associated with whirlpool use, although a prolonged outbreak of legionnaires' pneumonia among cruise ship passengers associated with exposure to a contaminated whirlpool spa has been described.[22]

Infection from bathing

Numerous case reports and reviews have associated bathing in swimming pools, natural fresh water and the sea with gastrointestinal, respiratory and cutaneous infection. In swimming pools there have been reports of infection with *Shigella*, *Giardia* and *Cryptosporidium* spp., and various viruses including hepatitis A virus.[23]

The association of sea bathing and disease is a major political issue because millions of dollars are spent in the developed countries in an effort to improve sewage disposal and enhance the 'quality' of bathing water. Microbiologic standards now exist for bathing water in Europe and North America. There is certainly a risk of infection from swimming in heavily contaminated water, but the risk of minor symptomatic infection from swimming in less heavily polluted water remains contentious.[24]

In the 1950s the UK Public Health Laboratory Service used a case-controlled method and showed no link between polio and sea bathing.[25] Cabelli's classic work under the aegis of the US Environmental Protection Agency in the 1970s suggested a dose-response relationship between the microbiologic contamination of bathing water and self-reporting of gastrointestinal symptoms.[26] These studies have been criticized for looking at self-reported symptoms in self-selected groups, with no control for other risk factors for gastrointestinal symptoms.

More recently, a large UK study attempted to address these criticisms by randomizing holiday makers to be 'swimmers' or 'non-swimmers'.[27] This study showed a significantly higher rate of gastroenteritis in the swimmers and demonstrated a dose-response relationship between occurrence of symptoms and concentrations of fecal streptococci (although only with the concentration measured at chest height). Currently, coliform counts are used to assess water quality and the authors of the above study could not demonstrate a correlation between symptoms and the coliform count.

In addition to gastroenteritis, an Australian study showed increased reporting of respiratory, eye and ear symptoms among swimming beach-goers as opposed to non-swimming beach-goers. The incidence of the reported symptoms increased with increasing levels of pollution.[28] The authors of the UK study have now published their results of non-enteric illness acquired during bathing and their results are in broad agreement with those of the Australian study.[29]

Infection in non-swimming recreational water activities

In addition to the hazards of bathing detailed above, many people are exposed to infection by recreational use of water where swimming is not the primary purpose. Such activities include angling, canoeing, water skiing, sailing and white water rafting.

Leptospirosis (see Chapter 181 and Chapter 230) is traditionally regarded as a significant risk. It is estimated that on average in the UK there are five million recreational water users each year exclusive of bathers, and yet among this at-risk population there are only 2.5 cases of leptospirosis a year.[30] The annual total incidence of leptospirosis in England and Wales is more than ten times that figure; it occurs principally among agricultural workers. Leptospirosis is a zoonotic infection that is mainly carried by rodents. It is estimated that about 25% of the rats in UK are infected. The risk of contracting infection relates less to the overall water quality than to the density of the local rodent population.

By the nature of the sport, canoeing involves high level exposure to water and, in addition to leptospirosis, other infections can be acquired. There is an increased incidence of gastrointestinal symptoms, and it has been shown that more than 50% of canoeists had experienced 'flu-like' symptoms shortly after canoeing. [31] An outbreak of blastomycosis has also been reported in canoeists along Wisconsin rivers in northern USA.[32]

Miscellaneous water-related infections

Naegleria and *Acanthamoeba* spp. are free-living amebae with no insect vector or human carrier state. They have been isolated on a worldwide basis from water and soil, and rarely they produce a severe amebic meningoencephalitis that is usually fatal (see Chapter 244). Schistosomiasis is dealt with in detail in Chapter 167 . The cercariae of human schistosomes penetrate intact human skin and then migrate to their favored site to commence their maturation. Within 24 hours the penetration of the skin can produce a pruritic papular rash that is called 'swimmer's itch'. Avian schistosomes are found in temperate climates, including in the Great Lakes of North America, and although they are unable to mature past the cercarial stage in a human host and therefore cannot give rise to later stage schistosomiasis, they can be responsible for producing a significant 'swimmer's itch'.

Katayama fever occurs typically 4–8 weeks after infection and is associated with fever, chills, headache and cough. There is hepatosplenomegaly and lymphadenopathy, and usually a significant eosinophilia. It is caused by both *Schistosoma japonicum* and *Schistosoma mansoni*, the latter being particularly recognized in swimmers who have bathed in lake Malawi and the other rivers and lakes in East Africa (see Chapter 67).

INFECTION SPREAD BY DIRECT CONTACT

Many sports require close physical contact on the sports field and may also involve close contact in the changing rooms with for example shared towels and shaving equipment. Tetanus is caused by contamination of a wound by the spores of *Clostridium tetani*. After contamination, the organism then elaborates a toxin that produces the clinical syndrome of tetanus. Although immunization against tetanus is widely practised there is still a risk to those playing contact sports (especially rugby and football), as well as to those pursuing more leisurely activities such as gardening.

The close contact in the scrum of rugby football may transmit herpes simplex virus and cause a condition called scrumpox or herpes gladiatorium. This is highly infectious and may spread rapidly between players. Aciclovir is effective treatment.

The moist atmosphere of changing rooms may promote the transmission of respiratory infections as well as a number of cutaneous infections such as verrucas, athletes foot (*Tinea pedis*) and dhobie itch (*Tinea cruris*). The spread of these tineal infections may be facilitated by sharing towels and washing equipment.

Gardening is usually considered a fairly safe past-time, but tetanus is a potential risk and sporotrichosis (see Chapter 239) can be acquired by scratches from rose thorns and similar injuries.

Blood-borne infection transmission in contact sport

The risk of transmission of blood-borne pathogens during contact sport is thought to be extremely low. There were large outbreaks of hepatitis amongst orienteers in Sweden from 1956 to 1966, and on the basis of the clinical and epidemiologic picture these were assumed to be due to hepatitis B virus (HBV), although a serologic test was not available.[33] As part of these outbreaks, 568 cases of hepatitis occurred between 1957 and 1963; several modes of transmission were postulated, including twigs contaminated with infected blood inoculating subsequent competitors, contaminated water in stagnant pools and transmission during washing after competition. It was established that 95% of orienteers received scratches or wounds during the competition. The outbreak was curtailed by the introduction of regulations that banned competitors who had hepatitis from competing for 15 months and that specified compulsory protective clothing. More cases were reported when these regulations were relaxed. There has also been a report of an outbreak of HBV infection among sumo wrestlers in Japan.[34] There is one report from Italy of an HIV-positive football player transmitting infection to another player during a collision when both players were bleeding profusely,[35] but the risks are generally considered to be negligible.

Numerous guidelines exist to limit the risk still further[34] — in rugby football, for example, a player with an open or bleeding wound must leave the field until the wound is covered and the bleeding controlled. Similar policies now apply for many college level and professional sports settings.

EFFECT OF EXERCISE ON THE IMMUNE SYSTEM

Although it is clear from the above that recreational activity can expose participants to numerous infective agents that they might not otherwise encounter, it is by no means so obvious whether recreation (in particular, vigorous exercise) has any clinically significant effect on immune function.[36] There is increasing evidence that physical exercise may bring benefit in terms of cardiovascular health. However, the evidence from the immunologic perspective is less obvious.

There are numerous anecdotal reports of increased incidence of upper respiratory infection in athletes and there have been attempts to examine this systematically. However, despite numerous reviews there is no consistent association between physical activity and incidence of clinical upper respiratory infection. Nor has any consistent immunologic abnormality been demonstrated in high-level athletes. This inconsistency has many parallels with the situation in chronic fatigue syndrome, and many top athletes who have recurrent infections develop a clinical condition indistinguishable from chronic fatigue syndrome.

The overall message from anecdotal reports, from case-controlled studies of symptoms, from animal studies and from laboratory tests of immune function seems to be that moderate regular exercise enhances immunity whereas sudden unusual exertion or consistent, very high-grade training may have a deleterious effect. This is described as the

TABLE 89-3 -- Effects of exercise on the immune system.

EFFECTS OF EXERCISE ON THE IMMUNE SYSTEM

Symptoms/self-reported infections (anecdote and case-control)	Most studies suggest that moderate regular exercise reduces frequency and severity of upper respiratory tract infections but excessive training increases it
	Many studies are subjective and it may be that athletes are more aware of their symptoms than are controls
	Some increase in infection may be due to local factors such as mouth breathing rather than to any change in systemic immunity
Animal studies	Exhaustive exercise during experimental viral infection increases mortality and morbidity from that viral infection; the effect may be attenuated by exercise prior to infection
	Similar results have been shown in pneumococcal infection — exercise prior to infection protected against mortality but forced exercise after infection enhanced mortality
Immune function studies	Moderate exercise in HIV-positive people has been shown to produce some increase in $CD4^+$ lymphocyte count Excessive training in non-HIV-infected people has been shown to suppress $CD4^+$ lymphocyte counts
	Heavy exercise decreases lymphocyte proliferation and levels of IgA; the decreased levels of IgA may correlate with increased incidence of upper respiratory tract infections
	Regular moderate exercise will increase levels of natural killer lymphocytes
	Exercise generally increases the release of proinflammatory cytokines and acute phase proteins

'J-shaped curve' correlating exercise and immunity.[36] [37] Animal studies suggest that exercising before infection is beneficial, whereas exercising when infected is harmful. Some of the reported immunologic effects of exercise are listed in Table 89.3 .

It is generally advised that people who are suffering from acute infections do not participate in vigorous exercise. This seems common sense and most people would probably not feel like doing so, although definite evidence of harm remains contentious.

CONCLUSION

Recreational activities can expose participants to novel infectious agents that they are less likely to encounter in other contexts. In many of these the diagnosis may not be very obvious unless the condition is considered. Physicians need to add 'recreational history' to the already extensive list of travel, occupational and animal exposure details about which they need to enquire when evaluating a patient with a suspected infection. Whether recreational activity can alter immune function remains more controversial, although there seems to be increasing consensus that regular physical exercise may be of benefit but that excessive exercise may increase the risks of infection.

Chapter 90 - Occupational Infections

Rodrigo L C Romulo

INTRODUCTION

Individuals may have an increased risk for acquiring certain infections as a result of their occupation. These include workers whose occupations involve significant exposure to potentially infectious material such as:

- health care workers exposed to patients who have communicable diseases;
- workers in contact with live animals (veterinarians, livestock handlers, animal trainers, hunters, trappers, zoo workers, laboratory animal workers, fishermen);
- workers in contact with animal carcasses or byproducts (butchers, abattoir workers, meat inspectors, raw animal product processers);
- biomedical laboratory workers exposed to infectious clinical specimens, cultures or infectious laboratory animals; and
- workers exposed to infections in outdoors environments such as arthropod-borne infections or major mycoses (forestry workers, agricultural workers, sewer and irrigation workers, wildlife workers).

Infections in health care workers are discussed in Chapter 88 . Those whose livelihood requires travel to and work in endemic areas have increased risk for malaria, leishmaniasis, trypanosomiasis, diarrheal diseases and other travel-related illnesses (see Section 6).

Groups of individuals working together or living as a result of their occupation may be at risk for outbreaks of airborne infections such as tuberculosis, pharyngoconjunctival fever or meningococcal disease. Such groups include military personnel living in barracks and factory shift workers.

This chapter provides a quick reference for clinicians faced with patients in whom an occupational infection is suspected. The information is presented entirely in tables which offer possible diagnoses for specific clinical presentations considering the patient's occupational exposure. The occupations have been loosely categorized as workers with animal contact; biomedical laboratory workers; farm, forestry and other outdoors workers; and sewer and irrigation workers.

TABLE 90-1 -- Workers who have animal contact: infections presenting with skin lesions.

WORKERS WHO HAVE ANIMAL CONTACT: INFECTIONS PRESENTING WITH SKIN LESIONS			
Clinical presentation	**Possible animal sources**	**Possible infectious agent**	**Comments**
Papular or vesicular lesions			
Enlarging pruritic papule that ulcerates and develops eschar and edema	Herbivores, particularly cattle, goats, donkeys, horses, water buffalo	*Bacillus anthracis* (cutaneous anthrax)	Transmission via contact with animals sick with or that have died from anthrax or with contaminated raw animal materials; bioterrorism-related outbreak in postal workers[1] (see Ch 9 , Ch 147 and Ch 226)
Papular or pustular lesions on arms or hands	Domestic and wild mammals, birds, fish, ticks, crustaceans	*Listeria monocytogenes* (primary cutaneous listeriosis)	Cases usually mild, resolve with treatment[2] (see Ch. 226)
Annular erythematous lesions with scaling, or erythematous scaling of scalp (tinea capitis, tinea corporis, tinea barbae)	Cattle	*Trichophyton verrucosum* (cattle ringworm)	Cases reported in dairy and cattle farmers, abattoir worker and veterinarian in Australia[3] (see Ch. 240)
Solitary papule on extremity with shallow ulceration and scar formation, followed by multiple subcutaneous nodules 'ascending' proximally	Fish, shellfish, other marine animals	*Mycobacterium marinum*	Risk factors include trauma while practicing water/fish-related occupation or hobbies (see Ch. 233)
Indurated papule, then ulcer, then sinus formation	Monkeys	*Mycobacterium simiae*	Case in wild animal handler acquired in Peruvian jungle[4] (see Ch. 233)
Vesicular lesions resembling smallpox	Monkeys from western and central Africa	Monkeypox virus	Rare in humans, most cases in Zaire (see Ch. 218)
Vesicles progressing to pustules, which coalesce and scab	Sheep and goats	Parapoxvirus (orf)	Transmitted via direct contact with animal lesions; lesions mild, but can become painful and pruritic and may persist for weeks (see Ch. 218)
	Cattle	Parapoxvirus (pseudocowpox, paravaccinia, milker's nodule)[5]	
	Gray seals	Parapoxvirus (sealpox)[6]	
Cellulitis/abscesses			
Localized painful cellulitis, slightly raised violaceous, peripheral spread with central fading	Wide range of vertebrates and invertebrates; mainly fish, swine, turkey, ducks, sheep	*Erysipelothrix rhusiopathiae* (erysipeloid)	Greatest risk in fishermen, fish handlers, butchers, abattoir workers, veterinarians[7] (see Ch. 226)
Acute painful cellulitis following animal bite or scratch	Mostly cats and dogs; other wild and domestic mammals	*Pasteurella* spp.	Must consider if cellulitis develops within 24 hours of bite or scratch (see Ch. 91)
Cellulitis of the hand	Freshwater fish grown by aquaculture	*Streptococcus iniae*	Outbreak in Canada from *Tilapia* fish imported from USA[8] (see Ch. 225)
Necrotizing cellulitis, fasciitis following fish-associated percutaneous injury	Fish and shellfish[9]	*Vibrio vulnificus*	Seen in fish 'farmers' or fishermen, often immunocompromised (see Ch. 230)
		Vibrio (Photobacterium) damsela	Severe cases from catfish puncture wound, knife cut while filleting bluefish, after rabbitfish bite (see Ch. 230)
		Edwardsiella tarda	Associated with fish spine injury (see Ch. 228)
		Aeromonas hydrophila	Not necessarily fish-related but may infect water-associated wounds (see Ch. 229)
Cellulitis, fulminant sepsis following bite or scratch	Mainly dog (also cat)	*Capnocytophaga canimorsus; C. cynodegmi* [10]	More rapid and severe progression in asplenic individuals, alcoholics and patients on corticosteroids (see Ch 91 and Ch 229)

Cutaneous or subcutaneous abscesses, sepsis syndrome in most cases	Animals not reservoir for human disease	*Burkholderia pseudomallei* (melioidosis)	Farmers in South East Asia and northern Australia; acquired by soil contamination of skin abrasions and possibly ingestion, inhalation or intranasal inoculation[11] (see Ch. 229)

TABLE 90-2 -- Workers who have animal contact: infections presenting with acute fever.

WORKERS WHO HAVE ANIMAL CONTACT: INFECTIONS PRESENTING WITH ACUTE FEVER			
Clinical presentation	**Animal exposure**	**Possible infectious agent**	**Comments**
Non-specific fever			
Fever, chills (endocarditis)	Pigs, wild boar	*Streptococcus suis*	Rare in humans; mostly in pig farmers, others who have close contact with pigs;[12] meningitis in hunter who butchered wild boar[13] (see Ch. 225)
	Horses	*Streptococcus equinus*	Case in UK farmer[14] (see Ch. 225)
	Fish	*Streptococcus iniae*	Endocarditis, meningitis and arthritis in diabetic who had rheumatic heart disease, osteoarthritis, renal failure after percutaneous injury while preparing fish[8] (see Ch. 225)
Fever, sweats, anorexia, headache, back pain	Mainly cattle, also buffalo, camels, yaks	*Brucella abortus*	Worldwide distribution, increased risk in veterinarians, livestock farmers, abattoir workers, meat inspectors (see Ch 180 and Ch 231)
	Goats, sheep, camels	*Brucella melitensis*	
	Swine	*Brucella suis* biovars 1–3	
	Reindeer, caribou	*Brucella suis* biovar 4	
	Dogs	*Brucella canis*	
Malaise, fatigue, fever, shaking chills, myalgias, arthralgias, dark urine	Cattle (in Europe)	*Babesia bovis, Babesia divergens* (babesiosis)	Thought to be transmitted to humans in Europe by cattle tick *Ixodes ricinus* (see Ch. 245)
Fever, myalgias, bacteremia	Cattle	*Bartonella vinsonii* subsp. *arupensis*	Case in rancher in Wisconsin, USA[15] (see Ch. 235)
Fever, chills, headache, vomiting, migratory arthralgias	Rats, mice, squirrels; also cats, dogs, pigs, ferrets, weasels	*Streptobacillus moniliformis* (USA), *Spirillum minus* (Asia) (rat-bite fever)	Increased risk in animal laboratory workers[16] (see Ch. 230)
Hemorrhagic fever			
Abrupt-onset fever, headache, rigors, nausea, vomiting, petechial rash or ecchymosis, generalized hemorrhage	Sheep, cattle	Rift Valley fever virus	Herdsmen, farm workers, wildlife rangers, abattoir workers and veterinarians exposed to infected animals or their products in Africa [17] (see Ch. 183 and Ch. 222)
	Cattle, sheep, goats, antelopes	Crimean-Congo hemorrhagic fever	Outbreak involving abattoir workers, livestock market employees, and animal skin processors in United Arab Emirates[18]
Fever and cough			
Undifferentiated febrile illness or atypical pneumonia	Most common reservoirs are cattle, sheep, goats	*Coxiella burnetii* (Q fever)	Worldwide distribution; usually affects those who have direct contact with infected animals[19] (see Ch. 235)
	Birds (poultry, parrot family, finches, pigeons, pheasants, egrets, seagulls, puffins); sheep	*Chlamydia psittaci* (psittacosis)	Increased risk in poultry farmers, pet shop workers, abattoir and processing plant workers (see Ch. 236)
Fever, chills, cough, chest pain, dyspnea, occasionally hemoptysis	Animals not reservoir for human disease	*Burkholderia pseudomallei* (melioidosis)	Farmers in South East Asia and Northern Australia; acquired by soil contamination of skin abrasions and possibly ingestion, inhalation or intranasal inoculation (see Ch. 175 and Ch. 229)
Other febrile syndromes			
Fever, chills, headache, myalgias, abdominal pain, conjunctival suffusion, muscle tenderness, jaundice	Wide range of mammals; rats most common source worldwide; also dogs, wild mammals, cats, pigs, other livestock	*Leptospira* spp. (Leptospirosis)	Worldwide distribution; cases usually result from contact with water or soil contaminated with infected urine; outbreak in Missouri, USA in humans exposed to infected swine[20] (see Ch. 181 and Ch. 230)
Recurrent fever, pleuropericardial effusion		*Campylobacter fetus* ssp. *fetus*	Case in slaughterhouse worker in UK[21] (see Ch. 230)
Abrupt-onset fever, chills, headache, malaise, anorexia, fatigue, tender lymphadenopathy, skin ulcer	Voles, squirrels, rabbits, hares, muskrats, beavers, hamsters	*Francisella tularensis* (tularemia)[19]	Transmitted via insect bite, aerosol, contact with contaminated water or mud, animal bites; increased risk in farmers, animal laboratory workers, veterinarians, hunters, trappers, meat handlers (see Ch. 176 , Ch. 177 and Ch. 231)
	Rats most important reservoirs worldwide; also squirrels, prairie dogs and other urban and sylvatic rodents	*Yersinia pestis* (plague)	

TABLE 90-3 -- Workers who have animal contact: infections presenting with acute fever and neurologic abnormalities.

WORKERS WHO HAVE ANIMAL CONTACT: INFECTIONS PRESENTING WITH ACUTE FEVER AND NEUROLOGIC ABNORMALITIES			
Clinical presentation	**Animal exposure**	**Possible infectious agent**	**Comments**
Fever, severe headache 3–5 days after flu-like illness	Rodents	Lymphocytic choriomeningitis virus	Increased risk in laboratory workers handling mice, hamsters (see Ch. 222)
Fever, headache, meningismus, declining sensorium (meningitis)	Pigs, wild boar	*Streptococcus suis*	Close contact with pigs documented in most cases; case in hunter who butchered wild boar[13] (see Ch. 225)
Fever, anorexia, nausea, vomiting, headache, pain or paresthesias at site of animal bite followed by hyperactivity, disorientation, bizarre behavior	In developing countries mostly dogs; farm animals (e.g. cattle, horses, sheep), wild mammals (e.g. raccoons, skunks, foxes, coyotes, wolves, jackals, mongoose, bats, cats)	Lyssavirus genotype 1 (rabies virus), genotype 3 (Mokola virus), genotype 4 (Duvenhage virus), genotype 5 (European bat lyssavirus 1), genotype 6 (EBLV 2), Australian bat lyssavirus	Incubation period usually 20–90 days: bites on head 25–48 days; on extremity 46–78 days; genotypes 3–6 found in Africa and Europe and associated with fatal encephalitis following bat bites (see Ch. 153)
High fever, myalgia, sore throat, dizziness, drowsiness, progressive encephalitis	Pigs	Nipah virus	Outbreak among pig farmers in Malaysia[22] and abattoir workers in Singapore;[23] also presents as atypical pneumonia (see Ch. 222)

Fever, progressive meningo-encephalitis following monkey bite or scratch	Macaque monkeys	Cercopithecrine herpesvirus 1 (herpes B virus)	Acquired from monkey bites or scratches or handling monkey tissues or cell cultures[24] (see Ch. 215)
Influenza-like prodrome, then progressive encephalitis	Horses	Hendra virus	Three cases reported in Queensland, Australia; all exposed during epidemics in horses[25] (see Ch. 222)

TABLE 90-4 -- Workers who have animal contact: infections presenting with diarrhea.

WORKERS WHO HAVE ANIMAL CONTACT: INFECTIONS PRESENTING WITH DIARRHEA			
Clinical presentation	**Animal exposure**	**Possible infectious agent**	**Comments**
Diarrhea or abdominal pain (pancreatitis)	Farm animals (cattle, sheep), laboratory animals (calves, rodents, rabbits)	*Cryptosporidium* spp.[26]	Transmission occurs animal to person, person-to-person, water-borne (see Ch. 243)
Acute diarrhea (watery or bloody), fever, abdominal pain	Wild and domesticated cattle, sheep, goats, swine, dogs, cats, rodents, fowl	*Campylobacter jejuni*	Worldwide distribution, transmission via ingestion of contaminated material, direct contact with infected animals (see Ch. 230)
	Swine	*Campylobacter coli, C. hyointestinalis*	
	Dogs	*Campylobacter upsaliensis*	
	Sheep, cattle, swine, poultry, reptiles	*Campylobacter fetus*	
	Cynomolgus macaque monkey	*Shigella* spp.	Outbreak of *S. flexneri* reported among workers in primate research unit (see Ch. 228)
	Rodents, rabbits, sheep, pigs, horses, cattle, dogs, cats	*Yersinia enterocolitica*	Transmission mainly by ingestion of contaminated food or drink, less commonly direct contact with infected animals; Finnish butchers documented at higher risk[27] (see Ch. 228)
Chronic diarrhea	Coho salmon, other salminoid fish	*Nanophyetus salmincola* (nanophyetiasis)	Transmission usually by ingestion; also by handling infected fish[28] (see Ch. 246)

TABLE 90-5 -- Workers who have animal contact: other infectious syndromes.

WORKERS WHO HAVE ANIMAL CONTACT: OTHER INFECTIOUS SYNDROMES			
Clinical presentation	**Animal exposure**	**Possible infectious agent**	**Comments**
Septic arthritis	Fish (catfish)	*Edwardsiella tarda*	Reported following catfish spine injury in Australia[29] (see Ch. 228)
Chronic upper abdominal pain or discomfort; jaundice weight loss	*Echinococcus granulosus* (hydatid disease, liver)	Mainly dogs	Worldwide distribution, predominantly South and Central America, European and African parts of Mediterranean area, Middle East, some sub-Saharan countries, Russia and China. Consider in workers having contact with dogs in endemic areas (e.g. ranchers, farm workers) (see Ch. 169 and Ch. 246)
	Echinococcus multilocularis (hydatid disease, liver)	Red and arctic foxes, domestic dogs and cats	Restricted to northern hemisphere. Human disease frequently reported in central and eastern France, Switzerland, Austria and Germany. Occurs in tundra zone of Russia, China and Japan. Cases reported in Manitoba, Minnesota and in Alaskan Eskimos. Consider in trappers, hunters, ranchers, farm workers, veterinarians and other workers in contact with foxes and dogs in endemic areas
Chronic cough, hemoptysis, pleuritic pain	*Echinococcus multilocularis* (hydatid disease, lungs)	Same as for *E. multilocularis* above	Same as for *E. multilocularis* above (see Ch. 169 and Ch. 246)

TABLE 90-6 -- Biomedical laboratory workers: infections presenting with skin lesions. [30] [31]

BIOMEDICAL LABORATORY WORKERS: INFECTIONS PRESENTING WITH SKIN LESIONS		
Clinical presentation	**Possible infectious agent**	**Exposure**
Cutaneous papules, pustules, nodules, ulcers or abscesses	*Coccidioides immitis* [32]	Direct percutaneous inoculation of contaminated material (see Ch. 185 , Ch. 226 and Ch. 238)
Verrucous skin lesions with peripheral microabscesses or initial pustule that spreads into ulcer with red granulation tissue	*Blastomyces dermatitidis* (cutaneous blastomycosis)[33]	
Enlarging pruritic papule, which ulcerates, develops eschar and edema	*Bacillus anthracis* (cutaneous anthrax)[34]	
Painless nodule at site of inoculation which ulcerates, develops satellite lesions around ulcer and along draining lymphatics	*Sporothrix schenckii* (cutaneous sporotrichosis)[35]	Percutaneous inoculation (see Ch. 239)
Enlarging papule that forms ulcer with a raised violaceous border	*Leishmania* spp. (cutaneous leishmaniasis)	Percutaneous inoculation, transmucosal, bites from insect vector in research laboratory workers (see Ch. 172 and Ch. 245)
Pseudotumoral destructive lesion in nasal or oropharyngeal mucosa	*Leishmania braziliensis* (mucocutaneous leishmaniasis)	
High fever, eschar, regional adenopathy, headache, myalgia, rash including palms and soles	*Rickettsia rickettsii* (Rocky Mountain spotted fever)[36]	Infectious aerosols, percutaneous inoculation, vector-borne in research laboratory workers (see Ch. 179 and Ch. 235)
High fever, headache, backache, generalized pain; eschars, adenopathy unusual	*Rickettsia prowazekii* (epidemic typhus) *Rickettsia typhi* (murine typhus)[37] [38]	
High fever, eschar, regional adenopathy, headache, myalgia, rash	*Orientsia tsutsugamushi* (scrub typhus)[39]	

TABLE 90-7 -- Biomedical laboratory workers: infections presenting with acute fever.[30] [31]

BIOMEDICAL LABORATORY WORKERS: INFECTIONS PRESENTING WITH ACUTE FEVER		
Clinical presentation	**Possible infectious agent**	**Exposure**
Gradually increasing fever, chills, headache, malaise	*Salmonella typhi*, *S. paratyphi* A, B	Oral, occasionally percutaneous inoculation (see Ch 228)
Fever, fatigue, malaise, night sweats, weight loss, lymphadenopathy, visceral abscesses	*Burkholderia mallei* (glanders) [40]	Infectious aerosols, possibly cutaneous inoculation (see Ch. 229)
Fever, severe headache 3–5 days after flu-like illness	Lymphocytic choriomeningitis virus	Parenteral inoculation, transmucosal, infectious aerosols (see Ch. 222)
Fever, sweats, sore throat, myalgias, maculopapular rash, headache, photophobia, meningismus	HIV (acute infection)	Percutaneous or mucous membrane exposure while processing infected blood or body fluid (see Ch 214 and Ch 221)
Fever, anorexia, malaise, then jaundice	Hepatitis viruses	
Swelling and/or redness at inoculation site, fever, rash adenopathy, myocarditis	*Trypanosoma cruzi* (North American trypanosomiasis, Chagas disease)	Needle, wound, transmucosal (aerosol?) (see Ch. 173)
Swelling and/or redness at inoculation site, fever, rash adenopathy, headache, fatigue, neurologic signs	*Trypanosoma brucei rhodesiense* and *gambiense* (African trypanosomiasis)	Needle, wound, transmucosal (aerosol?) (see Ch. 157)
Fever, shaking chills, fatigue, anemia	*Plasmodium* spp., *Babesia* spp.	Percutaneous inoculation, transmucosal (see Ch 166 and Ch 245)
Fever, chills, headache, vomiting, migratory arthralgias	*Streptobacillus moniliformis*, *Spirillum minus* (rat-bite fever)	Bite of laboratory rat (see Ch. 230)
Fever, chills, headache, myalgias, abdominal pain, conjunctival suffusion, muscle tenderness, jaundice	*Leptospira* spp. (leptospirosis)	Oral, percutaneous (see Ch 181 and Ch 230)
Fever, adenopathy, malaise, rash	*Toxoplasma gondii*	Oral, percutaneous, transmucosal (aerosol?)
Hemorrhagic fever	*Sabia virus*[41]	Aerosol (see Ch. 222)
Hemorrhagic fever with renal syndrome	Hantaan virus	Probable transmission via infectious aerosols, wound infection during animal handling;[42] [43] reported case probably due to contact with immunocytoma[44] (see Ch. 222)
Fever, purpuric/ecchymotic skin lesions, meningitis, shock	*Neisseria meningitidis*	Airborne; fatal cases described in laboratory workers[45] (see Ch. 227)
Fever, sweats, anorexia, headache, back pain	*Brucella* spp.[46]	Direct contact; air-borne spread among laboratory workers documented (see Ch 180 and Ch 231)
Abrupt-onset fever, chills, headache, malaise, anorexia, fatigue, tender lymphadenopathy, skin ulcer	*Francisella tularensis*	Infectious aerosols, percutaneous, transmucosal (see Ch 177 and Ch 231)

TABLE 90-8 -- Biomedical laboratory workers: infections presenting with fever and cough. [30] [31]

BIOMEDICAL LABORATORY WORKERS: INFECTIONS PRESENTING WITH FEVER AND COUGH		
Clinical presentation	**Possible infectious agent**	**Exposure**
Fever, chills, cough, pleuritic chest pain, soft tissue abscesses	*Burkholderia pseudomallei* (melioidosis) [47]	Infectious aerosols (see Ch 175 and Ch 229)
Mild fever, headache, chills, sweats, cough, maculopapular rash	*Coxiella burnetii* (Q fever)[19]	Infectious aerosols, percutaneous inoculation (see Ch. 235)
Fever, dermatitis, cough, hepatosplenomegaly, adenopathy	*Schistosoma* spp. (acute schistosomiasis)	Percutaneous (see Ch. 167)
Fever, cough, fatigue, arthralgias, pulmonary nodular lesions	*Blastomyces dermatitidis* (pulmonary blastomycosis)	Infectious aerosols (see Ch. 238)
Chronic cough, fever, night sweats, anorexia, weight loss	*Mycobacterium tuberculosis*	Infectious aerosols; laboratory-acquired case presenting as endometrial tuberculosis reported[48] (see Ch. 233)
	Coccidioides immitis	Inhalation of arthrospores from culture (see Ch. 238)

TABLE 90-9 -- Biomedical laboratory workers: other infections.[30] [31]

BIOMEDICAL LABORATORY WORKERS: OTHER INFECTIONS		
Clinical presentation	**Possible infectious agent**	**Exposure**
Diarrhea	*Shigella* spp., nontyphoidal *Shigella* spp., nontyphoidal *Salmonella* spp., *Campylobacter* spp., *Vibrio cholerae*	Oral, occasionally percutaneous inoculation (see Ch 228 and Ch 230)
	Cryptosporidium parvum	Oral, transmucosal (aerosol?) (see Ch. 243)
	Giardia lamblia	Oral (aerosol?) (see Ch. 242)
	Isospora belli	Oral (see Ch. 243)
Right upper quadrant pain, biliary colic, obstructive jaundice	*Fasciola hepatica*	Oral (see Ch. 246)
Conjunctivitis	*Neisseria gonorrhoeae*	Conjunctival contamination (see Ch. 227)

TABLE 90-10 -- Infections in farm, forestry and other outdoor workers.

INFECTIONS IN FARM, FORESTRY AND OTHER OUTDOOR WORKERS		
Clinical presentation	**Possible infectious agent**	**Exposure**
Red macule or papule with expanding borders and central clearing or migratory pain in joints, bursae, tendons, muscles; arthritis	*Borrelia burgdorferi* (Lyme borreliosis)	High seroprevalence in forestry workers, but asymptomatic infection more common (see Ch 54 and Ch 230)

Abrupt fever, headache, photophobia, vomiting, meningismus, seizures, altered sensorium	Russian summer-spring encephalitis virus/central European encephalitis virus (tick-borne encephalitis virus, TBEV)	Higher antibody levels to TBEV found in Polish forestry workers [49] (see Ch. 222)
Erythematous papulonodular lesion with several painless secondary nodules proximally along lymphatic channels	*Sporothrix schenckii* (sporotrichosis)	Outbreaks among forestry workers in USA associated with sphagnum moss;[50] higher skin-test positivity among those engaged in horticulture, gardening, woodwork and farming in northern India[51] (see Ch. 239)
Hemorrhagic fever with renal syndrome	Puumala virus (nephropathia endemica)	Higher seroprevalence among forestry workers in Sweden, but not in The Netherlands; high risk in farmers in Finland
	Hantaan virus	Increased seroprevalence in Dutch animal trappers and forestry workers (see Ch. 222)
Fever, chills, cough, chest pain, dyspnea, occasionally hemoptysis, soft tissue abscesses	*Burkholderia pseudomallei* (melioidosis)	Farmers in South East Asia and northern Australia; acquired by soil contamination of skin abrasions and possibly ingestion, inhalation or intranasal inoculation (see Ch 175 and Ch 229)
Fever, myalgias, jaundice	*Leptospira* spp.	Antibodies to *Leptospira* spp. found in 10–12% of farmers and forestry workers in Italian alpine region; only few clinical cases (see Ch 181 and Ch 230)
Fever, cough, fatigue, arthralgias, bilateral pulmonary nodular lesions	*Blastomyces dermatitidis* (pulmonary blastomycosis)	Two cases acquired during prairie dog relocation in Colorado; spores probably aerosolized during vigorous digging[52] (see Ch. 238)
Chronic cough, fever, night sweats, anorexia, weight loss	*Coccidioides immitis*	Cases among workers and students at archaeologic sites[53] (see Ch. 238)
Corneal ulcers	Fungal keratitis (organisms not specified)	Cases in onion harvesters in Taiwan[54]

TABLE 90-11 -- Infections in sewer and irrigation workers.

INFECTIONS IN SEWER AND IRRIGATION WORKERS		
Clinical presentation	**Possible infectious agent**	**Exposure**
Fever, malaise, anorexia, then jaundice	Hepatitis A	Sewer workers at higher risk than general population in developed countries (see Ch. 214)
Fever, chills, headache, myalgias, abdominal pain, conjunctival suffusion, muscle tenderness, jaundice	*Leptospira* spp. (leptospirosis)	Increased risk in sewer and public cleansing workers; in the Philippines associated with wading in flooded city streets (see Ch 181 and Ch 230)
Intestinal parasitism	*Ascaris lumbricoides, Entamoeba histolytica, Enterobius vermicularis*	More common in Egyptian sewer workers than in controls (see Ch. 246)
Fatigue, abdominal pain, intermittent diarrhea, hepatosplenomegaly	*Schistosoma japonicum, S. mansoni, S. mekongi* (schistosomiasis)	Rice farmers and freshwater fishermen in endemic areas (see Ch 167 and Ch 246)
Terminal hematuria, dysuria	*Schistosoma haematobium*

Chapter 91 - Infections from Pets

Ellie JC Goldstein

INTRODUCTION

Domestic pets, particularly dogs and cats, can be dated back prior to Ancient Egypt. Currently, more than one-third of USA households keep some pet including 53 million dogs, 57 million cats and a plethora of other animals from birds to fish to reptiles.[1] In Australia, 66% of households have a domestic pet.[2] It is therefore not surprising that transmission of infection from animals to humans and humans to animals is common.

DOG-ASSOCIATED INFECTIOUS DISEASES

Dog bites

Table 91.1 lists some of the infectious organisms associated with dogs and canine contact. Of the over four million Americans bitten annually by a dog, only 15–20% will seek, or need, medical attention and 3–18% will become clinically infected. Dog bites account for 1% of all emergency department visits and result in 10,000 hospitalizations and 1–10 deaths annually.[1] Most dog bites are inflicted by the victim's own pets or an animal known to them, often while separating the dog in a fight with another dog. Half of dog bite wounds are to the hands and pose a special risk for penetration into the bones and joints and potential spaces of the hand. It is possible for nerves and/or blood vessels to be damaged. Approximately 15% of dog bites are to the head and neck, 20% to the leg or foot and 15% to the upper extremity.[1] [2]

The incidence of dog bite wounds peaks in the summer months and on weekends. The median age of dog bite victims is 28 years old and over 60% are male. Most dog bite wounds are punctures (approximately 60%) with the remainder being lacerations (10%) or combinations of the two (30%). Most patients attempt some form of self-therapy before presenting for medical attention, which include washing with soap and water, applying a topical iodophor or alcohol product. The median time for presentation for medical care is 35 hours post-injury, usually after the onset of clinical signs of infection.

TABLE 91-1 -- Infections transmissible from dogs.

INFECTIONS TRANSMISSIBLE FROM DOGS			
Bacteria	**Fungi**	**Parasites**	**Viruses**
Normal flora	*Blastomyces* spp.	*Giardia* spp.	Rabies
Pasteurella spp.	*Microsporum* spp.	*Babesia* spp.	LCM (lymphocytic choriomeningitis)
Capnocytophaga canimorsus	*Trichophyton* spp.	*Toxocara* spp.	Influenza
Tularemia		*Dipylidium canium*	Mumps
Ehrlichiosis		Echinococcosis	
Brucellosis		*Ancyclostoma* spp.	
Mycobaterium fortuitum		Scabies	
Campylobacter spp.		*Cheytelliella*	
Anaerobiospirillum thomasii			
Yersinia spp.			

At presentation approximately 60% of wounds exhibit a purulent exudate, 30% have signs of infection but are without exudates and 10% are abscesses. Approximately one-third of patients reporting to an emergency department will require hospitalization for intravenous antibiotics. When cultured, these wounds yield an average of five isolates, usually three aerobes and two anaerobes. Mixed aerobic and anaerobic infection occurs in 50% of dog bite wounds and 35% grow only aerobes. Common aerobic isolates include *Pasteurella* species, 50% (*Pasteurella canis*, 26%; *Pasteurella multocida* subspecies *multocida*, 12%; *Pasteurella stomatis*, 12%; *P. multocida* subspecies *septica*, 10%), streptococci, 46%, staphylococci, 46% (half of which are *Staphylococcus aureus*), and *Neisseria* spp., 16%.[1] *Capnocytophaga canimorsus* has been associated with fatal sepsis, especially in asplenic patients and those with liver disease. Common anaerobes isolated include *Fusobacterium* spp., 32%, *Bacteroides* spp., 30%, especially *Bacteroides tectum*, *Porphyromonas* spp., 28%, *Prevotella* spp., 28%, especially *Prevotella heparinolytica*, and peptostreptococci 16%.[1] [2] [3]

Table 91.2 outlines the susceptibility patterns of common bite isolates. For those patients hospitalized, the mean duration of stay is 3 days, with approximately 30% requiring incision and drainage and 25% requiring debridement of the wound. Severely penicillin-allergic patients may need a combination of agents. Fluoroquinolones, tetracyclines and sulfa drugs are contraindicated in pregnant patients; tetracyclines and fluoroquinolones are relatively contraindicated in patients younger than 18 years old. Agents (mono-therapy) associated with therapeutic failure include first-generation cephalosporins and macrolides. The duration of therapy will depend upon the severity of the wound. For wounds that are seen less than 8 hours post-injury and require prophylaxis (moderate-to-severe wounds) the duration of prophylaxis is usually 3–5 days (see also Chapter 96e). Therapy for a cellulitis is usually 7–10 days, while the therapy for septic arthritis and osteomyelitis is often 4–6 weeks. Cases of endocarditis and infection of prosthetic joints following bites have been reported, albeit rarely. The principles of wound care are noted in Table 19.3.

TABLE 91-2 -- Activity of selected antimicrobials against animal bite isolates.

ACTIVITY OF SELECTED ANTIMICROBIALS AGAINST ANIMAL BITE ISOLATES					
	Pasteurella multocida	***Staphylococcus aureus***	**Streptococcus spp.**	***Capnocytophaga***	**Anaerobes**
Penicillin	+	-	+	+	V

TABLE 91-3 -- Components of care for animal bites.

COMPONENTS OF CARE FOR ANIMAL BITES	
History	Situation, pet ownership/identity
Geographic location	
Examination	Nerve function
	Tendon function
	Blood supply (pulses)
	Presence of edema, crush injury
	Proximity to joint
	Bone penetration
Diagram (or photograph) of wound(s) for the record	
Wound care	Irrigation (important)
	Debridement (cautious)
	Elevation (important)
Antimicrobials	Prophylaxis, 3–5 days (oral)
	Therapy for established infection (oral vs im initial dose)
	Empiric vs specific (animal specific)
Management:	
Culture (if infected)	
Baseline radiograph if in proximity to a bone or joint	
Tetanus toxoid (0.5ml im) if required	
Rabies prophylaxis (rabies immune globulin/human diploid cell vaccine) if needed	
Health Department report (if required)	
Indications for hospitalization	Fever >100.5°F (38°C)
	Sepsis
	Compromised host
	Advance of cellulitis
	Patient noncompliance
	Acute septic arthritis
	Acute osteomyelitis
	Severe crush injury
	Tendon/nerve injury or severance
	Tenosynovitis

Rabies

Approximately 7000 animals per year test positive for rabies in the USA. Most are wild animals, such as raccoons, foxes and bats. Dog-associated rabies is uncommon in developed countries as a result of stray animal control programs and widespread rabies vaccine use by dog owners. It has occurred in areas where endemic foci of infected raccoons and skunks are common. Canine transmission of rabies to humans infrequently occurs in the USA, but it is not uncommon in Latin American countries, Africa and particularly in the Indian subcontinent and other regions in Asia. The World Health Organization reported over 50,000 cases of animal rabies worldwide annually over the past decade (see Chapter 153 and Chapter 219). [4]

Enteric diseases from dogs

Giardiasis

Giardia lamblia is a flagellated protozoan parasite that is an important cause of diarrheal disease worldwide and can cause diarrhea in many mammalian species including dogs and humans. In many hospitals that have pet visitation programs, *G. lamblia* is the most frequent infectious agent identified on screening. The disease is transmitted by fecal-oral spread and causes flatulence, foul smelling stools, abdominal discomfort and malaise in humans. Diagnosis is by stool exam. Therapy is with metronidazole; relapses are not infrequent.

Echinococcosis

Echinococcus granulosis is a dog tapeworm found in the small intestine whose ova are shed into the stool. The illness is associated with dogs found in sheep raising

areas, especially if the dogs are fed offal. These ova may remain viable for up to 1 year in appropriate climatic conditions. Humans can ingest the ova, which hatch in the small intestine into oncospheres that penetrate the bowel wall. Humans will act as an intermediate host. Usually these oncospheres reach the liver and occasionally the lung, but may also reach the systemic circulation and be spread widely.

While most infestations are asymptomatic in humans, symptomatic disease, when it occurs, can be found in the liver (60%), and lung (25%). Rupture of a hydatid cyst can cause catastrophic disease and anaphylaxis. A variety of serologic tests are available to assist in diagnosis. However, the presence of septation in a liver cyst (indicating daughter cysts) is considered diagnostic. Therapy for this disease includes surgery. Some suggest aspiration is acceptable, although there is a risk of spillage and complications. Scolicidal agents such as albendazole and mebendazole remain as adjunctive therapies.

Echinococcus multilocularis causes a severe form of alveolar hydatid disease, again often involving the human liver. This parasitic infection is found primarily in the artic regions of the Northern Hemisphere and often necessitates aggressive surgical resection for successful removal. *Echinococcus vogeli* is found in canines of Columbia, Ecuador, Panama and Venezuela and can also cause human disease. The diagnosis and management of echinococcosis is further reviewed in detail in Chapter 168 .

Miscellaneous infections acquired from dogs

Isospora spp. infection of the gastrointestinal tract is common in dogs and while transmission to humans is not proven, it remains possible, especially in the immunocompromised patient. *Trichuris vulpis*, the whipworm of dogs, which resembles the human whipworm *Trichuris trichuria* but whose ova is twice its size, have been reported in children, institutionalized patients and rarely in immunocompetent adults associated with dog contact.

Toxocara canis is a ubiquitous roundworm in dogs that causes both cutaneous larva migrans and visceral larva migrans in humans, and affects many puppies (often less than 6 months old) and adult dogs (via ingestion of embryonated ova). Infection in humans is usually associated with children who have pica (1–6 years old) who acquire it from backyards and contaminated sandboxes. Most infection in humans is asymptomatic and eosinophilia (=30%) may be the only sign. However, the larva may migrate anywhere in the human body and their final location determines the associated symptoms. Some patients develop an asthma-like illness others pallor, weight loss, hepatomegaly or pruritic skin lesions. Diagnosis is based on a compatible history coupled with specific serology. Dogs may also transmit *Ancyclostoma canium* and *Ancyclostoma braziliense*, which also cause cutaneous larva migrans.

Transmission of infections from contact with dog urine

Leptospirosis

Leptospires are finely coiled, motile spirochetes that can be carried asymptomatically for many months by dogs. Dogs may also become ill manifested by fever, jaundice, conjunctivitis and hematuria. Dogs are often vaccinated for leptospirosis, but vaccine failures (over 1 year postvaccination) have been reported. Humans may become infected through contact from the urine of an infected dog, from contact with infected tissues or indirectly from contaminated soil or water. Slightly alkaline or neutral pH, temperature of 22°C (71.6°F) or slightly higher and moist soil favors survival of leptospires in the environment.

Most humans will have subclinical infection or an anicteric 'viral type' illness. Some may develop the classic biphasic illness and proceed to Weil's disease. During the first phase, leptospires may be isolated from the blood, urine and spinal fluid. Later, antibodies may develop and recrudescent fever arthralgia, hepatitis, skin rash and conjunctival suffusion may appear along with other complications (see Chapter 181 and Chapter 230). Some studies suggest that therapy with penicillin G (benzlpenicillin) or doxycycline may shorten the course of disease if started within the first 4 days of illness. Jarisch-Herxheimer reaction can occur after the first dose of therapy.

Brucellosis

Brucellosis is a disease of both wild and domestic animals that is transmitted to humans. Dogs may be infected with *Brucella canis*, a small Gram-negative coccobacillary organism that is found in kennel-raised dogs and is the least common cause of human brucellosis. Many infections with *B. canis* are laboratory animal acquired. Dogs may have persistent carriage of the organism and shed it in urine, and gestational tissues. It can be transmitted between dogs during mating. Human disease occurs 2–4 weeks after exposure and has protean manifestations with both an acute and chronic form (see Chapter 180).

Tick/flea-borne infectious diseases associated with dogs

Ehrlichiosis

Canine ehrlichiosis was first described in 1932 in Algeria. Since then it has been noted that dogs can be hosts to a variety of tick-borne, intraerythrocytic parasites including *Ehrlichia canis*, *Ehrlichia chaffeensis* (associated with human monocytic ehrlichiosis), *Ehrlichia phagocytophilia* (associated with human granulocytic ehrlichiosis), *Ehrlichia ewingii*, and *Ehrlichia platys* that cause canine pancytopenia and have a worldwide distribution. Although dog-to-human transmission is unlikely, the disease has this potential. In humans, ehrlichiosis is contracted by a tick bite that inoculates the organism into the skin and then spreads via the lymphatics. In humans it causes fever, headache, chills and malaise with an associated leukopenia, thrombocytopenia and elevated liver enzymes. Therapy in humans is tetracycline or doxycycline.

Infections acquired from direct contact with dogs

Canine scabies due to *Sarcoptes scabiei* var. *canis* is also known as mange. The mites feed on the stratum granulosum of the skin and deposit the eggs in a burrow. After hatching the larval form migrates to the surface. Transmission to humans has been noted and is manifested as an erythematous nonfollicular dermatitis, in part due to hypersensitivity. Skin scrapings will not demonstrate the mite. Diagnosis is by history and clinical response to scabicides. Dogs should also be treated with the application of a scabicidal agent. A similar condition known as 'walking dandruff' in dogs is due to *Cheyletiella* (mites). These mites do not burrow and disease is manifested in humans with erythematous macules, which may become pustular or vesicular or have other manifestations of allergic reaction such as urticaria and erythema multiforme (see Chapter 155).

CAT-ASSOCIATED INFECTIOUS DISEASES

Cat bites

Cats can transmit a number of diseases to humans as listed in Table 91.4 . Most physicians will encounter cat bites as the most common cat-related disease, with approximately 500,000 cat bites in the USA alone on an annual basis, usually when owners handle their own cat. Most wounds are trivial and do not need medical care. Cat bites affect more women (72%) than men, with an average age of 39 years for the victim. [1] At the time of presentation a non-purulent wound with cellulitis (42%) is the most common condition encountered; however, the wounds may also develop into a purulent cellulitis (39%) and even abscess formation (19%). An associated lymphangitis may be present in 28% of cases. An average of six bacterial species are isolated in the typical wound (range 0–13). Approximately 85% of cat bite injuries involve puncture wounds, less than 5% are lacerations and approximately 10% are combinations of both.[2] [3] Cats' teeth are small but sharp and easily penetrate the bones, tendons and joints of the hand and lead to osteomyelitis, tendonitis and septic arthritis, respectively.

The bacteriology of these wounds reflects the normal oral flora of the biting cat. Several recent studies[1] [5] [6] have shown *Pasteurella* species to be present in 75% of cases with *P. multocida* subspecies *multocida* in 54% of wounds, *P. multocida* subspecies *septica* in 28%. These two subspecies are associated with more severe injury and have a propensity for bacteremia and central nervous system infections, respectively. Other common aerobic isolates include oral streptococci (46%), staphylococci (35%) but not *S. aureus* (4%), *Neisseria* spp. (especially *Neisseria weaverii*), *Moraxella* spp. (35%), and *Corynebacterium* spp. (28%). *Capnocytophaga canimorsus* is an unusual nonfermentative Gram-negative aerobic rod that is associated

TABLE 91-4 -- Possible infections transmissible from cats.

POSSIBLE INFECTIONS TRANSMISSIBLE FROM CATS				
Inhalation	**Vector-borne**	**Fecal-oral**	**Bites, scratches**	**Direct contact**

Bordetellosis (*Bordetella bronchiseptica*)	Ehrlichiosis	Campylobacterosis	Normal flora isolates (including *Pasteurella* spp.)	Dermatophytosis
Plague	Cat-scratch disease	*Helicobacter* spp.	Rabies	Histoplasmosis
Q fever	Bacillary angiomatosis	Cryptosporidiosis	*Erysipelothrix rhusiopathiae*	Dermatophytosis
		Toxoplasmosis	Anthrax	Scabies
		Salmonellosis	Tularemia	*Cheyletiella* mites
		Anaerobiospirillum diarrhea		
		Yersiniosis		
		Toxocariasis		
		Opisthorchiasis		
		Dipylidiasis		

with bacteremia and significant mortality rates in compromised patients such as those with asplenia or liver disease.

Anaerobes are present in 63% of cases, usually in mixed culture, and when present were associated with more severe infection and abscesses. Common anaerobic isolates include *Bacteroides tectum* (28%), *Fusobacterium* species (33%), especially *Fusobacterium nucleatum* and *Fusobacterium russii*, *Porphyromonas* spp. (30%), and *Prevotella* spp. (19%).[5] [6] [7] Most anaerobes isolated from cat bites are not producers of ß-lactamase, but unusually compared to human oral isolates, the cat-associated *F. nucleatum* species are often resistant to fluoroquinolones and a new subspecies (*F. nucleatum* subspecies *canifelium*) has been proposed (personal communication, G. Conrads, DM Citron, EJC Goldstein).

In addition, *Erysipelothrix rhusiopathiae* has been isolated from cat bites. Although usually a localized infection manifested by painful ulceration and a papular skin lesion, a disseminated form exists.

Anthrax uncommonly infects cats and results from contact with infected soil, especially associated with herbivores. The differential diagnosis of the cutaneous papular lesion that starts as a vesicle and can progress to brawny edema and central necrosis also includes brown recluse spider bite, cat-scratch disease, [8] tularemia and plague. Tularemia has been associated with cat bites.

Antimicrobial selection is delineated in Table 91.2 . Severely penicillin-allergic patients may need a combination of agents. Fluoroquinolones, tetracyclines and sulfa drugs are contraindicated in pregnant patients; tetracyclines and fluoroquinolones are relatively contraindicated in patients younger than 18 years old. Agents (monotherapy) associated with therapeutic failure include first-generation cephalosporins and macrolides. The principles of wound care are noted in Table 91.3 . Pain, out of proportion to the injury and in proximity to a bone or joint suggests periosteal penetration (see also Chapter 96e).

Rabies

Rabies is a widespread zoonotic infection affecting numerous wild animals in many regions of the world. Domestic cats account for less than 5% of rabid animals and usually acquire it from a 'spillover effect' from exposure to infected wildlife. This disease is covered in Chapter 153 and Chapter 219 .

Cat-scratch disease

Bartonella henselae is a fastidious Gram-negative rod that is the etiologic agent of cat-scratch disease in the general population and bacillary angiomatosis in individuals with HIV infection. Cat-scratch disease is of worldwide distribution, has an autumn and winter prevalence in temperate climates and may be transmitted by direct

inoculation (scratch or bite) or by fleas. Over 80% of cases are in people under 21 years of age; children under 14 years of age are typically infected after exposure to a newly-acquired pet cat or kitten. Strays and cats from pounds have a higher frequency of infection and may be bacteremic (>40% in one San Francisco study) compared to household cats (6% in one New York City study). Most infections in cats are asymptomatic and can last for several months.[8]

Approximately 1 week (range 3–10 days) after injury or exposure, 25–60% of patients may develop a primary inoculation papule at the site of injury, which may become vesicular or crust. In approximately 2 weeks (5–120 days) tender, regional lymphadenopathy may develop. Scratches on the face may involve the eye (Parinaud's oculoglandular syndrome). Regional nodes may be the only manifestation in approximately half of the cases, often lasts over 3 weeks (6–12 weeks) and usually resolves spontaneously, but may suppurate in approximately 15% of cases. Accompanying symptoms include fatigue and malaise (28%), fever of 101–106°F (38.3–41.1°C) (12%), exanthem (4%), parotid swelling (2%) and seizures (<1%). Other manifestations may include ocular granuloma, erythema nodosum, thrombocytopenic purpura and osteomyelitis. Endocarditis due to *Bartonella quintana*, a related organism, and rarely *B. henselae*, both associated with cat fleas, has been reported in homeless men (see Chapter 235).

Diagnosis is usually on clinical grounds coupled with a history of cat exposure. The organism is very difficult to isolate (chocolate media or CDC agar after 2–3 weeks) except in the research setting and serologies are of variable reliability. Biopsies are sometimes performed to exclude diseases such as Hodgkin's lymphoma, and show granuloma formation with stellate microabscesses. While the Warthin-Starry stain has been recommended, it is difficult to interpret, especially in the absence of a positive control specimen.

Therapy is usually supportive. Antimicrobial therapy with azithromycin has been reported to diminish the size and duration of the adenopathy. Doxycycline and rifampin (rifampicin) have been used for cat-scratch disease-associated retinitis. In-vitro resistance to first-generation cephalosporins has been correlated with clinical therapeutic failure. Prevention is by control of fleas in pets and sometimes treatment of the pet at the time of acquisition.

Bacillary angiomatosis is cat-scratch disease in a compromised host (usually with HIV infection) that manifests either as purplish skin lesions resembling Kaposi's sarcoma or as colorless subcutaneous nodules. Biopsy of the lesions yields a characteristic histopathologic picture of vascular proliferation. DNA probes have also been used to diagnose this disease. These patients may also be symptomatic from the disease and have associated fever and even peliosis hepatis. Antimicrobial therapy, although its efficacy is poorly defined, is usually employed in this situation and includes macrolides, quinolones or doxycycline (see Chapter 128).

Cat-associated enteric infections

Cats may acquire salmonellosis from infected foods, especially offal, live prey (such as songbirds), uncooked meat or fishmeal, or contaminated water. Kennel transmission has also occurred. Cats may shed *Salmonella* spp. via the feces, the conjunctiva or the oral route. In addition their fur may become contaminated and pass infection as can their water dishes. Newly acquired young cats are more likely to carry *Campylobacter jejuni* than older cats. *Helicobacter bizzozeronii* and *Helicobacter felis* are found in cat stomachs and association with human cases has been noted, albeit rarely. *Helicobacter pylori* has also been isolated from cats and is thought to have been transmitted to them by human caretakers. Cryptosporidiosis can affect cats that, along with other animals, are definitive hosts. Naturally infected cats exhibit watery diarrhea and some cats can be colonized. Transmission between cats and humans has been reported.[1] [2]

Cats are definitive hosts for *Toxoplasma gondii* and millions of oocysts may be excreted daily in their feces. Approximately 1% of cats in the USA are thought to be excreting oocysts on any given day. Although ingestion of undercooked meat is the usual mode of transmission of toxoplasmosis, infection may develop from exposure to fecal oocysts when changing litter boxes or gardening in soil contaminated with oocysts by cat feces. The oocysts that pass from the feces are noninfectious and nonsporulated. However, 2–3 days after shedding, the oocysts may sporulate depending on temperature (>39.2 and <98.6°F; >4 and <37°C) and climactic factors. These may remain infective in soil for up to 1 year.

Less common isolates include *Anaerobiospirillum thomasii*, which causes diarrhea in cats and is associated with bacteremia in humans. Cats may be asymptomatic carriers or infected with *Yersinia pseudotuberculosis*, which can cause diffuse diarrhea and abdominal pain in humans. *Toxocara cati* is a helminthic parasite that affects cats with which humans may become incidentally infected when ingesting infected cat feces (usually children in the ages of pica). Most human infection is asymptomatic but can present as asthma, abdominal pain, hepatomegaly and eosinophilia. The disease is usually self-limiting. The cat liver fluke, *Opisthorchis felineus* can be transmitted to man from ingestion of rare or raw fish infected with the parasite. *Dipylidium caninum* is a cat tapeworm that can be transmitted to humans, usually

children, when they ingest infected fleas. Patients develop mild abdominal discomfort and eosinophilia. Demonstrating proglottids upon parasitologic examination of the feces makes the diagnosis.

Infectious diseases associated with direct contact with cats

Dermatophytosis

Domestic cats can harbor a wide variety of dermatophytes on the hair of their coat and skin. They may also acquire human dermatophytosis from their owners and transmit it to others with an incubation period of 1–3 weeks. Asymptomatic, as well as symptomatic carriage occurs. *Microsporum canis* has been found in up to 90% of longhaired show cats. Up to 50% of exposed humans will develop symptomatic infection, including ringworm and tinea capitis. Other organisms isolated include *Epidermophyton floccosum*, *Microsporum* spp. and *Trichophyton* spp. Infectious arthrospores can disseminate from the hair and skin to the local environment where they remain viable for months. Contaminated fomites may also act as vectors of transmission. In cats, dermatophyte infection can manifest as patchy alopecia or even a scaly dermatitis. To break a cycle of transmission, cats may be treated with topical antifungals and on occasion oral antifungals. In addition, cleaning areas of cat hair and removal of dander from carpets and restriction of pet cats from the bedroom may facilitate control. Diagnosis is by skin scrapings and microscopic examination after potassium hydroxide addition or by use of a Wood's lamp. Human infection can be treated by topical or oral antifungals.

Cats may also directly transmit *Dermatophilus congolensis*, an actinomycete that can cause cutaneous exudative or pustular dermatitis. In cats, the hair around the lesion should be clipped and the lesion kept dry. The human dermatitis is usually self-limiting but on occasion antimicrobial therapy (penicillin) may be required if extensive skin involvement with cellulitis develops.

Cryptococcus neoformans can infect cats and cause feline disease that sheds viable organisms into the environment. However, human transmission from infected cats has not, as yet, been documented. [9]

Mites

Cats may become infected with *Sarcoptes scabiei* (scabies) and transmit this to humans. The mites cause a hypersensitivity reaction in humans manifested by pruritic papular lesions and nocturnal

itching. As cat scabies do not burrow into human skin, skin scrapings will not be diagnostic and diagnosis is by clinical presentation. Therapy is by removal of the mites from the cat and laundering the household bedding and clothing. *Cheyletiella* spp. are another type of animal mite that can be transmitted from cats to humans.

Cat infections acquired by inhalation

Bordetella bronchiseptica is a Gram-negative coccobacillus that can be found in the respiratory tracts of domestic cats and for which they should be vaccinated. In dogs it has been associated with 'kennel cough' but its clinical manifestations are often less prominent in cats. When cough appears in cats there may be an associated pneumonia. This organism can cause a pertussis-like (whooping cough) illness in humans, especially children or compromised hosts (e.g., those with HIV infection). Although cross-immunity may exist in humans from 'whooping cough' vaccination as children, the immunity probably wanes by the time adulthood is reached. Human illness may range from a mild upper respiratory tract infection to frank pneumonia. The organism can be cultured on special media but is often not thought of and occasionally misidentified by routine clinical laboratories.

Yersinia pestis is the Gram-negative coccobacillus that causes plague. Cat fleas are considered poor vectors for transmission, but the cats themselves may contract the illness, especially in the summer months by exposure to rat fleas. Reports of fatal cases in humans of inhalation plague and exposure to infected cats have been reported.

Direct exposure of humans to infected material from parturient or aborted tissue from cats infected with Q fever (*Coxiella burnetii*) may also acquire disease. Cats may acquire infection from a tick bite or from infected material in the environment.

INFECTIOUS DISEASES ASSOCIATED WITH BIRD EXPOSURE

Contact with pet birds may vary from kissing or feeding the bird from the owner's mouth to cleaning cages or allowing the bird free range of a home or a yard. It is difficult to determine how often some of the organisms, such as *Campylobacter jejuni*, *P. multocida* or *Mycobacterium tuberculosis*, are passed to humans, but *Chlamydia psittaci* is regularly transmitted, as are *Salmonella* spp.

Inhalation infections from birds

Psittacosis

Chlamydia psittaci can be carried by any bird, pet or wild, not just psittacine birds such as parakeets or parrots, and all birds that carry the organism can pass it on to humans. The disease is better called ornithosis rather than psittacosis. Ducks and turkeys have been responsible for outbreaks of ornithosis in humans as well as birds kept in the home. Respiratory symptoms are the usual result of transmission from bird to humans, and there have been reports of human-to-human transmission, but apparently this is not common. Too little is known about the incidence of infection with *C. psittaci* because few studies have been done of different human populations using modern, accurate serologic techniques. If the respiratory symptoms are mild, the infection is often undiagnosed. Even in patients who have pneumonia, the diagnosis needs to be confirmed by showing a fourfold rise in acute and convalescent serum titers 2–4 weeks apart, but this is seldom pursued.

The diagnosis of acute disease is dependent on a high index of suspicion, and therapy must be empiric because rapid diagnostic techniques are not available. A history of contact with a sick bird is highly suggestive, but well birds can carry the disease and a number of cases have been reported without a history of bird contact, although presumably there has been inapparent contact with bird excreta in the environment. Pigeon and other birds' feces abound in many urban environments, as do chicken and duck feces in rural environments.

The pneumonia in humans can be severe, and is often lobar accompanied by high fevers and chills. The sputum may be purulent with a lack of potential pathogens on smear because *C. psittaci* does not take the Gram stain.

Once empiric therapy is decided upon, tetracycline is preferred, although erythromycin has been reported to be effective. A safe duration of therapy is 2 weeks, although a shorter period may be adequate. Complications such as meningoencephalitis, arthritis or endocarditis may occur.

A specific diagnosis is important because epidemiologic factors may need to be investigated. A bird dealer may be importing carriers without appropriate quarantine or treatment and cases of human-to-human transmission may be uncovered, including possible nosocomial spread. Control measures for *C. psittaci* infection of birds and humans have been detailed by the US Public Health Service.

Histoplasmosis

Histoplasma capsulatum has been found in bird droppings, especially from chicken and blackbirds. *Histoplasma capsulatum* has been found throughout the world, but it is especially common in river valleys of central North America, parts of Mexico and in the Caribbean and is thus considered a 'regional' fungus. Histoplasmosis is usually not due to exposures to pets, with the exception of exposure to chickens, which are sometimes kept and regarded as pets. The fungus grows in the feces of chickens, but does not infect them. Most human infections are asymptomatic but others may result in an influenza-like illness or rarely a progressive pneumonia (see Chapter 39 and Chapter 238). The majority of symptomatic infections are self-limiting; however, treatment when necessary (especially in the immunocompromised host) can begin with amphotericin B followed by itraconazole or fluconazole for acute progressive infections or itraconazole or fluconazole alone for more indolent disease. Prevention strategies should include advising immunocompromised people to avoid bird feces, especially from chickens.

Cryptococcosis

Cryptococcus neoformans in found in soil throughout the world, but it appears to thrive in pigeon feces. Pigeon fanciers who keep flocks of pigeons for sport are exposed to *C. neoformans* more than the general population, as demonstrated by serologic testing; however, an increased incidence of disease has not been documented in these people. Cryptococcosis initially begins as a self-limiting respiratory infection. The fungus may disseminate widely to multiple organs including the central nervous system. It has a predilection for people who have T-helper-4 lymphocyte defects, and if untreated the meningitis it causes is associated with a high mortality rate (up to 50%). There may be significant morbidity and sequelae (e.g. noncommunicating hydrocephalus, blindness) (see Chapter 111 and Chapter 126).

The diagnosis is aided by the presence of cryptococcal polysaccharide antigens in the blood or cerebrospinal fluid, and a decrease in antigen titer is usually associated with a response to therapy in patients who do not have AIDS. In patients who have AIDS, high levels of antigen may persist indefinitely despite an excellent clinical response to treatment. Amphotericin B with or without flucytosine is the treatment for the acute episode, followed by fluconazole for more chronic therapy. Prevention should include advising immunocompromised people to avoid contact with pigeons.

Tuberculosis has been seen in patients in households where tuberculosis has been recognized in macaws.[10] It is difficult to determine whether spread is from bird to humans or vice versa. Other psittacine birds may become infected with *M. tuberculosis*.

Enteric diseases associated with bird exposure

All of the organisms listed in Table 91.5 have been isolated from birds; some, such as *Salmonella* spp. and *Giardia lamblia*, are clearly implicated in transmission to humans. Parasites that may spread to humans from birds include *G. lamblia* and *Cryptosporidia* spp, although direct spread from the latter is not as well documented as the former. Methods of diagnosis and treatment are covered in detail in Chapter 163 , Chapter 242 and Chapter 243 . Mites may be spread by direct and indirect contact with infested birds.

Viral diseases from pet birds

The alphaviruses and flaviviruses that pass from birds to humans are carried to humans by mosquitoes and ticks (see Chapter 222). These birds are almost always wild and not pets. Identical strains of influenza virus have been found in both humans and ducks where contact has been documented. The incidence of ducks or other birds serving as reservoirs for influenza is not certain. In 1998, a large out-break of influenza in Hong Kong was associated with chickens and caused several deaths. Thousands of birds were slaughtered in an attempt to control the infection.

SMALL MAMMAL PETS

Small mammal pets include mice, rats, hamsters, gerbils, guinea pigs and rabbits. People may also keep more exotic animals such as mink, ferrets and ocelots. These animals carry organisms similar to those carried by mice and rats; ocelots carry organisms similar to those carried by cats. Table 91.5 lists organisms carried by small mammal pets.

Most pets, regardless of type, can carry *Salmonella* spp. and *Campylobacter* spp. Many, including rabbits, carry *P. multocida* as part of their mouth flora. There are some that are more likely to carry certain organisms.

Rat-bite fever

Rats can carry *Spirillum minus* and *Streptobacillus moniliformis*. Rat-bite fever or spirillarly fever due to *S. minus* is seen worldwide, but is most common in Asia. A rash with reddish or purplish plaques accompanies the fever. The healed bite wound may reactivate when fever develops. The diagnosis requires highly specialized laboratories for confirmation. Treatment consists of penicillin or a tetracycline.

Rate-bite fever due to *S. moniliformis* (also called Haverhill fever) may be due to a rat bite or to exposure to contaminated milk or water during an outbreak. The fever is usually accompanied by a

TABLE 91-5 -- Organisms carried by small mammal pets.

ORGANISMS CARRIED BY SMALL MAMMAL PETS			
Bacteria	**Fungi**	**Parasites**	**Viruses**
Campylobacter spp.	*Sporothrix schenckii*	*Crytosporidium* spp.	Lymphocytic choriomeningitis virus
Spirillum minus			
Streptobacillus moniliformis	*Penicillium marneffei*		Hantavirus
Salmonella spp.			
Leptospira interrogans			
Francisella tularensis			
Yersinia pestis			
Listeria monocytogenes			
Pasteurella multocida			
Burkholderi pseudomallei			

maculopapular or petechial rash that is most pronounced on the extremities. Arthritis of large joints is common, as are relapses. Focal abscesses and endocarditis may occur. A specialized laboratory confirms diagnosis unless a sterile site is positive on culture. Treatment is with penicillin or a tetracycline.

Penicillium marneffei is endemic in South East Asia and southern China. It is carried by the bamboo rat and is found in water inhabited by these rodents. It is usually contracted in a natural setting and not through pets. In humans it causes a granulomatous disease resembling pulmonary tuberculosis, except that skin lesions are common in penicilliosis. It is usually seen in immunocompromised hosts and, when diagnosed early, responds well to itraconazole or amphotericin B.

Lymphocytic choriomeningitis virus is carried by mice and other rodents, including pet Syrian golden hamsters. It has been isolated from guinea-pigs and dogs. Infection in humans results from exposure to the urine, feces or saliva of the rodent and may result in no symptoms, although a flu-like syndrome or meningitis may occur. The flu-like syndrome may be followed by recovery and then relapse with meningitis. Orchitis, parotitis and thrombocytopenia have also been observed. Diagnosis is made by isolation of the virus from a sterile site such as the cerebrospinal fluid or acute and convalescent serum specimens showing a fourfold rise in titer. There is no treatment. If a case occurs in one pet such as a hamster, the virus should be looked for in others in the hamster colony.

Hantavirus is spread from rodents to humans through urine and feces throughout the world (see Chapter 222). It is possible, but highly unlikely that pet rodents in cages in homes would be exposed.

MISCELLANEOUS PETS

Monkeys

The most insidious and disastrous viral infection that a pet monkey can pass to a human is herpes simiae (herpes B virus). This latent infection of often-asymptomatic monkeys can be passed to humans by saliva or by a bite. It is almost always fatal in humans, in whom it causes progressive encephalitis, which if not fatal will leave

severe sequelae in most cases (see Chapter 215). If diagnosed early, treatment with aciclovir or other antiviral herpes agent, may result in improvement and even recovery. Although it is a legal requirement to screen imported pet monkeys, this does not always occur and may even miss carriers. Nonhuman primates can also transmit hepatitis A and B, monkeypox (which is clinically indistinguishable from smallpox), salmonellosis, shigellosis, campylobacteriosis, amebiasis, strongyloidiasis, giardiasis, yersiniosis and dermatophyte infection.

Reptiles and amphibians

Any reptile or amphibian may carry *Salmonella* spp., which are excreted in the feces and may infect humans caring for the pet. This has been best exemplified by outbreaks in humans who have pet turtles.

Fish

Fish may harbor *Salmonella* spp., *Aeromonas hydrophila*, *Citrobacter diversus*, *Pseudomonas aeruginosa*, *Providencia stuartii* and *Vibrio* spp. including *Vibrio vulnificus* (which can cause a rapidly fatal infection in patients with liver dysfunction) and other halophilic bacteria (salt water). In addition, *Mycobacterium marinum* has been found in fish tanks (both fresh and salt water) and can cause a purplish rash with granulomatous lesion usually of the

hands in those cleaning the tanks and handling the fish. The diagnosis is made when the skin lesion is biopsied and cultured. Treatment with rifampin and ethambutol, minocycline or trimethoprim-sulfamethoxazole (co-trimoxazole) have all been successful in eradicating this infection.

Erysipelothrix rhusiopathiae is an uncommon infection of food handlers, especially fishmongers. It causes erypsieloid, painful, indurated, irregular skin lesions, usually on the hands. It is very susceptible to penicillin. Penicillin-allergic patients can be treated with clindamycin.

Chapter 92 - Infections Acquired From Animals Other Than Pets

Daniel S Shapiro

Zoonotic infections may be acquired from farm animals, beasts of burden, fish and wild animals via a number of routes (Fig. 92.1). Many of the emerging infectious diseases are zoonotic in origin.

The approach to the patient with a potential zoonotic infection involves the generation of a reasonable differential diagnosis that includes those infectious agents that are potentially transmissible from the specific animal to which the patient was exposed. This may be a more challenging task for the clinician when the exposure has been to a rarely encountered animal than is the case for a commonly encountered pet, as there may be limited literature upon which to generate a differential diagnosis. Historical points worth considering are summarized in Table 92.1 .

Although the number of infectious agents potentially transmissible from a specific animal to humans may be great, many of these infections are limited geographically and need not be considered in the differential diagnosis. Examples include the lack of plague transmission outside endemic areas such as the Western USA, countries that are free of brucellosis and the limitation of tularemia to the Northern hemisphere. In some cases a good history of animal exposure will be elicited but a review of the medical literature will not be able to identify a published reference on zoonotic transmission of any relevant diseases from that specific animal. Although a search of the veterinary literature may identify the animal as a potential reservoir of a zoonotic agent, access to these journals is not routinely available to nonveterinarians. One additional difficulty is that the lack of an effective veterinary or human public health system in a given country may result in a lack of knowledge of zoonotic infections transmitted from even commonly encountered animals. In such cases, it is worthwhile to consider similar animals with known flora or from which zoonoses have been acquired and infections of the animal with known zoonotic agents. Examples include the following.

- *Escherichia coli* O157:H7 infections have been most commonly transmitted to humans via the ingestion of undercooked ground beef. Deer, like cattle, are grazing herbivores and have transmitted this infection to humans via the consumption of venison.
- Camels have been noted to have serologic evidence of infection with *Coxiella burnetii*, but human cases of Q fever as a result of contact with camels have not been documented. It is possible that this is, in part, due to the lack of active case finding in those parts of the world in which camels are common.
- The environment of the animal, which may include exposure to fresh water or salt water, is important. For example, shark bite wounds may be infected with *Vibrio* spp., which are commonly found in salt water and as part of the normal oral flora of sharks, whereas fresh-water alligator bites are most commonly infected with *Aeromonas hydrophila*, an organism that is found in fresh water and as part of the normal alligator oral flora.
- Consider the diet of the animal. Cattle that have been fed material that includes nervous tissue are at increased risk of having bovine spongiform encephalopathy (BSE).
- Consider other species with which the animal has had contact, including contact with humans while in captivity. Tuberculosis, measles and shigellosis are not thought to normally be infectious agents of nonhuman primates. Rather, they are acquired from human contact. Similarly, the housing of camels indoors with cattle increases the risk that the camels will acquire bovine tuberculosis.

Good communication with the clinical microbiology laboratory is essential in the diagnosis of zoonotic infections. In some cases the diagnosis is established serologically, whereas in others a particular pathogen, perhaps one that requires special culture media or handling, may be found. In addition to increasing the probability of correctly identifying the etiology of the patient's illness, good communication is essential for safety, especially when infections due to *Francisella tularensis, Brucella* spp., cercopithecine herpesvirus type 1 (herpesvirus simiae; B virus) and other highly biohazardous agents are under consideration.

The following discussion is organized by type of animal, as this is helpful for the clinician who is attempting to generate a reasonable differential diagnosis.

DOMESTICATED HERBIVORES (CATTLE, SHEEP, GOATS, PIGS, CAMELS, HORSES AND RELATED ANIMALS)

Bacterial infections

Brucella melitensis is most commonly acquired from goats but has been acquired from sheep and dromedary camels. *Brucella abortus* is associated with cattle and, although horses can occasionally become infected, transmission to humans from horses, if it occurs, is very rare. *Brucella suis* can be transmitted to humans from both domesticated and feral pigs. Of note, the specificity of the association between the species of *Brucella* and the animal host is far from absolute. Examples include the occurrence of *B. melitensis* in cattle in parts of southern Europe, Israel, Kuwait and Saudia Arabia and the establishment of *B. suis* biovar 1 in cattle in Brazil and Colombia. [1] Many other animals have contracted brucellosis. Infection of bison in Yellowstone Park has been of concern to cattle ranchers in the Western USA. There have not, however, been documented cases of transmission of brucellosis from bison to humans. *Brucella* infections of caribou have been known to spread disease to humans.

Transmission of anthrax by this group of animals is the normal means by which the infection is acquired by humans. Cutaneous anthrax, inhalation anthrax (woolsorter's disease) and gastrointestinal anthrax all are most commonly associated with the domestication of sheep, goats and cattle. In parts of the world in which water buffalo are domesticated, these animals have served as the source of outbreaks of human anthrax, as have oxen. Animal products can transmit the disease. For example, during the early 1900s cutaneous anthrax was transmitted via contaminated shaving brushes made of animal hair.

