Foreword

The COASTAL SEDIMENTS '07 conference was organized as a technical specialty conference devoted to the physical aspects of sediment processes and morphology change in the coastal and inlet environment. Following previous conferences in the Coastal Sediments series that were held in 1977, 1987, 1991, 1999, and 2003, COASTAL SEDIMENTS'07 celebrated 30 years of the Coastal Sediments series and promoted exchange of information and views among specialists in the fields of coastal engineering, geology, oceanography, and related disciplines. The theme of COASTAL SEDIMENTS '07 was "Coastal Engineering and Science in Cascading Spatial and Temporal Scales," which established the trend of thinking and approach of the conference, as well as determined in part the composition of the papers that were presented. This theme was chosen to stimulate research devoted to the various scales of processes and their interactions at which coastal engineers and scientists must work in developing knowledge and capabilities to assist society in managing the coast under present and future conditions. Emphasis was on papers that recognize and relate to coastal morphology change of long-term consequence.

The COASTAL SEDIMENTS '07 conference returned to the site of the 1987 conference, New Orleans, Louisiana, because of the extraordinary morphologic change along the coasts of Louisiana, Mississippi, and Texas, caused by Hurricanes Katrina and Rita that struck in August and September, respectively, of 2005. In addition to the recent hurricanes, this coast is experiencing long-term natural and anthropogenic change including rapid and differential subsidence, severe reduction in renewable sediment supply, deltaic adjustment of fine-grained material, and oil and gas exploration and extraction. The theme is intended to generate papers and discussion of coastal sediment processes from the micro-scale to the regional scale at which integrated coastal design and management must be accomplished. Participants were given an overview of recent hurricane damage within the context of the long-term morphologic change in Louisiana in the Keynote Address delivered by Mr. James R. (Randy) Hanchey, Deputy Secretary of the Louisiana Department of Natural Resources.

Professor Leo van Rijn of Delft Hydraulics and the University of Utrecht, The Netherlands, accepted the 2007 Coastal Award at the Conference Awards Luncheon on May 16th. Starting in 2001, the Coastal Award has been presented every 2 years alternately at the Coastal Dynamics conference and the Coastal Sediments conference through coordination between the organizing committees of these two technical specialty conferences. The Organizing Committee of Coastal Sediments '07 joins conference participants and the extended research community in celebrating Professor van Rijn's research contributions that have greatly influenced engineers and geologists working in the areas of coastal sediment transport and morphology change.

These *Proceedings* volumes are the permanent record of the conference, containing the latest thinking and progress of the world's leading scientists and

engineers in the areas of coastal sediment transport and morphology change. The contents are a valuable source of information on coastal sediment and morphology processes ranging from basic research to case studies and lessons learned. The papers contained herein provide the most recent results and ideas in a wide range of approaches and viewpoints not assembled elsewhere in both quality and breadth. The *Proceedings* were produced in hard copy in two volumes in black and white and also provided to conference participants as a CD ROM with searchable index of PDF files in color. All papers are available to the public in PDF format via the ASCE Research Library at www.ascelibrary.org.

Three-hundred fifty abstracts were submitted to the Conference Steering Committee. On average, each abstract received five reviews, and 225 submissions were invited for development into full papers and presentation over 3 days of technical sessions. The 197 papers appearing in these Proceedings originated from approximately 24 countries, demonstrating the international scope of COASTAL SEDIMENTS '07. Each paper included in these *Proceedings* received positive peer review. Each paper is eligible for discussion in the *Journal of Waterway, Port, Coastal and Ocean Engineering* and can be nominated for ASCE awards.

The Steering Committee of COASTAL SEDIMENTS '07 gratefully acknowledges the assistance of many individuals, both known and anonymous, in the 2 years of preparations by an all-volunteer committee. Numerous individuals assisted the Steering Committee in review of abstracts and final papers. The efforts of the following persons are acknowledged: Matthew Arsenault, U.S. Geological Survey (USGS); Mark Byrnes, Applied Coastal Research and Engineering, Inc.; Duncan FitzGerald, Boston University; Guy Gelfenbaum, USGS; Cheryl Hapke, USGS; John Headland, Moffatt & Nichol; Todd Holland, Naval Research Laboratory; Peter Howd, USGS; Bruce Jaffe, USGS; Magnus Larson, University of Lund; Jeffrey List, USGS; Randy Parkinson, Coastal and Environmental Geological Consulting; Robert Morton, USGS; James O'Connell, Woods Hole Oceanographic Institution; Lisa Robbins, USGS; Vladimir Shepsis, Coast and Harbor Engineering; Donald Stauble, U.S. Army Corps of Engineers; Marcel Stive, Delft Hydraulics; Hilary Stockdon; USGS; and Curt Storlazzi, USGS.

We also thank the session moderators for agreeing to lend their time and experience to run the conference smoothly and productively. We are indebted to the tour leaders and their organizations for arranging and conducting memorable and stimulating technical trips. The "Geology of the Louisiana Coastal Zone: Implications for Coastal Management and Restoration" tour was led by Mark Kulp, University of New Orleans (UNO); Mike Miner, UNO; Duncan FitzGerald, Boston University; and Ioannis Giorgiou, UNO. The "Wax Lake-Atchafalaya Delta Complex Sedimentation, Stratigraphy" tour was led by Harry Roberts, Louisiana State University. Finally, we thank Lucy King of ASCE for assisting and often leading in conference logistics; Donna Dickert of ASCE for accurately producing the Proceedings; and Lesa Rair and Chris Hanson of COPRI for assisting with conference arrangements, including exhibitors and sponsors.

We also would like to thank our exhibitors and sponsors for Coastal Sediments 2007 for their support:

Contents

Volume One

Sediment Transport Fundamentals I

Wave-Related Transport and Nearshore Morphology 1
Leo van Rijn, Gerben Ruessink, Bart Grasmeijer, Jebbe van der Werf, and Jan Ribberink

Closed Form Solution for Threshold Velocity for Initiation of Sediment Motion under Waves 15
Hans Hanson and Benoît Camenen

Influence of Velocity Moments on Sand Bar Movement During CROSSTEX 28
Gregory Guannel, H. Tuba Özkan-Haller, Merrick C. Haller, and James T. Kirby

Development of a New Practical Model for Sand Transport Induced by Non-Breaking Waves and Currents 42
Jebbe J. van der Werf, Jan S. Ribberink, and Tom O'Donoghue

A Total Load Formula for the Nearshore 56
Benoît Camenen and Magnus Larson

Sediment Transport Fundamentals II

Longshore Sand Transport Rate Measurements Using Small-Scale Physical Models 68
Roshan Suminda Ranasinghe and Shinji Sato

Pressure-Induced Subsurface Sediment Transport in the Surf Zone 82
Ole Secher Madsen and William McKinney Durham

Tracking Sediment Particles under Wave-Current Coexisting Field 96
Yoshimitsu Tajima, Masayuki Kozuka, Masahito Tsuru, Toshimasa Ishii, Takeharu Sakagami, Kazuo Momose, Nobuo Mimura, and Ole S. Madsen

Sediment Transport in Response to Wave Groups Generated by High-Speed Vessels 110
Philip D. Osborne, Neil J. MacDonald, and Shaun Parkinson

Sediment Transport Fundamentals III

Flume Experiments under Cat-Scan to Measure Internal Sedimentological Parameter During Sediment Transport 124
Stéphane Montreuil and Bernard F. Long

The Effects of Bed Slope and Wave Skewness on Sediment Transport and Morphology 137
D. J. R. Walstra, L. C. van Rijn, M. van Ormondt, C. Briére, and A. M. Talmon

Sediment Transport off Northeast Florida Outside the Surf Zone during Hurricanes 151
Michael Krecic, Christopher Bender, and Kristen Odroniec

Longshore Transport

Geomorphic and Sedimentologic Evidence for Net Littoral Drift—A Review 165
Terry Healy

Cross-Shore Variation of Predominant Longshore Sediment Transport Rate 179
Yoshiaki Kuriyama and Hikari Sakamoto

Longshore Sand Transport Calculated by Time-Dependent Shear Stress 193
Ernest R. Smith and Nicholas C. Kraus

Sediment Budget of the Danube Delta Coastal Zone 207
Sebastian Dan, Marcel Stive, Dirk Jan Walstra, and François Sabatier

Field Measurements and Modeling of Longshore Sediment Transport 221
J. J. Williams, L. S. Esteves, M. A. Lisniowski, and H. L. S. Perotto

Sediment Transport Fundamentals IV

Infragravity Waves in Mobile-Bed Laboratory Experiments 235
Florent Grasso, Hervé Michallet, and Eric Barthélemy

Large-Scale Laboratory Modeling of Suspended Sand Concentration Fluctuations under Irregular Waves 248
Joachim Grüne, Ruben Kos'yan, Hocine Oumeraci, Igor Podymov, Reinold Schmidt-Koppenhagen, and Chris E. Vincent

Change in Longitudinal Profile Using Sand of Mixed Grain Size in Large Wave Tank and its Numerical Simulation 259
Massaya Fukuhama, Takaaki Uda, Masumi Serizawa, and Toshinori Ishikawa

Probabilistic-Deterministic Modelling of Swash Zone Morphology 272
T. E. Baldock, P. Kim Son, P. Manoonvoravong, M. P. Barnes, and J. M. Alsina

Modelling Sheet Flow Sediment Transport Using Convolution Integrals 286
P. Guard, I. Teakle, P. Nielsen, and T. Baldock

Shoreline Change Modeling

A Middle-Term Evolution Model for Beaches 300
Soledad Requejo, Raul Medina, and Mauricio Gonzalez

Model for Predicting Beach Changes on Coast with Sand of Mixed Grain Size Based on Bagnold's Concept 314
Masumi Serizawa, Takaaki Uda, Toshiro San-nami, Kou Furuike, Toshinori Ishikawa, and Takayuki Kumada

A Circulation Modeling Approach for Evaluating the Conditions for Shoreline Instabilities 327
Jeffrey H. List and Andrew D. Ashton

An Alternative Explanation for the Shape of 'Log-Spiral' Bays 341
Ryan Littlewood, A. Brad Murray, and Andrew D. Ashton

The Response of Spit Shapes to Wave-Angle Climates 351
Andrew D. Ashton, A. Brad Murray, and Ryan Littlewood

Observed Shoreline Change

Historical Shoreline Changes and Morphodynamics of Parramore Island, Virginia (1852-2006) 364
Trent M. Richardson and Randolph A. McBride

Temporal and Spatial Scales of Profile and Planform Adjustment on a Nourished Beach 378
Nicole A. Elko and Ping Wang

Shoreline Response to Dike Failure at Grand Marais Harbor, Lake Superior, Michigan 392
Rachel R. Roblin, Mohammad Dibajnia, Robert B. Nairn, and James P. Selegean

Successful Beach Modelling, Monitoring and Management for a Large LNG Facility 406
Jonathan A. Kemp, Tom C. Coates, Richard Head, and Jenny S. Harcourt

Gravel Coasts I

The Design of Stable and Aesthetic Beach Fills: Learning from Nature 420
Paul D. Komar

Variation in the Organization of Gravel-Dominated Coastal Systems: Evidence from Nova Scotia and Southern England 434
Julian D. Orford and Simon C. Jennings

Profile Dynamics and Particle Tracer Mobility of a Cobble Berm Constructed on the Oregon Coast 449
Jonathan C. Allan and Roger Hart

Mixed Sediment Beach Processes: Kachemak Bay, Alaska 463
Peter Ruggiero, Peter N. Adams, and Jonathan A. Warrick

Mixed Sand and Gravel Beach Design and Construction for Habitat Restoration 477
David Simpson, Michael Wray, John Houghton, and John Klekotka

Gravel Coasts II

Influence of Changing Management Regimes on the Morphodynamic Response of a Mixed Gravel and Sand Barrier Beach 492
Andrew P. Bradbury and Julian D. Orford

The Influence of Groundwater on Profile Evolution of Fine and Coarse Sand Beaches 506
Diane P. Horn, Tom E. Baldock, and Ling Li

Effects of Permeability on the Performance of Mixed Sand-Gravel Beaches 520
Kaiming She, Louise Trim, Diane Horn, and Paul Canning

Cross-shore and Longshore Transport of Tracer Pebbles on a Macrotidal Mixed Sediment Beach, Somme Estuary, France 531
J. Curoy, U. Dornbusch, C. A. Moses, D. A. Robinson, and R. B. G. Williams

Why Are Shingle Beaches Replacing Sandy Beaches? (Coastal Zone of NW Portugal) 545
Helena Granja and Eduardo Loureiro

Gravel Coasts III

Field Measurements of Shore Conditions to Assess Bulkhead Effects in Thurston County, South Puget Sound 561
Susan P. Tonkin, Tim Abbe, José Carrasquero, and Steve Morrison

Coral-Gravel Storm Ridges: Examples from the Tropical Pacific and Caribbean 572
Bruce M. Richmond and Robert A. Morton

Field Observations of Step Dynamics on a Macrotidal Gravel Beach 584
Daniel Buscombe, Martin J. Austin, and Gerhard Masselink

Large-Scale Scour of the Sea Floor and the Effect of Natural Armouring Processes, Land Reclamation Maasvlakte 2, Port of Rotterdam 598
Sander Boer, Edwin Elias, Stefan Aarninkhof, Dano Roelvink, and Tiedo Vellinga

Dunes and Profiles

Dune Erosion Prediction Methods Incorporating Effects of Wave Periods 612
Marcel R. A. van Gent, E. Martijn Coeveld, Hans de Vroeg, and Jan van de Graaff

Reevaluation of Equilibrium Beach Profile Scale Parameter 626
Zhanxian Wang and Robert G. Dean

Shoreface Response to Sediment Deficit 633
G. M. Kaminsky, M. A. Ferland, P. J. Cowell, H. R. Mortiz, and P. Ruggiero

Louisiana Coast

The Challenges of Restoring Louisiana Barrier Islands: From Design through Construction 647
Gordon G. Thomson, Greg M. Grandy, and Rachel Sweeney

Field Observations of Wave-Current-Sediments Dynamics, Atchafalaya Shelf, Louisiana, USA 661
Sergio Jaramillo, Alex Sheremet, and Mead Allison

Investigation of Morphosedimentary Processes on a Schematic Louisiana Barrier Island Using Process-Based Numerical Modeling 671
T. Campbell, B. de Sonneville, L. Benedet, D. J. W. Walstra, and C. W. Finkl

Restoration-Quality Sand from Ship Shoal, Louisiana: Geotechnical Investigation for Sand on a Drowned Barrier Island 685
Syed M. Khalil, Charles W. Finkl, Jeff Andrews, and Christopher P. Knotts

Mississippi River Sand for Barrier Island Restoration in Louisiana: Geophysical and Geotechnical Investigations for Sand Mining 699
Jeffrey L. Andrews, Syed M. Khalil, Charles W. Finkl, and Lindino Benedet

Mississippi River Delta

Re-Engineering the Mississippi River as a Sediment Delivery System 712
Harley S. Winer

Sediment Flux and Fate in the Mississippi River Diversion at West Bay: Observation Study 722
T. Mitchell Andrus and Samuel J. Bentley

Initial Morphologic and Stratigraphic Delta Evolution Related to Buoyant River Plumes 736
Joep E. A. Storms, Marcel J. F. Stive, Dano (J.) A. Roelvink, and Dirk Jan Walstra

Physical and Numerical Modeling of River and Sediment Diversions in the Lower Mississippi River Delta 749
Clinton S. Willson, Nathan Dill, William Barlett, Samantha Danchuk, and Ryan Waldron

A Geomorphic Process-Response Model for Chenier-Plain Evolution in Southwestern Louisiana, USA 762
Randolph A. McBride, Matthew J. Taylor, and Mark R. Byrnes

Marshes and Wetlands

Sediment Analysis for Habitat Restoration: Adaptation of Open-Coast Beach Nourishment Principles 776
Daniel J. Heilman, Joel T. Darnell, and M. Cameron Perry

Subsurface Exploration and Containment Dike Design Criteria for Coastal Louisiana Marsh Restoration 785
Russ Joffrion, Michael Poff, and Mitch Andrus

Ice Raft Formation, Dispersion and Sedimentation on New England Salt Marshes 798
Brittina A. Argow, Zoe J. Hughes, and Duncan M. FitzGerald

Effects of Large Scale Morphological Changes to a Back-Bay System 814
Lee L. Weishar, Theodore Keon, and Donald K. Stauble

Volume Two

Deltas and River Mouths

Morphodynamic Feedbacks on Deltaic Coasts: Lessons from the Wave-Dominated Danube Delta 828
Liviu Giosan

Coastal and River Mouth Morphology Change in Sri Lanka Due to 2004 Indian Ocean Tsunami 842
Hitoshi Tanaka, Kazuo Ishino, Bandara Nawarathna, Hajime Nakagawa, and Shinichiro Yano

Holocene Evolution of the Merrimack Embayment, Northern Massachusetts, Interpreted from Shallow Seismic Stratigraphy **856**
Christopher J. Hein, Duncan M. FitzGerald, and Walter A. Barnhardt

The Use of Historic Topography for the Characterization of Time-Dependent Geomorphic Change and Sediment Delivery **867**
David A. Jaffe

Impact of Hurricanes Katrina and Lili on the Inner Shelf of the Mississippi-Atchafalaya Delta **882**
Mead A. Allison, Timothy M. Dellapenna, Miguel A. Goñi, and Alex Sheremet

Storms I

Coastal-Change Impacts during Hurricane Katrina: An Overview **888**
Asbury Sallenger, C. Wayne Wright, and Jeff Lillycrop

Modeling Dune Response Using Measured and Equilibrium Bathymetric Profiles **897**
Laura A. Fauver, David M. Thompson, and Asbury H. Sallenger

Sediment Transport along the Southwestern Louisiana Shoreline: Impact from Hurricane Rita, 2005 ..... **911**
Walter S. Guidroz, Gregory W. Stone, and Dane Dartez

Heterogeneity and Dynamics on a Shoal during Spring-Winter Storm Season, South-Central Louisana, USA **921**
Daijiro Kobashi, Felix Jose, and Gregory W. Stone

Winter Storm and Tropical Cyclone Impacts on the Short-Term Evolution of Beaches and Barriers along the Northeastern Gulf of Mexico **935**
Gregory W. Stone, Baozhu Liu, and Felix Jose

Storms II

Impact of a Major Storm on Sediment Exchanges between the Dunes, Beach, and Nearshore **951**
Aart Kroon, Susanne Quartel, and Troels Aagaard

Storm Patterns and Climatic Trends Based on Water Level Fluctuations: Duck, North Carolina, USA **963**
Joan Pope

Hindcasting Potential Hurricane Impacts on Rapidly Changing Barrier Islands **976**
Hilary F. Stockdon, David M. Thompson, and Asbury H. Sallenger, Jr.

EOF Analysis of Morphological Response to Hurricane Ivan **986**
Chris Houser, Stuart Hamilton, Klaus Meyer-Arendt, and Jonathan Oravetz

Storm Surge and Sediment Process Owing to Hurricane Isidore in Terminos Lagoon, Campeche **996**
Juan C. Espinal, Paulo Salles. A de A, and Diana K. Moran

Tsunami I

Tsunami Damage Estimation in Consideration of Beach Transformation and Dike Failure 1008
Fuminori Kato, Masaya Fukuhama, Hiroyuki Fujii, and Toshimitsu Takagi

Beach Morphology at Banda Aceh, Indonesia in Response to the Tsunami on 26 December 2004 1019
Ella Meilianda, C. Marjolein Dohmen-Janssen, Ben H. P. Maathuis, Suzanne J. M. H. Hulscher, and Jan P.M. Mulder

Dune Morphology as an Indicator of Paleotsunamis 1033
James R. Goff

Sedimentological Characteristics of Regional-Scale Washover Deposits Caused by Hurricane Ivan 1047
Mark H. Horwitz and Ping Wang

Tsunami II

Impacts of the 2004 Indian Ocean Tsunami on the Southwest Coasts of Sri Lanka 1061
Robert A. Morton, James R. Goff, and Scott L. Nichol

Reconstructing Tsunami Run-Up from Sedimentary Characteristics—A Simple Mathematical Model 1075
Richard L. Soulsby, David E. Smith, and Alan Ruffman

Numerical Study of Tsunami Run-Up over Erodible Sand Dunes 1089
Takenori Shimozono, Shinji Sato, and Yoshimitsu Tajima

Predicted Sedimentary Record of Reflected Bores 1103
Bretwood Higman, Guy Gelfenbaum, Patrick Lynett, Andrew Moore, and Bruce Jaffe

Tsunami Inundation and Sediment Transport in Vicinity of Coastal Mangrove Forest 1117
Guy Gelfenbaum, Deepak Vatvani, Bruce Jaffe, and Frank Dekker

Sea Level Rise I

From Transgression to Regression: Coastal Evolution near The Hague, The Netherlands, around 5000 Years BP 1129
Ad J. F. van der Spek, Jelmer Cleveringa, and Sytze van Heteren

Changing Orientation of Ocean-Facing Bluffs on a Transgressive Coast, Cape Cod, Massachusetts 1142
Graham S. Giese and Mark B. Adams

Modeling Barrier Island Response to Sea-Level Rise in the Outer Banks, North Carolina 1153
Laura J. Moore, Jeffrey H. List, S. Jeffress Williams, and David Stolper

1880 to 2005 Morphological Evolution of a Transgressive Tidal Inlet, Little Pass Timbalier, Louisiana 1165
Michael D. Miner, Duncan M. FitzGerald, and Mark A. Kulp

Sea Level Rise II

Impacts of Rising Sea Level to Backbarrier Wetlands, Tidal Inlets, and Barrier Islands: Barataria Coast, Louisiana 1179
Duncan FitzGerald, Mark Kulp, Zoe Hughes, Ioannis Georgiou, Michael Miner, Shea Penland, and Nick Howes

Modeling Future Coastal Wetland Transition Induced by Relative Sea-Level Rise 1193
James C. Gibeaut

Morphological Interactions within UK Estuaries: A Preliminary Analysis of Critical Rates of Sea-Level Rise 1200
Kate Rossington, Robert J. Nicholls, and Michiel A. F. Knaapen

Variable Shoreline Responses to Sea-Level Rise and Climate Change 1214
A. Brad Murray, Lisa Valvo, Jordan Slott, Andrew Ashton, and Tom Crowley

Model Scenarios of Shoreline Change at Kaanapali Beach, Maui, Hawaii: Seasonal and Extreme Events 1227
Sean Vitousek, Charles H. Fletcher, Mark A. Merrifield, Geno Pawlak, and Curt D. Storlazzi

Wind-Blown Sand

Aeolian Processes, Coastal Dunes, and the *Coastal Engineering Manual*, Part III, Chapter 4—"Wind-Blown Sediment Transport" 1241
Frank Hopf and Douglas J. Sherman

Distribution of Horizontal Distance Traveled by Saltating Sand Grains in Air 1255

Abstract: This paper discusses the simulation of nearshore bar migration using the CROSMOR profile model. Two sediment transport formulations have been used : the method of Van Rijn (2006) and that of Van der Werf (2006). The model has been applied to two large-scale laboratory experiments in the Delta flume of Delft Hydraulics. Both transport models can represent the trends observed in the laboratory experiments.

INTRODUCTION

As surface gravity waves arrive at the shore from deep water, they transfrom primarily owing to shoaling, refraction, breaking, and non-linear wave interactions. These interactions cause dramatic transformations of the wave shape. From deep into intermediate waterdepths, the initially symmetric, nearly sinusoidal profiles develop into profiles with sharp crests and broad, flat troughs. This horizontal aymmetry is known as skewness. Into shallower water, the waves ultimately transform into pitched-forward, sawtooth profiles, known as (vertical) asymmetry, which have zero-skewness. Field studies, like those of Doering and Bowen (1995), have indicated that near-bed velocity skewness and asymmetry can be parameterized reasonably well with the local Ursell number, suggesting that wave non-linearity is determined locally, and does not depend on, for instance, beach slope. The mechanism for the wave shape transformation is nonlinear, near-reasonant triad interactions, involving the energy transfer from two primary waves with frequencies ω_1 and ω_2 to a secondary wave with frequency $\omega_1 + \omega_2$. This secondary wave is phase locked to the primary waves, initially with a phase difference of 0 degrees to result in a skewed wave profile, increasing to -90 degrees for a sawtooth wave.

The local non-linearity of the near-bed orbital motion is important to sediment transport. The recognition that skewed waves may induce onshore transport because of the much larger onshore than offshore velocities already dates back to the 19th century. The relevance of asymmetric waves to onshore transport (e.g., Hoefel and Elgar, 2003) is still under considerable debate (e.g., Henderson et al., 2004; Hsu et al., 2006). However, the notion that wave non-linearity leads to onshore transport only may be too simple. Fundamentally different physical processes determine sand transport rates above plane and rippled sand beds in oscillatory flow. Above plane beds, momentum transfer and associated sediment dynamics occurs primarily by turbulent diffusion. In contrast, in the bottom part of the boundary layer above rippled beds, momentum transfer and the associated sediment dynamics are dominated by coherent periodic vortex structures; above this, in a layer of thickness of about 1-2 ripple heights, the coherent motions break down and are replaced by random turbulence. The effect of this is that sand is entrained into suspension to considerably greater heights above rippled beds than above plane beds. In addition, the phase of sand pick-up from the bottom during the wave-cycle is also significantly different above rippled beds, with pick-up being linked to the phase of vortex shedding. This has potentially important consequences for the net sand transport rate beneath asymmetrical waves, which can be in the negative ('offshore') direction despite the larger positive ('onshore') orbital velocities (Van der Werf, 2006).
The aim of the present paper is to present preliminary work on the influence of bedforms, wave shape and phase-lags on wave-induced suspended sediment transport. Existing engineering transport formulations for wave-induced suspended sediment transport, like those of Houwman and Ruessink (1996), are reviewed and adjusted to incorporate phenomena like phase lags. We then incorporate the various formulations in the CROSMOR profile model and apply it to the prediction of sandbar migration in two large-scale laboratory tests. The CROSMOR model has been described earlier by the first author. Papers on the CROSMOR-model can be downloaded from www.leovanrijn-sediment.com.

CROSS-SHORE TRANSPORT PROCESSES

In recent years, many full-scale oscillatory flow tunnel experiments have been carried out in order to increase the insight of the complex nature of cross-shore sediment transport and to obtain reliable data for validation and further development of various types of models. One of the advantages of those type of experiments is that net sediment transport rates can be measured accurately. Figure 1 shows measured net sediment transport rates as a function of the mobility number $\psi=2(u_{rms})^2/((s-1)gd_{50})$, with u_{rms} =the root-mean-square orbital velocity, s=the relative sediment density, g =the acceleration due to gravity and d_{50} =the median grain-size (Van der Werf, 2006). The orbital flow was regular asymmetric with larger positive (‘onshore’) velocities and smaller negative (‘offshore’) velocities and the degree of flow asymmetry was similar across the experiments.
This figure shows that the net sediment transport rate is alternately negative (‘offshore-directed’) and positive (‘onshore-directed’), depending on presence or absence of ripples and the grain-size. For mobility numbers smaller than 100, the bed is covered with two-dimensional ripples. On the lee-side of these ripples vortices are generated, which are

ejected at times of flow reversal. As a consequence, there exists strong phase differences between the peak concentrations and peak velocities. Van der Werf (2006) shows that this results in negative net wave-induced sediment transport when suspension is dominant.

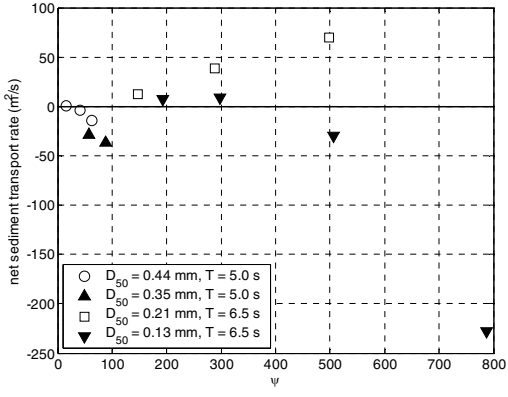

Fig. 1. Net sediment transport rates as function of mobility parameter

For larger mobility numbers, the ripples are washed out, the bed becomes plane again and the sheet-flow regime is entered. Sediment is transported in a thin layer of a few centimetres thick close to the bed. Experimental results show that net sediment transport rates mostly are in the 'onshore' direction in the sheet-flow regime, because the sediment responds almost instantaneously to the flow. However, phase lags between velocity and concentration (delayed pick-up and settling) become also important in the sheet-flow regime for finer sediments. When phase lags are important, the net sediment transport in oscillatory flow cannot be modelled in a quasi-steady way, and better agreement with the observed transport data may be obtained with the semi-unsteady transport model of Dohmen-Janssen (1999). Grasmeijer (2002) has found that the net wave-related suspended transport under irregular waves over a rippled bed in a large-scale laboratory flume (Delta flume of Delft Hydraulics) and at a field site (Egmond beach, The Netherlands) always is onshore-directed.

Figure 2 shows the schematic behaviour of the net sediment transport rate as a function of the Shields mobility parameter (θ') with: $\theta' = \tau'_{b,w}/((\rho_s-\rho_w)gd_{50})$; $\tau'_{b,w}$ = *wave-related bed shear stress*. In the ripple regime the net sand transport under low waves (mobility parameter $\theta'<1$) may become negative (in offshore direction) depending on the shape and dimensions of the ripples and the type of oscillatory flow (regular of irregular wave motion), (Van der Werf, 2006). For mobility parameters approaching 1 ($\theta' \cong 1$) the ripples will be washed out (sheet flow regime) and the net transport rate will become positive again. For very large mobility parameters ($\theta' \cong 5$ to 10) the net transport rate may become very small again due to the generation of phase lags between velocity and concentrations in the sheet flow layer (U_w=1.3 m/s, T=4 s and d_{50}=0.13 mm, see Dohmen-Janssen, 1999). Accurate modelling of wave-induced cross-shore transport and

nearshore morphology using a profile model thus requires an accurate modelling of the shape of the near-bed orbital flow and the bed form regime.

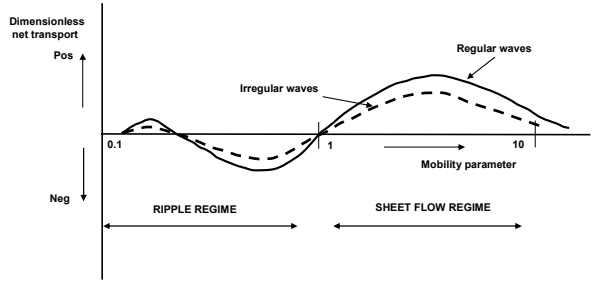

Fig. 2. Schematic behaviour of net sand transport rates (dimensionless) as function of grain-related mobility parameter

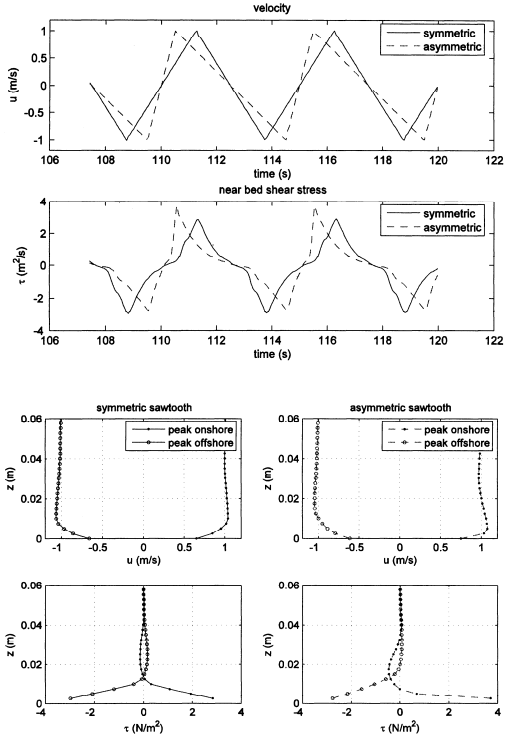

Fig. 3. Peak onshore and offshore velocities and bed-shear stresses in the case of symmetric and asymmetric saw-tooth waves

MODELLING OF BED-SHEAR STRESSES IN ASYMMETRIC WAVE MOTION

The peak orbital velocities in the CROSMOR model are computed by using the method of Isobe-Horikawa (1982), as modified by Grasmeijer (2002). This method can represent the skewness effect, but not the asymmetry effect under forward-leaning waves. In sinusoidal wave motion over a flat bed the instantaneous bed-shear stress is described as:

$$\tau'_{b,t}=0.5\ \rho_w f'_w\ |U_{w,t}|\ U_{w,t} \tag{1}$$

with: f'_w=grain-related wave friction factor, $U_{w,t}$=instantaneous orbital velocity at edge of wave boundary layer.

Basically, a detailed boundary layer model is required to compute the bed-shear stresses in strongly, asymmetric wave motion (saw-tooth waves). Figure 3 shows the bed-shear stresses in symmetric and asymmetric saw-tooth waves (strong forward leaning waves in asymmetric wave motion, U_{max}=1 m/s, T=5 s, $k_s=2.5d_{50}$) based on results from a boundary layer model including k-ε based turbulent shear stresses (Grasmeijer, 2004). It can be seen that the peak bed-shear stress increases by about 10% to 15% in asymmetric wave motion (second panel from top).

Nielsen (1992) has suggested a method to compute the instantaneous bed-shear stress under skewed wave motion including enhanced acceleration effects in asymmetric waves. This method includes the phase lead (φ_τ) of the bed-shear stress compared with the free-stream velocity.

The method of Nielsen (1992) for turbulent flow conditions reads, as:

$$\tau'_{b,t}=0.5\rho_w f'_w\ |[\cos(\varphi_\tau)\ (U_{w,t})+\omega^{-1}\sin(\varphi_\tau)(dU_w/dt)]|/[\cos(\varphi_\tau)(U_{w,t})+\omega^{-1}\sin(\varphi_\tau)(dU_w/dt)] \tag{2}$$

The time derivative can be evaluated as: $dU_w/dt= (U_{w,t+\Delta t} - U_{w,t-\Delta t})/(2\Delta t)$. In the case of a simple sinusoidal wave motion, Equation (2) yields a simple sinusoidal bed-shear stress shifted forward by the phase angle φ_τ. In the case of asymmetric wave motion the bed-shear stresses are enhanced during times of acceleration. For waves with saw-tooth type of asymmetry this leads to a dominant onshore shear stress and hence net onshore transport. This enhancement of the bed-shear stress from higher harmonics expresses the physical fact that high-frequency waves have thinner boundary layers and hence larger shear stresses. Wijetunge and Sleath (1998) have made velocity measurements using LDA in oscillatory flow in a wave tunnel to determine the phase lead effects. The phase lead of τ_{max} (with respect to free-stream velocity) is found to be about 45^o just above the non-moving bed and about 30^o at y=0 (initial bed) and about zero at 10 mm above the bed (near top of sheet flow layer).

The method of Nielsen (1992) has been used to compute the bed-shear stress under asymmetric waves described by $U=U_1\cos(\omega t)+U_2\cos(2\omega t)$. The data of an experiment of Ribberink et al. (2000) have been used as input data: U_{max}=1.45 m/s, U_{min}=-0.7 m/s, T=9 s, d_{50}=0.21 mm, d_{90}=0.32 mm, $q_{b,net}$=108 10^{-6} m^2/s=0.29 kg/s/m. Figure 4 shows the instantaneous free-stream velocity and the dimensionless mobility (Shields) parameter

$\theta' = \tau'_{b,t}/((\rho_s-\rho_w)gd_{50})$ with $\tau'_{b,t}$ based on Equation (2) without phase lag and with phase lag. The friction factor is taken as f'_w=0.01. Computed results are shown for phase leads of 0, 10°, 25° and 40° degrees (Figure 4). The curves are shifted forward for phase lags (leads) of 10°, 25° and 40° degrees. The peak bed-shear stress increases with increasing phase lag. Using a simple bed-load transport formula, Nielsen and Callaghan (2003) show that the inclusion of the acceleration effects leads to a much better agreement of the computed net sand transport rate with measured values for a large-scale wave flume experiment. Wave-related streaming effects were found to be much less important. Herein, it is assumed that the method of Nielsen (1992) yields sufficiently accurate results of the instantaneous bed-shear stress in asymmetric wave motion.

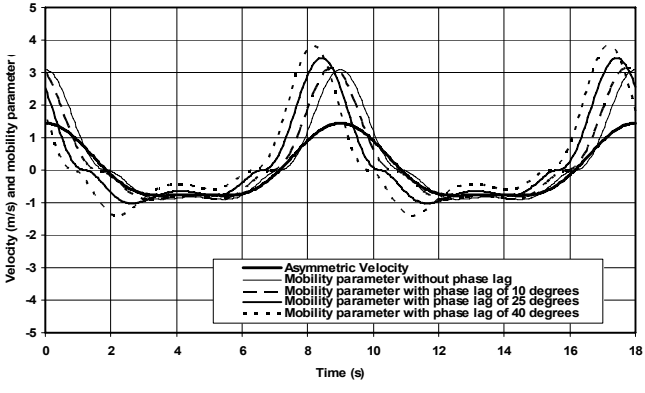

Fig. 4. Velocity and mobility (Shields) parameter as function of time; asymmetric velocity

BED FORM REGIME

As the value and direction of the net sediment transport is strongly related to the type of bed forms (ripples or flat bed), it is necessary to predict the type of bed forms and their effective bed roughness. Van Rijn (2006, 2007) has proposed a method to predict the effective bed roughness (k_s) of the bed forms in combined current and wave conditions.

CROSS-SHORE BED-LOAD TRANSPORT

It is assumed that the instantaneous bed-load transport rate (kg/s/m) is related to the instantaneous bed-shear stress, which is based on the instantaneous velocity vector (including both wave-related and current-related components) defined at a small height above the bed. The formula applied, reads as:

$$q_b = \gamma \rho_s d_{50} D_*^{-0.3} [\tau'_{b,cw}/\rho]^{0.5} [(\tau'_{b,cw} - \tau_{b,cr})/\tau_{b,cr}]^{\eta} \quad (3)$$

in which: $\tau'_{b,cw}$= instantaneous grain-related bed-shear stress due to both currents and waves= $0.5\,\rho f'_{cw} (U_{\delta,cw})^2$; $U_{\delta,cw}$= instantaneous velocity due to currents and waves at edge of wave boundary layer; f'_{cw} = grain friction coefficient due to currents and waves= $\alpha\beta f'_c + (1-\alpha) f'_w$; f'_c = current-related grain friction coefficient, f'_w = wave-

related grain friction coefficient, α= coefficient related to relative strenght of wave and current motion, β= coefficient related to vertical structure of velocity profile, $\tau_{b,cr}$= critical bed-shear stress according to Shields, ρ_s= sediment density, ρ= fluid density, d_{50} = particle size, D_* = dimensionless particle size, γ= coefficient= 0.5, η= exponent= 1 (based on calibration by using measured data, see Van Rijn, 2006).
The net bed-load transport rate can be obtained by time-averaging (over the wave period T) of the instantaneous transport rate using a bed-load transport formula for steady flow (quasi-steady approach), as follows: $q_b = (1/T) \int q_{b,t}\, dt$ with $q_{b,t}$ = F(instantaneous hydrodynamic and sediment transport parameters).
Equation (3) is based on the assumption that the sediment particles respond instantaneously (quasi-steady) to the oscillatory fluid motion near the bed. The net transport rate will always be in the direction of the largest peak orbital velocity. This assumption is reasonably valid for the sheet flow regime with sediment particles larger than about 0.2 mm. According to Dohmen-Janssen (1999), the phase-lag effects can be very well represented by the parameter $P=\delta_s\omega/w_s$ with δ_s= thickness of sheet flow layer (order of 0.01 m), $\omega=2\pi/T$=angular frequency, T= wave period. Phase-lag effects are important for fine sediment, large peak orbital velocities and small wave periods (P>0.5). Dohmen-Janssen (1999) proposed to correct the bed-load transport rates based on quasi-steady expressions, using a correction factor dependent on the P-parameter. Thus: $q_{b,net}= r\, q_{b,net,\ steady}$ with $r=F(p)$=correction factor between 0 and 1, $q_{b,net,\ steady}$=net bed-load transport according to quasi-steady expression. Using this approach, the net bed-load transport rate will be reduced but the net transport rate can not be against the direction of the largest peak velocity, which may occur over a rippled bed.