Yersinia pestis has been (rarely) transmitted to humans from both camels and goats in Libya and from camels in endemic areas of the

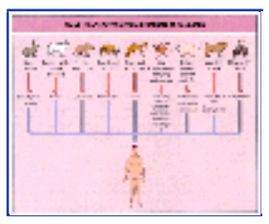

Figure 92-1 Examples of routes by which zoonoses are acquired.

TABLE 92-1 -- Selected historical points in patient exposure history.

SELECTED HISTORICAL POINTS IN PATIENT EXPOSURE HISTORY	
Historical finding	**Worth adding to differential diagnosis**
Contact with any vertebrate, especially reptiles	Salmonellosis
Exposure to urine, either directly or via contaminated water	Leptospirosis, as essentially all mammals can become infected with *Leptospira interrogans* and shed infectious organisms in the urine
Bites from wild mammals, with the exception of those from rodents other than groundhogs (*Marmota monax*)	Evaluate risk of rabies and the potential need for rabies prophylaxis
Itching and a history of cutaneous contact with a mammal	Allergic reaction, dermatophyte infection or infestation with ectoparasites, such as species-specific varieties of *Sarcoptes scabiei*
Consumption of undercooked wild mammals	Trichinellosis and toxoplasmosis
Consumption of fermented fish or marine mammals	Botulism, most commonly due to the type E toxin
Consumption of uncooked fish	Any of more than 50 parasitic infections, depending upon the species of fish eaten and the geographic locale

former Soviet Union via direct contact and in individuals who consumed the infected animals.[2]

Epizootics of tularemia, associated with heavy infestation by the wood tick, *Dermacentor andersoni*, occur in sheep. Human cases of tularemia have included cases in sheep shearers, owners and herders. In a review published in 1955, 189 human cases of tularemia had been reported in association with the sheep industry.[3] Tularemia has rarely been transmitted from pigs to humans.[4]

Tuberculosis due to *Mycobacterium bovis* subsp. *bovis* was the impetus for pasteurization of cow's milk. *Mycobacterium tuberculosis* infection can occur in cattle, but does not result in systemic infection. Infection with *M. bovis* is also associated with occupational exposure, as with slaughterhouse workers. The related *M. bovis* supsp. *caprae* has caused human infections after contact with cattle.[5]

Infection with *Listeria monocytogenes* may result from the ingestion of contaminated meat and dairy products or via direct cutaneous exposure during parturition. In the latter case, cutaneous listeriosis has been reported.[6] Infections transmitted by ingestion of animal milk are listed in Table 92.2 .

Yersinia enterocolitica, normally found in the fecal flora of pigs, has been transmitted from pigs to humans via contact and by ingestion of chitterlings (pig intestines).[7]

Erysipelothrix rhusiopathiae has been transmitted to humans from many different animals and animal products. It typically is an occupational illness, acquired via a hand wound while handling animal material. Alerting the clinical microbiology laboratory to its possibility is of help, as the organism's identification is not difficult if it is suspected.[8]

Streptococcus suis, especially type 2, a pathogen of pigs, is a common cause of bacteremia and bacterial meningitis among individuals working with pigs in Asia. *Rhodococcus equi* is commonly found in the feces of horses and in the soil. Exposure to farm animals, including horses, has been reported in some cases of human infection. The association of leptospirosis with swine is well known and one name for the illness is swineherd's disease. Cattle, goats and camels are also potential sources of human infection.

Exposure of pregnant women to the birth products of sheep and goats that are infected with *Chlamydophila abortus* (*Chlamydia psittaci*, serotype 1) has resulted in illness. Human infection with this organism has been reported in both Europe and the USA and can be severe, resulting in abortion.[9]

TABLE 92-2 -- Agents transmitted via milk products and cheese.

AGENTS TRANSMITTED VIA MILK PRODUCTS AND CHEESE	
Disease	**Source**
Clostridium botulinum toxin	Yogurt, cheese

Brucella spp.	Many animal's, milk and cheese
Campylobacter fetus	Cow's milk
Campylobacter jejuni	Cow's milk, cheese from goats
Campylobacter laridis	Cow's milk, contaminated by birds
Central European tick-borne encephalitis	Goat's milk, cheese from goats and sheep
Corynebacterium diphtheriae	Cow's milk
Corynebacterium ulcerans	Cow's milk
Escherichia coli O157:H7 and other strains	Cow's and goat's milk, cream, cheese
Listeria monocytogenes	Cow's milk, cheese
Mycobacterium bovis subsp. *bovis*	Cow's milk
Salmonella spp.	Many animal's, milk, cheese, ice cream
Staphylococcus aureus	Cow's milk
Streptobacillus moniliformis	Cow's milk (single outbreak in 1926)
Streptococcus zooepidemicus	Cow's milk, cheese
Toxoplasma gondii	Goat's milk
Yersinia enterocolitica	Cow's milk

Salmonellosis has been transmitted to humans by each of these animals, including camels. Pigs have been documented as a source of human cases of multidrug-resistant *Salmonella enterica* serotype *typhimurium* definitive phage type 104 (DT104) infection. [10]

Escherichia coli O157:H7 is often present in the gastrointestinal tract of cattle. The most common route of transmission is via ingestion of undercooked ground beef. Transmission due to fecal contamination of food products can occur, such as via unpasteurized apple cider prepared from apples that were on the ground in a cattle pasture and used for cider production. Deer, like cattle, are grazing herbivores and have been reported to transmit this infection to humans who have consumed venison. Outbreaks have been associated with visits to petting zoos.

Pasteurella aerogenes is the most commonly isolated organism from human infections following the bites of swine.[11] A number of other Gram-negative organisms have also been isolated from these infections. Camel bite injuries are typically infected and are particularly likely from male camels during the rutting season. Members of the genus *Actinobacillus* have been recovered from bites from horses and cattle and *Pasteurella caballi* has been isolated from wounds following horse bites. Rabies has been reported in all of these animals as well as in llamas.

Pig-bel, or enteritis necrotans, has been associated with the consumption of large quantities of pork in populations that have a low protein diet, such as in the highland Melanesians of Papua New Guinea and in Germany immediately following the Second World War. Evidence suggests that the major etiologic agent is *Clostridium perfringens* type C. Human cases of Q fever are acquired from sheep, goats and cattle. Infection can be transmitted for significant distances via the wind. The data on human acquisition via contaminated milk are less compelling.

Glanders, due to *Burkholderia mallei*, has been transmitted to humans via equids. The disease is now quite limited geographically and the isolation of this agent from a patient in North America or Europe must be assumed to be due to bioterrorism until proven otherwise.

Viral infections

Localized cutaneous involvement can be due to infection with the parapoxviruses orf virus (which causes contagious ecthyma and is transmitted by sheep and goats either directly or via fomites), bovine papular stomatitis virus and pseudocowpox virus; and by the orthopoxviruses cowpox virus (which is more commonly transmitted to humans via cats than cattle) and buffalopox virus. The host range of influenza A virus includes many other mammals, including swine and horses.

Variant Creutzfeldt-Jakob disease has been reported from the UK, France, Japan and other countries and appears to be associated with the consumption of meat from cattle that were infected with BSE. No cases of BSE have been identified in the USA. Prion diseases of large herbivores in the USA, including chronic wasting disease of cervids, have raised the possibility of the introduction of prion diseases into the human food supply. A detailed discussion of the molecular aspects of prion-associated disease is found in Chapter 223 and the clinical manifestations of the spongiform encephalopathies are found in Chapter 26 .

Rift Valley fever, which infects domestic ruminants, can be transmitted to humans both by mosquitoes and by contact with the tissues of slaughtered, infected animals such as sheep.[12] Similarly, Crimean-Congo hemorrhagic fever infects a variety of animals, including cattle and sheep, and is transmitted to humans via ticks (especially *Hyalomma* spp.), via contact with blood of infected animals and, if appropriate precautions are not taken, in the hospital setting.

Hendra virus, a paramyxovirus, caused an infection of horses and a few individuals in contact with these horses in Australia. The natural reservoir has been identified as a flying fox (bat). Nipah virus was the cause of an epidemic of encephalitis that affected more than 250 people in Malaysia and Singapore, killing 100 people. The vast majority of those infected had contact with pigs, which were culled in order to stop the epidemic. The natural reservoir of Nipah virus, a paramyxovirus that is related most closely to Hendra virus, has been identified as a bat. Menangle virus, a recently described paramyxovirus, caused an infection of pigs and infection in humans in contact with the pigs in Australia. The natural reservoir has been identified as a flying fox (bat).

Recent concern has been generated over the possibility of certain endogenous porcine retrovirus infections causing disease in humans following xenotransplantation of organ tissues from pigs. Some of these retroviruses can propagate in human cell lines and they could potentially induce immunodeficiency in experimental systems. [13] This poses a potential risk of activation of porcine retroviruses in the setting of an unnatural host such as an immunosuppressed, solid organ, human transplant recipient. Fortunately, it appears that commonly utilized porcine heterografts for heart valve replacement surgery are unlikely to be complicated by inadvertent activation of porcine retroviruses. The currently employed glutaraldehyde fixation and sterilization method for porcine heart valves eliminates infectivity of endogenous retroviruses.[14]

Parasitic infection

An epidemic of cryptosporidiosis occurred in 1993 in Milwaukee, Wisconsin, in which the public water supply was contaminated and more than 400,000 people were infected. The epidemic was traced to untreated water from Lake Michigan, from which the causative organism was incompletely removed by the water filtration process. Possible sources included cattle along two rivers, slaughterhouses and human sewage.[15] In addition to water-borne epidemics, human infections occur via direct contact with cattle and sheep (the disease primarily occurs in lambs), including infection as a result of farm visits.

Echinococcal disease, although not transmitted to humans from sheep, occurs in areas of the world in which sheep serve as an intermediate host and in which dogs ingest sheep viscera, subsequently excreting infective eggs in their feces. A different echinococcal strain occurs in dromedary camels.

The demonstration of the eggs of *Dicrocoelium dendriticum*, the lancet liver fluke of cattle, sheep and goats, in human feces may be due to a true infection (dicrocoeliasis) but is more often due to a pseudoinfection. In pseudoinfections, eggs obtained via the consumption of liver (sometimes eaten raw) are passed per rectum without causing an actual infection in the human.

The pig ascarid *Ascaris suum* has been reported to cause human infection. Illness, including pulmonary infiltrates as a result of larval migration, resulted in intubation in students who ingested intestinal contents of pigs as a result of a fraternity 'prank'.[16]

Taenia solium, the pork tapeworm, is acquired via the ingestion of undercooked infected pork. *Trichinella spiralis* is most commonly acquired from eating undercooked pork, but has also been acquired following the ingestion of horsemeat.[17] *Taenia saginata*, the beef tapeworm, is acquired via the ingestion of undercooked beef. Toxoplasmosis can be acquired via the ingestion of undercooked meat, especially lamb, as well as from contaminated goat's milk.

Dermatophyte infection

Infection with zoophilic dermatophytes commonly occurs in people in contact with these animals. These include, for example, *Trichophyton verrucosum* spread from cattle to humans, and *T. equinum* from horses,[18] among others.

BATS

Rabies virus is known to occur in many species of bat and transmission to humans via bite, scratch and inhalation of aerosolized saliva has been reported. Bats also account for many cases of rabies in livestock. Other lyssaviruses that have been transmitted to humans from bats include European bat lyssavirus-1, European bat lyssavirus-2 and, most recently, Australian bat lyssavirus.[19] Most recent reports of human rabies from bat exposure find no clear evidence of a documented bat bite. Transmission apparently occurs from inadvertent bites or from unrecognized contact with the bat saliva. This is the rationale for the administration of rabies immune globulin and rabies vaccine when a bat is found in the room upon awaking from sleep, in the room of a small child or in the room of an intoxicated or mentally challenged person[20] (see Chapter 219). As noted above, bats have been found to be reservoirs of the zoonotic paramyxoviruses Nipah virus, Hendra virus and Menangle virus.[21]

Many outbreaks of histoplasmosis due to *Histoplasma capsulatum* have been associated with exposure to bat guano in caves. Other bat-associated outbreaks have been the result of disturbing piles of bat guano from old buildings[22] and clearing debris from a bridge.[23]

NONHUMAN PRIMATES

The numerous pathogens that have been isolated from nonhuman primates (NHPs) include many human pathogens. Documented transmission of human pathogens include bacterial (*Shigella* and *Salmonella* spp.), mycobacterial (*M. tuberculosis*), viral (hepatitis A virus), parasitic (*Entamoeba histolytica*) and fungal (dermatophyte) agents. In addition, there are infectious agents of human origin that infect NHPs and that have not been reported to be transmitted back to humans. These include measles virus and (human) herpes simplex virus type 1.

Of concern are those infectious agents that are not normally regarded as human pathogens. Many of these are particularly virulent. Historically, it is worth noting that molecular evidence suggests that HIV-1 was originally a pathogen of chimpanzees, *Pan troglodytes troglodytes*, and that HIV-2 was originally a pathogen of sooty mangabees. There are numerous simian immunodeficiency virus (SIV) strains and it is possible that one or more might be transmitted to humans via contact, ingestion or by growing the pathogen. Transmission of SIV to a human has occured in a laboratory accident.[24]

The possibility of life-threatening infection with cercopithecine herpesvirus-1 must be considered in bites, scratches and contact with saliva from Asiatic macaques, especially from the rhesus monkey, *Macaca mulatta*. It is hypothesized that there are distinct genotypes of the virus and that the isolates from different species vary in their pathogenicity for humans. Institutions that work with macaques should have plans in place to prevent and treat infections with cercopithecine herpesvirus-1[25] and have access to testing by laboratories with special expertise in the isolation and serologic testing of this virus. The NIH B Virus Resource Laboratory at Georgia State University (phone (404) 651-0808, fax (404) 651-0814, e-mail bvirus@gsu.edu) is the reference laboratory for the USA.

Filovirus infections with both Ebola and the Reston strain of Ebola, which is less pathogenic for humans than are other strains of Ebola, have been transmitted from NHPs to humans. Marburg virus, a filovirus causing hemorrhagic fever with high mortality, has been transmitted from vervet, or green monkeys, to humans. The reservoir in nature of Ebola and Marburg viruses remains unknown.

Monkeypox, an orthopoxvirus, was initially identified in human cases of illness that were clinically consistent with smallpox. It is found in NHPs and in squirrels in Africa and has been transmitted from human to human. Tanapox (benign epidermal monkeypox) has been transmitted to humans both via mosquitoes and by direct contact with monkeys in primate centers in the USA, but has not been transmitted from human to human. Yabapox virus has, rarely, caused subcutaneous growths at the site of inoculation.

Kyasanur forest disease virus, a member of the tick-borne encephalitis subgroup, is found in Karnataka State, India, and has a number of NHP reservoirs. The presence of dead monkeys in the endemic area may precede an epidemic.

Rabies has been reported in NHP but, with the exception of a recent report in which the white-tufted-ear marmoset (*Callithrix jacchus*) was the source of eight human cases of rabies in Brazil,[26] there are only isolated case reports of transmission of rabies from NHPs to humans.

MUSTELIDS (FERRETS, SKUNK, OTTER, MINK, WEASEL, BADGER, MARTENS)

Influenza A virus has been transmitted in a laboratory setting in which a researcher was infected by a ferret that had been infected with a strain of influenza A virus and which 'sneezed violently at close range' while it was being examined.[27] Ferrets are susceptible to influenza A and B viruses. Mink on mink farms have been found to be infected with influenza A viruses.[28]

There is a report of *M. bovis* infection of the right palm more than 20 years following a ferret bite.[29] *Mycobacterium bovis* is known to infect wild ferrets and badgers. There is a case report of sporotrichosis complicating a badger bite. Rabies infection is known to occur in skunks, otters, badgers, weasels, mink and ferrets, including pet ferrets, in the USA. Transmission of rabies from skunks to humans has been documented.[30] A rabies vaccine has been licensed for use in ferrets and the National Association of State Public Health Veterinarians recommendations are for primary immunization at 3 months and booster immunizations annually.[31] The recommendations

regarding a healthy ferret that bites a human are the same as those for dogs and cats with respect to confinement and observation for 10 days, with evaluation by a veterinarian at the first sign of illness.[31]

Rat bite fever as a result of ferret and weasel bites was reported in the medical literature between 1910 and 1920. Only in a report of a weasel bite was there isolation of an organism from the patient's blood.[32] Trichinellosis has been reported in people who ate inadequately cooked or raw liver, spleen, blood and muscle of a badger.[33]

RODENTS

Yersinia pestis is transmitted in epidemics from rats to humans via the rat flea, *Xenopsylla cheopis*. Numerous rodents other than rats serve as reservoirs, some of which have been responsible for human plague. Similarly, tularemia is widely distributed in nature and has been transmitted to humans by many different rodents.

Leptospirosis is commonly associated with skin or mucous membrane exposure to water contaminated by the urine of rodents, including rats, mice and voles. It has rarely been reported to be transmitted via rodent bite.[34] Other uncommonly reported bacterial infections following rodent bites include *Pasteurella multocida*, the *Pasteurella* 'SP' group and sporotrichosis. Rat bite fever can be due to either *Streptobacillus moniliformis* or *Spirillum minus*. The former has been transmitted to humans not only by wild rats but also laboratory rats, mice and other rodents.

It is unclear how often rodents cause cases or outbreaks of human salmonellosis. However, given that *Salmonella* spp. are commonly recovered from rodent feces, the serotypes commonly recovered from rodents are similar to those recovered from cases of human disease, and rodents often infest human dwellings, restaurants and food production facilities, it is likely that they account for some fraction of human illness.

Many of the tick-borne relapsing fevers have wild rodents as reservoirs. This is also the case for *Babesia microti*, Lyme disease and human granulocytic ehrlichiosis. The reservoirs of Colorado tick fever include a number of squirrels, chipmunks and other rodents. Similarly, Powassan encephalitis, tick-borne encephalitis and Omsk

hemorrhagic fever virus are transmitted via ticks and have small mammals as reservoirs. *Leishmania* spp. are transmitted by sandflies and often have rodents as reservoirs.

Those members of the Hantavirus genus that are known to cause hantavirus pulmonary syndrome (HPS) are carried by New World rats and mice, family Muridae, subfamily Sigmodontinae, and are transmitted via the inhalation of rodent excreta or saliva or, rarely, via rodent bite. In the USA and Canada, the viruses include Sin Nombre virus, the main cause of HPS, transmitted by the deer mouse (*Peromyscus maniculatus*); New York virus, transmitted by the white-footed mouse (*Peromyscus leucopus*); Black Creek Canal virus, transmitted by the cotton rat (*Sigmodon hispidus*); and Bayou virus, transmitted by the rice rat (*Oryzomys palustris*).[35] In South America, viruses include Andes virus in Argentina, Chile and Uruguay transmitted by the long-tailed pygmy rice rat (*Oligoryzomys longicaudatus*), a virus for which there is epidemiologic evidence of person-to-person transmission; Juquitiba virus in Brazil; Laguna Negra virus in Paraguay, transmitted by the vesper mouse (*Calomys laucha*); and Bermejo virus in Bolivia.[36] Hantaviruses that are associated with hemorrhagic fever with renal syndrome in Europe and Asia include Hantaan virus, transmitted by the murine field mouse (*Apodemus agrarius*); Dobrava virus transmitted by the murine field mouse (*Apodemus flavicollis*); Seoul virus, transmitted by the Norway rat (*Rattus norvegicus*) in Asia; and Puumala virus transmitted by the bank vole (*Clethrionomys glareolus*).[37]

Arenaviruses are transmitted from rodents via the excreta and urine. These include lymphocytic choriomeningitis virus, which is found worldwide and has been transmitted to humans by hamsters[38] as well as mice; Machupo virus, which causes Bolivian hemorrhagic fever and is transmitted by *Calomys callosus*; Junin virus, which causes Argentinian hemorrhagic fever and is transmitted by *Calomys* spp.; Guanarito virus, which is found in Venezuela; Lassa fever virus, which is found in Africa and is transmitted by the multimammate rat, *Mastomys natalensis*; and a recently described New World arenavirus that caused three fatal infections in California and shared 87% identity with the Whitewater Arroyo virus at the nucleotide level.[37]

Reservoirs of cowpox virus include several rodents. This is consistent with the epidemiology of cowpox in which cat contact is implicated. Cowpox, or a similar virus, has also been transmitted via rat bite.[39]

Rickettsialpox has been associated with infestation of mice (*Mus musculus*) with mites which serve as the vector for human disease.[40] Rodents serve as reservoirs for many other rickettsial diseases, including murine typhus in which rats are the principal reservoir and the flea *X. cheopis* the principal vector; *Rickettsia prowazekii*, which has been associated with flying squirrels;[41] scrub typhus, in which rats are hosts of the trombiculid mite vectors; and members of the spotted fever group.

Although the issue of whether giardiasis is commonly zoonotic in origin is debated, beavers may have been the source of an outbreak of water-borne giardiasis.[42]

Ingestion of rodents has been associated with rare cases of trichinellosis, such as due to the ingestion of squirrel and bamboo rat.[43] There has been speculation on whether consumption of squirrel brains causes a spongiform encephalopathy, but data are limited.[44] Eating fermented beaver has resulted in botulism.[45]

Trichophyton mentagrophytes var. *mentagrophytes* is a common zoophilic dermatophyte, infecting humans and domestic animals. Rodents are regarded as the reservoir of infection.

LAGOMORPHS (RABBITS, HARES)

Tularemia, also known as rabbit fever, is acquired from rabbits and hares as a result of cutaneous contact and skinning of rabbits, presumably entering via microabrasions in the skin or conjunctiva, and via ingestion.[4] [46] Transmission via infectious aerosol has also been reported as a result of mowing over a rabbit.[47] Tularemia transmission to humans has not been reported from domesticated rabbits. Although uncommon, eight cases of human bubonic plague from 1950 to 1974 were reported as a result of contact (e.g. skinning) with rabbits and hares[48] in plague-endemic areas of the USA. Q fever has been transmitted to humans following contact with wild rabbits.[49]

A patient with *Bordetella bronchiseptica* respiratory infection was shown to have a strain that was indistinguishable by pulsed- field gel electrophoresis from the strain isolated from a respiratory tract isolate from one of 20 farm rabbits that slept with a cat with which she had contact.[50]

RACCOONS

The raccoon ascarid, *Baylisascaris procyonis*, has caused cases, including fatal ones, of meningoencephalitis, usually in young children who accidentally ingest infectious ova.[51] Ocular involvement has also been reported. Leptospirosis has been reported from contact with raccoons.[52] Rabies is common in raccoons, although transmission to humans in the USA has not been reported.

MONGOOSES

Leptospirosis is common among mongooses in Hawaii[53] and a number of Caribbean islands.[54] Rabies is quite common among many species

of mongoose and accounts for a significant number of cases of human exposure to rabies in the Caribbean, it is the principal rabies reservoir in South Africa and it may be an important source of wildlife rabies in India.[55]

INSECTIVORES

Hedgehog contact has transmitted salmonellosis[56] and dermatophyte infections due to *Trichophyton erinacei*. [53] In an outbreak of lepto-spirosis in Italy in which 32 of 33 confirmed cases were contracted by drinking water at the same water fountain, a dead hedgehog was found in a water reservoir connected to the system, although isolation of *Leptospira* spp. from the hedgehog was not attempted.[57]

The Asian house shrew, *Suncus murinus*, has been found to be infested with the oriental rat flea, *Xenopsylla cheopis*, and infected with *Yersinia pestis*. It may well be important in the maintenance of plague between epidemics. Insectivores also appear to be reservoirs of tick-borne encephalitis and tularemia.

MARINE MAMMALS (SEALS, SEA LIONS, WALRUS, WHALES, DOLPHINS, PORPOISES, MANATEES)

At the case report level, there are several infections that have been transmitted from marine mammals to humans. Leptospirosis, which is commonly encountered in seals and California sea lions, has been transmitted from an infected sea lion pup to a human. Two people developed leptospirosis after performing a necropsy on a sea lion that died of leptospirosis.[58] Human infection with *Erysipelothrix rhusiopathiae* has been reported on a few occasions among veterinarians and veterinary students caring for or performing autopsies on cetaceans.[59] In these reports, the isolation of the organism was not made from the human cases. Two of three people who cared for affected gray seals developed 'single milker's nodule-like lesions' on the fifth finger of the right hand. The lesions from the seal handlers demonstrated virus particles that were identical with the virus particles from the seals' pox lesions and were characteristic of the paravaccinia subgroup of poxviruses. [60]

Pulmonary tuberculosis due to *M. bovis* has been transmitted from seals in a marine park in Western Australia to a seal trainer who developed pulmonary tuberculosis 3 years after his last exposure to the animals with an isolate of *M. bovis* that could not be distinguished from the seal isolates on the basis of DNA restriction endonuclease analysis.[61] Seal trainers are in very close contact with seals who, by barking and coughing, are potentially able to transmit infection via the aerosol route.

Four people involved in necropsies of harbor seals from which influenza A virus, A/Seal/Mass/1/80 (H7N7), was isolated developed purulent conjunctivitis but did not have detectable antibodies in single serum samples 3–6 months after the exposure to the influenza A virus isolated from the seals.[62] A seal that was known to be infected with the influenza A virus sneezed into the face and right eye of a person who subsequently developed conjunctivitis from which the virus was isolated.[63] Influenza A virus has also been isolated from cetaceans.

Numerous cases of 'seal finger' have been reported in people who have been bitten or scratched by seals and from skinning or handling seals. Seal finger often responds to tetracycline therapy. The etiologic agent has not been established. Other organisms that have been transmitted via the bite of marine mammals include a single case report of *Mycoplasma phocacerebrale*, which was isolated from the drainage material from a patient's fingers and swabs from the seal's front teeth.[64]

Consumption of whale, seal and walrus meat is not uncommon among the Inuit in Canada, Alaska, Greenland and Siberia. There have been large epidemics of

salmonellosis resulting from consumption of whale meat from floating and beached whale carcasses that have been used as the source of food. Trichinellosis (trichinosis) has been acquired following the consumption of raw or undercooked walrus meat. The clinical presentation in arctic trichinellosis due to *Trichinella nativa* differs from that of classic trichinellosis caused by *Trichinella spiralis* in that the most prominent clinical symptoms in arctic trichinellosis are gastrointestinal, with prolonged diarrhea.[65] Food-borne botulism, typically due to *Clostridium botulinum* type E, has been acquired from the consumption of fermented foods included beluga whale meat, seal meat, seal flippers and walrus meat.

ARMADILLOS

Both experimental and naturally occurring leprosy in nine-banded armadillos has been noted and there has been a body of literature (reviewed by Blake *et al.*[66]) that suggests that contact with armadillos may have been the source of leprosy in some patients in the USA and Mexico. Sporotrichosis has been found to be highly associated with armadillo contact in Uruguay.[67]

BIRDS

Psittacosis is transmitted to humans not only via pet birds but also via turkeys, wild and domestic pigeons, ducks and other birds.[68]

Salmonellosis has been acquired from contact with birds and from consumption of birds (e.g. chicken, turkey) and eggs.[69] *Campylobacter jejuni* and *C. laridis* infections have been associated with both the consumption of birds and, interestingly, consumption of milk that has been pecked by magpies (*Pica pica*) and jackdaws (*Corvus monedula*). [70] *Erysipelothrix rhusiopathiae* has been acquired from bird contact. Newcastle disease virus of fowl, an occupational disease, causes an acute conjunctivitis which may be associated with pre-auricular adenitis.[71]

Histoplasmosis, often in large outbreaks, has been the result of inhalation of bird excreta.[72] Infection with *Cryptococcus neoformans*, which is known to be found in bird droppings, has at the case report level been linked to exposure to pet birds [73] and fancy pigeons.[74] Q fever has been reported in five members of a family as a result of exposure to either aerosolized, contaminated pigeon excreta or infected ticks, or both.[75]

Avian strains of influenza A virus represent a global concern, as the host range of the viruses may include humans. There exists the potential for pandemic influenza as a result of the introduction of an avian virus with a hemagglutinin to which humans lack immunity.[76] In 1997 in Hong Kong, there were 18 human cases of influenza A H5N1 infection and six deaths. The outbreak ended after the institution of control measures that included the culling of poultry in Hong Kong. In 1999 an H9N2 strain, closely related to a quail virus which cocirculated with H5N1 viruses in live poultry markets in Hong Kong in late 1997 and shown to possess a set of internal genes similar to those of the H5N1 viruses, infected two children.[77]

The recent epidemic of West Nile virus infection in the USA is largely attributable to the introduction of this flavivirus into a new ecologic niche in wild birds in North America. Black birds, crows, other wild birds and domestic chickens are susceptible to this viral illness and this forms the reservoir for this mosquito-transmitted infection that is responsible for a potentially lethal form of viral encephalitis.[78]

Tularemia has been acquired from wild birds. A case of Crimean-Congo hemorrhagic fever in an ostrich farm worker who was involved in the slaughter of ostriches, *Struthio camelus*, and handled the fresh blood and tissues of the birds has been reported. There were numerous adult *Hyalomma* ticks on the ostriches and he

likely was infected either directly due to skinning the ostriches or as a result of the presence of the ticks on the ostriches.[79]

FISH

In addition to the normal flora of the fish, a wound can become infected with environmental bacteria. The species of bacteria that live in water are dependent on both salinity and temperature. Freeliving estuarine and fresh-water bacteria include the genera *Vibrio, Aeromonas* and *Plesiomonas.* As a result, the etiologic agents isolated from an infected wound from a fish bite, spine or fin injury that occurs in salt water may well be different from one that occurs in fresh water. The normal flora of teeth in salt-water sharks includes, for example, *Vibrio* spp., including *V. carchariae*, an organism that was the cause of infection following the bite of a great white shark.[80] By contrast, *Edwardsiella tarda* is commonly isolated from catfish injuries occurring in fresh water. Other organisms that have caused wound injuries as a result of injuries from fish include *Aeromonas hydrophila, Erysipelothrix rhusiopathiae, Mycobacterium marinum, Mycobacterium terrae, Streptococcus iniae, Vibrio vulnificus* and *Vibrio vulnificus* serovar E (biotype 2; indole-negative) from eels.[81] *Vibrio alginolyticus, Photobacterium damselae* subsp. *damselae (Vibrio damsela), Shewanella putrefaciens, Pseudomonas aeruginosa* and *Halomonas venusta* have all been isolated from fish bites and injuries. It is not always clear whether the source of the organism is the fish or the water.

Ingestion of fish or fish products can pose a significant risk of acquiring both bacterial and parasitic infections unless the fish has been well cooked.

Vibrio spp., including *V. fluvialis, V. hollisae, V. parahaemolyticus* and *V. cholerae* O1,[82] have all been associated with fish consumption, as has *P. shigelloides*. Eel consumption has been associated with *Photobacterium damselae* subsp. *damselae (Vibrio damsela).*[83] *Listeria monocytogenes* infections have been associated with the consumption of fish, including vacuum-packed salmon and cold-smoked rainbow trout.[84]

Fish-associated botulism is usually due to type E toxin and in the USA is most common among Alaskans. Fermented fish eggs, fish eggs, home-marinated fish and dry salted fish have all been implicated. Consumption of apparently fresh (unpreserved and unfermented) fish in Hawaii resulted in three adults with botulism due to type B toxin.[85] Numerous parasitic infections have been reported following the consumption of raw, undercooked, pickled and lightly or cold-smoked fish. Selected cestodes, trematodes and nematodes acquired from the consumption of fish are listed in Table 92.3 .

AMPHIBIANS

Contact with amphibians has transmitted sparganosis, due to *Diphyllobothrium (Spirometra) mansoni*, which has been transmitted by the use of contaminated frog flesh as a poultice (reviewed by Huang and Kirk[86]), and intraocular *Alaria* spp. in a woman with a long history of frog collection and food preparation.[87]

Ingestion of amphibians has transmitted sparganosis. Infection with the trematode *Fibricola seoulensis* has been reported from Korea, including a report in which 10 Korean soldiers who ate raw or undercooked flesh of snakes or frogs during survival training acquired the infection. [88] A single case of a fatal infection in a 24-year-old man due to *Alaria americana* has been attributed to the consumption of undercooked frogs' legs, although there was no documentation

TABLE 92-3 -- Selected parasites transmitted via consumption of fish.

SELECTED PARASITES TRANSMITTED VIA CONSUMPTION OF FISH		
Parasite	**Type of parasite**	**Types of fish**
Diphyllobothrium latum	Cestode	Salmon, pike, perch, burbot
Diphyllobothrium pacificum	Cestode	Marine fish
Diphyllobothrium ursi	Cestode	Salmon
Nanophyetus salminicola	Trematode	Usually salmonids
Heterophyes heterophyes	Trematode	Mullet, tilapia, mosquito fish
Haplorchis yokogawai	Trematode	Mullet
Haplorchis taichui	Trematode	Mullet
Clonorchis sinensis	Trematode	Fresh-water fish
Opisthorchis viverrini	Trematode	Fresh-water fish
Opisthorchis felineus	Trematode	Fresh-water fish

Metorchis conjunctus	Trematode	Fresh-water fish
Anisakis simplex	Nematode	Salmon, tuna, herring, mackerel, others
Pseudoterranova decipiens	Nematode	Cod, pollock, haddock, salmon, Pacific rockfish
Eustrongyloides spp.	Nematode	Killfish, estuarine fish, minnows
Dioctophyma renale	Nematode	Fresh-water, estuarine fish
Capillaria philippinensis	Nematode	Fresh-water, estuarine fish
Gnathostoma spinigerum	Nematode	Fresh-water fish

of consumption. Two cases of intraocular infection with an *Alaria* spp. were reported in Asian-Americans in California who consumed cooked frogs' legs in Chinese dishes.[89] Although frogs' legs have a very high rate of contamination with *Salmonella*, there are no published reports of salmonellosis attributed to their ingestion. *Salmonella* infections remain a potential risk when handling reptiles, particularly turtles, lizards and snakes.

BEARS

There is a published report of transmission of leptospirosis to two zoo employees in which the most likely source was an ill polar bear cub.[90] There is a notable lack of published reports on infections following the bites of bears. A case report in which a man shot and killed a grizzly bear in Alaska and scratched his left index finger on one of the bear's teeth while removing the bear's tongue resulted in an infection with *Mycobacterium chelonae* subsp. *abscessus*.[91]

Consumption of undercooked bear meat has been associated with trichinellosis. Bears are known to have a high rate of toxoplasmosis and the possibility of a dual infection (trichinellosis and toxoplasmosis) in a person who ingested undercooked bear meat has been reported.[92] It is worth noting that acute hypervitaminosis A has been reported following the ingestion of polar bear liver.

LARGE HERBIVORES (ELEPHANTS, RHINOCEROSES)

Few infections have been transmitted from elephants and rhinoceroses to humans. These include documented transmission of *M. tuberculosis* from elephants,[93] *M. bovis* from rhinoceroses[94] and an orthopoxvirus (possibly cowpox). It is likely that cases of tuberculosis in elephants, which are almost all reportedly due to *M. tuberculosis*, are the result of human-to-elephant transmission.

Chapter 93 - Food-borne and Water-borne Infections

Christopher P Conlon

INTRODUCTION

Food and water are essential for human existence. However, there is a constant risk of food and water becoming contaminated with potentially pathogenic organisms. Every human being risks exposure to disease when ingesting either food or water that may be vehicles of infection. A large number of such infections simply result in acute diarrhea and/or vomiting, a syndrome usually called 'food poisoning'. The term 'food-borne illness' is used whether the vehicle of infection is food or water. Also included in the definition of food poisoning are gastrointestinal illnesses caused by natural plant toxins, by heavy metals and by toxins such as scombroid that are associated with eating some types of fish.

There are other food-borne and water-borne illnesses that are distinct from food poisoning. In these diseases, although food or water are the vehicles of infection and the gastrointestinal tract is the portal of entry, gastrointestinal symptoms are minimal and infection results in systemic symptoms or distant foci of disease.

Each year the average adult in a developed country drinks more than 500 liters of water and eats over 450kg of meat and vegetables, not to mention other foods. It is rare to find anyone who has not, at some time, been a victim of food poisoning. Many infections result from organisms derived from the gastrointestinal tract of other humans that have led to contamination of food or water, so-called fecal-oral transmission. Increasingly recognized, however, is the role of other species in food- and water-borne illness. Zoonoses such as brucellosis are well recognized and more unusual problems, such as trichinella infection related to wild boar meat, are occasionally reported.[1] Much recent interest has focused on prions crossing species barriers, with good evidence that new variant Creutzfeld-Jakob disease is related to the consumption of beef from animals suffering from bovine spongiform encephalopathy (see Chapter 26 and Chapter 223).

This chapter outlines the problems related to infection caused by what we eat and drink.

EPIDEMIOLOGY

Food

The provision of food and water supplies has become increasingly complicated as society has become more urbanized and as the global economy has become more complex. In developed countries, the production and distribution of food have become highly sophisticated so that it is frequently consumed a long distance from its source and a long time after it has been produced. Often there are large, centralized facilities for food production with the risk that contamination early in the production process may lead to widespread distribution of infected food to many different regions. In addition, there is an increasing tendency to eat food away from home and, in particular, there has been a huge increase in the consumption of convenience and 'take-away' foods. In contrast, in less developed countries food is usually consumed close to its source with much less centralization because refrigeration and other means of preservation are limited and food soon spoils if transported over any distance. Restaurants are less common and most food is prepared and consumed in the home. Thus, point source outbreaks of food poisoning, often on a massive scale, are relatively common in developed countries but rare in developing countries. In England and Wales between 1995 and 1999 there were 2374 reported outbreaks of food poisoning, and in the USA there were 2751 outbreaks over a similar time period.[2] [3] However, most cases of food-borne infection are sporadic (i.e. not part of an outbreak) whether they occur in the tropics or in temperate regions.

Almost every type of food has been associated with carrying infectious agents and some have been associated with noninfectious toxins (Table 93.1). There are numerous organisms that can cause food-borne infection, with some being recognized as very common causes of food poisoning. The data on the incidence and etiology vary geographically, largely because different countries have developed different surveillance systems. Most surveillance is passive, based on reports by clinicians and on laboratory reports of isolation of food-borne pathogens. In England and Wales, where food poisoning is notifiable and where laboratories report to the Public Health Laboratory Service, there were over 50,000 cases of food poisoning in 1991, giving a notification rate of 103 per 100,000 population. *Campylobacter* spp. were the most commonly reported cause of gastrointestinal illness, with *Salmonella* spp. infection second. The latter, however, was more commonly implicated in outbreaks. Similar figures are found in the USA, where it is estimated that over 76 million cases of food-borne disease occur each year, with about 3000 deaths. A program of active surveillance of food-borne diseases began in the USA in 1996. Called FoodNet, it surveys seven bacterial and two parasitic food-borne diseases in nine states, covering about 10% of the US population.[4] *Campylobacter* spp. are the most common cause of food-borne illness, with an incidence rate of about 25 per 100,000 population, and *Salmonella* spp. were second, with a rate of 16 per 100,000. There are regional and seasonal differences in the incidences of certain infections but the reasons for these are not clear. Information about food-borne illness in developing countries is scanty because few developing countries have any surveillance systems in place because of resource limitations.

The morbidity of food poisoning is considerable but, in developed countries, the mortality is relatively low. Most deaths occur in debilitated people, often at the extremes of age. Studies in the USA show that salmonellosis is the most likely infection to lead to death, although listerial infections are more likely to lead to hospitalization than other causes of food poisoning.[5] Statistics from the developing countries are not readily available but it is estimated that diarrheal disease (much of which is related to food-borne infection) is respons-ible for 3 million deaths a year in the tropics, mainly in children.[6]

Water

Water becomes a vehicle for infection when contaminated by human or animal feces or by organisms from another source. The probability

TABLE 93-1 -- Types of foods associated with various pathogens that cause food poisoning.

TYPES OF FOODS ASSOCIATED WITH VARIOUS PATHOGENS THAT CAUSE FOOD POISONING	
Pathogen	**Foods**
Staphylococcus aureus	Cream pastries, salads, meat products, cold foods
Bacillus cereus	Fried rice, vegetables, meat dishes, vanilla sauce
Clostridium perfringens	Cooked meats, gravies
Vibrio cholerae, *Vibrio parahaemolyticus*, *Vibrio vulnificus*	Shellfish, seafood
Campylobacter jejuni	Milk, poultry
Salmonella enteritidis	Eggs, poultry, other meats
Shigella spp.	Salads, milk, cold foods
Yersinia enterocolitica	Milk, pork products
Escherichia coli	Ground beef, milk, lettuce, unpasteurized cider

Listeria monocytogenes	Soft cheese, paté, milk, coleslaw
Clostridium botulinum	Meats, home-canned fruit and vegetables
Hepatitis A and enteric viruses	Shellfish, various foods

of becoming infected with an organism through this fecal-oral route depends on the availability of potable water. Thus, water-borne infection is relatively rare in developed countries where there are usually municipal supplies of treated drinking water and reliable sewage disposal systems to prevent contamination of the drinking water supply. However, failure of these sophisticated systems can result in large outbreaks of disease.[7] In recent years there have been outbreaks of illness caused by *Cryptosporidium* spp. from cattle feces contaminating reservoirs at times when water treatment procedures were inadequate. Sporadic water-borne infection may occur in developed countries as a result of poor hygiene but this is relatively uncommon. More common is the sporadic infection resulting from exposure to water inadvertently swallowed during leisure activities such as swimming, fishing, canoeing and surfing (see Chapter 89).[8] Some of these infections result from the dumping of raw sewage into rivers and into the sea (Table 93.2).

Water-borne infection is more common in developing countries, particularly in rural areas where basic sanitation may be rudimentary and access to clean water is limited. This can be a particular problem in times of drought. Contamination of drinking water is common and may even occur at the communal taps when piped water is supplied to a village. Firewood is usually scarce so drinking water is not boiled and water filters are usually too expensive. Constant exposure to unclean water not only leads to a large burden of acute and chronic diarrhea, but also increases the risk of parasitic disease (Fig. 93.1).

PATHOGENESIS AND PATHOPHYSIOLOGY

Host factors

The ability of the human gastrointestinal tract to withstand infection by contaminated food or water depends on a variety of host defenses, including human behavior. If food looks, smells or tastes bad because of contamination it may not be ingested. Most things we ingest are not sterile, even if they seem safe, but acid (pH<4) gastric secretions kill ingested bacteria relatively easily. Usually, a large inoculum of organisms is required to overcome this acid barrier. However, relative achlorhydria, whether due to disease or to drugs

(e.g. proton pump inhibitors or antacids), may allow bacteria to multiply within the stomach so that a relatively smaller initial inoculum is needed to cause disease.

Additional protection is provided by the normal bowel flora. In the human gut there are several hundred species of bacteria, almost all of which are anaerobes, and these organisms may physically prevent pathogenic bacteria from adhering to enterocytes, often a key prerequisite for causing disease.[9] This is sometimes termed colonization resistance. Normal gastrointestinal motility ensures a regular distribution of the bowel flora and may help to eliminate potential pathogens.

The human gastrointestinal tract is also extremely active immunologically. Lymphocytes in the lamina propria, intraepithelial lymphocytes and lymphoid nodules, such as Peyer's patches in the small bowel, make up what is known as the gut-associated lymphoid tissue. Plasma cells in the lamina propria make specific antibody and most importantly produce secretory IgA, which can effectively block bacterial adhesion to enterocytes. Neonates receive immunoglobulin and lactoferrin in the colostrum of breast milk, which provides

extra protection as compared with formula feeds. Patients who are immunodeficient, such as those who have HIV infection or transplant recipients, are at greater risk of infection by enteric pathogens. Debilitated people, the very young and the very old are also at increased risk.

Microbial factors

Food- and water-borne organisms that cause disease must either cause damage to the intestinal mucosa or must be able to invade via the gastrointestinal tract to cause systemic or distant infection. The specific pathogenetic mechanisms for individual organisms are detailed in Chapter 1 , Chapter 43 and Chapter 46 , but the general principles are outlined below.

Toxins

A large variety of toxins may be produced by enteric pathogens and these fall into three main categories:[10]

- enterotoxins,
- cytotoxins, and
- neurotoxins.

Enterotoxins

The best example of an enterotoxin is cholera toxin, which binds to the enterocyte by means of its five ß-subunits, thus facilitating the entry of the a-subunit into the cell, where it can activate adenyl cyclase; this in turn leads to net secretion of chloride ions and water into the gut lumen. This excess secretion overwhelms the normal resorptive capacity of the small and large bowel, leading to diarrhea. Most enterotoxins act in a similar manner, causing net secretion into the lumen but causing relatively little inflammation in the mucosa (see also Chapter 161).

Cytotoxins

Cytotoxins, such as those produced by *Shigella* spp. or by enterohemorrhagic *Escherichia coli*, bind to enterocytes and lead to inflammation and usually to mucosal damage. Such cytotoxins are often associated with bloody diarrhea or dysentery, because of the mucosal damage they cause.

Neurotoxins

Neurotoxins are less commonly implicated in food-borne illness. The most common example is staphylococcal food poisoning. The preformed toxin is ingested and causes profuse vomiting by stimulating the emetic center in the brain. Staphylococcal enterotoxins may also cause concomitant diarrhea. Much more rare but more serious is botulism. The preformed toxin is extremely potent and once absorbed it is widely disseminated, binding to nerve endings and inhibiting the release of acetylcholine, particularly in skeletal muscle. This leads to neuromuscular paralysis and, if not recognized and treated, death from respiratory failure.

Adherence

Most organisms cannot cause disease unless they can adhere to enterocytes. Some bacteria adhere using various adhesions, or fimbriae, which can be encoded by plasmids and are thus potentially transferable to other species.[11] Some protozoa have specially adapted ways of sticking to the gut mucosa. *Giardia* spp. have suction plates on their ventral surface and microsporidia have a polar element that is inserted into the enterocyte. The helminth *Taenia solium* has a sucker and small hooklets that allow it to remain attached to the mucosa. Viruses, such as rotavirus, stick to the mucosa via ligands such as hemagglutinin protein.

Invasion

The ability of some organisms to invade mucosal cells and damage them may be associated with antigens in the bacterial cell wall. Virulence in *Shigella* spp. is related to fully expressed, smooth O antigen in the lipopolysaccharide cell wall, which may make it resistant to attack by complement. The production of some outer membrane proteins may enable the bacteria to survive intracellularly. Some of the genes controlling these attributes are chromosomal but others are on plasmids.

Other factors

The ability of bacteria to multiply quickly also provides an advantage against host defenses and this rapid multiplication allows for the exchange of genetic material, possibly with the acquisition of new virulence characteristics. Motility of enteric pathogens may be important in causing disease, either by aiding colonization of the mucosa or by evading phagocytes. Some viruses appear to cause selective damage to epithelial cells in the intestinal villi while leaving secretory cells in the crypts intact, thus favoring net secretion and the production of watery diarrhea.

PREVENTION

Food poisoning and other food-borne illnesses are often preventable through a combination of public health measures, personal hygiene and immunization and, sometimes, by chemoprophylaxis.

Public health

The provision of adequate housing and sanitation along with education about basic hygiene and food handling are major reasons why diarrheal illness has become much less common in developed countries than in underdeveloped ones. Modern sewage treatment plants and well-organized drinking water treatment and distribution dramatically reduce the risk of transmission of infection via the fecal-oral route. Good standards of food production, refrigeration and distribution along with proper food handling in shops and restaurants are also important. For such systems to remain safe there need to be regular inspections, training of staff and registration of premises, all backed up by legislation. All of these methods are more likely to be found in developed countries but progress is also being made in less developed countries. Flush toilets are common in cities in the tropics and well-designed pit latrines, such as the Blair privy, are increasingly being built in urban townships and rural villages (Fig. 93.2).

These preventive efforts need to be strengthened by surveillance of food-borne illness based both on clinical case reporting and on laboratory reports. A system of compulsory notification of certain infections is essential. Such surveillance should lead to the prompt recognition of outbreaks, and the timely investigation of such outbreaks can often identify the source of the problem and lead to control measures aimed at preventing further infections (see Chapter 50a).

Personal measures

The individual can play a major role in preventing food-borne illness. Attention to personal hygiene, especially hand washing, is an important way to reduce fecal-oral transmission. Proper food handling involving careful storage and preparation of both raw and cooked food is essential and, of course, easier to achieve in developed countries.

In countries with unreliable supplies of potable water, individuals may treat their personal drinking water in a variety of ways to minimize the risk of infection. Boiling and filtering water are time-honored methods of reducing contamination. Water can also be treated by chemicals such as chlorine or iodine to attempt to sterilize it. These methods are often used by travelers to less developed countries but can also be used by local residents if the methods are available and affordable. Travelers and others can reduce the chances of food-borne infection by careful eating, avoiding uncooked and unwashed fruit and vegetables, ice cubes and unpasteurized dairy

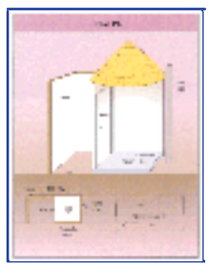

Figure 93-2 An example of a pit latrine.

produce. Chemoprophylaxis with drugs such as trimethoprim-sulfamethoxazole quinolones or doxycycline can reduce the risk of travelers' diarrhea (see Chapter 43 and Chapter 143). [12]

Immunization

Polio vaccination is the most successful example of prevention of a food-borne illness, the disease having been virtually eliminated from many parts of the world. Hepatitis A virus infection, formerly prevented by repeated doses of gammaglobulin, is now easily preventable with the new vaccines, although the cost of these is prohibitive in most parts of the world where the virus is endemic. The risk of acquiring typhoid can also be reduced markedly by immunization, either with a polysaccharide parenteral immunization or a live attenuated oral vaccine.

The old parenteral cholera vaccine offered less than 50% protection against infection and had serious side-effects. However, new oral vaccines directed against cholera toxin have looked extremely promising in field trials.[13] Because the toxin is very similar to the heat-labile toxin of enterotoxigenic *E. coli* (ETEC), immunization may protect against disease caused by this organism as well. Such a vaccine against infection with ETEC may also be used to protect against travelers' diarrhea.

CLINICAL FEATURES

The clinical consequences of food-borne infection depend, to some extent, on the infecting organism. However, with those organisms that cause food poisoning, with predominantly gastrointestinal symptoms, most patients develop diarrhea or vomiting or both and the clinical features relate to whether the small or large intestine is affected. Invasive organisms can cause a variety of clinical features. In these diseases, gastrointestinal symptoms are mild or nonexistent but fever is often a feature.

Bacterial food poisoning

Most patients who have food poisoning develop acute diarrhea, often with vomiting. Isolated vomiting may also occur but this is more unusual. Many infecting organisms, such as *Bacillus cereus*, elaborate enterotoxins that affect the small bowel, causing little mucosal inflammation and leading to a secretory diarrhea. Patients usually present with watery diarrhea without blood in the stool. There may be vomiting early on but this tends to settle before the diarrhea resolves. Other organisms such as *Shigella* spp. cause diarrhea via cytotoxins that cause inflammation of the intestinal mucosa and usually affect the distal small bowel and the large intestine. These patients may also have vomiting but diarrhea, often with blood (reflecting the mucosal inflammation), is the main feature and may last longer than with cases of secretory diarrhea. Generally, the incubation period from ingestion of the infected food or water until the onset of symptoms is longer with bacteria causing an inflammatory diarrhea. Some of the clinical features of individual infections are outlined below.

Infections with secretory diarrhea

Staphylococcal food poisoning

Often associated with cream-filled pastries and some tinned meats, staphylococci multiply in the food, producing various staphylococcal toxins. These preformed toxins are ingested and cause symptoms within a few hours. There is usually initial nausea followed quickly by severe vomiting. Diarrhea appears later and fever is rare. Most cases are self-limiting and recovery occurs within 24–48 hours. However, dehydration can be quite severe and, rarely, fatalities occur as a result of marked hypotension. In rare cases, other staphylococcal toxins may cause a toxic shock syndrome (see Chapter 224).

Bacillus cereus

There are really two syndromes associated with *B. cereus* infection, both toxin mediated.[14] In the first, ingestion of the preformed toxin, often in fried rice or vanilla sauce, leads to profuse vomiting within a few hours, accompanied by severe abdominal cramps. Diarrhea occurs in a minority of cases. The history of eating fried rice helps to differentiate this disease from staphylococcal food poisoning. The second syndrome has a longer incubation period (median 9 hours) and is characterized by watery diarrhea. In these cases, the bacteria multiply in the gut lumen and produce toxin. Both forms of *B. cereus* food poisoning are mild and resolve within 24 hours.

Clostridium perfringens

The clinical features of clostridial food poisoning are virtually indistinguishable from the diarrheal form of *B. cereus* infection. Most cases of infection due to *Clostridium perfringens* result from eating some form of cooked meat. The toxins are potent so there are often small outbreaks associated with a particular meal. This organism can sometimes cause a more serious infection, known as pigbel in the South Pacific, where it is associated with the consumption of pork.

Vibrio parahaemolyticus

This organism grows best in a salt-rich environment and is thus usually associated with food poisoning following the consumption of seafood and, especially, shellfish.[15] The incubation period can range from a few hours to several days, depending on the inoculum. The illness starts with explosive watery diarrhea followed by abdominal cramps and vomiting. Headache is often present and occasionally there is sufficient inflammation of the bowel to cause fever and,

rarely, some blood in the diarrhea. Most cases are self-limiting but may take several days to resolve.

Cholera

This disease, caused by *Vibrio cholerae*, is the classic example of a toxin-mediated secretory diarrhea.[16] Cholera usually follows the consumption of contaminated water but has been associated with eating shellfish. It is characterized by moderate to severe watery diarrhea without fever and with little vomiting. In severe cases, liters of fluid can be lost over 24 hours and severe prostration and even death may result from severe dehydration. In outbreaks, many infected people have few or no symptoms. With adequate fluid replacement, most cases are self-limiting. Almost all cases of cholera occur in the tropics and imported cases are rare, partly because of the short incubation period and the severity of symptoms and partly because the risk to travelers is small (Fig. 93.3).

Inflammatory diarrhea

Infections with *Campylobacter* spp., *Salmonella* spp. and *Shigella* spp.

Campylobacter jejuni, *Salmonella enteritidis* and other nontyphoidal salmonellae, *Shigella* spp. and enteroinvasive *E. coli* all produce an enterocolitis. *Campylobacter* spp. are sometimes associated with the consumption of milk or chicken and have also been associated with exposure to pets, such as puppies.[17] *Salmonella* spp. are particularly linked with poultry and eggs.[18] *Shigella* spp. have been found in association with a variety of foods and with contaminated water but these *Shigella* infections are rare in developed countries. The incubation period is often several days. Diarrhea is the principal symptom and there may be blood in the stool as a result of colonic inflammation. Vomiting is more common with *Salmonella* infection but can occur with any of these organisms. Abdominal pain is frequently severe and, particularly in *Campylobacter* and *Salmonella* infections, may mimic an acute abdomen. Most cases are mild and resolve over the course of about a week. However, sometimes symptoms can be prolonged, raising the possibility of inflammatory bowel disease as a differential diagnosis. *Campylobacter* spp. and *Salmonella* spp. occasionally become invasive and cause an enteric fever syndrome with positive blood cultures. This is more likely in the elderly and the immunosuppressed. Both *Salmonella* and *Campylobacter* infections are associated with extraintestinal symptoms in the absence of bacteremia, such as arthritis. Specific serotypes of *Campylobacter* species gastroenteritis are also strongly associated with Guillain-Barré syndrome (see Chapter 230).[19]

Figure 93-3 A cholera ward in Peru. *Courtesy of Dr J Sanchez.*

Yersinial infections

Yersinia enterocolitica can present in a number of ways. Most of the time it causes an entercolitis, presenting with acute diarrhea. Although it mainly affects young children, adults may sometimes be infected. The diarrheal illness may be severe and often resolves more slowly than that caused by other organisms. This organism may also cause a mesenteric adenitis and terminal ileitis in young children, which can mimic appendicitis. In such-cases, diarrhea is rarely a feature. Sometimes infection with *Y. enterocolitica* is associated with extragastro-intestinal features, such as arthritis, and rarely bacteremia occurs.

Escherichia coli 0157:H7

Infection with *E. coli* 0157:H7 causes an inflammatory colitis and is associated with hemolytic-uremic syndrome. It has become much more common in the past two decades and has been particularly associated with the consumption of hamburger meat.[20] This ground beef is often contaminated by intestinal contents and the production process may facilitate dissemination of the bacteria in large batches of meat that are then widely distributed. Sporadic cases occur but major outbreaks have highlighted the seriousness of this infection. In 1996 a large outbreak in Scotland caused 21 fatalities. The majority of cases present with diarrhea, which often contains frank blood and is usually occult blood positive. Most of these infections are self-limiting. However, a proportion of infected patients develop hemolytic-uremic syndrome, which occurs 5–7 days after the onset of diarrhea and which carries a significant risk of death from renal failure, bleeding or cerebral infarction (see also Chapter 43).

Botulism

This disease is caused by food poisoning with a preformed neurotoxin produced by *Clostridium botulinum.* Many cases are related to home canning of produce but outbreaks related to commercially prepared food also occur from time to time.[21] The neurotoxin causes predominantly bulbar and ocular palsies, and therefore swallowing difficulties, double vision, blurred vision and ptosis are common. Limb weakness and respiratory difficulty are often present. The differential diagnosis thus includes myasthenia gravis, Guillain-Barré syndrome and brainstem stroke.

Viral infections

Gastrointestinal disease

Viral gastroenteritis is common and is usually mild and self-limiting. [22] Sporadic cases are most commonly due to rotavirus, which mainly affects infants and small children. There is usually an abrupt onset of fever and vomiting, followed later by watery diarrhea. Severe dehydration can result, particularly if the diarrhea is profuse or prolonged, but most cases resolve within a week. Adenoviruses and astroviruses cause similar, although usually milder, symptoms.

Norwalk virus and other small round-structured viruses affect adults and older children and may cause sporadic disease, but they are often associated with outbreaks (Fig. 93.4). Infection may occur from eating contaminated food or infected shellfish or from drinking water contaminated by sewage. These viruses may cause diarrhea or vomiting or both. There are often other symptoms such as mild fever, myalgia and headache. Although the symptoms tend to be quite debilitating they resolve quickly, usually within 24–48 hours. Symptomatic disease with any of these viruses leads to excretion of large numbers of viruses in the stool, and so secondary cases are common.

Protozoal infections

Giardiasis

Giardia lamblia is the most common protozoal cause of diarrhea and is particularly common in travelers.[23] Affected people often develop

Figure 93-4 Electron micrograph of small round-structured viruses.

nausea and abdominal bloating, frequently accompanied by foul-smelling flatulence and belches tasting of hydrogen sulfide. The parasite affects the proximal small bowel so watery diarrhea is the main symptom; the diarrhea is often explosive. Steatorrhea and even malabsorption can occur and, if untreated, symptoms may persist for up to 6 weeks. In some patients sufficient damage occurs to the villus brush border enzymes that a secondary lactose intolerance occurs, with prolongation of the diarrhea.

Amebiasis (see also Chapter 164)

Infection with *Entamoeba histolytica* occurs mainly in the tropics and, as with giardiasis, many people are asymptomatic carriers of the parasite.[24] Ingested cysts mature into trophozoties in the bowel lumen and symptoms usually occur between 2 and 6 weeks after exposure. Amebic trophozoites damage the large bowel mucosa, leading to dysentery (Fig. 93.5). Most patients have blood in their stools but some may not — some do not even have fecal occult blood. In adults, dehydration is uncommon and the systemic symptoms, such as fever, are mild. Bacillary dysentery and a first episode of ulcerative colitis need to be considered in the differential diagnosis. Children tend to get more severe diarrhea and fluid loss and often have severe abdominal pain. Sometimes colonic perforation occurs and rarely, usually in debilitated or immunocompromised patients, a fulminant colitis may occur; this is clinically indistinguishable from severe ulcerative colitis. An uncommon complication (occurring in less than 1% of cases) is the development of an ameboma, usually in the ileocecum, when there is marked inflammation and bowel thickening that may resemble a malignant tumor or even Crohn's disease. Infection with the large protozoan parasite *Balantidium coli* may also produce a syndrome resembling amebic dysentery.

Figure 93-5 Amebic dysentery. A postmortem specimen. Note discrete flask-like ulcers with areas of hemorrhage.

Amebic trophozoites may also disseminate from the bowel and invade other tissues. Most commonly the parasite travels via the portal venous system to the liver, causing a mild hepatitis and, usually, an amebic liver abscess. These patients usually complain of right upper quadrant pain, often with shoulder tip pain as well, and are frequently febrile. Less common sites of spread are the lungs and brain. More than half of the patients presenting with amebic abscess have no history of previous dysentery. Sometimes there is direct extension of the infection from the bowel to the overlying skin.

Cryptosporidiosis

The coccidian protozoan *Cryptosporidium parvum* causes a secretory diarrhea. Infection is almost always associated with drinking contaminated water and it is a not infrequent cause of travelers' diarrhea.[25] In addition to the diarrhea, nausea and anorexia are common. The incubation period ranges from a few days to a couple of weeks. Most people clear the parasite easily and symptoms abate within a few days. However, this can be a serious disease in people who have HIV infection and in children who have severe congenital immunodeficiency syndromes, in whom it results in severe, prolonged cholera-like diarrhea that is associated with malabsorption and profound weight loss. Some patients who have AIDS develop an ascending cholangitis with upper abdominal pain, abnormal liver function tests and, occasionally, frank jaundice. The inability of immunocompromised patients to clear this parasite is a particular problem because no effective treatment exists (see Chapter 127 and Chapter 243).

Cyclospora cayetanensis

This coccidian parasite has only relatively recently been discovered and described as a human pathogen.[26] Most cases are related to water consumption but outbreaks associated with imported, contaminated soft fruit have occurred in the USA. Symptoms initially include watery diarrhea and anorexia and often vomiting. These infections are usually self-limiting but some patients may take several weeks to recover and many of these suffer anorexia, profound fatigue and marked weight loss even after the diarrhea has resolved. Immunocompromised patients, such as those who have HIV infection, may develop chronic symptoms of diarrhea that are indistinguishable from those seen in cryptosporidiosis (see Chapter 243).

Natural toxins

Patients may present with gastrointestinal or neurologic symptoms as a result of eating or drinking naturally occurring toxins. Such illnesses often mimic food- or water-borne infection.

Plant toxins

There are various alkaloids and other plant toxins that may produce symptoms in humans who consume them. People who have glucose-6-phosphate dehydrogenase deficiency are unable to reduce oxidants contained in some legumes or beans. These toxins accumulate and lead to a mixture of symptoms known as favism. Early symptoms are headache, nausea and vomiting with a mild fever. The main problem, however, is marked hemolysis with hemoglobinuria and jaundice.

If casava is not prepared and cooked properly, its naturally occurring cyanide precursors remain and are ingested.[27] In heavy, acute exposure breathlessness, paralysis and coma ensue. More commonly, chronic exposure leads to tropical spastic neuropathy. This is a particular risk for poor communities in times of severe drought.

Fish toxins

Neurotoxins associated with the consumption of shellfish lead to two distinct syndromes. Paralytic poisoning occurs within minutes to hours of ingestion and is characterized by breathlessness, muscle weakness and increasing respiratory difficulty.[28] Neurotoxic poisoning is milder, with some muscle weakness and paresthesiae but no respiratory problems.

Ciguatera poisoning follows the eating of fish that have consumed toxic microalgae. Such fish, like barracuda, feed around coral reefs where these algae are most commonly found. Symptoms include acute diarrhea and vomiting and there is often a macular erythematous rash. Neurologic symptoms are common with circumoral paresthesiae and sometimes paralysis. Most cases are mild and fatalities are rare.[29]

Scombroid poisoning resembles acute histamine toxicity. Coarse feeding oily fish, such as mackerel and tuna, are usually implicated.[30] The scombroid toxin is thought to be derived from the action of bacteria in the fish guts on histones in the flesh of the fish. The formation of the toxin is favored by heat, and so the risk is highest in poorly cleaned fish that have been inadequately stored before cooking. Symptoms include headache, diarrhea, erythema and, usually, a marked urticarial rash.

Mushrooms

Some mushrooms, such as *Psylocybe* spp., cause hallucinations and may be eaten intentionally for this effect. Other mushrooms may be eaten in error with grave consequences.[31] *Amanita phalloides* contains a deadly toxin that initially causes abdominal cramps and diarrhea. These symptoms improve somewhat to be followed by inexorable liver and renal failure, which is often fatal.

Other mushrooms contain muscarine-like toxins leading to cholinergic symptoms such as excessive salivation, blurring of vision, sweating and diarrhea.

Heavy metals

Ingestion of either cadmium or thallium may cause acute diarrhea and vomiting, somewhat resembling staphylococcal food poisoning. The symptoms may be severe enough to cause acute dehydration and collapse. More chronic ingestion of cadmium results in nephropathy; chronic ingestion of thallium causes a peripheral neuropathy.

Food-borne infections with systemic rather than gastrointestinal symptoms

Some organisms, after ingestion, invade through the intestinal mucosa and cause little in the way of gastrointestinal upset; rather, they result in myriad systemic symptoms. Many of these infections have fever as a prominent symptom and usually have longer incubation periods than those associated with food poisoning, so it is more difficult to recognize food-borne outbreaks with these organisms.

Typhoid

Typhoid, or enteric fever, is the classic example of a food-borne infection leading to systemic disease. This condition is characterized by a chronic *Salmonella typhi* bacteremia and fever is the main presenting complaint. Although older texts highlight relative constipation, diarrhea also occurs, although many patients have little in the way of bowel symptoms early in the course of the illness.[32] There is usually non-specific malaise and headache, and a nonproductive cough is common. Also common is the so-called 'typhoid facies', a rather lethargic and apathetic facial expression. Most patients appear subacutely unwell; very few are acutely toxic or look as if they have a Gram-negative sepsis. When the bacilli reinvade the bowel, particularly the Peyer's patches, inflammation results and may lead to intestinal hemorrhage, which is sometimes torrential. Occasionally, severe ulceration results in small bowel perforation. Less common complications include myocarditis and meningitis.

Some cases are mild and self-limiting but most require specific antimicrobial therapy. Rarely, infected people become chronic carriers and excretors of *Salmonella typhi*. Carriage is particularly associated with the presence of gallstones. Sometimes other organisms, such as *Salmonella paratyphi, Campylobacter fetus* and non-typhi *Salmonella* can produce an enteric fever-like illness (see also Chapter 163).

Brucellosis

This disease is usually caused by *Brucella melitensis* acquired by eating unpasteurized cheese or milk. Most cases present with a fever without localizing symptoms or signs, although orchitis is a well-recognized problem.[33] Associated symptoms such as headache, myalgia and chills are common. A less common presentation that has a more insidious onset is spondylitis; the main symptoms are back pain, related to the paraspinal inflammatory mass, and a milder fever. This may need to be differentiated from tuberculosis. Spinal cord compression is extremely rare in brucellar spondylitis. Rarely, both forms of brucellosis may have acute orchitis as a relatively early feature. Chronic brucellosis leading to chronic fatigue probably does not exist, but occasionally metastatic foci of infection in the joints may lead to chronic joint symptoms if appropriate antibiotics have not been administered (see Chapter 180).

Listeriosis

Infection with *Listeria monocytogenes* most commonly presents with an acute meningoencephalitis, which may be associated with a bacteremia. Patients present with headache, confusion and, sometimes, vomiting. Most cases have neck stiffness and other signs of meningeal inflammation. In the more encephalitic presentations, differentiation from herpes simplex virus encephalitis is impossible clinically, especially as both conditions may have lymphocytes and red cells in the cerebrospinal fluid. Central nervous system infection is most common in the elderly and the immunocompromised.

Less commonly, patients are bacteremic and present with mild influenza-like symptoms, although occasionally there is shock and renal impairment. Some cases may have impaired liver function tests as a result of a granulomatous hepatitis. Pregnancy carries an increased risk of bacteremia if *Listeria* is ingested, and infection in

early pregnancy may lead to spontaneous miscarriage. Late in pregnancy infection can result in stillbirth or in severe neonatal sepsis or meningitis. Intrauterine infection is almost always fatal even when the illness in the mother has been mild.[34]

Over the past few years it has become apparent that *Listeria* can lead to a syndrome of febrile gastroenteritis in immunocompetent people. In this setting, there is usually not invasive disease and routine stool analysis may not detect the organism. If *Listeria* is suspected as a cause of gastroenteritis, then the laboratory should be informed so that cultures can be kept longer and the organism specifically sought. *Listeria* gastroenteritis is usually associated with a large inoculum and is most commonly seen in the setting of a food-borne outbreak.[35]

Mycobacteria

Mycobacterium bovis

Although the majority of intestinal tuberculosis results either from swallowed infected sputum or from bacteremic spread from a pulmonary focus of *Mycobacterium tuberculosis*, in some areas of the tropics cases still occur from consuming unpasteurized milk and dairy produce contaminated by *M. bovis*, a closely related species.[36] Intestinal tuberculosis may present in a variety of ways, ranging from malabsorption if the proximal small bowel is affected to intestinal obstruction due to inflammatory strictures. Diarrhea may occur, as may intestinal hemorrhage, but both are rare presenting features. Intestinal tuberculosis may mimic Crohn's disease.

Mycobacterium avium-intracellulare

Mycobacterium avium-intracellulare (MAI) has become an important pathogen in the AIDS era. Late-stage HIV disease has been associated with an increased risk of disseminated MAI infection, which commonly presents with fevers, accelerated weight loss, anemia and chronic diarrhea. The organism is ubiquitous in the

environment.[37] Animal models of MAI infection suggest that the gastrointestinal tract is the portal of entry (see Chapter 129). Fortunately, with the advent of potent anti-HIV drugs that lead to improved immunity in those with HIV, MAI infection is now a relatively rare diagnosis.

Mycobacterium pseudotuberculosis

This organism is usually regarded as nonpathogenic. However, because of the similarities between intestinal tuberculosis and Crohn's disease, many researchers have sought a mycobacterial cause of Crohn's disease. Recently, molecular techniques have provided some evidence for the presence of *M. paratuberculosis* in the bowel of patients who have Crohn's disease, although this is controversial.[38] A causal link has yet to be proven.

Hepatitis viruses

Two of the hepatitis viruses, namely A and E, are acquired by the fecal-oral route. Hepatitis A virus is more common and is endemic in many countries, although its prevalence is highest in the tropics where it is a risk for nonimmune travelers. Hepatitis E virus is endemic in Asia, particularly in the Indian subcontinent, and is only rarely encountered as a disease of the returning traveler.[39] [40] Hepatitis A has an incubation period of 2–6 weeks; the incubation period of hepatitis E is less certain. Both hepatitis A and hepatitis E present, like most cases of acute hepatitis, with a relatively acute onset of malaise, nausea, anorexia and mild fever followed soon after by jaundice. In the prodrome, many patients who normally smoke find they no longer feel like smoking. The jaundice usually only lasts about 2 weeks but some patients develop marked cholestasis with prolonged jaundice.

Hepatitis A virus infection is usually asymptomatic in children below the age of about 8 years. It always causes symptoms in adults, which are usually mild but characterized by marked fatigue. Death from hepatitis A is very rare unless there is pre-existing liver disease and there is a case for immunizing those patients with chronic hepatitis B or hepatitis C infection. Hepatitis E virus infection may cause a fatal fulminant hepatitis in pregnant women. Recovery from hepatitis A results in lifelong immunity to reinfection, and the same is probably true for hepatitis E (see Chapter 48).

Prions

In the past decade an epidemic of bovine spongiform encephalopathy in cattle was recognized in the UK and some other European countries, linked to the consumption by the cattle of feeds made up partly of protein derived from other cattle. Although control measures have been introduced and such feeds stopped, there is evidence that the prions causing bovine spongiform encephalopathy in cattle have entered the food chain and resulted in human disease. An unusual form of Creutzfeld-Jakob disease has occurred in young people and is believed to be linked to the consumption of beef from cattle infected with bovine spongiform encephalopathy. These cases differ from 'classic' Creutzfeld-Jakob disease epidemiologically, clinically and histologically, and have a distinct molecular configuration of the prion protein. [41] Such cases of new-variant Creutzfeld-Jakob disease have aroused widespread public concern, but it remains uncertain whether a major epidemic of new-variant Creutzfeld-Jakob disease will occur or whether prions from species other than cattle will infect humans (see Chapter 223 for a detailed discussion).

Parasites

Protozoa

Most enteric protozoa, like *Giardia lamblia*, are associated with water or food contaminated with feces and are confined to the gut after ingestion. However, other protozoa with more complex life cycles are parasites of other species and may cause disease in humans when the meat of the intermediate host species is eaten. The most common example is infection with *Toxoplasma gondii* when tissue cysts are ingested with undercooked meat.[42] Many infections are asymptomatic. Acute symptoms include a febrile illness with or without generalized lymphadenopathy. This is usually self-limiting. Infection in pregnancy carries a risk of vertical transmission and congenital toxoplasmosis. Patients who have HIV infection may reactivate dormant cysts in the brain, develop toxoplasmal abscesses and present with the features of a space-occupying lesion (see Chapter 127). Toxoplasmosis is also a problem for some patients taking immunosuppressive medication, such as solid organ transplant recipients.

Helminths

Numerous helminths are ingested as infective ova, after which they undergo a complex life cycle that includes larval migration around the human host and then re-entry into the gastrointestinal tract, where they develop into adult worms that may or may not cause symptoms (Table 93.3).[43]

Other worms are ingested as ova or larva but migrate out of the gut and cause problems unrelated to the gastrointestinal tract. Table 93.4 outlines the main features of these infections, most of which are asymptomatic. Further details can be found in Chapter 46 , Chapter 165 and Chapter 246 .

TABLE 93-3 -- Food-borne helminthic infections that are confined to the gut.

FOOD-BORNE HELMINTHIC INFECTIONS THAT ARE CONFINED TO THE GUT
Ascaris lumbricoides
Ancylostoma duodenale
Trichuris trichiura
Enterobius vermicularis
Fasciolopis buski
Taenia saginata
Taenia solium
Hymenolepis nana

Diphyllobothrium latum

TABLE 93-4 -- Systemic helminthic infections that are transmitted by food or water.

SYSTEMIC HELMINTHIC INFECTIONS THAT ARE TRANSMITTED BY FOOD OR WATER	
Helminth	**Food vehicle**
Dracunculis medinensis (guinea worm)	Crustacea in drinking water
Trichinella spiralis	Pork
Toxocara canis	Contaminated soil ingestion
Opisthorchis viverrini	Raw fish
Opisthorchis sinensis (Clonorchis sinensis)	Raw fish
Fasciola hepatica	Contaminated vegetables, watercress
Paragonimus westermani	Freshwater crabs, crayfish
Taenia solium (cystlicercosis)	Pork
Echinococcus granulosis	Contaminated food or water (with eggs in animal feces)
Echinococcus multilocularis	

DIAGNOSIS

Food poisoning

Microbiology

When a patient presents with symptoms suggesting food poisoning there may be clues about the infecting organism in the dietary history. A recent restaurant or take-away meal may highlight suspect foods whereas a story of recent tropical travel may raise the possibility of a protozoan parasite. Recent consumption of mayonnaise, soft-boiled eggs or barbecued chicken, for example, hint that *Salmonella* spp. may be the cause.

The microscopy and culture of a stool specimen is probably the most useful test and the diagnostic yield can be maximized by examining at least three specimens obtained at different times. Most causes of secretory diarrhea will produce negative stool tests as the diarrhea is usually caused by toxins and there is little inflammation in the intestinal mucosa. The presence of pus cells in the stool suggests infection and also indicates an inflammatory colitis. Red blood cells in the stool indicate colitis and may occur with any cause of inflammatory colitis. Infection with *E. coli* O157:H7 usually causes a hemorrhagic colitis and so the presence of red cells in a stool specimen should alert the laboratory to the need to screen for this pathogen. If there is a history of tropical travel, blood in the stool may indicate shigellosis or amebic dysentery. Amebic trophozoites may be seen engulfing red cells but only if the stool is examined fresh or 'hot' because the trophozoites soon degrade in vitro.

Parasites, such as *Giardia* spp. and cryptosporidia, may be seen in stool specimens in heavy infections or in immunocompromised patients. However, because they infect the small bowel and are shed intermittently in small numbers in the stool they may be missed on microscopy.[44] Microscopic examination of duodenal aspirates or the use of the entero-test, or string test, is more likely to yield results with these small bowel parasites; however, these investigations are more invasive. It should be noted that the nonpathogenic *Entamoeba dispar*, found in up to 50% of people in endemic areas, has cysts that are indistinguishable from those of *E. histolytica*, so the finding of amebic cysts should be interpreted with caution in endemic areas or in patients returning from such areas (see Chapter 165).[45]

Electron microscopy has a role to play in the investigation of gastroenteritis caused by viruses. The characteristic appearances of rotavirus, astrovirus or small round-structured viruses such as the Norwalk virus clinch the diagnosis. Electron microscopy is particularly useful during outbreak investigations but it is not often routinely available for diagnosing individual cases.

Stool culture using a variety of selective media can identify the common bacterial causes of diarrhea unless the symptoms are due to preformed bacterial toxins in the food. The disadvantage is that the identification process can take several days. Stool cultures are relatively insensitive and hence not very cost-effective. Culture methods may also be used to investigate water or food vehicles in suspected outbreaks.

There are now several commercially available latex and enzyme-linked immunosorbent assay (ELISA) kits for the identification of rotavirus in stool or vomit. These allow prompt diagnosis without the need for electron microscopy. Increasingly, reverse transcription polymerase chain reaction is being used to identify a variety of viruses in stool lysates.[46] Although not used in routine laboratories, ELISA can be used to identify bacterial toxins and is important when investigating outbreaks.

Serology has a minor role in the diagnosis of invasive amebiasis. [47] There are several tests available with variable predictive values. In endemic areas, up to one-quarter of the population may have positive tests because of previous asymptomatic infection. Other than for epidemiologic studies, the current IgG ELISA is most useful in patients from nonendemic areas but it is usually used, because of its turnaround time, as a confirmatory test.

Hematology, biochemistry and immunology

Blood tests have little role in the specific diagnosis of food poisoning. The peripheral leukocyte count may be non-specifically raised but it is commonly normal. Eosinophilia rarely occurs with invasive amebiasis; rather it is a feature of metaozoan (i.e. worm) infection, not protozoan infection. There may be mild anemia in hemorrhagic colitis. One key finding on the blood film is fragmented red cells, which is indicative of intravascular hemolysis in hemolytic-uremic syndrome in association with enterocolitis caused by *E. coli* O157:H7.