CROSS-SHORE SUSPENDED LOAD TRANSPORT

Two methods to compute the cross-shore transport rates are herein explored on their ability to represent the cross-shore transport in a cross-shore profile model. (CROSMOR). Both models can deal with negative oscillatory suspended transport rates due to the presence of rippled beds.

Method of Houwman and Ruessink (1996)

The wave-related suspended transport can also be estimated by the approach introduced by Houwman and Ruessink (1996).
The wave-related suspended transport at level z is given by:

$$q_{s,w,z}=(1/T)\ {}_o\int^T <U_w C_w> \tag{4a}$$

Using: $C_w=k_1 / U_w^3 /$, it follows that:

$$q_{s,w,z}=(1/T)\ {}_o\int^T [k_1 U_w / U_w^3 /dt] \tag{4b}$$

Using: $U_w=U_{on}\, sin(\omega t)$ with $\omega=2\pi/T$ for $0<t<0.5T$ and $U_w=U_{off}\, sin(\omega t)$ for $0.5T<t<T$, the time-averaged concentration is given by:

$$c_z=(k_1/(0.5T))\ {}_o\int^{0.5T} / U_{on}^3 / sin^3(\omega t)dt + (k_1/(0.5T))\ {}_{0.5T}\int^T / U_{off}^3 / sin^3(\omega t)dt=$$

$$=k_1(2/T)\,[U^3_{on}+U^3_{off}]\ {}_o\int^{0.5T} \left|\sin^3(\omega t)\right| dt \tag{4c}$$

The k_1-coefficient of Equation (4c) is substituted in Equation (4b), resulting in:

$$q_{s,w,z}=(1/T)\ c\ {}_o\int^{T} [A^{-1}][U_w \left|U_w^{\,3}\right| dt] \tag{4d}$$

with: $A= (2/T)\,[U^3_{on}+U^3_{off}]\ {}_o\int^{0.5T} \left|\sin^3(\omega t)\right| dt$
This yields:

$$q_{s,w,z}=\gamma\,[(U^4_{on}-U^4_{off})/(U^3_{on}+U^3_{off})]\ c \tag{4e}$$

with: $\gamma=I_3/I_4;\ I_3=(1/T)\ {}_o\int^{0.5T} \sin^4(\omega t)dt;\ I_3=(2/T)\ {}_o\int^{0.5T} \left|\sin^3(\omega t)\right| dt$; the γ-value is $9\pi/64\cong0.44$.

The total wave-related suspended transport component in the near-bed region can be estimated, as follows:

$$q_{s,w} = \gamma f_P\,[(U_{on})^4-(U_{off})^4]/[(U_{on})^3+(U_{off})^3]\ \int c\ dz \tag{5a}$$

with: $U_{on}=U_{\delta,f}$= near-bed peak orbital velocity in onshore direction (in wave direction) and $U_{off}=U_{\delta,b}$= near-bed peak orbital velocity in offshore direction (against wave direction), c= time-averaged concentration (integrated over the wave boundary layer) and γ= coefficient, f_P= function to include phase lag effects. Grasmeijer (2002) has determined the γ-coefficient by fitting of Equation (5a) to the measured wave-related transport rates, yielding values in the range of 0.1 to 0.2
As phase lag effects are related to the wave conditions, sand size and bed geometry (ripples), the f_p-function is supposed to be a complicated function of these parameters (yielding negative values for very fine sand).

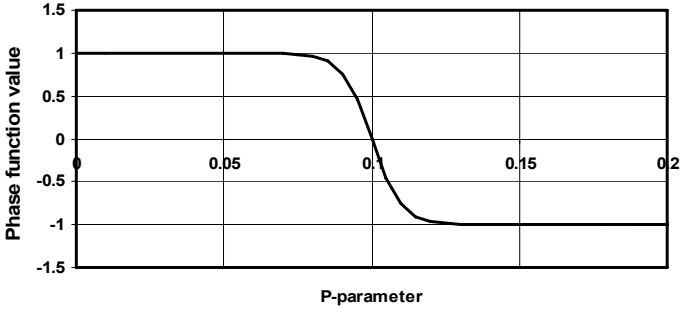

Fig. 5. Phase function of wave-related suspended transport

Assuming that the net suspended transport in onshore or in offshore direction is of the same order of magnitude (maximum values are about +0.02 or -0.02 kg/m/s), the phase

function is herein assumed to vary between +1 (fully onshore-directed) and -1 (fully offshore-directed). The phase function is tentatively described by (see Figure 5):

$$f_P = -\tanh[100(P-P_{cr})] \quad (5b)$$

with: $P=k_{s,w,r}/(w_s T_p)$, $k_{s,w,r}$=wave-related bed roughness height (estimate of ripple height), w_s= settling velocity of bed material, T_p=peak wave period, P_{cr}=0.1, yielding onshore transport for $P<P_{cr}$ and offshore transport for $P>P_{cr}$.
Simulation of the wave-related suspended transport according to Equation (5) requires computation of the time-averaged sand concentration profile and integration of the time-averaged sand concentration profile in vertical direction. Herein, the integration is taken over a near-bed layer with a thickness equal to about 10 times the thickness of the wave boundary layer (about 0.25 to 0.5 m), assuming that the suspended sand concentrations above this layer are not much effected by the high-frequency wave motion with periods in the range of T= 5 to 10 s. This assumption is satisfied if the fall time of a suspended sand particle over a distance of 0.25 to 0.5 m is much larger than the wave period ($T_{fall}= 0.5/w_s$ yielding about 25 s for d= 0.2 mm with w_s= 0.02 m/s). Furthermore, the data of the Deltaflume (Grasmeijer, 2002) show that most of the wave-related suspended transport occurs in the near-bed layer with a thickness of about 0.5 m (10 to 20 times the ripple height).

Method of van der Werf (2006)
Using a large amount of net transport data from oscillatory flow tunnel experiments, Van der Werf (2006) has developed a relatively simple model for net transport (mainly suspended sediments) in oscillatory flow over a rippled bed following the ideas of Dibajnia and Watanabe (1992). It is based on the division of the wave motion into an onshore and an offshore directed half wave-cycle. The net transport is the sum of both onshore and offshore quantities, as follows:

$$q_t = 6.75\,[Y/|Y|][|Y|^{0.64}][(s-1)g(d_{50})^3]^{0.5} \quad (6a)$$
$$Y = [U_c\,T_c\{(\Omega_{c1})^3+(\Omega_{t2})^3\} - U_t\,T_t\{(\Omega_{t1})^3+(\Omega_{c2})^3\}]/[(U_c+U_t)T] \quad (6b)$$

with:
q_t= net sand transport (m^2/s)
$P_w=\Delta_r/d_{50}$=vortex suspension parameter
$P_{w,cr}$=35
Δ_r=ripple height (measured or predicted); herein $k_{s,w,r}=\Delta_r$
$f'_w = exp(-6+5.2(A_w/2.5d_{50})^{-0.19})$=grain-related friction factor
A_w= orbital excursion amplitude
U_c= representative peak wave crest velocity (onshore-directed, positive value)
U_t= representative peak wave trough velocity (offshore-directed, positive value)
T_c= duration of wave crest phase
T_t=duration of wave trough phase
$T = T_c + T_t$=wave period
if $P_w \le P_{w,cr}$

$\Omega_{c1}=0.5\, f'_w\, (U_c)^2/((s-1)gd_{50})$=onshore-entrained and onshore-directed transport
$\Omega_{c2}=0$
$\Omega_{t1}=0.5\, f'_w\, (U_t)^2/((s-1)gd_{50})$= offshore-entrained and offshore-directed transport
$\Omega_{t2}=0$
if $P_w>P_{w,cr}$
$\Omega_{c1}=(P_w/P_{w,cr})0.5\, f'_w\, (U_c)^2/((s-1)gd_{50})$=onshore-entrained and onshore-directed tr.
$\Omega_{c2}=((P_w-P_{w,cr})/P_w)\ 0.5\, f'_w\, (U_c)^2/((s-1)gd_{50})$=onshore-entrained and offshore-directed
$\Omega_{t1}=(P_w/P_{w,cr})0.5\, f'_w\, (U_t)^2/((s-1)gd_{50})$= onshore-entrained and onshore-directed tr.
$\Omega_{t2}=((P_w-P_{w,cr})/P_w)\ 0.5\, f'_w\, (U_t)^2/((s-1)gd_{50})$=offshore-entrained and onshore-directed

The model has been developed for wave-only flows and is valid in the rippled bed regime only. Currently, a new practical model for net sand transport induced by non-breaking waves and currents is being developed within the SANTOSS research project (see the Coastal Sediments 2007 paper by Van der Werf et al.).

If P_w is larger than $P_{w,cr}$, the total amount of entrained sediment during a wave cycle should be divided in two parts: one part transported as bed load and near-bed suspended load during the same half wave cycle and a second part transported as suspended load (in the opposite direction) during the next half cycle. Net transport rates become negative (offshore-directed) when more sand is transported during the offshore half cycle than during the onshore half cycle. This occurs when P_w is approximately twice as large as $P_{w,cr}$. If P_w is smaller than $P_{w,cr}$, there is no sediment interaction between the two half wave cycles, transport takes place only very close to the bed, entrained and transported in the direction of the peak velocity.

Cross-shore morphology

Two tests from the LIP experiments (Sánchez-Arcilla, 1995) have been used to study the effect of wave-related transport on the nearshore morphology using the process-based CROSMOR profile model. Test1B simulates a storm condition with a breaker bar in the surf zone moving in offshore direction (offshore event). Test 1C simulates a typical swell condition (post-storm) with a breaker bar in the surf zone moving in onshore direction (onshore event). The bed material consists of sand with d_{10}=150, d_{50}=200, d_{90}=400 μm. The offshore water depth (h_o) to still water level is 4.1 m in all tests. The model is run in standard mode with all cross-shore wave, flow and sand transport processes included (Van Rijn 2006, 2007). The effect of the wave-induced fluid acceleration in asymmetric waves on the bed-shear stress and hence on the bed-load transport has been included. The computed wave-related net sand transport rates (due to wave asymmetry) are found to be in onshore direction, when the phase lag effects on sand transport processes are excluded. The wave-breaking induced undertow causes offshore-directed sand transport rates. Bed level changes depend on the gradients of the balance of these two transport components.

Test1B

Figure 6A,B shows the measured and computed wave heights, undertow velocities and peak orbital velocities for Test 1B. Computed wave heights are rather good. The

computed undertow velocites are in good agreement with the measured values with exception in the region close to the waterline. Computed peak orbital velocites are in good agreement with measured values. Measured data in the region close to the waterline are not available.

Figures 7A,B show the measured and computed bed levels after 18 hours using the transport method of Van Rijn. The generation and migration of the outward breaker bar is simulated rather well for Test 1B. When only the undertow transport component is taken into account, the simulated bar is in its most outward position (Fig. 7A). Conversely, when only the onshore wave-related transport components are taken into account, the simulated bar is in its most inward position (Fig. 7A). The observed bar behaviour is slightly better simulated if the acceleration effects based on the method of Nielsen are included (Figure 7B). Fluid acceleration effects do not seem to be very important for breaking wave conditions, because wave velocity skewness is suppressed in breaking wave conditions. Inclusion of phase lag effects has not much influence on the computed bed levels. The model also predicts an inner bar with sand eroded from the beach for Test 1B; the measured bed profile does not show this behaviour. Thus, the physics close to the shore are not simulated properly. Both the undertow velocity and the wave asymmetry have to be improved significantly.

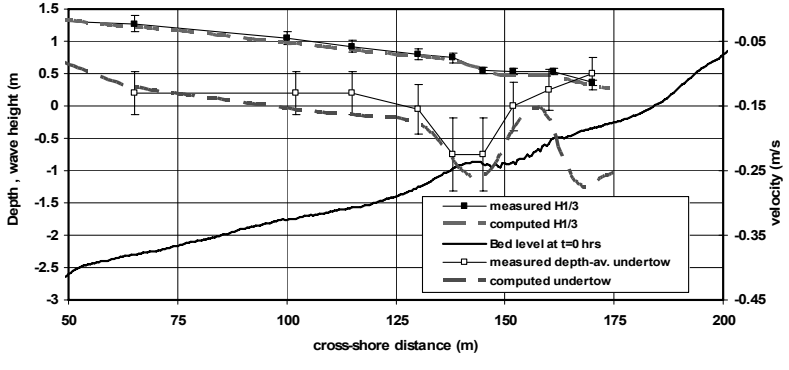

Fig. 6A. Measured and computed wave height and undertow for Test 1B

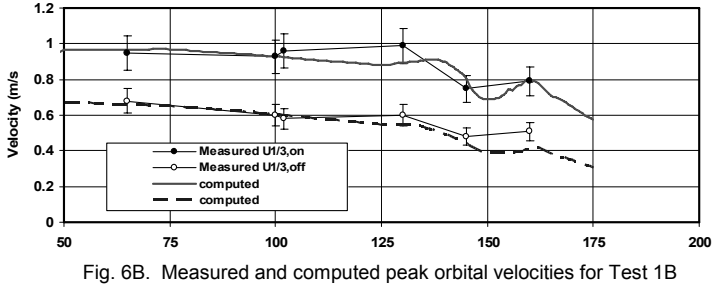

Fig. 6B. Measured and computed peak orbital velocities for Test 1B

Figure 7C shows measured and computed bed levels using the transport method of Van

der Werf (Equation 6). This method yields transport values of the right order of magnitude, but it can not yet simulate the undertow transport component. The offshore bar migration is much too small excluding the undertow transport component and much too large including the undertow transport component (based on the Van Rijn method).

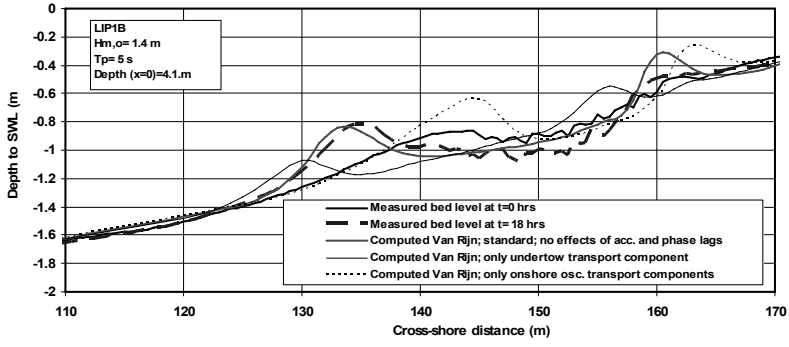

Fig. 7A. Measured and computed bed levels for Test 1B; method Van Rijn

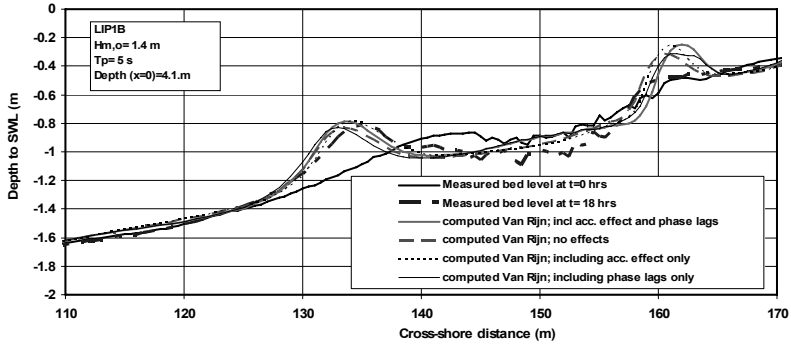

Fig. 7B. Measured and computed bed levels for Test 1B; method Van Rijn

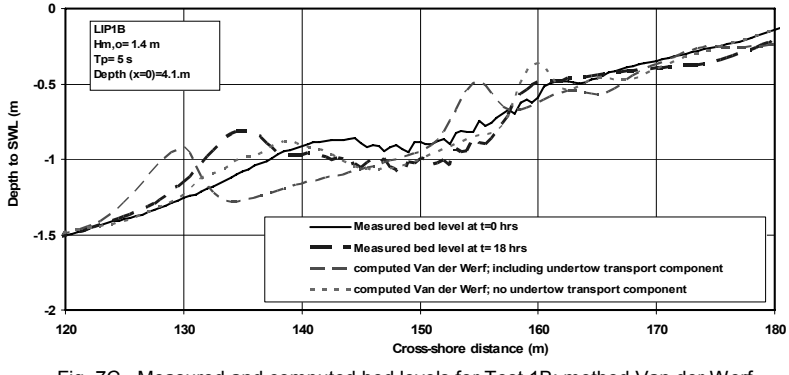

Fig. 7C. Measured and computed bed levels for Test 1B; method Van der Werf

Test 1C

Figure 8 shows that the standard model of Van Rijn also yields onshore bar migration, but the onshore migration is much too small. Inclusion of the acceleration effect on the bed-load transport improves the prediction. Inclusion of phase lag effects has almost no effect, which means that phase function predicts onshore-directed suspended load transport in agreement with the observed onshore bar migration. Probably, the observed bed ripples are not steep enough (under irregular waves) to generate strong vortex motions with phase lags between sediment concentration and orbital velocity and hence offshore-directed transport. The transport method of Van der Werf (Equation 6) produces similar trends (not shown) as for Test 1B; the transport rates are of the right order of magnitude. The bar moves onshore neglecting the undertow transport component, but it moves offshore including the undertow transport component.

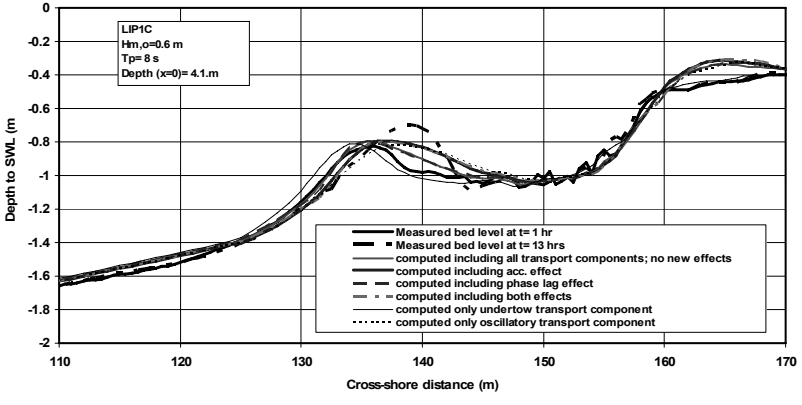

Fig. 8. Measured and computed bed levels for Test 1C; method Van Rijn

CONCLUSIONS

Summarizing, the model runs show that the sediment transport model of Van Rijn can simulate the qualitative aspects of the outer surf zone dynamics reasonably well. Fluid acceleration effects on bed-shear stress and hence on sand transport appear to be important for low wave conditions, but not for storm conditions (breaking waves). It is most important to model the onshore-directed wave asymmetry transport and the offshore-directed transport by the undertow correctly. Phase lag effects influencing the wave-related transport do not seem to be very important under irregular waves over a sand bed of about 0.2 mm. Future work will be focussed on improvement of the wave skewness and asymmetry close to the shore. The transport model of Van der Werf (2006) can represent the trends observed in the laboratory experiments. However, the validity of this model is limited to wave-only flows over rippled beds. Currently, the model is being extended to also cover the flat-bed/sheet-flow regime and to include the current-related related transport.

Abstract: The present paper presents a rational expression for the initiation of motion for non-cohesive sediment under rough turbulent wave conditions. Previously proposed relationships for the initiation of motion are examined as well as laboratory measurements corresponding to fully rough turbulent boundary layers (which is normally the case under prototype conditions). By combining the modified Shields criterion as proposed by Bagnold (1963) with the wave friction factor, f_w, from Jonsson (1966), an easily applied criterion for the threshold velocity for incipient motion under rough turbulent conditions. The new relationship is formulated as $U_{w,cr} = 4\sqrt{\varphi_{cr}}\left[1.1\ \log_{10}\left(\sqrt{\varphi_{cr}T}/(\pi d_{50})\right) - 0.08\right]^{1/0.9}$. Predictions with the new criterion are shown to be in good agreement with measurements over the full range of typically encountered engineering conditions.

INTRODUCTION

The threshold of sediment motion is of central concern in calculating littoral transport under wave action. Based on experimental data in steady current, Shields (1936) proposed a critical value for the bottom shear stress as a function of the grain Reynolds number $\Re_* = u_* d_{50}/\nu$ where $u_* = \sqrt{\tau/\rho}$ is the friction velocity, τ is the bottom shear stress, ρ is the fluid density, ν the kinematic viscosity of the fluid, and d_{50} is the median grain size. He proposed to use a dimensionless shear stress to characterize the threshold value for the sediment transport. This dimensionless shear stress is nowadays well-known as the Shields parameter:

$$\theta_{i,cr} = \frac{f_i U_i^2}{2(s-1)gd_{50}} \tag{1}$$

where the subscript i may be replaced by c (current related terms) or w (wave related terms), f is the friction factor, U is the horizontal near-bottom velocity, $s = \rho_s/\rho$ is the relative density of the sediment, and g the acceleration due to gravity. He found, using steady current data (*c.f.* Fig. 1), that the critical Shields parameter varies from 0.04 to 0.07 depending on the particular Reynolds number.

For practical applications, the Shields relationship is, however, inconvenient as the critical shear velocity appears on both sides. For this reason, many authors (Valembois 1960; Madsen and Grant 1976; van Rijn 1984; Soulsby 1997) proposed relationships between the critical Shields parameter and the dimensionless grain size $d_* = (g(s-1)/\nu^2)^{1/3} d_{50}$ (see Fig. 1). A simple algebraic expression that fits Shields' curve closely was proposed by Soulsby and Whitehouse (1997):

$$\theta_{c,cr} = \frac{0.24}{d_*} + 0.055\left[1 - \exp\left(-0.02 d_*\right)\right] \tag{2}$$

However, using more recent data, Soulsby (1997) observed much smaller values for $\theta_{c,cr}$ when $d_* < 2$. He thus proposed a modification of Eq. 2(Fig. 1):

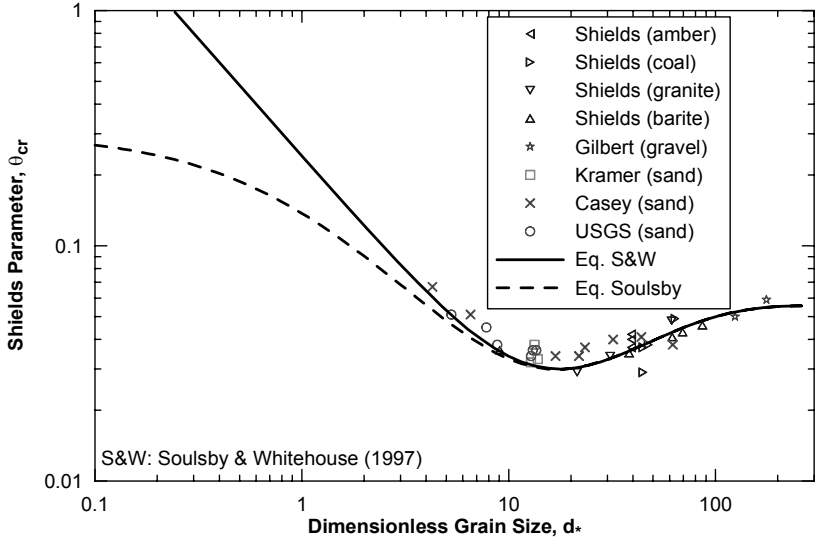

Fig. 1. Critical Shields parameter as a function of the dimensionless grain size for steady current data (data from Brownlie 1981).

$$\theta_{c,cr} = \frac{0.30}{1+1.2d_*} + 0.055\left[1-\exp\left(-0.02d_*\right)\right] \tag{3}$$

It is, however, difficult to define the exact threshold of sediment transport from the incipient motion regime where a few particles on the bed surface are seen to be moving and the general surface motion which corresponds to a well-defined and reproducible transition from occasional motion to general motion of the uppermost particles (Chan *et al.* 1972).

Many authors (van Rijn 1984; Soulsby 1997) also assumed that the results for steady currents can be extended to waves, and combined waves and currents using the maximum value of the Shields parameter over a wave cycle. However, large uncertainties about the critical Shields parameter seem to occur in the case of waves as the estimation of the wave-related friction coefficient strongly affects the results. As Camenen and Larson (2005) pointed out, the estimation of the critical Shields parameter has a significant influence on the bed load flux for low regimes. It is, thus, fundamental to provide better estimation of the threshold velocity and the critical Shields parameter for the inception of movement. The main objective of this study is to derive a closed form solution for the threshold velocity for initiation of sediment motion under oscillatory water waves that has a reasonable accuracy and that is easy to use.

ESTIMATION OF THE CRITICAL VELOCITY FOR THE INITIATION OF SEDIMENT MOVEMENT

Background

A large number of studies (mostly in laboratory) and empirical relationships concerning the threshold velocity for sediment motion have been presented in the literature. For example, Madsen and Grant (1976) demonstrated that the critical Shields parameter together with the non-dimensional parameter $S_* = \sqrt{(s-1)gd_{50}^3}/(4\nu)$, give a good description of reanalyzed older experimental data, provided that the boundary shear stress is related to the wave friction factor, f_w, as presented in Jonsson (1966). Like the ordinary Shields curve, this modified version is somewhat difficult to use in a practical situation. Here, the Shields parameter is based on the maximum value of the boundary shear stress during one wave period. Komar and Miller (1975) and Komar (1976) found, also using the results of Jonsson (1966), that the threshold condition is well described by:

$$\frac{U_{w,cr}^2}{(s-1)gd_{50}} = \alpha\left(\frac{2A_{w,cr}}{d_{50}}\right)^{\beta} \tag{4}$$

where $U_{w,cr}$ is the maximum near-bottom horizontal velocity and $A_{w,cr}$ is the water particle horizontal amplitude at the bottom according to linear wave theory. For grain sizes smaller than 0.5 mm, $\alpha = 0.21$ and $\beta = 0.5$, respectively; and for grain sizes greater than 0.5 mm the coefficient values are set to $\alpha = 0.68\pi$ and $\beta = 0.25$, respectively. These

two expressions are comprehensive and easy to use. There is, however, a discrepancy between the two expressions in the region of small wave periods and grain diameters around 0.5 mm. According to the authors themselves, the diagram should not be used in this area. Thus, it is not valid for waves and sediment typical for a large number of beaches around the world. Hallermeier (1980) proposed a very simple criterion where the threshold velocity only depends on sediment diameter and density according to:

$$U_{w,cr} = \sqrt{8(s-1)gd_{50}} \tag{5}$$

In the present study it will be shown, after comparison with experimental data, that this relationship is too simplistic. In conclusion, for the determination of threshold conditions for initiation of sediment motion, there seems to be a choice between more "accurate" curves which are somewhat complicated to use and more convenient curves which are not valid under typical field conditions.

Chan *et al.* (1972) investigated the effect of the kinematic viscosity (no significant influence found) and the relative particle density on the inception of the sediment transport (general movement of the upper layer). Using their own experimental data with various particles characteristics and fluid densities, they proposed the following empirical relationship, where T is the wave period:

$$U_{w,cr} = 0.37\left(\frac{2\pi}{T}\right)^{-0.5}\left[(s-1)g\right]^{0.75} d_{50}^{0.25} \tag{6}$$

Proposed threshold relationship

Employing the classical definition of the wave friction factor, f_w, according to $\tau_{w,cr} = 0.5 f_w U_{w,cr}^2$ together with the definition of the Shields parameter, $\theta_{w,cr}$ (cf. Eq. 1), we can derive:

$$f_w U_{w,cr}^2 = 2\theta_{w,cr}(s-1)gd_{50} \equiv \varphi_{cr} \tag{7}$$

In the rough turbulent case, the wave friction factor, f_w, is independent of the wave Reynold's number and related to the relative roughness k_s/A_w only (Jonsson 1966) as

$$\left(\frac{1}{4\sqrt{f_w}}\right) + \log_{10}\left(\frac{1}{4\sqrt{f_w}}\right) = \log_{10}\left(\frac{A_w}{k_s}\right) - 0.08 \tag{8}$$

where k_s is the Nikuradse roughness height. It is difficult to estimate k_s for a rippled and duned bottom, but for a plane horizontal bottom of non-cohesive material, it may be taken as $k_s = 2d_{50}$ (Yalin 1977). It should be noted however that Eq. 8 is not applicable for small values of A_w/k_s. In order to better fit the data (see below), the original formulation of (Jonsson 1966) is slightly modified in this study according to:

$$\left(\frac{1}{4\sqrt{f_w}}\right)^{0.9} + \log_{10}\left(\frac{1}{4\sqrt{f_w}}\right)^{1.1} = \log_{10}\left(\frac{A_w}{k_s}\right)^{1.1} - 0.08 \tag{9}$$

With $A_w = U_w T/(2\pi)$, Eq. (9) may be combined with Eq. (7) to yield a closed form solution of the critical threshold velocity as:

$$U_{w,cr} = 4\sqrt{\varphi_{cr}}\left[1.1\,\log_{10}\left(\frac{\sqrt{\varphi_{cr} T}}{\pi d_{50}}\right) - 0.08\right]^{1/0.9} \tag{10}$$

In order to evaluate this proposed Eq. (10), comparisons need to be made against experimental results. These will be made in three stages as the threshold velocity depends on the determination of the critical Shields parameter value as well as the wave friction factor.

COMPARISON AGAINST EXPERIMENTAL DATA

Wave Friction Factor

For the wave friction factor, Eq. (9) is plotted against the available data together with the proposed formulations of Jonsson (1966), Swart (1974), and Nielsen (1992) in Fig. 2. As seen from Table 1 (where *e.g.* $P_{1.2}$ means percentage of calculated values within a factor of 1.2 from the measurements) Eq. (9) and the Nielsen (1992) relationship appear to yield the best results among the studied formulas.

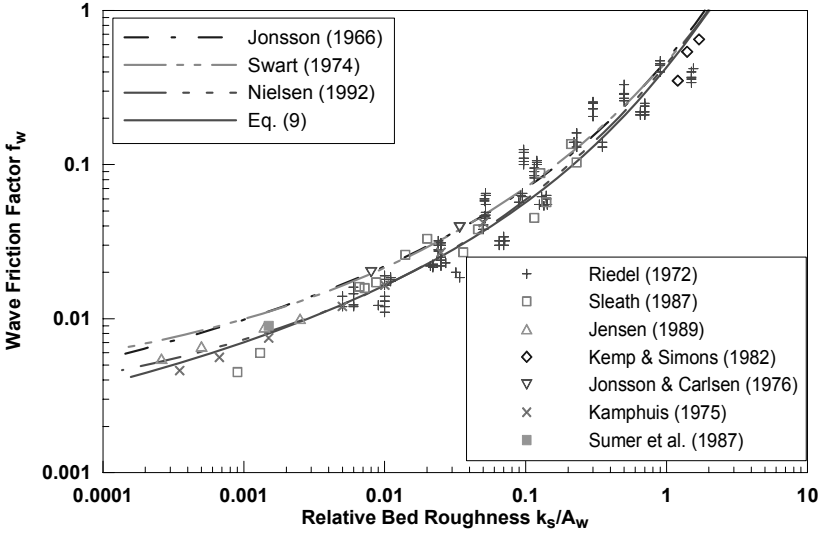

Fig. 2. Proposed relationships and measured values for the wave friction factor in the rough turbulent regime.

Table 1. Calculated measures of accuracy (%) of the calculated wave friction factor.			
	$P_{1.2}$	$P_{1.5}$	P_2
Jonsson (1966)	39	74	98
Swart (1974)	35	74	98
Nielsen (1992)	42	83	98
Eq. (9)	44	83	98

Critical Shields Parameter

As previously discussed, the Shields criterion may be extended to define the threshold of sediment motion under oscillatory water waves. Fig. 3 shows threshold data under waves together with the proposed expressions for a steady current (Eqs. 2 and 3). It is obvious that the data do not support the lines derived from the original Shields curve. Based on this result, two new expressions for the critical Shields parameter are proposed here. As opposed to the previous estimation based on steady current, it seems that $\theta_{w,cr}$ is not increasing with smaller values of d_* when $d_* < 10$ or for larger values of d_* when $d_* >100$. Also, it seems that larger values of $\theta_{w,cr}$ are observed for larger values of d_* under waves compared to the results for steady currents. As a straight-forward approach, a representative value on the critical Shields parameter of $\theta_{w,cr} = 0.07$ (based on a best fit) independent of grain size is suggested (dash-dot line in Fig. 3). One would suspect, however, that the critical Shields parameter for the inception of movement should be a function of the dimensionless grain size (*cf.* Eq. 5). For this reason, a simple relationship dependent on grain size (full line in Fig. 3) is also proposed for testing against the data:

$$\theta_{w,cr} = 0.08\left[1 - \exp\left(-15/d_* - 0.02d_*\right)\right] \tag{11}$$

Table 2 examines the accuracy of the predictions within specified limits for the different relationships together with the average value and standard deviation of the difference $\Delta U_{w,cr} = U_{w,cr,c} - U_{w,cr,m}$ where $U_{w,cr,c}$ and $U_{w,cr,m}$. are the calculated and measured values of the critical Shield parameter values, respectively. The *P*-values are a direct measure of the accuracy of the predictive relationship. A small avg($\Delta U_{w,cr}$) value indicates that the predicted values are evenly spread on either sides of the correct value while a small std($\Delta U_{w,cr}$) value indicates that the predicted values are close together. None of these two latter values are, however, a direct measure of accuracy.

Table 2. Calculated measures of accuracy (%) and spreading of the calculated critical Shields parameter.					
	$P_{1.2}$	$P_{1.5}$	P_2	avg($\Delta U_{w,cr}$)	std($\Delta U_{w,cr}$)
Soulsby & Whitehouse (1997)	19	51	86	-0.0200	0.0152
Soulsby (1997)	19	49	82	-0.0208	0.0159
$\theta_{w,cr} = 0.07$	34	73	94	0.0114	0.0171
Eq. (11)	56	88	99	0.0045	0.0137

As seen from Table 2, Eq. (11) significantly improves the results compared to the other relationships. This equation is quite similar in its form to that of Eq. (2) (Soulsby and Whitehouse 1997) except that it does not grow for smaller values of d_*. The minimum

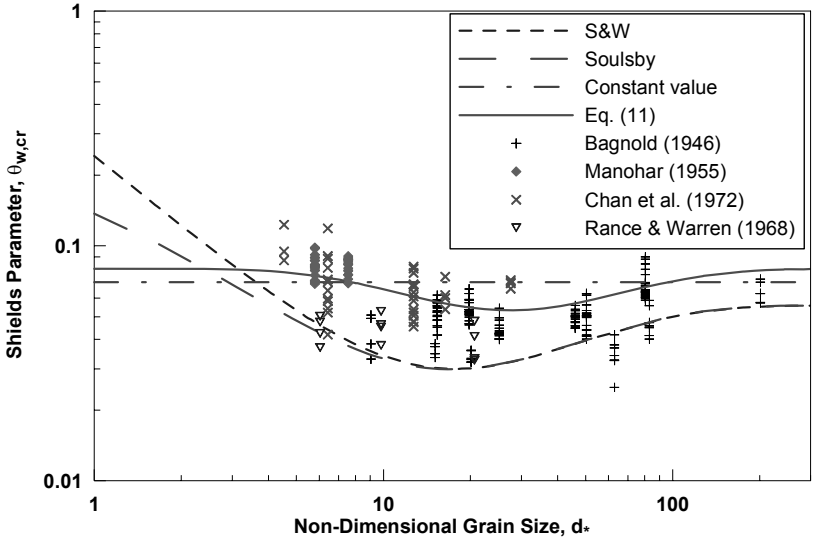

Figure 3: Critical Shields parameter as a function of the dimensionless grain size under oscillatory water waves.

value for $\theta_{w,cr}$ is also observed for a larger d_* ($d_{*,min}$ = 40 instead of 20 looking at the Shields study). Soulsby (1997) suggested that the average rather than the peak bed shear stress may be used in case of waves (and wave and current interaction). Using Eq. (3), this would, however, lead to an underestimation of the results for the critical Shields parameter prediction The results for the fixed Shields parameter value is doing surprisingly well, much better that Soulsby and Whitehouse (1997) or Soulsby (1997). While the constant value has no dependency on grain size, the other two seem to be too sensitive to the grain size. It appears, thus, that the results for a steady current cannot so easily be extended to situations involving waves.

Critical Velocity for Initiation of Motion

In order to compare Eq. (10) with experimental results, portions of the data from Bagnold (1946), Manohar (1955) and Rance and Warren (1968), corresponding to fully rough turbulent conditions, as well as the data from Chan *et al*. (1972) were examined. Measured values of the incipient velocities $U_{w,cr,m}$ are compared to those given by Eq. (10) $U_{w,cr,c}$, where Shields parameter is given as a constant and by Eq. (11), respectively (*cf*. Tab. 3). In addition, the proposed solution is compared to those of Chan *et al.* (1972), Komar and Miller (1975), and Hallermeier (1980), respectively. Statistically, the proposed Eq. (10) using a fixed Shields parameter doing somewhat better than that of Komar and Miller and significantly better than that of Chan *et al*. or Hallermeier. Eq. (10) in combination with a varying Shields parameter according to Eq. (11) is not strong on the $P_{1.2}$ level but doing much better on the other two levels.

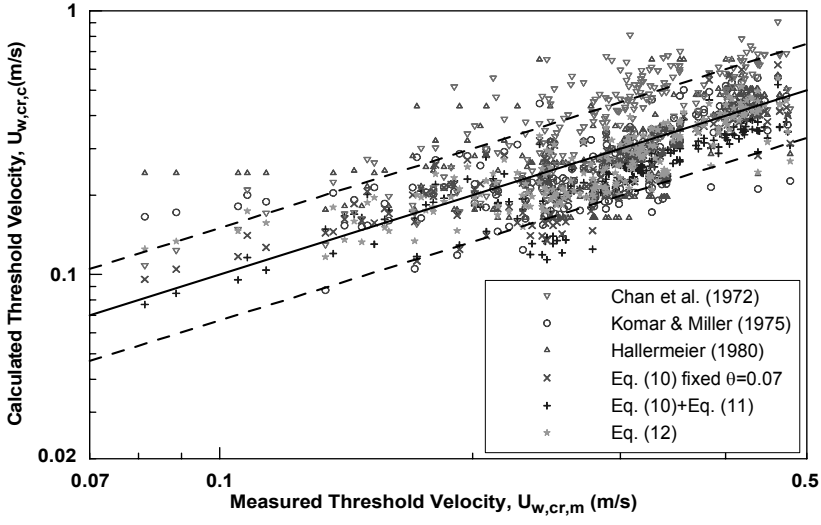

Figure 4: Calculated vs. measured threshold velocities for the initiation of motion under oscillatory water waves. Solid line indicates calculated value = measured value. Dashed lines indicate values within a factor of 1.5.