Biochemical tests are useful for gauging the extent of dehydration or renal impairment. Serum albumin may be low in more chronic diarrhea or if there is severe colonic inflammation or sepsis. The C-reactive protein may be significantly elevated in cases of inflammatory colitis due, for example, to *Campylobacter* spp. None of these tests is in any way specific.

Radiology

A plain abdominal radiograph is useful for assessing the severity of infective colitis. Infection with organisms causing inflammatory diarrhea may mimic ulcerative colitis and lead to large bowel dilation and, sometimes, to a toxic megacolon. Plain radiographs may also show small bowel dilatation or fluid levels when there are inflammatory strictures in the ileocecum caused by infections with *Yersinia* spp. or amebae.

Barium enema examination can be used to demonstrate inflammation of the colon and may show ulceration in amebic dysentery, but this has largely been superseded by fiberoptic endoscopy. Computerized tomography (CT) scans, magnetic resonance imaging (MRI) and labeled leukocyte scans have no role in the diagnosis of food poisoning.

Other investigations

Although stool culture and microscopy are the most important diagnostic tools, a useful adjunct is flexible sigmoidoscopy and large bowel biopsy. Endoscopy may show an active colitis, which can be macroscopically similar to that seen in ulcerative colitis, although the finding of frank pus points more toward infection. Amebic colitis causes inflamed mucosa around discrete ulcers with patches of normal mucosa in between, a useful feature that distinguishes it from ulcerative colitis. Rectal or

colonic biopsy may show histologic features that differentiate between infection and inflammatory bowel disease (Fig. 93.6).

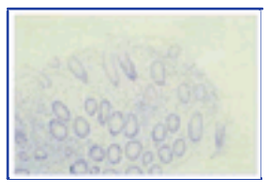

Figure 93-6 Histology of infective colitis caused by *Campylobacter jejuni.*

Microbiology

Many of the bacterial infections described above share the feature that, although they enter via the gastrointestinal tract, they disseminate from there. Many of these spread via the bloodstream and hence, particularly early in the course of disease, blood cultures are essential. Typhoid is most easily diagnosed by blood culture, although bone marrow culture is even more sensitive.[48] Stool culture is less sensitive but is still valuable, particularly in areas where blood culture facilities are less readily available. Even a rectal swab can be used to diagnose typhoid with a sensitivity of about 30%. Brucellosis and listeriosis are also commonly diagnosed by positive blood culture. Brucella spondylitis may result in a paravertebral mass, which may be positive on culture if aspirated or biopsied. *Listeria* may present with a meningoencephalitis, in which case the cerebrospinal fluid culture should be positive.

Mycobacterial infections affecting the gut are best diagnosed by tissue biopsy; specimens may show granuloma and, occasionally, acid-fast bacilli on histology, but they should always be sent for mycobacterial culture. In the setting of HIV infection, infection with MAI is associated with large numbers of mycobacteria and very poorly formed granulomas. Patients may be bacteremic or have positive bone marrow cultures. Not infrequently, large numbers of acidfast bacilli are seen in the stool, which will also be positive on culture. Intestinal biopsies will often show numerous acid-fast bacilli with little in the way of inflammatory reaction and certainly no caseation.

Serologic tests for brucellosis are useful in patients from nonendemic areas but even in endemic regions a rising titer can be diagnostic. The Widal test for typhoid is widely used in the tropics and is only partially useful in endemic areas if the test patterns in the population have been well studied and validated. It cannot be relied upon to exclude typhoid in returning travelers or in patients in nonendemic areas. Previous typhoid immunization will lead to false-positive results.

Hepatitis due to enterically acquired viruses is diagnosed by appropriate serologic tests, usually in the form of an ELISA.

There are now a variety of commercial and research tests to detect pathogens by means of molecular biologic techniques.

Most diagnostic laboratories are not able to culture protozoa. Diagnosis of invasive protozoa such as *T. gondii* rely on serologic tests such as an IgM seroconversion. In many cases there is detectable IgG to *Toxoplasma* spp., but this only defines previous exposure and does not prove that the current clinical problem is a disease caused by toxoplasmal infection. Usually, tissue samples are needed for histologic diagnosis.

Helminthic infections may be diagnosed by finding eggs in the stool or by the identification of adult worms passed in the stool (Fig. 93.7). Tapeworm infections may be diagnosed by finding segments, or proglottids, in the stool. Serologic tests may help identify invasive parasites causing problems such as cysticercosis or hydatid disease. However, these tests are best suited to returning travelers and are relatively unhelpful in endemic areas where large numbers of the population may be asymptomatically exposed.

Hematology and biochemistry

So-called routine blood tests are really of little value in the diagnosis of invasive food-borne infections and only serve an indirect purpose of assessing disease severity. Invasive helminths will commonly cause a peripheral blood eosinophilia. Viral hepatitis will result in raised levels of aminotransferase, such as aspartate aminotransferase, and in severe cases liver synthetic function is affected and hypoalbuminemia and abnormal clotting occur. Liver function tests may be abnormal in hydatid disease affecting the liver or if the biliary tree is obstructed by worms such as *Opisthorchis sinensis*.

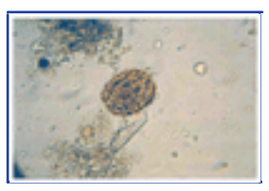

Figure 93-7 Unfertilized egg of *Ascaris lumbricoides*.

Immunology

There are no specific immunologic tests that help in diagnosis. There are proponents of tuberculin testing to aid in the diagnosis of mycobacterial disease but in practice this is of limited use and is of no value in diagnosing atypical mycobacterial infections, such as MAI.

Radiology

Plain radiographs are of little value in the diagnosis of these invasive diseases. Sometimes spondylitis caused by brucellosis may be seen on plain vertebral radiographs. Partially calcified hydatid cysts may be seen on plain radiographs but this usually represents inactive disease. Contrast radiology using, for example, a barium enema may find areas of disease, such as ileocecal abnormalities in intestinal tuberculosis, but will not yield a specific diagnosis.

Computed tomography scanning and MRI are particularly useful in delineating intracerebral lesions. In AIDS, cerebral toxoplasmosis appears as (usually multiple) ring-enhancing lesions or abscesses on CT scans or as multiple lesions on MRI. Neurocysticercosis presents with discrete, multiple lesions on these scans or with hydrocephalus if a cyst is blocking the fourth ventricle.

Histopathology

Tissue biopsy remains an important means of reaching a diagnosis in invasive disease. In addition to the histologic findings, specimens can be sent for culture (for *M. bovis*, for example). In-situ hybridization is increasingly used to demonstrate the infecting pathogen in tissue sections.

MANAGEMENT

Fluids

The mainstay of medical management for acute gastroenteritis is the administration of adequate fluid and electrolyte replacement to correct the intravascular volume and prevent cardiovascular collapse and renal impairment. For the vast majority of patients, oral dehydration is adequate but it should include electrolyte replacement as well as water.[49] [50] Many commercial preparations of oral rehydration salts exist with flavorings to make them more palatable. They are based on the World Health Organization recommendations for oral rehydration therapy but those for use in developed countries tend to have a lower sodium content (Table 93.5) because fecal sodium losses are lower in temperate climates than in the tropics. The glucose content of these solutions is essential to allow active transport of water and electrolytes across the mucosa from the lumen (see also Chapter 144).

TABLE 93-5 -- **Oral rehydration solution — World Health Organization formula.**

ORAL REHYDRATION SOLUTION — WHO FORMULA
Sodium 90mmol/l
Potassium 20mmol/l
Chloride 80mmol/l
Citrate 10mmol/l
Glucose 110mmol/l
Total osmolality 310mmol/l
Note that commercial oral rehydration solutions for use in developed countries have a lower osmolality (240mmol/l) with a lower sodium content (60mmol/l) because fecal sodium losses are lower in developed countries than in the tropics.

Intravenous fluid replacement is required for those who are too frail and for those who are vomiting too much to tolerate oral therapy, as well as for those who have severe dehydration and near circulatory collapse. Crystalloid solutions are usually appropriate, and Ringer's lactate with 5% dextrose is the preparation recommended by the World Health Organization. In difficult settings, infusion of fluids subcutaneously can be life saving.

Antidiarrheal agents

Drugs that inhibit intestinal motility have a small role to play in patients who have gastroenteritis. Loperamide, diphenoxylate and codeine phosphate all act in this way. Calmodulin, an antisecretory drug, may also have a role in reducing diarrhea. Only codeine is absorbed, with the advantage that it can act as an analgesic for those who have abdominal pain, but it carries the risk of side-effects, such as nausea, and the danger of accumulation in patients who have renal impairment. Kaolin-pectin has no role in the management of diarrheal illness but some studies have shown a beneficial role of bismuth subsalicylate. Although one report suggested that diphenoxylate-atropine use is associated with an increased risk of bacterial invasion in acute shigellosis, no other studies have found this.[51] Equally, there is little evidence to suggest that these agents significantly prolong the carriage of infecting organisms or that they increase the risk of the development of toxic megacolon.[52]

Other supportive measures

Patients who have severe shock from fluid loss may require intensive support, but this is very rarely needed with gastrointestinal infections. Some patients, particularly the elderly, may develop acute renal failure and require temporary renal support with hemofiltration or hemodialysis. This has been particularly true for those who have hemolytic-uremic syndrome following infection with *E. coli* O157:H7. There is also anecdotal evidence to suggest that patients who have hemolytic-uremic syndrome benefit from plasmapheresis.[53]

Some food poisoning, such as botulism or paralytic shellfish poisoning, results in neurologic disease and impaired respiration. These cases often require respiratory support with artificial ventilation along with intensive physiotherapy.

Antimicrobial therapy

Most cases of food poisoning resolve spontaneously and do not require specific therapy. There is controversy about the role of antibiotics in community-acquired bacterial diarrhea but recent guidelines help to clarify some of these issues.[54] Specific therapy may shorten the duration of illness and prevent complications but this is unproven in most cases. However, tetracycline treatment may reduce the duration of diarrhea in cholera both by killing bacteria and by interrupting toxin synthesis, and its use is important in epidemics. One problem is that therapy for most cases of diarrhea usually has to be empiric initially because it may take several days to isolate and identify a causative organism. Widespread use of empiric antibiotics for diarrhea may encourage the spread of resistant organisms, promote the development of diarrhea caused by *Clostridium difficile* and increase adverse reactions, such as rash. Studies have shown that the use of ampicillin for *Salmonella* enterocolitis may prolong excretion of the organism. There are also case-control study data to suggest that children who have hemolytic-uremic syndrome caused by *E. coli* O157:H7 who receive antibiotics may have a poorer outcome than those who do not, but this continues to be controversial.

Empiric antibiotics are appropriate for the elderly (aged over 70 years), those who have severe systemic symptoms, such as fever or joint inflammation, and the immunocompromised. In these cases, initial therapy is with a quinolone, such as ciprofloxacin (500mg q12h orally or 200mg q12h intravenously), because these drugs are well absorbed orally but are also available as intravenous preparations. They are effective against pathogens that can be invasive, such as *Salmonella* spp., *Campylobacter* spp. and *Yersinia* spp.; however, quinolone-resistant *Campylobacter* isolates are already well described.[55] [56] There is also concern about increasing quinolone resistance in nontyphoidal *Salmonella* in some parts of the world.[57] It is widely recognized that resistance in these common enteric pathogens frequently derives from the increased use of antibiotics in animal husbandry. Such use can lead to resistant organisms becoming established in animals destined for human consumption.[58]

Most protozoa that cause food poisoning are treated with specific agents. Benzimidazoles, such as metronidazole or tinidazole, are effective against *Giardia* spp. (metronidazole 400–500mg q8h orally for 5 days) and amebae (metronidazole 750–800mg q8h orally for 5 days), although some strains of *Giardia* are relatively resistant to metronidazole. This resistance can be a problem because culture and sensitivity methods are not routinely available. In practice, those giardial infections that do not respond to metronidazole or tinidazole usually respond to mepacrine (100mg q8h orally for 7 days). It should be remembered that patients who have *E. histolytica* dysentery may reinfect themselves with amebic cysts carried in the gut. Following killing of trophozoites by a benzimidazole, these patients should be given a luminal cysticide, such as diloxanide furoate (500mg q8h orally for 10 days). Infections with *Isopora belli* and *Cyclospora cayetanensis* respond to 10–14 days of oral trimethoprim-sulfamethoxazole (160mg TMP/800mg SMX q12h). There is no specific treatment for cryptosporidiosis.

Viral infections are self-limiting. Rarely, patients who have acute hepatitis A virus infection may become deeply jaundiced with prolonged cholestasis. In such cases, a short course of oral prednisone (prednisolone; 0.5mg/kg daily reducing to nothing over 4 weeks) may reduce inflammation around the bile canaliculi and lead to resolution of the jaundice.

Most helminthic infections need specific therapy, which can be tailored to the parasite that is detected.

Most invasive food-borne infections, such as typhoid, need to be specifically treated, so it must be re-emphasized that every effort should be made to obtain samples for culture and sensitivity testing. This is increasingly important as antibacterial resistance of enteric organisms increases. The specific treatments for these conditions are described in Chapter 43 .

Surgery

Surgery has little role in the management of these infections. Infections caused by *Yersinia* spp., *Salmonella* spp. and other

organisms may present in a manner resembling acute appendicitis, leading to laparoscopy or laparotomy. In severe, infective enterocolitis a toxic megacolon may arise. This sometimes leads to colectomy or to a decompressing colostomy. Surgery may also be required for the complications of typhoid, such as acute hemorrhage or intestinal perforation. Although surgical intervention may also be used to obtain tissue biopsies for histology and culture, such specimens are more often obtained by percutaneous biopsies guided with imaging techniques such as ultrasound or CT scanning.

Public health issues

Hospitalized patients who have diarrhea or who are infected with an organism that can be spread by the fecal-oral route should be isolated in single rooms. Gloves and aprons should be worn when dealing with the patient's excreta to prevent nosocomial spread.

The diagnosis or suspicion of a food- or water-borne illness should be notified to the relevant public health officer (see also Chapter 50a). This is particularly important

in suspected outbreaks, in institutions or when a food-handler is involved. Public health aspects have also come more to the fore in recent years, following September 11 2001 and the use of anthrax as a tool of bioterrorism. Organisms that cause food-borne disease can and have been used intentionally to contaminate food.[59] Systems must be in place to provide surveillance for such a scenario, to recognize the risk and to initiate an appropriate public health and clinical response.[60] One example of this is the establishment of PulseNet, a network to type food-borne organisms by pulse field electrophoresis to more rapidly identify point source outbreaks.[61] The establishment of good public health surveillance and good communication with clinicians and the public can help to provide reassurance during food-borne outbreaks, whatever the origin.

Chapter 94 - Chronic Fatigue

Nelson M Gantz

Fatigue is one of the most common complaints in ambulatory care and in one report in an adult primary care clinic, 24% of patients indicated that fatigue was a major problem.[1] Laboratory tests are not helpful in determining the cause of the fatigue in the majority of patients and at 1-year follow-up, about 75% of patients have persistent fatigue. Over the past decade there has been a worldwide increase in attention to patients reporting fatigue, cognitive difficulties, malaise, weakness, myalgias, arthralgias, headache and low-grade fever. This disorder has in recent years been called the chronic fatigue syndrome (CFS), myalgic encephalomyelitis and the postviral fatigue syndrome.[2] [3] [4] In the press, the disorder has been referred to as 'yuppie flu'. Many patients and some physicians believe that the current name, CFS, does not adequately characterize the illness and is disparaging and promotes misunderstanding.

The diagnosis of CFS continues to stir controversy. It is a waxing and waning illness, the fundamental nature of which remains uncertain. Some physicians deny its existence, while others specialize in the disorder. Management strategies also evoke a diverse spectrum of responses. Some physicians use symptomatic treatment and others immediately prescribe a variety of exotic therapies, ranging from antiviral drugs to vitamins and herbal agents. Difficulty in identifying the cause of CFS has complicated the disorder's diagnostic definition, which, in turn, has introduced a measure of uncertainty when considering treatment options. The diagnosis is made by exclusion.

In my experience, about 20% of patients gradually improve and 80% have intermittent exacerbations. Unfortunately, some patients fail to respond to symptomatic therapy and must be considered disabled. Among those who fare poorly, some have a history of psychiatric illness, particularly depression. Unless an etiologic agent or unifying pathophysiology for CFS is identified, diagnosis will remain empiric and treatment largely supportive. It is important that clinicians recognize that CFS can be disabling, and provide support as the patient and family go through the difficult process of seeking disability benefits.

HISTORY

Chronic fatigue syndrome is not a new medical disorder. Patients who have a syndrome of fatigue, malaise and other somatic complaints have been recognized in the literature for more than 200 years (Table 94.1). In 1750, Sir Richard Manningham described febricula or little fever, an illness in which patients had weariness all over, pain, forgetfulness and low-grade fever.[5] In 1869, Beard coined the term neurasthenia to describe patients who lacked 'nerve strength', which he believed was the cause for the chronic fatigue.[6] Shortly after Beard's work was published, DaCosta described a syndrome of fatigue, breathlessness, palpitations, digestive problems, chest pain, sleep difficulties and dizziness in Civil War soldiers. DaCosta attributed the syndrome to an 'irritable heart'.[7] This syndrome was subsequently called the effort syndrome and the diagnosis continued to stir controversy in the 20th century, even though it was supported on psychologic and physiologic grounds. In the 1940s, DaCosta's syndrome lost support as a distinct clinical entity.[15] Since then, numerous reports have appeared in the literature describing patients similar to those characterized by Beard with neurasthenia. Some of these outbreaks are listed in Table 94.1 .[8] [9] [10] [11] [12] [13] [14] In the British Commonwealth, because neurologic symptoms have been prominent in some of the case clusters, the syndrome has been called benign myalgic encephalomyelitis.

Reports of patients who have fatiguing illnesses have also been attributed to various pathogens and to metabolic and environmental factors. In the 1930s, *Brucella* was erroneously linked as a cause of CFS.[16] Similarly, hypoglycemia, *Candida albicans* and the 'total allergy syndrome' have also been popular but unproved causes of this syndrome.[17] [18] In the 1980s, chronic infection with Epstein-Barr virus (EBV) was thought to be associated with CFS.[19] [20] However, when appropriate control populations were studied, EBV was not found to be a cause of CFS.[14] Other pathogens such as *Borrelia burgdorferi*, human herpesvirus-6 and human retroviruses have also been erroneously implicated as having a causative role in this disorder.[21] [22] [23] [24] [25]

Fibromyalgia, formerly called fibrosis, is a disorder that also has a long history and is seen commonly by rheumatologists.[26] The illness was described in the French literature in the 1850s and the clinical features overlap those seen in patients who have CFS.[27]

EPIDEMIOLOGY AND CASE DEFINITION

In 1987, the Centers for Disease Control and Prevention (CDC) convened a group of experts to develop a case definition for CFS for research and epidemiologic purposes. The definition required severe fatigue to be present for at least 6 months and no evidence of various illnesses that could produce chronic fatigue. In addition to these major criteria, the definition required the presence of eight criteria from the following symptoms or physical signs:

- the symptom criteria were fever and chills, sore throat, swollen neck or arm glands, muscle weakness, myalgias, post-exertional malaise, headaches, arthralgias, sleep disturbance, neuropsychiatric symptoms such as problems with memory, concentration and depression, and an acute onset;[2] and
- the physical sign criteria were low-grade fever, nonexudative pharyngitis and cervical or axillary lymphadenopathy.

In 1991, a conference organized by the National Institutes of Health (NIH) proposed that certain patients be excluded:

- those who have chronic medical conditions, such as malignancy or autoimmune disease, psychotic depression, bipolar disorder or schizophrenia; those prone to substance abuse; and
- those who have ongoing infectious diseases, such as chronic active hepatitis B or C, untreated Lyme disease or HIV infection.[28]

Patients who have a diagnosis of fibromyalgia, nonpsychotic depression, somatoform disorders, or anxiety or panic disorders were to be included. The original case definition and the modifications proposed by the NIH conference were developed by consensus based on the anecdotal experience of the participants. Using this case definition, the CDC implemented a surveillance system in four US cities. The

TABLE 94-1 -- Selected fatiguing disorders.

SELECTED FATIGUING DISORDERS	
Condition	**Year reported**
Febricula[5]	1750
Neurasthenia[6]	1869
DaCosta's syndrome[7]	1871
Atypical poliomyelitis[8]	1934
Icelandic disease[9] (Akureyri disease)	1948
Epidemic of poliomyelitis-like illness[10] , Adelaide, Australia	1949
Royal Free disease[11]	1955
Punta Gorda illness, Florida[12]	1956
Myalgic encephalomyelitis[13]	1956
Lake Tahoe illness[14]	1987

case records of 565 patients were reviewed and 23% were found to have fulfilled the case definition, 18% had unexplained chronic fatigue plus insufficient symptoms to meet the case definition, 42% had psychiatric disease before the onset of the fatiguing illness and 18% were found to have other medical disorders (unpublished CDC data). In this and another study, the physical examination criteria were found infrequently and did not contribute to the diagnosis.[29] The purpose of the definition was to select a homogeneous group of patients who have 'true CFS'. However, although the case definition did distinguish CFS cases from healthy controls and patients who have multiple sclerosis or depression, the criteria failed to separate CFS patients from other persons who have prolonged fatigue.[29]

At about the same time, a UK case definition and an Australian case definition were published.[30] [31] [32] The UK definition required the presence of severe fatigue and cognitive impairment. Patients who have medical conditions known to produce chronic fatigue and psychiatric disorders, such as schizophrenia, manic depressive illness, substance abuse, eating disorders, or organic brain disease, were excluded. Patients who have a fatiguing illness with a documented postinfectious onset should be identified.[30] The Australian case definition is similar to that of the UK;[31] [32] three subtypes are recognized — a postinfectious type, a neuropsychologic type with depression and one associated with fibromyalgia.

In 1993, a meeting was held at the CDC to revise the original case definition published in 1988. The study group consisted of worldwide experts including persons involved in the earlier UK and Australian case definitions. The criteria for diagnosis are given in Table 94.2 .[33] Unexplained fatigue must be present for at least 6 months and CFS remains a diagnosis of exclusion. Four symptom criteria must be concurrently present for 6 months. Selected laboratory tests and mental status examination are performed to identify disorders that should be excluded (Table 94.3). Patients who have severe fatigue for 6 months, the absence of other conditions to explain the fatigue, but less than four symptom criteria are designated as having idiopathic chronic fatigue. Patients who have anxiety and mild depression are not excluded. Fibromyalgia and depression are important overlapping disorders. The revised case definition has flaws and an international group plans to propose a new case definition in the future.

Chronic fatigue syndrome has been reported worldwide, with most of the studies from the UK, Australia and the USA. The prevalence varies from study to study, reflecting differences in surveillance methods and in the case definition used. In a study from Australia, the prevalence rate was 37/100,000 persons.[32] A CDC study that collected data from four USA cities found a prevalence rate of 2–7.3/100,000 persons using the 1988 case definition.[35] In a large community survey of fatigue in Washington state, USA, the

TABLE 94-2 -- Revised (1994) CFS case definition criteria.*

REVISED (1994) CFS CASE DEFINITION CRITERIA
1. Clinically evaluated, unexplained, persistent or relapsing fatigue for at least 6 months that:
• Is of new or definite onset
• Is not the result of ongoing exertion
• Is not substantially alleviated by rest
• Results in substantial reduction in previous levels of occupational, educational, social or personal activities
2. Four or more of the following concurrent symptoms on a persistent or recurrent basis during 6 or more consecutive months of illness, none of which may predate the fatigue.
• Self-reported impairment in short-term memory or concentration that is severe enough to cause substantial reduction in previous levels of occupational, educational, social or personal activities
• Sore throat
• Tender cervical or axillary lymph nodes
• Muscle pain
• Multijoint pain without joint swelling or redness
• Headaches of a new type, pattern or severity
• Unrefreshing sleep
• Postexertional malaise lasting more than 24 hours
Both 1 and 2 are required conditions for a diagnosis of CFS

** With permission from Quadrant Healthcom.*[34]

TABLE 94-3 -- Conditions that exclude the diagnosis of CFS.*

CONDITIONS THAT EXCLUDE THE DIAGNOSIS OF CFS
• Any active medical condition that may explain the presence of chronic fatigue (e.g. untreated hypothyroidism, sleep apnea, narcolepsy, adverse effects of medications, HIV disease)
• Any previously diagnosed medical condition without resolution documented beyond reasonable clinical doubt, and for which continued activity may explain the chronic fatiguing illness, (e.g. previously treated malignancies and unresolved cases of hepatitis B or hepatitis C virus infection)
• Any past or current diagnosis of major depression with melancholic or psychotic features, bipolar affective disorder, schizophrenia of any subtype, delusional disorders of any subtype, dementias of any type, anorexia nervosa or bulimia
• Alcohol or other substance abuse within 2 years before the onset of the chronic fatigue and any time afterwards
• Severe obesity as defined by a body mass index (BMI) =45: $BMI = \frac{\text{weight in kg}}{(\text{height in m})^2}$
• Any unexplained physical examination finding or laboratory or imaging test abnormality that strongly suggests the presence of an exclusionary condition

** With permission from Quadrant Healthcom.*[34]

prevalence rate of CFS ranged from 98 to 267/100,000 persons and the frequency of fatigue alone was much higher.[36] In a small study from Scotland, the prevalence of CFS was much higher with a rate of 560/100,000 persons. [37] In a large community based study in Chicago, the prevalence of CFS was 422/100,000 which compares with a rate of 373/100,000 based on a CDC study conducted in Wichita, Kansas (Reyes M, personal communication).[38] Most studies show a female (75%) predominance with the average age ranging from 30 to 40 years. Disease also occurs in adolescents and the

elderly.[39] All socioeconomic groups are affected. Cases occur sporadically and in outbreaks or clusters. No differences have been noted in sporadic cases compared with epidemic cases. Patients report three patterns of symptom onset: an acute onset of illness without precipitating cause, postinfectious onset or gradual onset of symptoms. Further studies are needed to compare the type of onset with the course of the illness. Chronic fatigue syndrome does not appear to be contagious.

PATHOGENESIS AND PATHOLOGY

The etiology and pathogenesis of CFS are unknown. Patients who have CFS often report an infectious illness such as a presumed viral respiratory tract infection as the inciting event. Much attention has focused on EBV as a possible cause of CFS in response to two reports in 1987.[19] [20] However, other studies failed to demonstrate a difference in EBV antibody levels between cases and controls.[14] [40] One UK report found higher levels of enterovirus in the stools of patients who have postviral fatigue syndrome than in those of control patients.[41] In another study, enteroviral RNA was identified in muscle biopsies from 20% of CFS patients compared with zero in control patients.[42] However, persistent enterovirus infection was not supported by a report from The Netherlands and another case-control study from the USA.[43] [44] In one report, human T-cell leukemia/lymphoma virus (HTLV)-1 antibodies were detected in 50% of adults who had CFS and in none of the controls.[23] In the same study, HTLV-II gag sequences were found in the sera of 83% of adults who had CFS, 72% of children who had CFS and in none of the controls. These results were not confirmed by a study of 21 patients conducted by the CDC.[24] Other investigators have also failed to confirm the retrovirus finding and have not detected antibody to spumavirus, another CFS implicated retrovirus.[25] Antibody levels of other agents, including arboviruses, cytomegalovirus, human herpesvirus-6, varicella-zoster virus, respiratory viruses (adenovirus, parainfluenza virus types 1, 2 and 3, respiratory syncytial virus), hepatitis viruses, measles virus, *Rickettsia* spp., *Bartonella* spp., *B. burgdorferi*, *Chlamydia* spp. and *C. albicans*, were not found more frequently in CFS patients than in matched controls.[44] Although many different infectious agents have been suspected of having an etiologic role in CFS, none qualifies as the sole cause of the illness. It also appears that after certain acute infections, such as influenza, brucellosis or adequately treated Lyme disease, CFS can develop.[45] [46] [47] The mechanism that accounts for CFS in this setting after an acute infection is unknown.

Chronic fatigue syndrome may be a neuroendocrine rather than an infectious disorder. There is a clear association between stress, the immune system, the endocrine system and CFS. Symptoms of CFS such as fatigue, myalgias and sleep problems occur in patients who have adrenal insufficiency. Patients who have CFS have been reported as having reduced serum levels of basal evening glucocorticords and decreased 24-hour urinary free cortisol excretion compared with controls.[48] Plasma adrenocorticotropic hormone (ACTH) levels were not reduced and a decreased response of ACTH to ovine corticotropin-releasing hormone was noted. These results do not suggest either adrenal or pituitary insufficiency, but a possible hypothalamic problem. A controlled study that compared normal replacement doses of hydrocortisone with placebo doses in patients who have CFS showed no significant improvement in symptoms in those treated with drug and a high frequency of adrenal suppression. [49] Low-dose hydrocortisone, 5–10mg/day, was found to be beneficial in one study when given for 1 month but this finding has not been confirmed.[50] Plasma levels of 5-hydroxyindoleacetic acid, a metabolite of serotonin, were noted to be increased in patients who have CFS.[51] In another study, prolactin levels were normal.[52] The interpretation of these various findings is unclear.

In addition to fatigue, patients who have CFS often complain of lightheadedness and cognitive dysfunction. Reports have shown abnormal tilt table tests in patients who have CFS; 96 versus 29% for controls.[53] Various therapies using increase in dietary salt intake, fludrocortisone, ß-adrenergic blocking agents and disopyramide alone or in combination were reported to cause a reduction in symptoms in an uncontrolled study, but a controlled trial using drugs to treat patients who have abnormal tilt

table tests found no difference in symptoms in those patients treated with fludrocortisone compared with placebo.[54]

A high frequency of atopy and positive immediate skin tests has been reported in patients who have CFS.[55] [56] Immunologic abnormalities similar to those reported with acute viral infections have frequently been noted in CFS patients.[57] [58] [59] Alpha-interferon and other cytokines such as interleukin (IL)-6 may be elevated in some patients who have CFS.[60] Flu-like symptoms have been associated with increased levels of various cytokines. The finding of persistent cytokine abnormalities in some studies along with an increase in $CD8^+$ lymphocyte cell subsets showing activation markers is intriguing;[61] however, they do not provide a diagnostic test for CFS. It is important not to overinterpret the lymphocyte phenotyping data because the results have not been consistent, nor identified in the majority of patients who have CFS. These abnormalities of increased cytokines and evidence of immune activation in many cases of CFS have led some to suggest that the illness be named 'chronic fatigue immune dysfunction syndrome'. This name or illness should not be confused with immune deficiency.

Possible factors in the pathogenesis of CFS are summarized in Table 94.4 . Likely predisposing factors include psychiatric illness, and genetic and environmental factors such as allergy. Delayed recovery from influenza virus infection was noted more frequently in patients who have pre-existing psychiatric illness.[46] Some studies have found a higher prevalence of psychiatric disorders such as depression in CFS patients before the onset of the illness compared with controls.[62] [63] [64] In contrast, another study reported the prior prevalence of major depression (12.5%) and of all psychiatric disorders (24.5%) in patients who have CFS to be no higher than in the general community.[65] Not surprisingly, depression and anxiety were common symptoms after the onset of the illness. A twin study is underway to evaluate the role of genetic factors in patients who have CFS. Infection or stress are often historically the precipitating or triggering factors. Possible perpetuating factors include physical deconditioning, concurrent psychiatric illness, misattribution of physical symptoms and increase in cytokines.

PREVENTION

There are no specific preventative measures for CFS because the etiology and mode of transmission are unknown.

TABLE 94-4 -- Possible pathogenesis of CFS.

POSSIBLE PATHOGENESIS OF CFS		
Predisposing factors	**Precipitating factors**	**Perpetuating factors**
Psychiatric illness	Infection	Physical deconditioning
Genetic	Stress	Concurrent psychiatric illness
Environment (e.g. allergy, chemicals)		Misattribution of physical symptom
		Raised cytokines

CLINICAL FEATURES

Fatigue is the hallmark of CFS and by definition should be present for at least 6 months (see Table 94.2). The fatigue refers to a state of severe mental and physical exhaustion that is not caused by activity or lack of rest. The fatigue is usually made markedly worse by activity and is not readily relieved by rest. This should not be confused with sleepiness, which indicates that the patient may have a sleep disorder such as sleep apnea, narcolepsy or depression. The fatigue is so severe that approximately 25% of patients report being often bedridden and unable to work.[66] Unfortunately, the precise measurement and definition of fatigue are difficult. The natural history of fatigue is poorly understood. Fatigue is usually measured using self-report instruments but these have limitations.

The majority of patients are female (about 75%) with a mean age of 35–40 years. Most patients (85%) report that the illness began suddenly, often with an initial 'flu-like' illness, although some report a gradual onset of symptoms with no triggering event. The disorder affects persons in all socioeconomic groups, but in most studies the patients are middle class.

In addition to the fatigue, patients note low-grade fever, myalgia, sleep disturbance, impaired cognition, depression, headache, sore throat, post-exertional malaise, arthralgia and dizziness.[66] The symptoms are present most of the time in the majority of patients and the illness typically waxes and wanes. As there is no diagnostic laboratory study, the clinical diagnosis rests upon the CFS case definition. Patients who have a diagnosis of fibromyalgia made by a rheumatologist often fit the case definition for CFS. Persons who have severe fatigue but fewer than four symptoms are classified as having idiopathic chronic fatigue.

The history is key in establishing the diagnosis. Epidemiologic clues related to travel, occupational and animal exposures, and substance abuse or alcohol misuse should be carefully sought. Patients should be questioned for HIV risk factors and, if positive, evaluated by testing.

A mental status examination is important to look for psychiatric disorders; if abnormalities are noted then a psychiatric or neurologic evaluation can be invaluable. Particular attention should be directed to depression, anxiety, suicide thoughts and a history of sexual abuse.

The diagnosis is based on self-reports and the physical examination is only helpful in identifying other causes of the patient's symptoms. The physical examination is usually normal and no pathognomonic physical findings have been reported. If a patient is found to have a temperature higher than 38.4°C (101°F), then another cause for the fever should be pursued. Similarly, generalized lymphadenopathy or a single large lymph node suggest another diagnosis.

The differential diagnosis of fatigue is extensive (Table 94.5). Psychologic disorders, particularly depression, are the most common causes of chronic fatigue. Other causes for fatigue such as multiple sclerosis, systemic lupus erythematosus or hypothyroidism should be considered.

DIAGNOSIS

No diagnostic tests are specific for CFS and the laboratory testing is to exclude possible causes for the fatigue and other symptoms. Laboratory studies should investigate the various diagnostic possibilities suggested by the history and physical examination. A minimum set of recommended screening laboratory tests to evaluate a patient who has suspected CFS is given in Table 94.6 . The erythrocyte sedimentation rate is a key test, and results tend to be normal or low in patients who have CFS. Neuropsychologic testing to measure cognitive function as well as tests to screen for the presence of psychiatric disease may be beneficial. Various immunologic

TABLE 94-5 -- Most common differential diagnoses of chronic fatigue.

MOST COMMON DIFFERENTIAL DIAGNOSES OF CHRONIC FATIGUE	
Habit patterns	Caffeine habituation
	Alcoholism
	Other substance abuse
Psychosocial	Depression
	Anxiety
	Stress reaction
Medications	Corticosteroids
	Sedatives
	Chemotherapy
Sleep disorders	Sleep apnea
	Narcolepsy

Pregnancy	Anemia
	Weight gain
	Fluid retention
Infectious diseases	Mononucleosis, cytomegalovirus, or EBV infection
	HIV infection
	Chronic hepatitis B or C virus infection
	Lyme disease
	Fungal disease
	Chronic parasitic infection
	Tuberculosis
	Brucellosis
	Subacute bacterial endocarditis
	Occult abscess
Autoimmune disorders	Systemic lupus erythematosus
	Multiple sclerosis
	Thyroiditis
	Rheumatoid arthritis
	Myasthenia gravis
Occult malignancy	Lymphomas
	Gastrointestinal malignancy
Endocrine disorders	Hyperparathyroidism
	Hypothyroidism
	Apathetic 'hyperthyroidism'
	Adrenal insufficiency
	Cushing syndrome
	Hypopituitarism
	Diabetes mellitus
Hematologic problems	Anemia
	Myeloproliferative syndromes
Metabolic disorders	Hyponatremia
	Hypokalemia
	Hypercalcemia
Cardiovascular disease	Low-output states
	Silent myocardial infarction
Hepatic disease	Alcoholic hepatitis or cirrhosis
Renal disease	Chronic renal failure
Respiratory disorders	Chronic obstructive pulmonary disease
Miscellaneous	Sarcoidosis
	Wegener's granulomatosis
This list is not meant to include every illness that can cause chronic fatigue. Rather, it is intended to highlight some of the illnesses that most commonly do so.	

tests can yield abnormal findings, but they are not indicated in clinical practice. A search for a diagnostic marker to identify patients with CFS has not been successful. One study found increased levels of a 37kDa 2-5A binding protein in patients with CFS but further data are needed.[67] Studies measuring cytokine levels and natural killer cell activity are best obtained in the research environment.

TABLE 94-6 -- Minimum recommended tests to evaluate suspected CFS.

MINIMUM RECOMMENDED TESTS TO EVALUATE SUSPECTED CFS
Complete blood count
Erythrocyte sedimentation rate
Alanine aminotranferase
Total protein
Albumin
Globulin
Alkaline phosphatase
Creatinine
Thyroid-stimulating hormone
Calcium
Phosphorus
Electrolytes
Glucose
Blood urea nitrogen
Urinalysis
Other tests are based on history and results of physical examination

TABLE 94-7 -- Managing the patient who has CFS.

MANAGING THE PATIENT WHO HAS CFS
1. Establish the diagnosis
2. Provide emotional support and refer patient to support groups
3. Prevent further disability by establishing a graded exercise program
4. Treat symptoms with appropriate medications, avoiding exotic untested remedies, and with cognitive behavior therapy
5. Follow up regularly and re-evaluate

There is no value in obtaining a battery of viral serologies, such as EBV titers, when chronic fatigue is suspected. Magnetic resonance imaging and single-photon emission computed tomography studies of the head of CFS patients are under investigation as diagnostic studies in such patients.

MANAGEMENT

Strategies for managing the patient who has CFS are outlined in Table 94.7 .[68] The objectives of therapy are:

- to help the patient develop realistic goals and expectations through education;
- to provide symptomatic relief; and
- to preserve and improve the patient's ability to function.

At the outset it is very important to acknowledge the sense of illness and debility expressed by these patients. Patient support groups can play an important role in helping patients and their families cope with this frustrating chronic illness.

Nonpharmacologic therapies

Patients with CFS often avoid activity because they fear exacerbating their symptoms. Complete bed rest should be avoided because of the problems associated with physical deconditioning. I believe that a balance between moderate levels of exercise and rest, dictated by common sense, is essential and that physical activity should be gradually increased as tolerated.

Cognitive behavior therapy attempts to alter attitudes, perceptions and beliefs that can contribute to maladaptive behavior. Controlled trials using cognitive behavior therapy with a graded exercise program show reduced symptoms and increased activity in patients who have CFS and fibromyalgia, an illness that overlaps with CFS.[69] In some patients hypnotherapy and physical therapy are helpful for morning stiffness and muscle pain.

Pharmacologic therapy

Many therapeutic agents have been used to treat CFS (Table 94.8). Information on the efficacy of most of these medications in treating CFS patients is limited to anecdotal reports, often in publications that are not peer-reviewed.[70] [71] [72]

Antiviral medications

Current data do not indicate the use of antiviral drugs. In a well designed placebo-controlled trial of 27 patients who have CFS, 46% of those given high-dose intravenous aciclovir and 41% given placebo responded favorably (P >0.05).[73] In the aciclovir-treated group, most persons reported a return of symptoms soon after treatment was discontinued; immunologic tests and EBV serologic assays were unaffected and 12% developed reversible renal failure.

Amantadine, an agent used for the treatment of Parkinson's disease and influenza A virus, has been reported to decrease fatigue in patients who have multiple sclerosis. Only anecdotal information is available regarding its use in patients with CFS, however.

Immunologically active medications

Immunoglobulin has been given to patients who have CFS based on the theory that CFS results from an immunoregulatory defect and because specific immunoglobulin subclass deficiencies have been found in some CFS patients. Two well-designed controlled studies of high-dose intravenous immunoglobulin in CFS patients were conducted. In the USA, 28 adult CFS patients were given either placebo or 1g/kg intravenous immunoglobulin each month for 6 months; about 20% in each group improved symptomatically. [74] In Australia, 49 adult CFS patients were given either placebo or 2g/kg intravenous immunoglobulin each month for 3 months; 43% of those given immunoglobulin reportedly felt better compared with 12% of those given placebo.[75] Symptomatic improvement, however, was noted only at 3 months after the final infusion, and symptoms and disability returned 6 months after the end of therapy. Phlebitis occurred in 55% of patients and constitutional symptoms, such as headache, fatigue and diminished concentration, occurred in 82% of patients. Possible explanations for the different results between these studies include the smaller sample size and lower doses of immunoglobulin used in the USA study, and differences in study populations and outcome assessments. There are no controlled studies on the value of immunoglobulin administered intramuscularly.

Transfer factor is a component of leukocytes that can transfer delayed-type hypersensitivity. In a double-blind trial, transfer factor given intramuscularly over a 4-week period was no more effective than placebo in improving immunologic parameters or the functional status of CFS patients.[61]

Poly(I)-poly(C_{12} U) (Ampligen) consists of double-stranded RNA molecules with possible antiviral and immunomodulatory effects.[76] In a double-blind placebo-controlled study of 92 patients who have CFS, poly(I)-poly(C_{12} U) given intravenously twice weekly for 6 months was associated with an enhanced capacity to perform activities of daily living and an improvement in memory.[76] Adverse effects included hepatic toxicity. This drug cannot be recommended until more data are available on its safety and efficacy. Controlled studies are in progress to evaluate this drug.

Trials of interferon-a given subcutaneously have been associated with improvement in some patients but the data are limited. Inosine pranobex, IL-2 and prednisolone in doses of 10–60mg/day have been attempted without beneficial effect.[34]

Antidepressant medications

Depression is common in patients with CFS. In addition to their antidepressive effects, antidepressants may help improve sleep,

TABLE 94-8 -- Selected list of agents used to treat CFS patients.

SELECTED LIST OF AGENTS USED TO TREAT CFS PATIENTS	
Antidepressants	Tricyclic antidepressants
	Amitriptyline
	Desipramine
	Nortriptyline
	Monoamine inhibitors
	Phenelzine
	Moclobemide

Selective serotonin reuptake inhibitors	Bupropion
	Fluoxetine
	Nefazodone
	Paroxetine
	Sertraline
	Venlafaxine
Immune modifiers	Transfer factor
	Poly(I)-poly(C_{12} U)
	Interferon-a
	Corticosteroids
	Cyclophosphamide
	IL-2
	Isoprinosine
	Thymic extract
Antibacterials	Ceftriaxone
	Ciprofloxacin
	Doxycycline
	Fusidic acid
Antivirals	Aciclovir
	Amantadine
	Ganciclovir
Anti-inflammatory agents	Hydroxychloroquine
	Nonsteroidal anti-inflammatory drugs
	Cyclobenzaprine
Opium antagonists	Naltrexone
Calcium channel blockers	Nifedipine
	Nimodipine
Stimulants	Amphetamines
	Modafinil
Vitamins and minerals	Cyanocobalamin
	Ascorbic acid
	Zinc
	Magnesium
Psychoactive agents	Benzodiazepines
	Alprazolam
	Clonazepam
	Non-benzodiazepines
	Carbamazepine
	Buspirone
Antifungals	Ketoconazole
	Fluconazole
	Nystatin
Antihistamines	H_2 -receptor antagonists
Other agents	Germanium
	Kutapressin
	Primrose oil
	Vasopressin
	Herbs
	Pentoxifylline
	Essential fatty acids
	Hydrogen peroxide
	Galanthamine hydrobromide
	Quinacrine
	Fludrocortisone
	Atenolol
	Disopyramide
	NADH

fatigue and pain symptoms, and are a mainstay in the treatment of CFS (Table 94.9). Anecdotal reports suggest that antidepressant doses lower than normal may be effective; dosing can be increased gradually if there is no effect. The chosen agent should be used for 4–6 weeks before therapeutic failure is considered. The choice of agent depends, to a large extent, on expected side effects.

Although large controlled studies are limited, tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) appear to be beneficial. Tricyclic antidepressants are associated with sedative and anticholinergic effects. Anecdotally, patients who have difficulty sleeping sometimes respond well to agents such as amitriptyline or doxepin taken daily at bedtime.

In a study of patients who had fibromyalgia, 25mg amitriptyline at bedtime (rather than the usual dosages of 100–150mg) decreased fatigue and myalgias and improved sleep compared with placebo. Responses were usually seen in 3–4 weeks.[77] Desipramine is a less sedating tricyclic antidepressant. When sedation is not desirable, SSRIs, such as fluoxetine, citalopram, sertraline or paroxetine, can be helpful. In a study of 79 patients with CFS treated with 50mg sertraline daily for 6

months, 65% showed improvement in fatigue, myalgias, sleep disturbance and depression. Adverse effects, limited

TABLE 94-9 -- Antidepressants used to treat CFS/fibromyalgia.

ANTIDEPRESSANTS USED TO TREAT CFS/FIBROMYALGIA	
Drug	**Usual dose (mg/day)**
Amitriptyline	100–150
Citalopram	20–40
Doxepin	100–150
Desipramine	150–200
Nortriptyline	75–100
Fluoxetine	20–40
Sertraline	50–150
Paroxetine	20
Bupropion	200–300
Venlafaxine	75–225
Nefazodone	200–500

mainly to nausea and diarrhea, occurred in 8% of the patients.[78] Bupropion or another drug, venlafaxine, may be effective in patients who are unable to tolerate a tricyclic agent or SSRI.[79] However in a

small placebo-controlled trial, fluoxetine or venlafaxine were not beneficial in treating patients with CFS.[80]

Anxiolytic medications

Panic disorders and anxiety occur frequently in patients who have CFS.[81] Although controlled studies in CFS patients are lacking, alprazolam plus ibuprofen were more effective than placebo in reducing pain and anxiety in patients who have fibromyalgia.[82]

Anecdotally, clonazepam, other benzodiazepines and buspirone also appear beneficial. Alprazolam may be particularly helpful in managing panic attacks; however, a dosage schedule of 3–4 times a day is required and the potential for habituation is substantial.

Pain medications

Acetaminophen, aspirin and other nonsteroidal anti-inflammatory drugs are often used to treat myalgias and arthralgias in CFS patients. In a study of patients who have fibromyalgia, naproxen (500mg q12h) plus amitriptyline were more effective than placebo in decreasing muscle aches.[77] In another randomized trial, amitriptyline (10–50mg at bedtime) was more effective than placebo in reducing myalgia in fibromyalgia patients.[83] Response was seen as early as 1–2 weeks after beginning therapy. In a placebo-controlled trial of the muscle relaxant cyclobenzaprine, a dosage of 10–40mg at bedtime for 12 weeks resulted in decreased pain and improved sleep in fibromyalgia patients. [84] In a small controlled trial of patients with fibromyalgia, tramadol decreased pain.[85]

Sleep medications

Problems falling asleep and maintaining sleep, as well as awakening unrefreshed from sleep, are very common in CFS patients. Low doses of amitriptyline (25–50mg) or cyclobenzaprine (10–20mg) at bedtime may be beneficial. Other agents that have been anecdotally reported to be helpful are trazodone (25–50mg), doxepin (10–50mg) and clonazepam (0.5–1mg). In a controlled study, 10mg zolpidem improved sleep in patients with fibromyalgia.[86]

Allergy medications

New allergies or exacerbation of old allergies are commonly reported by patients with CFS. Food elimination diets, royal jelly, herbs and dietary supplements have not been shown to be helpful, however. Non-sedating antihistamines such as terfenadine, astemizole or loratadine can be tried, but in a small trial oral terfenadine versus placebo did not have a clinical benefit in alleviating CFS symptoms.[87] In one controlled study, nystatin did not reduce symptoms in patients who have the 'yeast connection'.[88] The yeast connection is a hypothesis that the *Candida* spp. present in the body produce products that cause symptoms of fatigue; however, there is no proof linking yeast with CFS.

Vitamins, minerals, fatty acids and stimulants

Liver extract, folic acid and vitamin B12 given intramuscularly were no better than placebo in adults who have CFS.[89] In a controlled trial intramuscular magnesium sulfate given weekly for 6 weeks was associated with increased energy, less pain and improved emotional state in patients who have CFS. In this study, red blood cell magnesium levels were lower in CFS patients than in healthy controls and became normal after treatment.[90] Other investigators have not found lower red blood cell magnesium levels in patients with CFS.[91] I do not recommend magnesium therapy in CFS unless abnormally low red blood cell magnesium levels have been documented.

The treatment of CFS patients who have essential fatty acids has led to conflicting results. In one study, a combination of evening primrose oil and fish oil led to improvements in 85% of patients after 15 weeks, compared with 17% of those treated with placebo.[92] In another study, no difference was found between patients receiving essential fatty acids and those receiving placebo.[93] Amphetamines are not usually beneficial because of the development of tolerance. Another stimulant, modafinil, appears useful for selected patients and controlled trials are in progress. Modafinil is well tolerated and does not have the problem of tolerance.

Treatment of neurally mediated hypotension

Despite the lack of controlled trials, patients who have CFS and a positive tilt table test should be tried on an increased dietary salt intake and fludrocortisone, 0.1–0.2mg/day, with the addition of a ß-blocker or disopyramide if no response occurs with fludrocortisone. Midodrine, an alpha-1 agonist, may be beneficial but controlled trials are lacking.[53]

Chapter 95 - Psychological Aspects of Infectious Diseases

James Rubin
Trudie Chalder
Simon Wessely

The commonly held belief that psychosocial factors can influence susceptibility to disease dates back to antiquity and is by no means unique to Western culture. Yet although early research provided some interesting empiric support for this notion (see review by Cohen and Williamson),[1] it is only relatively recently that advances in immunology have enabled us to explore in detail the possible role of the immune system in mediating this process. The study of the complex bi-directional interactions between the immune system and the central nervous system (CNS) that are central to the influence psychosocial factors exert on physical health has been termed 'psychoneuroimmunology' (PNI).

An ever-growing number of PNI studies have now identified a wide variety of psychologic states and traits as being associated with dysregulation of the immune system.[2] [3] Perhaps the best documented of these is stress, the cognitive and emotional reaction experienced when we perceive that environmental demands exceed our ability to cope, [4] although other psychosocial factors including psychiatric illness, depression, social disruption, personality and coping style have also been linked to changes in immune status.[2] [5] Despite being of obvious theoretic interest, however, the clinical significance of such changes is not always clear. The immunologic sequelae of psychosocial factors are typically small in magnitude and rarely result in any given immune parameter moving outside its normal range of values. Given the high degree of overlap within the immune system it is not always clear whether such alterations have any real clinical significance. Nevertheless, several well-conducted studies have noted that host susceptibility to infectious diseases, as well as the progression of these diseases can be affected by alterations in psychosocial status. In this chapter we review some of the more compelling examples of this evidence in humans and provide a brief description of the various pathways through which psychologic factors can exert their influence on physical health. Clinical features of the host, stress-inducing stimulus and pathogen that can moderate the impact of psychologic stress on disease status are also summarized, as are potential techniques for diagnosing, preventing and managing stress-related downregulations of immunocompetence.

EPIDEMIOLOGY

As noted, although a large body of work has confirmed that a multitude of psychologic processes have the potential to downregulate various aspects of the immune system,[3] much less evidence is available regarding the clinical significance of this for infectious diseases in man. Nevertheless, several important studies have revealed that psychosocial factors can alter host susceptibility and disease progression in acute viral infection, HIV infection, other latent viral infections and bacterial infection.[6]

Acute viral infections

Due to their relatively benign nature, acute viral infections such as common colds and influenza have proved popular paradigms for experimental studies examining the role of PNI in infectious diseases. Early research, although frequently suffering from methodologic drawbacks,[1] suggested that higher levels of emotional disturbance may predict longer convalescence from such infections.[7] These findings have been confirmed and extended by more recent research. Of particular note is the seminal work of Cohen, Tyrrell and Smith[8] who questioned 394 healthy volunteers about current and recent stress levels before exposing them via nasal droplets to one of five respiratory viruses. Patients were subsequently quarantined and closely monitored for 1 week. The results showed that pre-infection stress levels had a dose-response relationship to the risk of succumbing to a verified clinical infection, regardless of the specific virus examined. This finding has since been replicated for several more respiratory viruses using similar methodologies, with the additional finding that pre-infection stress levels also predict greater postinfection symptom severity (mucus secretion and self-reported symptoms).[8] Limited diversity in a participant's social network has also been shown to predict risk of infection, and extroverts appear to be less likely to develop clinical cold symptoms than more introverted participants.

Human immunodeficiency virus infection

The progression of HIV following initial infection remains relatively unpredictable and can only be partially explained by, for example, specific viral strain, demographics and lifestyle. This has resulted in speculation about the possible role of psychosocial variables in determining disease progression, and over 50 studies have now been published that examine this issue in some detail (see review by Cole and Kemeny).[9] These have typically failed to identify any significant effect of general negative life events or personality traits on immune status or clinical outcome in HIV-positive individuals, although some inconclusive evidence does exist to suggest that both bereavement and a general tendency to inhibit expression of significant thoughts or feelings may be associated with a decline in clinical and immunologic status. By contrast, highly specific aspects of an individual's emotional and cognitive response to personally important negative events have been reported to predict disease progression. For example, self-reproach or denial in response to bereavement or notification of HIV status have been shown to predict increased decline in $CD4^+$ T-cell levels and faster progression to AIDS in HIV-positive gay men, while 'finding meaning' in bereavement and demonstrating an active coping response to HIV are both associated with an attenuated decline in $CD4^+$ T-cell levels and slower disease progression.

Several studies have also reported that large social networks and high perceived social support may predict increased rate of $CD4^+$ T-cell decline and a higher risk of symptom onset in HIV-positive gay men.[9] This somewhat counter-intuitive finding possibly reflects the psychologic drain that an extensive social support network can represent for this population, particularly in terms of the need to provide care-giving for other HIV-positive individuals and the increased risk of bereavement. In line with this theory, results from nonhuman primate studies have demonstrated that although disruption of a stable social environment accelerates disease onset in Rhesus macaques inoculated with simian immunodeficiency virus (SIV), living within an unstable social hierarchy is also associated with significantly reduced survival times.[10]

Other latent viral infections

Numerous studies have found that episodes of stress are associated with an increase in antibody levels to latent viruses such as the herpes simplex viruses (HSV) and Epstein-Barr virus (EBV).[1] Rather than implying improved immunocompetence, such results are normally taken as indicative of a decreased capacity of the cellular arm of the immune system to control viral replication. In terms of the clinical significance of this phenomenon, there is some evidence that for genital and oral herpes, negative mood and low social support can significantly predict onset of disease recurrence.[6] Not all studies have confirmed these findings, however, and it is possible that the link between mood and disease recurrence may be at least partially mediated by an increased susceptibility to other minor infectious diseases such as common colds.

Psychosocial variables have also been reported to increase susceptibility to, and severity of, primary infection with latent viruses. For example, in a 4-year follow-up study of trainee army officers initially seronegative to EBV, high motivation to achieve, poor academic success and having an 'overachieving' father were found to be significant risk factors for seroconversion, clinical mononucleosis and longer hospitalization following clinical infection.[11]

Bacterial infections

Good quality research into the role of psychosocial variables in the development of bacterial infections is limited,[6] although the data available suggest that stress may well be an important risk factor. One early prospective cohort study[12] noted that higher stress levels significantly predicted the development of streptococcal pharyngitis, while in a second study[13] 'psychologically vulnerable' individuals were found to experience greater severity of illness (number of hours of fever and self-reported symptoms) following experimental inoculation with typhoidal-type tularemia than those defined as 'psychologically nonvulnerable'. More recently, depression has also been associated with altered bactericidal activity of leukocytes in children infected with *Staphylococcus aureus*. [14]

PATHOGENESIS

The major pathways through which psychosocial factors can affect the onset or course of an infectious disease are illustrated in Figure 95.1 . Perhaps the most obvious of these is via the increased exposure to pathogens that can result from stress-related changes in sexual behavior, for example, or interaction with one's social support network. Other behavioral changes common during stress, including increased smoking, higher caffeine and alcohol consumption, poor

Figure 95-1 Potential health effects of stress. Indirect (behavioral) and direct (neural and neuroendocrine) mechanisms through which psychologic distress can alter the onset and course of infectious disease.

diet and altered sleep patterns, can also alter the course of an infection through their own direct effects on various aspects of immunocompetence.[1]

Even carefully controlling for such behavioral pathways, however, several studies have demonstrated that psychosocial factors remain significantly associated with the onset or course of infectious diseases, suggesting that more direct, biologically based pathways also exist. Of these, the interactions between the CNS and the immune system are believed to be the most important.[3] The impact of the CNS on the immune system is principally mediated by changes in the activity of the hypothalamic-pituitary-adrenal (HPA) and sympathetic adrenal-medullary (SAM) axes. Activation of these systems as part of the stress response causes an upregulation in plasma levels of glucocorticoids and catecholamines, classes of immunomodulatory hormones capable of binding to cytoplasmic receptors on leukocytes and altering their functioning and distribution. Thus animals administered glucocorticoids following experimental inoculation with a pathogen typically demonstrate reduced resistance to infection,[6] while administration of adrenergic blockers to prevent catecholamines from binding to immune cells has been shown to reduce the effects of stress on the immune system.[15] As well as these hormonal pathways, direct innervation by the sympathetic nervous system of lymphoid organs such as the spleen is also known to exist, providing a further mechanism through which neuroimmunomodulation can occur.

In addition to affecting immunocompetence, it is possible that psychologic processes can also produce changes in an organism's anatomic and functional barriers to infection. For example, it has been suggested that the direct effects of stress on host susceptibility to respiratory viruses may be partly mediated by an alteration in the nasal mucosa, while stress-induced increases in glucocorticoid and catecholamine levels may help to protect female mice against bladder infection by increasing

vesical epithelial shedding.

Finally, another biologically based pathway between psychologic processes and infection has been highlighted in several in-vitro studies with reports that glucocorticoids can directly promote viral replication in latent viruses including HIV and EBV,[6] presumably through encouraging alterations in the genetic expression of these agents.

PREVENTION

A limited number of randomized controlled trials (RCTs) have investigated whether psychologically preparing an individual for an impending stressful event can help to buffer against resulting

immunologic dysregulation. Two RCTs examined this issue by training medical students in self-hypnosis/relaxation therapy and subsequently comparing the degree of immunologic changes that occurred in the run-up to stressful academic examinations in these groups with those in students randomized to no-treatment control groups. Disappointingly, although both interventions were found to significantly reduce the stress of sitting an examination, neither study was able to identify any major effect of the training on stress-induced immune changes. These results may partially reflect the nature of the stressor and samples that were used, however. Examination stress is normally relatively short-lived and tends to provoke transient immune changes that may be qualitatively different to those caused by more chronic stress (see Clinical features, below). Furthermore, it may be that a more severely distressed sample would have been more motivated to learn the techniques on offer and would have had more to gain through their effective use.

In an attempt to redress these issues, one RCT assessed whether group training in cognitive-behavioral stress management and progressive muscle relaxation had any benefit for asymptomatic gay men awaiting notification of their HIV serostatus. [16] Among men subsequently informed that they were HIV positive, the intervention package significantly reduced post-notification distress and enhanced some immunologic markers including $CD4^+$ T-cell and natural killer (NK) cell counts in comparison to an assessment-only control group. A 2-year follow-up to this study further revealed that men who took part in the intervention continued to show reduced declines in $CD4^+$ T-cell counts over this period and were less likely to have progressed to AIDS. Well-structured interventions for people awaiting highly stressful events may thus have good justification from a clinical point of view, although further research is still required in this area.

CLINICAL FEATURES

Certain important features of potentially stressful situations, or 'stressors', have been identified that increase the likelihood that the stressor will provoke immunologic dysregulation. Attempts have also been made to identify what differentiates people who are likely to suffer immunocompromise as a result of stress from those who are not.[17] Finally, it would appear that even when a particular stress-related alteration of the immune system is apparent, its clinical significance is likely to be determined by various characteristics of the infectious pathogen under consideration.[6] Thus clinical features

TABLE 95-1 -- Aspects of the stressor, host and pathogen that may alter the clinical significance of a stressful event.

ASPECTS OF THE STRESSOR, HOST AND PATHOGEN THAT MAY ALTER THE CLINICAL SIGNIFICANCE OF A STRESSFUL EVENT	
Stressor	Appraisal of stressor and own resources
	Acute vs. chronic stressor
	Severity
	Perceived predictability
	Perceived controllability
Host	Age?
	Race?
	Culture?
	Sex?
	Personality
	Coping style
	Availability and quality of social support
	Pre-existing stress levels
Pathogen	Virulence

of the stressor, host and pathogen may all be important in determining whether psychosocial factors play a role in the course or onset of any particular infectious disease (Table 95.1).

Stressors

Stress is a fundamentally subjective phenomenon and it is possible for an experience that one person finds highly traumatic to represent a relatively mundane matter for someone else. Rather than being intrinsic to any specific situation or event, the experience of stress is instead determined by an individual's own cognitive appraisal of the stressor and their beliefs regarding their ability to cope with it.[4] Hence, changing the way we think about a situation and the resources we have available to us can frequently transform a highly stressful occurrence into something much more benign, a fact that has clear implications for our immunologic response to the stimulus.

Having said this, certain stressor characteristics do appear to increase the likelihood that they will elicit dysregulation of the immune system as well as influencing both the quantitative and qualitative nature of this response. The duration of the stressor is one such determinant. Acute stressors, such as public speaking, anticipation of a mild electric shock or sitting an important examination, typically elicit transient immune activation, including temporary upregulation of NK-cell numbers and function, increased $CD8^+$ T-cell numbers and, more uncertainly, decreased T-helper and B-cell numbers.[3] In contrast, chronic stressors, such as caring for a relative or partner with Alzheimer's disease, divorce or bereavement, are more likely to lead to downregulated immunity (e.g. reduced T-cell numbers, decreased number and function of NK cells and decreased proliferative response to mitogens).[3] This acute/chronic distinction almost certainly has important implications for the clinical significance of a stressor, and it is typically chronic stressors that have been linked to altered health outcomes in the literature. For example, a clear dose-response relationship would appear to exist between the duration of a previous stressful life event and the risk of developing a common cold following experimental inoculation.[8]

Unsurprisingly, a similar relationship also seems to exist between stressor severity and the likelihood of a clinically relevant alteration in immunocompetence, with stressors causing greater psychosocial turmoil resulting in increased chance of infection.[2]

The perceived controllability and predictability of a stressor are further characteristics that may partially determine an individual's immunologic response. Numerous laboratory studies have demonstrated that biologic and emotional reactions to a stressor are reduced when, for example, a buzzer is sounded before the onset of an unpleasant stimulus or participants are able to terminate the stressor by pressing a button. Immunologic responses seem to obey similar rules. Thus, although exposure to an apparently uncontrollable acute stressor may decrease NK cell activity, the same level of exposure to a stressor that is perceived as controllable does not. [18] Similarly, presenting a warning noise before inescapable footshocks attenuates decrements in lymphocyte reactivity in rats. By necessity, studies investigating these issues have typically used short-lived and somewhat artificial stressors. How these factors affect chronic stress and what their clinical implications may be in such settings therefore remain unclear.

Hosts

Unfortunately, the study of how individual differences affect the immune response to stress has been somewhat neglected in the PNI literature. Little is known about how age, race or culture might affect immunologic responses, for example, although it is conceivable that all three may be important moderators of the pathways linking

stress to infection.[3] Similarly, although some evidence exists to suggest that the immunologic response to stress in humans may be accentuated

by female sex hormones,[3] more research is required before any firm conclusions can be drawn regarding the importance of gender in this context.

In contrast, the role of personality traits and coping styles as moderators of the CNS-immune system interactions have received a greater degree of attention. Both clearly play an important role in shaping our appraisal of potential stressors and our cognitive and emotional reactions to stress, and accordingly there is some evidence to suggest that these variables can affect an individual's immunologic response to stress as well as having an impact on the immune system in their own right. For example, individuals who scored highly on measures of trait worrying were found to show a far greater decline in peripheral blood levels of NK cells following an earthquake than low worriers, a difference that persisted for 4 months after the event.[19] Similarly, higher levels of trait hostility have been found to predict larger increases in NK cell cytotoxicity following a brief social confrontation, while optimism appears to predispose individuals to greater decreases in NK-cell activity following more prolonged exposure to a stressor.[17] In terms of coping style, repressive and escape-avoidance coping when faced with stress have both been associated with decreased immunocompetence, although denial has been found to have some protective effects for gay men awaiting notification of HIV status.[2]

There is some evidence that individuals with more good quality social support available to them may be at less risk of suffering clinically significant immune changes as a result of stress than those with less support. For example, high-quality social support has been linked to a low incidence of oral herpes recurrence, reduced susceptibility to common colds and attenuated SIV progression in monkeys, [6] although it is not always clear whether this is due to social support acting as a buffer against stress having some direct effect independent of the presence of a stressor, or a combination of the two.

Finally, several studies have noted that high baseline levels of stress may predispose individuals to increased reactivity in response to a novel stressor, predicting greater declines in NK-cell function following a stressful mental arithmetic task,[20] for example. Individuals already suffering from high levels of chronic stress may therefore be most at risk of succumbing to an infection following a new stressful event.

Pathogens

Whether immune dysregulation as a result of stress is likely to alter infectious disease processes in other animals is partly dependent on the specific species and strain of the pathogen.[6] For instance, whilst high levels of stress may increase mortality rates in mice infected with a mildly virulent strain of *Staphylococcus aureus,* it does not appear to have the same effect in those exposed to a highly virulent strain.[21] Similar factors are likely to be important in determining the clinical significance of stress in humans.

DIAGNOSIS

No diagnostic test exists for assessing whether psychologic factors are affecting the course of a patient's infectious disease. However, where a full psychosocial assessment of the patient reveals that stress or negative mood is a problem, these deserve to be treated in their own right. Useful tools for measuring negative affect in the context of physical illness include the 12-item general health questionnaire[22] and the perceived stress scale. [23]

MANAGEMENT

The potential for psychologic interventions to modify the human immune response, and hence the potential for them to prove clinically useful in the management of infectious diseases have been examined in over 85 published studies and been the subject of an excellent review and meta-analysis by Miller and Cohen. [24] They characterized this literature as assessing five basic approaches to 'psychoimmunotherapy':

- stress management,
- relaxation,
- disclosure,
- hypnosis with immune suggestion, and
- classical conditioning.

The possible clinical usefulness of these are outlined below, together with the role that pharmacologic interventions may have in reducing dysregulation of the immune system due to stress or depression. Clearly, other psychologic approaches that do not rely on psychoneuroimmunomodulation but instead seek to reduce the risk of infection or alter the course of disease by encouraging health behaviors such as dental hygiene or adherence to drug regimen are also possible and can be highly effective, but fall beyond the scope of this chapter.

Stress management and relaxation

Stress management interventions typically attempt to reduce the distress associated with an event or illness by employing a complex therapeutic package consisting of any of a number of components including:

- education about a particular illness;
- cognitive therapy aimed at identifying and reducing cognitive distortions and automatic thoughts;
- anger management training;
- coping skills training; and
- help in identifying sources of social support.

Relaxation interventions tend to be slightly more straightforward and normally provide training in one of several techniques such as progressive muscle relaxation, biofeedback-assisted relaxation or relaxation-focused self-hypnosis.

By altering the recipient's cognitive appraisals of a stressor and of their ability to cope with it or by altering their emotional response to a stressor, these types of intervention certainly have the prima facie potential to reduce immunologic dysregulation, particularly in people suffering from chronic stress. In practice, however, they have usually been tested on individuals suffering from chronic illness, a fact that can make interpretation of the results difficult: chronic illness does not necessarily equate to chronic stress and many people are able to adapt to their condition and often retain or even exceed their pre-morbid quality of life.[24] Despite this caveat, however, several studies have identified positive effects of both stress management and relaxation therapies in individuals living with HIV,[9] with interventions such as bereavement-specific and generalized stress management programs, and progressive muscle relaxation showing the capacity to attenuate declines in $CD4^+$ T-cell levels.[9] These results are by no means universal for this population, however, and more work is required to identify which characteristics of the interventions or recipients might alter the therapeutic potential of such techniques.

Stress management and relaxation approaches may also be effective in other chronic infections and there are indications that they might be useful in the treatment of herpetic recurrences[25] and recurrent childhood upper respiratory tract infections[26] in particular.

Disclosure

Disclosure interventions require the patient to reveal traumatic events from earlier in their lives that had not previously been extensively discussed with anybody else. This normally takes the form of writing or speaking about the event for short periods (e.g.

15–20 minutes) over the course of a week and is believed to be able to affect the immune system by altering the individual's cognitive appraisal of the traumatic event and instilling an improved sense of personal control. Thus, one major RCT on the PNI effects of this intervention identified a significantly greater immunologic response to hepatitis B vaccination following 4 days of writing about a traumatic topic when compared to writing about an innocuous topic.[27] Disclosure has also been found to reduce EBV antibody titers, suggesting that it may have some clinical usefulness for herpes recurrences and HIV infection.

Hypnosis with immune suggestion

Hypnosis incorporating suggestions about immunomodulation has been attempted by several authors with varying degrees of success.[24] Reliable increases have been reported in salivary immunoglobulin A levels and neutrophil adherence following this technique, suggesting that it may have some clinical usefulness. In particular, there have been some interesting demonstrations of the efficacy of hypnosis in the treatment of warts and recurrent herpes.[6] [28] The precise mechanism through which hypnosis can affect the immune system remains unclear, however, and further work is required in this area.

Classical conditioning

A large body of research has confirmed that the immune system is receptive to classical conditioning such that after pairing an initially non-immunomodulatory stimulus such as saccharin-flavored water (the conditioned stimulus) with administration of an immunosuppressant drug (the unconditioned stimulus), subsequent presentation of the conditioned stimulus by itself is sufficient to cause downregulation of the immune system.[29] Upregulation through classical conditioning has also been demonstrated in humans, with upregulated NK-cell function, for example, having been elicited by a sweet flavoring that had previously been paired with an epinephrine (adrenaline) injection. The therapeutic effects of immunomodulatory conditioning have yet to be properly explored within the context of infectious diseases, however, although this approach may eventually prove useful as an adjunct to conventional therapy in the treatment of HIV infection.

Pharmacologic treatments

Benzodiazepines have the potential to attenuate negative mood and may be useful in patients in whom high levels of stress may be affecting the course of their infection. The immunomodulatory effects of benzodiazepines depend upon the specific molecule and dose used, however, and alter according to the immune parameters under consideration.[3] The effects of antidepressants are similarly inconsistent, and treatment of depression in HIV-positive patients using sertraline, imipramine or fluoxetine does not appear to affect $CD4^+$ T-cell levels.[9] Further research is required into the precise immunologic effects of these drugs before any recommendations can be made regarding their use in patients who have infectious diseases.

Chapter 96 - Practice Points

96.a Management of candiduria in the intensive care unit

Shiranee Sriskandan

Introduction

Candiduria can be defined as the presence of greater than 10^5 fungal cfu/ml urine, though as little as 10^3 cfu/ml can result in disease in certain 'at-risk' groups. The prevalence of candiduria varies between 6.5% and 20% amongst hospitalized patients and presents a dilemma to clinicians, who must decide if the finding represents colonization alone or is a feature of invasive fungal infection. Probably only 3–4% of cases of candiduria lead to candidemia, but 10% of all cases of candidemia are associated with a prior episode of candiduria. Indeed, studies based in the intensive care unit (ICU) have shown that candiduria can be associated with a rise in mortality from 19% to 50%.

Pathogenesis

Candiduria can arise in several ways: simple contamination of specimens at the time of procurement can account for many such cases, hence the need for a confirmatory second specimen. Colonization of the urinary tract may occur in the catheterized patient. Local infection of both the lower urinary tract (cystitis, urethritis) and upper tract (pyelonephritis) with *Candida* spp. is encouraged by urological instrumentation, in particular catheterization. Other factors predisposing to such infections include ongoing broad-spectrum antibiotic therapy, diabetes mellitus, renal insufficiency and anatomic anomalies of the urinary tract. finally, patients with disseminated candidiasis may seed the urinary tract from bloodstream spread (Table 96a.1).

Microbiology

The majority (50–70%) of *Candida* isolates from urine in the ICU are *C. albicans*, which is sensitive to fluconazole. Indeed, provided that patients have not previously been exposed to fluconazole, it is reasonable to assume that any germ tube-positive yeast will be sensitive to fluconazole. However, increasing numbers of yeasts other than *C. albicans* occur in the ICU setting and the prevalence varies between units. In particular, *C tropicalis* and *C glabrata* account for 10–20% of such isolates, the latter species being notable for its resistance to azole drugs.

Clinical features

Candiduria alone does not cause symptoms; local infection can cause classic cystitis or urethritis and pyelonephritis may lead to flank pain. Patients who have candiduria as a feature of disseminated candidiasis may have evidence of systemic candidal disease, which should be assiduously checked for: clinical features include sepsis, fever, lesions of the optic fundi, skin lesions and hepatosplenomegaly.

Investigations

From Table 96a.1 , it is clear that a repeat fresh urine sample must be sent to the microbiology laboratory to confirm candiduria. Microscopy for the presence of white blood cells may be useful in differentiating colonization from urinary tract infection, but the finding can be nonspecific in a catheterized patient; the presence of granular casts containing hyphae is a rare finding which would confirm true renal infection. If the patient has not been catheterized or had

TABLE 96.a-1 -- Etiology of candiduria and laboratory investigation.

ETIOLOGY OF CANDIDURIA AND LABORATORY INVESTIGATION	
Source of candiduria	**Laboratory investigations**
Inadvertent contamination	Repeat sample: clear
Colonization of lower tract	No WBCs in urine, patient well
Infection of lower tract	WBCs in urine
	Ultrasound if not instrumented
	Screen for diabetes, renal disease
Infection of upper tract	WBCs + casts in urine
	Ultrasound
	Screen for diabetes, renal disease
Disseminated *Candida* infection	Blood cultures/other sterile site: positive for *Candida*
	CXR, abdominal ultrasound
	High CRP

TABLE 96.a-2 -- Management of candiduria in the ICU.

MANAGEMENT OF CANDIDURIA IN THE ICU		
Suspected cause of candiduria	**Action**	**Additional considerations**
Contamination	None	-
Colonization	No antifungal	If patient is at risk of infection, e.g. neutropenia or undergoing urological procedure, fluconazole 200mg/day for 7–14 days
	Remove/replace catheter	
	Stop antibacterials if possible	
Lower UTI	Fluconazole 200mg/day for 7–14 days if *C. albicans*	
Upper UTI	Fluconazole 6mg/kg/day for 2–6 weeks if *C. albicans*	Surgical drainage may be needed.
		Amphotericin B if patient unstable or if non-*albicans*

Disseminated infection likely	Fluconazole 6–12mg/kg/day (if *C. albicans*) *or* amphotericin B 0.7–1.0mg/kg/day, depending on severity, for at least 2–6 weeks	If dissemination confirmed: follow up for at least 3–6 months after discharge from ICU in case of distant seeding Use of lipid formulations of amphotericin B necessitates doses of 3–5mg/kg/day

urological instrumentation recently, it is prudent to screen for diabetes mellitus and renal insufficiency by biochemical testing, and anatomic anomalies using ultrasound. Ultrasound of the renal tract can also demonstrate the presence of fungal balls in patients who have persistent candiduria. Simple tests to screen for the possibility of disseminated candidiasis would include a chest X-ray, abdominal ultrasound, C-reactive protein, cultures of other potentially infected sites (e.g. tracheal aspirate or bronchial lavage, bile, surgical drains, intravascular line tips) and blood cultures.

Management

The modern management of candiduria in the ICU setting is determined by the likely source of fungi (see Table 96a.2). It is clear that colonization can be treated by simply replacing the urinary catheter or, better, permanent removal. In all cases, rational reduction in the spectrum of antibacterial agents administered to patients will help eliminate fungal colonization and infection. These simple measures allow up to 40% of patients with candiduria to clear fungi from the urine. True infection of the urinary tract should be treated with a definitive course of an antifungal, usually fluconazole, in addition to catheter removal or exchange. Fluconazole can be administered intravenously in the ICU or via the nasogastric tube in the oral form, if the patient's gastrointestinal system is functioning. Infection with germ tube-negative *Candida* spp. (other than *C. albicans*) may require intravenous amphotericin B. There is no clear case for local intermittent or continuous bladder irrigation with amphotericin B; the procedure necessitates instrumentation of the urinary tract which might otherwise be unnecessary. Furthermore, although local irrigation with amphotericin B can achieve prompt clearance of funguria, the effect is short-lived compared with clearance rates achieved by fluconazole.

Finally, the candiduric patient who may have invasive fungal infection warrants more aggressive antifungal therapy. This must be based on careful assessment of combined clinical and laboratory findings. If *C. albicans* is isolated and the patient is stable, it is reasonable to treat with high-dose fluconazole for 2–6 weeks (400–800mg/day for a 70kg adult). However, if the same patient is clinically unstable or if the isolate is non-*albicans*, it would be prudent to treat with amphotericin B, as indicated in Table 96a.2 or with one of the newer agents such as voriconazole or caspofungin, although they have not yet been formally evaluated in this setting (see Chapter 208). The appropriate duration of therapy in this setting is unclear and must be determined according to the individual clinical situation and response to therapy.

96.b Management of fever that relapses and remits

Nicholas Price

The patient who has recurrent febrile episodes commonly presents a particularly difficult diagnostic challenge. In addition to the classic criteria for fever of unknown origin (FUO; Chapter 82), Knockaert *et al.* have defined 'recurrent' FUO as repeated febrile episodes with fever-free intervals of at least 2 weeks. The number of relapses or overall duration was not specified but, in practice, the clinical course is typically protracted. One limitation of this definition is that several important infectious diseases that are characteristically associated with a recurrent fever pattern are excluded. However, a clear definition and strict adherence to defining criteria are helpful because they focus the diagnostic approach and are essential for meaningful comparative studies.