Following the work by Chan *et al*. (1972) and Hallermeier (1980) but using all the available data, a simple empirical function for the threshold velocity is proposed (see Eq. (12) in Fig. 4 and Table 3):

$$U_{w,cr} = 0.5\sqrt{\left[(s-1)g\right]^{1.25} d_{50}^{0.75} T^{0.5}} \tag{12}$$

The comparison against the experimental data shows that Eq. (12) yields better results than even Eq. (10) with a fixed Shields parameter. Also, it yields much better results compared to the other formulas.

Table 3. Calculated measures of accuracy (%)and spreading of the calculated threshold velocity for initiation of motion under oscillatory water waves.

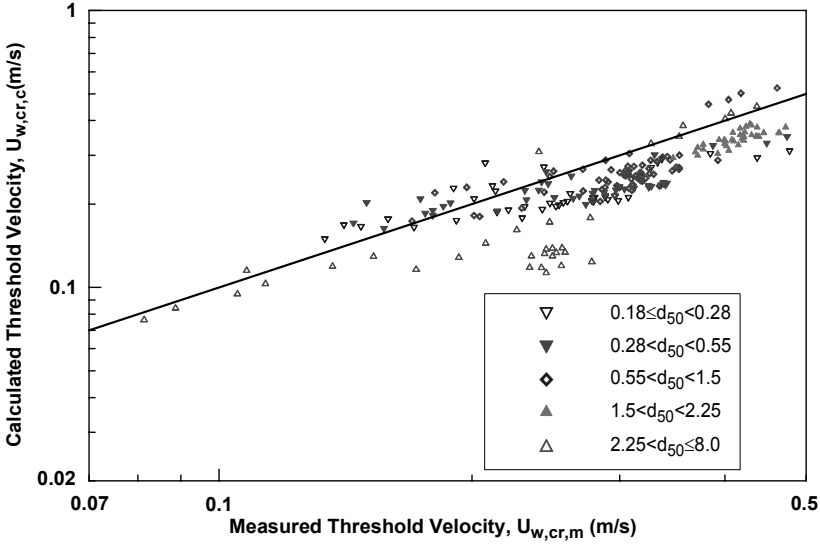

Fig. 5. Estimation of the threshold velocity; comparison between Eqs. (13)-(15) and experimental data. The straight line indicates calculated value = measured value.

Recommended Relationships

From these results it would be tempting to recommend Eq. (12). However, as the threshold velocity and the critical Shields parameter are linked it seems more appropriate to use a coherent set of $\theta_{w,cr}$ and $U_{w,cr,m}$ that both are in reasonable agreement with data. Thus, this study leads to the recommendation to use Eq. (11) for $\theta_{w,cr}$ and then use Eq. (10) in combination with Eq. (11) to calculate $U_{w,cr,m}$, *i.e.*

$$\theta_{w,cr} = 0.08\left[1-\exp\left(-15/d_* - 0.02d_*\right)\right] \tag{13}$$

$$U_{w,cr} = 4\sqrt{\varphi_{cr}}\left[1.1\,\log_{10}\left(\frac{\sqrt{\varphi_{cr}T}}{\pi d_{50}}\right)-0.08\right]^{1/0.9} \tag{14}$$

with

$$\varphi_{cr} = 2\theta_{w,cr}\left(s-1\right)gd_{50} \tag{15}$$

In Fig. 5, the threshold velocity $U_{w,cr}$, estimated from Eqs. (13)-(15) is compared to experimental measurements. It shows the very good correlation between the theory and the data. It seems, however, that the predictions are slightly underestimated for all grain sizes, especially for the coarser particles.

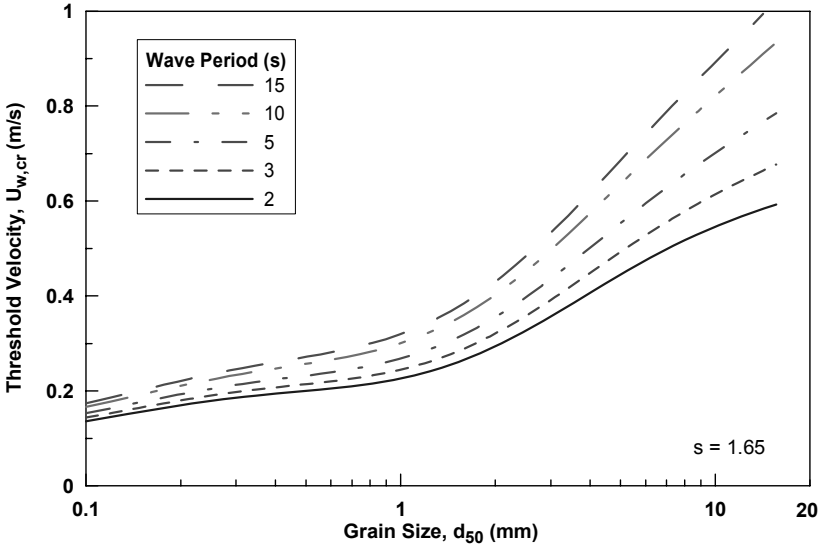

Fig. 6. Proposed near-bottom velocities for initiation of motion under rough, turbulent oscillatory water waves.

Having gained confidence in Eq. (14) it is now possible to draw proposed "design curves" for the threshold velocity for initiation of motion as shown in Fig. 6. For smaller grain sizes, the influence of wave period is less pronounced than for coarser sediments.

Critical Wave Height for Initiation of Motion

With the critical bottom velocity determined by Eq. (10), the corresponding critical wave height H_{cr} at a particular depth h_{cr} may be calculated according to linear wave theory as:

$$H_{cr} = \frac{U_{w,cr}T}{\pi}\sinh\left(\frac{2\pi h_{cr}}{L}\right) \tag{13}$$

where L = wave length at depth h_{cr}. This relation is displayed in non-dimensional form in Fig.7. Inversely, this relationship may be solved for the water depth h_{cr} out to which sediment will move under a specific wave condition to yield:

$$h_{cr} = \frac{L}{2\pi}\ln\left(\frac{\pi H_{cr}}{U_{w,cr}T} + \sqrt{\left(\frac{\pi H_{cr}}{U_{w,cr}T}\right)^2 + 1}\right) \tag{14}$$

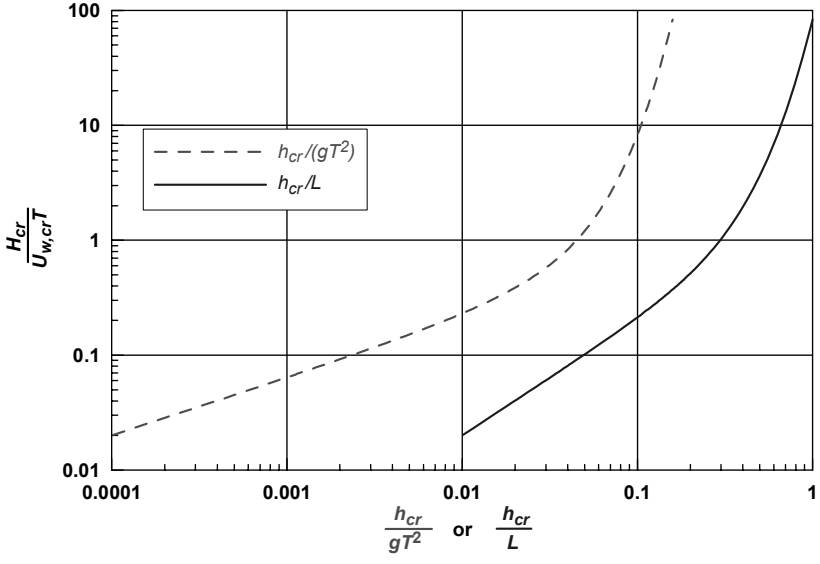

Fig. 7. Non-dimensional wave height $H_c/(U_{w,cr}T)$ versus non-dimensional water depth $h_c/(gT^2)$for the initiation of motion under rough, turbulent oscillatory water waves.

CONCLUSIONS

A study of the threshold velocity and critical Shields parameter has been undertaken for rough oscillatory flows. New relationships were proposed for the estimation of the critical Shields parameter as well as the threshold velocity for initiation of sedment motion under waves (Eqs. 13-15). The expression for the threshold velocity is an easy to use criterion for practical evaluation of sediment threshold conditions under rough, turbulent field wave conditions. The proposed relation has no ambiguity for any applicable grain size or wave period.

The proposed relationship for the threshold velocity has a tendency to underpredict measured threshold velocities, especially for coarser grain sizes. These discrepancies are mainly caused by factors inherent in this simplified derivation but also due to the difficulties in identifying the threshold situation in the laboratory. However, threshold velocities in nature are expected, as a result of sloping and rippled bottom, to be lower than those measured for plane horizontal bottom in the laboratory.

Abstract: During the 2005 CROSSTEX laboratory experiments, a series of bar generation and degeneration events and repeated cycles of offshore and onshore transport were documented. These changes were driven by regular modifications to the specified incident wave field. Based on collected bathymetric data we first assessed the spatial and temporal movement of two sand bars. We used hydrodynamic and video data to relate the movement of these bars to the occurrence of wave breaking and the magnitudes of undertow, velocity skewness and acceleration skewness. This analysis indicates that undertow currents generated the first sand bar through offshore-directed transport. The second bar was formed by onshore transport, with the first bar serving as the likely sediment source. On the other hand, onshore migration and degeneration of both sand bars correlated well with acceleration skewness.

INTRODUCTION

Many investigations in the recent past have focused on identifying processes responsible for cross-shore sediment movement and sand bar migration in the surf. It is now widely accepted that undertow currents move sediment offshore (Thornton and Humiston, 1996; Gallagher et al., 1998; Elgar et al., 2001) and are responsible for the formation of sand bars. On the other hand, processes responsible for onshore sediment movement are more difficult to pinpoint, although recent efforts indicate that acceleration skewness and other factors, such as drift velocity, boundary layer

streaming, pressure gradients, or plug flow might play significant roles (e.g. Hoefel and Elgar, 2003; Henderson et al., 2004, Foster et al., 2006).

Experimental data is required in order to evaluate the relative importance of the various transport processes. However, while there is currently a wealth of data involving offshore bar migration events, there is relatively little concerning onshore migration. To fill that gap, the CROSSTEX (CROss-Shore Sediment Transport EXperiment) experiment was conducted at the O. H. Hinsdale Wave Research Laboratory (HWRL) at Oregon State University.

Four different teams of investigators were involved in CROSSTEX, each focusing on different processes, such as the evolution of sand ripples, turbulence, sand bar migration and swash zone processes. The present authors were principally involved in the sand bar migration portion of these experiments, which will be discussed in further detail in the remainder of this paper.

In the following sections, we will first describe the set-up and implementation of the experiment. Then we will describe the spatial and temporal evolution of the bars, and relate the evolution to the measured velocity moments. Finally, we will investigate correlations between the spatial and temporal evolutions of two of these bars with variables such as wave breaking, the undertow strength, velocity skewness, and acceleration skewness.

EXPERIMENTS AND BED RESPONSE

Experimental set-up

CROSSTEX took place in the HWRL's 104m-long Large Wave Flume (LWF; see Figure 1) from June to September 2005. This flume was selected because its dimensions are ideal to conduct most experiments at near prototype scale. For these experiments the LWF was filled with well sorted, fine to medium sand mined from Florence, Oregon, with a median grain size D_{50}=0.22mm, and a standard deviation of σ_Φ=0.3. Prior to our experiments, the bed profile was adjusted to an average slope of 1V:20H through wave action.

The LWF is equipped with a flap wavemaker that can generate regular and irregular waves, a mobile cart with a vertically moving frame where various instruments can be mounted, as well as a Multiple Transducer Array (MTA) to conduct bathymetric surveys. The coordinate origin is located on top of the east wall of the tank and aligned with the wave paddle. Consequently, in all tables and figures presented in this paper, X is onshore positive and Z is positive up.

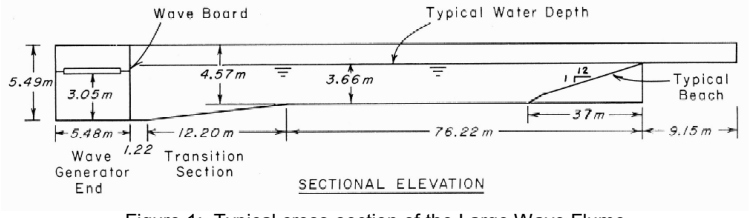

Figure 1: Typical cross-section of the Large Wave Flume

The cross-shore evolution of water surface elevation was measured with twelve resistance-type wave gauges mounted along the walls of the flume. Eight wall-mounted Vectrino Acoustic Doppler Velocimeters (ADVs) and Optical Backscatter Sensors (OBSs) were also deployed in order to observe the near-bottom hydrodynamics and sediment concentrations, as depicted in Figure 2 and in Table 1.

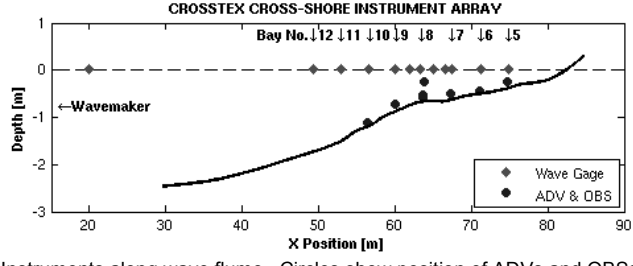

Figure 2: Instruments along wave flume. Circles show position of ADVs and OBSs, and diamonds show position of wave gages.

Table 1: Position of Wall Mounted ADVs and OBSs

Bay		5	6	7	8			9	10
X [m]	ADV	75	71	67	64	64	64	60	56
	OBS	75	71	67	64	64	64	60	56
Dist. Abv Bed [cm]		10	2	7	9	5	42	9	4

In addition to wall-mounted instruments, one wave gauge, eight ADVs, four Electromagnetic Current Meters (EMCMs), seven OBS, and twenty Fiber-Optic Backscatter Sensors (FOBSs) were also placed on the cart's mobile frame. Typical elevations of the cart instruments during deployments are presented in Figure 3.

Cart instruments were deployed at different cross-shore locations during different runs, and lowered before each wave run so that the lowermost ADVs would capture velocity fluctuations at one centimeter above the bed, and the lowermost FOBS sensor would sit one centimeter inside the fixed bed. Finally, three ARGUS cameras (Holman, et al., 1993) were installed above the LWF and are used here to evaluate percent wave breaking at various cross-shore locations.

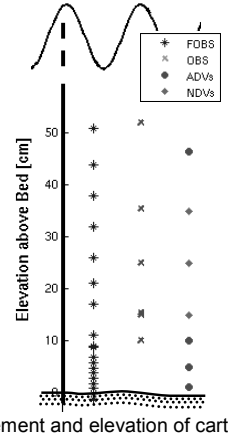

Figure 3: Typical arrangement and elevation of cart mounted instruments.

Experimental conditions

The objectives of the experiment were to first generate an offshore breaker bar and then to move that bar onshore. Consequently, the generated wave field (TMA spectrum) was modified as the experiment progressed. At the beginning, relatively high energy waves were generated to move sediment offshore. Once an offshore bar was generated, wave height and period were adjusted to create conditions conducive to onshore bar movement (see Table 2). Regular bathymetric surveys were performed to verify that designed waves were indeed causing the bar(s) to move in the intended direction.

Table 2: Consecutive Wave Conditions during Experiment

Wave Height [m]	Wave Period [s]	Wave Time [min]
0.60	4.0	210
0.30 – 0.32	8.0	675
0.55 – 0.35	3.5	135
0.40 – 0.32	5.5	330
0.320 – 0.175	3.5	795

The experiment involved approximately 36.5 hours of wave action (36.5 wave hours), and consisted of several fifteen minutes runs (or 15 wave minutes). This length was determined based the limitations of the data acquisition system, and to limit effects of seiching.

Bed evolution

Three main stages of bed evolution were identified during the course of the experiment:

1. Generation of an offshore bar (Figure 4a), during the first 210 minutes of waves.
2. Recession of the offshore bar and growth of a "middle bar" (Figure 4b), from wave time 210 to 900 minutes.
3. Recession of middle bar and smoothing of profile (Figure 4c), from wave time 900 to 2200 minutes.

It is worth mentioning that we also observed the rapid formation and decay of a nearshore terrace/bar very close to shore, while the middle bar was still evolving. Also, we observed the formation of mega-ripples (Figure 4b, final profile) between the middle bar and the nearshore terrace, or bar. We will not evaluate the dynamics of these bedforms in this paper.

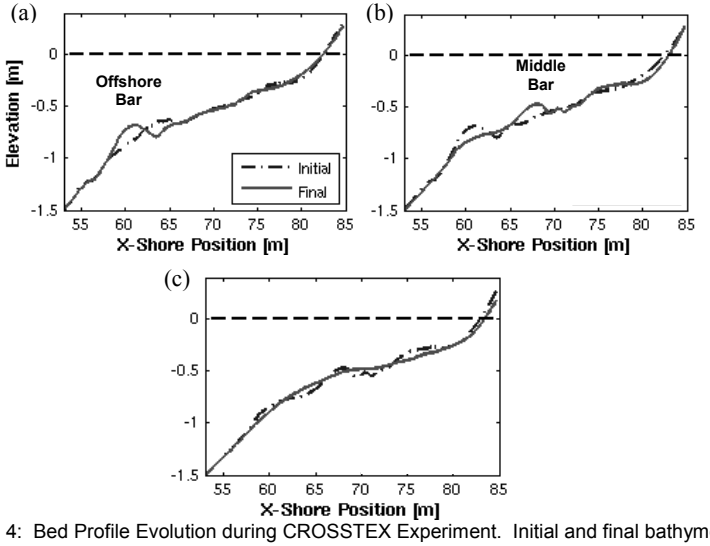

Figure 4: Bed Profile Evolution during CROSSTEX Experiment. Initial and final bathymetries are shown by the dashed and solid lines, respectively.

In conclusion, during this experiment we were able to generate three sand bars and other bedforms by varying wave conditions in the tank. Furthermore, we collected detailed bathymetric, hydrodynamic and sediment concentration data at various locations throughout the tests. These data will enable us to better evaluate wave conditions and processes responsible for cross-shore sediment movement. In the remainder of this paper, we will focus on the life cycle of the offshore and middle bars.

WAVE CONDITIONS AND SAND BAR GENERATION/DEGENERATION

In order to characterize the morphologic response to the range of wave fields generated in the LWF, we identified several representative parameters for the offshore and middle sand bars, as defined in Figure 5, and tracked their evolution

through time. These parameters were bar height and position, and bar half-width. Together, these parameters provide a good, general representation of the spatial and temporal evolution of the two bars.

As mentioned earlier, undertow and acceleration skewness have been recognized as cross-shore velocity moments that correlate well with cross-shore migration of sand bars. So, in order to assess their role in the evolution of the sand bars, we will relate these quantities, as well as amount of breaking, to the temporal and spatial characteristics of the bars. Some of the hypotheses drawn from this analysis will be confirmed by looking at sediment flux values, which provide information about sediment sources and pathways.