Causes

Infections, malignancy and multisystem inflammatory diseases are responsible for 60–70% of cases of classic FUO. If recurrent FUO is

TABLE 96.b-1 -- Causes of recurrent fever of unknown origin.*

CAUSES OF RECURRENT FEVER OF UNKNOWN ORIGIN
Infectious diseases
Focal bacterial infection (e.g. chronic prostatitis, subacute cholangitis)
Q fever endocarditis (*Coxiella burnetti*)
Rat-bite fever (*Spirillum minor, Streptobacillus moniliformis*)
Relapsing fever (*Borrelia recurrentis, Borrelia duttoni*)
Trypanosomiasis (*Trypanosoma gambiense, Trypanosoma rhodesiense*)
Whipple's disease (*Tropheryma whippelii*)
Yersiniosis (*Yersinia pseudotuberculosis, Yersinia enterocolitica*)
Multisystem diseases
Connective tissue diseases and vasculitides:
Churg-Strauss disease
Giant cell arteritis
Polymyalgia rheumatica
Mixed connective tissue disease
Polyarteritis nodosa
Systemic lupus erythematosus
Wegener's granulomatosis
Rheumatologic diseases:
Ankylosing spondylitis
Relapsing polychondritis
Rheumatoid disease
Still's disease
Inflammatory diseases:
Sarcoidosis
Neoplasia
Atrial myxoma
Colonic carcinoma
Lymphoma
Miscellaneous conditions
Castleman's disease
Cholesterol embolism
Crohn's disease
Cyclic neutropenia
Drug fever
Extrinsic allergic alveolitis
Factitious fever
Familial Mediterranean fever, familial Hibernian fever
Fume fever, hypersensitivity pneumonitis
Gaucher's disease, Fabry's disease
Hyper-IgD syndrome
Hypertriglyceridemia (type IV)
Mollaret's menigitis
Seizures ('thermal epilepsy')
Sweet's syndrome
The more common causes are indicated in bold type.

** Adapted from Knockaert et al., 1993.*

considered as a subset of classic FUO, these three causes account for only 20% of the cases; 50% go undiagnosed and a collection of diverse 'miscellaneous' conditions forms the largest subgroup (Fig. 14.6). Patients who have recurrent febrile episodes that persist for more than two years rarely have infections or malignant disorders.

Infectious causes

A silent focus of bacterial infection is the most common infectious cause that should be considered, rather than any of the limited number of specific infections listed (Table 96b.1). Other infections on the list of differential diagnoses that present with a relapsing and remitting fever pattern, which may not fulfill the stringent criteria for

Figure 96.b-1 Characteristic evanescent rash of Still's disease.

recurrent FUO, include malaria, brucellosis, secondary syphilis, tuberculosis, trench fever (caused by *Bartonella quintana*), filariasis and visceral leishmaniasis. However, it is important to note that malaria does not always produce the classic 'quartan' or 'tertian' fever patterns since parasites may mature asynchronously.

Neoplastic causes

Many malignancies can cause FUO; however, those listed (Table 96b.1) have been specifically reported as causing recurrent FUO.

Multisystem disease

All vasculitides or connective tissue diseases can flare up suddenly and remit spontaneously, producing a recurrent fever. Still's disease is a seronegative arthritis of unknown etiology; it is essentially a diagnosis of exclusion. The diagnosis should be strongly suspected in a young adult who has the classic triad of high fever above 104°F (40°C), evanescent rash (Fig. 96b.1) and arthritis (particularly if pharyngitis is also reported).

Miscellaneous causes

Familial Mediterranean fever is a clinical diagnosis characterized by recurrent polyserositis but a molecular diagnosis may also be established by identifying mutations of the pyrin gene (*MEFV*), located on the short arm of chromosome 16. Similar to familial Mediterranean fever, 'hyper-IgD syndrome' is an autosomal recessive inherited disorder that has been described in European families and was recently linked to a locus on chromosome 12. Patients characteristically have elevated IgD levels, and cervical lymphadenopathy and abdominal pain are prominent clinical features. Tumor necrosis factor (TNF)-receptor-associated periodic syndrome (TRAPS) is another rare hereditary condition, first described in a large Irish family and originally called familial Hibernian fever. Affected individuals are thought to be unable to neutralize TNF because serum levels of soluble type 1 TNF receptor are typically low. Inheritance is autosomal dominant and common features are localized myalgia and conjunctivitis.

Crohn's disease is an important cause of recurrent FUO and may present with weight loss, fever and anemia without any gastrointestinal symptoms. Castleman's disease (angiofollicular lymph node hyperplasia) may present with focal mediastinal or generalized lymphadenopathy. The localized type occurs in young adults and is curable by surgery. The generalized form affects older patients, has a less benign prognosis and may undergo malignant transformation. Sweet's syndrome is characterized by a painful neutrophilic dermatosis and is

Figure 96.b-2 Clinical features associated with recurrent fever of unknown origin. SLE, systemic lupus erythematosus; FMF, familial Mediterranean fever.

associated with joint pains and malignancy. Very rarely, epileptic seizures may produce periodic febrile confusion.

'Idiopathic granulomatosis' and 'granulomatous hepatitis' should not be readily accepted as final diagnoses because it is likely that they encompass a variety of different underlying conditions, which may be revealed during careful long-term follow-up.

Clinical assessment

As for any FUO, a detailed history and thorough clinical examination are paramount and repeated assessments are often necessary. Associated clinical features are illustrated in Figure 96b.2 . In general, the pattern of the fever is seldom of diagnostic value but a notable exception is cyclic neutropenia, which has a classical 'periodic' fever pattern that reoccurs predictably after every 21 days. In addition, high fevers recurring at fixed intervals of 2–8 weeks are characteristic of the rare 'PFAPA' (*p*eriodic *f*ever, *a*phthous stomatitis, *p*haryngitis and cervical *a*denitis syndrome) that has recently been described in children.

Hereditary causes of recurrent FUO almost always present before 20 years of age, and febrile attacks start in the first year of life in hyper-IgD syndrome. In addition, a detailed family history and inquiry about racial background is particularly important in the evaluation of these inherited conditions. A thorough travel history should be obtained and in the tropical traveler the risk of disease transmission by insect vectors should be assessed by asking about visits to game parks, accommodation (camping, downmarket hotels, log cabins) and protective measures such as bed nets. A bite from a tsetse fly (vector in African trypanosomiasis) is often memorably painful and leaves an indurated lesion for days. In contrast, the bite in tick-borne relapsing fever is characteristically painless. Specific enquiry should also be made about consumption of unpasteurized milk (a cause of brucellosis), occupational exposure (e.g. fume fever), animal contact (e.g. rat-bite fever, Q fever, psittacosis), previous medical conditions (e.g. episodes of cholecystitis) and drug treatment (especially if taken intermittently). Repeated attacks of fever may also represent a relapse of a pre-existing infection, particularly if treatment fails or is discontinued. Treatment compliance or antimicrobial resistance may therefore need to be addressed.

Investigations

The investigative work up is the same as for classic FUO (Chapter 82). Because the range of potential underling causes is so diverse, no comprehensive diagnostic algorithms exist.

Hematologic indices occasionally provide useful clues but are not always reliable (e.g. eosinophilia may indicate lymphoma, Churg-Strauss disease, drug reaction or parasitic infection). In addition to malaria, the causative organisms in relapsing fever and trypanosomiasis may be visualized on a thick blood film taken during a febrile episode. A moderately elevated acute phase response is not remarkable in itself, although it does exclude factitious fever. However, in some conditions, inflammatory indices are exceptionally high: an erythrocyte sedimentation rate above 100mm/h is seen in drug fever, malignancy, giant-cell arteritis and Still's disease. Serum ferritin is nonspecifically elevated in inflammatory conditions, but extremely high levels (>1000mg/l) are also typical in Still's disease and a raised serum angiotensin converting

enzyme may indicate a granulomatous disorder. Although there may be a polyclonal increase in immunoglobulins, hyper-IgD syndrome is diagnosed by characteristic clinical findings and continuously high IgD levels (>100U/ml). Serologic and immunologic tests should be done as appropriate but, as in classic FUO, they are often unrewarding unless these are suspected to yield significant results beforehand.

Radioisotope-labeled white cell imaging may be useful in identifying occult foci of infection but often does not contribute more than computed tomography scanning of abdomen/ pelvis and chest. Magnetic resonance imaging is valuable when bone infection is suspected. There should be a low threshold for investigating the gastrointestinal tract (e.g. by endoscopy, small bowel transit study or barium enema) in order to look for inflammatory bowel disease and malignancy. In an elderly patient who has a very elevated erythrocyte sedimentation rate, temporal artery biopsy may be useful diagnostically where there is no prior localizing information.

General approach

Because the cause of recurrent FUO is generally not life threatening, if no clues are provided by diagnostic tests, a 'watch-and-wait' strategy can often be adopted. Periodic outpatient assessment is likely to reveal significant pathology in time and many of the undiagnosed cases may resolve spontaneously. It is useful to ask patients to record their own temperature using a digital thermometer and to keep a symptom diary. In order to make a more valuable clinical assessment it is often helpful to ask patients to come up to the hospital immediately when they become unwell or pyrexial.

In general, empiric trials of antibiotic or anti-inflammatory therapy as diagnostic tests are inadvisable. However, if empiric treatment is felt to be absolutely necessary, a full course should be prescribed so that complications arising from inadequate therapy are avoided. In the future, genetic studies will probably identify other rare causes of recurrent FUO that persist and are presently undiagnosed.

96.c Infections associated with near drowning

Alastair Miller

It is thought that about 100 million North Americans use the marine environment for recreation each year. This leads to an estimated 8000 deaths from drowning per annum in the USA and at least 150,000 deaths worldwide. The epidemiology of 'near drowning' is less well known and estimates vary between two and 20 times the deaths from drowning. Drowning implies death due to cerebral hypoxia as a result of immersion in water. In the majority of cases water is aspirated into pulmonary air spaces. This produces a variety of pathologies depending on whether fresh or sea water is inhaled, but the end result is alveolar dysfunction, causing venous blood to be shunted into the systemic circulation past underventilated alveoli to cause hypoxemia. In a minority of cases hypoxemia can result from apnea caused by several different mechanisms. Although 'near drowning' by definition means that the victim survives the initial hypoxic insult, a number of complications may then ensue, including pulmonary edema, convulsions and infective problems such as pneumonia or sepsis.

Pathogenesis

The majority of people who have near drowning episodes have aspirated either sea water or fresh water. The resulting lung damage produces inflammation and edema, which damage alveolar defense mechanisms and enhance the risk of infection. The relatively anaerobic conditions may also favor infection. Infecting organisms may include those already colonizing the lungs or upper airways, which have been carried distally with the aspiration and have then taken advantage of improved conditions for growth. Alternatively, organisms in the aspirated water may give rise to infective problems. Finally, an ill patient who has lung damage may be admitted to hospital (and to an intensive care unit) and therefore be exposed to all the risks of nosocomial pneumonia.

Microbiology

The literature on the microbiology of near drowning consists mainly of single case reports rather than large-scale reviews but some common themes do emerge. Organisms that have been implicated are shown in Table 96c.1 , and these can be divided into those that are characteristically associated with pneumonia (either community-acquired or nosocomial) and those that are more specifically associated with immersion incidents. Gram-negative organisms predominate in the aquatic environment (both sea water and fresh water) but anaerobic organisms and *Staphylococcus* spp. can also be found. There may be some organisms that are more likely depending on whether immersion took place in sea water or fresh water and depending on whether the water was clean or contaminated. Certain organisms may be more common in particular geographic areas. For example, one might anticipate exposure to *Burkholderia pseudomallei* following a near-drowning episode in the paddy fields of South East Asia (Chapter 175).

Several cases of infection with *Aeromonas* spp. exist in the literature and these are associated with a high proportion of positive blood cultures and a high mortality. Fungal infections can also cause problems and there are reports of *Aspergillus* pneumonia and disseminated aspergillosis after immersion incidents. *Pseudallescheria boydii* is also reported. Infection is commonly polymicrobial.

Clinical features

The clinical features of infection after near drowning are similar to those seen when the particular infection arises from more conventional causes and depend on the site of infection. The main complication is pneumonia (as might be predicted from the portal of entry) but there is often an associated bacteremia, which may produce clinical features of sepsis. There have also been case reports of meningitis after near drowning.

TABLE 96.c-1 -- Micro-organisms implicated in pneumonia or sepsis after near drowning.

MICRO-ORGANISMS IMPLICATED IN PNEUMONIA OR SEPSIS AFTER NEAR DROWNING
Conventional respiratory pathogens (including atypical organisms and those associated with nosocomial pneumonias)
Staphylococcus aureus
Haemophilus influenzae
Streptococcus pneumoniae
Escherichia coli
Pseudomonas spp.
Moraxella spp.
Klebsiella spp.
Legionella spp.
Pathogens specifically related to immersion
Aeromonas spp.
Pseudomonas putrefaciens
Francisella philomiragia
Chromobacterium violaceum
Burkholderia pseudomallei
Vibrio spp.
Pseudallescheria boydii
Aspergillus spp.

Noninfective pulmonary edema is a common complication of near drowning and can progress to full adult respiratory distress syndrome. Pulmonary edema can be difficult to distinguish clinically and radiographically from pneumonia. In one series of 125 near drowning episodes, the incidence of pulmonary edema was 43% whereas the incidence of pneumonia was 14.7%. These figures are sensitive to changes in case definition, and clearly many patients who initially have pulmonary edema may subsequently go on to develop pneumonia, which tends to be a later complication.

Most patients who have pneumonia have fever (although recognition of this may be confounded if there is any residual hypothermia from the immersion). They may have clinical features of pulmonary consolidation or edema, or both.

Investigations

Near-drowning victims should have a chest radiograph on admission and this may well be clear or show nonspecific shadowing. They should also have a full blood count and arterial blood gas analysis. It is unlikely that an asymptomatic patient who has normal arterial blood gases and chest radiograph will develop any pulmonary complications. Leukocytosis is usual in patients who have pneumonia but is not specific for infection.

Pulmonary secretions must be examined microbiologically; these may include expectorated sputum or tracheal aspirates in intubated patients. There may be pus cells in the samples and it is common to find infecting micro-organisms by stain and by subsequent culture. Blood cultures must always be taken because there is a high rate of bacteremia. Empyema may develop later in the natural history, necessitating pleural aspiration.

Management

Patients who have survived a near drowning episode require emergency evaluation to determine whether they are at risk of subsequent delayed complications. If they are asymptomatic, with no abnormalities on physical examination and with a normal chest

radiograph, arterial blood gases and full blood count, they can be safely discharged because they are at low risk of pulmonary problems. However, any abnormality on this initial evaluation should prompt hospital admission for observation. The level of monitoring required depends on the clinical status and may include serial arterial blood gas analysis or oxygen saturation monitoring, serial full blood counts and chest radiographs in addition to frequent clinical evaluation.

If hypoxemia is present, supplemental oxygen should be given. If this does not correct the situation, it may be necessary to admit the patient to an intensive care unit for further respiratory support.

In common with many other intensive care situations, there used to be a widespread practice of administering glucocorticoids to patients who had undergone aspiration. There has never been evidence of benefit in near-drowning incidents and this practice is not recommended.

Antibiotics

Prophylactic antibiotics have been shown of no benefit in at least one study and their use is not recommended. However, there should be a low threshold for instituting antimicrobial therapy if there is any suspicion of developing pneumonia or sepsis (Table 96c.2). Features giving rise to concern include deteriorating arterial blood gases, new infiltrates on chest radiograph, hemodynamic disturbance or the development of fever or leukocytosis. It is likely that antibiotics will have to commence before any microbiologic information is available from the laboratory (although initial Gram stains may be helpful). Therefore, broad-spectrum empiric cover with good pulmonary penetration is indicated.

Numerous antibiotics have been used, including aminoglycosides, monobactams, carbapenems, cephalosporins and extended-spectrum penicillins (with and without ß-lactamase inhibitors). There are no large-scale trials to guide rational therapy. I suggest the use of clindamycin, which has good penetration and will provide good Gram-positive cover as well as treating anaerobic infection. This should be combined with ciprofloxacin to cover the Gram-negative organisms and also provide some cover against *Legionella* spp. Other reasonable combinations would be ticarcillin-clavulanate with gentamicin and ceftazidime with metronidazole, although neither of these two regimens offers cover against *Legionella* spp. Clearly the

TABLE 96.c-2 -- Antibiotic regimens for pneumonia and sepsis associated with near drowning.

ANTIBIOTIC REGIMENS FOR PNEUMONIA AND SEPSIS ASSOCIATED WITH NEAR DROWNING	
Dose for average adult patient	
Clindamycin	900mg q8h
Ciprofloxacin	400mg q12h
Ticarcillin-clavulanate	3g q6h
Gentamicin	5mg/kg/day
Ceftazidime	2g q8h
Metronidazole	500mg q8h
All these antibiotics are administered intravenously.	

initial regimen may need to be modified in the light of subsequent information from the microbiology laboratory, but it is important to remember that polymicrobial infection is common. If there is no adequate response, it may be necessary to consider the use of antifungal treatment.

96.d Initial management of a suspected outbreak of smallpox

Andrew W Artenstein

Introduction

Smallpox, the human disease caused by infection with variola virus, was a worldwide scourge for thousands of years, recognized from the inception of recorded history. The disease accounted for more deaths than any other epidemic disease in history, and its impact on the course of human civilizations has been extensive and well documented. Following an intensive campaign from 1966–77 by the World Health Organization (WHO), smallpox was certified as 'eradicated' from the world in 1980, although viral stocks were officially deposited in the former Soviet Union and at the CDC in Atlanta. There have been persistent concerns about the availability of these stocks outside of their presumed secure internment.

The clinical occurrence of even a single case of smallpox would be pathognomonic for bioterrorism because natural disease no longer occurs and there is no known animal reservoir for the virus. The intentional re-introduction of variola virus would be an international public health crisis of massive proportions for the following reasons:

¦ case fatality rates were historically 25–30%;
¦ the virus is efficiently transmitted person to person among close contacts in an amplified fashion, with the potential for air-borne transmission over longer distances;
¦ most of the world's population are susceptible hosts, either because vaccination against smallpox ceased in most areas more than two decades ago or because of waning of previous vaccine-induced immunity; and
¦ vaccine supply is currently limited and there are no antivirals proven to be effective against this pathogen.

Clinical features

After an average incubation period of 10–12 days, a 2- or 3-day prodromal illness ensues characterized by the abrupt onset of high fevers, chills, malaise, prostration, headache, backache and vomiting. The temperature defervesces concurrent with the appearance of enanthema involving the oral mucous membranes and, a day later, by a macular rash that begins on the face and extremities and becomes papular over a 1–2-day period and subsequently vesicular over an additional 1–2 days, rapidly becoming generalized. All the lesions are generally present by day four of the eruption and evolve into umbilicated pustules over the next few days. The rash is typically centrifugal, not only in onset, but it remains denser peripherally than centrally (Fig. 96d.1) and involves the palms and soles Fig. 96d.2). Additionally, the lesions are typically synchronous (i.e. at similar stages of evolution and appearance). This distribution and appearance help to distinguish ordinary-type smallpox (variola major) from other eruptive illnesses (see Table 6.3 , Chapter 6).

The vesicles and pustules of smallpox are described as 'shotty', almost nodular, epidermal lesions. By the second week of the rash the lesions begin to crust and the scabs begin to separate, a process that is complete by day 21. The period of infectiousness

Figure 96.d-1 Typical centrifugal distribution of the rash in smallpox. *Courtesy CDC and Dr Paul B Dean.*

Figure 96.d-2 Patient with smallpox, Kosovo, Yugoslavia epidemic, March and April 1972. The scabs will eventually fall off leaving marks on the skin that will become pitted scars. The patient is contagious until all scabs have fallen off. *Courtesy CDC and Dr William Foege.*

extends from the onset of the enanthema to the complete separation of all scabs, although most transmission occurs during the first 7–10 days of illness, when virus is replicating to high titers in the oropharynx.

Variola major, 'ordinary' type of smallpox, traditionally accounted for nearly 90% of cases; the remaining cases during epidemics were generally distributed among a few different forms of the disease. 'Modified' type is a milder form more commonly noted in previously vaccinated individuals and less likely to be fatal. The malignant or 'flat' type of smallpox is characterized by the slow progression of flattened vesicular lesions that coalesce and is associated with death in the vast majority of cases. Historically, hemorrhagic smallpox accounted for less than 3% of cases but was associated with rapid progression to death in nearly 100%. Although pregnant women appear especially vulnerable to this form, it is likely that other forms of immune suppression may predispose to it. Both malignant and hemorrhagic smallpox pose difficult diagnostic dilemmas.

Diagnosis

The possible diagnosis of smallpox is suggested by clinical features and mandates the immediate institution of isolation procedures with contact and air-borne precautions and prompt notification of public health officials. The public health authorities will be essential in orchestrating an effective community-wide response to a smallpox outbreak. This will necessitate:

¦ coordination between hospitals and emergency personnel;
¦ prompt dissemination of vital health information for the public; and
¦ co-operation with military and law enforcement official investigations.

Epidemiologic information will be helpful in secondary cases or once a known outbreak is underway; however, early cases presenting before a bioterrorism event is recognized may be missed unless clinicians consider the diagnosis.

Recently immunized health care providers adhering to air-borne and contact precautions should obtain blood, aspirates from vesicular or pustular fluid and scrapings of crusts and skin lesions. This will generally require collaboration with public health officials because these specimens must be processed by designated laboratory facilities with high-level containment capabilities. Diagnostic assays for variola virus include electron microscopy, immunohistochemical analysis of viral antigens, or polymerase chain reaction for viral genetic sequences. Confirmation is obtained by viral isolation on chorioallantoic membranes.

Management

The initial management of a suspected case of smallpox involves immediate institution of appropriate infection control precautions, contact tracing, strategic deployment of pre- and post-exposure vaccine, and possibly the use of antiviral agents. A patient who has suspected smallpox must be placed in a negative-pressure respiratory isolation room. Contact and air-borne precautions are necessary; most transmission occurs between close contacts but in selected circumstances the virus is capable of longer distance dissemination via aerosol suspension. Standard N-95 masks (95% efficiency, small particle, filter masks used for prevention of

tuberculosis transmission) are widely available and useful to prevent transmission to health care workers.

If the number of suspected smallpox cases in an institution exceeds the number of negative-pressure rooms, cohorting may be necessary. In extraordinary circumstances portable high-efficiency particulate air filtration units with ultraviolet lights should be used. Overflow of patients in a massive outbreak will require coordination and assistance with the public health authorities.

Access to suspected smallpox cases should be limited. Clothing, linens and equipment in contact with the patient are considered to be contaminated and must be autoclaved or incinerated after use. Diagnostic specimens and body fluids must be collected and handled using rigorous biosafety precautions under the guidance of proper public health authorities.

Pre-exposure vaccination using live vaccinia virus is highly effective in inducing immunity against smallpox. Immunity after primary vaccination appears to wane after 5–10 years, a phenomenon also noted historically in those having experienced natural infection. There is, however, immunologic evidence that multiply revaccinated individuals maintain immunity for more than 30 years. In the event of confirmed or a highly suspected case(s) of smallpox, pre-exposure vaccination of healthcare and laboratory workers within an institution would be indicated.

Post-exposure immunization, using the ring vaccination and containment strategy, has shown proven effectiveness in controlling the spread of infection. Based on this strategy, persons exposed to an aerosol release of agent, those with face-to-face or household contact with an infected individual, or those caring for infected individuals should receive smallpox vaccine. Vaccination within 4 days of exposure may attenuate disease course, prevent death or prevent disease altogether.

Smallpox vaccination is generally contraindicated in immunocompromised individuals, pregnant women and those with eczema or other exfoliative skin disorders due to the high potential for complications. Additionally, vaccination is relatively contraindicated in close personal contacts of those in these risk groups. In the event of mass casualties related to bioterrorism the risks would need to be weighed against the potential benefits of vaccinating high-risk groups.

A number of serious complications have been described in association with smallpox vaccine. These include:

- postvaccinial encephalitis, a rare and potentially fatal neurologic syndrome;
- progressive vaccinia, a frequently fatal complication in immunocompromised recipients;
- generalized vaccinia, usually self-limited in primary vaccines;
- eczema vaccinatum, a severe dissemination of the vaccine virus in patients with active or previous eczema; and
- accidental infection, involving either auto-inoculation of virus from the skin lesion or transmission via close contact to household members.

A large, national survey reported at the end of the vaccine era in the USA noted 1254 complications and one fatality per million primary vaccines in 1968. These rates would likely be higher today given the increased prevalence of immunocompromising conditions and eczema. Vaccinia immune globulin (VIG), a preparation of pooled antibodies from hyperimmune individuals, is available in limited supply and may be beneficial in the management of selected vaccine complications.

Specific treatment of patients with smallpox involves:

- supportive care:
- the administration of fluids;
- adequate nutrition; and
- possibly systemic antimicrobial agents to treat secondary bacterial infections that may occur with the disruption in skin or mucosal integrity.

Recent data have demonstrated that cidofovir, currently licensed for the treatment of cytomegalovirus infections in humans, protects animals from lethal aerosol challenges with related orthopoxviruses. Despite the absence of direct efficacy data in humans, the use of this agent to treat smallpox should be considered an experimental option. VIG has no proven efficacy in the management of smallpox.

Conclusion

The initial management of a suspected outbreak of smallpox involves controlling the spread of the infection among susceptible hosts. Central to this is the early recognition of disease, followed by the expeditious institution of isolation procedures and the rapid deployment of contact tracing with ring vaccination. The general approach of integrating clinical observations, epidemiologic investigation, preventive actions and treatment strategies in the management of an outbreak is applicable to a wide variety of pathogens.

96.e Prophylactic antibiotics for animal bites

Patricia Cristofaro

Annually, 1 to 2 million patients with animal bites are treated by US physicians; one out of every two people will be bitten in their lifetime. Wound infection is the most common complication. Other less frequent infectious complications include tenosynovitis, septic arthritis and osteomyelitis. Even more serious problems such as sepsis, meningitis, peritonitis and endophthalmitis result from severe penetrating and crushing injuries. Could any of these sequelae be prevented by prophylactic antibiotics and, if so, who should receive them, under what circumstances and which antibiotics? This practice point will discuss the use of prophylactic antibiotics in patients who have sustained cat, dog or human bites.

Given an accurate estimate of the potential for infection for each unique wound, one could calculate a risk:benefit ratio taking into account antibiotic toxicity/cost and setting a limit to treat when the risk of infection is greater than x%. Such precise data are not available. However, many experiential data and a number of prospective and randomized clinical studies as well as retrospective analyses have attempted to refine the concept of appropriate antibiotic use. Unfortunately, the use of antibiotics to prevent bite wound infection is so ingrained in current medical practice that this aspect of therapy can not be randomized. Wound decontamination, debridement and closure are also variables of clinical care that cannot be adequately controlled. Nonetheless, the following opinions represent a reasonable consensus of current information and practice.

Antibiotic prophylaxis is considered reasonable if the risk of infection is 5–10%. Dog bite wounds carry reported infection rates from 1.6% to 30%; cat bite wounds 15.6–50%; and human bite wounds 10–20% (although these infections may be quite severe due to location and microbiology). For comparison, simple lacerations seen in the emergency room carry an infection rate of 4.5–15.1%. Toxicity outside of frank allergy is unlikely to be significant from a 3–5 day course of oral antibiotics. That stated, how can these wounds be stratified so that those most likely to be problematic receive anticipatory treatment?

Type and depth of wounds; extent of contamination; proximity to tendon, joints and bones or prosthetic joints; potential for functional loss, especially of the dominant hand; and disfigurement are all variables that must be considered. Immunocompromised states of the host because of diabetes, renal or vascular insufficiency, cirrhosis, collagen vascular disease or its therapy, transplant-associated immunosuppression, age and frailty, as well as the potential for the complications of sepsis such as infectious endocarditis of a prosthetic valve, are all complicating factors. Obstruction of lymphatic or venous drainage of the involved body part predisposes to infection. In the absence of statistical data, clinical judgment would tend toward use of prophylactic antibiotics in these circumstances.

A 3–5 day course of antibiotics is now recommended for each of the following conditions:

- wounds seen less than 8 hours after infliction that are moderate or severe, with crush injury or edema;
- those that might involve bones or joints;
- hand wounds;
- cat bites;
- punctures, especially near a joint;
- wounds adjacent to a prosthetic joint; and
- wounds in those with co-morbid conditions that predispose them to serious infections.

Treatment of wounds in these situations should decrease the rate of wound infection from 15–20% down to approximately 5%. Wounds that are seen after 24 hours and are not infected are not likely to become infected.

Which antibiotics should be used? Cultures of the uninfected bite wound are likely to yield the mouth flora of the offending animal but are not predictive of which organism or organisms will cause infection, if any. Antibiotics are chosen on epidemiologic grounds. All bites deemed appropriate for therapy must be covered for *Staphylococcus aureus* and streptococcal species. Cat and dog bites must be covered for *Pasteurella multocida* (cats>dogs); human bites require coverage for *Eikenella corrodens*. Oral Gram-negative rods and anaerobes must also be considered.

TABLE 96.e-1 -- Types of wounds for which antibiotic prophylaxis should be considered (high risk).

TYPES OF WOUNDS FOR WHICH ANTIBIOTIC PROPHYLAXIS SHOULD BE CONSIDERED (HIGH RISK)	
Location	Hand, wrist or foot
	Scalp or face in infants
	Possibly involving bones or joints
	Near a prosthetic joint
Type of wound	Puncture (impossible to irrigate)
	Tissue crushing that cannot be debrided
	Edema less than 8 hours after infliction
Species	Domestic cat
	Human hand bite wounds

TABLE 96.e-2 -- Types of patients for whom prophylaxis should be considered (high risk).

TYPES OF PATIENTS FOR WHOM PROPHYLAXIS SHOULD BE CONSIDERED (HIGH RISK)
Diabetic
Renal insufficiency
Vascular insufficiency
Cirrhotic
Asplenic
Taking immunosuppressive drugs
Age <2 or >50 years
Drainage impairment to affected extremity (venous or lymphatic)
Valvular heart disease
Transplant

TABLE 96.e-3 -- Choice of agents.

CHOICE OF AGENTS

Allergy to penicillin	Preferred prophylactic antibiotic regimen
No	Amoxicillin-clavulanate 875/125mg po bid
Yes	Clindamycin 600mg po tid plus ciprofloxacin 500mg po bid (adults only) or Clindamycin plus TMP-SMX (adults or children)
	If feasible first dose may be given parenterally

Amoxicillin-clavulanate (875/125mg orally q12h) is the treatment of choice for both human and animal bites as it covers *E. corrodens* and most other major pathogens. For penicillin-allergic patients the choice is problematic. No single available agent is effective against all potential pathogens and a combination of agents must be used. Clindamycin plus trimethoprim-sulfa methoxazole (TMP-SMX) or clindamycin plus ciprofloxacin should provide adequate coverage in most situations. If erythromycin alone is used, then the patient will require closer follow-up. The first dose of antibiotic should be given parenterally if feasible, in order to ensure adequate tissue levels. Duration of therapy should be 3–5 days if the wound remains uninfected.

96.f Management of a health care worker exposed to tuberculosis

E Jane Carter

Tuberculosis (TB) has been a recognized hazard for health care workers (HCW) since the discovery of the contagious nature of TB over a century ago. Patients with active pulmonary tuberculosis — both unsuspected and diagnosed — continue to be a risk to HCWs. Transmission of TB to HCWs has been documented in a variety of health care settings, most commonly in general medical wards but also in operating rooms, autopsy rooms, ICUs, renal transplant units and outpatient HIV clinics. The most common methods by which occupational exposure to TB occurs are either by exposure to the unsuspected case where effective chemotherapy for TB has not had the opportunity to reduce contagion risk or by failure of environmental controls, such as inadequate ventilation or lack of protective masks, to block transmission in identified cases with active TB. In developed countries the former risk is greater while in resource-poor countries, the latter risk often predominates. In low incidence regions of the world where TB is uncommon, the constant vigilance required to consider and actively pursue the diagnosis of TB has lessened over time. This increases the risk that an unsuspected case of TB will go unrecognized and expose HCWs to the possible risk of infection.

Typical case

A 40-year-old US-born patient with insulin-dependent diabetes and chronic renal failure is referred for persistent cough. One year earlier, she was diagnosed with asthma. Treatment with asthma medications resulted in disappearance of her symptoms. Six months later she developed increasing cough, unresponsive to intensification of her asthma regimen. A chest radiograph revealed a right mid-lung field cavity with surrounding infiltration. An outpatient bronchoscopy was performed without specific TB precautions. One day post bronchoscopy the patient experienced fever and dyspnea. She was admitted following a 10-hour wait in the emergency room (ER). Later on the day of admission, her bronchoscopy smear was reported as 4+ acid-fast bacilli (AFB) smear positive. Expectorated sputum was also 4 + AFB positive. Exposed HCWs included the admission clerks, the bronchoscopy nursing staff, the recovery room staff and the ER staff (nursing, physicians, respiratory therapy, maintenance and transport personnel).

Diagnosis/management options

Mycobacterium tuberculosis is spread through the air as droplet nuclei by a source case that aerosolizes the organism generally through cough, sneezing and respiration. The organism may stay suspended — and thus transmissible — in the air for as long as 6 hours. Exposure occurs to all individuals who share the air space with the source case and this exposure risk is delineated by history.

This case was not suspected so appropriate hospital infection control methods — placement in an isolation room, masking of individuals entering the room — were not performed. This is the most common clinical setting for HCW exposure. Risk of infection from exposure varies widely and is determined by multiple factors: contagiousness of the source case, time spent in the infected air space by the susceptible HCW, proximity to the index case, ventilation of the contaminated air space and the immune status of the susceptible host (Table 96f.1). Although a large number of individuals were exposed in this instance, their respective risks of actual infection are not equivalent.

The first step in evaluating the HCW's exposure risk is to evaluate the source case. How contagious is the patient? This evaluation is based on the expectorated sputum. In this instance, the source case was very infectious, with heavily positive smears. In addition, the source case was coughing; cough is an effective aerosolization method. For a proportion of the HCWs exposed, the issue was not just cough but rather a cough-inducing procedure — bronchoscopy. Although it is standard in the USA to mask HCWs for a bronchoscopy, masks are generally removed immediately following the procedure. HCWs remain in the room in which the patient is recovered. Patients are most

TABLE 96.f-1 -- Risk of infection to HCWs once exposed to tuberculosis.

RISK OF INFECTION TO HCWs ONCE EXPOSED TO TUBERCULOSIS	
Directly related to	**Inversely related to**
Contagion status of source case	Ventilation of the infected air space
Effectiveness in aerosolizing the organism (e.g. bronchoscopy vs random cough)	Time since institution of chemotherapy for the source case
Time spent in the infected air space	Distance between HCW and index case
Immune status of the exposed individual	Efficiency of room ventilation and efficiency of face mask

contagious in the hours after the bronchoscopy due to increased cough provoked by residual congestion following instillation of fluid in the form of lavage or washings.

The next step in evaluating the HCWs' exposure risk is to evaluate the time of exposure in the infected air space. The longer the time spent in the infected air space, the greater the risk of infection. Thus, the nurse who spent 45 minutes in the room will be at more risk than the dietary aide who was present for a few minutes only. Analysis of exposure time as well as the intensity of exposure leads to the development of a hierarchy of urgency in performing the subsequent evaluations.

The only test presently available for TB infection is the tuberculin skin test or purified protein derivative (PPD). In many countries, health care facilities are required to have TB screening programs in place. Therefore, HCWs should know their PPD status. Tuberculin skin testing is offered to exposed individuals to assess TB infection. Not every exposed HCW needs to be tested simultaneously; those with the most exposure — as determined by time exposed and/or presence at cough-inducing procedures — should undergo testing first.

It takes 2–10 weeks after infection for the tuberculin skin test to turn positive. Thus, the first or immediate test is to determine if the HCW has been infected by another, possibly unsuspected, exposure since last testing. Prior receipt of BCG immunization by the HCW can complicate the interpretation of the PPD. In general, BCG vaccination in childhood does not affect the interpretation of the PPD in adults, but the receipt of multiple BCG immunizations may cause positive PPDs, particularly at levels surrounding the 10mm cutoff. In these situations the risks and benefits of treatment for possible recent infection should be considered on an individual basis. Further discussion about BCG and its impact on PPDs is found in Chapter 37 and Chapter 233 . The follow-up skin test 10–12 weeks after the exposure tracks this exposure as the cause of resultant infection.

Circles of exposure, based on length of time and intensity of exposure, are performed until the percentage of positive skin tests within the circle meets the incidence of positive skin tests in the community at large. Thus if, in the circle of 2-hour exposure, there are no positive skin tests then it is reasonable to expect that individuals who were exposed to the source case for less than 2 hours are not at risk. If 25% of the individuals in the 2-hour circle show evidence of infection based on a positive skin test than further testing of individuals with lesser exposure must be initiated, e.g. those exposed for 1 hour only (Fig. 96f.1).

HCWs with latent TB infection (LTBI) should be evaluated for TB disease with a chest radiograph and a physical examination. Signs or symptoms of active TB or chest radiographic abnormalities are pursued. For those with a normal chest radiograph and no TB symptoms, treatment of LTBI should be offered. The first 2 years after TB infection is the highest risk period for development of disease; therefore, the risk: benefit ratio of treatment of LTBI is always in favor of treatment in a new infection. There are three LTBI treatment regimens approved in the United States: isoniazid for 6–9 months (9 months is the preferred length of therapy), rifampin/pyrazinamide for 2 months (60 doses) or rifampin for 4 months. The ultra-short course regimen of rifampin/pyrazinamide has been associated with 17 deaths due to hepatitis since its approval; patient selection for this regimen must involve screening for hepatitis risk and active blood surveillance throughout therapy. The choice of rifampin alone is not based on any clinical trial data, only expert opinion. Susceptibility testing of the source case must be checked to verify susceptibility to the drugs being used to treat contacts.

The rifampin or rifampin/pyrazinamide regimen is recommended when the index case is known to harbor an INH-resistant strain of *M. tuberculosis*. The treatment

options are much more limited in the event of exposure to multidrug-resistant (MDR) TB. MDR-TB is increasingly prevalent in eastern European countries and some regions of Asia and Africa. Latent infection with TB from INH and rifampin-resistant strains is generally managed with empirical chemoprevention therapies that include pyrazinamide with ethambutol or a fluoroquinolone such as levofloxacin or ofloxacin. None of these regimens have been shown to be clearly efficacious in controlled clinical trials.

Questions arise regarding recommendations for the immunocompromised HCW due to HIV infection or other medical problems. HIV-infected HCWs exposed to TB should be approached in the same manner as a young child. HIV-infected individuals, like children, may develop disease in an accelerated fashion so they should be quickly evaluated for active disease. If no disease is noted, primary prophylaxis is instituted until the issue of TB infection is determined. LTBI therapy is initiated even before any skin testing results can be obtained and is continued until both (baseline and follow-up) PPDs can be performed. If the HIV-infected HCW is in a circle in which the conversion rate of PPDs is high, consideration should be given to completion of INH therapy regardless of skin test results. If the contact evaluation is performed solely in the context of the work environment, knowledge of the medical conditions of the HCW may not be known; therefore, clear instructions regarding risk should be conveyed to the HCW for discussion with a personal physician in a confidential setting.

If a HCW is known to be PPD positive prior to exposure, treatment decisions are based on the prevalence of TB infection that occurs in the circle of exposure to which that HCW belongs. If the previously infected HCW is in a circle of exposure where the conversion rate is high, the HCW should be considered as reinfected and evaluation for retreatment pursued. If the rate of conversion is low, no further evaluation of the previously positive HCW need be performed.

Following completion of LTBI therapy, no further evaluation need be done. Surveillance chest radiographs for treated — or for untreated — individuals with LTBI are of low yield. Individuals should be counseled regarding the signs and symptoms of active TB; only symptom-driven chest radiographs should be considered.

HCWs cannot be barred from work for failure to participate in programs of screening or for refusing LTBI treatment. Only individuals with contagious TB can be barred from the workplace.

Conclusion

Health care workers are at risk for occupational exposure to TB, especially in low incidence areas where the awareness and necessary active surveillance for TB are difficult to maintain. Risk of exposure is related primarily to the unsuspected case of TB. Risk of infection is based on contagiousness of the source case, extent and length of exposure to the index case and immune status of the HCW. Skin test screening for exposure is based on a circle of contact approach; circles are determined by length and intensity of contact. Treatment of LTBI,

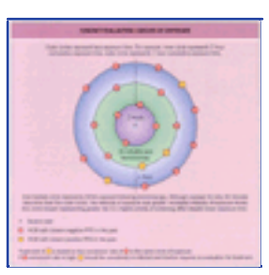

Figure 96.f-1 Contact evaluation: circles of exposure. Circles are constructed based on length of time of exposure and intensity of exposure. The innermost circle represents the highest risk; individuals in this circle are the first priority for screening. Circles of risk are constructed with each having less exposure — and thus less risk — until the PPD conversion rate in a circle is equivalent to the prevalence of LTBI in the local population.

if it occurs, should be offered and is effective in protecting against the development of TB disease.

96.g Management of a health care worker with chickenpox and the subsequent infection control problem

Katherine N Ward

Definition of the problem

Chickenpox (varicella) is caused by primary infection with varicellazoster virus (VZV). After primary infection, the virus remains latent in sensory ganglia for life. Shingles (herpes-zoster) occurs when VZV reactivates.

In children the complications of chickenpox are sepsis, cerebellar ataxia and, rarely, encephalitis whereas in adults, especially pregnant women and those who smoke, the most common complication is pneumonia which may be fulminating. Neonates and the immunocompromised are at risk of severe disseminated disease. Varicella in pregnancy during the first two trimesters carries a small risk (probably <1%) of congenital varicella syndrome, which is characterized by one or more of the following: microcephaly, microphthalmia, mental retardation, chorioretinitis, Horner's syndrome, limb hypoplasia, contractures and skin scarring.

Chickenpox is very contagious and up to 90% of susceptible household contacts will develop the disease. Transmission is person to person by direct contact, droplet or air-borne spread of vesicle fluid or respiratory secretions. The usual incubation period for varicella is 14–16 days (range 10–21) and the infectious period about a week, i.e. from 2 days before the rash appears until the vesicles dry up. In shingles, VZV is shed from vesicle fluid but not respiratory secretions and is thus less transmissible, especially if covered by clothing. Virus transmission to antibody-negative contacts causing varicella occurs from the day of onset of the zoster rash until crusting of vesicles. In disseminated zoster the patient is infectious for longer, i.e. from 2 days before onset of rash. Finally, contagiousness may be prolonged in the immunocompromised with either varicella or zoster because of continuing virus replication.

Nosocomially acquired varicella is increasingly recognized as a problem. Sources of VZV infection include patients, visitors, especially children, and staff. For susceptible contacts, significant exposure includes sharing a hospital room with an infectious patient or prolonged, direct, face-to-face contact with an infectious person; in each case the type of infection, whether varicella or zoster, and the timing and closeness of exposure must be assessed. A common problem is that of the susceptible health care worker, inadvertently exposed to either chickenpox or zoster, who subsequently develops varicella and may transmit VZV to other staff and patients, e.g. in the antenatal clinic or hematology ward, with consequent morbidity and mortality.

Typical case

A medical student, attached to the hematology unit of a university teaching hospital during his elective, telephones his educational supervisor on a Friday to say that he has developed chickenpox. The rash appeared the day before when he briefly visited the sickle cell anemia outpatient clinic but had felt unwell and returned to his lodgings in the student hostel. On the previous 2 days, i.e. Tuesday and Wednesday, he had been clerking patients on the bone marrow transplant unit. His supervisor contacts the medical school's general practitioner who visits the student later that day and confirms varicella, adding that the patient smokes 20 cigarettes a day. The practitioner also reports that the student did not recall having chickenpox as a child but 2 weeks previously was present when samples were taken from a patient for the diagnosis of shingles.

Diagnostic methods

For the purposes of hospital infection control and timely patient management, laboratory tests should give a rapid result, preferably on the same working day.

Varicella and zoster can be reliably diagnosed clinically. However, where there is doubt, for example if only a few vesicles are present, the diagnosis can be confirmed with the help of the laboratory. The relevant samples are vesicle fluid and cells scraped from the base of the lesion and useful rapid tests are immunofluorescence to detect VZV antigen in cells from the lesion, electron microscopy to detect a herpesvirus in vesicle fluid and PCR to detect VZV DNA in either sample. Tests for VZV IgM or IgG antibody are of little help in diagnosis, although they may sometimes be used to detect the absence of IgG antibody in the acute illness to confirm chickenpox or to exclude zoster.

As regards immunity to VZV, more than 90% of adults are immune although rates of immunity may be lower for adults raised in certain tropical or subtropical areas. A reliable history of varicella is a valid indicator because the rash is distinctive. In contrast, a negative history of varicella is not a reliable test of lack of immunity since the infection may not be recalled or may have been subclinical. Moreover, in the immunosuppressed a past history of varicella does not guarantee the presence of antibodies and hence immunity. Therefore antibody tests are often required to determine susceptibility to infection with VZV. The criteria for assay selection include sensitivity, specificity and the length of time required to obtain results. In particular, the test must be capable of detecting low levels of antibody such as may be found many years after primary infection with VZV. Thus, enzyme-linked immunosorbent assay or latex agglutination tests are appropriate whereas complement fixation tests are not sensitive enough. Assays that are too labor intensive or time consuming include indirect immunofluorescence and neutralization.

Management options

The medical student with varicella

Valaciclovir or high-dose oral aciclovir is indicated, especially in a smoker, and should be given within 24 hours of the onset of rash to reduce the duration and severity of the illness. The student should be warned of the risk of varicella pneumonia and asked to report any respiratory symptoms, in which case he should be admitted to the hospital's infectious diseases ward for assessment and treatment with high-dose intravenous aciclovir. He should not otherwise return to the hospital until all his vesicles are dry and if at all possible he should move to alternative accommodation away from the hostel, e.g. be collected by his parents and taken home. In any case his contacts should be known to be immune to VZV (either by history or antibody positive). Finally, the question as to how this susceptible student was allowed to visit a patient with shingles and help to collect samples for diagnosis should be reviewed. No doubt there was a policy in place that only staff known to be immune should be exposed to VZV but it is all too easy to overlook the occasional visitor such as this elective student.

Susceptibility of contacts

A list should be made of patients and staff in the clinic and on the ward who had significant exposure to the student whilst infectious. Possible contacts in the student hostel should also be investigated. The lists should state whether each individual has had chickenpox or not and whether anyone was pregnant or immunosuppressed. Blood

should be taken for VZV antibody testing from persons with no history of chickenpox and from all immunosuppressed patients so as to determine susceptibility. Those with antibody can be regarded as immune and reassured.

In the event it was found that the student had been in the sickle cell anemia clinic before any patients arrived but had spent 15 minutes having tea and biscuits in the company of the receptionist who has no history of chickenpox and no antibody to VZV.

In contrast, the student had spent all of the previous 2 days on the hematology ward where there were 16 inpatients, all of whom had received a bone marrow transplant for various hematological malignancies. He had been on a ward round and had also visited and taken a history from several of the patients. All 16 patients were tested for VZV antibody and two were found to be seronegative. The student had also been in the ward kitchen for some time with the pregnant ward cleaner, who was not a permanent member of staff but had been supplied by an agency. She had lived in Bangalore, India, for the first 15 years of her life, her English was poor

and she gave an uncertain history of chickenpox. On antibody testing she was susceptible to varicella. Finally in the hostel, two students living in rooms on the same corridor as the student did not recall having chickenpox as children although both were in fact VZV seropositive and hence immune to varicella.

Management of susceptible health care workers

There were two susceptible health care workers, one of whom was pregnant and will be considered later. The other was the receptionist in the sickle cell anemia clinic who should be excluded from patient contact just before the incubation period for chickenpox has elapsed, i.e. 8–21 days after her exposure to VZV. This could either take the form of paid leave or, less realistically perhaps, reassignment to a location in the hospital well away from patients, such as the financial department. A less practical option is to screen daily for skin lesions, fever and systemic symptoms and exclude her from the clinic if she develops varicella. However, on some days of the week bone marrow transplant patients are reviewed in the clinic and this is therefore an especially high-risk strategy. Aciclovir prophylaxis is not recommended as it may not prevent varicella and may prolong the infectious period, but it might be appropriate if on enquiry the receptionist is a heavy smoker. Likewise, the use of human varicella-zoster immunoglobulin (VZIg) for prophylaxis is not an option as it does not necessarily prevent varicella and may prolong the incubation period for a week or more. VZIg is prepared from pooled plasma from blood donors with a history of recent chickenpox or zoster or from those who on screening are found to have suitably high titers of VZV antibody and is usually reserved for neonates, pregnant women and the immunosuppressed. Finally, if varicella develops valaciclovir or high-dose oral aciclovir is indicated.

Management of susceptible pregnant or immunosuppressed contacts

The pregnant ward cleaner and the two bone marrow transplant recipients should be given VZIg to prevent or modify varicella. During the likely infectious period, which may be longer than normal, the member of staff should be managed as described above except that aciclovir prophylaxis and treatment with valaciclovir are both contraindicated in pregnancy. As regards the two bone marrow transplant patients, they should be appropriately isolated, preferably on an infectious diseases unit, and only be cared for by immune staff. Both of these patients were receiving oral low-dose aciclovir to prevent herpes simplex virus infections but there are insufficient data to suggest that this could replace VZIg. If varicella develop high-dose intravenous aciclovir should be given.

Conclusion

The infection control measures described above may seem straightforward but in practice, tracing contacts of varicella and zoster and obtaining blood samples for VZV antibody testing is time consuming and expensive. Excluding potentially infectious health care workers from the hospital is also expensive as they must be replaced by agency staff. Moreover, contacts may be missed because people are unaware they have been in contact or ignorant of the risks. Secondary cases may then occur with further risk of transmission.

In summary, the control of varicella in hospitals will remain a considerable burden unless the pool of susceptibles is reduced. Fortunately varicella vaccine is now licensed in both the United States and the UK and vaccination of all health care workers identified as VZV antibody negative at the time of employment and before any possible exposure in hospital should become the preferred method for preventing nosocomial varicella outbreaks.

Chapter 97 - Innate and Acquired Host Defenses against Infections

Helen L Collins
Stefan HE Kaufmann

INTRODUCTION

This chapter focuses on the immune response to infections, mainly concentrating on bacterial pathogens. As examples of different types of infection we primarily focus on three pathogens:

- *Listeria monocytogenes* as an example of an acute infection;
- *Mycobacterium tuberculosis* as a characteristic persisting chronic infection; and
- *Salmonella enterica* var *typhimurium* as a pathogen that falls somewhere between the two.

In such a broad review it is impossible to cover all aspects of immunity to even this limited range of pathogens, and therefore for further details additional reviews are recommended.[1] [2] [3] A functional immune response is paramount for the control of infections, as evidenced by the increased susceptibility to infection resulting from a range of immunodeficiency disorders. Some of these disorders will be referred to in the text of this chapter, and a more complete list is included in Table 97.1 .

INNATE IMMUNE RESPONSES

The innate immune response co-ordinates the initial response to pathogens in a rapid and non-specific way (Table 97.2). The recognition of microbial compounds by cells of the innate immune system generally leads to the production of cytokines and other effector molecules, which either activate cells for the initial control of the pathogen, or promote the development of the acquired immune response. The cells involved in this response include macrophages, dendritic cells and natural killer (NK) cells, which have the ability to recognize and respond to a wide variety of pathogens long before the development of antigen-specific acquired immunity. It is now clear, however, that these early events are critical in determining the nature of the adaptive immune response.

Innate immune mechanisms are critical for the control of pathogens encountered regularly and can be divided roughly into two stages. The initial immediate response occurs within the first 4 hours of the immune response and relies on preformed, non-specific components such as the activation of the complement cascade. Three distinct pathways of complement activation result in the generation of the key enzyme C3 convertase:

- the alternative pathway is activated by specific activation of complement on the pathogen surface;
- the classical pathway requires the formation of antigen-antibody complexes; and
- the mannose binding lectin pathway is activated via the binding of this lectin molecule to mannose residues on the pathogen surface.

Cleavage of C3 by its convertase can result in either direct lysis of the pathogen via the membrane attack complex or opsonization of the organism to facilitate phagocytosis.

A second, slightly delayed response (4–96 hours) has been termed the early induced response and relies on the recruitment of effector cells such as macrophages and neutrophils via the production of chemokines and the activation of these cells by cytokines, which will be discussed below.

Pathogen recognition

Pattern recognition receptors

In order to respond rapidly to the presence of a large variety of pathogens, innate immune recognition is based on the detection of conserved microbial products including bacterial peptidoglycan as well as lipopolysaccharide (LPS) specific for Gram-negative bacteria and lipoteichoic acid (LTA) of Gram-positive bacteria. A characteristic entity for fungi, zymosan, is used while double-stranded (ds) RNA and cognate structures of imidazoquinolines serve as characteristic markers for viral pathogens. These molecules are expressed exclusively by the pathogen and therefore signal the presence of infection. Although these compounds are not identical between all strains, they invariably contain a conserved molecular pattern, which is recognized by the immune system. This is exemplified by LPS, where it is the lipid A portion of the molecule rather than the strain-specific O antigen that activates the innate immune response. These conserved molecular patterns are termed pathogen-associated molecular patterns (PAMPs) and have two important characteristics:

- first, they are produced exclusively by the pathogen and have no host equivalent; and
- second, they are essential for microbial survival.

However, there are no unique differences in PAMPs between pathogenic and nonpathogenic strains of the same species, and how the innate immune system distinguishes this difference is unclear.

The receptors of the innate immune response are termed pattern recognition receptors (PRR), which are germline-encoded receptors including CD14, macrophage mannose receptor and the scavenger receptor of macrophages. Recently the Toll-like receptor (TLR) family have been shown to have an essential function in immunity.[4] [5]

Toll receptors were first identified to play a critical role in immune defense of *Drosophila* against bacteria and fungi, and it is now known that there are at least 10 human homologs, each with a distinct function. The TLRs are transmembrane receptors with a leucine-rich extracellular domain and an intracellular Toll/interleukin (IL)-1 receptor (TIR) domain. To date a wide variety of ligands have been identified for TLRs, but TLRs also exist for which no known ligands have been identified (Fig. 97.1).

It is now clear that TLRs are involved in the detection of and discrimination between an extensive variety of pathogens, and direct differential immune responses accordingly. Thus, TLR2 and TLR6 are recruited to the phagosome containing yeast and Gram-positive bacteria and initiate an inflammatory response, whereas the response to Gram-negative bacteria is mediated primarily via TLR4.[6] More recently, flagellated proteins from both Gram-positive and Gram-negative bacteria have been shown to be recognized by TLR5,[7] while unmethylated bacterial CpG sequences activate cells via TLR9.[8] The demonstration that dsRNA is recognized

TABLE 97-1 -- Diseases resulting from deficiencies in components of the immune system.

DISEASES RESULTING FROM DEFICIENCIES IN COMPONENTS OF THE IMMUNE SYSTEM			
Component	**Disease**	**Description**	**Infections**
Phagocytes	Chronic granulomatous disease	Abnormal NADPH oxidase	*Staphylococcus aureus*
	Chediak-Higashi disease	Deficient degranulation	*Pseudomonas* spp.
	Glucose-6-phosphate dehydrogenase deficiency	Deficient NADPH oxidase	*Escherichia coli*
			Aspergillus spp.
Complement	C1,C4,C2 deficiency	Deficiency of the classical pathway	Encapsulated bacteria
			Streptococcus pneumoniae
	C3, factor H, factor I	Deficiency	Pyogenic bacterial infections
	C3bi, properdin	Deficiency in the alternative pathway	Severe neisserial infections
	C5,6,7,8,9	Deficiency in the membrane attack complex	Meningococcal meningitis
Cytokines	IL-12	Mutation in ß1 chain of IL-12 receptor	*Salmonella* spp
			Mycobacteria spp
	IFN-?	Mutation in IFN-? receptor I	Atypical mycobacterial infections
	X-linked severe combined immunodeficiency (SCID) no T cell function	Mutation in common ? chain of IL-2, 4,7,9,13,15 receptors	Recurrent bacterial and viral infections with all opportunistic pathogens
MHC I/II	Bare lymphocyte syndrome	Defective cell-mediated immunity	Opportunistic pathogens (e.g. *Candida albicans*)
			Cryptococcus neoformans
			Intracellular bacteria
T cells	DiGeorge syndrome	Deletion on chromosome 2	Intracellular pathogens (e.g. mycobacteria)
		Failure in thymic development	
	AIDS	$CD4^+$ T-cell deficiency due to HIV infection	*Pneumocystis carinii*
			Invasive fungal infections (e.g. *Candida albicans*)
	Hyper IgM syndrome	Deficiency in CD40L signaling to B cells.	Pyogenic bacterial infections
		Isotype switching is blocked	*Cryptosporidium parvum*
B cells	X-linked agammaglobulinemia (Bruton's agammaglobulinemia)	Deletion of Bruton's tyrosine kinase	*Haemophilus influenzae*
		Block in pre-B cell maturation	*Streptococcus pneumoniae*
		No circulating B/plasma cells	
		Very limited antibody production	
T/B cell function	Adenosine deaminase deficiency	Accumulation of metabolites within T and B cells leading to impaired proliferation. Total lack of humoral and cellular function.	Recurrent infections with opportunistic pathogens (e.g. *Pneumocystis carinii,* mycobacteria)
	Wiskott-Aldrich syndrome	Deficiency in sialophorin	*Pneumocystis carinii*
			Herpes
			Pyogenic bacteria

by TLR3 and results in nuclear factor ?B (NF?B) activation suggests an additional role for TLR in the early response to viral antigens.[9] Furthermore, it is now apparent that co-operation between TLRs further extends their ability to direct a differential immune response to a variety of ligands. Toll-like receptor 2, in combination with TLR6, can recognize peptidoglycan, whereas TLR2 along with TLR1 interacts with lipopeptides. Interestingly, the cytoplasmic tail of TLR2 cannot induce tumor necrosis factor (TNF) production and requires co-operation with the signaling domains of TLR1 or TLR6 to do so.[10]

Evidence for the role of TLR expressed on cells of the innate immune system being critically involved in the orchestration of the specific immune response has been provided by studies using mice deficient in the signaling adaptor protein MyD88. The MyD88 signaling pathway is used by all TLRs, and a deficiency in this molecule results in a specific block of $CD4^+$ T helper (Th)1 responses; however, Th2 responses appear to remain intact.[11] Note that an additional MyD88-independent pathway exists.[12] In summary, TLR signaling fulfils two major functions:

- ¦ it induces an inflammatory response mediated by proinflammatory cytokines; and
- ¦ it induces expression of co-stimulatory molecules and immunoregulatory cytokines such as IL-12, thus promoting development of interferon (IFN)-? producing Th1 cells (see below).

Ligands for TLR that induce Th1 cells but no inflammation serve as regulatory molecules and are potential adjuvants.

Other receptors

Cells of the innate immune system express additional receptors that are important in the initial interaction with microbial pathogens. In particular the complement receptors (CRs), the receptors for immunoglobulin (FcR) and the fibronectin receptor are exploited by intracellular pathogens to gain access to their chosen host cell. The binding of bacteria to these receptors is mediated by serum components such as complement (C), immunoglobulins and fibronectin. The choice of receptor for entry into the cell can greatly influence the fate of the micro-organism. Thus, IgG opsonized *M. tuberculosis* induces antimicrobial defense mechanisms, whereas entry of complement-opsonized mycobacteria fails to do so. To this end, mycobacteria have evolved a mechanism to promote their uptake via CRs, by their ability to cleave C2 to become the C3 convertase, facilitating the fixation of C3b and entry via CR1 or CR3.[13]

TABLE 97-2 -- A comparison of the innate and acquired immune responses.

A COMPARISOn OF THE INNATE AND ACQUIRED IMMUNE RESPONSES		
	Innate	**Acquired**
Time (h)	0–4 (early)	>96
	4–96 (induced)	
Receptors	Not rearranged	Rearranged
Specificity	Broad specificity	Unique specificity
	Recognition of conserved molecular patterns	Recognition of specific epitopes
Cells	Macrophages	CD4 T cells
	Neutrophils	CD8 T cells
	NK cells	B cells
Soluble effectors	Complement	Cytokines (IFN-?, IL-4)
	Defensins	Antibodies
	Chemokines (IL-8, MIP, MIG)	
	Cytokines (TNF-a, IL-12, IL-6)	
	Interferons (IFN-a/ß)	
Effector mechanisms	Phagocytosis	Complement activation
	Cell recruitment	Cytotoxicity
	Macrophage activation	Pathogen destruction
	Pathogen destruction	

Innate effector functions

Chemokines

Recent interest has focused on a group of small molecular weight cytokines that regulate leukocyte migration. On the basis of a conserved cysteine (C) motif, four subgroups can be distinguished: CC chemokines (e.g. macrophage inflammatory protein (MIP)-1a,ß monocyte chemoattractant protein (MCP-1), RANTES); CXC chemokines (e.g. IL-8, monokine induced by interferon-? (MIG)); the CX_3 C chemokines (e.g. fractalkine); and the C chemokines (e.g. lymphotactin). Related members of these families are recognized by distinct chemokine receptors enabling further systematic grouping. Chemokines not only regulate physiologic leukocyte trafficking, but are also involved in the mobilization of leukocytes at sites of microbial invasion. Similarly, chemokines also attract members of the acquired immune response, namely T cells, to sites of inflammation. Hence, chemokines play a role at various stages throughout the infectious process.[14] [15] [16] [17]

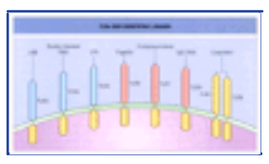

Figure 97-1 Toll-like receptors and identified ligands to date. The identified ligands that bind and signal via TLRs are shown here. Note that TLR2 and TLR6 combine to form a functional heterodimer to recognize peptidoglycan, and probably further combinations of TLRs will be identified, which will increase the diversity of ligands that are recognized. LAM, lipoarabinomannan.

Chemokines including IL-8 and MIP-1a also regulate selective migration of T-cell populations to the inflammatory foci. The chemokines involved bind to glycosaminoglycans on the endothelial surface, thereby attracting lymphocytes to the underlying tissues. Differential expression of chemokine receptors on Th1 and Th2 cells, as well as naive and memory T cells, allows the selective attraction of the required T-cell population.

Tumor necrosis factor-a

Tumor necrosis factor-a is produced by several cell types, including innate and acquired immune cells, such as monocytes, macrophages, neutrophils, mast cells and T cells. It has various pleiotropic effects on the immune system including leukocyte recruitment and macrophage activation. From experiments using mice deficient in TNF-a or its receptors, this cytokine has a proven role in host defense against acute infections such as listeriosis and salmonellosis, as well as in more chronic infections such as tuberculosis. One of its major functions in mycobacterial immunity is in the formation of granulomas, a critical process in which the bacilli are contained within a focus of infection and controlled by activated macrophages and T cells. Although the formation of granulomas is a highly complex process involving many cell types, chemokines and adhesion molecules,[18] the absence of TNF-a results in incomplete granuloma formation and/or disintegration. [19] [20] Treatment of rheumatoid arthritis patients with neutralizing monoclonal antibodies to TNF-a reactivates *M. tuberculosis* infection, illustrating the central role for this cytokine in containing mycobacteria in a dormant stage. [21] However, it must be noted that although TNF-a is required for effective host responses to a variety of pathogens, it is also responsible for many of the pathologic consequences of infection,[22] as discussed below. Its production must therefore be tightly regulated.

In addition to TNF-a, other proinflammatory cytokines are produced, including IL-1 and IL-6, which together with TNF-a induce the acute phase response in the liver. This results in the production of serum proteins such as C-reactive proteins and mannan binding lectin, which can directly, or indirectly via the activation of complement, facilitate phagocytosis. Additionally, these three cytokines act as endogenous pyrogens to raise the body temperature, which produces an unfavorable environment for the pathogen to grow in.

Interleukin-12/interleukin-18/interferon-?

One of the most important cytokine cascades in the early immune response is the production of IL-12 and IL-18 leading to the secretion of IFN-? by NK cells. These cytokines are induced by a variety

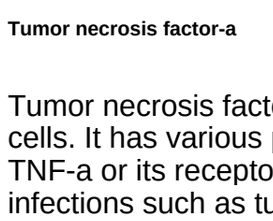

Figure 97-2 Pathways for the generation of the major antimicrobial effector mechanisms of macrophages. This shows the pathways for the generation of ROIs from NADPH oxidase, a process initiated by FcR cross-linking, or exposure of cells to IFN-?. Similar activation can also induce the production of RNIs from L-arginine, catalyzed by inducible nitric oxide synthase (iNOS). Also listed are various examples of bacterial genes or gene products that are known to counteract components of these pathways.

of bacterial products including LAM of mycobacteria, lipoteichoic acid (LTA) and oligonucleotides with an unmethylated CpG motif. The importance of this cytokine pathway has been well illustrated in patients with a mutation affecting IL-12 or IFN-? signalling, who are highly susceptible to infections with mycobacteria and *Salmonella* spp.[23] Interferon-? is the central cytokine required for the activation of macrophages for antimicrobial effector mechanisms outlined below, and the production of all three cytokines is the critical determinant for the development of a CD4 Th1 cell response, as discussed in the acquired immunity section.

Production of reactive nitrogen and oxygen radicals

Neutrophils and activated macrophages restrict the growth of or even kill pathogens that reside inside them. The primary mechanisms for this are the generation of highly toxic reactive oxygen and nitrogen intermediates (ROI and RNI, respectively), which act, alone or in synergy, on the pathogen to inactivate iron-sulfur containing enzymes or to damage DNA (Fig. 97.2).[24]

The production of ROIs is initiated by the activation of the NADPH oxidase following FcR ligation or exposure to IFN-? and LPS. Following further metabolic reactions, which are catalyzed by superoxide dismutase and require iron as a co-factor, oxygen radicals are generated. Reactive nitrogen intermediates are derived from L-arginine in a reaction catalyzed by nitric oxide synthase 2, also known as iNOS. In many cases these two processes are activated in tandem and their respective products synergize for maximum effect.

One interesting example of the requirement for both of these processes is in the control of experimental *Salmonella* spp. infections. Using mice deficient in iNOS and gp96 phox, a component of the NADPH oxidase complex, it was demonstrated that both these mechanisms are required to control infection, but the kinetics of their activation differ. During the first 2–4 days of infection the production of ROIs is critical, while the effects of RNIs are not observed until later in infection, after 7 days.[25]

In mycobacterial infections the roles for RNIs and ROIs have been controversial and differ according to the pathogen investigated. Whereas iNOS-deficient mice were highly susceptible to *M. tuberculosis* infection, they controlled replication of *M. avium* just as efficiently as wild-type mice. Moreover phox-deficient mice showed only a transient loss of resistance to *M. tuberculosis* infection,[26] perhaps reflecting again the distinct temporal requirement for the production of ROIs and RNIs. Although RNI production by human macrophages is low to absent, the critical enzyme, iNOS, has been identified in specimens from patients with tuberculosis. It is therefore likely that RNIs also play a role in human infection although their impact may be smaller.

Antimicrobial peptides

Host cells such as neutrophils and epithelial cells can produce small cationic peptides with antimicrobial activities. These are divided into two families — defensins[27] and cathelicidins [28] — and are induced by microbial components and cytokines such as TNF-a and IL-1ß. Both defensins and cathelicidins have direct microbicidal activity against a wide variety of pathogens including bacteria and fungi. The mechanism of action appears to be perturbation of cell wall membranes via depolarization or permeabilization. As defensins interact with negatively charged components such as LPS, which are not present in host cells, the host is protected from the deleterious effects. In addition to effects on the pathogen, defensins have been demonstrated to potentiate host-acquired immune mechanisms. Increased T-cell proliferation and cytokine production were observed in vitro by the addition of a defensin, while in vivo increased IgG1 and IgG2a levels were seen, as well as the chemoattraction of naive T cells and dendritic cells.[29] Antimicrobial peptides are synthesized as precursors, which must be cleaved before they are active, and therefore host cells must produce enzymes that can perform this task. Neutrophil elastase has been shown to be critical in the activation of cathelicidins and the absence of this molecule severely impairs the host's ability to clear bacterial infections.[30]

Pathogens have evolved ways to counteract the action of defensins. As these antimicrobial peptides are charged they require electrostatic interactions with components of the microbial cell wall such as LPS or LTA. *Staphylococcus aureus* can esterify its LTA, reducing the capacity of the defensin molecules to interact, and while defensins

are generally fairly resistant to destruction by proteases, the extracellular proteases of *Pseudomonas aeruginosa* and *Streptococcus pyogenes* degrade proteoglycans to release dermatan sulfate, which inhibits the action of defensins.[31]

Restriction of nutrients

For intracellular pathogens in particular, the ability to acquire the appropriate nutrients inside the host cell is critical for their survival. Therefore, one potentially effective host defense strategy is to withhold essential compounds from the pathogen. Upon activation of macrophages by IFN-?, there is upregulation of the tryptophan degrading enzyme indoleamine 2,3 dioxygenase, which reduces the levels of tryptophan available within the cell. The absence of this amino acid potentiates the intracellular killing of pathogens including *Chlamydia* spp.[32] and *Bordetella pertussis*. [33]

Perhaps one of the most essential requirements for pathogens residing intracellularly is that of iron. As the host cell also requires iron as a cofactor for the production of ROIs and RNIs, competition for the available intracellular iron pool can markedly influence the outcome of infections with intracellular bacteria. The main pathway for iron acquisition in macrophages is via the transferrin receptor, which is internalized into early endosomal compartments after the binding of iron-loaded transferrin. Once internalized, the lowered pH facilitates the release of iron from its receptor. Most of the iron is transported to the mitochondria for use in the respiratory chain reaction, and excess iron is stored in the cytoplasm bound to ferritin. Limiting the supply of intracellular iron to pathogens is achieved by downregulating surface expression of the transferrin receptor following IFN-? activation, and for *Legionella* spp. this results in the death of the organism due to iron starvation. Therefore, to successfully compete for iron, many pathogens have specialized iron binding molecules called siderophores. For *M. tuberculosis* in particular, which establishes long-term residency within host cells, these molecules are critical, and a deficiency in this iron-uptake mechanism leads to attenuation of the bacteria. Indeed, in conditions of iron overload, either dietary or hereditary, the risk factor for tuberculosis increases significantly.[34] However, as the host also requires iron, it is not as simple as just removing iron from the pathogen. Recent experiments from our laboratory have indicated that chelation of iron exacerbates experimental infection with *Salmonella* spp. due to the inhibition of the NADPH-dependent respiratory burst,[35] illustrating that the availability of iron must be tightly controlled.

Neutrophil-mediated killing

In addition to the production of defensins and other toxic molecules contained within granules, it was assumed that neutrophils kill intracellular pathogens in much the same way as macrophages, that is via the generation of ROIs. However, recent evidence has demonstrated an additional mechanism by which neutrophils contribute to the innate host defense. Upon activation, there is a considerable potassium flux within the cell resulting in the activation of proteases such as elastase. In the absence of these proteases, microbicidal activity is reduced, despite the mechanisms for the generation of ROIs being intact.[36] Elastase in particular has been shown to specifically cleave the virulence proteins of *Shigella*, *Salmonella* and *Yersinia* spp., and an absence of this molecule results in the inability of neutrophils to contain the growth of these bacteria.[37]

ACQUIRED IMMUNE RESPONSES

In contrast to the rapid non-specific innate immune response outlined above, acquired or adaptive immunity relies on the recognition of specific foreign antigens (see Table 97.2). However, these two arms of the immune response are strongly inter-regulated, with events occurring early in infection dictating the direction of the adaptive response, while activation of acquired immune effector mechanisms has a direct feedback on cells of the innate system. The acquired immune response can be broadly divided into:

- T-cell activation and effector mechanisms, a so-called cell-mediated response; and
- the humoral response involving the maturation of B cells and the production of antibodies.

It must be stressed, however, that these two processes are highly interdependent, with B cells able to function as antigen-presenting cells (APCs) for T cells, and T-cell derived cytokines controlling isotype switching (Fig. 97.3).

Cell-mediated immune response

The T-cell response to infectious agents occurs in two consecutive stages. Initially the foreign antigen must be recognized, and this primarily occurs in the lymph nodes and spleen. Following presentation of antigen to naive T cells, they undergo a rapid and substantial proliferation and an increase in the expression of surface adhesion molecules such as selectins and integrins. During this process, the affinity of the adhesion molecules for their specific ligands within lymphoid organs decreases, facilitating the migration and homing of the activated T cells to the sites of infection and inflammation. The major subsets of conventional T cells, namely CD4 and CD8 T cells, undergo principally the same mechanisms of induction and activation, although their effector functions differ to a certain extent. We outline below the specific properties unique to each subset, as well as those for other, unconventional T-cell populations (Fig. 97.4).

CD4 T cells

CD4 T cells are critically important as effector T cells in the host defense against intracellular pathogens in particular. The induction of activated T cells occurs following the recognition of an antigenic peptide complexed to gene products of major histocompatibility complex (MHC) class II on the surface of APCs. Typically peptides are derived from exogenous protein, which are internalized by the APC and cleaved in endosomal/lysosomal compartments by intracellular proteases. Following this, the peptides are loaded onto MHC class II in a specialized MHC compartment and subsequently transported to the cell surface. Prior to the loading of the antigenic peptide, the MHC class II binding groove is occupied by a 23-amino acid peptide called class II-associated invariant chain peptide (CLIP), which is a cleavage product of the invariant chain. The antigenic peptides recognized by CD4 T cells are 15–22 amino acids in length and HLA-DM facilitates the exchange of CLIP for this peptide (Fig. 97.3).

Recognition of the MHC-peptide complex by the T-cell receptor (TCR) on CD4 T cells is itself not sufficient to result in T-cell activation. A second signal is required and this is provided by the interaction between co-stimulatory molecules and their ligands.[38] The major co-stimulation for naive T cells is the interaction between CD40 and CD40L, and the interaction between CD28 and members of the B7 family,[39] including the recently identified inducible co-stimulatory molecule (ICOS).[40] The primary APC for the generation of a CD4 T-cell response is the dendritic cell, which constitutively expresses high levels of MHC class II and co-stimulatory molecules. Macrophages are also efficient APCs, but require activation by IFN-? to reach full processing capacity because they express relatively low levels of MHC class II in the resting state. In such a complex process, there is always the potential that pathogens have developed strategies to interfere with the recognition of their antigens by the host immune system. Indeed, *M. tuberculosis*-infected cells have an impaired capacity to present exogenous antigens due to a downregulation of the synthesis of MHC class II molecules.[41] *Yersinia pseudotuberculosis* produces Yop H, an outer membrane protein that decreases the expression of B7-2 on APCs.[42]

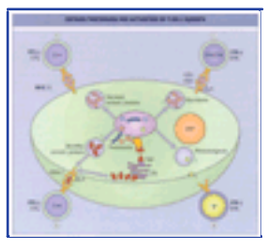

Figure 97-3 Pathways of antigen processing for activation of T-cell subsets. (a) CD4 T cells: within the APCs secreted or somatic antigens are digested by vacuolar proteases, which generate peptides of 15–22 amino acids in length — these peptides are loaded onto major histocompatibility complex (MHC) class II molecules in a specialized compartment before being transported to the cell surface. (b) CD8 T cells: endogenous antigens are cleaved in the cytoplasm by the proteasome to generate peptides of a final length of 8–9 amino acids — these are loaded onto MHC class I molecules in the endoplasmic reticulum (ER) and transported to the cell surface in association with ß$_2$ -microglobulin (ß$_2$ m). (c) CD1-restricted T cells: glycolipid antigens are presented by CD1 molecules on the surface of APC. Recent observations suggest that some processing events are required that involve components of the MHC class II pathway, but that antigen is loaded onto CD1 in the ER, similar to the MHC class I. (d) ?d T cells: to date no processing event or presentation molecule has been identified, but there is some suggestion that the nonpolymorphic Qa-1 molecule can function in antigen presentation. CTL, cytotoxic T lymphocyte; TAP, transporter associated with antigen processing.

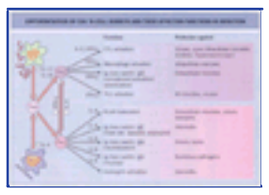

Figure 97-4 Differentiation of CD4 T-helper cell subsets and their effector functions in infection. Under the influence of cytokines produced by dendritic cells (DC) and NK cells, Th0 cells differentiate into Th1 cells (promoted by IL-12 and IL-18) or Th2 cells (promoted by IL-4). These differentiated T cells produce a characteristic pattern of cytokines, which perform various effector functions to eliminate pathogens. The major cytokine produced by Th1 cells is IFN-?, which promotes macrophage activation, critical in the elimination of intracellular pathogens. Th2 cells produce IL-4 and IL-5, which are critical for B-cell maturation and immunoglobulin class switching and hence are important in the control of helminths and extracellular pathogens. Note that via the production of these cytokines, each subset of Th cells can downregulate the differentiation of the other. DC1, myeloid dendritic cells derived from CD14$^+$ monocytes, which produce mainly IL-12; DC2, lymphoid dendritic cells derived from CD4$^+$ precursors, which produce mainly IL-4.

Following antigen recognition, CD4 T cells differentiate into Th cells that are capable of producing large amounts of cytokines (see Fig. 97.4). Murine Th cells were initially subdivided into Th1 and Th2 cells according to which cytokines they secreted. Thus, Th1 cells are characterized by the production of IFN-? and lymphotoxin-a, whereas Th2 cells secrete IL-4, IL-5, IL-6 and IL-13. In recent years other molecules including cytokine and chemokine receptors and transcription factors have provided additional markers to distinguish these cell types[43] and it is now clear that a similar dichotomy of CD4 T-cell subsets occurs in humans.[44]

The differentiation into polar subsets is determined by the initial encounter with the pathogen during the innate phase. Generation of Th1 cells is promoted by IL-12 and IL-18 produced by macrophages and dendritic cells in response to pathogens. These two cytokines are induced by a variety of microbial compounds, including LTA from Gram-positive bacteria such as *L. monocytogenes*, LPS from Gram-negative bacteria including *Salmonella* spp. and LAM from mycobacteria. In contrast, the central cytokine for the promotion of Th2 cell development is IL-4, although to date the precise cellular source for this cytokine is unclear. Once sufficient Th2 cells have

been generated, the autocrine IL-4 production can act as a growth factor and promote further differentiation. As described above, recognition of microbial PAMPs by TLRs are critical early events in the induction of immune responses to infectious agents driving the acquired immune response toward the Th1 pole. Consistent with this notion, mice deficient in MyD88 central to TLR signaling cannot mount Th1 responses to microbial pathogens.[45]

Such a polarization of the CD4 T-cell response obviously has an effect on the subsequent immune response. The production of IFN-? by Th1 cells is critical for the activation of macrophages for antibacterial effector mechanisms such as the generation of RNIs and ROIs and the downregulation of the transferrin receptor. Therefore, a Th1 response is considered to be optimal for resolution of infections with intracellular bacteria. In contrast, Th2 responses and the production of IL-4 and IL-5 promote the development of the humoral arm of the immune response, directing the differentiation of B cells into antibody-producing plasma cells secreting IgE and IgA. Consequently, a Th2 response predominates for the control of helminth infections and is critical for the production of antibodies that neutralize toxins. One of the best examples of the T-cell dichotomy in human disease is the host response to infection with *Mycobacterium leprae,* where Th1 responses characterize the tuberculoid form of the disease leading to the activation of macrophages, few detectable organisms and the formation of granulomas. In contrast, toward the lepromatous end of the disease spectrum, a Th2 cell response results in increased levels of IgE and IgG1, little granuloma formation and increased numbers of bacilli.

CD8 T cells

Like CD4 T cells, CD8 T cells also recognize peptide antigen in the context of MHC molecules on the surface of APCs. However, these are generally (with some exceptions discussed below) of cytoplasmic origin, either self-peptides or those generated from pathogens that reside in the cytoplasm of cells such as viruses or intracellular bacteria, such as *L. monocytogenes*. For CD8 T-cell activation, peptides are presented in the context of classical MHC class Ia molecules, which, in contrast to the relatively restricted expression of MHC class II, are expressed on almost every nucleated cell. Stable surface expression requires noncovalent association with ß$_2$ -microglobulin. Peptides for binding to MHC class Ia molecules are generated by the proteasome, a 28-subunit complex located in the cytoplasm (see Fig. 97.3). Peptides of 5–15 amino acids in length are generated, which are precursors of the final MHC class Ia binding peptides, which are eight to nine amino acids long. These are transported to the endoplasmic reticulum, where they bind to newly synthesized MHC class Ia molecules in a process involving molecular chaperones such as calnexin and gp96.

Regardless of the antigen-presenting molecule used, following antigen recognition and the appropriate co-stimulatory events, including cytokines produced by CD4 Th cells, CD8 T cells acquire two major effector functions:

- first, as for CD4 T cells they contribute to macrophage activation via the production of IFN-? and TNF; and
- second, CD8 T cells can directly lyse infected cells by one of two pathways — the perforin/granzyme pathway and a second pathway that induces apoptosis via the interaction of Fas and Fas ligand.

The perforin/granzyme pathway is the one now thought to be primarily responsible for the lysis of pathogen-infected cells. Perforin can effect lysis, but its primary role is to create channels in the membrane of the target cell through which cytolytic and bactericidal molecules such as granulysin can be introduced. Indeed, this particular

molecule has direct bactericidal activity against a variety of pathogens and is introduced directly into the bacterial phagosome.[46] The second pathway, which induces apoptosis via the interaction of Fas and Fas ligand, is now believed to be primarily responsible for the control of lymphocyte proliferation and activation.

Due to the nature of the antigens recognized by CD8 T cells, the activation of this T-cell population has been primarily considered to be involved in the control of viral infections and of pathogens that reside in the cytoplasm. Indeed, in the murine model of experimental listeriosis, mice deficient in components of the MHC class I processing machinery or in CD8 T cells themselves are highly susceptible to infection. Using MHC class I tetramers specific for immunodominant listerial antigens it has been shown that CD8 T cells dominate both the initial and the memory phase of infection.[47] The reason for this is the ability of *Listeria* to escape from their initial phagosomal location into the cytoplasm by means of the pore-forming enzyme listeriolysin. Once in the cytoplasm, listerial antigens are readily accessible to components of the MHC class I processing machinery.

There is now considerable evidence, however, that even pathogens that remain in a phagosomal compartment within the APC can induce a CD8 T-cell response. Thus, despite the obligate requirement for CD4 T cells in the control of *M. tuberculosis* infection described above, experimental evidence from mice lacking classical MHC class I has also supported a critical role for conventional CD8 T cells.[48] Additionally, CD8 T cells recognizing specific mycobacterial antigens in an MHC class I-restricted manner have been isolated from patients with tuberculosis.[49] Similarly, in *Salmonella* spp. infections, CD8 T cells contribute significantly to the control of infection.[50]

CD1-restricted T cells

The nonpolymorphic MHC-related CD1 molecules share some sequence homology with both MHC class I and MHC class II molecules and are expressed on the cell surface noncovalently bound to ß$_2$ -microglobulin. In contrast to protein-derived antigens presented by classical MHC molecules, CD1 present glycolipid antigens to T cells (see Fig. 97.3). [51] The CD1 molecules can be divided into two groups and are discussed separately.

Group I CD 1 molecules (CD1a, b, c) are present in humans but not in mice and are mainly expressed on professional APCs such as dendritic cells and B cells. To date a wide variety of glycolipid antigens, mainly derived from mycobacteria, have been described to bind to group I CD1 molecules for T-cell recognition and activation,[52] although antigens derived from *Haemophilus influenzae* as well as self-antigens can also be presented.[53] [54] In contrast to MHC I and II molecules, the processing requirements for antigens presented by group I CD1 have not been completely elucidated. The T cells that respond to CD1a-, b- and c-presented glycolipids express the a/ß TCR and are either CD8 positive or double negative. As with conventional CD8 T cells they are capable of both cytolytic activity and IFN-? secretion.[55]

Group II CD1 molecules consist of human CD1d and murine CD1.1 and the nonexpressed pseudogene CD1.2. The crystal structure of CD1.1 has been resolved and bears similarity to the MHC class I molecule in that it has a deep, highly hydrophobic antigen-binding groove. It is believed that ligands are bound by CD1 exclusively via hydrophobic interactions. Until recently, the only identified ligand for CD1d, a-galactosylceramide, was not of microbial origin but derived from a marine sponge. There have been controversial publications suggesting that glycosylphosphatidyl inositol moieties of parasites can bind to CD1d for T-cell activation. Recently, our laboratory has identified mycobacterial derived phosphatidyl-inositol-tetramannoside as the first bacterial ligand for CD1d. The T cells that recognize CD1d are termed NK T cells, and are characterized by a TCR consisting of the invariant a chain, Va14Ja281 in

mice and the homologous combination Va24JaQ in humans, together with the expression of the NK1 receptor. Upon activation, these cells rapidly produce large quantities of cytokines such as IL-4 and IFN-?. Bacterial infection rapidly shifts these T cells to Th1 promoting IFN-? production.[56]

?d T cells

In both mice and humans there is a minor population of cells that expresses the ?d TCR. The majority of human, but not murine, ?d T cells respond to bacteria-derived, nonprotein, phosphate-containing antigens.[57] In adult humans, 50% of these cells express a TCR comprising an invariant gamma chain (V?2) and delta chain (d2) and it is notable that, at least in vitro, all T cells expressing this TCR combination can be activated by mycobacterial phospholigands. Thus, if this were to hold true in vivo, then 1–2% of the entire T-cell population would have the potential to respond to infections with mycobacteria. Recent infection experiments with nonhuman primates revealed that profound activation of ?d T cells indeed takes place after *M. tuberculosis* infection.[58] To date no specific processing event or antigen-presenting molecule has been identified for ?d T-cell activation and it is assumed that there is direct activation of the TCR by the ligand. Murine ?d T cells recognize peptides rather than phospholigands, but again the mechanism of activation has not been elucidated. Functionally, ?d T cells produce cytokines such as IFN-? and IL-10 and these cells have been suggested to play primarily a regulatory role by downregulating conventional T-cell responses and limiting tissue damage. ?/d T cells and NK T cells express a marked TCR bias to few antigens of microbial origin, which allows their rapid activation. It is thus conceivable that these T cells perform regulatory functions at the very first encounter with microbial pathogens (Fig. 97.5).

HUMORAL IMMUNE RESPONSES

Humoral immune responses are considered to play a primary role in the counteraction of extracellular bacteria. As these bacteria replicate outside cells, their primary goal is to avoid internalization and killing by cells of the innate immune system. As a result of this the host relies on the activation of complement and the production of specific antibodies to counteract these pathogens. The absence of serum immunoglobulin from patients suffering from Bruton's agammaglobulinemia

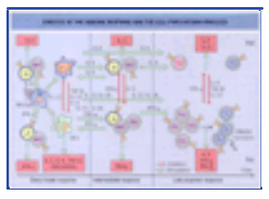

Figure 97-5 Kinetics of the immune response and the cell populations involved. Summary of the kinetics of the immune response to infection, from the recognition of microbial agents that initiates events, through to the generation of an effector T-cell response. The effector cytokines have been colored red for inhibitory and green for stimulatory.

renders them highly susceptible to infections with extracellular bacteria.

Like the induction of T-cell mediated immune responses, specific antibody responses are initiated via the interaction of antigen with a subset of mature B cells in the peripheral lymphoid organs. These B cells express either the IgM or the IgD receptor, and the antigen recognized can be divided into two groups, both of which are present in microbial pathogens.

T-dependent antigens

T-dependent antigens are proteins that are presented by B cells to activate CD4 Th cells. Following binding of the antigen to the membrane immunoglobulin of a specific B cell, it is internalized into endosomal compartments, processed and presented to CD4 T cells as previously described. Following activation, the resulting T-cell derived cytokines heavily influence the type of antibody produced due to their influence on isotype switching. Thus, the production of IFN-? will result in the production of IgG2a and IgG3. Both these isotypes activate the complement cascade to generate C3b and iC3b, and IgG2a can bind to the Fc?R1 receptor. Thus, under the influence of IFN-?, opsonization and phagocytosis of bacteria are promoted, consistent with the role of this Th1 cytokine in the control of many bacterial infections. The production of Th2 cytokines, such as IL-4 and IL-5, promotes the secretion of IgA and IgE. These isotypes cannot bind to FcR or CRs and consequently act primarily to block the adhesion of bacteria to host cells or to neutralize the harmful effects of toxins produced by extracellular bacteria. One example of this is the neutralization of the exotoxin of *Corynebacterium diphtheriae* by high-affinity IgA. These antibodies are also induced following vaccination against diphtheria where modified toxin molecules that retain the receptor binding site but lack the toxic activity are used.

T-independent antigens

T-independent antigens are nonproteins and stimulate antibody production by B cells in the absence of antigen-specific T-cell help.[59] The antibody class induced by these antigens is generally low-affinity IgM, and is the initial antibody produced against all bacterial infections. T-independent antigens are polymeric with repetitive epitopes, which facilitate the cross-linking of multiple immunoglobulin molecules

on the B cell surface. In particular the polysaccharides and glycolipids contained within the cell walls and capsules of many bacteria are particularly effective at inducing IgM responses.

Role of antibody in intracellular bacterial infections

Although it is clear that the major effector mechanisms against intracellular pathogens are those of the T-cell mediated response, there has been renewed interest in the protective role of antibody in such infections. For most intracellular bacteria, *L. monocytogenes* being a notable exception, there is a period of extracellular existence, either before initial internalization or as they are released from one cell to enter another. Thus, under such circumstances they are prone to complement-mediated lysis, and antibody may play a further role in facilitating phagocytosis via opsonization or in preventing entry of bacteria into cells. Experiments using B-cell deficient mice have revealed a role for humoral responses in the control of infections with *S. typhimurium*[60] and a role for Fc regulation of protective immunity in *Chlamydia trachomatis* infections have been proposed.[61] Even for *L. monocytogenes*, which spends relatively little time extracellularly due to its ability to spread directly from cell to cell, it has been shown that an antibody against listeriolysin is protective, and seems to function by neutralizing the activity of listeriolysin preventing the escape of *Listeria* into the cytoplasm.[62] Although such antibodies may be interesting vaccine candidates, apparently they do not contribute to protection during natural infection.

IMMUNOREGULATION

Despite the fact that the induction of an immune response is critical in preventing disease, it must be tightly regulated to prevent immunopathology. Most microbial infections induce an inflammatory response mediated by T cells and cytokines, which if not kept in check can result in tissue damage. The production of TNF-a is a classic example of such a problem — it is critical in the formation of granulomas for the control of intracellular bacteria such as *M. tuberculosis*, and yet is a key mediator of immunopathology when produced in excess, contributing for example to clinical conditions, such as severe sepsis and septic shock, or the adult respiratory distress syndrome that may result in fibrosis of lung tissue, which reduces lung function. Therefore, regulatory mechanisms must be in place to dampen down or switch off the ongoing immune response (see Fig. 97.5). This is mainly achieved by the production of cytokines such as IL-10 and transforming growth factor (TGF)-ß, which inhibit macrophage activation. However, in some cases T-cell activation is so overwhelming that these mechanisms fail and pathology results. One such case is the activation of T cells by so-called superantigens, which bind to the MHC molecule outside the peptide-binding site and activate a much larger population of T cells than processed protein antigen, resulting in the overproduction of T-cell derived cytokines. Thus, the fatal outcome of toxic shock is due to polyclonal T-cell activation by superantigenic exotoxins such as the toxic shock syndrome toxin 1 and enterotoxins of *S. aureus*.

T-cell-mediated immunopathology can also occur following recognition of cross-reactive epitopes between the microbial pathogen and the host — so-called autoimmunity. For example, the inflammatory damage to heart muscle in mice infected with *Chlamydia* spp. is caused by T cells that recognize peptides derived from the outer membrane protein of the pathogen, as well as a heart muscle-specific protein a-myosin.[63]

It is not only uncontrolled or cross-reactive T cells that can induce immunopathology, but also the induction of inappropriate effector mechanisms. This has been implicated in the pathology of leprosy discussed above, and also in infections with *Borrelia burgdorferi* where an inappropriate Th1 T-cell response leads to the development of arthritis. Recently, there has been a renewed interest in a subset of CD4T cells, namely the suppressor or regulatory T cells.[64] These cells have been described by many groups and have various characteristics including the expression of CD25 and the production of IL-10. It remains to be seen whether these T cells eventually turn out to be one population that develops in the absence of Th-cell-derived cytokines, and whose function is to downregulate an inappropriate Th1 or Th2 response.[65] Recent experiments identified CD4- and CD25-positive regulatory T cells in the listeriosis model. During secondary responses, CD8 T cells were markedly downregulated by these regulatory T cells. These findings suggest that pathologic sequelae of exaggerated T-cell responses are prevented by regulatory T cells once the pathogen has been eradicated.

In addition to dysregulated cell-mediated immune responses, immunopathology also commonly results following an uncontrolled humoral response. This is generally manifest as the deposition of immune complexes at tissue sites remote from the site of infection. Poststreptococcal glomerulonephritis can occur following the deposition of antigen-antibody complexes in the kidneys that activate complement and induce tissue damage. Like the situation described for T cells, cross-reactive antibodies can also occur, for example in infections with *Streptococcus pyogenes*. In this case, antibodies against the outer surface M protein of the bacteria cross-react with cardiac myosin proteins and so damage the heart valves. Poststreptococcal rheumatic fever occurs in up to 3% of people if the initial infection is left untreated.

IMMUNOLOGIC MEMORY

A major goal of the immune system is to develop long-lived immunologic protection, such that recovery from the initial encounter with an infectious agent provides an enhanced response that either resolves the infection completely or greatly reduces disease severity. To achieve this there are specialized populations of both T and B cells. Memory B cells and long-lived plasma cells secrete high-affinity neutralizing antibodies[66] whereas memory T cells (both CD4 and CD8) rapidly acquire effector functions such as the secretion of cytokines.

Memory T cells can be subdivided into two groups — central and effector memory T cells. This has been best characterized for the CD8 T-cell population but has parallels in the CD4 T-cell subset. These subsets are distinguished based on their expression of chemokine receptor 7 (CCR7) and L-selection (CD62L). Effector memory cells are located in the peripheral organs where they can rapidly respond to invading organisms. The maintenance of this cell population at these sites is achieved by low expression of CD62L and no expression of CCR7. These cells can rapidly produce effector cytokines such as IL-4 and IFN-?, but relatively little IL-2, and this population contains intracellular perforin. In contrast, central memory T cells home to the lymphoid organs as a result of the expression of CCR7, but produce IL-2 rather than IFN-? or IL-4. Thus, a model has been proposed that suggests that effector memory T cells are the direct progeny of effector T cells generated during the primary response. In contrast, central memory T cells do not acquire effector functions during the primary immune response, but persist in lymphoid tissues to form a reservoir to provide secondary effector T cells upon a second encounter with antigen.[67]

CONCLUSION

The central role of the immune system in the combat of infectious diseases finds increasing support from systematic analysis of the genetic basis for elevated susceptibility of immunodeficiency patients toward infection. Moreover, the realization that different infectious

diseases are preferentially associated with distinct types of immunodeficiency has provided support for the notions that:

- different pathogens have chosen distinct survival strategies in the host; and
- reciprocally that different immune mechanisms are responsible for the control of different infectious agents.

During the past decades, we have learned much from experimental infection studies with mouse mutants with distinct immunodeficiencies concerning the fine tuning of the anti-infective immune response. Transgene expression, knockin and knockout gene mutations — either constitutive or inducible — have all been developed in this species. Frequently, this hypothesis-driven research has proven the predicted role of distinct genes in the control of infection, such as the role of genes involved in IFN-? signaling in resistance to intracellular bacteria. In some cases unexpected results were obtained from infection experiments using mice with a gene deficiency thus far not associated with anti-infective control. Generally, however, meaningful predictions of functions of unknown genes were virtually impossible by this method.

The recent availability of the complete sequence of the human and murine genomes as well as of the genomes of all major pathogens has allowed a quantum leap. Using functional genomics, in particular transcriptome and proteome analyses, the cross-talk between host and pathogen can now be analyzed globally. In this way, the signature imprinted by the pathogen on the host can be elucidated. This will not only lead to the identification of novel genes that are expressed during infection and — by inference — can be considered as participants of the host response. It will also for the first time allow elucidation of co-ordinated gene expression profiles, which will lead to the identification of complete gene expression pathways relevant to susceptibility/resistance in the host. It goes without saying that the reciprocal analysis (i.e. the analysis of the global responses in the pathogen to the host) is equally possible. Although the plethora of data obtained through functional genomics is immense and can only be dealt with by computational bioinformatics, it will provide deep insights into the fine tuning of the host response to diverse pathogens and therefore provide the basis for novel intervention strategies against infectious diseases in normal as well as immunodeficient individuals. Such strategies include both manipulation of the host and the pathogen, such as immune replacement therapies or therapies with novel chemotherapeutic agents, respectively. With increasing incidences of multidrug-resistant strains, novel intervention strategies are urgently needed.

Chapter 98 - Immunodeficiencies

Richard-Fabian Schumacher
Sergio D Rosenzweig
Luigi Notarangelo
Steven M Holland

INTRODUCTION

White blood cells can be easily classified into lymphoid (T, B and natural killer (NK) cells) and myeloid (neutrophils, eosinophils, basophils and monocytes/macrophages) by virtue of their lineage-restricted progenitor's origin. Defects in these cells lead to defects in their respective pathways of host defense and specific and reproducible patterns of infection susceptibility. Therefore, the study of genetic immunodeficiencies is fundamentally about understanding the mechanisms of resistance to infection.

MYELOID CELLS AND DEFECTS

Mature neutrophils develop in the bone marrow from a myeloid stem cell over about 14 days. Mature neutrophils spend only 6–10 hours in the bloodstream before exiting by diapedesis to sites of inflammation.[1] Myeloid disorders can be generally divided into quantitative and functional disorders. Neutrophilia (>7500 neutrophils/ml in adults) is typically dependent on causes extrinsic to the neutrophils (e.g. acute or chronic infection, steroids, epinephrine (adrenaline)). On the other hand, neutropenia (mild: <1500 neutrophils/ml; moderate: 1500–1000 neutrophils/ml; severe: <500 neutrophils/µl) can be intrinsic or extrinsic to neutrophils or their progenitors. Although neutropenia can accompany many immunodeficiencies, the most common cause remains drug-induced (e.g. chemotherapy).

One should suspect a myeloid disorder in patients who have recurrent, severe bacterial or fungal infections. Unusual organisms (e.g. *Burkholderia cepacia, Chromobacterium violaceum*) or uncommon locations (e.g. liver abscess) should always prompt questions about neutrophil integrity (Table 98.1). Severe viral and parasitic infections are not typically increased in these patients and should direct attention to disorders involving lymphocytes or monocytes. Laboratory evaluation should consider the clinical presentation and where the defect is likely to be. Some assays, such as repeated white blood cell counts with differentials or microscopic evaluation of neutrophils, are relatively simple and can readily exclude certain disorders. Assays such as oxidative burst testing, phagocytosis, chemotaxis or flow cytometry are more difficult and few laboratories do them routinely.

SEVERE CONGENITAL NEUTROPENIA

Severe congenital neutropenia (SCN) or Kostmann syndrome (Online Mendeliain Inheritance in Man (OMIM)# 202700 see www.ncbi.nlm.nih.gov) comprises a heterogeneous group of disorders with variable inheritance patterns, that share the common characteristics of bone marrow granulocytic maturation arrest at the promyelocyte or myelocyte stage, severe chronic neutropenia (<200 neutrophils/µl) and increased susceptibility to acute myeloid leukemia. In 1956, Kostmann described a Swedish kindred who had severe congenital neutropenia inherited in an autosomal recessive pattern.[2] Recently, 22 out of 25 patients who have severe congenital neutropenia have been found to have heterozygous mutations in the gene encoding neutrophil elastase (*ELA2*, 19p13.3). [3] Interestingly, mutations in this same gene are also responsible for cyclic neutropenia. The clinical manifestations of this disease appear promptly after birth; 50% of affected infants are symptomatic before the first month of life and 90% within the first 6 months. Omphalitis, upper and lower respiratory tract infections, and skin and liver abscesses are the most frequent infections. Subcutaneous recombinant granulocyte colony- stimulating factor (G-CSF; 5µg/kg per day; range 1–120µg/kg depending on patient response) has dramatically changed the prognosis of these patients, leading to fewer infections and hospitalizations, and increased survival.[4]

Recently, an X-linked form of severe congenital neutropenia (XLN) due to discrete mutations in the Wiskott-Aldrich syndrome protein (WASP) has been identified.[5]

CYCLIC NEUTROPENIA/CYCLIC HEMATOPOIESIS

Although cyclic neutropenia (OMIM# 162800) is an autosomal dominant trait characterized by regular cyclic fluctuations in all hematopoietic lineages, it is only symptomatic because of variations in neutrophils. Neutrophil counts cycle about every 21 days (range 14–36 days), causing bouts of severe neutropenia (<200/µl), which last 3–10 days.[6] Heterozygous substitutions in *ELA2* (neutrophil elastase 2, 19p13.3) have been identified in all families studied.[6] Most patients have clinical manifestations of neutropenia in early childhood. Oral ulcers, gingivitis, lymphadenopathy, pharyngitis/tonsillitis and skin lesions are the most frequently reported findings. Early loss of permanent teeth due to chronic gingivitis and periapical abscesses is common. Bone marrow aspirates during neutropenia show maturation arrest at the myelocyte stage, or, less frequently, bone marrow hypoplasia. Granulocyte colony-stimulating factor lifts both the peak and nadir counts in cyclic neutropenia and dramatically improves quality of life and survival in these patients. [7] Interestingly, infections and hospitalizations appear to lessen naturally with age.

IMMUNE-MEDIATED NEUTROPENIAS

Alloimmune neonatal neutropenia

Alloimmune neonatal neutropenia (ANN) is caused by the transplacental transfer of maternal antibodies against NA1 and NA2, two isotypes of the immunoglobulin receptor Fc?RIIIb, leading to immune destruction of neonatal neutrophils.[8] This problem typically arises in otherwise normal children of apparently normal healthy mothers. The mothers do not express Fc?RIIIb on their own neutrophils, leading to the elaboration of antibodies against Fc?RIIIb expressed on fetal neutrophils to which the mother is sensitized during pregnancy. Antibody-coated neutrophils are phagocytosed and removed from the circulation, leading to neutropenia and infections. These antineutrophil antibodies can be detected in 1 in 500 live births and should be sought in all infants who have neutropenia. Omphalitis, cellulitis and pneumonia within the first 2 weeks of life may be the presenting infections. Detection of neutrophil-specific alloantibodies in maternal serum is diagnostic. Parenteral antibiotics

TABLE 98-1 -- Infecting agents and myeloid defects.

INFECTING AGENTS AND MYELOID DEFECTS		
Disease or syndrome	**Defect**	**Characteristic infections**
Chediak-Higashi syndrome	CHS1/LYST	*Staphylococcus aureus*
		Streptococcus pneumoniae
		Other streptococcal infections
		Haemophilus influenzae
		Gram-negative rods (skin and lung)

Specific granule deficiency	C/EBPepsilon/others	*S. aureus*
		S. pneumoniae
		Other streptococcal infections
		H. influenzae
		Gram-negative rods (skin and lung)
Myeloperoxidase deficiency	MPO	*Candida* spp. (when accompanied by DM)
Leukocyte adhesion deficiency 1	CD18	*S. aureus*
		Pseudomonas aeruginosa
		Gram-negative rods (skin and bowel)
Chronic granulomatous disease	NADPH oxidase	*S. aureus* (skin, liver, lymph nodes)
		Serratia marcescens (lung, skin, bone, sepsis)
		Burkholderia cepacia (lung, sepsis)
		Chromobacterium violaceum (skin, sepsis)
		Nocardia spp. (lung)
		Aspergillus spp. (other filamentous fungi; lung, bone)
Hyper-IgE syndrome (Job's)	Unknown	Primary pathogens:
		S. aureus (lung and skin)
		S. pneumoniae (lung)
		H. influenzae (lung)
		Pneumocystis carinii (lung)
		Secondary pathogens in lung cavities:
		Pseudomonas aeruginosa
		Aspergillus spp.
Interferon-?/interleukin-12 pathway	Multiple	Nontuberculous mycobacteria
		Salmonella spp.
		Mycobacterium tuberculosis
		Some DNA and RNA viruses

and G-CSF should be given; intravenous gammaglobulin may not be effective in reversing ANN. It resolves spontaneously with the waning of maternal antibody levels.

Primary autoimmune neutropenia

Primary autoimmune neutropenia (AIN) is the most common cause of chronic neutropenia (absolute neutrophil count <1500/µl lasting at least 6 months) in infancy and childhood.[9] It has a slight female preponderance and occurs in about 1:100,000 live births. Antibodies directed against different neutrophil antigens can be detected in almost all patients, almost 85% of which are IgG. Detection of granulocyte-specific antibodies may require repeated testing. Approximately one-third of these autoantibodies are directed against NA1 and NA2. Other antigens include CD11b/CD18 (Mac-1); CD32 (Fc?RII); and CD35 (C3b complement receptor).[10] The average age at diagnosis is 8 months. The majority of patients present with skin or upper respiratory infections but the diagnosis may be incidental, as patients may remain asymptomatic despite low neutrophil counts; severe infections are infrequent. Neutrophil counts are usually between 500 and 1500/µl at the time of diagnosis. The neutrophil count may transiently increase during severe infections, and bone marrow may be normal or hypercellular. The prognosis of primary AIN is good, since it is usually self-limited. The neutropenia remits spontaneously within 7–24 months in 95% of patients, preceded by the disappearance of autoantibodies. Antibiotics for infections are usually sufficient. In severe infections or emergency surgery G-CSF is used.[11]

Secondary autoimmune neutropenia

Secondary AIN can be seen at any age but is more common in adults and has a more variable clinical course. Systemic lupus erythematosus, Hodgkin's disease, large granular lymphocyte proliferation or leukemia, Epstein-Barr virus infection, cytomegalovirus infection, HIV infection and parvovirus B19 infection have been associated with secondary AIN. Antineutrophil antibodies typically have pan-Fc?RIII specificity, rather than to the Fc?RIII subunits, making the resulting neutropenia more severe. Anti-CD18/11b antibodies have been detected in a subset of patients. Secondary AIN responds best to therapy directed at the underlying cause.

DEFECTS OF GRANULE FORMATION AND CONTENT

Chediak-Higashi syndrome

Neutrophil granules house critical enzymes for bacterial and fungal killing, and are mobilized to the phagosome immediately after ingestion of an invader (Fig. 98.1). This intracellular trafficking requires molecular motors, which move granules inside the cell. The Chediak-Higashi syndrome is a rare and life-threatening autosomal recessive disease clinically characterized by oculocutaneous albinism, frequent pyogenic infections, neurologic abnormalities and a relatively late-onset lymphoma-like 'accelerated phase'. Affected patients show hypopigmentation of the skin, iris and hair. The latter is light brown to blonde, with a characteristic metallic silver-gray sheen. Under light microscopy, hair shafts in Chediak-Higashi syndrome show pathognomonic small aggregates of clumped pigment. Giant azurophil granules form from the fusion of multiple primary granules in neutrophils, eosinophils and basophils, but enlarged cytoplasmic granules are found in all granule-containing cells. Mild neutropenia is common as a result of intramedullary destruction of neutrophils.[12]

Chediak-Higashi syndrome is due to mutations in the lysosomal trafficking regulator gene, *LYST* or *CHS1* (1q42.1-q42.2; OMIM# 214500),[12] but the mechanism and pathophysiology of the syndrome are still elusive. Monocyte and neutrophil chemotaxis are diminished. Phagocytosis is normal or increased but bacterial killing is delayed, probably because of low levels of primary granule enzymes. Natural killer cells show very low cytotoxicity but neutrophil and monocyte antibody-dependent cellular cytotoxicity is intact. B cell function is usually unaffected. Progressive involvement of the peripheral and central nervous systems is common, with neuropathy of the legs, cranial nerve palsies, seizures, mental retardation and autonomic dysfunction.

The accelerated phase is one of the main causes of death in Chediak-Higashi syndrome and is clinically indistinguishable from other hemophagocytic syndromes. It is characterized by fever, hepatosplenomegaly, lymphadenopathy, cytopenias, hypertriglyceridemia, hypofibrinogenemia, hemophagocytosis and tissue lymphohistiocytic infiltration. Etoposide (VP16), steroids and intrathecal methotrexate (when the central nervous system is involved) have been effective. However, without successful bone marrow transplantation, the accelerated phase usually recurs.

Neutrophil-specific granule deficiency

The CCAAT/enhancer binding proteins (C/EBPs) are transcription factors that guide myelopoiesis and cellular differentiation.[13] Neutrophil-specific granule deficiency is a rare, heterogeneous, autosomal recessive disease characterized by the profound reduction

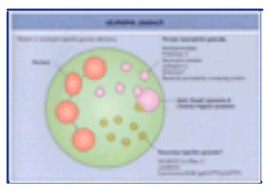

Figure 98-1 Neutrophil granules. Neutrophils contain primary, secondary and tertiary granules, each of which has specific contents that are produced at different points in myeloid ontogeny. The larger, azurophilic primary granules contain a host of proteins, only some of which are listed here. Note that secondary granule deficiency affects both all secondary granule contents as well as the primary granule defensins. Primary granules fuse in Chediak-Higashi syndrome, along with a smaller number of secondary granules, to give the characteristic cell inclusions.

or absence of neutrophil-specific granules and their contents, as well as the primary granule product, defensins (OMIM# 245480).[14] In several cases a homozygous, recessive mutation was found in C/EBPepsilon (14q11.2). However, other cases do not have mutations in C/EBPepsilon, suggesting genetic heterogeneity. These patients have markedly increased susceptibility to pyogenic infections of the skin, ears, lungs and lymph nodes. Neutrophils show bilobed nuclei (pseudo-Pelger-Huët anomaly). Electron microscopy shows absent peroxidase-negative granules in some patients and empty peroxidase-negative granules in others. Staphylococcidal activity may be reduced because of poor phagocytosis but candidacidal activity and superoxide production are normal. Hemostatic abnormalities, due to reduced levels of platelet-associated high-molecular-weight von Willebrand factor and platelet fibrinogen and fibronectin, may occur.

The diagnosis of specific granule deficiency is suggested by the peripheral smear and confirmed by electron microscopy and specific enzyme detection. Eosinophils may not be detectable on routine smears. Management is complicated by poor inflammatory responses. Gram-positive cocci infections are common. Aggressive diagnosis of infection, prolonged and intensive therapy, and early use of surgical excision and débridement are necessary.

DEFECTS OF OXIDATIVE METABOLISM

Chronic granulomatous disease

The nicotinamide-adenine dinucleotide diphosphate (NADPH) oxidase is the enzyme complex required for the generation of super-oxide and its metabolites hydrogen peroxide and bleach (Fig. 98.2). The nascent enzyme complex exists as two groups of components: a heterodimeric membrane-bound complex embedded in the walls of secondary granules, and four distinct cytosolic proteins.[15] The structural components are referred to as *phox* proteins, for phagocyte oxidase. The secondary granule membrane complex is cytochrome b_{558} , composed of a 91kDa glycosylated ß chain ($gp91^{phox}$) and a 22kDa nonglycosylated a chain ($p22^{phox}$), which binds heme and flavin. The cytosol contains the structural components $p47^{phox}$, $p67^{phox}$ and the regulatory components $p40^{phox}$ and Rac. On cellular activation the cytosolic components $p47^{phox}$ and $p67^{phox}$ are phosphorylated and bind tightly together. In association with $p40^{phox}$ and Rac, these

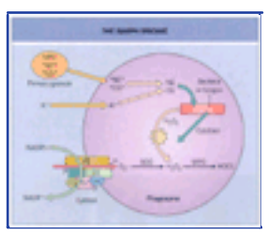

Figure 98-2 The NADPH oxidase. Cellular activation leads to assembly of the nascent NADPH oxidase by joining of secondary granule membrane and cytosolic components. The generation of an intravacuolar charge is rectified by potassium influx, which in turn liberates neutrophil elastase (NE) and cathepsin G (CG) from their associated matrix (**). As classically conceived, an ingested organism is shown degrading its own hydrogen peroxide, thus eliminating a supplement to the defective metabolic pathway in CGD. However, the pathologic relevance of the role of catalase in bacterial or fungal virulence is unclear.

proteins combine with the cytochrome complex ($gp91^{phox}$ and $p22^{phox}$) to form the intact NADPH oxidase. Following assembly, an electron is taken from NADPH and donated to molecular oxygen, leading to the formation of superoxide. In the presence of superoxide dismutase, this is converted to hydrogen peroxide, which, in the presence of myeloperoxidase and chlorine in the neutrophil phagosome, is converted to bleach. Reeves and co-workers[16] have recently shown that phagocyte production of reactive oxygen species facilitates activation of certain primary granule proteins inside the phagocytic

vacuole. This new paradigm for NADPH-oxidase-mediated microbial killing suggests that reactive oxidants are most critical as intracellular signaling molecules, leading to activation of other pathways.

Mutations in any of the structural components of the NADPH oxidase cause chronic granulomatous disease (CGD), a genetically heterogeneous disease characterized by recurrent life-threatening infections, due to catalase-positive bacteria and fungi, and exuberant granuloma formation (OMIM# 306400, 233690, 233700, 233710). The most common genotype involves mutations in the X-linked $gp91^{phox}$ and accounts for about two-thirds of cases.[15] The remainder of cases are autosomal recessive; there are no autosomal dominant cases of CGD. The frequency of CGD in the USA may be as high as 1:100,000. Clinically, CGD is quite variable but the majority of patients are diagnosed as toddlers and young children. Infections or granulomatous lesions are usually the first manifestations.[17]

The lung, skin, lymph nodes and liver are the most frequent sites of infection (see Table 98.1). The overwhelming majority of infections in CGD are due to only five organisms: *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Nocardia* spp. and *Aspergillus* spp. Trimethoprim-sulfamethoxazole (co-trimoxazole) prophylaxis has reduced the frequency of bacterial infections in general and staphylococcal infections in particular. On prophylaxis, staphylococcal infections are essentially confined to the liver and cervical lymph nodes. Staphylococcal liver abscesses encountered in CGD are dense, caseous and difficult to drain, requiring surgery in almost all cases.[17] With the great successes in antibacterial prophylaxis and therapy, fungal infections, typically those due to *Aspergillus* spp., are now the leading cause of mortality in CGD.[17] The recent introduction of itraconazole prophylaxis should further reduce the incidence of fungal infection.

The granulomatous manifestations of CGD are particularly troublesome, often involving the gastrointestinal and genitourinary tracts (Fig. 98.3). Esophageal, jejunal, ileal, cecal, rectal and perirectal involvement with granulomata mimic Crohn's disease. Gastric outlet obstruction is common and may be the initial presentation of CGD.[15] Bladder granulomata, ureteral obstruction and urinary tract infection are also common. Steroid therapy is quite effective and surprisingly well tolerated when used for treatment of obstructive lesions.[15] Prednisone

Figure 98-3 Manifestations of chronic granulomatous disease. (a) Pneumonia due to *Aspergillus* spp. can present subtly, both clinically and radiographically. This patient was asymptomatic but had multifocal pneumonia due to *Aspergillus fumigatus*. (b) Wound dehiscence typically presents 5–10 days postoperatively. It is an exuberant granulation tissue on biopsy and is best treated with short courses of corticosteroids. (c and d) Liver abscesses due to staphylococci are quite common in CGD ((c) arrow) and typically require *en bloc* resection because of their dense, granulomatous nature (d).

(prednisolone) given at about 1mg/kg for a brief initial period and then tapered to a low dose on alternate days is quite successful. The frequency of relapse/recurrence of gastrointestinal granulomatous disease is high, so prolonged low-dose maintenance is often necessary. Other therapies for severe granulomatous complications include cyclosporin A and colostomy for refractory rectal disease. Several cases have been treated with infliximab. The latter therapy must still be viewed with caution, as infliximab increases the rates of fungal infection, even in normal individuals.

The X-linked carriers of $gp91^{phox}$ have two populations of phagocytes, one that produces superoxide and one that does not, yielding a characteristic mosaic pattern on oxidative burst testing. Discoidlupus-erythematosus-like lesions, aphthous ulcers and photosensitive rashes have been seen in $gp91^{phox}$ carriers. Infections are not usually seen in these female carriers unless the normal neutrophils are below 5–10%; then, these carriers are at risk for CGD-type infections. [15] [17]

The diagnosis of CGD is made by a measure of superoxide production. Currently, we prefer the dihydrorhodamine (DHR) assay because of its relative ease of use, its ability to distinguish X-linked from autosomal patterns of CGD on flow cytometry and its sensitivity to even very low numbers of functional neutrophils. [15] Immunoblot and mutation analysis are required to identify the specific affected protein and genetic lesion respectively. Male sex, earlier age at presentation and relatively severe disease suggest X-linked disease, but these are only rough guides. Autosomal recessive forms of CGD (mostly $p47^{phox}$ -deficient) have a significantly better prognosis than X-linked disease. In a retrospective voluntary registry, mortality for the X-linked form of the disease was about 5% per year, as compared with 2% per year for the

autosomal recessive varieties.[17] The precise gene defect should be determined in all cases, as it is critical for genetic counseling and is prognostically significant.

Prophylactic trimethoprim-sulfamethoxazole (5mg/kg per day based on trimethoprim) reduces the frequency of major bacterial infections from about once every year to once every 3.5 years without increasing serious fungal infections in CGD. The greatest cause of mortality in CGD in developed countries remains *Aspergillus* pneumonia but itraconazole prophylaxis prevents fungal infection in CGD (100mg daily for patients under 13 years or 50kg; 200mg daily for those over

13 years or 50kg).[18] A large, multinational, multicenter, placebo-controlled study showed that interferon (IFN)-? reduced the number and severity of infections in CGD by 70% compared with placebo regardless of the inheritance pattern of CGD, sex or use of prophylactic antibiotics. Interestingly, no significant difference could be detected in terms of in-vitro superoxide generation, bactericidal activity or cytochrome b levels.[19] Therefore, our current recommendation is to use prophylaxis with trimethoprim-sulfamethoxazole, itraconazole and IFN-? (50µg/m^2) in CGD.

Since the differential diagnosis for a given process in these patients includes bacteria, fungi and granulomatous processes, a microbiologic or histopathologic diagnosis is critical. In severe infections, leukocyte transfusions are often used, although their efficacy is anecdotal. Bone marrow transplantation leading to stable chimerism has been successfully performed in patients who have CGD. Seger *et al.*[20] have reviewed the European experience with bone marrow transplantation for refractory infection, predominantly with *Aspergillus* spp. Horwitz *et al.*[21] performed low-intensity nonablative transplant from HLA-identical siblings into CGD patients. Success was greater in children than adults but transplant-related toxicities, such as graft-versus-host disease, remain problematic. Clinical trials of $p47^{phox}$ gene therapy have shown marking of cells in the periphery for several months but clinical benefit has not been shown, presumably because of the low numbers of corrected cells in the circulation (<0.01%).

Myeloperoxidase deficiency

Myeloperoxidase (MPO; 17q23) is synthesized in neutrophils and monocytes, packaged into primary granules and released either into the phagosome or the extracellular space, where it catalyzes the conversion of H_2O_2 to hypohalous acid (in neutrophils the halide is Cl^- and the acid is bleach). Myeloperoxidase deficiency is the most common primary phagocyte disorder; 1/4,000 individuals have complete MPO deficiency and 1/2,000 have a partial defect[22] (OMIM# 254600). It is an autosomal recessive trait with a variable range of expressivity. Despite in-vitro studies showing that MPO-deficient neutrophils are markedly less efficient than normal neutrophils in killing *Candida albicans* and hyphal forms of *Aspergillus fumigatus*, clinical infection in MPO deficiency is rare. Of the MPO-deficient patients who have had clinical findings, infections due to different *Candida* strains were the most common, and diabetes mellitus appears to be a critical cofactor. [22] Definitive diagnosis is established by neutrophil or monocyte peroxidase histochemical staining or

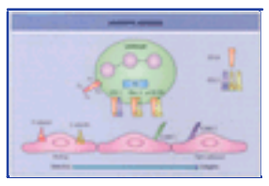

Figure 98-4 Leukocyte adhesion. Neutrophils sample the endothelium in the postcapillary venules through a series of receptors. Depicted here are the selectin and integrin pathways, which are critical for neutrophil adhesion (monocytes and eosinophils have other ligand and receptor options). CD15s binds to selectins on the endothelium with loose adhesion, allowing closer sampling of the endothelium for tight adhesion in the setting of endothelial activation, mediated through the integrins. Neutrophil integrins bind to intercellular adhesion molecules (ICAMs).

specific protein detection. There is no specific treatment for MPO deficiency.

THE LEUKOCYTE ADHESION DEFICIENCIES

For over a century, leukocyte movement from the bloodstream toward inflamed sites has been recognized as critical in preventing and fighting infections. Leukocyte adhesion to the endothelium, to other leukocytes and to bacteria is critical in the ability of leukocytes to travel, communicate, inflame and fight infection. Different families of adhesion molecules mediate these processes, critical among which are the integrins and selectins (Fig. 98.4).

Leukocyte adhesion deficiency type 1

The leukocyte $ß_2$ integrins are heterodimeric molecules on the surface of neutrophils, monocytes and lymphocytes that bind to intercellular adhesion molecules (ICAMs) on the endothelial surface in order to attach and exit the circulation.[23] ICAMs can also be expressed on other leukocytes, allowing for cell-cell adhesion. In addition, certain $ß_2$ integrins can bind directly to pathogens or to complement. Leukocyte integrins are composed of an a chain (CD11a, CD11b or CD11c), noncovalently linked to a common $ß_2$ subunit, CD18. The aß heterodimers of the $ß_2$ integrin family include CD11a/CD18 (lymphocyte-function-associated antigen 1, LFA-1), CD11b/CD18 (macrophage antigen 1, Mac-1, or complement receptor 3, CR3), and CD11c/CD18 (p150,95 or complement receptor 4, CR4). Since CD18 is required for normal expression of the aß heterodimers, recessive mutations in CD18 lead to either very low or no expression of CD11a, CD11b and/or CD11c, with resulting inability to bind to endothelium, each other, certain pathogens or complement opsonized particles (ITGB2, 21q22.3; OMIM# 116920). This disease is known as leukocyte adhesion deficiency type 1 (LAD1).[24]

The severe phenotype of LAD1 is caused by less than 1% of normal expression of CD18 on neutrophils, while the moderate phenotype can show up to 30% of normal. However, patients who have normal CD18 cell surface expression but no functional activity have been described, indicating that functional assays must be performed if the clinical suspicion of LAD1 is high.

Patients who have the severe phenotype of LAD1 characteristically have delayed umbilical stump separation and omphalitis, persistent leukocytosis (>15,000/µl) even in the absence of obvious active infection, and severe, destructive gingivitis and periodontitis

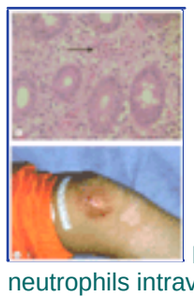

Figure 98-5 Examples of leukocyte adhesion deficiency type 1. (a) A biopsy from the bowel of a patient with extensive inflammation and intestinal ulceration. Note the abundance of neutrophils intravascularly (arrow) but the paucity of neutrophils in the parenchyma. (b) Characteristic dystrophic or 'cigarette paper' scarring following skin ulceration in a boy who has LAD1.

with associated loss of dentition and alveolar bone. Recurrent infections of the skin, lung, bowel and perirectal area are common and usually due to *S. aureus* or Gram-negative bacilli. Necrosis and ulceration without pus accumulation or neutrophil invasion of the infected site are common (Fig. 98.5). Impaired wound healing is characteristic of LAD1; scars tend to be dystrophic and have a 'cigarette-paper' appearance. In contrast to the severe phenotype, patients who have the moderate phenotype tend to be diagnosed later in life, have normal umbilical stump separation, have fewer life-threatening infections and live longer. However, leukocytosis, periodontal disease and delayed wound healing are still common. Aggressive medical management with antibiotics, and surgery when indicated, are requisite. Neutrophil transfusions may be helpful in severe cases but their use is anecdotal.

Complement-mediated phagocytosis is severely impaired because of absence of CD11b/CD18 (CR3/Mac-1) and antibody-dependent cell-mediated cytotoxicity is diminished. However, IgG-mediated phagocytosis is unaffected, as is superoxide production and primary and secondary granule release. At present, bone marrow transplantation is the only definitive corrective treatment. Gene therapy of LAD1 is not yet of clinical benefit in humans.

Other defects in leukocyte adhesion

Selectins are the molecules that mediate the loose, rolling adhesion of neutrophils along postcapillary venules.[23] Leukocyte adhesion deficiency type 2 is a metabolic defect now referred to as congenital disorder of glycosylation type IIc (CDG-IIc).[25] It is a very rare autosomal recessive inherited disease due to mutations in the GDP-fucose transporter (11p11-q11; OMIM# 266265)[26] leading to defective fucosylation of a variety of molecules, most notably the neutrophil ligand sialyl-Lewis^X . Patients have infections of the skin, lung and gums, leukocytosis and poor pus formation, as well as mental retardation, short stature, distinctive facies and the Bombay (hh) blood phenotype. In vitro, LAD2 cells show impaired neutrophil migration, aggregation and adherence to endothelial cells. Fucose supplementation may be helpful.

Defects in endothelial expression of E-selectin[27] and in the Rho GTPase RAC2 (RAC2, 22q12.13-q13.2; OMIM# 602049)[28] also lead to abnormalities in adhesion and increased infections.

INTERFERON-?/INTERLEUKIN-12 PATHWAY DEFECTS

The mononuclear phagocyte is critical for protection against intracellular infections. It mediates antigen presentation, lymphocyte stimulation and proliferation, and cytokine production and response. Mycobacteria infect macrophages, leading to production of interleukin (IL)-12, which in turn stimulates T cells and NK cells to produce IFN-?. Interferon-? increases production of tumor necrosis factor (TNF)-a, IL-12 and other cytokines, as well as mediating mycobacterial killing through unknown mechanisms. Interferon-? signaling depends on the signal transducer and activator of transcription 1 (STAT1), while TNF-a signaling depends on the nuclear factor (NF)?B essential modulator (NEMO; Fig. 98.6). Defects in several critical members of the pathway involving IFN-?, IL-12, TNF-a and their respective receptors and signaling molecules have been clearly identified at the functional and genetic levels as being responsible for infections with mycobacteria, salmonellae and certain viruses.[29] [30]

The IFN-? receptor is composed of ligand binding (IFN-?R1) and signal transducing (IFN-?R2) chains. Autosomal recessive mutations in either chain that lead to abolition of IFN-? signaling have severe infection phenotypes, predominantly with mycobacteria. Patients who have complete defects tend to present early in life, especially if they have received bacilla Calmette-Guérin (BCG) vaccination. They have poor or absent granuloma formation (but normal tuberculin skin tests) and typically develop repeated, disseminated, life-threatening infections due to mycobacteria, salmonellae and some viruses. Mortality is overwhelmingly due to mycobacterial disease. Treatment relies entirely on antibiotic and antiviral therapy. Rare recessive mutations with partial function have intermediate phenotypes and more curable infections.

The most common mutation in IFN-?R1 is due to a four-base deletion at or around base 818 (818del4), located just inside the intracellular domain of the molecule. This mutation allows the protein to remain stuck on the cell surface, where it interferes with the normal product and inhibits signaling[31] (Fig. 98.7). Patients who have this autosomal dominant mutation in IFN-?R1 usually present before age 7 with pulmonary nontuberculous mycobacterial infection but then often go on to develop recurrent multifocal nontuberculous osteomyelitis. Interferon-? signaling persists in this disease, but at a greatly reduced level compared to normal. Interferon-? therapy, sometimes at high dose, can be effective. Long-term prophylaxis against environmental mycobacteria with a macrolide seems prudent.

Mutations in IL-12p40, IL-12 receptor ß1 and STAT1 are typically not as severe as complete IFN-? receptor defects but they also

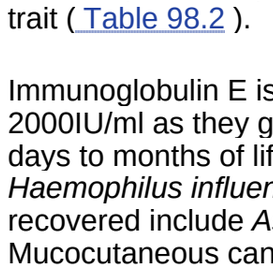

Figure 98-6 Critical cytokine pathways in the control of mycobacteria. Mycobacteria and salmonellae stimulate the elaboration of IL-12 by infected macrophages, leading to the production of IFN-? by T cells and NK cells. IFN-? in turn stimulates macrophages to produce TNF-a and IL-12. The critical signaling molecules STAT1 and NEMO are also indicated. IL-12-independent pathways for IFN-? production are also indicated (IL-15, IL-18), which work in concert with IL-12 for lymphocyte stimulation. Other, as yet undefined pathways are also suggested.

usually present with disseminated BCG, nontuberculous mycobacteria or *Salmonella* infections.[29] [30] Because these defects have preserved IFN-?R function, IFN-? can be used therapeutically, in addition to antimycobacterials.

Immune signaling, through the receptors for IL-1, IL-18, TNF-a, CD40 and the Toll-like receptors, and signaling for ectodermal (teeth, hair, sweat gland) formation converge at the activation of NF?B, a process dependent on the proper phosphorylation of its inhibitor, I?B. The X-linked gene for NEMO is necessary for this process. Defects in *NEMO* cause ectodermal dysplasia, along with a complex and overlapping set of immunodeficiencies with dysfunction in the innate (Toll-like receptors, TNF-aR, IL-1R) and acquired (CD40, IL-18) immune systems, due to disruption of their common signaling pathway. [32] [33] These patients typically require intravenous immune globulin, because of ineffective immunoglobulin class switching, as well as antibiotics. Macrolide prophylaxis to prevent the acquisition of environmental mycobacterial infection appears prudent.

HYPER-IgE RECURRENT INFECTION SYNDROME

Hyper-IgE recurrent infection syndrome (HIES; Job's syndrome) is a rare autosomal disorder characterized by recurrent infections, typically of the lower respiratory system and skin, eczema, extremely elevated levels of IgE, eosinophilia and abnormalities of the connective tissue, skeleton and dentition (Fig. 98.8). The majority of patients have characteristic facial abnormalities, including a broad, somewhat bulbous nose.[34] Failure of primary dental deciduation, leading either to failure of eruption of secondary dentition or retention of both sets of teeth, is common. Many patients also have abnormalities of bone formation and metabolism, which may result in fractures, scoliosis, kyphosis and osteoporosis. HIES occurs spontaneously in all racial and ethnic groups, and in many cases is transmitted as an autosomal dominant trait (Table 98.2).

Immunoglobulin E is greatly elevated at some point in the life of all patients who have HIES but about 20% have been observed to drop their IgE levels below 2000IU/ml as they get older while retaining their susceptibility to infection. The clinical manifestations of HIES are quite distinct. Eczema usually presents within the first days to months of life. Other early signs include mucocutaneous candidiasis and severe diaper rash. Sinus or pulmonary infections, predominantly with *S. aureus* or *Haemophilus influenzae*, are common, as are postinflammatory pneumatoceles. Otitis media and otitis externa are common. Other pathogens that have been recovered include *Aspergillus* spp., *P. aeruginosa, S. pneumoniae*, group A streptococci, *Cryptococcus neoformans, Pneumocystis carinii* and *C. albicans*. Mucocutaneous candidiasis involving the mouth, vagina, intertriginous areas, fingernails and toenails affects about 50% of HIES patients. Bony abnormalities are frequent, as are pathologic fractures.

A prolonged course of high-dose intravenous antibiotics is required for eradication of infection and to prevent bronchopleural fistula formation and bronchiectasis. Empiric acute coverage should consider *S. aureus, H. influenzae* and *S. pneumoniae*. The former two organisms account for the majority of acute infections. Infection of pneumatoceles and bronchiectatic lung with *P. aeruginosa* and *Aspergillus* spp. is common and can be especially problematic. Most experts use prophylactic antibiotics (e.g. a synthetic penicillin or trimethoprim-sulfamethoxazole) directed at coverage of *S. aureus*.

T AND B CELL IMMUNE DEFICIENCIES

T and B cell immune deficiencies comprise a heterogeneous group of disorders, all characterized by profound impairment in the development or function of the cellular and/or the humoral parts of the immune system. T cells not only directly mediate resistance to

intracellular pathogens but also interact with B lymphocytes and antigen-presenting cells in the defense against extracellular pathogens. Consequently, defects in T cell development or function result in a combined immune deficiency with variable defects also seen in the B cell and/or NK cell compartments. Among combined immune deficiencies, the forms with most severe T cell depletion (also known as severe combined immune deficiency (SCID)) lead to increased susceptibility to severe infections from birth and must therefore be considered medical emergencies (Fig. 98.9). Failure to thrive, chronic diarrhea and interstitial pneumonia (often due to opportunistic organisms, such as *P. carinii, Candida* and *Aspergillus* spp., or viruses) are typical clinical features (Fig. 98.10). The overall frequency of combined immune deficiency is estimated to be 1 in 50,000 live births. Lymphopenia should raise suspicion. Quantification of the absolute $CD3^+$ cell count, analysis of human leukocyte antigen (HLA)-DR expression and T cell activation allow identification almost 98% of all SCID babies (Fig. 98.11).

Vaccination with live attenuated viruses or with BCG may lead to fatal disseminated infection (Fig. 98.12). Graft-versus-host disease, due to transplacental passage of alloreactive maternal T cells or transfusion of unirradiated blood products, can cause skin rash, diarrhea, hepatitis or bone marrow failure. If untreated, patients who have SCID die within the first few years of life. Prophylactic trimethoprim-sulfamethoxazole (to prevent *P. carinii* pneumonia) and aciclovir (for herpesviruses), immunoglobulin substitution therapy and aggressive treatment of any and all infectious episodes may prolong survival but only early allogenic bone marrow transplantation or (in selected cases) gene therapy or enzyme replacement therapy offer a chance to cure the disease.

In recent years molecular diagnosis has been achieved for most immune deficiencies (Fig. 98.13) and mutation databases have been established that are constantly updated and accessible via the Internet.[35] This has allowed precise and early diagnosis but has also demonstrated that defects in one gene may result in several different phenotypes (phenotypic heterogeneity) and that the same phenotype can be caused by different gene defects (genetic heterogeneity).

Severe combined immunodeficiency

In typical SCID, severe intestinal infections with malabsorption and failure to grow are prominent. The intestinal mucosa shows variable degrees of villus atrophy. The most frequently isolated pathogens include *Campylobacter, Salmonella, Shigella, Cryptosporidium parvum* and *Giardia lamblia*. The liver is often involved, ranging from hepatomegaly with elevated transaminases, to sclerosing

Note the development of bilateral aspergillomata with inflammation of the cavity walls. (b) A panoramic radiograph of the dentition of a 33-year-old woman who has HIES shows the characteristic retention of primary teeth due to failure of deciduation. (c) Extensive scoliosis is demonstrated in this radionuclide bone scan of a 25-year-old woman who has HIES. A list of some of the characteristic features of the syndrome is included in Table 98.2 .

TABLE 98-2 -- Features of Hyper-IgE syndrome.

FEATURES OF HYPER-IgE SYNDROME	
Feature	**%**
Eczema	100
Characteristic facies (> 16 years)	100
Skin boils	87
Pneumonias	87
Mucocutaneous candidiasis	83
Lung cysts	77
Scoliosis (> 16 years)	76
Delayed dental deciduation	72
Pathologic fractures	57

cholangitis due to *Cryptosporidium parvum*. Central nervous system involvement can also occur, mostly due to viral infections (herpes simplex virus (HSV), enterovirus, echovirus, adenovirus and poliovirus). Since SCID is typically classified by the presence or absence of T cells, B cells and NK cells, its nomenclature is complexly composed of cellular, genetic and molecular names.

$T\text{-}B^+$ severe combined immunodeficiency

X-linked severe combined immunodeficiency

The most common SCID phenotype is absence of mature T (and NK) cells in the blood and peripheral lymphoid organs, with a normal to increased number of B cells ($T\text{-}B^+$ SCID). Most commonly, this disease is inherited as an X-linked trait (SCID-X1, OMIM# 300400). SCID-X1 has an estimated incidence of between 1 in 150,000 and 1 in 200,000 live births and accounts for 35–40% of all cases of SCID. It is caused by mutations in the *IL-2RG* gene located at Xq13. The common gamma chain (?c) encoded by this gene is a cytokine receptor subunit, shared by the receptors for IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21, involved in the maturation of T, B and NK cells[36] (Fig. 98.14). Lacking intrinsic catalytic activity, these cytokine receptors need an intracellular signal transducer, which for ?c is JAK3, a member of the Janus-associated kinase (JAK) family of protein tyrosine kinases. Therefore, absence of ?c leads to marked impairment of signaling for multiple cytokines.

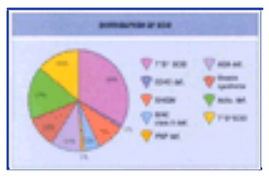

Figure 98-9 Distribution of severe combined immunodeficiency. Distribution of diagnoses in 100 consecutive SCID babies at the Children's University Hospital, Brescia,

Italy.

As in all forms of SCID, clinical onset of SCID-X1 is usually within the first few months of life with persistent diarrhea, pneumonia, failure to thrive and severe or persistent candidiasis. The diagnosis is usually suspected because of lymphopenia, with low to absent T and NK cell counts and normal to elevated B cell counts. Mitogen-induced proliferation is virtually absent and serum immunoglobulin levels are low to undetectable. Serum IgG may initially be normal because of persistence of transplacentally passed maternal antibodies. The thymus lacks a clear corticomedullary demarcation, Hassall's corpuscles are absent and in general there is a severe depletion of lymphoid tissues, with absent lymph nodes.

The diagnosis can be made by immunofluorescence analysis of ?c expression on the surface of lymphocytes or monocytes. However, some *IL2RG* gene mutations allow expression of nonfunctional ?c on the cell surface. Therefore, normal ?c expression does not rule out a diagnosis of SCID-X1. Further complicating matters, engraftment of maternal T cells (observed in as many as 50% of cases of SCID) may lead to an atypical immunologic phenotype, representing a diagnostic challenge. HLA typing and molecular analysis at highly

Figure 98-10 Typical severe combined immunodeficiency baby. Note the wasting and malnutrition.

polymorphic DNA loci can be used to identify the presence of maternal T cells. Other forms of SCID may present with the same cellular phenotype (T-B$^+$ SCID) and should be considered if ?c expression is normal. Detection of a mutation in *IL2RG*, most often inherited from the mother, confirms the diagnosis. Mutations found in different families are listed at http://www.nhgri.nih.gov/DIR/GMBB/SCID/IL2RGbase.html.

The standard treatment for SCID-X1 is allogeneic human stem cell (usually bone marrow) transplantation (BMT) was described in 1968.[37] It achieves success rates near 100% when an HLA-identical sibling is used as donor. Excellent results are also achieved with BMT from matched unrelated donors but, since early treatment is crucial and the search for a compatible donor often takes several months without a guarantee of finding one, haploidentical family donors have been increasingly used since the 1980s.[38] Prevention of graft-versus-host disease by elimination of T cells from the donor marrow or the

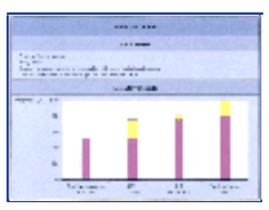

Figure 98-11 Diagnosis of severe combined immunodeficiency. Clinical and laboratory elements useful in the diagnosis of SCID.

Figure 98-12 Axillary BCGitis in a T-B$^+$ severe combined immunodeficiency baby who has generalized BCG infection. Note the extensive cutaneous ulceration.

use of positively selected peripheral blood stem cells after mobilization is crucial to successful HLA-mismatched transplantation[39] and is now successful in as many as 70–80% of patients. Even in the absence of myeloablation, engraftment of donor T (and often NK) cells is easily achieved. In contrast, engraftment of donor-derived B cells is facilitated by chemotherapy or irradiation conditioning of the recipient. When functional B cell deficiency persists in patients without donor B cell engraftment, regular intravenous immunoglobulin substitution is required.[39] In-utero stem cell transplantation has been successfully performed in affected fetuses with good clinical and laboratory T cell reconstitution. However, this technique can only be applied after prenatal diagnosis.

Because functional ?c expression provides strong proliferative advantage to lymphocyte precursors, SCID-X1 is an ideal model for

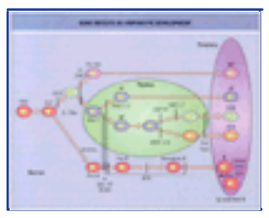

Figure 98-13 Gene defects and lymphocyte development. Model of lymphocyte development with the relative gene defects that may lead to immune deficiencies shown in red (for details see text).

gene therapy. Five patients have been successfully treated and have achieved normal T and NK cells and function after retrovirus-mediated ?c gene transfer into autologous CD34$^+$ bone marrow cells.[40] However, gene therapy is still quite new and may have unanticipated results, including leukemia in some recipients.

JAK3 deficiency

After the X-linked form, autosomal recessive *JAK3* mutations (19p12-13.1) are the second most common form of T-B$^+$ SCID (JAK3 deficiency, MIM#600173).[41] Because ?c and JAK3 are necessary components of the same signaling pathway (Fig. 98.15), JAK3 deficiency may be clinically and immunologically indistinguishable from SCID-X1. Diagnosis of JAK3 deficiency is established by immunoblot for JAK3 in patient lymphocytes or cell lines and/or demonstration of *JAK3* gene mutations. Since JAK3 deficiency is compatible with the presence of significant numbers of circulating, although poorly functioning, T cells, JAK3 deficiency should be considered in all undefined cases of combined immune deficiency, especially those presenting with a high proportion of peripheral B lymphocytes. Prenatal diagnosis, based on DNA analysis of chorionic villus biopsies, has been performed. As is the case for SCID-X1, definitive treatment of JAK3-deficient SCID is allogeneic BMT. *JAK3* gene transfer into hematopoietic stem cells in *jak3* knockout mice has been successful, indicating the possibility for *JAK3* gene therapy in humans. The mutations in *JAK3* are listed at http://www.uta.fi/imt/bioinfo/JAK3base.html.

IL-7Ra deficiency

Interleukin-7 is produced by stromal cells in the bone marrow and in the thymus and provides survival and proliferative signals to IL-7-receptor-bearing (IL-7R$^+$) cells. The IL-7 receptor consists of two subunits, the ?c chain and the IL-7Ra chain, which maps to chromosome 5p13. IL-7Ra is specific for the IL-7R, is expressed by lymphoid precursor cells and is essential for differentiation of early thymocytes. Consequently, mutations that impair expression of IL-7Ra result in an early block in T cell development, leading to SCID with absent T cells but normal (to elevated) B and NK cells.[42] The clinical picture is similar to that of other forms of SCID. Allogenic stem cell transplantation is the only curative treatment.

Figure 98-14 Receptors using the ? chain/JAK3 pathway. The six interleukin receptors that use the common ? chain/JAK3 pathway for signaling.

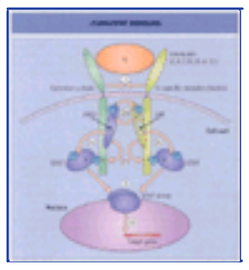

Figure 98-15 ?c/JAK3/STAT signaling. ?c/JAK3/STAT signaling is initiated by binding of the cytokine to its receptor. Heterodimerization (1) of the receptor chains (one IL-specific chain and the ?c) allows for reciprocal tyrosine phosphorylation (2a) of JAK3 and other JAK molecules, leading to their activation. Activated JAKs then phosphorylate (2b) tyrosine residues on both receptor subunits, creating docking sites for the STATs. These signaling elements are themselves tyrosine phosphorylated by the JAKs (2c), in order to dimerize and translocate to the nucleus (3), where they bind to consensus sequences within regulatory regions of cytokine-inducible genes and act as transcription factors driving transcription of the target genes.

IL-2Ra deficiency

IL-2Ra is another member of the IL-2 receptor complex required for IL-2-mediated signaling and peripheral T cell homeostasis. Consequently, mutations in the *IL2Ra* gene lead to an autosomal recessive immunodeficiency with reduced numbers of T cells and a normal number of B and NK cells. Autoimmunity and a progressive lymphoproliferative syndrome are typical, reflecting disturbed peripheral immune homeostasis.[43]

CD45 deficiency

CD45 modulates signaling through the T cell receptor (TCR)/CD3 complex. The immunologic phenotype is one of complete lack of T cells, with normal to increased B cell counts.[44]

T-B- severe combined immunodeficiency

Recombination of DNA in T cells and B cells is required for the generation of the immune diversity that is the hallmark of the mammalian immune system. This process requires specific gene products that cut and recombine DNA as well as specific sites to be acted upon. The genes that control these processes are responsible for phenotypes of SCID causing complete absence of both T and B lymphocytes in the periphery. The majority of these patients have a defect in the recombination process. [45] [46]

RAG1/RAG2 deficiency

To recognize foreign antigens, B and T cells use specialized receptors, namely the immunoglobulin (Ig) receptor and the TCR, respectively. These are characterized by highly polymorphic antigen-recognition sites, which are the coding products of variable (V), diversity (D) and joining (J) gene segments that undergo somatic rearrangement due to a mechanism known as V(D)J recombination. V(D)J recombination is crucial for the differentiation of T and B lymphocytes and is triggered by the lymphocyte-specific proteins recombinase activating gene (RAG)1 and RAG2. These gene products act together to recognize specific recombination signal sequences that flank each of the V, D and J gene elements in the Ig and TCR genes and break the DNA double strand there. Several ubiquitously expressed DNA repair proteins (including Ku70, Ku80, DNA-PKcs, XRCC4, DNA ligase I and IV, and Artemis — the latter involved in another form of SCID) then mediate the final steps of the V(D)J recombination process (Fig. 98.16).

The clinical presentation of RAG-deficient SCID (OMIM #601457) is very similar to that of the other autosomal recessive SCID forms (early onset, severe respiratory infections, chronic diarrhea leading to failure to thrive, persistent candidiasis). Frequent transplacental passage of maternal T cells leads to cutaneous manifestations suggestive of graft-versus-host disease. The immunologic phenotype is characterized by severe lymphopenia, with virtual absence of T and B lymphocytes. Almost all autologous circulating lymphocytes are NK cells. No specific immunoglobulins can be produced. Curative treatment is bone marrow transplantation.

Omenn syndrome

Omenn syndrome (OMIM #603554) affects infants of both sexes, who present with a prominent, generalized papular skin eruption or scaling exudative erythrodermia, alopecia, enlarged lymph nodes, hepatosplenomegaly, hypoproteinemia with edema, and eosinophilia,

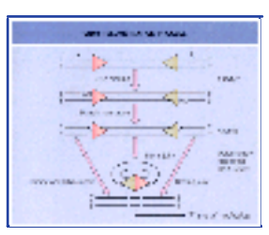

Figure 98-16 V(D)J recombination process. Diagram showing the V(D)J recombination process with the genes involved in T- B- SCID and Omenn syndrome.

Figure 98-17 A baby who has Omenn syndrome. Note the diffuse erythema.

associated with severe respiratory infections, chronic diarrhea and failure to thrive [47] (Fig. 98.17). This clinical phenotype may mimic histiocytosis X of the Letterer-Siwe type, or graft-versus-host disease, and may in fact be occasionally seen in SCID infants with transplacental passage of alloreactive maternal T cells. While the latter condition is also referred to as Omenn-like syndrome, the term Omenn syndrome is reserved for cases in which the presence of alloreactive T cells has been ruled out.

The molecular pathogenesis of Omenn syndrome long remained a mystery. However, the demonstration of a variable number of autologous, oligoclonal, autoreactive, activated T cells in Omenn syndrome infants, and the simultaneous occurrence of Omenn syndrome and T- B- SCID in two siblings suggested a genetic relationship. This hypothesis was proven when mutations in *RAG1* and *RAG2* were demonstrated in Omenn syndrome patients. [48] In contrast to T- B- SCID, each patient carried at least one mutant allele that allowed expression of a partially functioning RAG protein, resulting in a leaky V(D)J rearrangement defect, with reduced, but not abolished, intrathymic T cell differentiation.

In contrast to other forms of SCID, Omenn syndrome may have leukocytosis with marked eosinophilia and variable (up to normal) T cell counts. A characteristic finding is the co-expression of activation/memory markers (HLA-DR, CD45R0, CD25, CD95, CD30) on the surface of T cells, which predominantly secrete T helper (Th)2-type cytokines such as IL-4 and IL-5. B lymphocytes are typically absent from peripheral blood and lymphoid tissues and immunoglobulin levels are markedly diminished, but IgE is usually elevated. Lymph nodes show lymphoid depletion and an increased proportion of interdigitating reticulum cells, eosinophils and histiocytes. Thymus also shows lymphoid depletion and lack of corticomedullary demarcation.

Omenn syndrome is diagnosed by its characteristic features after engraftment of allogenic T cells has been excluded. Mutation analysis of *RAG1* and *RAG2* confirms the diagnosis and can be used for prenatal diagnosis in affected families. Interferon-? may reduce the Th2-type T cell activity and ameliorate the clinical status but,

unless treated by BMT, Omenn syndrome is usually fatal within the first year of life. Steroids and cyclosporin A may be used for treatment of the graft-versus-host-disease-like skin reaction.

Radiation-sensitive severe combined immunodeficiency (Artemis deficiency)

Mutations in the RAG genes do not account for all V(D)J recombination defects in T^- B^- SCID patients. A subgroup of patients also show increased cellular radiosensitivity (even in nonlymphoid lineages), due to mutations in *Artemis*, a gene located on the short arm of chromosome 10 (OMIM #602450) that participates in the later phases of V(D)J recombination.[49] This latter form of T^- B^- SCID, radiation-sensitive SCID (Rs-SCID), is more common among Athabascan-speaking Native Americans, among whom the incidence is estimated to be approximately 1 in 2000 live births. The encoded protein seems to be involved in the opening of the hairpin necessary to join the selected V(D)J regions (see Fig. 98.16). To date, *Artemis* mutations have been severe, resulting in a complete T^- B^- SCID phenotype.

Adenosine deaminase deficiency

Adenosine deaminase (ADA) is an ubiquitously expressed intracellular enzyme responsible for the transformation of adenosine to inosine, and of deoxyadenosine to deoxyinosine. The *ADA* gene is on chromosome 20 and the disease is inherited as an autosomal recessive trait (OMIM *102700). Deficiency in ADA results in intracellular accumulation of deoxyadenosine and its phosphorylated metabolites, among which dATP is particularly toxic to lymphoid precursors.[50] Consequently, patients who have complete ADA deficiency present with a typical T^- B^- SCID phenotype with marked lymphopenia. Partial ADA defects may result in less severe clinical presentations with delayed (in infancy) or late (during adolescence or even adulthood) onset.[51] Since the enzyme is ubiquitously expressed, nonhematopoietic organs such as kidney, bone, cartilage and the central nervous system may also be involved.

Optimal treatment is BMT from an HLA-identical family donor. When this is not available, enzyme substitution treatment with pegy-lated bovine ADA (PEG-ADA) results in effective and sustained reduction of toxic metabolite levels and immune reconstitution.[52] *ADA* was the first SCID-causing gene to be cloned and ADA deficiency was the first human disease to be treated with gene therapy, although it was not curative.[53] Some 10 years after the first attempts, improvements in vector design, cell targeting and recipient preparation have resulted in improved outcomes of gene therapy for ADA deficiency.[54]

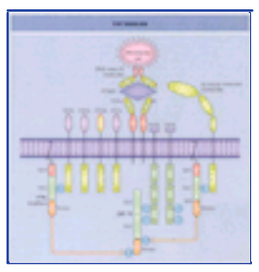

Figure 98-18 T cell receptor signaling. Stimulation of T cells through the CD3/TCR complex results in activation of p56lck, a src-tyrosine kinase, that mediates tyrosine-phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in the CD3-?, -d, -epsilon and -? chains. ZAP-70, an intracellular tyrosine kinase, is then recruited into the CD3/TCR complex through binding of its SH2 domains to phosphorylated ITAMs of the ? chain. ZAP-70 itself becomes phosphorylated by Src-family protein tyrosine kinases. Phosphorylation triggers ZAP-70 activation, allowing phosphorylation of downstream signaling molecules such as linker for activation of T cells (LAT) and SLP-76.

Purine nucleoside phosphorylase deficiency

Purine nucleoside phosphorylase (PNP) is another purine metabolism enzyme downstream of ADA that converts guanosine to guanine and deoxyguanosine to deoxyguanine. The *PNP* gene is on chromosome 14q13 and is inherited as an autosomal recessive trait. The accumulation of deoxyguanosine and its phosphorylated metabolites (dGTP in particular) inhibit ribonucleotide reductase, whose activity is essential to DNA synthesis. Although PNP is widely expressed, its deficiency is particularly deleterious to lymphoid development, especially T cells.[50] Consequently, patients who have PNP deficiency experience a dramatic and progressive T cell lymphopenia during the first years of life, leading to a SCID phenotype.[55] Toxicities of the metabolites also involve the central nervous system, with symptoms ranging from behavioral problems and low cognitive function to ataxia or tetraparesis. The only therapeutic option is BMT, since enzyme replacement therapy is not yet available.

Defects of the P56lck/ZAP-70 pathway

Stimulation of T cells through the CD3/TCR complex (Fig. 98.18) results in a complex series of activations focusing on p56lck, a Src-tyrosine kinase, immunoreceptor tyrosine-based activation motifs (ITAMs) and ZAP-70, an intracellular tyrosine kinase.[56] ZAP-70 itself becomes phosphorylated by Src-family protein tyrosine kinases. In humans, ZAP-70 is required for development of $CD8^+$ T cells in the thymus and peripheral blood T cell proliferation in response to mitogens and antigens.

Defective expression of p56lck leads to panhypogammaglobulinemia, lymphopenia with a reduced proportion of $CD4^+$ T cells and reduced in-vitro proliferation.[57] Defects in ZAP-70 result in impaired T cell development and function.[58] Infants who have ZAP-70 deficiency present with typical clinical features of SCID, virtual absence of $CD8^+$ T cells, and nonfunctional $CD4^+$ T cells. Both p56lck and ZAP-70 are autosomal recessive.

Major histocompatibility complex class II deficiency

T cells recognize foreign antigens in the context of self-MHC class II molecules expressed by antigen presenting cells. Major histocompatibility complex class II molecules are critical for numerous aspects of immune function, including antibody production, T-cell-mediated immunity, induction of tolerance and inflammatory responses. Therefore, MHC class II deficiency leads to an inability of T cells to recognize foreign antigens that would normally be presented by MHC class II and a combined humoral and cellular immune deficiency. This autosomal recessive immunodeficiency (OMIM #209920), also referred to as the bare lymphocyte syndrome type II (BLS II), is genetically heterogeneous and may be due to mutations in any of four components of transcription factors that control MHC class II gene expression:[59] class II transactivator (CIITA), RFXANK/RFX-B, RFX5 and RFXAP[60] (Fig. 98.19). The hallmark of MHC-II deficiency is the absence of HLA DR, DQ and DP molecules on B cells, monocytes and dendritic cells (which constitutively express HLA class II), and IFN-?-activated T cells. $CD4^+$ T cell counts are low, whereas $CD8^+$ T cells are normal to increased. In-vitro response to mitogens is often reduced and immunoglobulin levels are low. In the absence of allogenic BMT, patients generally die between the ages of 5 and 18 years.

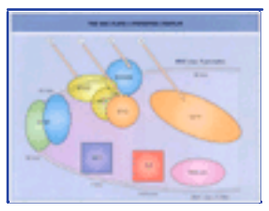

Figure 98-19 The major histocompatibility complex class II promoter complex. Mutations in these transcription factors account for the various complementation groups identified in MHC class II deficiency.

A moderate phenotype has also been described, with survival into adulthood.

TAP deficiency

Human leukocyte antigen class I molecules are polymorphic cell surface glycoproteins that play an essential role in presenting antigenic peptides to cytotoxic T lymphocytes and in modulating the activity of NK cells that bear HLA class I binding receptors. HLA class I molecules are composed of a polymorphic heavy chain, encoded by *HLA-A*, *HLA-B* and *HLA-C* genes, associated with the invariant ß$_2$ -microglobulin (ß$_2$ M). The assembly of HLA class I molecules occurs in the lumen of the endoplasmic reticulum, where they are loaded with peptides derived from the degradation of intracellular organisms or proteins. These peptides are transported into the endoplasmic reticulum via transporter-associated-with-antigen-presentation (TAP) proteins.[61] The TAP complex consists of two structurally related subunits (TAP1 and

TAP2), which interact to form a functional peptide transporter system. Defects in either TAP1 or TAP2 result in impaired peptide-HLA class I/ß$_2$ complex formation and reduced surface expression of HLA class I molecules.