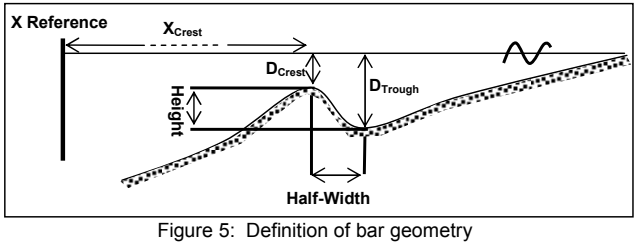

Figure 5: Definition of bar geometry

Spatial and Temporal Evolution of Sand Bars

Using the computed bathymetric data, we first plotted bar height versus cross-shore position for the two bars (Figure 6). These figures show that the bars take different paths during generation when their heights start to increase and during degeneration, when height decreases; initial and final position during this cycle are close, but not identical.

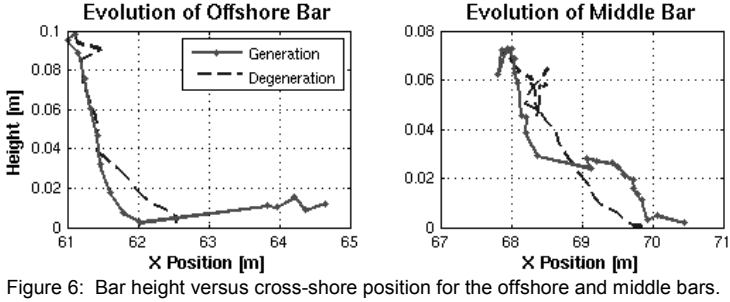

Figure 6: Bar height versus cross-shore position for the offshore and middle bars.

We also plotted bar height and position as a function of time for both sand bars, as shown in the third and fourth panels of Figure 7. In this figure, we also show percent of wave breaking (color bars, second panel) computed from the Argus videos that were collected during 23 runs. We do not have data for the other runs, so most of the color bars are separated by white space.

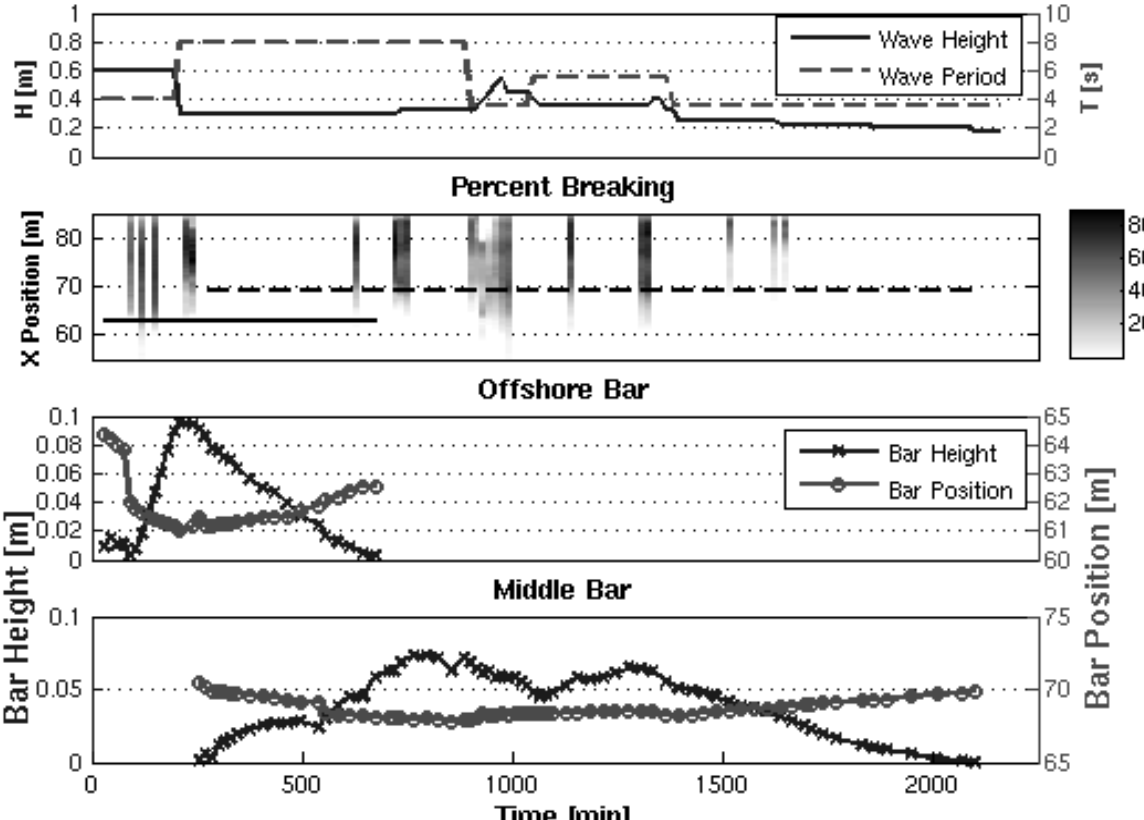

Figure 7: Spatial and Temporal evolution of the offshore and middle bars. Generated wave field is shown in top panel, and percent of wave breaking for 23 discrete runs by the color bars in 2nd panel, where solid and dashed line show average position of the offshore and middle bars, respectively. Third and fourth panel show bar height (solid line with crosses) and position (solid line with circles).

At the beginning of the experiment, under the attack of fairly high, energetic waves (Figure 7, top panel), sediment moved offshore and started to accumulate at approximately x = 64m to form an offshore bar (Figure 7, third panel). This bar continued to move offshore at a speed of approximately 1 cm/min as it grew in height, until wave conditions changed at wave time 210 min. During that period, approximately 40 percent of the waves were breaking on the offshore bar, and approximately 70 percent of the waves were breaking just shoreward of it (Figure 7, second panel).

Almost immediately after the change in wave field, offshore bar height started to decrease as the bar moved onshore at a speed of approximately 0.3 cm/min. Simultaneously, the middle bar started to form. Similarly to the offshore bar, its height increased as it moved offshore (Figure 7, third and fourth panels), but its speed was approximately 0.3 cm/min. The middle bar generation, which will be referred as Phase I in the remainder of this paper, continued until wave conditions were changed, at around wave time 900 min. During this period, between 30 and 40 percent of the waves were breaking on top of the middle bar. In contrast, approximately less than five percent of the waves were breaking on top of the offshore bar, which continued to degenerate.

Successive changes in wave conditions, between wave time 900 and 1350 min, resulted in changes in middle bar height (slight decrease during Phase II and slight increase during Phase III), while it continued to move very slowly onshore. Reduction in wave height and period at wave time 1350 min led to the final decay and onshore migration of the middle bar (Phase IV). During this phase, less than five percent of the waves were breaking on top of the bar, and the bar moved onshore at a speed of approximately 0.1 cm/min, which is smaller than the onshore migration speed of the offshore bar.

The information gathered from these figures along with bar half-width data (not shown), describe the bars temporal and spatial evolution. Both bars were generated when wave breaking was moderate above their crest, and as they moved offshore, they grew higher and wider. After changes in wave conditions, the bars decayed and moved onshore, while getting shorter and narrower, with almost no wave breaking on them. The two sand bars are very dynamic, responded quite rapidly to changes in the wave field, and are probably interdependent.

Moreover, we expect undertow currents to be associated with the principal mechanisms of bar formation, but play a weaker role in bar decay. Other processes, such as the ones correlated with acceleration skewness, are expected to become more predominant during bar degenration. The relationship between velocity moments and sand bars temporal and spatial evolution will be analyzed in more detail in the next section.

Influence of Velocity moments

To compute values of undertow, acceleration skewness and velocity skewness, and to evaluate their influence on the evolution of the bars, we used records of wall instruments located immediately shoreward and offshore of the bars. These records have been band-passed to remove turbulence and seiching signals.

During offshore bar generation, Figure 8, undertow and velocity skewness values were relatively high shoreward of the bar, while acceleration skewness was relatively modest. Furthermore, while gradients of undertow and acceleration skewness seemed to be fairly strong on top of the bar, there was no significant change in velocity skewness in that region.

During offshore bar degeneration, overall undertow and velocity skewness values decreased, while acceleration skewness values shoreward of the bar increased. Again, gradients in undertow and acceleration skewness seemed to be strong near the bar, while velocity skewness did not vary much. Also, it is interesting to note that while acceleration skewness values were higher offshore of the bar during the generation phase, they became larger shoreward of the bar during the bar degeneration.

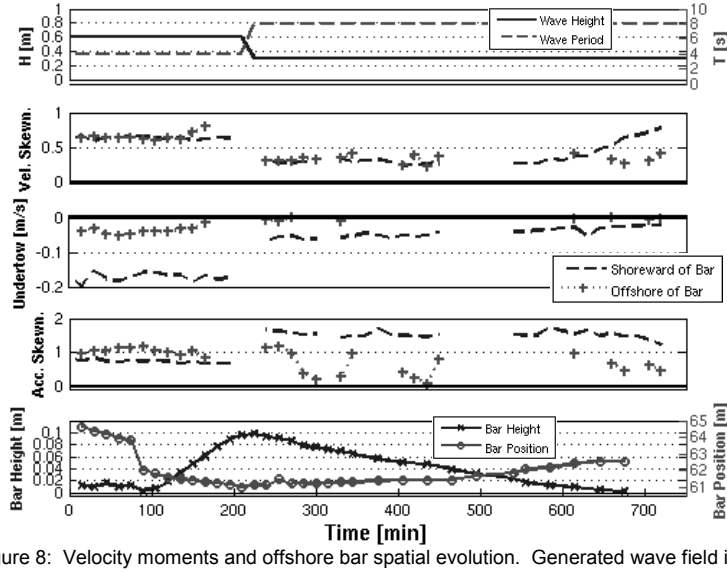

Figure 8: Velocity moments and offshore bar spatial evolution. Generated wave field is shown in top panel, velocity skewness, undertow and acceleration skewness shoreward (dashed lines) and offshore of the bar (dotted lines with crosses) in 2nd, 3rd, 4th panels, and bar height (solid line with crosses) and position (solid line with circles) in bottom panel.

Another way to look at the influence of wave moments on the evolution of the offshore bar is presented in the left panel of Figure 9, where undertow values

measured during generation and degeneration phases are plotted as a function of acceleration skewness. This figure, combined with the information presented in previous figures, show that the bar generated during strong undertow conditions, but degenerated in the presence of very weak undertow and strong accelerations skewness.

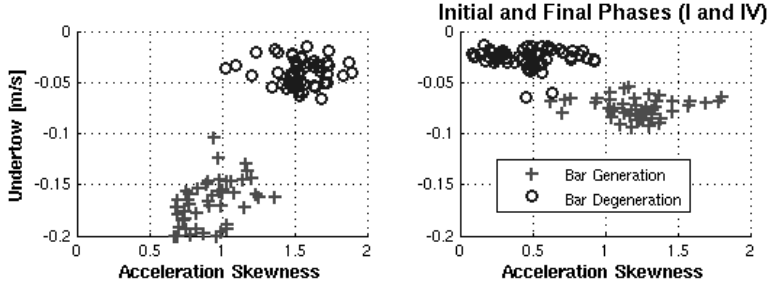

Figure 9: Undertow current versus acceleration skewness values during offshore (left panel) and middle (right panel) bar generation (crosses) and degeneration (circles).

A similar analysis was conducted for the middle bar, as shown in Figure 10. During middle bar initial generation, Phase I, values of velocity skewness offshore and shoreward of the bar decreased, compared to values it had from the beginning of the experiment to wave time 210 min. On the other hand, gradients of that moment increased. Undertow strength shoreward of the bar remained stable, but it decreased from values it had before wave time 210 min. Gradients of undertow decreased also during that period. Finally, acceleration skewness values on either side of the bar decreased during that period. The reduction of that moment was stronger offshore than shoreward of the bar.

During Phases II and III, strength of the undertow near the bar did not change much, velocity and acceleration skewness varied. However, as mentioned earlier, these are intermediate states in the evolution of the middle bar, and we will not evaluate influence of moments on Phases II and III any further.

During the bar final degeneration, Phase IV, velocity skewness values decreased, and undertow current is almost null, and both have almost zero gradient over the bar. On the other hand, acceleration skewness values decreased, although its gradient is still significant on top of the bar.

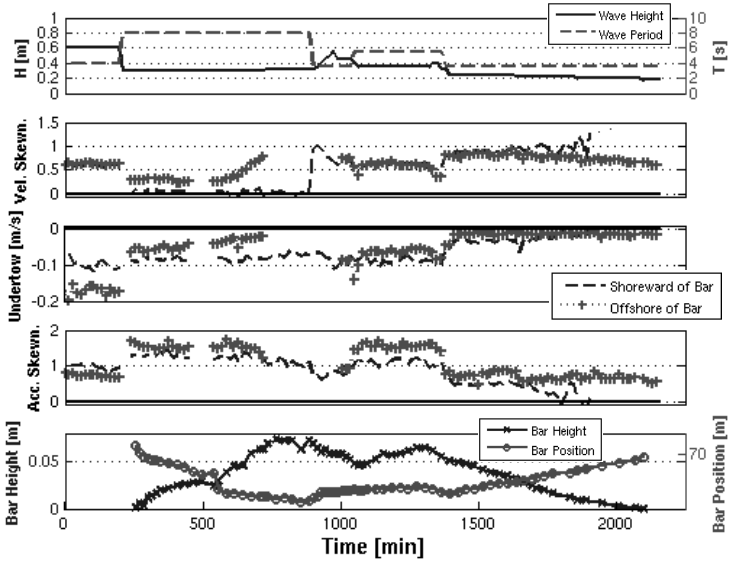

Figure 10: Velocity moments and middle bar spatial evolution. Generated wave field is shown in top panel, velocity skewness, undertow and acceleration skewness shoreward (dashed lines) and offshore of the bar (dotted lines with crosses) in 2nd, 3rd, 4th panels, and bar height (solid line with crosses) and position (solid line with circles) in bottom panel.

When we combined information presented in the previous figure with the distribution of undertow versus acceleration skewness values (right panel of Figure 9), we see that the middle bar formed when undertow currents were approximately 50 percent lower than what they were during generation of the offshore bar. Also, acceleration skewness values during that period were 50 percent higher than what they were during generation of the offshore bar. This situation suggests that the middle bar was not undertow-formed, which is characteristic of most sand bars (such as the offshore bar). On the other hand, because gradients of acceleration skewness were moderate over the middle bar during that bedform degeneration, but undertow currents were almost non-existent, it is likely that processes related to this moment were responsible for the decay of that bar.

In summary, the information presented in these figures indicates that 1. velocity skewness did not seem to be a major factor in the life cycle of either bedforms; 2. undertow currents were probably responsible for the offshore bar growth, but might have been only been partially responsible for the formation of the middle bar. Other processes, probably correlated with acceleration skewness, might have been more prevalent.

It is likely that processes correlated with acceleration skewness led to the degeneration of both bars, but that the value of that moment played a role in the

onshore migration speed of both bars: the offshore bar moved onshore quicker than the middle bar probably because acceleration skewness was higher in one case than the other. One way to assess some of these hypotheses is to compute sediment flux values Q and evaluate the origin of sediments that led to the generation of these bars.

Sediment Flux Calculation

Sediment fluxes that led to the generation of the offshore and middle bars (Figures 11) were computed from the integration of the difference between pre- and post-sandbar generation bed profiles. In this figure, negative flux means offshore sediment transport, while negative flux signifies onshore movement.

Analysis of the left panel of Figure 11 shows that the offshore bar was mostly generated by the offshore movement of a fair amount of sediments, and to a lesser extent by sediment that moved from offshore regions. Most of the sediments that moved offshore seem to originate to regions less than five meters shoreward of the bar.

Based on results of previous sections, we can infer that most sediment that moved offshore was mobilized and moved by undertow currents. Offshore of the bar, because undertow currents were weak, wave processes (possibly acceleration skewness) became predominant and moved some sediment onshore. Sediments accumulated at the final bar location due to the confluence of erosive (i.e. undertow driven) and accretive (i.e. acceleration skewness driven) processes.

If we now look at the middle bar (Figure 11, right panel), it appears that most of the sediments that led to its formation moved onshore from the offshore bar that was degenerating. This movement of sediment, probably driven by acceleration skewness related processes, seemed to have continued beyond the location of the middle bar, but at a lower rate. The change in flux intensity near the trough of the middle bar suggests that onshore sediment movement shoreward of the bar was probably slowed by other processes, such as the undertow.

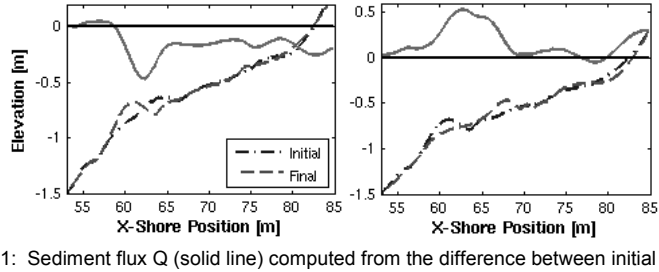

Figure 11: Sediment flux Q (solid line) computed from the difference between initial (dashed dotted line) and final (dashed line) profiles during generation of offshore (left panel), and middle bars (right panel). Offshore sediment movement corresponds to a negative Q.

CONCLUSIONS

During this portion of the CROSSTEX experiment, the generation and degeneration of an offshore and a middle bar was studied in a controlled environment. The analysis of the temporal and spatial evolution of these bars showed that they were quite responsive to changes in wave conditions, interdependent, and sensitive to velocity moments.

Our analysis indicates that the offshore bar was formed by the action of undertow currents, caused by intense wave breaking. On the other hand, the middle bar appears to have been formed by the onshore movement of sediments originating from the offshore bar. Undertow currents and acceleration skewness played a role in this movement, but their relative importance is different from what occurred during the life cycle of the offshore bar. Finally, the degeneration of these bars is correlated with weaker undertow currents, higher acceleration skewness, and almost non-existent breaking. What separates them is their rate of decay, which is probably dictated by the value of acceleration skewness.

In conclusion, the two sand bars were probably formed by different processes, but were extremely interdependent. In a sense they might even represent the same bedform that evolved in different ways because of the ever changing balance between processes that drive cross-shore sediment movement. These processes are correlated with moments such as undertow and acceleration skewness, but their exact nature, and the way they mobilize sediment particles and move them has yet to be determined. This is especially true for acceleration skewness related processes. Further analysis of the data that was collected might shed a light on the role of that moment.

ACKNOWLEDGEMENTS

We wish to thank all the faculty and staff of the O.H. Hinsdale Wave Research Laboratory for their time and support during the experimental phase of CROSSTEX. The O.H. Hinsdale Wave Research Laboratory is partially supported by the George E. Brown Jr. Network for Earthquake Engineering Simulation (NEES) Consortium Incorporated contract OMSA v.3.1 through their National Science Foundation Cooperative Agreement CMS-0402490. Some of the instrumentation used in this project was purchased under National Science Foundation NSF-0429219. Also, we would like to thank Patricio Catalan for his help in computing percent of wave breaking from the Argus videos. Finally, we would like to thank our sponsors for this study, NSF Grant OCE-0351297 and OCE-0351153, and Sea Grant grant NA16RG1039.

Abstract: A new practical model for net sand transport induced by non-breaking waves and currents is being developed within the SANTOSS research project. Phase I of model development is reported here. In comparison with existing models, the main improvement is the description of the wave-related transport. More specifically, phase lag effects in the sheet-flow and ripple regime – which potentially have a large effect on the net transport – are accounted for in a parameterized way. The santoss model is calibrated against a large set of data from oscillatory flow tunnel experiments covering a wide range of flow and sand conditions. The new model is seen to perform better than existing practical transport models, and is applicable to a larger range of conditions.