Patients who have defective HLA class I molecule expression due to defects in either TAP1[61] or TAP2[62] have a far less severe clinical phenotype than that observed in MHC class II expression. They often have nasal polyposis and recurrent sinopulmonary infections caused by *H. influenzae*, *S. pneumoniae*, *S. aureus*, *Klebsiella* spp. and *P. aeruginosa*. Deep skin ulcers may also occur. The diagnosis is made by demonstration of low expression of HLA class I molecules on mononuclear cells.

IMMUNE DEFECTS WITH PREDOMINANT IMMUNOGLOBULIN DEFICIENCY

B cell differentiation is a multistage process regulated by transcription factors that leads to a complex scheme of gene activation resulting in specific intracytoplasmic and membrane-bound proteins. While B cell differentiation in the bone marrow is antigen-independent, later stages of B cell development in the periphery depend upon contact between the B cell and its cognate antigen (Fig. 98.20).

Immunodeficiency with predominant defects in antibody production

X-linked agammaglobulinemia

X-linked agammaglobulinemia (XLA), the prototype humoral immunodeficiency, was first described in 1952 by Bruton[63] (OMIM *300300). The most important clinical features are shown in Table 98.3 . A block in B cell differentiation at the pre-B-cell stage due to a mutated tyrosine kinase of the Src family (denominated Bruton tyrosine kinase, BTK) leads to a complete lack of circulating B lymphocytes and virtually no immunoglobulin production.[64] The disorder should be considered in males who have recurrent bacterial infections, low immunoglobulin levels and absent B cells. A positive family history on the maternal side is suggestive. T cell count and function are usually normal. Diagnosis can be confirmed by analysis of BTK protein expression (immunoblotting or flow cytometry) and DNA mutation analysis. No genotype-phenotype correlation has yet emerged. Therapy consists of lifelong immunoglobulin replacement, usually 400–500mg/kg every 3 weeks. Despite this, patients remain at risk for certain enteroviral infections of the central nervous system that can be especially devastating. The mutations are listed at http://www.uta.fi/laitokset/imt/bioinfo/BTKbase.

Autosomal recessive agammaglobulinemia

The recognition of females who had agammaglobulinemia, and the fact that in some kindreds boys and girls are equally affected, led to the search for autosomal recessive causes of agammaglobulinemia, which accounts for 5–10% of all patients with complete B cell deficiency.

The clinical picture is similar to that of XLA, with a somewhat earlier onset and perhaps a more severe progression. The disease is genetically heterogeneous, with defects identified in the genes that encode for the µ heavy chain,[65] the ?5 chain (part of the surrogate light chain),[66] the Iga chain of the membrane-expressed pre-B-cell receptor (BCR; involved in signal transduction),[67] and in BLNK,[68] an intracytoplasmic adapter that is phosphorylated by the tyrosine kinase Syk upon BCR signaling.

Figure 98-20 Blockage of B cell maturation. Model of B cell differentiation with the various proteins involved in the different stages shown below. The vertical red lines indicate a maturation block caused by the molecules indicated above.

TABLE 98-3 -- Characteristics of X-linked agammaglobulinemia.

CHARACTERISTICS OF X-LINKED AGAMMAGLOBULINEMIA
Onset after 6 months of life (when maternal antibodies wane)
Lack of tonsils and B lymphocytes (<2%)
Recurrent bacterial infections of the upper and lower respiratory tract
Risk of development of bronchiectasis
Gastrointestinal *Giardia lamblia*
Susceptibility to enteroviral encephalitis (echovirus, poliovirus)
Susceptibility to arthritis caused by enteroviruses and mycoplasmas

Selective IgA deficiency and common variable immune deficiency

Common variable immune deficiency (CVID) has an incidence of 1 in 10,000–100,000 live births and is characterized by low IgG and IgA levels associated with defective specific antibody production in the setting of a normal B cell count. In about 30% of patients, IgM levels are also low. The inability to produce specific antibodies puts patients at risk for frequent bacterial infections, predominantly in the respiratory and gastrointestinal tracts. The clinical picture may be complicated by the presence of autoimmune disorders such as hemolytic anemia, thrombocytopenia, inflammatory bowel disease and others. There are early-onset (usually between the ages of 1 and 5 years) and late-onset (during adolescence) clinical phenotypes, suggesting that there may be different molecular mechanisms underlying CVID.[69]

Selective IgA deficiency

Selective IgA deficiency (IgAD) is characterized by low IgA levels in the serum (<5mg/dl) and absent secretory IgA and occurs in 1/700 live births. IgG and IgM levels are normal, but defects in IgG2 and IgG4 have been described in a subgroup of patients. Circulating B cells are normal in number. In general, IgA deficiency is a benign disorder, with only 30% of affected patients being susceptible to bacterial infections, usually confined to the respiratory and gastrointestinal tract, or to autoimmune manifestations. A minor defect in IgA production (with levels <2SD), partial IgA deficiency, is characterized by a good prognosis, with a tendency of IgA levels to normalize with age. Little is known about the molecular bases of IgAD/CVID. However, given the fact that both may occur in the same family and that in some cases selective IgA deficiency has evolved into CVID, a common pathogenic mechanism for both forms of this humoral immune defect has been hypothesized. The best candidate gene seems to be located at position 6p21. There is also evidence that environmental factors, such as anti-inflammatory and antirheumatic drugs or perhaps viral infections may accelerate the development of IgAD and CVID.

The hyper-IgM syndromes

Four distinct genetic defects have been identified in hyper-IgM (HIGM). These syndromes are typically characterized by low IgG and IgA levels, normal to increased IgM and a normal number of circulating B cells. Both X-linked and autosomal forms of the disease are known. The clinical picture is variable, with most of the patients suffering from recurrent bacterial infections of the respiratory and gastrointestinal tracts.[70] In addition, some patients who have HIGM are susceptible to opportunistic pathogens including *P. carinii*, *Cryptosporidium* spp. and cytomegalovirus.

HIGM1

CD40 ligand (CD40L), encoded by the X-linked *TNFSF5*, is predominantly expressed by activated $CD4^+$ T cells.[71] Interaction of CD40L with CD40 on B cells, dendritic cells, monocytes and some activated epithelial cells is necessary for immunoglobulin isotype switching, high affinity immunoglobulin production, somatic hypermutation and the formation of germinal centers in secondary lymphoid organs. In addition, CD40L plays a crucial role in efficient interaction between T cells and

antigen-presenting cells, guiding the adaptive immune response to intracellular pathogens. HIGM1 (XHIM or CD40L deficiency, OMIM# 308230) is one of the two X-linked variants of HIGM. CD40L deficiency usually presents within the first year of life. Neutropenia is common. By the end of the first decade sclerosing cholangitis is common. Later in life, the incidence of gastrointestinal tumors is elevated.[72]

The diagnosis is made by demonstration of absent CD40L on activated T cells and confirmed by mutation analysis of the *TNFSF5* gene. Mutations are catalogued at http://www.uta.fi/imt/bioinfo/CD40Lbase. Despite regular administration of immunoglobulins, mortality is as high as 40% by age 25. Bone marrow transplantation should be pursued in appropriate cases. In murine models, unregulated CD40L expression has led to an increased incidence of autoimmune and lymphoproliferative diseases, making optimism for

human gene therapy without the authentic regulatory elements premature. A phase I/II trial with soluble trimeric CD40L is underway.

Hyper-IgM syndrome with hypohidrotic ectodermal dysplasia (ectodermal dysplasia with immunodeficiency)

This X-linked recessive immunodeficiency (NEMO deficiency; OMIM #300291) associates the HIGM phenotype with hypohidrotic ectodermal dysplasia, as mentioned above.[32] [33] Affected boys have defects in the sweat glands, relatively thin hair, dental abnormalities (conical or peg teeth) and suffer from a wide range of infections such as pneumonia, osteomyelitis and meningitis. Complete functional absence of NEMO in males leads to intrauterine death, whereas boys who have partial expression present as HIGM. In contrast, females heterozygous for severe mutations present with incontinentia pigmenti, a syndrome that may include various defects involving the skin, eyes and brain. Skewed X-inactivation in hematopoietic cells in females usually, but not always, avoids manifestation of the immune defect.

HIGM2

This autosomal recessive variant of HIGM, HIGM2 (activation-induced cytidine deaminase, AID, deficiency) is characterized by a pure B cell defect, with lack of immunoglobulin isotype switching, impaired somatic hypermutation and absence of high affinity antibodies (OMIM #606258).[73] Located at 12p13, AID encodes an mRNA editing protein that co-localizes with DNA-repair enzymes and is selectively expressed in activated B cells in germinal centers. Clinical symptoms include recurrent respiratory and gastrointestinal infections but systemic bacterial infections such as meningitis and sepsis are also common.[74] In contrast to the HIGM syndromes involving CD40-CD40L interactions, germinal centers are large, leading to hyperplasia of secondary lymphoid organs (tonsils). Surveillance for lymphoproliferative complications are indicated.

HIGM3

CD40 is the cognate receptor for CD40L. Consequently, lack of CD40 expression (CD40 deficiency, HIGM3; at 20q12, OMIM #606843) results in clinical and immunologic features very similar to those seen with CD40L deficiency, HIGM1. [75] Lack of isotype switching, impaired somatic hypermutation, defective memory B cell generation and lack of germinal center formation are typical features. The diagnosis is made by analysis of CD40 expression, and is confirmed by mutation analysis. Similarly to HIGM1, treatment requires regular administration of intravenous immunoglobulin, prophylactic anti-biotics and use of sterile/filtered water to prevent *Cryptosporidium* infection. Bone marrow transplantation should be considered in view of the poor long-term prognosis. Since CD40 is also expressed on some nonhematopoietic cells, unlike CD40L, patients who have defective expression of CD40 are not fully corrected by BMT. The clinical implications of this remain to be determined.

SYNDROME-ASSOCIATED IMMUNE DEFICIENCIES

Immune deficiency may also be part of a broader clinical syndrome. In some of these disorders, signs related to immune deficiency predominate and direct the clinical evolution of the disease; in other cases, immune deficiency is variable and does not represent the most important clinical problem. In spite of their complexity, most of these diseases are monogenic, with the affected gene encoding a protein with pleiotropic functions. Alternatively, as in DiGeorge syndrome, the disease may result from a chromosomal microdeletion.

Immune deficiencies due to DNA repair defects

In addition to Artemis deficiency, immunodeficiencies due to DNA repair include ataxia telangiectasia and several related disorders.[76] [77] Ataxia telangiectasia is due to mutations in the ataxia-telangiectasiamutated (*ATM*) gene (11q22-23; OMIM #208900; mutations catalogued at http://www.vmresearch.org/atm.htm). Ataxia telangiectasia is typically associated with increased chromosome radiosensitivity and defective DNA repair, leading to somatic translocations that involve the T cell receptor and immunoglobulin loci. Translocation between chromosomes 7 and 14 is particularly common. IgA, IgG2, IgG4 and IgE levels are low and a progressive decline in T cell number and function is typically observed. Most patients do not survive beyond young adulthood because of lymphomas and leukemia. Neurologic problems are a predominant sign of the disease.

The same clinical phenotype can be caused by mutations in the nearby gene *hMRE11*, which accounts for the so-called ataxia-telangiectasia-like syndrome (OMIM #600814).[78] *hMRE11* encodes a protein involved in the earmarking of DNA double-strand breaks. Mutations in *Nbs* (or nibrin) are the cause for the Nijmegen syndrome (OMIM #251260), another immunodeficiency characterized by growth failure, microcephaly and a characteristic bird-like facies. The DNA ligases are also involved in DNA repair, and mutations can cause immunodeficiency. [79] [80]

Di George syndrome; velocardiofacial syndrome

This syndrome (OMIM# 188400) has a wide range of clinical presentations, including thymus and parathyroid defects (hypocalcemia), overt facial abnormalities, growth failure, neurologic and neuro-psychiatric manifestations and heart defects, such as tetralogy of Fallot.[81] The predominant immunologic feature is a variably low T cell count predisposing to *Candida* and other infections. The molecular defect lies in a microdeletion in 22q11.21-23 (in 90% of the patients this occurs de novo). This defect is sometimes referred to as CATCH 22 (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, chromosome 22).[82] However, this is a very common syndrome with quite variable expressivity. The frequency in the general population is thought to be 1 in 4000 live births and it can be transmitted as an autosomal dominant trait.

Wiskott-Aldrich syndrome

The Wiskott-Aldrich syndrome (WAS) protein, encoded by *WASP* at Xp11.2, is expressed selectively by cells of the hematopoietic lineages. It is involved in the activation-induced reorganization of the cytoskeleton, particularly actin polymerization. Eczema, thrombocytopenia and immunodeficiency are the three main features of Wiskott-Aldrich syndrome (OMIM #301000).[83] Microthrombocytes (low mean platelet volume) in a male neonate who has thrombocytopenia and eczema are highly suspicious, even before the immune deficiency characterized by recurrent bacterial airway infections is manifest. Immunoglobulin responses to polysaccharides are typically impaired and immune globulin replacement is often needed. Later in life there is an elevated incidence of leukemia, lymphoma and autoimmune diseases.

There is a relatively benign variant of WAS, X-linked thrombocytopenia, which occurs without eczema or immunodeficiency. Interestingly, most patients who have this variant show missense mutations in exons 1 or 2 of *WASP* that permit expression.[84] In some less severe cases, thrombocytopenia is intermittent, but mean platelet volume is consistently low. Interestingly, there is also one family reported that has a *WASP* mutation (L270P) leading to isolated X-linked neutropenia.[5] The diagnosis is confirmed by mutation analysis of the *WASP* gene. Given the recognized genotype-phenotype correlation, determination of specific mutations gives important prognostic information. Gene therapy may become another option, as there has been report of spontaneous mutation reversion in *WASP* leading to expansion of a 'normalized' lineage.[85]

X-linked lymphoproliferative syndrome

Patients who have X-linked lymphoproliferative syndrome (Duncan's syndrome, OMIM *308240) show an increased susceptibility to severe manifestations after Epstein-Barr virus (EBV) infections.[86] Hepatitis, lymphomas and/or hemophagocytic lymphohistiocytosis kill about 70% of affected males in their first decade. Those who survive, mostly affected by a milder variant, may present with hypogammaglobulinemia. The defective gene, *SH2D1A*, located at Xq25, encodes SLAM-associated

protein (SAP), an SH2-domain-containing protein expressed selectively in lymphocytes. SAP has a regulatory effect on cytokine production and is essential for the cytotoxic activity of NK cells. Other herpesviruses have also been shown to trigger XLP. The mutations are cumulated at http://www.uta.fi/imt/bioinfo/SH2D1Abase. Several mutational hot-spots have been identified, but so far no genotype-phenotype correlation has been recognized. BMT should be considered before EBV infection if an HLA-compatible donor is available.

Familial hemophagocytic lymphohistiocytosis

Similar to X-linked lymphoproliferative syndrome, familial hemophagocytic lymphohistiocytosis is an autosomal recessive inherited disease characterized by severe viral infections leading to hepatosplenomegaly, acute bone marrow failure with histiocytic activation, coagulopathy and hypertriglyceridemia. Onset is during the first few months of life; accelerated phases occur repeatedly, often with life-threatening hemorrhagic episodes.[87] The immunologic defect consists in virtually absent NK cytotoxicity due to a functionally deficient perforin (encoded by *PRF1* at 10q21-22), a protein normally released from the intracytoplasmic granules after the membranes of effector (NK or T cells) and target cells have fused.[88] The resulting prolonged contact between infected and 'intended' cytotoxic cell leads to increased cytokine (IFN-?) production that is thought to activate macrophages and histiocytes. [89] Forms of this disease that do not have clear genetic predispositions may be triggered by various infections or by drugs. Accelerated phases, which are true medical emergencies, may be brought into remission by chemotherapy

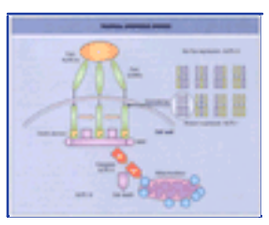

Figure 98-21 Fas/Fas ligand apoptosis system. The Fas/FasL apoptosis system and the various forms of ALPS caused by defects in it.

(etoposide) and maintained with immunosuppression, but the only curative treatment is BMT.

Autoimmune lymphoproliferative syndrome (Canale Smith syndrome)

At the core of normal development is the proper coordination of cell death. When cell death occurs in a programmed way (i.e. not through lysis by infecting agents or necrosis due to toxic events), it is referred to as apoptosis. Proper Fas/Fas ligand (FasL) interaction is critical for normal apoptosis (Fig. 98.21). The correct Fas/FasL interaction leads to the formation of the death inducing signaling complex (DISC), which acts through different caspases to induce mitochondrial damage and finally proteolytic cell death. Fas (CD95), encoded by *APT1* (*TNFRSF6*), is a transmembrane protein with an intracellular death domain. Death signaling requires assembly of homotrimers. The autoimmune lymphoproliferative syndrome type I (ALPS I) is caused by heterozygous mutations in Fas that lead to disruption of normal homo-oligomerization resulting in deranged lymphoid homeostasis due to defective apoptosis.[90] In this autosomal dominant disorder, only one in eight homotrimers will have three normal Fas molecules. However, the story remains quite complex, as the mutations in Fas have variable penetrance and expressivity. In contrast to these dominant mutations, those which abrogate protein expression are inherited as recessive traits. This complete null recessive form of the disease, ALPS O, may be especially severe with symptoms presenting during fetal life (hydrops). Autoimmune lymphoproliferative syndrome type 1 usually presents with lymphadenopathy, hepatosplenomegaly and hematologic symptoms of autoimmunity such as hemolytic anemia, autoimmune neutropenia, and immune thrombocytopenia. There is a markedly increased risk (up to 50 times) of lymphoma and leukemia.[91] Diagnostic findings include increased numbers of T cells that lack both CD4 and CD8 molecules, referred to as double-negative T cells.

Autoimmune lymphoproliferative syndrome type Ib is caused by mutations in the FasL (*TNFSF6*).[92] Defects in the caspases lead to a similar failure of lymphocyte apoptosis denominated ALPS II. ALPS

III is the name currently used for the ALPS phenotype for which genetic defects have not been identified.

IPEX

The clinical entity characterized by dysregulated immunity (anemia, lymphadenopathy), autoimmune **p**olyendocrinopathy (diabetes, thyroiditis), (inflammatory) **e**nteropathy of **X**-linked transmission is named IPEX (OMIM: #304930, #304790).[93] The molecular defect resides in the *FOXP3* gene, encoding scurfin, a protein expressed predominantly in the thymus and spleen. It appears to have a repressive role in T cell activation and cytokine expression.[94] Severely affected boys usually do not survive the first year of life. There is evidence for a somewhat milder phenotype associated with mutations sparing the coding sequence but affecting the polyadenylation signal. Opportunistic infections are not a part of IPEX, indicating that this is less a defect in protective immunity than a defect in regulation of cytokine production. Immunosuppression has proved beneficial in some patients who have IPEX, underlining the importance of *FOXP3* in the control of autoreactive cell clones.

Chapter 99 - Immunodeficiencies Associated with Immunosuppressive Agents

Pierre-Alexandre Bart
Giuseppe Pantaleo

INTRODUCTION

The goal of this chapter is to review the immunologic effects (e.g. the degree of immunodeficiency) associated with therapeutic interventions involving the use of immunosuppressive agents commonly used in transplantation and in the treatment of rheumatic and autoimmune diseases. The immunodeficiency caused by chemotherapeutic agents used in cancer therapy will not be the object of this chapter. Analyses of the mechanisms of action of the different immunosuppressive agents and of their immunologic target(s) show substantial qualitative and quantitative differences in the type of immunodeficiency caused by the therapeutic interventions. These differences can be explained by the ability of the immunosuppressive agents to target single or multiple components of the immune system. This translates into an impairment of the host immune defenses against bacteria, viruses, fungi and parasites. Furthermore, the intensity of the immunodeficiency is substantially influenced by the number of agents administered because immunosuppressive agents are mostly used in combination. Therefore, the clinical consequences associated with the administration of immunosuppressive agents result from their mechanisms of action and from the extent of perturbation of the fine regulatory immune mechanisms needed for the effective control of a variety of pathogens.

HOST DEFENSES — GENERAL CONCEPTS

The immune system represents the primary mechanism of defense against a variety of pathogens.[1] To understand the potential interference of immunosuppressive agents on the immune system, it is important to examine the different components of the immune system and the sites of action of these agents to predict the immunologic dysfunctions eventually caused by the treatment. Furthermore, on the basis of the functional impairment of one or more components of the immune system, it is possible to predetermine the pathologic conditions, mostly infectious, that can complicate the clinical picture during immunosuppressive treatment.

We also briefly review the effects of immunosuppressive agents on the natural mechanisms of defense such as the anatomic barriers.

Anatomic barriers

The natural mechanisms of defense are mediated by the anatomic barriers, primarily by the skin and mucosal (gastrointestinal and urinary tract) barriers. The ability of these barriers to protect against invading pathogens is dependent upon the intrinsic physical structure as well as a series of factors including the physicochemical features of the environment (e.g. the pH and temperature), the local bacterial microflora and soluble local mediators such as secretory IgA and a variety of proteins with enzymatic activity (e.g. lysozymes).

Immunosuppressive treatment may severely compromise the integrity of the mucosal barrier because the particularly high turnover of cell division of the mucosal epithelium is very sensitive to the antiproliferative activity of immunosuppressive agents. This in turn may cause lesions of the epithelium, and the clinical picture may be complicated by the emergence of mucositis of variable severity. As discussed below, this type of complication is relatively frequent in cancer immunosuppressive regimens but is rare in the fields of transplantation and immunologic diseases.

Innate immunity

Innate immunity is non-specific, and the rapidity of the response (e.g. previous antigen exposure is not required) and the lack of immunologic memory [2] represent the main characteristics of this immune response. The effector components of innate immunity include soluble and cellular mediators (see Chapter 97). Among the former, the complement (C) proteins play a critical role in the recruitment and activation of neutrophils (the C3a and C5a factors), the opsonization of bacteria (the C3b factor) and the destruction of certain micro-organisms through the C5–C9 factors. C-reactive protein (CRP) and lipopolysaccharide (LPS)-binding protein are additional soluble mediators of the innate immunity involved in the opsonization of bacteria or activation of C (e.g. CRP).

The cellular effector components of innate immunity include neutrophils, monocyte/macrophage cells and natural killer (NK) cells. These different types of cells, which are recruited at the site of infection or inflammation by the soluble mediators mentioned above, mediate either direct (e.g. phagocytosis and killing of bacteria) or indirect defense mechanisms (e.g. recruitment of other types of immune cells through the secretion of cytokines and chemokines).

Among the immunosuppressive agents, glucocorticoids (GCs) may markedly downregulate the innate immune response by causing both qualitative and quantitative defects. The pathologic conditions associated with this type of immunosuppression are characterized by an increased risk for bacterial infections caused by viridans streptococci, *Staphylococcus aureus,* coagulase-negative staphylococci, Gram-negative bacilli and certain fungi, mainly *Candida* and *Aspergillus* spp.

Adaptive immunity

Adaptive immunity[1] (see Chapter 97) is specific; it requires a certain time to become fully functional — the time is necessary for the generation, maturation and expansion of antigen-specific T and B cells — and is associated with the generation of immunologic memory following clearance of the pathogen.

T cells are a critical component of adaptive immunity. The mechanisms of antigen (Ag) recognition by T cells are extremely specific. Following appropriate processing and presentation by professional antigen-presenting cells (APCs), T cells recognize a complex formed by the major histocompatibility complex (MHC) products and the Ag peptide on the surface of APC. Two types of T cells (CD4 and CD8) are involved in the immune response against pathogens.

Based on their ability to produce different cytokines, CD4 T cells can generally be distinguished into two populations:

- T helper (T_H)1, which are mostly characterized by the production of interferon (IFN)-? and interleukin (IL)-2; and
- T_H2, which produce mostly IL-4, IL-5 and IL-10.

T_H1 CD4 T cells are necessary for the maturation, expansion and maintenance of the CD8T cell response, of NK cells and for the activation of macrophages; these latter cells are involved in the elimination of pathogens such as mycobacteria and fungi. Th2 CD4 T cells mediate the maturation and the activation of pathogen-specific B lymphocytes.

CD8 T cells are the primary effector component of adaptive cell-mediated immunity. They are able to lyse directly virus-infected cells and also tumor cells in particular.

It is therefore clear that immunosuppressive therapy, which is one of the primary causes of secondary immunodeficiency, may significantly impair T cell-mediated immunity and determine an increased susceptibility to a variety of pathogens including:

- viruses — herpes simplex virus (HSV), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV);
- bacteria — *Mycobacterium tuberculosis, Legionella* spp., *Listeria monocytogenes, Salmonella typhi*;

¦ fungi — *Candida* spp., *Apergillus* spp., *Histoplasma capsulatum*, *Cryptococcus neoformans*, and the closely related micro-organism *Pneumocystis carinii*; and
¦ parasites (*Toxoplasma gondii*, crytosporidia and *Leishmania* spp.

B lymphocytes mediate the immune response against pathogens through the production of immunoglobulins (Ig). Immunoglobulins may inhibit the entry of the pathogen into the target cells by binding to certain regions of the pathogen that are critical for the interaction with specific receptors on the surface of the target cells, a phenomenon known as neutralization. Furthermore, the primary role of Ig is the opsonization of bacteria and the activation of C and the different components of innate immunity that may lead to elimination of the pathogen.

The pathologic conditions associated with the absence or a quantitative defect of Ig are well known, particularly in the case of primary immunodeficiencies such as common variable immunodeficiency (CVID). A selective defect in the production of Ig characterizes CVID and is associated with recurrent infections of the upper and lower respiratory tract caused predominantly by *Streptococcus pneumoniae* and *Haemophilus influenzae*.

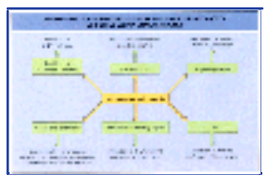

Figure 99-1 Mechanism of action of the different immunosuppressive agents currently in use in clinical practice.

IMMUNOLOGIC TARGETS OF AND CLINICAL ISSUES ASSOCIATED WITH IMMUNOSUPPRESSIVE THERAPY

In order to evaluate correctly the risk for infectious diseases associated with an impairment of immune function(s), it is essential to know the degree of the defect and most importantly the component(s) of the immune system targeted by the immunosuppressive agents. For these reasons, the mechanisms of action of the most frequently used immunosuppressive agents in the fields of transplantation, autoimmunity and rheumatology, and the clinical implications of the therapy are examined in detail.[3]

Glucocorticoids

Glucocorticoids (GC) are the cornerstone in the treatment of the majority of inflammatory diseases. They are also used in the treatment of asthma, acute rejection of transplanted organs and some hematologic malignancies. Their immunologic effects are extremely broad.

Mechanism of action

Glucocorticoids are highly lipid soluble and so they penetrate easily through the cell membrane. They bind in the cytoplasm to a specific receptor (glucocorticoid receptor, GR) present in all nucleated cells. This provides part of the explanation for why it is not possible to dissociate their anti-inflammatory effects from their metabolic effects. Following the interaction of GC with a GR, the GR migrates to the nucleus and there is a dimerization of the GC-GR complex. These dimers can bind to GC-response elements (GRE) of GC-responsive genes. Through the above mechanism GCs modulate gene transcription in a positive (e.g. transactivation) or negative (e.g. trans-repression) fashion.[4] [5] [6] [7]

Glucocorticoids block the transcriptional activity of certain transcriptional factors (Fig. 99.1) through direct inhibition of ubiquitous factors such as nuclear factor-kappaB (NF-?B) and activator protein-1 (AP1), or more specific elements such as NFAT (nuclear factor of activated T cells) or STATs (signal transducer and activator of transcription). They can also inhibit NF-?B through the induction of expression of its specific inhibitor (I?Ba). The transcription factors mentioned above are essential for the transcription of proinflammatory cytokine genes. Therefore, the broad effects of GCs result from

the suppression of ubiquitous and specific transcription factors. This explains why different cell types (e.g. macrophages, lymphocytes and neutrophils) involved in the inflammatory reaction and immune response are all targets of this class of drugs.

Anti-inflammatory effects

Glucocorticoids act on the early phase of the inflammatory reaction by inhibiting the production of chemotactic factors and proinflammatory cytokines such as IL-1, IL-6, tumor necrosis factor (TNF)-a and IL-8. This results in a reduced recruitment of monocytes/macrophages and neutrophils at the site of inflammation. Furthermore, they block the release of histamine and serotonin and the expression of adhesion molecules, such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). These effects result in a reduction of the capillary permeability and migration of cells with phagocyte activity through the endothelial barrier. Finally, GCs inhibit the synthesis of inflammatory mediators such as the eicosanoids (e.g. prostaglandins, leukotrienes and thromboxanes).

Immunosuppressive effects

The most important immunosuppressive effects of GCs include:

¦ inhibition of IL-2 receptor synthesis;
¦ suppression of antigen presentation by causing a reduction in the expression of MHC molecules on the surface of APCs;
¦ inhibition of lymphocyte proliferation by suppression of IL-2 production; and
¦ suppression of IFN-? production.

Apoptotic effects

Glucocorticoids may also mediate a cytotoxic effect through the induction of apoptosis. Two hypotheses have been proposed to explain this effect:

¦ apoptosis is triggered by the activation of death-inducing genes; and
¦ induction of apoptosis by inhibition of transcription of survival genes.

TABLE 99-1 -- Type of infection related to the immune system and immunosuppressive agents.

TYPE OF RISK INFECTION RELATED TO IMMUNE SYSTEM AND IMMUNOSUPPRESSIVE AGENTS		
Immunodeficiency	**Immunosuppressive agent or chemotherapy**	**Infectious risk**
Anatomic barriers (mucositis)	High-dose chemotherapy	Bacterial: Gram positive — staphylococci, viridans streptococci, enterocci; Gram-negative — Enterobacteriacae, *Pseudomonas* spp.
		Fungal: *Candida* spp.
		Viral: herpes simplex virus
Innate immunity (quantitative defects) (qualitative defects)	High-dose chemotherapy, radiotherapy	Bacterial: Gram positive — staphylococci, viridans streptococci, *Nocardia* spp.; Gram-negative — bacilli (*Escherichia coli*, *Klebsiella* spp., *Pseudomonas* spp.)
		Fungal: *Candida* spp., *Aspergillus* spp.
Adaptive immunity		

Cellular	High-dose chemotherapy, radiotherapy Immunosuppressive therapies (glucocorticoids, cyclophosphamide, ciclosporin A, tacrolimus, methotrexate, azathioprine, rapamycin, anti-lymphocyte serum, monoclonal antibodies)	Bacterial: *Legionella* spp., *Mycobacterium tuberculosis*, atypical mycobacteria, *Listeria monocytogenes*, *Salmonella* spp.
		Fungal: *Candida* spp., *Aspergillus* spp., *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*
		Viral: cytomegalovirus, varicella-zoster virus, herpes simplex virus, Epstein-Barr virus, live viral vaccines (measles, mumps, rubella, poliovirus)
Humoral	High-dose glucocorticoids, cyclophosphamide, mycophenolate mofetil	Bacterial: Gram-positive — streptococci (S. pneumoniae, others); Gram-negative — *Haemophilus influenzae*, *Neisseria meningitidis*, *Capnocytophaga canimorsus*
		Viral: enterovirus
		Parasites: *Giardia lamblia*

Clinical effects

Due to their broad mechanisms of action, GCs may influence the function of a large number of different types of cells that are crucial for the regulation of the immune response and metabolic cascades. With regard to the immunosuppressive effects, they affect the function of cells of innate immunity (e.g. monocytes/macrophages and neutrophil) and adaptive immunity, particularly T cells. Humoral immunity (e.g. production of Ig) is affected only at high dosage.

The clinical picture of patients receiving treatment with GCs may be complicated by a variety of infections[8] caused by bacteria, fungi and viruses. The severity of these infectious complications depends upon the degree of immunosuppression resulting from the treatment (Table 99.1). Retrospective studies on large cohorts of patients treated with GCs have clearly demonstrated that the risk of infections (including lethal infections) in these patients is significantly increased compared to control groups. Furthermore, it is important to underscore that the GC dosage is strictly linked to the risk of infections. A dosage of prednisone of more than 20mg/day is associated with a risk of infection that is twice that of a control group, while patients receiving a dosage of less than 10mg/day do not show an increased risk of infection.

The type of infection complicating the clinical picture is related to the components of the immune system predominantly affected. The most frequent bacterial infections are those caused by Gram-positive (*S. aureus* or coagulase-negative staphylococci) and Gram-negative bacteria (*Escherichia coli*, *K. pneumoniae, Pseudomonas* spp. *or Salmonella* spp.).[8] Although less frequent, *Nocardia* spp. and anaerobic bacteria (e.g *Prevotella bivia*) may cause cerebral or joint infections. These infections result from the direct impairment of phagocytic function of neutrophils and monocytes/macrophages by GC treatment. Mycobacterial, fungal (*Aspergillus fumigatus* and *Candida* spp.) and viral (particularly enterovirus) infections are caused by the impairment of adaptive immunity, mostly cellular immunity.

The anatomic site most frequently affected by the infectious complications is the lung. The typical radiologic finding is the presence of

infiltrates. In this regard, it is important to mention that the presence of lung infiltrates is also typical of autoimmune and rheumatic diseases such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE) and Wegener's granulomatosis. Therefore, in these pathologic conditions it is important to distinguish between a lung pathology caused by the underlying disease and the infection caused by GC treatment. The microbes most frequently isolated in the lungs in infections complicating GC treatment[8] include *Streptococcus pneumoniae, K. pneumoniae*, *Legionella* spp. and *P. carinii*.

Alkylating agents

Mechanism of action

The alkylation of DNA is responsible for the cytotoxic, mutagenic and chemotherapeutic properties of this class of immunosuppressive agents. Cyclophosphamide (CYC) is a very potent alkylant (nitrogen mustard-derived alkylating agent) that catalyzes the alkylation of purines within the DNA and RNA (see Fig. 99.1). DNA and RNA alkylation leads to an aberrant base pairing, ring cleavage and depurination. The ultimate result is cell death due to a loss of the ability to divide. Cyclophosphamide is effective on both 'resting' and dividing (e.g. activated) lymphocytes. Both T-cell (particularly T-helper) and B-cell functions are severely suppressed by CYC treatment.

Clinical effects

On the basis of the potent immunosuppressive effects on B and T cells, CYC is largely used in the treatment of autoimmune and rheumatic diseases. In particular, it is used as primary treatment in severe SLE, vasculitis[9] (anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis) and severe RA. [10] Cyclophosphamide treatment is generally very effective in obtaining remission of the underlying disease. However, hematologic toxicity and the oncogenicity due to its antiproliferative and mutagenic properties are major adverse effects. The hematologic toxicity is due to bone marrow suppression with associated leukopenia (particularly neutropenia and CD4 T-cell lymphopenia) of variable severity. The nadir of the leukopenia is generally observed 7–14 days after one pulse of intravenous administration. The toxicity of CYC is dependent upon the dosage and the duration of treatment (cumulative dose).

The infectious complications associated with CYC treatment (see Table 99.1) include bacterial (*S. aureus* (septic shock), *K. pneumoniae* pneumonia), fungal (*Candida albicans*) and viral (herpes zoster) infections.[11] The pathogens responsible for these infections are mostly typical opportunistic pathogens. It is important to underscore that CYC is generally used in association with GCs and therefore the risk of infectious complications is substantially increased, particularly if GC dosage is more than 0.5mg/kg per day in patients aged over 60 years and with a leukocyte nadir of less than 3×10^9 /l. In this regard, a recent study on the use of CYC in patients with autoimmune diseases has clearly demonstrated that age represents a crucial risk factor for infection. [11] The proportion of patients with infectious complications was significantly higher in patients aged over 65 years (34.2%) than in a control group aged less than 65 years (8.3%). To prevent infectious complications, patients treated with CYC require close hematologic and immunologic monitoring, and in certain cases the use of antimicrobial prophylaxis. Anti-pneumocystis prophylaxis with trimethoprim-sulfamethoxazole (co-trimoxazole) is recommended:[12]

- when there is continuous oral administration of CYC; and
- if the CD4T-cell count is less than 200/mm^3 .

Although no definitive demonstration is available, the general perception is that continuous oral administration of CYC carries an increased risk of infection compared with intravenous pulses.[13] [14]

As mentioned above, CYC also has oncogenic properties. In particular, CYC therapy was found to be associated with an increased risk for bladder carcinoma. [15] However, it should be underscored that this specific oncogenic effect of CYC is only in part due to the immunosuppression, but is mostly the result of the effect of acrolein,[16] a toxic metabolite of CYC. The relationship between acrolein and the risk for bladder carcinoma is supported by the fact that chlorambucil, another alkylating agent, does not exhibit similar toxicity. Although it is well known that patients with immunologic diseases have an increased risk for cancer, it is also clear that the risk is increased by the immunosuppressive treatment.[17] It seems that alkylating agents are more oncogenic than other immunosuppressive agents. In this regard, recent studies[18] that examined the risk for cancer in patients who received CYC treatment and were followed up for more than 24 years have shown that the risk for cancer correlates with the cumulative dosage of CYC and the duration of follow-up.

Immunophilin binding agents

Immunophilins are a large family of broadly expressed proteins that bind to certain immunosuppressive agents, such as cyclosporine A (CsA), tacrolimus (also known as FK-506) and rapamycin (also known as sirolimus). Due to their potent immunosuppressive effects that target predominantly T cells, these agents are fundamental components of the immunosuppressive regimens in both solid organ[19] [20] and bone marrow transplantation.[21]

Mechanism of action

Ciclosporin A is a lipophilic undecapeptide reversible inhibitor of T-cell activation that acts by interfering with calcineurin and thus IL-2 synthesis and release.[22] Ciclosporin A activity is lymphocyte specific and it blocks quiescent lymphocytes in G_0 –G_1 phase, thus reducing the number of cells that can be activated.

Physiologically, T-cell receptor (TCR) signaling induces an elevation in the concentration of Ca^{2+} in the cytoplasm and activates the transcription factor AP-1. Ca^{2+} binds to calcineurin, which in turn dephosphorylates the cytoplasmic form of NFAT. Once NFAT migrates into the nucleus, it forms a complex with AP-1, thus inducing the transcription of genes required for T-cell activation including IL-2. When CsA is present in the cytoplasm, it forms a complex with cyclophilin (Cyp). The CsA-Cyp complex can bind to calcineurin, blocking its ability to activate NFAT, and therefore inhibiting T-cell activation (Fig. 99.2). Furthermore, the other effects of CsA, such as renal toxicity and hypertension, can be explained on the basis of the increased activity of the endothelin-converting enzyme that causes increased production of endothelin-1 (ET-1), a vasoconstrictive and proinflammatory peptide. Endothelin-1 is potentially involved in transplant vasculopathy and chronic rejection.

Like CsA, tacrolimus binds to immunophilins, and in particular to the FK-506 binding proteins (FKBPs).[23] Although tacrolimus binds all FKBPs, FKBP 12 is the protein preferentially bound. Unlike CsA, tacrolimus is an antibiotic belonging to the macrolide class. Although CsA and tacrolimus bind to different proteins, their mechanism of action is very similar because tacrolimus also inhibits calcineurin. Tacrolimus, however, is 10- to 100-fold more potent than CsA and acts on multiple transcriptional factors such as NFAT and NF-?B, thus influencing the production of several cytokines, including IL-2, IL-3, IL-4, IL-5, IFN-?, granulocyte-macrophage colony stimulating factor (GM-CSF) and TNF-a, and proto-oncogenes c-*myc* and c-*rel*. Like CsA, tacrolimus exerts a potent suppression of T cells (particularly Th1 cells). However, it also has a substantial inhibitory effect on Th2 cells, thus influencing the production of Ig and humoral immunity.

Rapamycin (sirolimus) is also a macrolide antibiotic. Discovered before tacrolimus, it was first used either as an antifungal or as antiproliferative agent in the treatment of certain tumors (prostate, lymphoma, glioblastoma, melanoma and small cell lung tumors).

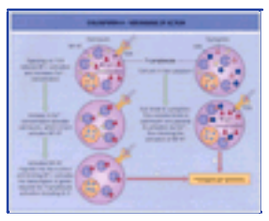

Figure 99-2 Mechanism of action of ciclosporin A. Ciclosporin A inhibits T-cell activation by interfering with calcineurin. It is a lipophilic undecapeptide reversible inhibitor of T-cell activation that acts by interfering with calcineurin. The T-cell receptor induces signaling through an elevation in concentration of Ca^{2+} in the cytoplasm. This activates the transcription factor AP-1. The Ca^{2+} binds to calcineurin, which in turn dephosphorylates the cytoplasmic form of NFAT. Then NFAT migrates into the nucleus and forms a complex with AP-1. This complex can induce the transcription of genes required for T-cell activation including IL-2. In the presence of CsA a complex forms with cyclophilin (Cyp). The CsA-Cyp complex can bind to calcineurin, blocking its ability to activate NFAT, and therefore inhibiting T-cell activation.

Sirolimus binds to the FKBP. However, the sirolimus-FKBP complex does not bind calcineurin, but binds to a protein called the mammalian target of sirolimus (mTOR), which regulates the translation of mRNA necessary for cell division. Therefore, sirolimus interferes with the transition from the G_1 to S phase of the cell cycle. The immunosuppressive potency of sirolimus is very similar to that of CsA and FK-506 but the toxicity profile is different. Finally, a derivative of sirolimus, everolimus, has recently been developed.[24] [25] [26] The clinical efficacy of this new agent, particularly in combination with CsA, is currently under investigation.

Clinical effects

Due to the selective immunosuppressive effects on T cells, the infectious complications associated with immunophilin binding agents are predominantly caused by viral and fungal infections (see Table 99.1). However, it should be emphasized that because these agents are often used in combination with other classes of immunosuppressive agents, it is difficult to identify infectious complications specific to a particular class of immunosuppressive agents. Since the immunophilin binding agents are predominantly used in the field of transplantation, the infectious complications that will be discussed are those encountered in transplanted patients. Two viral infections, namely CMV[27] [28] [29] [30] [31] and BK virus[32] [33] infection, are thought to be strictly related to the immunosuppressive treatment with CsA or tacrolimus. The risk of CMV disease also depends on the degree of immunosuppression, and it has been clearly shown that the concomitant use of other agents, such as monoclonal antibodies[34] (see below), increases the risk for CMV disease. Preliminary studies seem to indicate that everolimus, the sirolimus derivative, is associated with a lower frequency of CMV disease than CsA.[25]

The BK virus, a polyomavirus, is widely distributed in the healthy population. On the basis of its tropism for the urinary tract,[32] [33] BK virus causes pathologic conditions of variable severity such as asymptomatic hematuria, BK virus-induced interstitial nephropathy and BK virus-associated nephritis. At the present time, renal biopsy is the only valid diagnostic approach to confirm BK virus involvement when clinical signs of nephritis are present. The demonstration of viral inclusions in the proximal and distal tubules is typical of BK virus infection. Serology has no diagnostic value because of the large distribution of the virus in the healthy population.

Administration of immunophilin binding agents as well as other immunosuppressive agents increases the risk for cancer and particularly lymphomas. [27] The mechanisms responsible for the development of lymphomas or lymphoproliferative syndromes are directly related to EBV.[37] [38] In fact, in the case of transplantation in children, the incidence of post-transplant lymphoproliferative disease (PTLD) is up to 10% with a mortality rate of 60% and an elevated morbidity that may lead to loss of the transplant. PTLD is caused by an EBV primary infection and depends upon the intensity of the immunosuppressive treatment. There is spontaneous regression of PTLD following the decrease in intensity of immunosuppression, thus confirming the crucial role played by T cells, particularly CD8T cells, in the control of EBV. [39]

Finally, the toxicity profiles (e.g. renal toxicity, hypertension and neurotoxicity) of CsA and tacrolimus are very similar. Typical of CsA are hirsutism, coarsening of facial features and gingival hyperplasia, while diabetes and neurotoxicity are more frequently seen in patients treated with tacrolimus.

With regard to sirolimus, the infectious complications are similar to those of CsA and tacrolimus. However, the toxicity profile of sirolimus is quite different from that of CsA and tacrolimus. Nephrotoxicity, hypertension and neurotoxicity are rarely associated with sirolimus treatment. Side-effects associated with sirolimus include hyperlipidemia, leukopenia and thrombocytopenia. On the basis of the different toxic profile, sirolimus can be used in combination with CsA or tacrolimus.

Inhibitors of nucleotide synthesis

Azathioprine

Mechanism of action

Azathioprine (AZA) and its metabolite 6 mercaptopurine (6-MP) belong to the class of thiopurines. The targets of these drugs are the

enzymes involved in the de-novo synthesis of purines. In particular, AZA interferes with the de-novo synthesis of inosinic acid through a feedback inhibition of the 6-thioinosinic acid. Furthermore, it inhibits the conversion of puric bases, such as inosine, into adenosine or guanine ribonucleotides. Therefore, AZA inhibits DNA replication in dividing cells including lymphocytes (see Fig. 99.1). Activated T cells are the primary target of AZA. Azathioprine does not exert any cytotoxic effect on T cells before an antigen challenge, and the most potent immunosuppressive activity occurs following antigen stimulation. On the basis of this mechanism of action, AZA has no effect on memory T cells. In addition to activated T cells, AZA exerts potent immunosuppression on B cells. Due to its selective effect on dividing cells, AZA rarely causes severe lymphopenia and only prolonged treatment may be associated with a substantial reduction of circulating lymphocytes. Like other immunosuppressive agents, AZA also mediates an anti-inflammatory effect by inhibiting cell division of the different lineages of hematologic precursors.

Clinical effects

Originally largely used in the field of transplantation, AZA has been progressively replaced by more potent purine inhibitors such as mycophenolate mofetil (MMF, see below). However, it continues to be used in the treatment of autoimmune [40] and rheumatic diseases. Azathioprine has the advantage of being well tolerated and is

particularly effective against the hematologic, pulmonary and skin manifestations of autoimmune and rheumatic diseases. Furthermore, it may be safely administered during pregnancy and there is no evidence for an increased risk of malignancies in patients with SLE.

Three major side-effects characterize AZA administration:

- bone marrow suppression,
- gastrointestinal intolerance, and
- infections.

It is, however, important to underscore the moderate severity of the toxicity profile of AZA, which rarely requires the interruption of treatment and is rapidly reversed by the cessation of treatment. Severe bone marrow suppression has been reported in patients with concomitant treatment with allopurinol.

On the basis of the selective inhibition of actively dividing T and B cells following antigen-specific stimulation, the infectious complications

Figure 99-3 Mechanism of inhibition of purine synthesis by mycophenolic acid. MPA inhibits inosine monophosphate dehydrogenase (IMPDH) and leads to the depletion of guanosine nucleotides. PRPP, 5-phosphoribosyl-1(a)-pyrophosphate; ribose-5P, D-ribose-5'-phosphate.

associated with AZA treatment are predominantly caused by viruses (particularly herpesviridae) and to a lesser extent by fungi and parasites. The infectious complications are rarely observed in patients with autoimmune and rheumatic diseases. They have been mostly observed in the field of renal transplantation in patients receiving AZA as a part of a multiple immunosuppressive regimen. The most common infectious complication (see Table 99.1) was CMV infection, which was more frequent in the group receiving an immunosuppressive regimen including MMF compared with one including AZA.[41] As mentioned above for the other classes of immunosuppressive agents, the age of the patients (>60 years of age) represents an important risk factor for infectious complications during immunosuppressive therapy.[42]

The potential oncogenic properties of AZA are likely the result of the uptake of 6-thioguanosine triphosphate into cell DNA. An increase in the incidence of tumors, including non-Hodgkin's lymphoma (NHL), squamous skin cell carcinoma and others,[43] has been reported in nontransplanted patients receiving therapy with AZA, CYC or chlorambucil. In these studies the appearance of NHL occurred shortly after the initiation of the immunosuppressive treatment. However, several studies did not show an increased risk of tumors in patients with SLE, RA and inflammatory bowel disease treated with AZA.

Mycophenolate mofetil

Mechanism of action

Mycophenolate mofetil is the prodrug of mycophenolic acid (MPA). It is a highly selective noncompetitive inhibitor of inosine monophosphate dehydrogenase (IMPDH),[44] an enzyme involved in the denovo synthesis of guanosine nucleotides. In this regard, it is of note that purine synthesis may occur through two different pathways:

- de novo, and
- by the salvage pathway (Fig. 99.3).

Blood cells originating from the erythrocyte, megakaryocyte and myeloid lineages may use the salvage pathway if the de-novo pathway is inhibited. In contrast the salvage pathway is not functional in B and T cells. Therefore, the suppressive activity of MMF is quite selective for T and B cells, and particularly proliferating lymphocytes. The inhibition of IMPDH results in a depletion of

guanosine nucleotides that are critical for DNA synthesis and thus cell proliferation (see Fig. 99.1).

From an immunologic standpoint, MMF has no effect on resting B and T cells, but strongly suppresses proliferation of activated T cells by inducing apoptosis. It is a potent suppressor of primary and secondary T-cell responses. It also mediates potent inhibition of primary humoral immune response, but seems to be less effective in the inhibition of secondary humoral responses.[45] The dual effect on T and B cells is responsible for the infectious complications (particularly CMV infection, see below) associated with MMF therapy. Furthermore, due to the potent suppression of primary humoral immune responses, vaccination generally fails to induce humoral immune responses in patients under MMF treatment. Mycophenolate mofetil also reduces the synthesis of adhesion molecules, such as very late antigen 4 (VLA-4) and VCAM-1, which results in a decreased recruitment of lymphocytes in the transplanted organ.[44] In contrast to CsA and tacrolimus, MMF does not inhibit the synthesis of IL-2 and IL-2 receptor.

Clinical effects

Mycophenolate mofetil is predominantly used in the field of solid organ transplantation and has replaced AZA in combinations of immunosuppressive agents to prevent acute and chronic rejection. A series of studies have clearly demonstrated the superiority of MMF over AZA. Mycophenolate mofetil was initially used in renal [46] transplantation, but has also recently been used in heart and liver transplantation.

Mycophenolate mofetil is generally a well-tolerated drug that has the advantage of not being metabolized through cytochrome P450. The most common side-effects associated with MMF treatment are gastrointestinal (nausea, vomiting and diarrhea) and hematologic. These side-effects are quite important during the first 4 weeks of therapy and generally become less important after prolonged treatment. Serious adverse events are extremely rare and may include pancreatitis, hemorrhagic gastritis and cholestasis.

The infectious complications (see Table 99.1) are very similar to those described for AZA.[41] The frequency of CMV infection has been reported to be greater in patients receiving high (>3g/day) doses of MMF than in those receiving AZA or placebo. The increased incidence of CMV infection in patients treated with MMF has been confirmed in the fields of renal[41] and allogeneic stem cell[47] transplantation. The mechanism by which MMF treatment is associated with an increased risk for CMV infection is unclear. It has been proposed that the suppression of B in addition to T cells may play an important role.[48] It is, however, unclear whether CMV-specific humoral immunity has any protective role. In patients treated with MMF, but receiving aciclovir or ganciclovir for anti-CMV prophylaxis, the incidence of CMV infection was comparable to that in patients not treated with MMF. In contrast to CMV, treatment with MMF is not associated with an increased risk of infection with other herpesviruses. *Pneumocystis carinii* pneumonia (PCP) is also a typical infectious complication of transplanted patients.[49] The analysis of a large number of patients who underwent renal transplantation has shown an absence of PCP in the group of patients treated with MMF.[50] In this regard, it is noteworthy that it has been shown that MMF is extremely active against *P. carinii* in animal models.[51]

Like AZA, an increased risk for skin cancer and NHL has been associated with MMF treatment. Although some studies have shown a higher incidence of lymphoproliferative disorders in MMF-treated versus AZA-treated patients, other studies have failed to confirm a more potent oncogenic property for MMF. As already mentioned for other immunosuppressive agents, the oncogenicity is dependent upon the state of general immunosuppression caused by combination therapy rather than one particular immunosuppressive agent.

Methotrexate

Mechanism of action

Originally developed as an anticancer agent, methotrexate (MTX) is an antifolate[52] with a potent immunosuppressive action. Methotrexate has a structure similar to that of the folates and uses the same mechanisms of transport to cross the membrane. In particular, two mechanisms have been identified:[52]

- via a low affinity transporter, and
- via a folate-binding-protein (FBP) associated with the cell membrane.

In addition, MTX can also passively cross the membrane.

Methotrexate has numerous enzymatic targets. Critical for its cytotoxic activity and for the selectivity of its mechanisms of action is the fact that MTX, like folates, is subjected to a polyglutamation that increases the intracellular half-life.[53] The importance of the polyglutamation is demonstrated by the finding that cell lines defective in polyglutamyl synthetase, the enzyme that catalyzes the polyglutamation, are resistant to MTX treatment. It is indeed the polyglutamate form of MTX that is immunosuppressive. The primary target of MTX is the dihydrofolate reductase (DHFR) that blocks the formation of tetrahydrofolate (FH_4) from dihydrofolate (FH_2) within the metabolic cycle of the thymidylate (dTMP). The thymidylate synthase is the enzyme that catalyzes the reaction from uracyl-5'-monophosphate (dUMP) to thymidine-5'-monophosphate dTMP. The inhibition of DHFR is the primary mechanism of suppression of pyrimidine synthesis. Inhibition of pyrimidine synthesis by MTX also occurs through the suppression of another enzyme, thymidylate synthase. Furthermore, MTX inhibits the de-novo synthesis of purines by blocking the enzymatic activity of the 5-amino-imidazole-4-carboxamide-ribonucleotide (AICAR) transformylase. Therefore, the immunosuppressive effect of MTX is mostly the result of the suppression of pyrimidine and purine synthesis (see Fig. 99.1).

With regard to the anti-inflammatory effect, it has been shown that MTX reduces the chemotaxis of neutrophils, inhibits the synthesis of leukotriene B4 and reduces the synthesis of IL-1. In addition, the inhibition of the activity of AICAR transformylase induces an increase of adenosine, which is the most potent endogenous anti-inflammatory factor. In this regard, it is thought that the anti-inflammatory effect of MTX is mostly due to the increase in endogenous adenosine. Finally, it has been shown that MTX induces apoptosis of activated but not resting CD4 and CD8 T cells.[54]

Clinical effects

As mentioned above, MTX at higher dosage (100–1000mg/m^2 per cycle) has been extensively used in the field of oncology. At lower doses (5–25mg/week) it is essentially used as an anti-inflammatory agent and as an immunomodulator in the treatment of autoimmune diseases and in particular in patients with RA. Methotrexate as well as leflunomide (see below) are also known as disease-modifying anti-rheumatic drugs (DMARDs).[55] Furthermore, due to its anti-inflammatory and immunosuppressive effects, MTX together with CsA or tacrolimus is used in the treatment of graft versus host disease.[56]

A variety of side-effects have been described in patients treated with MTX. These include severe liver and lung (interstitial pneumonitis)[57] toxicity, and infectious complications (upper respiratory tract infections, urinary tract infections). In addition, the defect in folate concentration caused by MTX may be responsible for severe toxic effects such as myelosuppression, hepatotoxicity and diarrhea.[58] [59] These latter toxic effects can be in part prevented or controlled by the administration of folic or folinic acid, which compete with the activity of MTX.[60]

Leflunomide

Mechanism of action

Like MTX, leflunomide is an inhibitor of de-novo pyrimidine synthesis [61] (see Fig. 99.1). Leflunomide inhibits the mitochondrial enzyme dihydro-orotate dehydrogenase (DHODH), which is involved in the de-novo synthesis of ribonucleotide uridine monophosphate pyrimidine (rUMP). The active metabolite of leflunomide, A77 1726, inhibits DHODH. This inhibition is reversible, but prevents the denovo synthesis of pyrimidines. The inhibition of the de-novo synthesis of pyrimidines particularly affects lymphocytes as compared with other cell lineages. The inhibition of DHODH prevents the accumulation of sufficient levels of pyrimidine within lymphocytes in order to support DNA synthesis and thus proliferation.[62] In addition to the inhibition of DHODH, leflunomide suppresses TNF-a production by inhibiting NF-?B activity.[63]

Clinical effects

Leflunomide is used in the treatment of RA.[55] [62] The efficacy and toxicity of leflunomide are comparable to those of MTX.[58] [59] [64] These latter include particularly diarrhea, abdominal pain, nausea, vomiting and alteration of liver function parameters. The gastrointestinal effects are particularly important during the first 2 weeks of treatment and tend to decrease thereafter. In addition, allergic reactions have been reported following leflunomide treatment, and also reversible alopecia. Diarrhea has been more frequently associated with leflunomide than MTX treatment while oral ulcers are more frequent with MTX.

The most frequent infectious complications affect the upper respiratory tract.[59] These infectious complications are generally more frequent during the first year of treatment but only exceptionally cause an interruption of therapy.[58]

Monoclonal antibodies

Antilymphocyte antibodies are an important therapeutic tool in the field of immunosuppression and transplantation, and are among the first immunosuppressive agents used in liver transplantation.[20] A major limitation of these agents is their lack of specificity and their partial efficacy. In fact, the risk for acute or chronic graft rejection remains elevated. Another issue of serious concern is the toxicity profile, with an increased risk for opportunistic infections and malignancies.

The first antilymphocyte antibody preparations developed in the field of transplantation were polyclonal. As mentioned above, they are potent immunosuppressive agents that cause massive depletion of T cells. Although the clinical efficacy when used as an inductive immunosuppressive agent is controversial (the survival of the graft was improved[65] in certain studies but not in others[66]), they have been shown to be effective in the treatment of GC-resistant acute graft rejection.[66] Furthermore, the use of antilymphocyte antibodies is also difficult for a variety of reasons including:

- an increased risk for infectious complications and malignancies;
- intravenous administration in vessels of large caliber;
- side-effects such as thrombocytopenia;
- lack of specificity for the target;
- low proportion of antilymphocyte antibodies within the antibody preparations administered (about 2%); and
- neutralization of the therapeutic effect by the induction of anti-bodies directed against the antilymphocyte antibody preparations administered.[67]

On the basis of the limitations mentioned above, polyclonal antibodies have been progressively replaced by the development of a series of monoclonal antibodies.

Muromonab CD3

Muromonab CD3 is a highly specific monoclonal antibody directed against the surface antigen CD3 expressed by the majority of T cells. Although the use of muromonab CD3 is not associated with allergic reactions or serum sickness, its toxicity profile is characterized by the so called 'cytokine release syndrome'. [68] In fact, the CD3 surface antigen is physically linked to the TCR and the CD3 complex represents the signal transduction machinery for T cells. Therefore, the binding of anti-CD3 antibody to the CD3 surface antigen causes massive activation of T cells. The latter is responsible for cytokine release and the clinical picture may be complicated by a pharmacologic shock of variable severity. For these reasons, the use of muromonab CD3 has been abandoned.

Anti-interleukin-2 receptor antibodies

Interleukin-2 is a major T cell growth factor necessary for the expansion of T cells following antigen-specific stimulation, which represents a fundamental step in the generation of the T-cell-mediated immune response. Anti-IL-2 receptor (R) monoclonal antibody formulations for clinical use have been developed to interfere with the initial expansion of T cells. These antibodies are directed against the a chain of the IL-2R (anti-CD25 antibody).[69] The original preparations of anti-IL-2R antibodies were of murine origin. Recently, chimeric forms of antibodies have been generated. These contain the majority of sequences of human IgG with incorporated murine sequences in the hypervariable region specific for the achain of IL-2R.[69] Two preparations of IL-2R antibodies are currently available for clinical use: basiliximab [70] [71] and daclizumab. [72] [73] [74] Basiliximab is a chimeric antibody that contains less than 10% of murine sequences while daclizumab is a humanized antibody. The half-life of these antibody preparations is 6.5 and 11 days, respectively.

The primary goal of using anti-IL-2R antibody in the field of transplantation is to reduce the incidence of acute graft rejection[75] and eventually the dose of the other immunosuppressive agents (particularly the inhibitors of calcineurin). Combination of IL-2R antibody with other immunosuppressive agents has been shown to be effective in the prevention of acute rejection in renal and liver transplantation even if inhibitors of calcineurin are not part of the therapeutic combinations.

Therapy with IL-2R antibody is extremely safe and well tolerated. No increased risk for viral and bacterial infections has been reported.

Inhibitors of tumor necrosis factor-a

Tumor necrosis factor-a is a potent cytokine and a primary mediator of inflammatory reactions.[76] It plays a central role in many inflammatory diseases including inflammatory bowel and rheumatic diseases. Several studies have demonstrated the fundamental role of TNF-a in the pathogenesis of RA.[76] [77] Transgenic mice with a deregulation of the TNF-a gene develop a destructive arthritis similar to RA. In addition, TNF-a is clearly implicated in the pathogenesis of juvenile RA and psoriatic arthritis and Crohn's disease.[78]

Two specific inhibitors of the function of this cytokine have been developed:[77] infliximab and etanercept. Infliximab is a chimeric (human/mouse) monoclonal antibody directed against TNF-a. The Fc portion of infliximab is a human IgG1 while the antigen-binding variable domain that has a high affinity for the human TNF-a is of murine origin. Etanercept is the human recombinant form of the soluble TNF receptor. It is a dimerized fusion protein formed by an extracellular domain of the TNF type II receptor (p75) and by the Fc portion of a human IgG1. The mechanism of action of etanercept is the blocking of soluble and membrane-bound TNF and lymphotoxin a.

Both infliximab and etanercept are effective in blocking inflammation. [79] [80] The efficacy of etanercept has been extensively documented in clinical studies in patients with RA and even in the case of RA resistant to MTX treatment.[79] [80] In addition to the treatment of RA, juvenile RA and Crohn's disease, inhibitors of TNF activity can play an important role in the treatment of other pathologic conditions such as sarcoidosis, ankylosing spondyloarthritis and Wegener's granulomatosis.

With regard to the toxicity profile of TNF inhibitors, systemic (infliximab) and urticarial (etanercept) reactions never require discontinuation of treatment.[80] A major concern with treatment with TNF inhibitors is the increased risk for infectious complications. Infectious complications have been reported in 50 and 60% of patients treated with infliximab and etanercept, respectively. The increased risk for infections is the result of the dysfunction of the protective mechanisms against intracellular pathogens. Mycobacterial infections are those more commonly associated with the blocking of TNF-a activity. [81] Numerous cases of tuberculosis have been reported following infliximab administration. On the basis of these complications, the current guidelines for the therapeutic use of TNF inhibitors indicate that a purified protein derivative (tuberculin) test should be done before the initiation of treatment. In the case of a positive test without other signs of reactivation of the disease, treatment with isoniazid is advised during administration of infliximab.[82] The number of cases of reactivation of tuberculosis seems to be less important following treatment with etanercept. Other infections associated with TNF-inhibitor treatments include those caused by *P. carinii*, *Legionella* spp., *L. monocytogenes* and other fungi.[83] [84]

New immunosuppressive agents

FTY720

FTY720 is the synthetic derivative of myriocin, a potent immunosuppressive drug that was originally described in 1994.[85] This immunosuppressive agent has a unique mechanism of action. FTY720 induces an alteration of the homing and trafficking of lymphocytes through the modulation of the expression of cell surface molecules.[86] This results in a significant reduction in the number of lymphocytes. Neutrophils and monocytes are not affected by FTY720. The lymphopenia occurs 6–12 hours after administration and persists over time during treatment, but is reversed by an interruption in treatment. Apoptosis seems to be the mechanism responsible for the depletion of lymphocytes.

With regard to the clinical effects, the majority of data available have been generated in experimental animal models in the fields of transplantation and autoimmunity (autoimmune myocarditis and uveoretinitis or type I diabetes).[86] [87] [88] The results indicate that FTY720 is effective in prolonging the survival of the graft in renal, cardiac, liver and skin transplantation. Furthermore, as FTY720 is metabolized through cytochromes that differ from those involved in the metabolism of CsA, tacrolimus and rapamycin, the risk for pharmacologic interactions with other immunosuppressive agents is unlikely. Thus, FTY720 can potentially be used in combination with other immunosuppressive agents and this may allow the design of novel immunosuppressive therapeutic strategies for the prevention of the graft rejection.

Due to its selective effects on lymphocytes, FTY720 does not induce a global immunosuppression. The results obtained from animal models did not show the appearance of infectious complications even at high doses and after prolonged treatment. Similarly, there was no evidence for nephrotoxicity and mutagenicity.

CONCLUSION

Major advances have been made in the past two decades in our understanding of fundamental immunoregulatory mechanisms, in the development of novel immunosuppressive agents and in the prevention of the infectious complications associated with immunosuppressive therapy. Future goals in the field of immunosuppression should include an improvement in the management of the infectious complications and the development of novel and more selective agents. The generation of highly selective agents is the only valid strategy to maximize the immunosuppressive effects and minimize the immunodeficiency.

Chapter 100 - Infections in the Neutropenic Cancer Patient

Oscar Marchetti
Thierry Calandra

INTRODUCTION

Cancer occurs in one of every four people and is one of the leading causes of death in developed countries. Cancer can be subdivided in two main categories: solid tumors and hematological malignancies, which include leukemias, lymphomas and multiple myeloma. Solid tumors account for more than 90% of all new cancer cases and hematological malignancies for the remaining 5–10%.[1] Over the past decades, joint efforts of basic science and clinical research have resulted in substantial improvements of prevention, early detection and treatment of cancer. Indeed, overall 5-year survival rates in cancer patients have improved from 39% in the 1960s to 60% in the 1990s.[1] Solid tumors are frequently treated with combined treatment modalities including surgery, radiation therapy and chemotherapy. In contrast, chemotherapy is the cornerstone of the management of patients with hematological malignancies. New therapeutic options, such as immunotherapy and gene therapy, are being developed.

Infections frequently occur during treatment of cancer. Many factors contribute to increase the risk of infection: poor clinical and nutritional status, mechanical obstruction of natural passages, damage to anatomic barriers (surgery, use of prosthetic and intravascular devices) and defects of humoral and cell-mediated immunity that are either disease associated or secondary to radiotherapy or chemotherapy. Cytotoxic agents exert their effects on both malignant cells and normally replicating progenitor cells and thus also cause major toxicity on normal tissues with high turnover (i.e. bone marrow and mucous membranes), resulting in myelosuppression and alteration of physiological barriers. Historically, hemorrhage and infections have been major complications and leading causes of chemotherapy-related mortality (10–20% and 50–80%, respectively).[2] In the 1960s, both the severity and duration of granulocytopenia were identified as major determinants of infectious complications.[3] In the early 1970s, prompt empirical antibiotic treatment became the cornerstone of management of febrile neutropenic patients, resulting in drastic reduction of the mortality of bacterial infections.[4] Since then, major progress has been made in the understanding of the pathogenesis and treatment of infectious complications of cancer patients. Development of novel diagnostic and treatment strategies continues to improve the outcome of febrile neutropenic cancer patients.[5] [6] [7]

EPIDEMIOLOGY

The majority of infections in granulocytopenic cancer patients are caused by micro-organisms of the patient's endogenous flora.[5] [6] [7] However, exogenous air-borne and food-borne pathogens, acquired either in the community or in the health care system, can also cause infection.

Bacterial infections

Gram-positive and Gram-negative bacteria are the predominant pathogens in this clinical setting (Table 100.1). [5] In the past decades, most cancer centers have experienced major changes regarding the etiology of bacterial infections in the neutropenic host.[5] [6] [7] [8] While Gram-negative bacteria were predominant in the 1970s and early 1980s, the frequency of Gram-positive bacteria markedly increased in the late 1980s and early 1990s, when they became the prevalent pathogens in many institutions. However, this trend reversed in the late 1990s. Gram-negatives and Gram-positives now account for an equal proportion of infections in Europe (Fig. 100.1).[8]

Many factors are involved in these epidemiological shifts. The increasing incidence of infections due to coagulase-negative staphylococci and other Gram-positive skin colonizers has been associated with the increased use of intravascular access devices. The emergence of viridans streptococcal infections, sometimes associated with acute respiratory distress syndrome (ARDS) and septic shock, has been attributed to several factors including the toxicity of high-dose chemotherapy with cytosine arabinoside on oral mucous membranes, the reactivation of oral HSV infection and the use of fluoroquinolone prophylaxis.[9] Among Gram-negative bacteria, *Escherichia coli, Klebsiella* species and *Pseudomonas aeruginosa* are the most common bloodstream isolates. However, the incidence of *Pseudomonas aeruginosa* infections, a predominant cause of bacteremia in the 1960s and 1970s, has substantially declined over the last 30 years. The use of fluoroquinolone prophylaxis has undoubtedly played a major role in the decreasing incidence of Gram-negative infections observed in the late 1980s and early 1990s.[10] The recent re-emergence of Gram-negative infections is probably due to the reduced use of fluoroquinolone prophylaxis in many centers out of concern about increased resistance.[11]

Fungal infections

Fungal infections are a major threat to neutropenic cancer patients. Disseminated mycoses have been demonstrated in 10–40% of autopsies in patients with hematological malignancies, especially in patients who have been treated with broad-spectrum antibiotics and corticosteroids.[2] Classically occurring as secondary infections in patients with prolonged and profound neutropenia, fungal infections also account for approximately 5% of initial infections episodes. Mixed fungal and bacterial infections may occur and the fungal infection may manifest as persistent fever after eradication of the bacterial pathogen. Eighty to ninety percent of fungal infections are caused by *Candida* species (mainly *C. albicans, C. tropicalis, C. glabrata, C. krusei, C. parapsilosis, C. pseudotropicalis*). *Aspergillus* (mainly *A. fumigatus* and *A. flavus*) and other emerging fungi including *Fusarium, Pseudallescheria boydii, Scedosporium, Rhizopus* and *Mucor* account for the remaining 10–20%.[2] Azole-resistant non-*albicans Candida* species (*C. krusei, C. glabrata*) have emerged in some cancer centers, usually in conjunction with several predisposing factors, including fluconazole prophylaxis.[12] [13]

Other pathogens

Reactivations of latent herpes simplex virus (HSV) and varicellazoster virus (VZV) infections are common in patients with hematological malignancies, especially after chemotherapy or treatment with corticosteroids.[5] [6] [7] In contrast to other immunocompromised

TABLE 100-1 -- Most common pathogens in neutropenic cancer patients.

MOST COMMON PATHOGENS IN NEUTROPENIC CANCER PATIENTS
Gram-positive aerobic bacteria
Coagulase-negative staphylococci
Viridans streptococci
Staphylococcus aureus
Other streptococci (*S. pneumoniae*, *S. pyogenes*)
Enterococcus spp.
Corynebacterium spp. (*C. jeikeium*)
Bacillus spp.

Listeria monocytogenes
Gram-negative aerobic bacteria
Escherichia coli
Klebsiella spp.
Pseudomonas spp.
Other Enterobacteriaceae (*Proteus*, *Enterobacter*, *Serratia*, *Citrobacter* spp.)
Other nonfermentative bacilli (e.g. *Stenotrophomonas maltophilia*)
Legionella spp.
Anaerobic bacteria
Bacteroides species
Clostridium species
Fusobacterium species
Propionibacterium species
Fungi
Candida species
Aspergillus species
Other molds (*Fusarium*, *Pseudallescheria boydii*, *Scedosporium*, *Rhizopus*, *Mucor*)
Viruses
Herpes simplex virus
Varicella-zoster virus
Respiratory viruses (influenza, respiratory syncitial virus)
Parasites
Strongyloides stercoralis
Other parasites in endemic areas (e.g. *Leishmania*)

patients, especially transplant recipients, cytomegalovirus (CMV) infections play a minor role in neutropenic cancer patients, as acquired immunity is less severely suppressed than innate immunity. Other viral infections such as respiratory viruses (influenza, respiratory syncytial virus) and parvovirus B19 occur occasionally. Primary

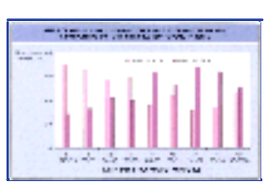

Figure 100-1 Single-organism bloodstream infections due to Gram-negative and Gram-positive bacteria in febrile neutropenic patients. European Organisation for Research and Treatment of Cancer — International Antimicrobial Therapy Group (EORTC-IATG) studies (1973–2000). *Adapted from reference* [8] .

parasitic infections as well as reactivations of latent infections, in particular those due to *Strongyloides* or *Leishmania*, only occur in patients who have lived in or visited endemic areas.

PATHOGENESIS

Underlying conditions

Microbial invasion and development of infection are facilitated by the presence of co-morbidities, immunosuppression and damage to anatomic barriers caused by the cancer itself or induced by chemotherapy.[5] [6] [7] Obstruction of the lumen of natural body passages (i.e. urinary, biliary, respiratory or digestive tract) by cancer impairs the flow of body fluids and secretions, creating conditions that promote microbial growth. Cytotoxic chemotherapy damages the epithelial tissue lining, resulting in loss of the integrity of the mucous membrane barrier. Development of mucositis therefore predisposes to infection by the patient's endogenous commensal flora and colonizing pathogens. Injury to the skin by venous puncture, presence of indwelling vascular access devices, bone marrow aspiration, lumbar puncture and other surgical interventions can also promote skin and soft tissue infections.

Defects of innate and acquired immunity

Neutropenia

Phagocytes (neutrophils, monocytes, macrophages and dendritic cells) are a critical component of the host innate immune defenses against infections. Thus, any alteration in function or number of these cells, especially neutrophils, will result in an increased risk of infection.[5] [6] [7] Neutropenia is defined as a neutrophil count <500 cells/mm^3 or <1000 cells/mm^3 with expected decrease to <500 cells/mm^3 within 48 hours. Studies performed in the 1960s have shown that there is an inverse relationship between the number of circulating neutrophils and the incidence of infections.[3] As the neutrophil count decreases to <1000 cells/mm^3 , the incidence of infections increases markedly (Fig. 100.2). The risk of severe infectious complications such as bloodstream infections is greatest when the neutrophil count drops below 100 cells/mm^3 .

The duration of neutropenia is also a major determinant of the risk of infection.[3] As shown in Figure 100.2 , the longer the duration of neutropenia, the greater the risk of infection. Profound and prolonged neutropenia (i.e. <500 cells/mm^3 for more than 10 days)

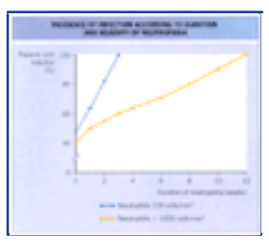

Figure 100-2 Incidence of infection according to duration and severity of neutropenia. *Adapted from reference* [5] .

is considered to be a major risk factor for both primary and secondary bacterial or fungal infections. Patients with neutropenia lasting less than 7–10 days are at low risk of complications.[5] Indeed, 95% of patients with neutropenia lasting less than 1 week respond to the initial empirical antibiotic therapy, while two-thirds of those with neutropenia for more than 2 weeks may require treatment modifications.[5] [14] Moreover, the risk of recurrence of fever and infection is also substantially lower (<1%) in patients with neutropenia of short duration than in those with neutropenia lasting more than 2 weeks (38%).[14]

Yet factors other than the severity and duration of neutropenia also help to identify who is at low or high risk of infectious complications (see Risk assessment, below).

Other immune defects

Neutropenia is the main immune defect of cancer patients. In general, defects of the humoral or cell-mediated components of acquired immunity are not predominant in these patients. However, specific immune defects directly associated with the underlying malignancy (e.g. hypogammaglobulinemia in chronic lymphatic leukemia or multiple myeloma) or its management (e.g. therapy with high-dose corticosteroids) may occur and further increase the risk of infections in conjunction with neutropenia.[5] [6] [7]

CLINICAL FEATURES

Fever

During neutropenia, fever develops in virtually all patients with hematological malignancies and in about half of those with solid tumors.[5] Although any temperature distinctly above baseline is indicative of fever, fever has been arbitrarily defined as a single temperature >101.3°F (38.5°C) or >100.4°F (38°C) on two or more occasions during a 12-hour period by the Consensus Expert Panel of the International Immunocompromised Host Society, or as a single temperature reading >100.9°F (38.3°C) or =100.4°F (38°C) during at least 1 hour by the Fever and Neutropenia Guidelines Panel of the Infectious Diseases Society of America.[5] [15] Temperature should be measured orally or by auditory canal probe. More than two-thirds of the febrile episodes are likely to be caused by infection, which may occur with or without focal symptoms or signs. Because of the impaired inflammatory response, the classic signs of infection (i.e. pain, heat, redness and swelling) are often reduced or may even be absent. Therefore, fever is generally the first and frequently the only sign of infection.[16]

Fever occurring in the context of neutropenia is considered to reflect ongoing infection unless proven otherwise. However, there are noninfectious causes of pyrexia, of which the most frequent are the underlying malignancy itself, cytotoxic chemotherapy, transfusion of blood products, antifungal and occasionally other antimicrobial agents, hematopoietic growth factors or allergic drug reactions. Uncommonly, infection may develop in the absence of fever because of the lack of inflammatory response such as during therapy with high-dose corticosteroids or when caused by certain micro-organisms (e.g. *Clostridium septicum*).

Types of infection

Classically, infections have been subdivided into three main categories. [5] [15]

- *Microbiologically documented infections* (MDI), subdivided into those with and without bloodstream infection. Bloodstream infections, caused predominantly by bacteria (bacteremia) and occasionally by fungi (fungemia), may be either primary (in the absence of a nonhematogenous focus of infection) or secondary to a proven focus of infection (e.g. pneumonia, cellulitis, catheter-related infection, urinary tract infection).
- *Clinically documented infections* (CDI) defined by the presence of a site of infection (e.g. pneumonia, cellulitis, oropharyngeal mucositis, enterocolitis, catheter exit site infection) without microbiological proof of the nature of infection.
- *Fever of unknown origin* (FUO) also designated as fever of undetermined origin, unexplained fever or pyrexia of unknown origin and defined as a febrile episode that is not accompanied by clinical or microbiological evidence of infection.

Figure 100.3 shows the proportions of MDI, CDI and FUO in febrile neutropenic patients with hematologic malignancies (mainly acute leukemia) or solid tumors in three consecutive multicenter studies conducted in the 1990s in Europe, the Middle East and North America.[17] [18] [19] [20] [21] Generally, MDI account for approximately 25–35% and 10–20%, CDI for 20–30% and 10–20% and FUO for 40–60% and 50–70% of the episodes of fever occurring in neutropenic patients with hematological malignancies or solid tumors, respectively.[17] [18] [19] [20] [21] Most episodes of MDI consist of bloodstream infections (Fig. 100.4), that occur almost exclusively in patients with profound neutropenia (<100 cells/mm^3). [3] [17] [18] [19] Although the etiology of fever remains by definition unclear in FUO, one may retrospectively assume that the fever was probably of infectious origin, if it resolved with antimicrobial therapy.

Sites of infection

The most frequent sites of infection in neutropenic cancer patients with hematological malignancies or solid tumors are, by decreasing order of frequency, the bloodstream, the oral cavity and nasopharynx, the skin and soft tissues, the respiratory tract, the gastrointestinal tract and the urinary tract (Fig. 100.4).[17] [18] [19]

Bloodstream

Bloodstream infections account for 80–90% of microbiologically documented infections (Fig. 100.3) and for half of the febrile episodes, for which a site of infection can be identified (Fig. 100.4). In primary bloodstream infections, the source remains unknown but disrupted physiological barriers (i.e. mucous membranes of the gastrointestinal tract and skin) are the most likely portals of entry. Bacteria are the most frequent blood isolates, accounting for over 90% of bloodstream

Figure 100-3 Causes of fever in neutropenic patients with hematological malignancies (n=1773) or solid tumors. *Data are derived from four consecutive EORTC-IATG studies conducted between 1991 and 2000 and from a North American study conducted between 1992 and 1997.*[17] [18] [19] [20] [21]

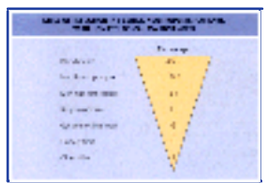

Figure 100-4 Sites of infection in febrile neutropenic patients with hematological malignancies. *Data are derived from three consecutive EORTC-IATG studies conducted between 1991 and 2000.*[17] [18] [19]

infections. A single micro-organism is implicated in the majority of the bloodstream infections, but polymicrobial infections occur in approximately 10% of the cases.

As previously mentioned, the epidemiology of single-organism bacteremia in neutropenic cancer patients has changed over the last 30 years (Fig. 100.1). Today, Gram-positive and Gram-negative bacteria cause an equal proportion of infections. The most common Gram positives are coagulase-negative staphylococci, viridans streptococci and *S. aureus*. Among Gram negatives, *E. coli, Klebsiella* spp. and other Enterobacteriaceae are predominant, while *P. aeruginosa* has declined progressively (Table 100.1). Resistant bacteria or fungi are classically isolated from blood in secondary febrile episodes occurring during antibiotic treatment. Bloodstream infections are potentially life threatening but with the prompt administration of empirical antibiotics at fever onset, severe complications such as severe sepsis and septic shock rarely occur today. Mortality rates between 1% and 3% have been reported in recent studies in febrile neutropenic cancer patients.

Mouth and pharynx

Maintenance of good oral hygiene and proper dental care are essential for the prevention of oral and systemic infections. Dental septic foci, such as braces and periodontitis, which may promote or facilitate the development of local and systemic infections, should be removed or treated prior to the initiation of chemotherapy. Indeed, infections of the oral cavity (e.g. mucositis, gingivitis, periodonitis) and pharynx occur in 15–25% of neutropenic cancer patients (Fig. 100.4). The frequency and severity of these infections are correlated with the degree of mucosal damage induced by cytotoxic chemotherapy and with the severity of neutropenia. Mucous

membranes of the mouth and pharynx are heavily colonized with viridans streptococci, Gram-positive rods and aerobic and anaerobic Gram-negative bacilli. Loss of integrity of the mucosal barrier is therefore a major portal of entry for infection. Neutropenic patients with no or minimal mucosal damage are at much lower risk of infection than patients with severe chemotherapy-induced mucositis. *Candida* also plays an important role in infections of the oropharynx, especially under the selective pressure of broad-spectrum antibiotics. Oral lesions caused by reactivation of HSV infection may

Figure 100-5 Cutaneous bacterial infections in neutropenic patients with acute leukemia. (a) Axillary *Pseudomonas aeruginosa* hydradenitis. (b) Ecthyma gangrenosum of fingers in a patient with *P. aeruginosa* sepsis.

mimic chemotherapy-induced mucositis and also serve as a portal of entry for bacterial infection.

Skin and soft tissues

Cutaneous infections are common in neutropenic cancer patients, causing about 10–20% of all septic episodes for which a source of infection is identified (Fig. 100.4). Primary skin and soft tissue infections often result from disruption of the integrity of the cutaneous barrier caused by needle punctures (venous or lumbar puncture, bone marrow biopsy) or by the presence of intravascular access devices. The anal and axillary areas are frequent foci of cutaneous infections as moisture, high bacterial colonization, relative skin frailty and microtrauma all facilitate the development of infection. Anal fissures are often complicated by perirectal cellulitis, classically caused by the fecal flora, including Gram-negative bacilli (Enterobacteriaceae, *P. aeruginosa*), enterococci and anaerobic Gram-negative bacilli. Axillary hydradenitis is a classic infection of neutropenic hosts caused by skin commensals and Gram-negative bacteria, including *P. aeruginosa* (Fig. 100.5a). Disseminated cutaneous infections may reflect the development of septic skin foci in patients with bacterial, fungal or viral bloodstream infections. Clinically, these skin lesions appear as papules or nodules (Fig. 100.6), which are usually associated with classic symptoms and signs of sepsis (i.e. fever, chills, headache, backache, myalgia and muscle tenderness). Ulcers, vesicles, hemorrhagic or crusted lesions that are either isolated (with or without dermatome distribution) or disseminated are typically associated with

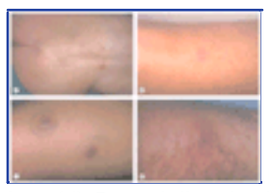

Figure 100-6 Cutaneous manifestations of disseminated fungal infections in leukemic patients. (a) *Aspergillus terreus*, back. (b) *Candida tropicalis*, arm. (c) *Fusarium*, leg. (d) *Pseudallescheria boydii*, leg.

herpetic skin infections, but may occasionally occur with staphylococcal or streptococcal infections.

A bacterial (e.g. *Pseudomonas* and *Aeromonas* species) or fungal etiology (*Fusarium, Aspergillus, Mucor* and *Rhizopus* species) should be suspected in cases of disseminated necrotic skin lesions. For example, ecthyma gangrenosum is a classic cutaneous complication in patients with *Pseudomonas* sepsis (Fig. 100.5b). Necrotizing fasciitis and metastatic musculoskeletal infections complicating bacteremia or fungemia have also been reported, albeit infrequently (Fig. 100.7a).

Intravascular access devices

Indwelling intravenous catheters, especially those inserted for prolonged periods of time (e.g. Broviac, Hickman, Port-a-cath), are a major source of infections, which most commonly arise at the exit site but may also occasionally affect the tunneled section of the catheter. Clinical manifestations include pain, erythema and tenderness with no or minimal swelling during marrow aplasia. Microbes of the skin flora (i.e. coagulase-negative staphylococci, *Propionibacterium* spp., *Corynebacterium* spp., *Bacillus* spp. and viridans streptococci), *Staph. aureus*, Gram-negative bacteria and *Candida* species are the most frequent pathogens. When skin necrosis occurs, infections due to *P. aeruginosa*, mycobacteria (especially *M. chelonae* and *M. fortuitum*) or molds (*Aspergillus, Fusarium* or *Mucor* species) should be suspected. Infection of intravascular access devices may be complicated by septic thrombophlebitis.

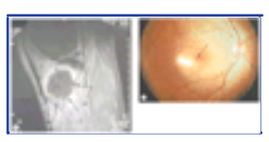

Figure 100-7 Disseminated *Staph. aureus* infection in a leukemic patient. (a) Muscular abscess, MRI. (b) Retinal infectious lesion with macular involvement and secondary bleeding (arrow), fundoscopy.

Respiratory tract

Respiratory infections account for 10–15% of the identified sites of infection in febrile neutropenic cancer patients (Fig. 100.4). Infections of the upper respiratory tract (sinusitis, otitis, epiglottitis, laryngitis and tracheitis) are uncommon, occurring in 1% of episodes. Sinusitis and otitis are mainly due to common community-acquired bacteria, but infections due to *Pseudomonas* species and anaerobes can occur. Fungal (*Candida, Aspergillus, Mucor, Rhizopus*) sinusitis is a severe and potentially life-threatening infection of patients with profound

Figure 100-8 Ethmoidal sinusitis due to *Aspergillus fumigatus* in a leukemic patient. The MRI shows a bone destruction with invasion of the orbit, optical nerve (upper arrow) and central nervous system (lower arrow).

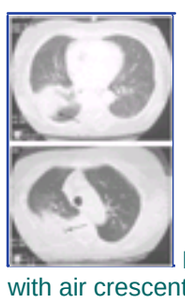

Figure 100-9 Invasive pulmonary aspergillosis in a patient with acute lymphoblastic leukemia. (a) Early stage with halo sign (arrow) during neutropenia, CT scan. (b) Late stage with air crescent sign (arrow) after bone marrow recovery, CT scan.

and prolonged neutropenia. It is often invasive and can infiltrate the nearby bone and skin and soft tissue structures of the orbit and extend into the central nervous system (Fig. 100.8).

Most frequently, lower respiratory tract infections (bronchopneumonia and pneumonia) are primary infections and account for about 10% of documented infections. However, they may occasionally be secondary to bloodstream infections. Due to the impaired inflammatory response, the classic symptoms and signs of pneumonia (such as fever, cough, dyspnea, chest pain, sputum and radiological infiltrates) are often attenuated or delayed, and present in only half to two-thirds of the patients.[16] Patients with profound neutropenia (<100 cells/mm^3) rarely produce sputum. The proportion of infections due to pneumonia tends to be lower in the first febrile episodes than in subsequent ones. Moreover, early-onset pneumonias are more likely to be of bacterial origin, while late-onset pneumonias are more likely to be due to fungi or other opportunistic pathogens

Figure 100-11 Pulmonary infections in neutropenic patients with hematological malignancies. (a) Interstitial pneumonia due to influenza virus. (b) Viridans streptococcal bacteremia with acute respiratory distress syndrome.

(Fig 100.9 , Fig 100.10a). Respiratory viruses (respiratory syncytial virus, influenza virus, parainfluenza virus, adenovirus) are rare (Fig. 100.11a).

Another classic pulmonary complication in febrile neutropenic cancer patients is the development of adult respiratory distress syndrome after viridans streptococcal bacteremia (Fig. 100.11b). This syndrome occurs despite adequate antibiotic therapy and is associated with important morbidity (respiratory failure requiring mechanical ventilation) and high mortality.[9]

Gastrointestinal tract and intra-abdominal organs

The gastrointestinal tract is the largest reservoir of micro-organisms of the human body and the endogenous gastrointestinal flora plays an important role in the pathogenesis of infections in neutropenic cancer patients. Extended chemotherapy-induced mucosal damage is therefore a major portal of entry of systemic infections. The

Figure 100-12 Neutropenic enterocolitis in a leukemic patient. Prominent thickening of a segment of ileum, CT scan (arrow).

gastrointestinal tract itself accounts for 4–8% of documented infections (Fig. 100.4). Esophagitis and enterocolitis are the two most frequent gastrointestinal infections in the neutropenic host. Esophagitis presents with severe retrosternal pain and dysphagia and is usually caused by the commensal bacterial flora, *Candida* species or reactivation of HSV. Symptoms and signs of enterocolitis include nausea, vomiting, bloating, abdominal discomfort, cramps, pain, constipation or diarrhea (often severe in the case of antibiotic-associated colitis). Typhlitis, a life-threatening necrotizing enterocolitis affecting the cecum or other bowel segments, typically occurs in patients with severe and prolonged neutropenia postchemotherapy for acute leukemia (Fig. 100.12). [22] The clinical manifestations are fever, abdominal pain (initially localized to the lower right abdominal quadrant, but becoming diffuse as the infection progresses) and diarrhea, that are often associated with a profound alteration of the patient's clinical condition. Typhlitis is caused by the endogenous gut aerobic and anaerobic bacterial flora, but yeasts and molds may also be implicated. Bleeding and perforation are the two major complications. Necrotizing fasciitis and septic shock can also occur, especially with clostridial infection, notably with *C. septicum*. Antibiotic-associated colitis due to *C. difficile* is a frequent cause of profuse diarrhea in neutropenic cancer patients exposed to multiple and prolonged antibiotic treatments.

Bacterial liver abscesses and viral hepatitis are rare in neutropenic cancer patients. Hepatosplenic candidiasis, a disseminated fungal infection mainly observed in patients with acute leukemia, classically becomes manifest at the time of marrow recovery after a prolonged period of neutropenia. Diagnosis should be suspected in patients with persistent fever, lack of appetite, abdominal discomfort or frank pain, hepatosplenomegaly and elevated alkaline phosphatase.[23] [24] Imaging techniques (ultrasonography, computed tomography (CT) scanning or magnetic resonance (MR)) show typical multiple target-like or bull's-eye lesions of the liver and spleen (Fig. 100.10b).

Urinary tract

Urinary tract infections are a rare cause of infection (1–3%) in neutropenic patients (Fig. 100.4) and are mainly due to common uropathogens, such as Enterobacteriaceae. They occur with minimal symptoms and dysuria is frequently absent, as is leukocyturia because of neutropenia. thus, diagnosis often relies on a positive urine culture in a febrile patient without evidence of another site of infection.

Other sites

Infections of the central nervous system, eye, heart, vasculature and bone are uncommon causes of sepsis in neutropenic patients with hematological malignancies and solid tumors (1% of all episodes; Fig. 100.4). Infections of the central nervous system comprise bacterial meningitis or brain abscesses. Acute primary bacterial meningitis occurs at a frequency similar to that of the general population. Bacterial meningitis also may occur in the context of bloodstream infections or as a complication of intrathecal chemotherapy. Infectious foci in the retina are observed in patients with disseminated bacterial and fungal infections (Fig. 100.7b). Endocarditis may occur even in the absence of risk factors, but is notably uncommon despite the frequency of bacteremia with organisms known to cause endocarditis. Clavicular osteomyelitis may be seen in patients with tunnel infections of subclavian intravascular access devices.

PREVENTION

Environmental measures

Preventive measures aimed at reducing the acquisition or transmission of nosocomial pathogens play an important part in reducing the risk of infection in neutropenic patients.[5] [6] [7] Special emphasis should be placed on careful handwashing by personnel, which can substantially diminish the risk of transmission of pathogens. Education of patients, family members, medical and nursing staff is essential. Contact with persons with overt respiratory or cutaneous infections must be avoided. Patients should receive well-cooked and low-microbial food and have access to safe water and ice supplies. For patients with severe and prolonged neutropenia, air ultrafiltration may be desirable in settings where *Aspergillus* infections are frequently observed. When an optimal protective environment is required, clean air is provided by means of constant positive-pressure air flow and/or high-energy particle air filtration. In addition, intensive disinfection measures are generally employed for high-risk patients. These include the use of antimicrobial mouthwash solutions, disinfectant soaps, creams and sprays and oral nonabsorbable antifungal agents. Proper oral and dental hygiene and careful attention to the anal region are essential. Insertion and manipulations of intravascular access devices and bone marrow aspiration should be performed with great care and under strict aseptic conditions. Whenever possible, the use of nasogastric tubing and urinary catheters should be

avoided.

Surveillance cultures of oropharynx, stools, urine and skin are of limited utility for the management of individual neutropenic patients, as they lack sensitivity and specificity for predicting and identifying the etiological agent of infection and are costly and time-consuming. However, these cultures might be useful for epidemiological studies and infection control purposes.

Antimicrobial prophylaxis

Prophylactic antimicrobial therapy has been used to suppress colonization by potential pathogens in high-risk neutropenic patients. Different strategies have been employed to prevent bacterial and fungal infections and reactivation of latent viral infections and have yielded mixed results. Thus, considerable controversy still srrounds the topic of antimicrobial prophylaxis for the prevention of infection in the neutropenic host.

Antibiotic prophylaxis

Oral nonabsorbable antibiotics have been used to achieve gut decontamination, since the bowel is the main reservoir of endogenous flora and an important source of infection in granulocytopenic cancer patients. However, the use of antibiotics such as vancomycin, gentamicin, polymyxin B, or colistin is associated with several problems. These antibiotics are nonpalatable and poorly tolerated, so that compliance

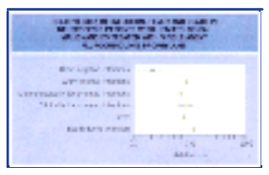

Figure 100-13 Relative risk of infection, fever and death in neutropenic patients with hematological malignancies treated with single-agent fluroquinolone prophylaxis. Yellow circles and black bars show relative risks with 95% confidence intervals in patients receiving fluoroquinolone prophylaxis compared to patients receiving placebo or other regimens. Adapted from reference [26] .

is poor. Clinical efficacy has not been clearly demonstrated. Furthermore, administration of prophylactic oral antibiotics may induce resistance among endogenous bacteria, such as resistance to vancomycin among enterococci. Thus, prophylaxis with nonabsorbable antimicrobial agents has been abandoned in most institutions.

Alternatively, attempts have been made to 'selectively' decontaminate the alimentary tract using antibiotics such as trimethoprim-sulfamethoxazole (TMP-SMX) to maintain the anaerobic flora, thereby preserving the 'colonization resistance' against aerobic bacteria and fungi. Results of initial studies suggested that TMP-SMX could decrease the incidence of infections, but this was not confirmed in subsequent studies. Furthermore, TMP-SMX is ineffective against *P. aeruginosa*, may prolong the duration of the bone marrow aplasia and promote the emergence of resistant organisms. Current guidelines recommend the use of TMP-SMX only in patients at high risk of *Pneumocystis carinii* infection.[5]

In contrast to all other antibiotics used for prophylaxis of bacterial infections, fluoroquinolones have been unequivocally shown to reduce the incidence of Gram-negative infections, but not of fever, microbiologically or clinically documented infections, or of infectious mortality (Fig. 100.13).[10] [25] [26] However, the use of fluoroquinolone prophylaxis was associated with an increased incidence of viridans streptococcal infections and emergence of resistance.[9] [11] Clinicians are divided on the utility and safety of antibiotic prophylaxis. While some consider that it should be strongly discouraged for the reasons mentioned above, others still favor the use of fluoroquinolones, especially in high-risk patients with hematological malignancies. However, because of a lack of compelling evidence of reduced morbidity and mortality, we do not use antibiotic prophylaxis in neutropenic cancer patients in our institution and therefore do not recommend this preventive measure.

Antifungal prophylaxis

Antifungal prophylaxis with fluconazole (400mg/d) has been shown to prevent infection with *C. albicans* and *C. tropicalis*, but not with *C. krusei*, in allogenic bone marrow transplant patients.[27] Its activity against *C. glabrata* is doubtful. In contrast, the place of antifungal prophylaxis in patients with hematological malignancies not undergoing bone marrow transplantation is uncertain. Prophylaxis with ketoconazole, amphotericin B, fluconazole or itraconazole was found to reduce the incidence of superficial infections, but no consistent effects were observed on the incidence of invasive fungal infections, empirical use of amphotericin B or mortality of invasive fungal infections.[28] [29] In some centers, the use of fluconazole prophylaxis was associated with a shift towards non-*albicans Candida* strains, that are either poorly susceptible (*C. glabrata*) or resistant (*C. krusei*) to azoles.[12] [13] Routine use of antifungal prophylaxis in all neutropenic patients is not recommended, but may be advisable in selected high-risk patients. The choice of the antifungal agent should be guided by local epidemiological data.[5] New azoles (e.g. voriconazole, posaconazole, ravuconazole) and a new class of antifungal agents, the echinocandins (e.g. caspofungin, micafungin, anidulafungin) are either available today or in clinical development. These new compounds, which are active against *Candida* and *Aspergillus*, may soon provide new prophylactic options against invasive mycoses in high-risk neutropenic patients.

Antifungal prophylaxis is not used routinely in neutropenic patients at our institution. However, we recommend the initiation of early empirical antifungal therapy in persistently febrile neutropenic patients at risk of invasive fungal infections (see Persistence of fever, below).

Antiviral prophylaxis

Viral serology tests should be performed at the outset of chemotherapy to determine whether patients with hematological malignancies have been previously infected with HSV, VZV or CMV, as these may reactivate during therapy. Reactivation of HSV infection occurs in 70–80% of patients with acute leukemia receiving chemotherapy. Aciclovir prophylaxis is therefore recommended for HSV-seropositive individuals.[30] Oral valaciclovir is an alternative to oral aciclovir. Patients unable to take oral medications should be switched to intravenous aciclovir. CMV-seronegative leukemic and hematopoietic stem cell or bone marrow transplant patients should receive leukocyte-depleted blood products to prevent CMV transmission. Those interested in further reading on antiviral prophylaxis should refer to Chapter 112 .

Immunoglobulins

Replacement therapy with intravenous immunoglobulins may be indicated for patients with low immunoglobulin levels, such as patients with chronic lymphatic leukemia or multiple myeloma or bone marrow transplant recipients in the post-engraftment period. Those interested in further reading on this topic should refer to Chapter 114 .

DIAGNOSIS

Evaluation of the febrile neutropenic cancer patient follows the universal principles guiding medical practice and includes a prompt and thorough medical history and physical examination and use of rigorous diagnostic measures. However, in contrast to the non-neutropenic patient, empirical broad-spectrum antibiotic therapy should be administered without delay after the onset of fever and before the results of the microbiological investigations become available.

Medical history

It is critical that cancer patients be thoroughly investigated at presentation with a special emphasis on the assessment of risk of infection. Medical history should include information on:

- travels to, or residence in, areas where infectious diseases (such as tuberculosis, fungal or parasitic infections, e.g. Leishmaniasis or Strongyloidiasis) are endemic, as these may reactivate during neutropenia;
- immunization history;
- and presence of vascular access devices.

Upon development of fever, the physician must obtain a meticulous history and be aware of the fact that symptoms may be modified because of the impaired inflammatory response.[5] [6] [7]

Physical examination

Physical examination should be particularly thorough and must be performed keeping in mind that the classic signs of infection are markedly attenuated (e.g. pain, redness and induration) or absent (pus) because of neutropenia.[5] [6] [7] The physician should look for subtle inflammatory signs at common sites of infection (e.g. oropharynx, esophagus, respiratory tract, skin, insertion site of intravascular catheters, gastrointestinal tract, perianal region). The mouth and pharynx should be examined for erythema, mucositis, gingivitis, white patches and pseudomembranes, vesicles and ulcerations. The anterior nares should be inspected for signs of congestion, rhinorrhea, crusts, bleeding and ulcers. The skin may present features of a localized (i.e. primary) infection or multiple lesions in distant areas suggestive of a disseminated infection (Fig. 100.5b , Fig. 100.6). Special attention should be paid to the presence of erythema, swelling and tenderness in the anal, perineal, axillary and periungual regions (Fig. 100.5a). Insertion sites of intravascular access devices and sites of cutaneous injury due to needle punctures or bone marrow aspiration should be thoroughly examined. Fundoscopy should be performed as it may reveal signs of systemic infection (Fig. 100.7b). Physical examination should be repeated frequently as clinical signs of infection may become manifest only a few days after the onset of fever.

Microbiology, radiology and histopathology

At least two sets of blood cultures should be obtained prior to the administration of antibiotics in the febrile neutropenic patient. It is recommended to perform blood cultures even in the absence of fever in any patient suspected of infection. Blood should be drawn from a peripheral vein and also from intravascular catheters, if present.[5] It is prudent to draw blood from every port of multilumen intravascular devices. Qualitative cultures are performed routinely, but quantitative cultures might be helpful for the diagnosis of catheter-related bloodstream infections.[31] Specimens (aspirate or biopsy) should be obtained from any site suspected of infection. The physician should carefully evaluate the benefits and risks (mainly bleeding in the thrombocytopenic patient) of initial (i.e. at the onset of fever) versus delayed (i.e. in those patients who are not responding to empirical therapy) invasive procedures to diagnose infections in poorly accessible sites. Exit sites of catheters should be cultured for bacterial, fungal and nontuberculous mycobacterial pathogens. Skin lesions should be aspirated or, whenever possible, biopsied for culture and/or histopathological examination. Lesions of the oral cavity, pharynx and paranasal sinuses can be brushed or biopsied. In the presence of severe dysphagia, endoscopy with brushing and biospy for cultures and histopathology should be considered. Stools from patients with diarrhea should be tested for *Clostridium difficile* toxins and cultured for bacteria (*Salmonella, Shigella, Campylobacter, Aeromonas* and *Yersinia*) and examined for protozoa (*Cryptosporidium*). Urinalysis and urine cultures should be performed routinely, even in the absence of urinary symptoms or of pyuria, a rare finding in neutropenic patients even when infection is present.

A chest radiograph is part of the standard investigation of febrile neutropenic patients. Whether and when to obtain additional radiological imaging (ultrasonography, CT, MRI) is guided by the patient's clinical condition and response to empirical broad-spectrum antibiotics. For example, severe abdominal complaints in neutropenic patients will prompt thorough investigations with standard radiography, ultrasonography, CT or MRI scans. Patients with lesions of the liver and spleen suggestive of hepatosplenic candidiasis should undergo CT-guided or laparoscopic liver biopsy. The presence of lung infiltrates has important implications for the management of neutropenic patients. Several studies have shown that CT scanning is superior to conventional radiography for revealing the presence of lesions indicative of invasive aspergillosis. That should prompt further investigations (bronchoalveolar lavage, transbronchial, transthoracic or open lung biopsy) to obtain samples for diagnosis.[32] Persistent or complicated sinusitis or otitis and suspected osteomyelitis or myositis are other indications for additional radiological imaging and tissue sampling. Once again, it should be remembered that radiological signs are attenuated and delayed in neutropenic patients and may become apparent only after bone marrow recovery.[16] Classic examples are hepatosplenic candidiasis and invasive pulmonary aspergillosis.[24] [33]

Baseline viral (HSV, VZV, CMV, EBV) and parasitic (*Toxoplasma gondii*) serology should be obtained in patients with hematological malignancies, but not in those with solid tumors as they are not at high risk of developing severe viral or parasitic infections.

Novel nonculture diagnostic tests including molecular and serological techniques have been described recently. These include the use of polymerase chain reaction (PCR) for the diagnosis of bacterial and fungal infections and the serological detection of circulating antigens (e.g. mannan for *Candida* species and galactomannan for *Aspergillus* species), metabolites (e.g. D-arabinitol for *Candida* species) and antibodies directed against fungal antigens (e.g. antimannan antibodies).[34] [35] [36] However, the utility of these diagnostic tools has not yet been fully validated and further studies are needed before they can be recommended.

Measurement of circulating biological markers of inflammation, such as C-reactive protein and proinflammatory cytokines (such as tumor necrosis factor-a, interleukin-1, 6 and 8), has not been found to be helpful for differentiating infectious from noninfectious causes of fever because of a lack of sensitivity and specificity. Procalcitonin, a circulating calcitonin precursor whose concentrations are markedly increased during sepsis and much less so in inflammatory diseases, looks promising and deserves further studies in febrile neutropenic cancer patients.

Other investigations

Hematology (complete blood count and differential) and chemistry tests (including electrolytes, tests of liver and kidney function) are an integral part of the monitoring of toxic reactions to cytotoxic and antimicrobial agents and should therefore be repeated at intervals. Moreover, a low threshold for measuring blood levels of antimicrobial agents should be maintained when renal or hepatic functions are altered, especially for agents with narrow therapeutic windows such as aminoglycosides or glycopeptides, but also when the patient does not respond to therapy despite demonstration of *in vitro* susceptibility.[5]

MANAGEMENT

Neutropenic patients with suspected infection, whether febrile or not, must receive prompt empirical antibiotic therapy with broad-spectrum antibiotics. The concept of treating these patients with empirical antibiotics as soon as they develop fever has radically changed the otherwise fulminant and almost uniformly fatal course of Gram-negative sepsis.[2] [4] This is the single most significant advance made over the last 30 years in the area of supportive care for cancer patients.

Risk assessment

Serious and potentially life-threatening complications may occur during the course of bone marrow aplasia, including hemorrhage,

TABLE 100-2 -- Factors associated with a low risk of severe complications in febrile neutropenic cancer patients.

Derived from references [5] [38] [39] .

FACTORS ASSOCIATED WITH A LOW RISK OF SEVERE COMPLICATIONS
Malignancy in remission
Absence of co-morbidities (chronic lung disease, diabetes mellitus, congestive heart failure, hemorrhage, liver disease, renal disease)
Absence of vomiting, diarrhea, dehydration
Outpatient status
Absolute neutrophil count =100 cells/mm^3
Absolute monocyte count =100 cells/mm^3
Anticipated duration of neutropenia <7–10 days
Normal chest radiograph
Peak temperature <102.2°F (39.0°C)
Absence of shivering
Does not appear ill
Absence of neurologic or mental alterations

Absence of abdominal pain
Absence of intravenous catheter site infection
Absence of septic complications (e.g. severe sepsis, septic shock, hypoxia, pneumonia or other deep organ infection)

disseminated intravascular coagulation, thrombosis, pulmonary embolism, organ dysfunction (such as congestive heart failure, renal insufficiency, respiratory failure) and septic complications (such as severe sepsis, septic shock, adult respiratory distress syndrome), that

Figure 100-14 Risk assessment and selection of oral or intravenous empirical antibiotic therapy in febrile neutropenic cancer patients. Severe sepsis and septic shock are defined according to reference[37] . *Adapted from reference[6] .*

may require admission to the intensive care unit.[37] [38] [39] Until recently, all febrile neutropenic cancer patients have been treated in a uniform fashion. Today, risk assessment is an important aspect of the evaluation of the febrile neutropenic patient. It is important to determine whether the patient is at low or high risk of serious infections and other medical complications because this will influence the treatment modalities and will have an impact on the patient's hospital course and length of stay. Several factors can be used to classify a given patient as low or high risk.

Factors associated with a *low risk* of complications are shown in Table 100.2 [5] [38] [39] Typically, a low-risk profile is defined by the following characteristics: cancer in remission, absence of severe comorbidities, outpatient status at onset of fever and neutropenia not likely to last for more than 7 days. Conversely, uncontrolled cancer, the presence of concomitant medical conditions (severe mucositis, hemorrhage, dehydration, renal, hepatic, respiratory, cardiac or circulatory failure, altered mental status), inpatient status and neutropenia likely to last for more than 10 days are factors likely to be associated with a *high risk* of complications. Different scoring systems have been proposed for risk stratification.[38] [39] The Multinational Association for Supportive Care in Cancer (MASCC) score is based on seven clinical factors derived and validated from prospective analyses of 756 and 383 episodes of febrile neutropenia, respectively.[39] A MASCC score greater than or equal to 21, on a maximum score of 26, was used to identify patients at low risk (<5%) of severe complications (sensitivity 71%, specificity 68%, positive predictive value 91%, negative predictive value 36%) and who might be candidates for outpatient empirical antimicrobial therapy. However, the experience with this and other scoring systems is still limited.[38] [39] Additional prospective studies are needed to more fully evaluate and finely tune the

use of these risk assessment systems. It will be important to determine whether patients identified as low risk may be safely treated on an outpatient basis with oral antibiotics (see Oral antibiotic therapy, below). An algorithm for risk assessment may be used to guide the choice of oral versus parenteral empirical antibiotic therapy (Fig. 100.14).

Empirical antibiotic therapy

Intravenous antibiotics

Over 90% of the first episodes of infection in neutropenic cancer patients are caused by Gram-positive or Gram-negative bacteria (see Fig. 100.1). Empirical antibiotic regimens must be broad spectrum and bactericidal, achieve high circulating and tissue levels and be nontoxic. For more than two decades, combinations of two or more intravenous antibiotics have been the 'gold standard' of empirical antibiotic therapy. Numerous combinations of antipseudomonal penicillins (e.g. mezlocillin, ticarcillin with or without clavulanic acid, azlocillin or piperacillin) or third- or fourth-generation cephalosporins (ceftazidime, ceftriaxone, cefpirome, cefepime) plus an aminoglycoside (e.g. gentamicin, tobramycin, netilmicin or amikacin) have been frequently utilized.[4] [17] [40] [41] But no particular one was shown to be superior to the others. However, aminoglycoside-containing regimens are associated with renal and auditory toxicity, especially in patients concomitantly receiving other toxic agents, and often require monitoring of drug levels.

Thus, new treatment approaches have been explored to avoid these complications, such as once-daily dosing of aminoglycoside or ß-lactam monotherapy. An international, multicenter trial by the EORTC-IATG showed that once-daily ceftriaxone and amikacin was as effective and at least no more toxic than a combination of ceftazidime and amikacin given thrice daily.[42] Monotherapy with broad-spectrum and highly bactericidal agents, such as third- or fourth-generation cephalosporins (ceftazidime, cefepime, cefpirome), carbapenems (i.e. imipenem and meropenem) or antipseudomonal penicillins combined with a ß-lactamase inhibitor (piperacillin/tazobactam), were found to be as effective as and less toxic than combinations of ß-lactam and aminoglycoside.[19] [43] [44] [45] [46] Choices of intravenous empirical antibiotic therapy for high-risk patients, typically those with hematological malignancies and long duration neutropenia, are shown in Figure 100.15 .

Choices should be guided by the patient's clinical condition and local epidemiological data. Consider using an aminoglycoside-containing

Figure 100-15 Choices of empirical intravenous antibiotics in high-risk febrile neutropenic cancer patients.

regimen in critically ill patients, such as those with severe sepsis or septic shock, when a *P. aeruginosa* infection is suspected or when resistant Gram-negative bacteria prevail.[5] [37] Consider using a glycopeptide antibiotic (i.e. vancomycin or teicoplanin) in patients with catheter-related infections, when penicillin-resistant streptococcal or methicillin-resistant staphylococcal infections are suspected or in critically ill patients (i.e. with severe sepsis or septic shock).[5] [37] However, outside these well-defined clinical circumstances encountered in a minority of patients, routine use of glycopeptide antibiotics is strongly discouraged. Empirical use of vancomycin has not been shown to improve patient outcome and is associated with increased costs, toxicity and emergence of resistance.

After proper investigations and microbiological cultures, it is reasonable to empirically use:

- an antifungal and/or antiviral agent in patients with esophagitis;
- a macrolide or 'respiratory' fluoroquinolone and/or TMP-SMX and/or an antifungal agent for coverage of opportunistic respiratory pathogens in patients with lung infiltrates;
- metronidazole in patients with an abdominal focus and/or severe diarrhea.

Oral antibiotic therapy

Several studies have examined the role of oral absorbable antibiotics as empirical therapy of fever and suspected infections in low-risk adult patients with solid tumors and neutropenia expected to be of short duration (less than 7 days). Oral antibiotic therapy is possible when the patient is compliant, can swallow tablets, has normal gastrointestinal motility and function and can be monitored for response to therapy, development of secondary infections and adverse reactions. Ofloxacin or ciprofloxacin given either alone or combined with amoxicillin/clavulanic acid have been studied in adult patients.[47] [48] However, ofloxacin and ciprofloxacin have suboptimal activities against Gram-positive bacteria and should not be used as monotherapy. New 'extended-spectrum' fluoroquinolones (i.e. levofloxacin, moxifloxacin and gatifloxacin) with improved activity against Gram-positive bacteria deserve further investigation in febrile neutropenic patients. In contrast, oral ciprofloxacin plus amoxicillin/clavulanic acid was found to be as efficacious and safe as standard parenteral treatment in two large studies of low-risk patients in an inpatient setting.[20] [21] However, it has not yet been shown that low-risk febrile patients can be safely managed on a fully outpatient basis. It is reasonable to discharge

compliant patients who have responded to therapy, despite persistence of neutropenia, provided that the patient is not alone at home, is under careful medical supervision and lives within a short distance of a hospital.

There are no data on upfront oral antibiotic therapy of fever in children with neutropenia. Limited information is available on early discharge of selected children on oral cefixime 48 hours after intravenous antibiotic therapy in a hospital setting.[49]

Reassessment of therapy

The appropriateness of the empirical antibiotic regimen should be reassessed within 24–72 hours based on the results of microbiological cultures and the patient's response to antibiotic therapy.

Therapeutic modifications based on culture results

If a pathogen has been isolated, antibiotic therapy is adapted based on *in vitro* susceptibility tests and clinical response (Fig. 100.16). Vancomycin (or teicoplanin, a glycopeptide antibiotic not approved by the US Food and Drug Administration and for which experience in neutropenic patients is limited) should be added if cultures grew methicillin-resistant staphylococci, penicillin-resistant streptococci or enterococci not covered by the empirical regimen. Two recently introduced antibiotics, quinupristin-dalfopristin and linezolid, an oxazolidinone, exhibit activities against methicillin-resistant staphylococci and vancomycin-resistant enterococci and might offer new

Figure 100-16 Algorithm for adjustment of empirical antimicrobial therapy based on results of microbiological cultures and clinical response.

therapeutic options for febrile neutropenic cancer patients. There is limited clinical experience with these antibiotics in this clinical setting. Moreover, linezolid may cause thrombocytopenia and anemia when used for more than 2–4 weeks.

Three studies have now clearly shown that there is no indication for empirical use of vancomycin in centers where resistance of Gram-positive bacteria to ß-lactam antibiotics is rare.[18] [50] [51] However, as mentioned previously, the empirical use of vancomycin is justified in critically ill patients with severe sepsis or septic shock, in presence of a catheter-related infection, and in centers with high levels of ß-lactam resistance among Gram-positive bacteria.[37] If suspicion of resistant Gram-positive infection is disproved by culture results, vancomycin should be rapidly discontinued. Likewise, empirical use of an aminoglycoside should be stopped if Gram-negative infection is ruled out.

Therapeutic modifications based on initial response to empirical antibiotic therapy

It is necessary to treat patients for 3–5 days before one can begin to evaluate the response to therapy with some degree of confidence. However, earlier treatment adjustments may be required if the patient's condition deteriorates. Treatment recommendations for patients who became afebrile and for those who remained febrile within 3–5 days after initiation of empirical therapy are presented in Figure 100.16 .

Resolution of fever

Intravenous (high risk) or oral (low risk) antibiotics should be continued in patients who have responded to therapy (Fig. 100.16). In low-risk patients receiving intravenous antibiotics, switching to oral antibiotics, such as ciprofloxacin and amoxicillin-clavulanic acid, should be considered. In the absence of microbiological proof and identified site of infection (i.e. FUO), it is usually not necessary to continue broad-spectrum antibiotics for longer than 7 days, if fever resolved quickly and the neutrophil count has returned to normal levels. Antibiotics can be stopped when the patient is afebrile for more than 48 hours and the neutrophil count is greater than 500 cells/mm^3 for two consecutive days.[5]

Opinions diverge regarding the optimal duration of therapy in patients with persistent neutropenia. Some physicians discontinue therapy in afebrile and clinically stable patients, while others prefer to continue broad-spectrum intravenous or oral antibiotics until recovery of neutrophils. Yet, the evidence supporting continuation of broad-spectrum antibiotics is not strong and is based on data obtained 20 years ago in a limited number of patients with FUO. In that study, nearly half of the patients with persistent neutropenia became febrile again within 3 days of stopping treatment and breakthrough infections and severe septic complications occurred. [52] Patients with microbiologically or clinically documented infections are usually treated for a total of 10–14 days (i.e. until cultures become sterile and clinical response is complete). However, one should keep in mind that prolonged antibiotic courses are costly and may be associated with toxicity and emergence of resistant bacterial or opportunistic fungal infections.

Persistence of fever

It is important to keep in mind that the median time to defervescence is 5 days in high-risk patients with hematological malignancies. Therefore, persistence of fever may not necessarily indicate that treatment is failing. If a specific causal organism or an infection site has been identified, treatment should be continued or modified, as appropriate.[5]

Considerable controversy surrounds the optimal management of a stable patient with unexplained fever after 3 days of empirical therapy. Persistence of fever may be due to a slow response, suboptimal levels of antibiotics, resistant pathogens, nonbacterial infection, development of a secondary infection or a noninfectious etiology (such as cancer, transfusion reaction or drug fever). A thorough clinical examination, follow-up microbiological cultures, extensive radiological imaging (including a CT scan of the chest and abdomen) and invasive investigations, whenever indicated, are an integral part of the investigation of the persistently febrile neutropenic patient. If the patient's clinical condition is deteriorating, the management depends on whether the patient has developed a clinically obvious focus of infection. If a focus of infection has been found, attempts should be made to identify the causative pathogen by culture or biopsy. The antimicrobial treatment should then be modified accordingly. Moreover, withdrawal of an infected intravascular catheter is indicated when the local signs of infection are extending, when the patient is clinically unstable, when a septic thrombophlebitis is documented or when infection is due to pathogens other than common skin colonizers.[5] In contrast, the utility of antibiotic lock solutions or rotation of antibiotic delivery via the different ports of multilumen catheters is controversial. If there is no obvious site of infection, the patient is not deteriorating and reassessment does not reveal a new focus of infection, the physician has the choice between several treatment options:

- continue the initial empirical antibiotics for 2 more days;
- change the antibiotics (change of broad-spectrum ß-lactam, addition of a glycopeptide or an aminoglycoside);
- empirical addition of an antifungal agent (classically intravenous amphotericin B, but other drugs including itraconazole, voriconazole or caspofungin may be considered).

Our approach in this situation is to continue the initial antibiotic regimen and initiate early empirical antifungal treatment, especially in patients with either:

- an expected long-lasting neutropenia (>10 days);
- recurrent episodes of fever during the same episode of neutropenia;
- prolonged therapy with broad-spectrum antibiotics;
- severe mucositis;

- *Candida* colonization;
- epidemiological data indicating a high incidence of mould infections.

Fungal infections due to *Candida* or *Aspergillus* are a frequent cause of persistent fever in this setting. Unfortunately, early diagnosis is difficult and infections were often diagnosed at autopsy in the past.[2] Empirical intravenous amphotericin B has been shown to promote the resolution of fever and reduces the morbidity and mortality due to invasive fungal infections. [53] [54] Treatment guidelines recommend to start empirical amphotericin B after 4–7 days of unexplained fever, but this is purely arbitrary as the optimal timing for starting therapy is unknown.[5] The potential advantage of an early start must be balanced against the risk of exposing many patients to unnecessary toxicity. Once started, it is recommended to continue empirical antifungal therapy until bone marrow recovery, at which time investigations should be repeated to confirm or rule out the presence of an until-then occult fungal infection. No further therapy is needed if an invasive fungal infection can be reasonably excluded. Conversely, any lesion suggestive of invasive mycosis, such as cavitating pulmonary or multiple hepatosplenic lesions, should be biopsied for culture and histopathology and treatment reassessed if a fungal pathogen is isolated. Prolonged antifungal therapy is often necessary when an invasive mycosis has been diagnosed, as the patient is likely to undergo multiple cycles of chemotherapy. On the other hand, surgical resection should be considered in between cycles of chemotherapy in the case of invasive pulmonary aspergillosis.[32]

For decades, amphotericin B deoxycholate, a fungicidal agent active against most species of *Candida* and *Aspergillus*, has been the standard treatment for fungal infections. However, renal and infusion-related toxicity often lead to suboptimal dosing or discontinuation of therapy and emergence of resistant fungi has been reported. Lipid forms of amphotericin B (lipid complex, colloidal dispersion and liposomal form) are better tolerated, but costly and thus mainly used as second-line treatment.[55] [56] Factors limiting the use of fluconazole as empirical antifungal treatment in persistently febrile neutropenic patients are fungistatic activity on *Candida*, lack of activity on *Aspergillus* and an increasing incidence of azole-resistant *Candida* species. Recent data suggest that itraconazole and voriconazole, a new azole antifungal, are treatment alternatives to amphotericin B for this indication.[57] [58] Moreover, higher than expected success rates for the treatment of invasive aspergillosis in immunocompromised hosts have been achieved with voriconazole.[59] Echinocandins, a new class of antifungal agents that inhibit fungal cell wall synthesis, show promising efficacy and toxicity profiles. Caspofungin has recently been licensed for salvage therapy of refractory invasive aspergillosis. A recent trial also showed that caspofungin was as effective and less toxic than amphotericin B for the treatment of invasive candidiasis.[60] Other new compounds, including ravuconazole, posaconazole, anidulafungin and micafungin, are in clinical development. Moreover, the efficacy and safety of combinations of antifungal agents of different classes are being intensively investigated.

Supportive care

Hematopoietic growth factors

The main goal pursued with the use of hematopoietic colony-stimulating factors (CSFs) is the acceleration of bone marrow recovery to reduce the severity and duration of neutropenia and thus the risk of infection. Several studies have examined the role of granulocyte colony-stimulating factor (G-CSF, filgrastim) and granulocytemonocyte colony-stimulating factor (GM-CSF, sargramostim) in the treatment of cancer patients not receiving bone marrow transplantation. Treatment with G-CSF or GM-CSF was found to moderately shorten the duration of neutropenia when given to patients with acute leukemia. Results were less striking in patients with solid tumors and other hematological malignancies. In some, but not all, of these studies, a shorter duration of neutropenia was associated with a reduction of infections, use of antibiotics and length of stay, but without clear-cut benefit on the incidence of severe infections and infection mortality. Moreover, no consistent effects on the duration of fever or antibiotic therapy, infection morbidity or mortality, or costs have been demonstrated using CSFs in febrile neutropenic patients. Recommendations for the use of CSFs have been published by the American Society for Clinical Oncology and by the European Society of Medical Oncology.[61] [62]

At the present time, the evidence supporting the use of CSFs in neutropenic patients not undergoing bone marrow transplantation is limited and expert opinions remain diverging.[5] [61] [62] Yet, high-risk patients with profound, long-lasting neutropenia and severe deep organ infections (e.g. pneumonia, typhlitis, invasive mycosis) not responding to appropriate antimicrobial therapy may benefit from an accelerated recovery of neutrophis. Although we occasionally use CSFs under such circumstances in our own institution, we acknowledge the fact that there is no definitive evidence to support the administration of CSFs in these clinical conditions. Intermittent administration of CSFs may be considered in patients with a myelodysplastic syndrome and recurrent infections due to chronic neutropenia.

Granulocyte transfusions

Some experts consider the transfusion of granulocytes in patients with profound neutropenia and life-threatening bacterial or fungal infections not responding to adequate antimicrobial treatment. However, the evidence of its efficacy is lacking and several problems are associated with this procedure, including transmission of CMV, alloimmunization, graft versus host reaction and damage to lung capillaries and risk of acute respiratory distress syndrome.

Acknowledgments

Chapter 101 - Stem Cell Transplant Patients

Kieren A Marr

HEMATOPOIETIC STEM CELL TRANSPLANTATION: BACKGROUND AND CURRENT PRACTICES

Hematopoietic stem cell transplantation (HSCT) has been increasingly used to treat hematologic and nonhematologic malignancies and inherited immunodeficiencies. Multiple practices, including conditioning regimens, stem cell sources and supportive care strategies have changed since the first successful bone marrow transplantations, owed principally to an evolving understanding of how overall success is achieved, and to the development of new technologies. As these factors impact on the severity and duration of infectious risks, and sometimes even the clinical presentations and outcomes, clinicians involved in the care of HSCT patients benefit greatly from a baseline understanding of transplant practices.

In order to allow for donor hematopoiesis to establish in the recipient, a conditioning regimen must be applied before infusion of stem cells. The primary aim of the conditioning regimen is to suppress recipient T cells that could ultimately mediate rejection of the graft. It was also hypothesized that myeloablative conditioning regimens could effectively eliminate residual malignant disease. To accomplish these goals, conventional regimens have been highly myeloablative, employing total body irradiation (TBI) and high-dose chemotherapy (e.g. busulphan, cyclophosphamide). In this setting, severe and protracted neutropenia, and regimen-related organ toxicities can contribute to early infectious complications.

The type of conditioning therapy has been shown to impact on overall risks and timing of infectious complications. Recently, non-myeloablative or reduced-toxicity conditioning regimens have been explored for patients who are not eligible for conventional myeloablative HSCT. Success of this strategy relies on the therapeutic potential of graft versus host (GVH) effects, which are produced when donor-derived immune cells recognize and eventually destroy host cells and tissues.[1] Although graft versus host disease (GVHD) negatively impacts on overall survival by causing organ injury, necessitating the need for increasingly immunosuppressive therapies, GVH effects also induce the beneficial effects of 'graft versus tumor', sometimes to a degree that can result in complete remission.[2] A number of alternative conditioning regimens have been developed, which typically are associated with fewer organ toxicities (e.g. gastrointestinal tract mucositis) and short (if any) durations of neutropenia.[3] [4] [5] [6] [7]

The most common causes of death in allogeneic HSCT recipients are infection (frequently in the setting of GVHD) and relapsed malignancy. One method transplanters use to minimize the risks for relapse and GVHD is manipulation of the cells that compose the infused graft. Cellular composition is dependent on stem cell source and treatment of the stem cell product before infusion. Peripheral blood stem cells (PBSCs) can be used instead of bone marrow; these are harvested from peripheral blood of granulocyte-colony stimulating factor (G-CSF or filgastrim)-mobilized donors. Peripheral blood stem cell products often undergo ex-vivo manipulation in order to decrease donor T cells (T-cell depletion), thereby decreasing the risk of GVHD, or to select for specific stem cell precursors, such as $CD34^+$ cell selection. The latter has been shown to reduce the incidence of relapse of malignancy by decreasing the number of contaminating tumor cells.[8] [9] However, as expected, T-cell depletion through either method (removal or selection against cells not expressing CD34) impacts on overall immune reconstitution and increases the risks for infections.

New technologies have allowed for the performance of more high-risk HSCTs, enabling transplantation from unrelated, human leukocyte antigen (HLA)-mismatched, or even haploidentical donors. As these patients have relatively high rates of severe GVHD, the overall infectious risks and duration of susceptibility are expanded. Supportive care practices and the general approach to patients must then consider the primary risk periods (conditioning or ablation engraftment, GVH), specifically the pace of immune reconstitution and how that impacts on the risks of infections.

RISKS FOR INFECTIONS: IMPACT OF THE GRAFT, THE HOST, AND OTHER COMPLICATIONS

Historically, we have been tempted to consider patients' risks for fungal infections based solely on the presence (or absence) of neutropenia. Although T-cell immunodeficiency is understood to impact on risks for some infections, such as those caused by herpesviruses, the importance of cell-mediated immunity (CMI) in conferring risks for fungal infections post-HSCT has not been well appreciated. With increasing reports of invasive mold infections occurring late post-HSCT during GVHD,[10] [11] [12] [13] the weaknesses of the neutropenia-based risk paradigm have become increasingly evident. In fact, T cells contribute significantly to responses against both *Candida* and *Aspergillus* spp.[14] [15] [16] [17] It is now clear that risks for fungal infections hinge on multiple factors that impact on immune reconstitution and organ toxicities, including the type of transplant, the host and other post-therapy complications.

The graft and type of transplant

Donor and HLA-matching of the graft impact on overall risks for infections, primarily by dictating the likelihood and severity of GVHD and the need for and intensity of immunosuppressive therapy. The cellular composition of the graft (stem cell source and ex-vivo manipulation) dictates risks for infection through effects on immune reconstitution and the pace and severity of GVHD.

Transplantation with PBSCs may yield faster reconstitution of platelets, $CD4^+$ T cells, neutrophils and monocytes.[18] [19] [20] [21] [22] A large study compared immune reconstitution after myeloablation followed by either peripheral blood stem cell transplant (PBSCT) or bone marrow transplant, comparing co-incident infections. During the first year after transplantation, most lymphocyte subsets, especially $CD4^+$ T cells, were higher in PBSCT recipients. This was accompanied by fewer bacterial and fungal infections in patients who received PBSCT than in recipients of bone marrow transplants. [18] However, there is concern that the success of PBSCT, especially from unrelated or HLA-mismatched donors, may be limited by a more rapid onset of severe GVHD.[21] [22]

Use of cord blood is associated with delayed hematopoietic recovery. Slow engraftment and impaired neutrophil function may work

together to increase the risk of infection, particularly early after transplantation. [23] [24] [25] [26] Studies have reported increased risks for aspergillosis, candidiasis and infections due to adenovirus and human herpesvirus (HHV)-6 in cord blood transplant recipients.[13] [24] [27] On the other hand, the low rates of GVHD, even in patients who receive cord blood from unrelated donors, may confer a relative protection from infection late after transplantation.[28]

Although T-cell depletion decreases the pace and severity of GVHD, T-cell depletion itself is associated with delayed immune reconstitution and an increased risk for infections.[29] [30] [31] [32] Because $CD34^+$ selection results in removal of T cells, natural killer (NK) cells and monocytes, this practice may increase the risk for infections after allogeneic and autologous transplantation.[33] [34]

It appears that immune reconstitution is similar after nonmyeloablative and myeloablative HSCT, although few large comparative studies have been performed, and reconstitution depends on multiple host and therapeutic variables.[35] [36] At least one study suggested that nonmyeloablative HSCT may be associated with more rapid reconstitution of immune responses assessed in vitro.[36] Of course, the short durations of severe neutropenia are an important difference. One case-control study suggested that this is associated with fewer early bacterial and candidal infections.[3] [37] In this context factors other than conditioning therapy and stem cell source impact on overall infectious risks in both nonmyeloablative and myeloablative HSCT. These factors include host age, underlying disease and therapy to prevent or treat GVHD.[3] [38] Late-onset GVHD after nonmyeloablative HSCT poses increased risks for late cytomegalovirus (CMV) disease and aspergillosis.[3] [37] [38] Infections (e.g. CMV) may occur at increased frequency early after nonmyeloablative transplant in patients who receive certain conditioning regimens (e.g. the antibodies anti-CD52 or Campath-1H).[39]

Host factors that impact on infection risks

Underlying disease is one of the most important factors impacting on risks for infection post-HSCT. Underlying disease presumably impacts on the risks for post-HSCT infection by virtue of the immunologic defects associated with the hematologic condition itself and previous cytotoxic therapies. Patients who receive HSCT for a hematologic malignancy beyond first remission, for aplastic anemia and for myelodysplastic syndromes have higher risks for aspergillosis.[10] [11] [12] [13] [40] [41] Patients who have protracted courses of primary immunodeficiencies may also have increased risks, although few large studies have been performed.

Multiple studies have reported that older people have increased risks for infections after HSCT.[12] [13] [41] [42] Although it is not clear why older age predicts higher risks, factors that have been suggested include cumulative exposure to previous cytotoxic therapy, underlying disease, severity of GVHD, baseline organ dysfunction, previous microbial exposure and waning cellular immunity. On the other hand, youth may present increased risks for other infections; adenoviral complications occur at increased frequency in young transplant recipients. [43] [44] This may be explained by an increased likelihood of primary infection in the young, or even the eventual elimination of adenovirus infection with age.[43] [45]

Other genetic factors may play a role in modulating risks for infectious complications. Factors that control innate immune responses in the host and donor may impact risks for infections, and for GVHD. Studies to determine how host and donor defense polymorphisms impact on the risk for infection post-HSCT should provide novel therapeutic targets in the future.

Complications that impact on infection risks

Multiple complications that occur after HSCT alter the risks for invasive yeast and mold infections. These complications may cause organ dysfunction and immune modulation and the need for potentially toxic and immunosuppressive therapies.

The most obvious organ dysfunction that occurs immediately following conditioning therapy is mucositis involving the gastrointestinal (GI) tract. Breakdown of the mucosa of the gut is a primary mode of entry for bacteria and *Candida* spp. that colonize the GI tract. Other, subtle manifestations of organ toxicities may also lead to subsequent infection risks. Patients with renal or hepatic dysfunction may not tolerate typical doses of prophylactic or empiric antibiotics or antifungals. Other biologic variables such as iron overload or metal chelating therapy may have an effect, given their associations with bacterial and filamentous fungal infections. [46] [47] However, this remains largely unexplored in the transplant setting.

Graft versus host disease and corticosteroid-based therapies are perhaps the most important post-HSCT complications leading to infections. Risks for all infections — bacterial, fungal and viral — are increased in patients with severe GVHD. These risks increase yet further in patients who receive high doses of corticosteroids. Most likely, this represents the combined impact of the direct immunosuppressive effects of GHVD, as well as the corticosteroid-induced impairment in neutrophil and monocyte/macrophage immunity and CMI. Corticosteroids administered for other post-HSCT complications, such as bronchiolitis obliterans, and 'idiopathic' pulmonary syndromes may also lead to equivalent, high risks for infections. The negative impact of corticosteroid exposure is not limited to the above risks; cumulative exposure to high-dose corticosteroids is an important variable predicting persistent infection and poor prognosis of treatment for viral or fungal disease.[48] [49] [50]

It has been hypothesized that infection with herpesviruses, especially CMV, may directly impact on risks for other infections by modulating immune responses. Historically, the association between CMV disease and subsequent infections was largely attributed to the myelosuppressive effects of antiviral drugs administered for prophylaxis or therapy. However, high risks for subsequent bacterial and fungal infections have been noted in patients with active CMV or latent CMV disease, even after controlling for secondary neutropenia in multivariable models.[13] [40] [51] Cytomegalovirus-seronegative recipients of stem cells from seropositive donors (D+/R-) have increased risks for bacterial and fungal infections, even in the absence of CMV-specific therapy.[52] Donor or recipient seropositivity may have the most impact on survival in patients who receive HSCT from unrelated donors.[53] Prevention and treatment of viral infections, including CMV post SCT is discussed in detail in Chapter 112 .

FUNGAL INFECTIONS IN HSCT PATIENTS: EPIDEMIOLOGY, PATHOGENS AND MANIFESTATIONS

The risk periods for fungal infection are presented in Figure 101.1 . The overall risks are dependent primarily on the factors that modulate the pace of immune reconstitution, organ toxicities and microbial exposures.

Infections caused by *Candida* species

Although the yeasts that cause infection in HSCT patients include multiple other organisms, such as *Cryptococcus neoformans*, the vast majority of superficial and invasive yeast infections are caused by *Candida* spp.

Invasive *Candida* infections can be separated into two primary syndromes: acute candidiasis (bloodstream infection) and chronic candidiasis (hepatosplenic infection).

Bloodstream infections occur either through an indwelling intravascular catheter or through a damaged GI tract. Acute infection usually manifests as fever and signs of sepsis. Adequate therapy is

Figure 101-1 Primary risk periods for infections after hematopoietic stem cell transplantation. Typical risk periods for the most common infections after each type of HSCT are shown. Risks are based on typical prophylaxis strategies, which include trimethoprim-sulfamethoxazole (co-trimoxazole) for *Pneumocystis carinii*, screened or filtered blood products and ganciclovir for CMV, aciclovir for herpes simplex virus, and fluconazole for candidemia. *Adapted from Bowden.*[54]

essential, not only to cure the acute episode, but also to decrease the likelihood of embolic manifestations that may occur later (e.g. chorioretinitis, endocarditis). [55]

Chronic candidiasis occurs when *Candida* spp. (usually *C. albicans*) enter the portal vasculature, disseminating to liver and spleen. Although the infection develops during a neutropenic phase, it usually presents after resolution of neutropenia, with fever, abdominal pain and liver function abnormalities, and multiple hypodense granulomatous lesions in the liver and spleen.[56] [57] *Candida albicans* is considered to be the most pathogenic species, and this is attributed to multiple virulence factors, such as adhesion molecules, secreted proteases and phospholipases, and the unique ability to generate hyphae in tissues.[58] This organism is usually susceptible to the azole antifungals.[59] [60] [61]

The widespread use of fluconazole, which is supported by numerous randomized trials carried out in the early 1990s,[62] [63] has decreased the incidence and mortality rate attributable to both acute and chronic infections caused by *C. albicans*.[40] [64] [65] This practice has resulted in improved overall survival in allogeneic HSCT patients.[63] However, the decreased incidence of early candidiasis due to azole susceptible species (*C. albicans* and *C. tropicalis*) and improved survival late after HSCT with GVHD has allowed for an increase in infections due to fluconazole-resistant *Candida* spp., such as *C. glabrata* and *C. krusei*.[40] [66] [67] [68] There has also been a shift from *Candida* spp. to molds as the primary fungal pathogens (Fig. 101.2).

The appearance of azole-resistant organisms is not a failure of prophylaxis but a shift to resistant yeasts and molds as pathogens, reflecting the success of supportive care strategies. In patients who underwent allogeneic HSCT from unrelated donors for chronic myelogenous leukemia (CML), two of the most important variables predicting HSCT survival in the 1990s were use of ganciclovir-based strategies and fluconazole.[70]

Infections caused by filamentous fungi

Infections with filamentous fungi are usually acquired through the respiratory route. Although the respiratory tract is the most frequent route of infection, filamentous fungi can also invade through a damaged GI tract.[71] ,72 The most common cause of fungal infections in HSCT patients is currently *Aspergillus fumigatus*.[12] [69] The day of onset of aspergillosis has changed, from primarily the early neutropenic period to later after allogeneic transplant.[11] [12] [13] The risk factors for early and late

disease are different (Fig. 101.3). Risks for

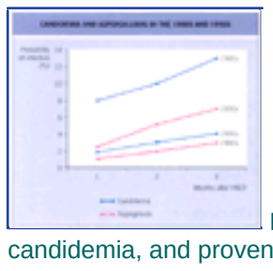

Figure 101-2 Probability of fungal infections in the late 1980s compared to late 1990s at the Fred Hutchinson Cancer Research Center. Probabilities of proven candidemia, and proven or probable aspergillosis are shown. *Data from the 1980s are provided by Dr Raleigh Bowden; data from the 1990s are abstracted from Marr et al.*[40] [69]

early disease are primarily those that impact on the pace of engraftment, such as the specific stem cell product. There is also some indication that a portion of patients who present with aspergillosis early after HSCT may have been exposed to the organism before conditioning therapy; this may explain some of the impact of 'host' variables, such as age and underlying diseases. Risks during the late period are largely those associated with GVHD and its therapies (see Fig. 101.3). Other infections, such as CMV disease, may pose both direct and indirect risks for subsequent disease. There has been an increase in invasive infections caused by Zygomycetes and *Fusarium* spp.[69] Patients who receive transplants from an unrelated or an HLA-mismatched donor, and patients with severe GVHD have particularly high risks for Zygomycetes infections. [69]

Filamentous fungi are usually acquired through the respiratory route. Conidia, which are present in the environment, are inhaled

Figure 101-3 Risk factors for aspergillosis after allogeneic hematopoietic stem cell transplantation. Specific risks are demonstrated according to primary risk period (shaded) and day of transplantation. [10] [13] [73] Day 0 represents day of receipt of stem cells. CML-CP, chronic myelogenous leukemia in chronic phase, LAF, laminar airflow.

into the lungs, and in the absence of an efficient phagocytic response, they can germinate into tissue-invasive hyphae. Although inhalation appears to be the most common mechanism of acquisition, with lungs the most common involved organ, these organisms can also invade through a damaged GI tract. Filamentous fungi, especially *Asperigillus* sp. and Zygomycetes, have been reported to cause neutropenic colitis and hepatosplenic disease in HSCT recipients[74] [75] .

SUMMARY

Infections remain a leading cause of death in HSCT patients, but the timing of onset and the spectrum of pathogens have evolved over the past two decades. Changes in transplantation practices, different hosts and the development of effective strategies to prevent early CMV disease and candidiasis have increased survival late after transplant with severe GVHD. This has resulted in the emergence of molds as a primary cause of death.

Chapter 102 - Infection in Solid Organ Transplantation

Nina E Tolkoff-Rubin
Robert H Rubin

INTRODUCTION

About 40,000 transplants are performed throughout the world each year, with 1-year graft survival rates of 90% or more at many transplant centers, making organ transplantation the most practical means of rehabilitating patients with end-stage kidney, heart, liver and lung disease. However, infectious challenges must be overcome for clinical success.[1] [2] [3]

Treatable infection must be eradicated in the recipient before transplant. Immunosuppression exacerbates infections and increases the possibility of vascular suture line infections, pulmonary infections and others. Donors must be screened for HIV, hepatitis viruses and other viruses. Bloodstream infections in the donor threaten the anastamoses of the transplanted organ and must be avoided. Technical issues include not only the transplant operation itself, but also the management of vascular access devices, the endotracheal tube, drains and catheters. Immunosuppression is needed to prevent and treat rejection. In addition, an antimicrobial strategy is needed to make this immunosuppressive program safe. The specifics of this therapeutic prescription are linked to the immunosuppressive therapy.[4]

Rejection and infection remain the two greatest hurdles to successful transplantation. They are closely linked by immunosuppressive therapy and by the array of cytokines, chemokines and growth factors elaborated. The response to both processes is quite similar, such that these two processes influence one another and, in many cases, amplify the extent of tissue injury. If infection occurs, the prognosis is in part determined by how early the diagnosis is made and how soon treatment is initiated. The anti-inflammatory effects of immunosuppressive therapy, particularly corticosteroids, render symptoms, signs and radiologic findings less overt. Therefore, the clinician must be aggressive in diagnosis with intensive imaging and invasive testing, where indicated. Up to 75% of transplant patients have evidence of microbial invasion in the first year post-transplant.[2] [3] [4]

RISK OF INFECTION

The risk of infection, particularly opportunistic infection, in transplant patients is determined primarily by the interaction of three factors:

- technical and anatomic mishaps,
- environmental exposures, and
- the net state of immunosuppression.

Devitalized tissue, fluid collections and invasive devices compromise the primary mucocutaneous barriers (Table 102.1). Technical and anatomic abnormalities are the major cause of infection in the first month post-transplant, with their incidence being related to the complexity of the particular transplant operation. Thus, these problems are most common in liver transplantation, particularly with split livers transplanted into children. These problems are also common in lung transplantation, less common in heart transplantation and least common in kidney transplantation. Optimal therapy for infections in patients with technical or anatomic abnormalities combines appropriate antimicrobial therapy with correction of the abnormality.

Important environmental exposures occur in the community and in hospital (see Table 102.1). Major concerns include recent or remote exposures to *Mycobacterium tuberculosis*, the systemic mycoses (blastomycosis, coccidioidomycosis and histoplasmosis) and *Strongyloides stercoralis*. [2] [3] [4] *Strongyloides* can persist in the gastrointestinal tract for decades after acquisition, owing to a unique autoinoculation cycle in humans. With immunosuppression, infestation may be greatly accentuated, leading to hemorrhagic pneumonitis, enterocolitis and disseminated strongyloidiasis (in which the filariform larvae penetrate the gut and invade other tissues). This last syndrome is often accompanied by Gram-negative bacteremia or meningitis unresponsive to conventional therapy. Therapy requires treatment of both the bacteria and the strongyloidiasis. Even so, the mortality is 50–75% with optimal therapy. Accordingly, our policy is to screen the patient serologically before transplantation for strongyloidiasis and to treat any patient with a positive serology pre-emptively.[5]

Community-acquired respiratory virus infection (e.g. influenza, respiratory syncytial virus, parainfluenza) is a particular problem in transplant patients. Although vaccines and antiviral agents exist, they are only marginally effective in the transplant population. Therefore, avoidance of exposure to respiratory infections is the best strategy.[2] [3]

Gardening has been associated with the acquisition of *Aspergillus* and *Nocardia* infection following inhalation of organisms aerosolized by digging in the soil. Similarly, aerosols generated in the south-west and mid-west of the USA, and elsewhere, can lead to infection with *Coccidioides immitis* and *Histoplasma capsulatum*. Construction sites in the community should likewise be avoided. Inadequately cooked food or contaminated water can convey *Salmonella, Listeria* and *Giardia* infection.[2]

Nosocomial exposures can be divided into domiciliary and nondomiciliary. Domiciliary exposures occur when contaminated air or potable water is present in the hospital room or ward where the patient is housed. Cases of this type are usually clustered in time and space. Outbreaks due to *Aspergillus* spp., *Legionella* spp., *Pseudomonas aeruginosa* and other Gram-negative bacilli are well documented. Filtration of air by a high-efficiency particulate filter, surveillance and treatment of water, and barring flowers and plants from the hospital environment have significantly reduced this problem. Far more difficult to detect and control are nondomiciliary environmental hazards encountered in the rest of the hospital, such as radiology suites undergoing construction, operating rooms, the waiting areas outside cardiac catheterization suites and endoscopy suites. Because of the lack of obvious clustering in time and space, outbreaks of this type are more difficult to identify. The best clue to the presence of an undetected environmental hazard is the occurrence of opportunistic infection when the patient's net state of immunosuppression should not predispose to it.[2] [6] [7]

An additional source of nosocomial infection is person-to-person spread, largely from the hands of medical personnel. Organisms such as methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci and azole-resistant *Candida* spp. are examples.

TABLE 102-1 -- Classification of infections occurring in transplant patient.

CLASSIFICATION OF INFECTIONS OCCURRING IN TRANSPLANT PATIENT

Infections related to technical complications*	Transplantation of a contaminated allograft
	Anastomotic leak or stenosis
	Wound hematoma
	Intravenous line contamination
	Iatrogenic damage to the skin
	Mismanagement of endotracheal tube leading to aspiration
	Infection related to biliary, urinary and drainage catheters
Infections related to excessive nosocomial hazard	*Aspergillus* spp.
	Legionella spp.
	Pseudomonas aeruginosa and other Gram-negative bacilli
	Nocardia asteroides
Infections related to particular exposures within the community	Systemic mycotic infections in certain geographic areas (*Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*)
	Stronglyloides stercoralis
	Community-acquired opportunistic infection resulting from ubiquitous saphrophytes in the environment† *(Cryptococcus neoformans*, *Aspergillus* spp., *Nocardia asteroides*, *Pneumocystis carinii*)
	Respiratory infections circulating in the community (*Mycobacterium tuberculosis*, influenza, adenoviruses, parainfluenza, respiratory syncytial virus)
	Infections acquired by the ingestion of contaminated food or water (*Salmonella* spp., *Listeria monocytogenes*)
Viral infections of particular importance in transplant patients	Herpes group viruses
	Hepatitis viruses
	Papillomavirus
	HIV
From Rubin[2]	

* All lead to infection with Gram-negative bacilli, *Staphylococcus* spp. or *Candida* spp.
† The incidence and severity of these infections and, to a lesser extent, the other infections listed, are related to the net state of immunosuppression present in a particular patient

The net state of immunosuppression (Table 102.2) is a complex function determined by a number of factors. Although the immunosuppressive therapy is the prime determinant, other factors are also important. Protein-calorie malnutrition, and presumably other metabolic derangements, contribute significantly to immunosuppression. If one stratifies patients by serum albumin level (<2.5g/dl or >2.5g/dl), there is a 10-fold increase in the incidence of life-threatening infection in the hypoalbuminemic. Approximately 90% of opportunistic infections occur along with one or more immunomodulating viruses. The 10% that are unassociated are usually due to previously unrecognized environmental hazards.[2] [3] [4] The immunogenetic makeup of the patient is probably important. For example, polymorphisms affecting the production of tumor necrosis factor (TNF)-a may be important, with low production of TNF-a being associated with an increased risk of infection. Platelets play an important role in controlling possible fungal infection. Given the

TABLE 102-2 -- Determinants of immune competence.

DETERMINANTS OF IMMUNE COMPETENCE	
Factor	**Examples**
Intensity of the immunosuppressive regimen	Monoclonal antibodies anti-TNF-a agents
	Calcineurin binding agents
	Corticosteroids
	Mycophenolate
Underlying immune dysfunction	Immunodeficiency
	Cytopenias
	Uremia
	Hyperglycemia
	Malnutrition
Breach of normal barriers	Intravenous catheters
	Urinary catheters
	Surgical drains
	Prolonged intubation
	Decubitus ulceration
Anatomic factors	Poor tissue perfusion
	Devitalized tissues
	Fluid collections
	Urinary retention
Immunomodulating infections	Cytomegalovirus
	Epstein-Barr virus
	HIV
	Hepatitis C virus
	Hepatitis B virus
Adapted from Fishman and Rubin[3]	

frequency of thrombocytopenia in liver transplant recipients, this may be important in these patients.[8] [9] [10] There is a semiquantitative relationship between environmental exposures and the net state of immunosuppression. The greater the exposure, the less immunosuppression is required to induce clinical infection. Conversely, the more profound the immunosuppression, the more trivial the exposure needed to induce disease.

TIMETABLE OF INFECTION IN THE ORGAN TRANSPLANT RECIPIENT

There is a definite temporal pattern to the types of infection that affect the transplant patient, which is useful in framing a differential diagnosis in a patient who presents with an infectious disease syndrome, in guiding cost-effective preventive strategies and as a tool for infection control (Table 102.3). Exceptions to the pattern usually

connote a previously unidentified environmental exposure. The basic timetable is identical for all solid organ transplant recipients, and can be divided into three time periods: the first month post-transplant, 1–6 months post-transplant, and more than 6 months post-transplant (Fig. 102.1).[2] [3] [4]

Infection in the first month post-transplant

Infections occurring in the first month post-transplant are usually due to infections conveyed with the allograft, infection that was present in the recipient before transplant that continues post-transplant, or infection caused by technical or anatomic difficulties. Active infection in the donor at the time of organ retrieval is a significant risk. HIV, hepatitis B virus (HBV), hepatitis C virus (HCV) and other systemic viral infections (such as West Nile virus) are efficiently transmitted via the allograft. Bloodstream infection in the donor at the time of donation is not uncommon, given the aggressive care (e.g. multiple

TABLE 102-3 -- Likely etiologies of various clinical presentations of infection in transplant patients.

LIKELY ETIOLOGIES OF VARIOUS CLINICAL PRESENTATIONS OF INFECTION IN TRANSPLANT PATIENTS	
Clinical presentations	**Etiology and considerations**
Fever	Rejection
	Post-transplant lymphoproliferative disease
	Viral infection (cytomegalovirus, Epstein-Barr virus, human herpesvirus-6)
	Bacteremia
	Often more pronounced in children
Bacteremia or sepsis	Related to indwelling lines (coagulase-negative staphylococci, *Corynebacterium jeikeium*, enterococci, Gram-negative rods, *Candida* spp.)
Urinary tract infections	Related to urinary dysfunction or catheters (Gram negative rods, enterococci, *Candida* spp.)
Pulmonary infection	Community-acquired (*Streptococcus pneumoniae*, *Legionella* spp., *Mycoplasma* spp., *Chlamydia* spp., seasonal viral infections)
	Nosocomial (Gram-negative rods, *Staphylococcus aureus*)
	Opportunistic infections (*Pneumocystis carinii*, *Nocardia asteroides* (which may disseminate), *Mycobacterium tuberculosis*, filamentous fungi, endemic fungi, viral infections (cytomegalovirus, varicella-zoster virus, adenovirus))
	Drug reaction (sirolimus, methotrexate)
Hepatitis	Viral hepatitis (hepatitis B, hepatitis C)
	Drug related
Cutaneous	Cellulitis (staphylococci, streptococci, Gramnegative rods)
	Papules (*Candida* spp., fungi, *Nocardia* spp.)
	Exanthems (viral, drug reaction)
	Ulcers or vesicles (herpes simplex virus, varicellazoster virus, cytomegalovirus)
	Necrosis (embolic fungal infection)
Retrosternal pain	Esophagitis (herpes simplex virus, *Candida* spp.)
Abdominal pain (with or without diarrhea)	Diverticulitis
	Enteric infection (*Salmonella* spp., *Campylobacter* spp., *Listeria* spp. (which may be bacteremic), *Clostridium difficile* colitis, *Strongyloides stercoralis*, cytomegalovirus)
Central nervous system	Meningitis (*Listeria* spp., *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, *Coccidioides immitis*, *Histoplasma capsulatum*)
	Focal cerebritis (bacterial, fungal, herpesviruses)
	Brain abscess (*Nocardia* spp., *Aspergillus* spp., *Toxoplasma gondii*, bacteria)
	Demyelination or dementia (JC virus (progressive multifocal leukencephalopathy))
	Drug related (fludarabine)

vascular access lines, bladder catheters, assisted ventilation) that many donors receive before brain death is declared. Although blood cultures that are positive for such commensal organisms as *Staphylococcus epidermidis*, diphtheroids and lactobacilli rarely cause a problem for the recipient, *Pseudomonas aeruginosa*, the Enterobacteriaceae and *S. aureus* may seed suture lines, resulting in mycotic aneurysms.[2] [3] [4] [11]

The first rule of transplant infectious disease is to eradicate all treatable infections before transplantation. Dialysis in patients undergoing renal transplantation provides the time and opportunity to accomplish this task. However, patients coming to transplantation of extrarenal organs may be quite debilitated and may require intubation, left ventricular assist devices or indwelling vascular catheters, all of which predispose to infection. Particular attention should be paid to lung injury, whether due to aspiration chemical injury, pulmonary infarction or bacterial infection. Transplantation in the setting of active pulmonary disease is highly associated with serial superinfections post-transplant, which carry an extremely high mortality.[2]

More than 95% of infections in the first month post-transplant are the same infections that occur in routine patients undergoing comparable surgery. Factors leading to deep wound infection include the need for re-exploration, fluid collections (a particular problem in liver transplantation) or bloodstream infection. [2] [3] [4] In the first month following transplantation the daily doses of immunosuppressives are at their highest, but opportunistic infections are extremely rare unless already present at the time of transplantation. Opportunistic infection during this period suggests an environmental hazard.[2] [3] [4]

Infection 1–6 months post-transplant

This is the period of the highest incidence of post-transplant infection resulting from the direct consequences of viral infection, such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), human herpesvirus (HHV)-6, HBV, HCV and HIV. Furthermore, there is a higher net immunosuppression caused by sustained immunosuppressive therapy in conjunction with immunomodulating viral infections, and opportunistic infections such as *Pneumocystis carinii*, *Listeria monocytogenes* and *Aspergillus* spp., with modest environmental exposure. Cytomegalovirus accounts for about two-thirds of all the febrile episodes during this period. Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX, co-trimoxazole) prevents infection with *P. carinii*, *L. monocytogenes* and *Nocardia* spp. as well as toxoplasmosis and urinary tract infection. A single-strength tablet daily at bedtime is preferred, although alternate-day double-strength therapy is acceptable. Without such prophylaxis, the incidence of *Pneumocystis* infection is about 15% during this period. For patients intolerant of TMP-SMX, *Pneumocystis* prophylaxis should be atovaquone (1500mg/day orally), pentamadine (300mg/month intravenously), dapsone (100mg/day) or pyrimethamine-sulfadoxine weekly. Prophylaxis with TMP-SMX is strongly preferred because of its wide range of prophylactic benefits.