INTRODUCTION

In recent years a substantial body of field- and laboratory-based research has been devoted to measuring sand transport processes induced by waves and currents, and predictive models for the net (wave-averaged) sand transport have been developed. In broad terms, the models can be classified as practical or research models. Research models represent many of the detailed physical processes involved in sand transport by waves and currents, and resolve the vertical and sometimes also the horizontal structure of the time-dependent (intra-wave) velocity and sand concentration fields. Such models are complex, require long computation times and are therefore generally not implemented in coastal morphological models. Practical models require short

computation times and can be implemented easily in coastal morphological models. However, they do not resolve the spatial and temporal structure of the velocity and sand concentration fields. Existing practical and research models to predict the net sand transport induced by waves and currents still have considerable shortcomings (see e.g. Davies et al., 2002).

This paper describes the development of a new practical model to predict the net sand transport in coastal waters. This model has been developed within the Dutch/UK research project SANTOSS (Sand Transport in Oscillatory Flows in the Sheet-flow Regime). Hence, the new model is called the santoss model hereafter.

The santoss model is being developed using the santoss database of experimental data. The database contains a large amount of net sand transport data from full-scale, non-breaking wave and non-breaking wave plus collinear current experiments (see Schretlen and Van der Werf, 2006). We use the net transport data from oscillatory flow tunnel experiments with uniform sediments, flow periods $T \geq 3$ s, and orbital flow asymmetries $R = \hat{u}_c / (\hat{u}_c + \hat{u}_t) \leq 0.7$, where $\hat{u}_c$ and $\hat{u}_t$ are the peak crest and peak trough orbital velocity respectively.

Table 1 presents an overview of the data used for the model development. The bedform regime (ripples or sheet-flow), the flow type (W: wave-alone; W+C: wave+current), and the experimental facilities (AOFT: Aberdeen Oscillatory Flow Tunnel; LOWT: Large Oscillating Water Tunnel; TUWT: Tokyo University Water Tunnel) are distinguished. Furthermore, the range of median grain size, D_{50}, is shown.

Table 1. Overview of the data used for the development of the santoss model. W: wave-alone experiments; W+C: wave-current experiments. AOFT: Aberdeen oscillatory flow tunnel; LOWT: large oscillating water tunnel; TUWT: Tokyo university water tunnel.

Bedform regime	Flow type	Facility	No.	D_{50} (mm)
Ripples	W	AOFT	23	0.22-0.44
		LOWT	16	0.21-0.35
		TUWT	0	-
	W+C	AOFT	0	-
		LOWT	1	0.35
		TUWT	0	-
Sheet-flow	W	AOFT	8	0.13-0.46
		LOWT	26	0.13-0.34
		TUWT	26	0.20-0.74
	W+C	AOFT	0	-
		LOWT	36	0.13-0.32
		TUWT	24	0.20

Figure 1 presents an overview of the hydraulic conditions covered by the data, based on the oscillatory flow period T and the wave mobility number given by:

$$\psi_w = \frac{\hat{u}^2}{\Delta g D_{50}} \tag{1}$$

where Δ is the relative density of sediment and g is acceleration due to gravity. Relative net current strength is given by $< u_b > / \hat{u}$, where $< u_b >$ is the net current strength at z = 0.15 m and $\hat{u}$ is the characteristic orbital velocity amplitude.

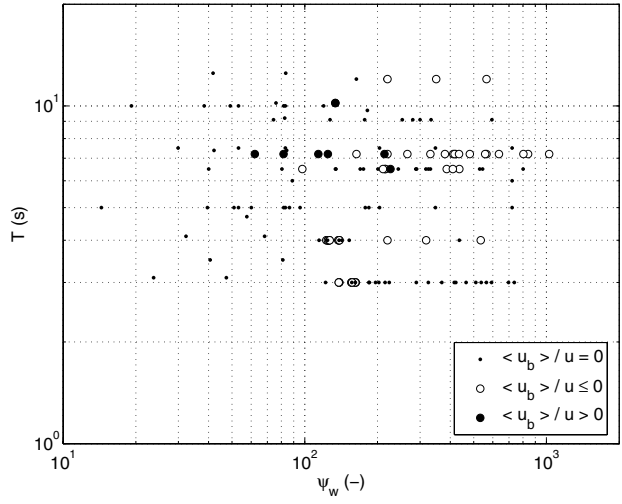

Figure 1. Overview of the data used for the model development in terms of the wave mobility number ψ_w, the flow period T, and the relative net current strength $< u_b > / \hat{u}$.

This figure shows that the net transport data simultaneously cover a wide range of full-scale flow periods ($T \approx 3 - 10$ s) and wave mobility numbers ($\psi_w \approx 40 - 700$). For $\psi_w >\approx$ 100 there is also a reasonable amount of net transport data in which $< u_b > / \hat{u} \leq 0.5$. There is a limited amount of net transport data from experiments with relatively strong net currents ($< u_b > / \hat{u} > 0.5$). In general, the experimental conditions can be characterized as wave-dominated.

The paper is organized as follows. Section 2 describes the state-of-the-art of practical sand transport modeling. In the next section the santoss model is presented, calibrated and compared with existing practical sand transport models. The conclusions are presented in Section 4.

STATE-OF-THE-ART FOR PRACTICAL SAND TRANSPORT MODELING

There are three types of practical sand transport models: 1) time-averaged models, 2) quasi-steady models, and 3) semi-unsteady models. Time-averaged models were the first models to be developed to derive the sand transport rate under waves and currents. The sand transport rate is described at a time scale much longer than the wave period using

the wave-averaged values of velocity and concentration. A widely-used time-averaged transport formula was developed by Bijker (1971), which describes the current-related transport (suspended load and bedload) with waves acting as stirring agent. In time-averaged models, the total net transport is always in the direction of the mean current and the wave-related transport component is not taken into account.

Quasi-steady models (e.g. Bailard, 1981; Van Rijn, 1993; Ribberink, 1998) consider the sand transport on an intra-wave scale, i.e. a time-scale much shorter than the wave period. These are based on the assumption of quasi-steadiness: the instantaneous sand transport is related to the instantaneous flow velocity or bed shear stress, as if the flow is steady at each phase during the wave-cycle. In this way the wave-related sand transport is implicitly included. The assumption of quasi-steadiness only holds for conditions where the response time of sand particles is short relative to the wave period. In other words, the pick-up and settling of sand particles must take place in a much shorter time than the wave period. This does not happen in the case of fine sand sheet-flow conditions (Dohmen-Janssen, 1999, O'Donoghue and Wright, 2004a) and rippled bed conditions (see Van der Werf, 2006). In these cases the phase lag between velocity and concentration can become so large than the net sand transport induced by asymmetric oscillatory flows (e.g. second-order Stokes) is offshore-directed (negative), i.e. against the orbital flow asymmetry. This is illustrated in Figure 2 which shows net transport data from wave-alone experiments with $T \geq 4$ s as a function of the wave mobility number.

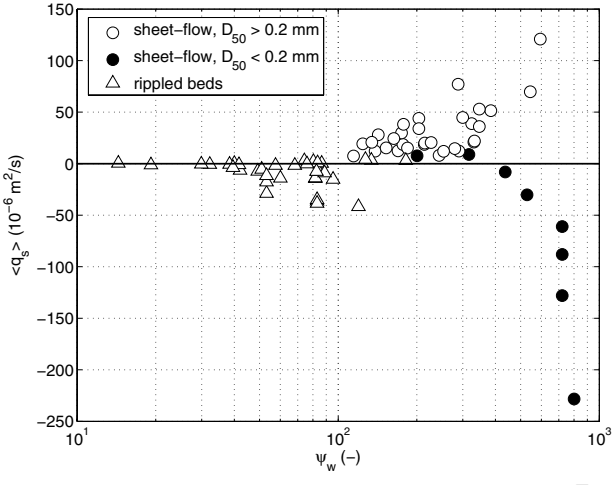

Figure 2. Net sand transport rate data from wave-alone experiments with $T \geq 4$ s as a function of the wave mobility number.

Quasi-steady models fail to predict the net transport correctly under conditions where phase lags are important. Semi-unsteady models account for these phase lag effects in a parameterized way. Existing semi-unsteady models are either mainly based on sheet-

flow data (e.g. Dibajnia & Watanabe, 1996; Camenen and Larson, 2006, Silva et al, 2006) or on ripple data (e.g. Nielsen, 1988; Van der Werf et al., 2006). Furthermore, these models are generally constrained to wave-alone cases. There does not exist a practical sand transport model capable of predicting net transport induced by non-breaking waves and currents including the phase lag effects in both the rippled bed and plane bed/sheet-flow regime.

NEW PRACTICAL SAND TRANSPORT MODEL

In comparison with existing sand transport models for the coastal environment, the main improvements of the santoss model lie in the description of the wave-related transport. The model will account for (i) phase lag effects in the sheet-flow and rippled bed regime (ii) surface wave effects and (iii) acceleration skewness effects. Model development is taking place in two phases. Phase 1 development is primarily based on existing knowledge (model concepts), making use of existing oscillatory flow tunnel experimental data. Surface wave and acceleration effects are not considered in Phase 1. Phase 2 development will incorporate new knowledge on surface wave and acceleration effects based on new experiments carried out during the course of the SANTOSS research project. This paper discusses the first phase of model development.

Velocities

The near-bed velocity vector at reference level $z = \delta$ above the bed due to the combined wave-current motion is defined as follows (see Figure 3):

$$\vec{u}_b(t) = \langle \vec{u}_b \rangle + \vec{u}_{b,osc}(t) \tag{2}$$

where $< \vec{u}_b >$ is the current velocity vector at $z = \delta$ and $\vec{u}_{b,osc}(t)$ the free-stream orbital velocity vector. Therefore, δ should be outside the wave boundary layer. We have taken $\delta = 0.15$ m.

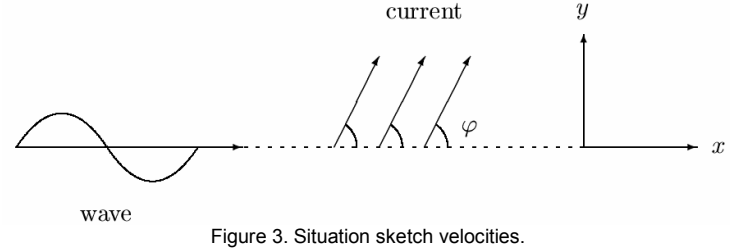

Figure 3. Situation sketch velocities.

The maximum velocity (under the wave crest, *c*) and the minimum velocity (under the wave trough, *t*) are defined as follows:

$$\vec{u}_{b,c} = \left\{ \hat{u}_c + \langle u_b \rangle \cos\varphi, \langle u_b \rangle \sin\varphi \right\} \tag{3}$$

$$\vec{u}_{b,t} = \left\{ \langle u_b \rangle \cos\varphi - \hat{u}_t, \langle u_b \rangle \sin\varphi \right\} \tag{4}$$

Irregular oscillatory flows are treated as regular oscillatory flows using $\hat{u}_c = u_{1/3,on}$, $\hat{u}_t = u_{1/3,off}$ and $T = T_p$, where $u_{1/3,on}$ is the mean of the highest one-third onshore orbital velocity peaks, $u_{1/3,off}$ the mean of the highest one-third offshore orbital velocity peaks, and T_p the spectral peak period. The degree of orbital flow asymmetry in the case of irregular oscillatory flows is defined by:

$$R = \frac{u_{1/3,on}}{u_{1/3,on} + u_{1/3,off}} \tag{5}$$

In cases where the orbital velocity amplitude under the wave crest, $\hat{u}_c$, and under the wave trough, $\hat{u}_t$, are not known, they are computed from the root-mean-square orbital velocity, $\tilde{u}_{rms}$, and the degree of flow asymmetry, R, as follows (assuming a second-order Stokes velocity function):

$$u_1 = \sqrt{\frac{\tilde{u}_{rms}^2}{(2R-1)^2 + 1}} \tag{6}$$

$$u_2 = (2R-1)u_1 \tag{7}$$

$$\hat{u}_c = u_1 + u_2 \tag{8}$$

$$\hat{u}_t = u_1 - u_2 \tag{9}$$

The characteristic orbital velocity amplitude, $\hat{u}$, is given by:

$$\hat{u} = \sqrt{0.5\hat{u}_c^2 + 0.5\hat{u}_t^2} \tag{10}$$

Bed shear stress

We use the method of Ribberink (1998) to calculate the bed shear stress due to the waves and currents. The wave-related Shields parameter under the wave crest and trough are computed using:

$$\left|\tilde{\theta}_{b,c}\right| = \frac{f_w \hat{u}_c^2}{2\Delta g D_{50}} \tag{11}$$

$$\left|\tilde{\theta}_{b,t}\right| = \frac{f_w \hat{u}_t^2}{2\Delta g D_{50}} \tag{12}$$

where the wave friction factor, f_w, is computed using the formula of Swart (1974).

Following Madsen and Grant (1976), the combined wave-current friction factor is calculated as a linear combination of the wave friction factor and the current friction factor:

$$f_{cw} = \alpha f_c + (1-\alpha) f_w \tag{13}$$

$$\alpha = \frac{\langle u_b \rangle}{\langle u_b \rangle + \hat{u}} \tag{14}$$

where f_c is the current friction factor computed assuming a logarithmic net current profile. The wave crest and trough Shields parameters for the wave-current condition are then:

$$|\theta_{b,c}| = \frac{f_{cw}|u_{b,c}|^2}{2\Delta g D_{50}} \tag{15}$$

$$|\theta_{b,t}| = \frac{f_{cw}|u_{b,t}|^2}{2\Delta g D_{50}} \tag{16}$$

The wave and current roughness height include additional roughness related to the sheet-flow layer in the following way:

$$k_{sc} = \max\left\{3D_{90}, D_{50}\left[1 + 6\left(\langle|\theta|\rangle - 1\right)\right]\right\} \tag{17}$$

$$k_{sw} = \max\left\{D_{50}, D_{50}\left[1 + 6\left(\langle|\theta|\rangle - 1\right)\right]\right\} \tag{18}$$

where $\langle|\theta|\rangle$ is the time-averaged absolute Shields parameter.

Transport contributions

Following an approach as proposed by Dibajnia and Watanabe (1992), we assume that there are four contributions to the sand transport:

$$\Omega_i = \begin{cases} \left(|\theta_{b,i}| - \theta_{cr}\right)^n & \text{if } P_i \le P_{cr} \\ \dfrac{P_{cr}}{P_i}\left(|\theta_{b,i}| - \theta_{cr}\right)^n & \text{if } P_i > P_{cr} \end{cases} \tag{19}$$

$$\Omega_i' = \begin{cases} 0 & \text{if } P_i \le P_{cr} \\ \dfrac{(P_i - P_{cr})}{P_i}\left(|\theta_{b,i}| - \theta_{cr}\right)^n & \text{if } P_i > P_{cr} \end{cases} \tag{20}$$

where $i = c$ (wave crest) or t (wave trough). Ω_c represents the amount of sand that is entrained and transported when the x-component of the velocity vector is positive; Ω_c' represents the amount of sand that is entrained when the x-component of the velocity vector is positive and is transported when the x-component of the velocity vector is negative; Ω_t represents the amount of sand that is entrained and transported when the x-component of the velocity vector is negative; Ω_c' represents the amount of sand that is entrained when the x-component of the velocity vector is negative and is transported

when the *x*-component of the velocity vector is positive. The critical bed shear stress, θ_{cr}, is computed using the formula of Soulsby (1997). Of course $\Omega_i = \Omega_i^{'} = 0$ if $|\theta_{b,i}| \leq \theta_{cr}$.

We take the phase lags in the ripple and sheet-flow regime into account through phase lag parameter *P*, following Dibajnia and Watanabe (1992), Dohmen-Janssen (1999) and Van der Werf et al. (2006):

$$P_c = \frac{\alpha_r \eta}{35 D_{50}} + \frac{\alpha_s \delta_{s,c}}{w_s T_c} \tag{21}$$

$$P_t = \frac{\alpha_r \eta}{35 D_{50}} + \frac{\alpha_s \delta_{s,t}}{w_s T_t} \tag{22}$$

where η is the ripple height, $\delta_{s,c}$ and $\delta_{s,t}$ are the sheet-flow layer thicknesses under the wave crest and trough computed using the formula of Dohmen-Janssen (1999), w_s the fall velocity of suspended sand computed using the formula of Soulsby (1997) and α_r and α_s are fit parameters. The critical phase lag parameter, P_{cr}, has a value of 1. T_c and T_t are the times during which the *x*-component of the velocity is positive (*c*) and negative (*t*), respectively. In what follows, we use the a priori knowledge on the bedform regime (rippled bed or flat bed) and the measured ripple height as input.

The net sediment transport is then computed as follows:

$$\vec{\Phi}_c = \left(\Omega_c + \Omega_t^{'}\right) \frac{\vec{u}_{b,c}}{|u_{b,c}|} \tag{23}$$

$$\vec{\Phi}_t = \left(\Omega_t + \Omega_c^{'}\right) \frac{\vec{u}_{b,t}}{|u_{b,t}|} \tag{24}$$

$$\left\langle \vec{\Phi} \right\rangle = \frac{\left\langle \vec{q}_s \right\rangle}{\sqrt{\Delta g D_{50}^3}} = \frac{m}{T}\left(T_c \vec{\Phi}_c + T_t \vec{\Phi}_t\right) \tag{25}$$

where it is assumed that the transport contributions Ω_c and $\Omega_t^{'}$ are in the direction of the velocity vector $\vec{u}_{b,c}$, and the transport contributions Ω_t and $\Omega_c^{'}$ are in the direction of the velocity vector $\vec{u}_{b,t}$. *m* and *n* are calibration factors.

Calibration

There are four fit parameters: i) phase lag parameter α_s for the plane bed/sheet-flow regime, ii) phase lag parameter α_r for the ripple regime, iii) proportionality coefficient *m*, and iv) power law of the excess Shields parameter *n*. *m* and *n* have the same value in the ripple and sheet-flow regime. *n* is set equal to 1.5 following for example Nielsen (1992) and Soulsby and Damgaard (2005).

In the calibration procedure the coefficient of determination r^2 is optimized. In our case, r^2 represents the quality of fitting a straight line with zero intercept to the measured and predicted net transport values. The calibration procedure is as follows. (i) Tune α_s to find highest r^2 for sheet-flow experiments. (ii) Tune α_r to find highest r^2 for ripple regime experiments. It is necessary that α_s is tuned first, since α_s also affects the net transport rates predicted for rippled bed cases. (iii) Tune m to find highest r^2 for the combined sheet-flow and ripple regime data.

The calibration procedure resulted in the following parameter values: $\alpha_s = 3.3$, $\alpha_r = 0.89$ and $m = 4.2$. Figure 4 shows a comparison between all measured transport rates contained in the santoss database (160 cases) and the transport rates predicted by the santoss model with these parameter settings.

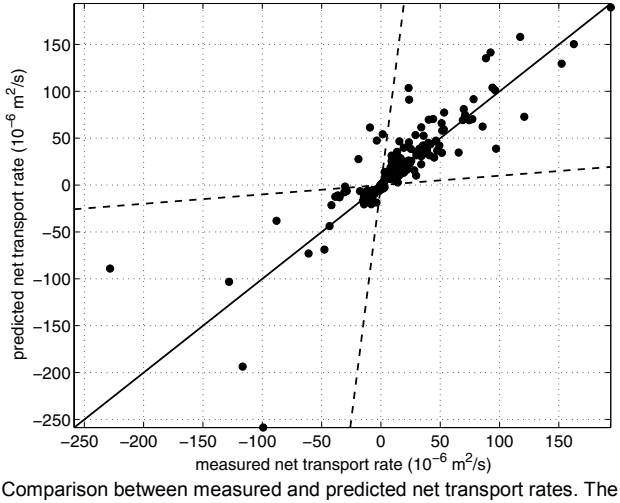

Figure 4. Comparison between measured and predicted net transport rates. The solid line denoted perfect agreement, the dashed lines a factor 10 difference.