Infection more than 6 months post-transplant

Immunosuppressed patients with functioning allografts more than 6 months post-transplant fall into three categories. Approximately 80% will have good allograft function and minimal maintenance immunosuppression without chronic viral infection. Their biggest routine infectious disease risk is community-acquired respiratory virus infection and its sequelae. The most common opportunistic infection is an asymptomatic pulmonary nodule due to *Cryptococcus neoformans.* Approximately 15% will have a chronic viral infection with the hepatitis viruses, papillomavirus, HHV-8 or HIV. Without effective antiviral therapy, progressive liver disease, hepatocellular carcinoma, squamous cell carcinoma, Kaposi's sarcoma from HHV-8, or overt AIDS will occur. Approximately 10% will have a poor result with acute and chronic rejection, severe immunosuppression and, often, chronic immunomodulating viral infection. These patients are at highest risk of infection with *P. carinii, C. neoformans*,

Nocardia spp., *Aspergillus* spp., *L. monocytogenes* and other opportunistic organisms. Decreased immunosuppressive therapy, consideration of

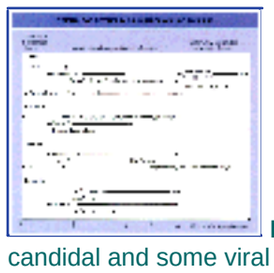

Figure 102-1 Timetable of infection in the organ transplant recipient. The typical infections are plotted by time following transplantation. Note the occurrence of bacterial and candidal and some viral infections in the first month. This is followed by predominantly viral infections between 1 and 6 months, and then fungal and chronic viral infections after 6 months, largely in patients who have chronic rejection and who are receiving more intensive immunosupression. Infections that deviate from this schema suggest a higher level of immunosuppression or a more intense environmental exposure. *Reproduced with permission from Fishman and Rubin.*[3] *CMV, cytomegalovirus; EBV, Epstein-Barr virus; PTLD, post-transplantation lymphoproliferative disease; VZV, varicella-zoster virus.*

re-transplantation, and lifetime prophylaxis with TMP-SMX and perhaps fluconazole are the important elements of management.[2] [3] [4]

ANTIMICROBIAL THERAPY IN THE TRANSPLANT RECIPIENT

Antimicrobial drugs in the transplant patient may interact with ciclosporin and tacrolimus, both of which are metabolized by hepatic cytochrome P450 enzymes, which are in turn modulated by certain antimicrobial agents. Rifampin (rifampicin), nafcillin and isoniazid upregulate ciclosporin and tacrolimus metabolism, resulting in lower blood levels and an increased risk of rejection. The macrolides (erythromycin more than clarithromycin and much more than azithromycin) and the azole antifungals (ketoconazole more than itraconazole more than voriconazole and much more than fluconazole) downregulate ciclosporin and tacrolimus metabolism, resulting in higher blood levels, an increased risk of nephrotoxicity and the possibility of excessive immunosuppression.

Synergistic nephrotoxicity (accelerated nephrotoxicity) can also develop. Renal injury commonly develops when nephrotoxic drugs (e.g. amphotericin deoxycholate, gentamicin) are added to calcineurin inhibitors. Renal toxicity can be observed after exposure to 100mg or less of amphotericin, just a few doses of aminoglycoside, or vancomycin. Single doses of amphotericin B, vancomycin, TMP-SMX and gentamicin can precipitate oliguric renal failure in the setting of calcineurin inhibitor therapy (idiosyncratic nephrotoxicity). A single strength TMP-SMX tablet is well tolerated in the face of calcineurin inhibitor therapy, but treatment doses for *Pneumocystis* infection are almost invariably associated with renal toxicity. Similarly, 250mg of ciprofloxacin twice daily is well tolerated in the face of ciclosporin or tacrolimus therapy, but 500mg twice daily is associated with a significant rate of renal injury (dose-related nephrotoxicity). It is not known whether these forms of renal injury have a similar pathogenesis.

Every effort should be made to avoid aminoglycosides, amphotericin and vancomycin, replacing them with compounds that are free of synergistic toxicity. The changes in calcineurin inhibitor metabolism induced by the drugs noted above can be managed by checking blood levels of ciclosporin and tacrolimus and making appropriate adjustments. The clinician must be alert for the need to adjust doses both at the initiation and cessation of antimicrobial therapy.

IMMUNOSUPPRESSIVE THERAPY AND INFECTION IN THE TRANSPLANT RECIPIENT

The standard immunosuppressive regimen employed today is a three-drug regimen consisting of cyclosporine or tacrolimus, azathioprine or mycophenolate, and prednisone. Antilymphocyte antibody therapy and monoclonal antibodies against the interleukin (IL)-2 receptor (daclizumab and basilixmab) are used as induction therapy in patients with oliguric renal injury in order to shorten the duration of the injury, or to treat rejection. Optimal use of these agents, as well as rapamycin (sirolimus), is still evolving. For detailed discussions of the mechanisms of action and toxicities of these agents, see Chapter 99 .

Corticosteroids have been important tools for immunosuppression since the early days of clinical transplantation. However, their extensive side-effect profile has driven the search for so-called corticosteroid-sparing therapies. Corticosteroids have anti-inflammatory and immunosuppressive effects. They inhibit proinflammatory cytokine production, decrease the accumulation of polymorphonuclear leukocytes at sites of inflammation, increase the ratio of B lymphocytes to T lymphocytes, increase the ratio of $CD8^+$ cells to $CD4^+$

cells, inhibit arachidonic acid metabolites, block vascular permeability in inflammatory processes and impede nitric oxide production. Therefore, by the time of clinical presentation, the microbial burden may be unusually large.[2] [3] [4]

Azathioprine is converted into 6-mercaptopurine after absorption. It inhibits both early stages in purine synthesis as well as steps in the purine salvage pathway, thus depleting purine stores and inhibiting nucleic acid synthesis. It is a potent inhibitor of actively dividing lymphocytes, with little impact on mature elements of antigenic memory. Its major toxicity is on rapidly dividing cells in the bone marrow. The key enzyme in its metabolism, thiopurine methyltransferase, exhibits considerable genetic heterogeneity resulting in fast and slow metabolizers with resulting effects on both immunosuppression and toxicity.

Mycophenolate mofetil (MMF) is a prodrug that is cleaved by plasma esterases to yield the immunosuppressive molecule mycophenolic acid, an inhibitor of inosine monophosphate dehydrogenase, which plays a key role in the de-novo biosynthesis of guanosine.[12]

Ciclosporin and its fellow calcineurin inhibitor, tacrolimus, have revolutionized organ transplantation, increasing 1-year cadaveric donor renal allograft survival from 50% to about 90%. Inhibition of IL-2 production is the dominant effect, resulting in a profound suppression of T-cell function and effect. In particular, a dose-related inhibition of microbial specific T-cell cytotoxic activity is of prime importance. Ciclosporin and tacrolimus amplify the level of replicating virus (i.e. viral load), which is of particular importance in CMV and EBV infection. Epstein-Barr virus-associated post-transplant lymphoproliferative disease occurs at an increased rate in patients achieving high levels of the calcineurin inhibitors. Therefore, antiviral therapy directed against the herpesviruses is necessary for any therapeutic prescription that includes ciclosporin or tacrolimus.[2] [3] [4] [13]

Tacrolimus shares a number of properties with ciclosporin. The immunophilins that bind to tacrolimus (FK506 binding proteins) are distinct from those binding ciclosporin. T-cell activation is blocked as a result of calcineurin inhibition. Tacrolimus and ciclosporin affect a similar array of cytokines, with IL-2 inhibition being the most important. The net result is inhibition of T-cell proliferation, inhibition of primary and secondary cytotoxic T-cell responses, and blockage of B-cell response to vaccine and other antigens. Secondary antibody responses, natural killer cell activity, and antibody-dependent cytotoxic cell functions are unaffected. Tacrolimus is 10–100 times more potent than ciclosporin.[4] [14]

Although rapamycin is similar in structure to tacrolimus, its mechanism of action and immunosuppressive effects are entirely different. Rapamycin enters the cell and forms a complex with FK506 binding proteins, but instead of targeting calcineurin and cytokine transcription, it binds to a protein kinase termed the 'target of rapamycin' (TOR), which results in a blockage in the translation of mRNAs encoding cell cycle regulators. In terms of infection, it decreases microbial specific T-cell function and should have similar effects to those of the calcineurin inhibitors. [4]

Polyclonal antilymphocyte preparations of either equine or rabbit origin are potent T-cell-depleting agents. OKT3, a murine monoclonal antibody directed against the CD3 T-cell receptor complex, is the most potent agent in the treatment of acute cellular rejection. The infectious disease impact of OKT3 is essentially identical to that of the polyclonal agents.[2] [3] [4]

The monoclonal antibodies daclizumab and basilixmab are both directed against the IL-2 receptor. These do not cause the massive release of proinflammatory cytokines associated with the other antibody preparations. These appear to be less potent in terms of predisposing to infection, while still having benefits in terms of preventing allograft rejection. However, optimal deployment of these agents is still being defined.[2] [3] [4]

IMPORTANT INFECTIONS IN ORGAN TRANSPLANT RECIPIENTS

Herpesviruses

Herpesviruses such as CMV, EBV, herpes simplex virus (HSV)-1, HSV-2, varicella-zoster virus (VZV), HHV-6, HHV-7 and HHV-8 are the most important class of pathogens affecting the transplant recipient. They demonstrate lifelong latency but can be reactivated in response to a variety of stimuli, particularly proinflammatory cytokines. In general, primary disease, as opposed to reactivation disease, is more severe.

Herpesviruses should be considered oncogenic until proven otherwise. This is exemplified by the relationship between EBV and post-transplant lymphoproliferative disease (PTLD) and between HHV-8 and Kaposi's sarcoma; direct effects of these viruses are critical to the pathogenesis of these neoplastic states. Cytomegalovirus disease increases the risk of subsequent PTLD by between 7 and 10 times.

Cytomegalovirus

Cytomegalovirus is the single most important pathogen affecting transplant patients, both directly as a cause of infectious disease syndromes and indirectly through cytokines and other mediators elaborated in response to viral replication and invasion. Acquisition of CMV can be through transfusion of a viable leukocyte-containing blood products from a CMV seropositive donor, transplantation of an organ from a CMV seropositive donor, reactivation of endogenous CMV post-transplant in a seropositive recipient, and, least often, acquisition of primary infection. The serologic status of the donor and recipient at the time of transplant and the immunosuppressive regimen determine the outcome of CMV infection.[2] [3] [4]

There are four key elements in the pathogenesis of CMV:

- reactivation;
- amplification and systemic dissemination;
- development of MHC-restricted, virus specific, cytotoxic T-cells; and
- elaboration of cytokines, chemokines and growth factors in response to the replicating virus.

Reactivation of virus from latency is largely accomplished by any processes that induce TNF-a. A 'second wave' phenomenon is seen when patients present with and are cured of bacterial sepsis, only to present 2–3 weeks later with active CMV infection. The stress catecholamines, epinephrine (adrenaline) and norepinephrine (noradrenaline), and proinflammatory prostaglandins are less important pathways in this regard. Inflammatory processes thus have a high probability of reactivating CMV from latency.[2] [3] [4] [15] [16]

Different immunosuppressive drugs have different effects on CMV. Ciclosporin, tacrolimus, prednisone and rapamycin have no ability to reactivate CMV from latency, but once replicating virus is present these drugs potentiate viral amplification.

Without antiviral prophylaxis, clinical CMV disease typically occurs 1–4 months post-transplant. An antiviral program may delay the onset of clinical disease for weeks to months, at which time the clinical effects are identical to those observed without prophylaxis. Most aspects of clinical CMV disease are identical in most forms of organ transplantation. However, the transplanted organ is usually far more affected by the virus than is the native organ. Thus, although transient abnormalities in liver function can be seen in all solid organ transplant patients, clinically, symptomatic hepatitis is only an issue in liver transplant patients; similarly, myocarditis is an issue in heart recipients and pancreatitis in pancreatic allograft recipients. The incidence of CMV pneumonia is far greater in lung transplant recipients than in other solid organ transplant patients.[17]

Cytomegalovirus infection can involve any part of the gut, causing enteritis, focal ulceration, or perforation. Functional abnormalities in

motility have been observed in the absence of gross abnormalities on endoscopy but with CMV clearly visible on biopsy. It is important to keep in mind that CMV enteritis can occur without demonstrated viremia.[2] [3] [4] Cytomegalovirus chorioretinitis is the major late complication of CMV (usually >6 months post-transplant), with the virus causing necrosis of the retina, but retinal detachment or anterior uveitis may occur.[2]

Cytomegalovirus infection may augment immunosuppression with potentiation of superinfection, such as *P. carinii,* invasive aspergillosis, Gram-negative infection (both colonization and subsequent invasion of the respiratory tract), bacteremia, listeriosis, candidemia and HCV increase.

In 1970, Richard Simmons first postulated that CMV infection could be linked to allograft injury.[18] Recently, trials of anti-CMV therapy have demonstrated a decrease in acute rejection and, probably, in chronic allograft injury, apparently substantiating this view.[19] [20]

The diagnosis of CMV has advanced significantly in the past decade (see Chapter 112 and Chapter 215). Viremia is the major determinant of prognosis. Serologic tests for CMV are most valuable pre-transplant, since they provide essential information for assessing risk of CMV disease and guide the appropriate preventive strategy. Serial blood samples assessing the patient's response to infection do not provide timely information for making therapeutic decisions, and determination of IgM anti-CMV antibody adds little.

The cornerstone of the treatment of CMV infection is ganciclovir. Valganciclovir should permit the successful oral treatment of CMV disease. Patients at risk of primary CMV infection (seronegative recipients with a seropositive donor) have 50% or higher incidence of clinical disease. In contrast, seropositive recipients treated with conventional immunosuppression have a less than 20% incidence of disease. Either prophylactic or pre-emptive regimens are acceptable.[2] [3] [4] Many centers use intravenous ganciclovir for the first several days of therapy, and then complete therapy with valganciclovir; optimal duration of therapy is unclear. Our approach is to employ full treatment doses until viremia is cleared, and then decrease the dose to prophylactic levels, continuing oral valganciclovir for an additional 2–3 months. If ganciclovir resistance develops, foscarnet is used, despite significant renal toxicity (see also Chapter 205).

Epstein-Barr virus

The natural reservoir for EBV is the epithelial cells of the upper respiratory tract. Long-lived B lymphocytes become infected as they travel through the lymphoid tissue of the oral cavity, which results in latent infection of these cells and subsequent immortalization. Antiviral therapy of these infections has little effect on the symptoms noted by the patient. It is likely that EBV produces clinical effects that are comparable to those produced by CMV (e.g. mononucleosis, hepatitis, fever). The major clinical effect of EBV that is recognized is its role in the pathogenesis of EBV-associated PTLD,[2] [3] [4] [21] [22] a number of pathologic entities that range from the benign to the frankly malignant (Table 102.4). Complicating the pathologic evaluation of biopsies of PTLD is the lack of uniformity within a particular lesion or in different lesions in the same patient. Thus, there can be sites of polyclonality, oligoclonality and even monoclonality in the same patient, making the staging of the process and evaluation of therapy difficult.

The incidence of PTLD is different in different forms of transplantation, at least in part related to the intensity of immunosuppression: 1–3% among kidney, heart and liver allograft recipients, but higher (7–33%) after lung, intestine and multivisceral transplantation. The pathogenesis of EBV-associated PTLD involves the number of B lymphocytes transformed by EBV (a function of viral load, which is dependent on the intensity of the immunosuppressive therapy) and the activity of EBV-specific cytotoxic T-cells, which is

TABLE 102-4 -- Society of Hematopathology classification of post-transplant lymphoproliferative disease (PTLD).

SOCIETY OF HEMATOPATHOLOGY CLASSIFICATION OF PTLD	
Lymphoid hyperplasia (early lesions)	Included in this category are plasma cell hyperplasia, lesions resembling infectious mononucleosis, and other forms of atypical lymphoid hyperplasia with preservation of the underlying architecture. These lesions are usually polyclonal and often regress with reduction of immunosuppression
Polymorphic PTLD	These are destructive lesions that infiltrate and destroy underlying tissue, with a wide range of B-cell maturation being present. Molecular studies suggest that virtually all of these tumors are monoclonal. Oncogene or tumor suppressor gene abnormalities are not a feature of these tumors. A lower percentage of these tumors respond to reduction of immunosuppression

Lymphomatous or monomorphic PTLD	Most such tumors are of the diffuse large B-cell lymphoma subtype, although Burkitt-like lymphomas and mucosa-associated lymphomas (MALT lymphomas) may also occur as variants of B-cell disease. Abnormalities in the ras or p53 genes of the diffuse B-cell lymphomas are not uncommon. These tumors are monoclonal, with only a minority responding to decreased immunosuppressive therapy. In addition, such uncommon forms of PTLD as T cell, null cell and NK cell lymphoma are placed in this category. A minority of these non-B-cell tumors are EBV-positive, and response to decreased immunosuppression is uncommon
Other forms of PTLD	Included in this category are such uncommon tumors as plasmacytoma, myeloma and T-cell-rich/Hodgkin's disease-like large B-cell lymphoma. These tumors may or may not be EBV-positive and tend to be clinically aggressive
In general, Epstein-Barr virus (EBV)-positive tumors occur in the first 6 months post-transplant; in contrast, although the EBV-negative PTLDs can occur as early as 6 months post-transplant, they occur at a mean time of 4 years post-transplant	

also affected by the immunosuppressive regimen. The cytokine milieu is an additional factor. Preceding CMV disease increases the incidence of PTLD 7- to 10-fold. Durandy used a monoclonal antibody against IL-6 in a group of 12 PTLD patients who had failed conventional therapy; six went into complete remission and six went into partial remission.[2] [3] [4] [23] [24]

Approximately 90% of adults harbor latent EBV and are EBV-seropositive; they develop PTLD as a consequence of EBV reactivation. Most children are EBV-seronegative before transplant; primary EBV infection is associated with higher viral loads than reactivation and hence with a higher incidence of PTLD (see Table 102.4).[2] [3] [4]

Post-transplant lymphoproliferative disease may present with unexplained fever, mononucleosis, gastrointestinal bleeding, abdominal pain, gut perforation or obstruction, hepatocellular dysfunction, acute cholecystitis, or focal disease in the brain. In pediatric transplant patients, a common presentation is with 'tonsillitis', which, on pathologic examination, is found to be lymphomatous. Post-transplant lymphoproliferative disease may behave like a B-cell lymphoma in the normal host, or it may be entirely extranodal. The allograft itself may be a privileged site for PTLD.[2]

Optimal management of PTLD has not yet been established. The first step is usually to stop immunosuppression or, if this is not possible,

to decrease it by 50–75%. About one-quarter of patients with PTLD, particularly children, will respond to this approach. Most centers use ganciclovir, acyclovir or foscarnet; antilymphoma chemotherapy, radiotherapy and surgery have not been particularly successful. Anti-B-cell monoclonal antibodies have a success rate of >60%.[2] [24]

Human herpesvirus-6

Human herpesvirus-6 infects and replicates within a variety of leukocyte populations, resulting in elaboration of a broad array of proinflammatory cytokines. Thus, HHV-6 may cause similar effects to those of CMV. Human herpesvirus-6 can also cause bone marrow suppression and encephalitis and has been reported to correlate both with prolonged hospital stay and with need for readmission.[25]

Replication of HHV-6 occurs in 30–50% of patients 1–6 months post-transplant, precisely when CMV is most active. The combination of two or more simultaneous herpesvirus infections (e.g. CMV plus HHV-6) may have worse consequences than a single infection. Human herpesvirus-6 infection is best diagnosed by polymerase chain reaction (PCR) assay on blood, and susceptibility to ganciclovir and foscarnet is similar to that of CMV. Clinical activity of these drugs has been reported in HHV-6 encephalitis.

Hepatitis viruses

The incidence of chronic hepatitis in solid organ transplant patients has remained largely unchanged for two decades, with 10–15% of transplant recipients infected, almost all of which are with HCV. Immunosuppression usually means that transplant patients will not clear HCV and HBV. The clinical impact of chronic hepatitis is far greater than in the normal host, and the time necessary to produce end-stage liver disease or hepatocellular carcinoma is shortened. The current antiviral therapies are less effective than in nonimmunosuppressed patients with similar infections. [2]

Hepatitis B virus

In immunosuppressed patients, reversion from HBV anticore antibody (anti-HBc) to HBV surface antigen (HbsAg) positivity has been documented, but is uncommon. A bigger concern is the impact of transplanting organs from an HbsAg-negative, anti-HBc-positive donor. Liver allografts from such donors carry a significant risk of transmitting HBV infection, with PCR on such livers often showing virus. In contrast, other organs transplanted from such donors carry a minimal risk of transmitting HBV infection.[26]

When HBV infection is already present, corticosteroid therapy promotes virus replication, with a marked increase in HBV DNA polymerase activity, HBV DNA, HBV e-antigen (HbeAg) and HbsAg. The calcineurin inhibitors also increase the probability of chronic, progressive infection. Kidney, heart and lung transplant recipients with active HBV infection do relatively well over the first 18–24 months post-transplant, but then begin to show evidence of chronic liver disease or hepatocellular carcinoma, or both. By 8–10 years post-transplant, patients with HBV-associated chronic liver disease have had increased death rates from hepatic failure, hepatocellular carcinoma and sepsis — rates above that seen with other forms of chronic liver disease.[2] Evidence of active viral replication at the time of transplantation has been associated with poor outcomes. Two approaches have markedly improved the outcome for these patients: indefinitely prolonged immunoprophylaxis with hepatitis B immunoglobulin at approximately monthly intervals, and prolonged therapy with lamivudine.[27] The combination of these two therapies has been proven effective, perhaps at a lower cost. Development of drug-resistant mutants usually becomes apparent after 12 or more months of lamivudine therapy (the incidence at 1 year being as high as 30% and at 2 years 38%). There is considerable debate about the optimal time for initiating therapy — before transplant, early post-transplant or later.[28] [29] Multidrug regimens akin to those used in HIV infection are likely to be needed.

Fibrosing cholestatic hepatitis may occur in liver transplant patients with either HBV or HCV infection, but it is more common with HBV. This presents as rapidly progressive hepatic failure, often in the first 6 months post-transplant, resulting in death within 4–6 weeks of presentation. Histology shows minimal inflammatory cells, ballooning of the hepatocytes, cholestasis and high HBV loads in hepatocytes and in the circulation. It is believed that this form of liver injury is caused by a direct cytopathic effect of the virus; lamivudine may be effective. [2] [30]

Hepatitis C virus

Hepatitis C virus accounts for >80% of the progressive liver disease that occurs post-transplant, and HCV liver disease is currently the most common indication for liver transplantation.[2] Risk factors that are associated with an increased morbidity and mortality from HCV include HCV genotype 1b, high viral load, intense immunosuppression, graft rejection, co-incident CMV viremia, iron overload, major histocompatibility complex (MHC) class II matching, and donor TNF-a promoter genotype.[2] [31] [32] [33] [34] Fibrosing cholestatic hepatitis, glomerulonephritis (both membranoproliferative glomerulonephritis, with and without cryoglobulinemia, and membranous glomerulonephritis), acute and chronic transplant glomerulopathy and thrombotic microangiopathy with anticardiolipin antibody are associated with HCV infection in the transplant patient.[2] [35] [36] [37]

The first step in therapy is to decrease immunosuppression. At present, IFN-a with ribavirin induces response in about 50% of cases (see Chapter 207).

Papovaviruses

The polyomaviruses BK virus and JC virus are normally acquired in childhood and reactivated post-transplant.

JC virus

JC virus is the cause of a subacute, progressive, demyelinating disease of the central nervous system (CNS) that is known as progressive multifocal leukoencephalopathy. Progressive multifocal leukoencephalopathy is characterized by the development of progressive motor and sensory deficits and dementia, with

death within 3–6 months. At present, there is no therapy except to decrease immunosuppression. [2] [38]

BK virus

BK virus infection causes a tubulointerstitial nephritis that mimics rejection in renal allografts. The increase in this condition in recent years has been linked to increased immunosuppression, particularly the use of tacrolimus with mycophenolate. BK virus nephritis adversely affects allograft function. Major reduction in immunosuppression is the only known way to ameliorate this process. [39] [40] [41]

Papillomaviruses

In post-transplant patients, papillomaviruses most commonly cause warts, which can be so extensive as to be disfiguring. The intensity of immunosuppression appears to be critical, with azathioprine and mycophenolate being particularly associated. These warts can undergo malignant transformation, particularly in sun exposed areas. Skin cancers in transplant patients are thought to occur through the interaction of papillomavirus infection, immunosuppression and ultraviolet irradiation.[42] A particular group of papillomaviruses, the epidermodysplasia verruciformis-associated types, appear to play a significant role in the pathogenesis of cutaneous and anogenital squamous cell carcinoma, which are more common in transplant

TABLE 102-5 -- Pulmonary radiographic presentations.

PULMONARY RADIOGRAPHIC PRESENTATIONS	
Acute infiltrates	Community-acquired pneumonias:
	Streptococcus pneumoniae
	Chlamydia pneumoniae
	Legionella spp.
	Gram-negative rods
	Respiratory viruses (e.g. respiratory syncytial virus, influenza virus)
Subacute or chronic infiltrates	*Nocardia* sp.
	Fungi (*Aspergillus* spp., *Mucorales* spp.)
	Pneumocystis carinii
	Mycobacterium tuberculosis
	Nontuberculous mycobacteria
	Mycoplasma pneumoniae
Diffuse infiltrates	*Pneumocystis carinii*
	Viruses (cytomegalovirus, influenza)
Miscellaneous	Sirolimus pulmonary toxicity
	Pulmonary embolism
	Pulmonary edema
	Atelectasis

patients. Similarly, cervical papillomavirus infection has been linked to cervical cancer.[2] [42] [43]

Fungal infections

Fungal infections have grown in importance in organ transplant recipients, as a result of endemic, geographically restricted systemic mycoses (blastomycosis, coccidiomycosis, histoplasmosis), opportunistic organisms (*Candida* spp., *Aspergillus* spp. and *C. neoformans*) and 'new and emerging' fungi (*Fusarium* spp., *Scedosporium* spp. and *Trichosporon* spp.) that cause opportunistic infection (see Table 102.5).

The endemic mycoses can present in a variety of ways in these patients:

- progressive primary infection with likely hematogenous dissemination,
- reactivation infection with secondary dissemination, or
- infection due to re-exposure after immunosuppression has attenuated previously acquired immunity.

Therapy of the endemic mycoses in the past has relied on amphotericin to gain control, followed by an azole to complete therapy. At present, itraconazole is the azole of choice, but this will probably change with the licensing of the newer azoles. [2] [44] [45] (see Chapter 208)

Candida has become one of the more important pathogens for transplant recipients. Although a great deal of candidal infection is clearly derived from endogenous sources (the gut and the female genital tract being the most common), person-to-person spread does occur, particularly on the hands of medical personnel. Candidal syndromes common in transplant patients include pharyngitis, esophagitis, wound infection and candidemia. In addition, candidiuria is of special concern because fungal balls can form at the ureterovesical junction, particularly in patients with poor bladder emptying, causing a form of obstructive uropathy that is difficult to eradicate. We advocate treatment of asymptomatic candidiuria, usually with fluconazole. A single blood culture positive for *Candida* requires systemic chemotherapy, to reduce the risk of presenting later with endophthalmitis or osteomyelitis. The isolation of *Candida* in the sputum does not indicate pneumonia, as primary candida pneumonia rarely, if ever, occurs.

Aspergillus infection is a therapeutic emergency. As with *Fusarium* and *Scedosporium*, *Aspergillus* is vasculotropic, and early blood vessel involvement leads to hemorrhage, infarct and spread. Fully 50% of patients have metastatic disease at the time of initial diagnosis, and mortality rates, particularly in lung transplant patients, have exceeded 50% despite treatment with amphotericin. Survival with voriconazole is better. Our approach has been to use voriconazole. In about 25% of transplant patients with cryptococcosis, skin lesions are the first manifestation of systemic infection. The most common presentation of the patient with cryptococcal involvement of the CNS is headache, fever or mild-moderate cognitive dysfunction. Signs of meningeal irritation are absent in many patients. Cerebrospinal fluid typically shows increased intracranial pressure, lymphocytic pleocytosis, elevated protein and depressed sugar, in addition to a positive cryptococcal antigen test. Immunosuppression (especially corticosteroids) should be decreased and induction therapy begun, typically a lipid amphotericin preparation with flucytosine. After control is achieved, consolidation with high-dose fluconazole (800–1200mg/day) is initiated. Therapy is continued until all evidence of disease is gone, with an additional 2–4 weeks of therapy as a 'buffer' added to the regimen.[2] [46]

Bacterial infections

Acute gastroenteritis syndromes in the transplant patient include the gut toxicity of mycophenolate, a variety of viruses and certain bacteria. *Clostridium difficile* appears to be more common, more symptomatic and more difficult to treat in the transplant patient, with a much greater propensity for relapse. Our policy is to treat it with metronidazole for 1 week after symptoms have resolved. Non-typhoidal *Salmonella* infections pose a particular hazard to the transplant patient. Whereas in the normal host *Salmonella* gastroenteritis is associated with bacteremia in <5% of cases, it occurs in more than 50% of transplant patients with gastroenteritis. Seeding of the urinary tract, with positive urine cultures, is common. Preexisting atherosclerotic lesions, aneurysms or fistulae can become infected. Therefore, *Salmonella* bacteremia is treated for an extended course, preferably with a fluoroquinolone. [2] [3] [4]

The portal of entry for *Listeria* is the gastrointestinal tract, with bacteremia sometimes preceded by a non-specific gastroenteritis. On occasion, the organism can be

isolated from the stool. Once bloodstream invasion occurs, bacteremia may cause endocarditis or CNS syndromes. Acute pyogenic meningitis typically presents with headache and fever, but overt meningeal signs are often absent. Focal or diffuse cerebritis may be manifestations of meningoencephalitis. Rhomboencephalitis involves the brainstem and produces a syndrome that resembles bulbar polio. Therapy is usually with high-dose intravenous ampicillin with or without gentamicin for 7–10 days, followed by ampicillin alone for a further 7–10 days. In patients who are allergic to ampicillin, high-dose TMP-SMX is used with success. In patients who allergic to both, we desensitize to the ampicillin and use the first regimen.[2] [3] [4] Prophylaxis with TMP-SMX protects against *L. monocytogenes*.

The manifestations of tuberculosis in transplant patients ranges from cavitary to miliary disease in the lung, from bowel to skeletal disease, and from skin to CNS disease. There appears to be a particularly high rate of skeletal involvement in transplant patients. Transmission of tuberculosis within an allograft has been documented. The usual approach to a positive tuberculin skin test is isoniazid prophylaxis. However, underlying liver function test abnormalities are common in these patients, and since the major toxicities of isoniazid, rifampin and pyrazinamide are hepatic, alternative

strategies have evolved. We have followed more than 125 patients with positive tuberculin tests but no other risk factors for more than 10 years without prophylaxis, without a single case of active disease. However, any of the following risk factors in addition to a positive tuberculin test should trigger therapy, often with nonclassical regimens. Risk factors requiring prophylaxis include:[2] [47]

- recent tuberculin skin test conversion;
- non-Caucasian ethnicity;
- other immunosuppressive conditions such as protein calorie malnutrition;
- a history of active tuberculosis, particularly if inadequately treated; and
- significant abnormalities on chest radiograph.

Transplant patients with active disease are initially tried on isoniazid, rifampin and pyrazinamide, with or without ethambutol. If this is not tolerated, we have used regimens such as ofloxacin and ethambutol for 2–3 years.

Nocardiosis is quite similar to the invasive molds in terms of pathogenesis and clinical effects. Nocardia typically has a subacute presentation caused by inhalation of organisms, which establish a pulmonary portal of entry followed by hematogenous dissemination to the skin, CNS and the skeletal system. Prophylaxis with low-dose TMP-SMX prevents this infection; high-dose TMP-SMX is used to treat it (see Table 102.5).[2] [47]

SUMMARY AND CONCLUSION

In organ transplantation the therapeutic prescription has two components:

- immunosuppression to prevent and treat rejection, and
- antimicrobial agents to make it safe.

Rejection and infection are closely linked. Infection is better prevented than treated, but if treatment is needed, the earlier such treatment is initiated, the better the outcome. Finally, the risk of infection is determined by the interaction of technical and anatomic factors, the net state of immunosuppression, and environmental exposures. These factors logically lead to a timetable of infections that helps to predict problems and solutions.

Chapter 103 - Lung and Heart-Lung Transplant Patients

Klara M Posfay-Barbe
Michael DL Green
Marian G Michaels

INTRODUCTION

Lung and heart-lung transplantation has been clinically available for more than 20 years. Progress in candidate and donor selection, allograft preservation technique, recipient surgery and postoperative management have greatly improved the outcome of thoracic transplantation.[1] Despite these improvements, infectious complications remain an important cause of morbidity and mortality in patients undergoing these procedures.[2]

EPIDEMIOLOGY

Lung and heart-lung transplantation is offered to patients with chronic progressive pulmonary failure. Because of the high risk of rejection and infection, demanding postoperative care and severe shortage of grafts, these transplants are only considered when other treatment options are exhausted. Lung transplantation can be performed as an isolated procedure (double- or single-lung) or as a heart-lung transplant. Candidates for isolated lung transplantation are typically referred because of the presence of cystic fibrosis, interstitial lung disease, emphysema or pulmonary hypertension without important cardiac damage. The most common current underlying diagnoses of people undergoing heart-lung transplantation include complex congenital heart disease with secondary pulmonary hypertension, or pulmonary hypertension with significant cor pulmonale. Current 1-year survival for isolated lung and heart-lung transplantation are 74% and 62% respectively.[3]

PATHOGENESIS AND PATHOLOGY

Patients undergoing heart-lung or lung transplantation are at high risk for developing infectious complications. These account for approximately 40–50% of all deaths in these patients.[4] Unique among heart-lung and lung transplant recipients is the relationship between the presence of chronic rejection and bronchiolitis obliterans with chronic infection of the airway. This relationship may be explained in part by the fact that lung transplant recipients have altered lung immunity due to impaired ciliary clearance, poor cough reflex and abnormal lymphatic drainage, predisposing these patients to lower respiratory tract infections. Clinical manifestations of infection with these pathogens may be indistinguishable from rejection of the lung and may strongly resemble a classic 'pulmonary exacerbation' (increased cough and sputum production with a measurable decline on formal pulmonary function testing) seen with cystic fibrosis patients. The patient's underlying lung disease impacts on the presentation and the type of infection that occur after these procedures. This is illustrated by the increased risk of early and severe pneumonia with multiple antibiotic-resistant bacteria seen in cystic fibrosis patients undergoing heart-lung or lung transplantation. The high degree of immunosuppression required by heart-lung/lung transplant recipients also puts these patients at high risk of opportunistic pathogens, including cytomegalovirus (CMV), Epstein-Barr virus (EBV) and *Pneumocystis carinii* pneumonitis (PCP). The frequency and severity of disease due to these opportunistic pathogens exceeds that reported after most other types of organ transplantation.

Timing and patterns of infectious complications

The timing of infections follows the typical pattern observed after other solid organ transplant procedures and can be divided into early (<1 month), intermediate (1–6 months) and late periods (>6 months). Risk factors for infection after thoracic transplantation are described in Table 103.1 . During the early period, infections are related to the surgical site (including mediastinitis[4] [5]), presence of foreign bodies (e.g. central venous catheters) or nosocomial acquisition of infection.

A unique feature of cystic fibrosis patients who are undergoing lung/heart-lung transplantation is that they may develop bacteremia with organisms that normally inhabit their airway (*Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Alcaligenes xylosoxidans*, *Stenotrophomonas maltophilia*). Viral infections are infrequent in the early period, although herpes simplex virus (HSV) can reactivate during this period as a result of the stress of surgery and induction of immunosuppression. While uncommon, development of acute infection with adenovirus, influenza or respiratory syncytial virus (RSV) during this period can be severe.

The intermediate time period is characterized by reactivation of donor-transmitted disease from latent organisms such as CMV or

TABLE 103-1 -- Risk factors for infection after thoracic transplantation.

RISK FACTORS FOR INFECTION AFTER THORACIC TRANSPLANTATION
Recipient pretransplant factors
• Organ transplanted (heart-lung vs double-lung vs single lung)
• Underlying disease (cystic fibrosis)
• Severity of illness prior to transplant:
Malnutrition
Requirement for intensive care
Requirement for assist devices
• Age:
Immunologic immaturity
Primary exposure
Immunization history
Donor factors
• Latent infections
• Colonization of respiratory tract
Intraoperative factors
Post-transplant factors
• Technical problems
• Immunosuppression
• Indwelling cannulas
• Nosocomial exposure

EBV. Reactivation of latent infections from donor organs can also occur with histoplasmosis, tuberculosis and toxoplasmosis. The latter is more common in recipients of heart-lung transplants. PCP, which is more frequent after lung/heart-lung transplantation compared with other organ transplants, also most frequently presents in the intermediate period in the absence of chemoprophylaxis.

The pattern of infections seen during the late post-transplant time period is unique in lung/heart-lung transplantation compared to other organ recipients. The lung is the most important site of late infection in these patients and the presence of chronic rejection or bronchiolitis obliterans is the major risk factor for these infectious complications. Pathogens found in these late pulmonary infections can be the same as those recovered from cystic fibrosis patients, regardless of their underlying disease. They include *P. aeruginosa*, *A. xylosoxidans*, *S. maltophilia* and *Aspergillus fumigatus*. The presence of one or more of these potential pathogens may be associated with asymptomatic colonization or fatal disease. Opportunistic infection with *Nocardia* or *Cryptococcus* spp. can also occur late after transplantation.

TABLE 103-2 -- Prophylactic strategies in lung and heart-lung transplantation.

PROPHYLACTIC STRATEGIES IN LUNG AND HEART-LUNG TRANSPLANTATION				
Indication	**Prophylaxis**	**Dose and duration**		**Comments**
		Adults	**Children**	
Perioperative prophylaxis				
Not colonized prior to transplant and perioperative cultures from donor and recipient negative	Cefazolin	0.5–2g q8h iv	20–30mg/kg q8h iv	If all cultures negative, treat 48h; if any culture positive, treat 10–14d
Recipient with underlying colonization (e.g. cystic fibrosis)	Drugs tailored to previous sputum culture			
Pneumocystis carinii	TMP-SMX	80 or 160mg of TMP component daily	5mg/kg of TMP component 3 times a week or daily	May also give protection against toxoplasmosis
Aspergillus spp.	Liposomal amphotericin B	3mg/kg/day until perioperative cultures available from donor and recipient		If cultures negative: stop, if positive: continue 1–2 weeks, consider oral itraconazole
Candida spp.	Nystatin	5ml q6h po for 1 month	If <2 years old: 2ml q6h po for 3 months	
			If >2 years old: 5ml q6h po for 1 month	
Herpes simplex virus	Acyclovir	200mg po q8h for 3 months	5mg/kg q8h (max. 200mg) for 3 months	Used only for HSV-positive patients Begin once patient off ganciclovir
Cytomegalovirus				
Donor +, recipient -	Ganciclovir	5mg/kg iv q12h for 14d		Then 5mg/kg iv q24h for 7–14d if patient remains in hospital; then start valganciclovir to complete 90d of therapy (adults: 900mg po q24h; children: contact pediatric infectious disease specialist)
Donor ±, recipient +	Ganciclovir	5mg/kg/d iv q12h for 14d, then 5mg/kg iv q24h for 7–14d if patient remains in hospital		
Donor -, recipient -	No treatment			
Toxoplasma gondii				
High-risk: donor +, recipient -	Pyrimethamine	1mg/kg (max. 25mg) q24h for 2 weeks, then 3 times a week for 6 months	1 mg/kg (max. 25mg) q24h for 2 weeks, then 3 times a week for 6 months	*plus* folinic acid 5mg 3 times a week for 2 weeks then once a week
Low-risk: donor ±, recipient +	TMP-SMX	80 or 160mg of TMP component daily	5mg/kg of TMP component 3 times a week	Will also give protection against *P. carinii* pneumonia
SMX, sulfamethoxazole; TMP, trimethoprim				
These are the strategies used at the Children's Hospital of Pittsburgh.				

Regardless of the time period, differentiation between rejection and infection can often be difficult in thoracic transplant recipients. Accordingly, biopsy and cultures are often important to obtain to assist in appropriate management. Prophylactic strategies to prevent infection in thoracic transplantation patients used at the Children's Hospital of Pittsburgh are described in Table 103.2 .

INFECTIOUS SYNDROMES

Cytomegalovirus infection

Clinical presentation

Cytomegalovirus is the most common and important viral agent in thoracic transplantation patients. It can cause primary infection in a previously seronegative patient or secondary infection (with a different strain, or reactivation of their own CMV) in a previously seropositive person. Primary infection is usually transmitted via the donor graft or blood products. Infection with CMV typically presents between 1 and 6 months after transplantation as CMV syndrome

(with malaise, fever and bone marrow suppression), pneumonitis or invasive disease. [4] [6] Cytomegalovirus pneumonitis is particularly severe in high-risk patients — CMV-positive donor (D+)/CMV-negative recipient (R-) — but fatal pneumonitis has been less frequent since the availability of ganciclovir.[7] Invasive CMV disease involves the gastrointestinal tract, liver or lungs. Chorioretinitis due to CMV is infrequent after thoracic transplantation. Symptomatic CMV infection is associated with superinfection with bacteria and fungi as a consequence of viral alteration of cellular immunity. Interestingly, CMV infection has also been associated with an increased frequency of acute and chronic allograft rejection in lung/heart-lung transplant recipients.[8]

Diagnosis

The diagnosis of CMV infection is defined by the presence of symptoms attributable to CMV in a patient with a positive culture or histology in the absence of another pathogen explaining these symptoms. While the diagnosis of CMV should be made using strategies similar to those used for other organ transplant recipients, histologic stains and CMV cultures from bronchoalveolar lavage cells or lung biopsy material are useful in confirming the diagnosis in this patient population.[9]

Prevention

To combat the numerous deleterious effects of CMV, strategies of prevention, pre-emptive treatment and monitoring have been developed. Efforts at prophylaxis of CMV infection and disease have focused on the use of intravenous or oral ganciclovir for 1–3 months following transplant. While moderately effective in low-risk patients (D-/R+ or D+/R+), the use of long-term prophylactic ganciclovir delays the symptoms of CMV disease but has not prevented primary disease in the high-risk population (D+/R-). Accordingly, the use of viral load monitoring as an indicator for initiating pre-emptive ganciclovir therapy has also been used after lung and heart-lung transplantation. Unfortunately, specific cut-offs for different assays (e.g. pp65 antigenemia assay or CMV quantitative polymerase chain reaction (PCR)) as well as the route (oral ganciclovir or valganciclovir versus intravenous ganciclovir) and duration of pre-emptive therapy have not been well defined. In our hospital, we follow the prophylactic regimen described in Table 103.2 .

Treatment

Cytomegalovirus disease following heart-lung or lung transplantation should be managed similarly to strategies for other organ transplant recipients. Ganciclovir is the principal anti-CMV agent used. However, resistant strains have appeared and represented up to 10% of lung transplant recipients in one series.[10] Ganciclovir-resistant CMV infection has been associated with more frequent disease, earlier onset of bronchiolitis obliterans and shorter survival.[11] Foscarnet and cidofovir have been used as alternatives but resistance to foscarnet has also been reported and both drugs are associated with greater toxicities than ganciclovir (for dosage, see Table 103.3). These toxicities include nephrotoxicity, neutropenia, metabolic acidosis and electrolyte disturbances. Both drugs should be adjusted to renal function. New drugs may offer benefits for the near future. Duration of therapy has traditionally been 2–3 weeks. More recently, in many centers duration of therapy is titrated to clearance of CMV viral load.

Epstein-Barr virus infection

Clinical presentation

Disease due to EBV, including EBV-related post-transplantation lymphoproliferative disease (PTLD), is an important problem in lung/heart-lung transplant recipients. Epstein-Barr virus related PTLD is more common after primary EBV infection. The incidence of PTLD after pulmonary transplantation has been reported to be as high as 20% in children and 8% in adults.[12] [13] More than half of patients are symptomatic, with clinical signs ranging from a mononucleosis-like picture with lymph node swelling through isolated PTLD lesions in the lung or gastrointestinal tract to disseminated disease or lymphoma.

Diagnosis

When PTLD is suspected, computerized tomography of the neck, chest, abdomen and pelvis should be considered to identify occult lesions. Biopsies should be obtained from suspicious lesions and sent for histologic evaluation. The use of immunohistopathologic stains for the presence of EBV (e.g. Epstein-Bar-encoded RNA — EBER — in-situ hybridization) is necessary to distinguish EBV-infected cells from non-specific lymphocytic infiltrates. Patients with active EBV disease typically have an elevated EBV viral load in the peripheral blood. Elevated loads may be present prior to the onset of EBV disease and may remain persistently high even after resolution of PTLD.

Prevention

The high rates of morbidity and mortality attributed to PTLD have prompted efforts aimed at the prevention or pre-emptive treatment of EBV. Serial monitoring of the EBV viral load using quantitative PCR assays has been shown to predict occurrence of PTLD in other transplant populations[14] and is increasingly being used to guide initiation of pre-emptive therapy. However, specific target levels of load and specific site to sample (blood versus bronchoalveolar lavage), as well as therapeutic pre-emptive treatment regimens, vary from center to center and remain to be evaluated in prospective, comparative studies.

Treatment

The management of patients with PTLD is controversial. Reduction of immune suppression is the major therapeutic manipulation for transplant recipients with EBV-PTLD. This is felt to allow the body to develop a cytotoxic T lymphocyte response to control the infectious process. Concerns over the development of rejection can limit this approach. While frequently used, antiviral therapies (primarily nucleoside analogues — e.g. ganciclovir — and immunoglobulin) are probably of only limited benefit for the treatment of EBV-PTLD. The use of the new anti-CD20 monoclonal antibody (rituximab) appears very promising for these patients. The use of chemotherapy may be necessary for patients who fail to respond to reduction of immunosuppression or in whom the PTLD lesions are judged to be malignant.

Toxoplasma gondii infection

Clinical presentation

Toxoplasma gondii is most commonly found as a pathogen after cardiac or heart-lung transplantation.[15] Primary infection is associated with the transmission of latent *Toxoplasma* cysts via the donor organ.[16] The highest risk and most severe symptomatic disease occur in seronegative recipients of heart grafts from seropositive donors (D+/R-). Transmission in this scenario can be as high as 60%. Reactivation of the patient's own toxoplasmosis on immunosuppression is around 7% but does not generally result in significant disease. Severe toxoplasmosis due to community acquisition post-transplantation has not been reported but is theoretically possible. Donor-associated toxoplasmosis most commonly occurs within 1–6 months after transplantation. Clinical signs and symptoms occur in more than 10% of patients and range from asymptomatic seroconversion to severe disease with fever, chorioretinitis, myocarditis, neurologic abnormalities and interstitial pneumonia.

TABLE 103-3 -- Treatment strategies in lung and heart-lung transplantation.

TREATMENT STRATEGIES IN LUNG AND HEART-LUNG TRANSPLANTATION			
	Treatment	**Dose and duration**	**Comments**
Cytomegalovirus	Ganciclovir (first line therapy)	5mg/kg iv q12h for 14–21d	Maintenance therapy Smg/kg/d iv q24h or consider valganciclovir
	Foscarnet	180mg/kg/d divided q8h iv for 14–21d	Maintenance therapy: 90–120mg/kg/day iv
	Cidofovir	5mg/kg once weekly for 2 weeks iv	Continuing therapy: 5mg/kg iv once every 2 weeks as clinically needed
Toxoplasmosis: adults	Pyrimethamine	200mg q24h po	Then 75–100mg q24h po
			Total treatment 3–6 weeks
	Sulfadiazine	1–1.5g q6h po	
	Folinic acid	10–15mg q24h	
Toxoplasmosis: children	Pyrimethamine	0.5–1mg/kg/day po	(max 25mg)
			Total treatment 3–6 weeks
	Sulfadiazine	60–75mg/kg q12h po	
	Folinic acid	10–15mg q24h	

Aspergillus	Liposomal amphotericin B	5mg/kg/day iv q24h for 10–14d	Followed by itraconazole indefinitely:
			Adults: 100–200mg q12h po
			Children: 3–5mg/kg/d q24h po
			Alternative treatment: variconazole
Community-acquired viruses: RSV, adenovirus, parainfluenza virus (consider treatment in severe cases or early after transplantation)	Ribavirin	6 g/day in continuous aerosolization 12–18h daily if intubated	**Specific antiviral therapies are not proven to work but can be considered**
	Cidofovir	5mg/kg once weekly for 2 weeks iv	Continuing therapy: 5mg/kg once every 2 weeks as clinically needed
			Probenecid must be administered orally with each dose, as well as hyperhydration
			Alternative dosing strategies have been used
Influenza virus	Amantadine	Adults: 200mg/d	
		Children: 2.5mg/kg q12h po	Max. 200mg/d
	Rimantadine	Adults: 100mg q12h po	
		Children: 5mg/kg/d po	Max. 150mg/d
	Oseltamivir	Adults: 75mg q12h po	
		Children>1 year old: 2mg/kg q12h po	
	Zanamivir	Adults: 10mg q12h inhaled	Duration of therapy for influenza may depend on clearance
These are the strategies used at the Children's Hospital of Pittsburgh.			

Diagnosis

When suspected, toxoplasmosis should be looked for in bronchoalveolar lavage fluid, by histologic examination of biopsies from suspected tissues, or by PCR.

Prevention

Symptomatic toxoplasmosis is rarely seen outside of the high-risk (D+/R-) setting. Accordingly, preventive strategies have focused on these high-risk patients, who are treated with pyrimethamine for 6 months following heart-lung transplantation. *Toxoplasma gondii* serologies are monitored in order to identify those patients developing primary infection despite prophylaxis. Use of this preventative strategy in mismatched patients reduces their risk of acquiring *Toxoplasma* from over 50% to less than 15%. Daily prophylaxis with trimethoprim-sulfamethoxazole is an alternative and protects against PCP as well as toxoplasmosis.[17] [18] Corticosteroids given for rejection treatment increase the risk of toxoplasmosis. High-risk patients treated for acute rejection should therefore be monitored carefully.

Treatment

Treatment of toxoplasmosis following heart-lung transplantation is similar to that for other immunosuppressed patients. The combination of pyrimethamine and sulfadiazine is the mainstay of therapy (see Table 103.3).

Other organisms

Pneumocystis carinii pneumonia is a frequent pulmonary infection in immunocompromised hosts. It has a higher attack rate among lung and heart-lung transplant recipients than in other organ transplant patients.[19] Infections tend to occur within the first year after transplant[4] but have on occasion been seen later. Symptoms range from isolated fever to serious respiratory distress leading to death. Prophylaxis with trimethoprim-sulfamethoxazole given as a single daily dose or three times a week is usually successful in preventing *P. carinii* pneumonia.[17] Recurrent *P. carinii* colonization regardless of prophylaxis has been reported in heart-lung transplant recipients.[20]

Multiply-resistant organisms

Cystic fibrosis patients represent an important cohort of heart-lung and lung transplant recipients. These patients, as well as those with a prolonged intensive care stay just prior to transplantation, are at high risk of being colonized with unusual organisms and with multiply-resistant pathogens. These organisms can take advantage of the reduced immunity and diaphragmatic dysfunction after lung/heart-lung transplantation to cause infection. It is therefore important to have baseline cultures prior to transplant to identify potential pathogens. A 2-week course of appropriate antimicrobial

therapy is recommended for all patients with cystic fibrosis based upon these culture and susceptibility results. The use of reference laboratories for the performance of synergy studies for multiply-resistant organisms should be considered.

When lung-heart-lung transplant recipients are ill with pneumonic processes it is imperative to obtain cultures from the lower respiratory tract; empiric antibiotics should be initiated after obtaining these cultures. Bacteria to consider include methicillin-resistant *Staphylococcus aureus* and resistant *P. aeruginosa* as well as more common respiratory pathogens such as *Streptococcus pneumoniae*. [21] Patients with bronchiolitis obliterans are often colonized with *Pseudomonas*, *Stenotrophomonas* or *Alcaligenes* spp. Accordingly, initial antimicrobial regimens in these patients should consider these pathogens.

Fungal infections occur frequently in lung/heart-lung transplant recipients. Fungal pathogens may be newly acquired or reactivate from sites of latent infection within lung transplant recipients.[22] *Aspergillus* spp. can present as airway colonization (25% of the transplant recipients) or invasive disease (around 5%). Colonization at the time of transplantation can result in serious disease and may be associated with dehiscence of thoracic anastomoses. However, the presence of fungi preoperatively is not a contraindication to transplantation; we recommend a prophylactic course of liposomal amphotericin B (to avoid nephrotoxicity) intravenously or via the aerosol route post-transplantation for these colonized patients, followed by oral itraconazole (see Table 103.2).

More than half of all diagnoses are made in the first 6 months after transplantation. *Aspergillus* and other filamentous fungi have also been identified as causing colonization and disease in patients who develop bronchiolitis obliterans. Currently, we use itraconazole prophylaxis in patients with bronchiolitis obliterans to prevent this complication. Incidence of progression from airway colonization to invasive disease is less than 5%. Most of the patients with isolated tracheobronchitis respond to antifungal therapy and/or surgical debridement. However, the survival rate of invasive aspergillosis is less than 50%.[23]

Nocardia species

Nocardia infection is found in 2% of lung transplant recipients and has an attributable mortality rate of 30–40%. [24] Infection with *Nocardia* typically presents in lung/heart-lung transplant recipients more than 2 years after transplantation[4] and characteristically begins in the lungs as rounded nodular infiltrates, which can cavitate. Hematogenous spread can occur to the central nervous system, skin or, occasionally, other organs. Drainage of abscesses may be beneficial and long-term antibiotics are necessary.

Viruses other than CMV and EBV cause disease in up to one-third of all lung/heart-lung transplant recipients. An important feature of these infections is that they can

mimic rejection.[4] Herpes simplex virus can reactivate or cause primary pneumonitis, which can be fatal. Acyclovir prophylaxis (see Table 103.2) is effective in preventing this problem. The community respiratory viruses such as RSV, parainfluenza virus, influenza virus and adenovirus are also important causes of disease in this population. They often involve the lower respiratory tract and may be associated with significant morbidity and mortality.[25] In addition, the insult from these viruses (particularly adenovirus) can lead to chronic sequelae such as bronchiolitis obliterans.[26] The mainstay of treatment for severe disease from community-acquired viruses is decreasing immunosuppression and supportive care. Antiviral treatments are controversial and, while licensed therapies are available for RSV (ribavirin) and influenza (e.g. amantadine, rimantadine, oseltamivir, zanamivir), no proven therapies are available for parainfluenza or adenovirus (see Table 103.3). Controlled studies are needed to help guide in their use in the lung/heart-lung transplantation population.

Chapter 104 - Heart Transplant Patients

Patricia Muñoz
Claudia Rodríguez
Emilio Bouza

INTRODUCTION

According to the 2001 Registry of the International Society for Heart and Lung Transplantation, 57,818 heart transplants (HT) were performed in the year 2000.[1] The main indications for transplantation are coronary artery disease (46%) and cardiomyopathy (45%) in adults, and congenital heart disease (75%) in children.

Overall 1-year survival for HT is 80% and from the second year on, 4% of the patients die every year. Early mortality (first year) is mainly due to postsurgical problems (10%), primary graft failure and infection (30% of first-month deaths, 45% of deaths between 1 and 3 months and 9.7% thereafter). Late mortality (after the first year) is mainly caused by cardiac allograft vasculopathy (CAV), nonspecific graft failure and malignancy (8.8% at 5-year follow-up).[2] Patient median half-life is 9 years (11.6 after the first year) and approximately 40% of the patients are working at 5 years.

Infection is a very important cause of morbidity and mortality in HT recipients and it is a variable of special interest, since it is amenable to prevention and intervention. We will now briefly review some specific characteristics of infectious complications in this population.

EPIDEMIOLOGY AND SPECIFIC RISK FACTORS FOR INFECTION

The incidence of infection after a HT ranges from 30% to 60% (with a related mortality of 4–15%) and the rate of infectious episodes per patient was 1.73 in a recent series.[3] Infections are more frequent and severe than those occurring in renal transplant recipients, but less frequent than those occurring after liver or lung transplantation. Infection was found to be the leading cause of death occurring more than 30 days after transplantation (33%).[3] The most common agents responsible for infection, the expected chronology and the main forms of clinical presentation are summarized in Table 104.1 . Bacteria or viruses cause most infections. However, fungal pathogens, *P. carinii* and parasitic infections are also important.

The time of appearance of infection after transplantation is an essential component of the evaluation of the etiology of infection. Early infections occurring within the first month after transplantation are generally similar to nontransplant patients who have undergone major heart surgery. Intermediate infections (2–6 months) are usually caused by opportunistic micro-organisms, such as CMV, fungi and multiresistant bacteria. Finally, late infections (after 6 months) may be caused either by common community pathogens in healthy patients or by opportunistic micro-organisms in patients with chronic rejection.

Many different factors influence the incidence and type of infections in HT patients (Table 104.2). They may be classified into factors related to the patient (before and after transplantation) and those due to technical complications during the operative and perioperative periods. The need for ventricular assist devices is a specific risk factor for infection in HT recipients. In some series, up to one-third of the patients on biventricular assist devices will eventually die of sepsis; bacteremia (59%), driveline infection (28%) and pump infection (11%) are also common.

As in other solid organ transplant (SOT) patients, the degree of immunosuppression and epidemiological risk factors, such as the exposure to specific microbial pathogens, are key factors that will influence the etiology of infections occurring in the postoperative period.

SPECIFIC CLINICAL SYNDROMES

We will address only a few infectious problems of special interest in the heart transplant recipient. The remaining complications do not differ from what has been mentioned in the general chapter dealing with infection in all types of solid organ transplant patients (see Chapter 102).

Pneumonia

In HT recipients, both fatal and nonfatal infections predominantly involve the lung (28% of all infections), probably as a consequence of multiple prior episodes of congestive heart failure. The etiological agents of pneumonia are similar to those of other SOT patients: 60% are caused by opportunistic micro-organisms (mainly CMV), 25% by nosocomial pathogens and 15% by community-acquired bacteria and mycobacteria.[4] Pneumonia is one of the leading causes of death after HT. Mechanical ventilation is required in 37% of the cases of pulmonary infections and death occurs in 23–31% of the patients. This rate varies widely depending on the etiology of infection. *Aspergillus* pneumonia has the worst prognosis (mortality 50–62%), followed by nosocomial pneumonia (overall mortality 26%, and up to 50% for those patients on mechanical ventilation) and CMV pneumonia (mortality 13%).[4]

Nodular lesions may be detected in 10% of HT patients. They are mainly caused by *Aspergillus, Nocardia* and CMV. *Nocardia* nodules usually appear later (median 100 days, range 89–100) after transplantation and some clinical manifestations may suggest the etiology and may help determine empiric treatment in selected cases.[5]

Other pathogens such as *Rhodococcus equi* [6] and tuberculosis should also be considered. [8] *Pneumocystis carinii* was the third cause of pneumonia in our study (13% of the isolates). The incidence was 3.6% cases per 100 HTs (2–8% in other studies). Prophylactic trimethoprim-sulfamethoxazole reduces the incidence of *P. carinii* pneumonia to nearly zero. *Mycobacterium tuberculosis* deserves special attention. The incidence of tuberculosis in HT patients in Spain is 1.35 cases/100 heart transplant-years, more than 20-fold the national average.[8] On average, tuberculosis develops 76 days post transplantation and extrapulmonary disease is common. Reactivation may be triggered by antirejection therapy, although it may be acquired from the hospital environment or even from the allograft in heart-lung transplantation. Besides the potential difficulty in establishing a diagnosis, due to its atypical, paucisymptomatic presentation, the major problem of tuberculosis in this population concerns antituberculous therapy. It has been suggested that tuberculosis should be considered in HT patients with prolonged and culture-negative febrile episodes. If the patient's condition deteriorates,

TABLE 104-1 -- Etiology, incidence and timing of infections in heart transplant patients.

ETIOLOGY, INCIDENCE AND TIMING OF INFECTIONS IN HEART TRANSPLANT PATIENTS	
Etiology	**Incidence**
Bacteria	44–60%
Viruses	40–45%
Fungi	7–15%
P. carinii	2–8%

Parasites	0.5–2%

Chronology of infection	**Most common syndromes**
Early infection (1st month)	Pneumonia
	Surgical wound infection
	Mediastinitis
	Urinary tract infection
	Catheter-related infection
	Bloodstream infection
	Antibiotic-associated diarrhea
	Herpes simplex stomatitis
	Infections transmitted with the allograft
Intermediate infections (2–6 months)	Opportunistic infections (similar to other solid organ transplant; see Chapter 102)
Late infections (after 6th month)	Common community-acquired infections
	Respiratory tract infections
	Urinary tract infections
	Varicella-zoster infections
	Opportunistic micro-organisms

prompt specific therapy should be initiated after obtaining samples for culture. There is much controversy regarding what constitutes optimal antituberculous therapy. The benefit of rifampin must be balanced against the problem it causes by interfering with the metabolism of immunosuppressive drugs, especially cyclosporin. Rifampin results in a substantial decrease in the blood levels of cyclosporin, which has been associated with fatal allograft rejection. Although some authors have suggested that rifampin may be safely used as long as therapeutic cyclosporin levels are maintained with increased

TABLE 104-2 -- Risk factors for infections in heart transplant patients.

RISK FACTORS FOR INFECTIONS IN HEART TRANSPLANT PATIENTS		
Preoperative period	**Intraoperative period**	**Postoperative period**
Pulmonary hypertension not responsive to vasodilators	Prolonged operative time	Prolonged stay in ICU
Critically ill status and mechanically ventilated patients at time of transplantation	Complicated surgical procedure	Mediastinal complications and need for reintervention
Renal insufficiency	Need for large number of blood transfusions	Prolonged hospitalization
Cardiac cachexia Prior sternotomy	Need for ventricular assist devices	Prolonged antibiotic use
Donor's CMV positive serology	Presence of pathogens in the transplant allograft	Renal insufficiency
Older age		Induction therapy with OKT3
Repeated hospital admissions		Immunosuppressive drugs and treatment of allograft rejection
Lack of pathogen-specific immunity		Immunosuppression due to concomitant viral infections
Latent infections in the donor or recipient		Retransplantation

doses, we, and others, have found that it is very difficult to manage.[8] In the improbable case that the use of rifampin is mandatory, the cyclosporin dose should first be increased 3–5-fold, with the frequency of administration increased from twice to thrice daily. Cyclosporin levels should be monitored daily until levels are stable.

Postsurgical mediastinitis and sternum osteomyelitis

HT patients have a higher risk of postsurgical mediastinitis and sternal osteomyelitis than other heart surgical patients.[7] This complication may manifest as a bacteremia or sternum instability or dehiscence (Fig. 104.1). The main causes are bacterial pathogens (staphylococci, Gram-negative rods), but *Mycoplasma*, mycobacteria and other less common pathogens should be suspected in 'culture-negative' wound infections. A bacteremia of unknown origin during the first month after HT should always suggest the possibility of mediastinitis. Risk factors are prolonged hospitalization before surgery, early chest reexploration, low output syndrome in adults and the immature state of the immune response in infants. Therapy consists of surgical debridement and repair, and antimicrobial therapy given for 3–6 weeks.

Cardiovascular infections

Infective endocarditis is a relatively rare complication of HT (1.7–6%). Most of the cases are associated with previous nosocomial infections, mainly venous access devices and wound infections. Interestingly, 80% of SOT patients who developed endocarditis in one series had no previous history of valvular disease. As in other SOT patients, fungal etiology is a common cause of endocarditis. CMV, *Toxoplasma* and parvovirus B19 may cause myocarditis in this population.

Therapy of established infections is similar to that of other immunosuppressed patients. We will therefore focus our attention on some issues related to the prophylaxis of infection.

ANTIMICROBIAL PROPHYLAXIS

Viral infections

The most common viral infections are caused by HSV (24%), varicella-zoster (25%) and disseminated CMV (14%). Kaposi's sarcoma (KS) is caused by HHV-8 and its incidence after HT (0.75%) is higher than after kidney transplant (0.28%). KS usually

Figure 104-1 Postsurgical mediastinitis due to *aureus* in a HT recipient.

Figure 104-2 Kaposi's sarcoma in a HT recipient. Primary infection by HHV-8 was demonstrated.

develops a median of 24 months after SOT and the mortality is 28.5% (Fig. 104.2). Primary infection was found to be an important risk factor for KS in our experience.[16]

TABLE 104-3 -- Most commonly used antimicrobial prophylactic therapies in heart transplantation.

MOST COMMONLY USED ANTIMICROBIAL PROPHYLACTIC THERAPIES IN HEART TRANSPLANTATION				
Prophylaxis	**Indication**	**Dose and duration**	**Comments**	
Pre-transplant vaccination for *S. pneumoniae*, *H. influenzae*, hepatitis A and B, varicella zoster	As in other patients. *S. pneumoniae*, *H. influenzae* may be repeated after 5 years Annual influenza vaccine			
	Cefazolin	Perioperative prophylaxis	1–2g every 8h iv for 48h	Should be adjusted based on resistance patterns
Trimethoprim-sulfamethoxazole	*Pneumocystis carinii*	80 or 160mg of trimethoprim component po once daily or every 12h on weekend days, or three times a week	May protect against *Nocardia* spp., *Listeria* spp., *Toxoplasma* and other bacteria	
Ganciclovir	Cytomegalovirus	po: 1g tid iv: 5mg/kg bid plus hyperimmune globulins for mismatched cases	Used as prophylaxis or pre-emptive therapy; may protect against HHV-6 and HHV-7; valganciclovir may be used if available	
Isoniazid	*M. tuberculosis*	300mg/d for 6–12 months	Low risk of toxicity	
Pyrimethamine*	Toxoplasmosis (D+R-)	25mg/d for 6 weeks	With folinic acid	

* Trimethoprim-sulfamethoxazole three times a week is an effective protection for both PCP and toxoplasmosis

CMV is the most common etiological agent of infection in HT recipients. In this group of patients focal disease usually presents as pneumonia (27%) or gastrointestinal disease (19%). Depending upon the serological CMV status of both recipient and donor, without anti-CMV prophylaxis 30–90% of HT patients will show laboratory data of infection and 10–90% associated clinical manifestations (CMV disease). Recurrent CMV infections will occur in 10–25% of patients who developed CMV disease, often in the context of severe hypogammaglobulinemia.[8] Epidemiological data suggest that there might be a link between CMV and transplant atherosclerosis.[9]

Antiviral prophylaxis

The most important aspect of prophylaxis against viral infections is anti-CMV therapy. Mismatched recipients should receive prophylaxis immediately after transplantation. Currently, ganciclovir and gammaglobulins (4–6 weeks) seem to be the most effective combination (Table 107.3).[10] In seropositive recipients and in patients receiving OKT3 or antithymocyte globulins, prophylaxis against CMV may be performed with either intravenous or oral ganciclovir.[11]

Pre-emptive therapy is warranted in those with clinical or laboratory signs of CMV infection. Anti-CMV immunoglobulins plus ganciclovir seem to be more effective than ganciclovir alone for preventing the sequelae of CMV infection.[12] Valaciclovir was found to prevent CMV reactivation in HT patients.[13] Surveillance with antigenemia or PCR is recommended for patients not receiving prophylaxis.

Other aspects to consider regarding prophylaxis of viral infections in HT patients include the following.

¦ Annual immunization with influenza vaccine (recommended).
¦ Due to the relatively benign nature of most cases of herpes simplex infection, a majority of experts suggest that 'early therapy' rather than broad and long-term anti-HSV prophylaxis is the best approach.
¦ VZV vaccine should be given to seronegative patients before transplantation. Seronegative patients should be treated with hyperimmune globulin when exposed to patients with varicella-zoster infections. The benefit of VZV vaccination after HT is unknown.
¦ Transplantation of thoracic organs in HBsAg-positive and HBV-DNA-negative recipients is followed by HBV reactivation in a high percentage of cases. However, the clinical outcome and the availability of lamivudine suggest that these patients should not be excluded from transplantation. Vaccine against hepatitis B virus should be administered to susceptible transplant candidates.

Bacterial infections

Most bacterial infections occur early after transplantation and are often associated with invasive procedures. Micro-organisms involved are *Staphylococcus aureus, Pseudomonas aeruginosa* and some enterobacteria. In addition, infections caused by *Listeria monocytogenes* and *Rhodococcus equi* usually occur in severely immunocompromised patients.[6] Finally, some patients may develop late infections, such as pneumoccocal penumonia.

Antibacterial prophylaxis

Patient should receive antibacterial prophylaxis (2–3 doses of cefazolin) for surgery (Table 104.3). Surgery and postsurgical management should be carefully performed and mechanical ventilation, chest tubes and catheters withdrawn as soon as possible.

Perioperative selective bowel decontamination is not recommended in HT patients.

S. pneumoniae and *Haemophilus influenzae* vaccines should be offered to this population, if possible before transplantation. Pneumococcal vaccination may be repeated after 5 years.

Patients should be checked for previous exposure to tuberculosis (tuberculin test and chest X-ray). Antituberculous chemoprophylaxis is indicated in patients with tuberculin test conversion, with a clear-cut history of exposure to tuberculosis or with old tuberculous lesions on chest X-rays. Tuberculin-positive patients should submit samples for mycobacterial culture and receive chemoprophylaxis with isoniazid (Table 104.3).

Fungal infections

The most common fungal pathogen after HT is *Aspergillus*. The overall incidence of invasive aspergillosis in HT patients has decreased in recent years. It reached 25% before the cyclosporin era and decreased afterwards to 3.3–14%. Aspergillosis should be considered in the differential diagnosis of all pulmonary infections in a HT

patient (Fig. 104.3).

Prompt recognition of this fungal infection is essential for achieving a successful outcome with intensive antifungal therapy. However, both clinical symptoms and radiological manifestations may be nonspecific at early stages of the disease. The isolation of *Aspergillus* species from nonsterile respiratory samples may indicate invasive infection, colonization or laboratory contamination, and therefore make decisions about treatment of symptomatic transplant recipients difficult. Isolation of *Aspergillus* is not uncommon in the transplant population. We recovered it from 10.5% of the HT recipients in our institution and rates of 1.5–4.5% have been reported in liver and kidney recipients. Our data suggest that the isolation of any species of *Aspergillus* from any respiratory tract samples obtained in a HT recipient with suspicion of infection has a positive predictive value (PPV) of 60–70%. When analyzed by species, the PPV of recovering *A. fumigatus* was 78–91%. The PPV increased to 88–100% when *A. fumigatus* was recovered from a respiratory specimen other than sputum.[17]

Antifungal prophylaxis

Very few data are available on prophylaxis against *Aspergillus* in HT.[14] We have used oral itraconazole with good results and inhaled amphotericin is used at Stanford University.[3] The role of the new

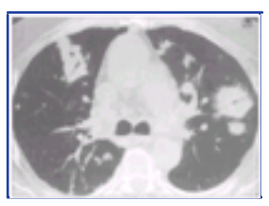

Figure 104-3 Bilateral invasive aspergillosis in a HT recipient.

antifungal drugs in *Aspergillus* prophylaxis in high-risk HT recipients remains to be determined. Anti-*Candida* prophylaxis is usually not necessary in HT patients.

Heart transplant recipients are at a substantial risk of *P. carinii* pneumonia which presents with an abrupt onset and a high mortality. Cyclosporin immunosuppression, older age, need for mechanical ventilation, low serum albumin and CMV co-infection have been reported as poor prognostic factors for *Pneumocystis* infections. Weekend TMP-SMX chemoprophylaxis has been very effective at our institution. [15]

Parasitic infections

The risk of primary toxoplasmosis is greater in HT patients (more than 50%) than either liver (20%) or kidney recipients (<1%). Patients with toxoplasmosis present with fever, altered mental status, focal neurological signs, myalgias, myocarditis or lung infiltrates. Infection transmitted by the transplanted organ is more often associated with acute disease (61%) than reactivation of latent infection (7%).

Chagas' disease is one of the principal indications for heart transplantation in some countries of South America.[16] Reactivation of the disease is a common problem that may be diagnosed by detection of *Trypanosoma cruzi* in blood or tissues, in association with symptoms or signs of infection. These episodes respond to treatment with benznidazole or allopurinol.

Antiparasitic prophylaxis

Toxoplasma-seronegative patients with positive donors are usually given 6 weeks of pyrimethamine with folinic acid. These patients may develop *Pneumocystis* infections despite standard 6-week prophylaxis against toxoplasmosis. We therefore recommend prescription of a double-strength tablet of TMP-SMX 3 days a week as prophylaxis for *Pneumocystis* infections.[17] This approach prevents both *Pneumocystis* infection and toxoplasmosis in high-risk HT patients.

Chapter 105 - Liver Transplant Patients

Raymund R Razonable
Carlos V Paya

INTRODUCTION

The care of liver transplant recipients is a challenge considering the infectious complications that contribute to significant patient morbidity and mortality rates. Up to 70% develop bacterial, viral, fungal or parasitic infections following liver transplantation. Like other organ transplant recipients, the risk for infection among liver transplant recipients is influenced by the state of immunosuppression and the epidemiologic exposures of the recipient and the donor. Furthermore, the complexities of liver transplantation surgery with the potential break in areas of high microbial load (i.e. gastrointestinal tract), and the underlying medical and infectious indications for transplantation (e.g. fulminant hepatitis, chronic viral hepatitis) predispose liver transplant recipients to unique infectious complications that may not be commonly observed among other organ transplant recipients.

The detection of active infection in the liver transplant candidate may further complicate the decision of whether and when to perform liver transplantation. Infections related to underlying cirrhosis such as ascending cholangitis and spontaneous bacterial peritonitis are not uncommon before liver transplantation. In general, all infections identified before liver transplantation should be adequately controlled before, during and after the transplant procedure. Furthermore, an underlying infection does not absolutely contraindicate liver transplantation, unless it is systemic and uncontrolled. To illustrate, advances in the control of HIV infection, a condition once considered to be a contraindication to transplantation, have paved the way for the successful management of HIV-infected liver transplant recipients.

Thus, it is essential that liver transplant candidates undergo evaluation before transplantation so that they are adequately assessed for their risks of disease caused by, for example:

- human herpesviruses — cytomegalovirus (CMV), herpes simplex virus (HSV) and Epstein-Barr virus (EBV);
- HIV;
- hepatitis viruses (A–E);
- fungi (e.g. *Coccidioides immitis*, *Histoplasma capsulatum, Aspergillus fumigatus*);
- *Treponema pallidum*;
- *Mycobacterium tuberculosis*;
- *Strongyloides stercoralis*

Likewise, potential donors should be screened for infectious pathogens that could potentially be transmitted through allograft donation.[1] The recognition of these risks will guide the implementation of preventive, diagnostic and therapeutic measures following liver transplantation (Table 105.1).

This chapter emphasizes the risk factors and infectious syndromes that are more prevalent, if not unique, to liver transplant recipients, and the strategies for their prevention and treatment. Risk factors and strategies for prevention and treatment that are common to all organ transplant recipients are discussed elsewhere in this book.

RISK FACTORS

Risks related to epidemiologic exposures, underlying diseases and characteristics of the recipient and the donor

Unlike other solid-organ transplant populations, infection-related indications for liver transplantation are relatively common. Hepatitis C virus (HCV)-induced cirrhosis is the most common indication for liver transplantation.[2] Liver failure from hepatitis B virus (HBV) infection with or without a superimposed hepatitis D virus (HDV) infection or from acute fulminant hepatitis A or B infections are other infection-related indications for liver transplantation.[3] In the absence of effective therapy, the majority of patients transplanted for HBV- and HCV-induced cirrhosis will develop recurrence of the infection following liver transplantation.[2] [3] [4] [5] Fulminant hepatitis, regardless of etiology, also increases the risk for post-transplant viral and fungal infection.[6] Active or latent infection that involves the donor or recipient liver (e.g. *H. capsulatum*, tuberculosis) may be unrecognized before liver transplantation and may manifest clinically during the post-transplantation period.

Risks related to surgical factors

One major factor that influences the occurrence of infection relates to the liver transplantation procedure itself.[6] A prolonged and complicated surgical procedure and the amount of blood loss are directly related to the risk of infection following liver transplantation. The urgency of the procedure, as commonly observed during liver transplantation for fulminant hepatitis, could result in less time for optimal preparation of patients. Abdominal re-exploration, regardless of indication (e.g. need for re-transplantation, abdominal bleeding and other vascular complications), and the type of biliary duct anastomosis (e.g. choledochojejunostomy) further predispose the liver transplant recipient to bacterial and fungal infections.

Risks related to immunosuppression

Pharmacologic immunosuppression, for example with mycophenolate mofetil (MMF), prednisone or tacrolimus, to prevent acute rejection unfortunately place patients at high infectious risk. OKT3 monoclonal antibody and high-dose corticosteroids for induction or treatment of acute rejection is associated with CMV disease and other opportunistic infections such as human herpesvirus (HHV)-6, *Aspergillus* spp. and *Pneumocystis carinii* infection. Likewise, the type and degree of immunosuppression may influence HCV replication.[2] The combination of OKT3 and MMF has been reported to accelerate the course of post-transplant HCV infection.[2] Furthermore, the reactivation of immunomodulating viruses (e.g. HHV-6 and CMV) resulting from the use of immunosuppressive agents may paradoxically enhance the state of immunosuppression and influence the occurrence of superimposed bacterial and fungal opportunistic infections.[7] It has also been suggested that CMV and HHV-6 accelerate the progression of HCV infection following liver transplantation.[2]

TABLE 105-1 -- Risk factors for acquiring infection following liver transplantation.

RISK FACTORS FOR ACQUIRING INFECTION FOLLOWING LIVER TRANSPLANTATION		
Preoperative period	**Intraoperative period**	**Postoperative period**
Lack of pathogen-specific immunity	Presence of pathogens in the transplant allograft	Prolonged hospitalization
Severity of underlying clinical illness	Prolonged operative time	Prolonged duration of stay in intensive care unit
Fulminant hepatic failure	Complicated surgical procedure	Prolonged antibiotic use
Renal insufficiency	Profound blood loss and infusion of large volume of blood products	Renal insufficiency

Anemia	Choledochojejunostomy	Gastrointestinal and biliary complications
Previous fungal infection (i.e. endemic mycoses)		Vascular complications
		Corticosteroid use and treatment of allograft rejection
		Immunosuppressive drugs
		CMV and HHV-6 reactivation
		Re-operation within 1 month post-transplantation
		Re-transplantation

CLINICAL PRESENTATION