The new practical sand transport model shows good agreement with the data. In 71% of the cases it predicts the net transport within a factor 2, in 88% of the cases within a factor 5, and in 91% of the cases within a factor 10.

Comparison with other practical sand transport models

In this section we compare the new model with the practical transport models of Dibajnia and Watanabe (1996) (DW96), Camenen and Larson (2006) (CL06), and Silva et al. (2006) (S06). There is substantial overlap in the data that are used to calibrate these four models.

The data set consisting of 160 different net transport measurements (see Table 1) is randomly divided into two: the first half is used for calibration of the santoss model and

the second part is used for the intercomparison of the DW96, CL06, S06, and the santoss model. In this way, the data sets used for calibration and validation are (at least to a certain extent) independent. This procedure is repeated 100 times. For all 100 times, the santoss model predicts the largest number of cases within a factor 2, 5 and 10. Therefore, we conclude that the santoss model is better capable of predicting the net sand transport rates for this large data set covering a wide range of flow and sand conditions than existing transport models.

It is important that a sand transport model is able to predict the correct behavior of net sand transport as function of important flow and sand parameters. Figures 5-8 show example comparisons between the measured and predicted behavior of the net sand transport as a function of the median grain size D_{50}, flow period T, net current strength $\langle u_b \rangle$, and the root-mean-square orbital velocity $\tilde{u}_{rms}$. Measured data are selected such that only one variable varies and the others are constant or nearly constant. The following coding is used: ia: irregular asymmetric orbital flow; ra: regular asymmetric orbital flow; fb: flat beds; rb: rippled beds. DIB1992 denotes Dibajnia and Watanabe (1992); ODO2004 O'Donoghue and Wright (2004b); RIB1994 Ribberink and Al-Salem (1994); VEA2007 Van der Werf et al. (in press).

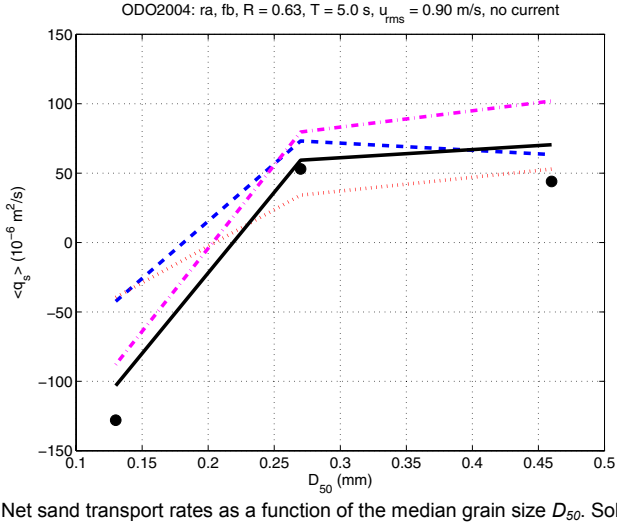

Figure 5. Net sand transport rates as a function of the median grain size D_{50}. Solid circles: measured; dashed line: DW96 model; dotted line: CL06 model; dashed-dotted line: S06 model; solid line: santoss model.

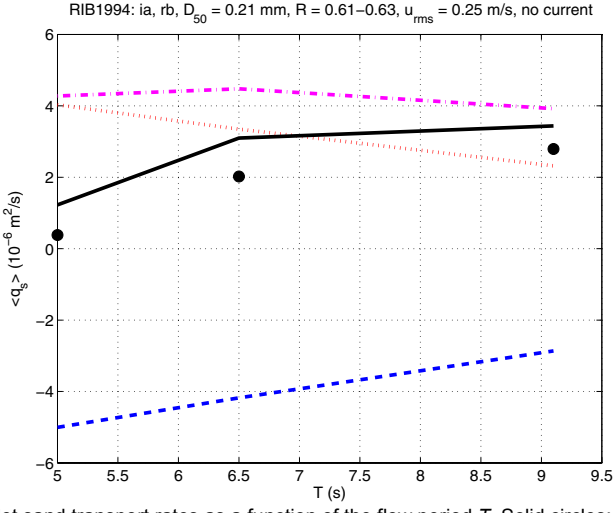

Figure 6. Net sand transport rates as a function of the flow period *T*. Solid circles: measured; dashed line: DW96 model; dotted line: CL06 model; dashed-dotted line: S06 model; solid line: santoss model.

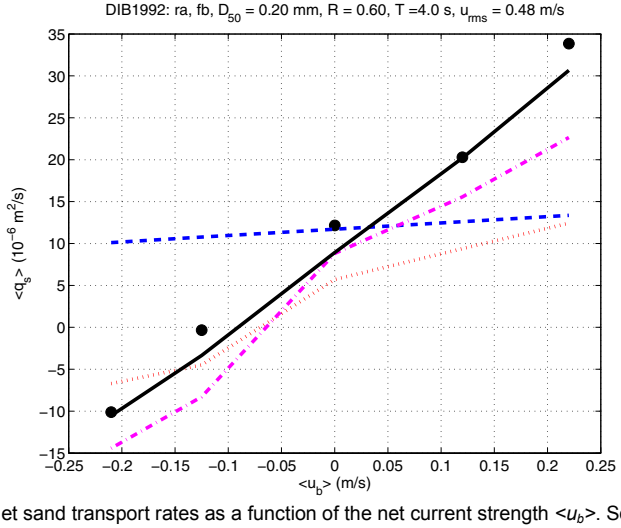

Figure 7. Net sand transport rates as a function of the net current strength $<u_b>$. Solid circles: measured; dashed line: DW96 model; dotted line: CL06 model; dashed-dotted line: S06 model; solid line: santoss model.

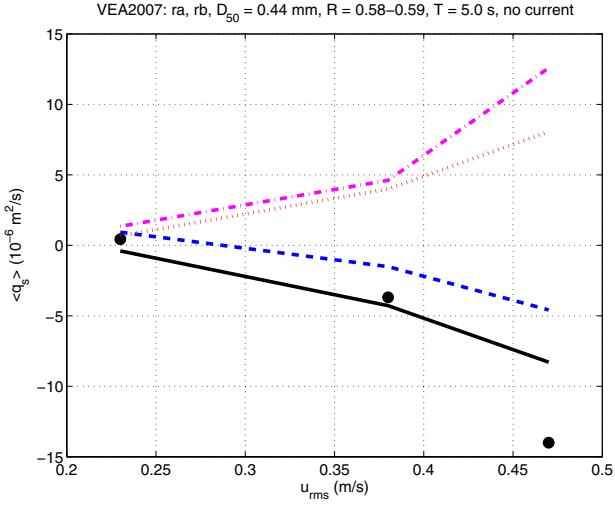

Figure 8. Net sand transport rates as a function of the root-mean-square orbital velocity $\widetilde{u}_{rms}$. Solid circles: measured; dashed line: DW96 model; dotted line: CL06 model; dashed-dotted line: S06 model; solid line: santoss model.

The following observations are made from Figures 5 to 8 and from a large number of similar plots:

- The CL06 and S06 models are (mainly) developed for plane bed, sheet-flow conditions and cannot correctly predict the offshore-directed net transport rates observed in the ripple regime.
- All of the models are able to predict the measured change from onshore to offshore net transport for decreasing grain size in the sheet-flow regime.
- In the rippled bed experiments of RIB1994, net transport decreases with flow period, but stays onshore-directed. Only the santoss model is able to pick up this behavior.
- The influence of the net current on the net transport is well-predicted by the S06 and the santoss models. The DW96 model and, to a lesser extent, the CL06 model underpredict this influence.

CONCLUSIONS

A new practical model for net sand transport induced by non-breaking waves and currents is being developed within the SANTOSS research project. Phase I of model development is reported here.

The main improvements compared to previous practical sand transport models lie in the description of the wave-related sand transport, particularly for cases where phase lag effects are important. The model can deal with regular and irregular oscillatory flows, wave-alone and combined wave and collinear current cases, and flat beds and rippled

beds. Model development uses a large dataset compiled from existing oscillatory flow tunnel experiments involving uniform sediments. The net transport data cover a wide range of full-scale flow periods and wave mobility numbers. In general, the experimental conditions are wave-dominated.

The Phase 1 santoss model has been compared with the semi-unsteady transport models of Dibajnia and Watanabe (1996), Camenen and Larson (2006) and Silva et al. (2006). The santoss model proves to be best capable of predicting both the absolute values of the net sand transport and the behavior of the net sand transport as functions of the median grain size, flow period, root-mean-square orbital velocity and net current strength. Furthermore, the new model is applicable to a larger range of conditions.

Surface wave and acceleration skewness effects will be included in the Phase 2 development of the santoss sand transport model, using new data and insights from new large-scale tunnel and wave flume experiments carried out as part of the SANTOSS project.

ACKNOWLEDGEMENTS

This work has been carried out within the project SANTOSS ('Sand Transport in Oscillatory flows in the Sheet-flow regime') funded by the UK's EPSRC (GR/T28089/01) and the Dutch research organization STW (TCB.6586).

Abstract: A total load sediment transport formula based on recent studies on the bed load and suspended load transport for the nearshore is presented . Phase-lag in the sheet-flow layer or due to ripples, as well as acceleration effects, is included in the formula. A sensitivity analysis is performed to better qualify and quantify the current-related and wave-related sediment transport. It appeared that the prediction of the ripple characteristics is fundamental for a proper estimation of the suspended load in the direction of the waves. For the longshore sediment transport where the current-related total load prevails, the formulas are not as sensitive to ripples.

INTRODUCTION

Accurate prediction of sediment transport rates is an important element in morphological studies for the coastal environment. Most of the existing formulas used in numerical models compute current-related sediment transport only. This component of the sediment transport generally prevails in the longshore direction. However, in the cross-shore direction the waves do not only increase the quantity of sediment available for transport, but they also strongly affect the direction of the sediment transport (Dibajnia and Watanabe, 1992; Ribberink and Al Salem, 1994; Van der Werf and Riberink, 2004). First, asymmetric waves induce onshore wave-related sediment transport. Second, phase-lag in the sediment suspension (which occurs in case of ripples or sheet flow) may reduce the total net sediment transport and even induce a net transport opposite to the wave direction. Ribberink and Al Salem (1994) showed that, assuming the velocity ($u(z)$) and concentration ($c(z)$) equal to a constant part ($\overline{u}(z)$ and $\overline{c}(z)$) and a fluctuating part ($\widetilde{u}(z)$ and $\widetilde{c}(z)$), the net sediment transport rate ($q_{s,net}$) may be written

as the sum of a current-related sediment transport and a wave-related sediment transport according to:

$$q_{s,net} = \int_0^h \bar{u}(z)\bar{c}(z)dz + \int_0^h \tilde{u}(z)\tilde{c}(z)dz \tag{1}$$

where h is the water depth and z a vertical coordinate. Both components of the sediment transport may be significant in the nearshore zone.

A TOTAL LOAD FORMULA

Camenen and Larson (2005a, b; 2006a, b; 2007) proposed a bed load and suspended load formula for the nearshore calibrated with a large amount of data from both laboratory and field measurements, described in the following.

Bed load sediment transport

The bed load transport (q_{sb}) is expressed as follows (Camenen and Larson, 2005a, 2006a):

$$\begin{cases} \dfrac{q_{sb,w}}{\sqrt{(s-1)gd_{50}^{\ 3}}} = a_w \sqrt{\theta_{cw,net}}\,\theta_{cw,m} \exp\left(-b\dfrac{\theta_{cr}}{\theta_{cw}}\right) \\ \dfrac{q_{sb,n}}{\sqrt{(s-1)gd_{50}^{\ 3}}} = a_n \sqrt{\theta_{cn}}\,\theta_{cw,m} \exp\left(-b\dfrac{\theta_{cr}}{\theta_{cw}}\right) \end{cases} \tag{2}$$

where the subscripts w and n correspond, respectively, to the wave direction and the direction normal to the wave direction, s (= ρ_s/ρ) is the relative density between sediment (ρ_s) and water (ρ), g the acceleration due to gravity, d_{50} the median grain size, a_w, a_n and b are empirical coefficients, $\theta_{cw,m}$ and θ_{cw} the mean and maximum Shields parameters due to wave-current interaction, θ_{cn} the current-related Shields parameter in the direction normal to the wave direction, and θ_{cr} the critical Shields parameter for the inception of transport. The net Shields parameter $\theta_{cw,net}$ in Eq. 2 is given by:

$$\theta_{cw,net} = (1-\alpha_{pl,b})\theta_{cw,on} + (1+\alpha_{pl,b})\theta_{cw,off} \tag{3}$$

where $\theta_{cw,on}$ and $\theta_{cw,off}$ are the mean values of the instantaneous Shields parameter over the two half periods T_{wc} and T_{wt} ($T_w = T_{wc} + T_{wt}$, in which T_w is the wave period; *cf.* Fig. 1, where φ is the angle between the wave and the current directions), and $\alpha_{pl,b}$ a coefficient for the phase-lag effects (Camenen and Larson 2006a). The Shields parameter is defined by $\theta_{cw,i} = 1/2 f_{cw} U_{cw,j}^{\ 2} / \left((s-1)gd_{50}\right)$ with f_{cw} being the friction coefficient taking into account wave and current interaction. Madsen and Grant (1976) suggested that f_{cw} could be obtained as a linear combination of f_c and f_w ($f_{cw} = X_v f_c + (1-X_v) f_w$ with $X_v = |U_c| / \left(|U_c| + U_w\right)$ and U_c being the steady current

velocity and U_w the wave orbital velocity amplitude). A constant value on the friction coefficient over the wave period was also assumed when calculating the Shields parameter. Drake and Calantoni (2001), Nielsen (2002, 2006), Antunes Do Carmo *et al.* (2003), and Watanabe and Sato (2004) showed that in general the wave friction coefficient depends also on the acceleration of the fluid near the bottom and thus may strongly influence the direction of the sediment transport in the wave direction. This effect will be discussed later.

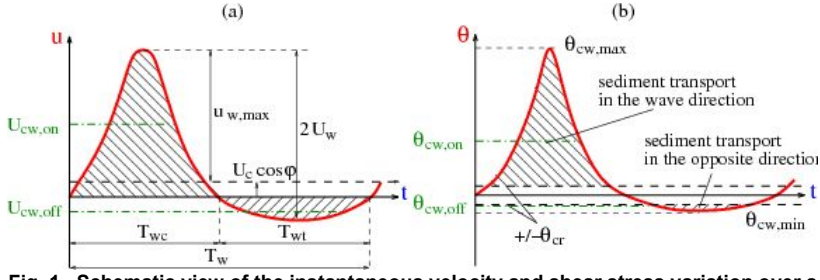

Fig. 1. Schematic view of the instantaneous velocity and shear stress variation over a wave period and in the direction of the waves

Phase-lag effects in the sheet flow layer were included through the coefficient $\alpha_{pl,b} = \alpha_{b,onshore} - \alpha_{b,offshore}$ (Camenen and Larson, 2006a) with:

$$\alpha_{b,i} = \frac{\nu^{0.25} U_{wj}^{0.5}}{W_s T_j^{0.75}} \exp\left[-\left(\frac{U_{w,crsf}}{U_{wj}} \right)^2 \right] \tag{4}$$

where ν is the kinematic viscosity of water, $U_{w,crsf}$ the critical velocity for the inception of sheet flow, and the subscript j should be replaced either by *onshore* or *offshore*.

Suspended load sediment transport

The suspended sediment load (q_{ss}) may be obtained from (Camenen *et al.*, 2005b; Camenen and Larson 2006b, 2007):

$$\begin{cases} q_{ss,w} = U_{cw,net} \dfrac{c_R \varepsilon}{W_s} \left[1 - \exp\left(-\dfrac{W_s h}{\varepsilon} \right) \right] \\ q_{ss,n} = U_c \sin\varphi \dfrac{c_R \varepsilon}{W_s} \left[1 - \exp\left(-\dfrac{W_s h}{\varepsilon} \right) \right] \end{cases} \tag{5}$$

where c_R is the reference concentration at the bottom, W_s the sediment fall speed, ε the sediment diffusivity, and $U_{cw,net}$ the net mean current ($U_{cw,net} = U_c$ for a steady current).

The bed reference concentration is written as follows based on the analysis of a large data set on sediment concentration profiles (see Camenen *et al*., 2005; Camenen and Larson, 2007):

$$c_R = 3.510^{-3} \exp(-0.3 d_*) \theta_{cw,m} \exp\left(-4.5 \frac{\theta_{cr}}{\theta_{cw}}\right) \tag{6}$$

where $d_* = \sqrt[3]{(s-1)g/\nu^2}\, d_{50}$ is the dimensionless grain size. The sediment diffusivity was related to the total energy dissipation, in which the energy dissipation from wave breaking (D_b) and from bottom friction due to current (D_c) and waves (D_w) were added:

$$\varepsilon = \left(\frac{k_c{}^3 D_c + k_w{}^3 D_w + k_b{}^3 D_b}{\rho}\right)^{1/3} h \tag{7}$$

where k_b, k_c and k_w are coefficients with $k_b = 0.01$ corresponding to an efficiency coefficient related to dissipation due to wave breaking, whereas k_c and k_w are associated with the Schmidt number. Assuming the Rouse parabolic profile to be a correct approximation of the vertical sediment diffusivity, its mean value over the depth may be written as follows, for a steady current or non-breaking waves, respectively:

$$\varepsilon_{c/w} = k_{c/w}\left(\frac{D_{c/w}}{\rho}\right)^{1/3} h = \frac{C_w \sigma_{c/w}}{6} \kappa u_{*c/w} h \tag{8}$$

where $\sigma_{c/w}$ is the Schmidt number or the ratio between the vertical eddy diffusivity of the particles ε_v and the vertical eddy viscosity ν_v, $u_{*,c/w}$ is the shear velocity due to current or waves only, respectively, κ von Karman's constant, and $C_w = 1$ in case of current or $C_w = 2/\pi$ in case of waves (this coefficient results from a time-average assuming a sinusoidal wave). Based on the analysis of experimental data, the following expressions were developed for the Schmidt numbers $\sigma_{c/w}$:

$$\sigma_{c/w} = \begin{cases} A_1 + A_2 \sin^2\left(\dfrac{\pi}{2}\dfrac{W_s}{u_{*,cw}}\right) & if\ \dfrac{W_s}{u_{*,cw}} \le 1 \\ 1 + (A_1 + A_2 - 1)\sin^2\left(\dfrac{\pi}{2}\dfrac{u_{*,cw}}{W_s}\right) & if\ \dfrac{W_s}{u_{*,cw}} > 1 \end{cases} \tag{9}$$

where $A_1 = 0.4$ and $A_2 = 3.5$ in case of a steady current only, and $A_1 = 0.15$ and $A_2 = 1.5$ in case of waves only. For wave-current interaction, a weighted value is used for the Schmidt number, $\sigma_{cw} = X_t \sigma_c + (1 - X_t)\sigma_w$ with $X_t = \theta_c / (\theta_c + \theta_w)$ and θ_c being the current Shields parameter and θ_w the wave Shields parameter.

The net current $U_{cw,net}$ is defined in a similar way to the net Shields parameter $\theta_{cw,net}$ in order to take into account a possible sediment transport due to wave asymmetry, as well as phase-lag in the suspended concentration due to ripple effects (Van der Werf and Ribberink, 2004; Camenen and Larson, 2006):

$$U_{cw,net} = (1-\alpha_{pl,s})U_{cw,on} + (1+\alpha_{pl,s})U_{cw,off} \tag{10}$$

where $\alpha_{pl,s}$ is the coefficient describing phase-lag effects on the suspended load and $U_{cw,j}$ is the root-mean-square value of the velocity (wave plus current) over the half period T_{wj} (*cf.* Fig.1), where the subscript j should be replaced either by on (onshore) or off (offshore). In the same way as for the bed load formula, phase-lag effects in the suspended load due the ripples were included through the coefficient $\alpha_{pl,s} = \alpha_{s,onshore} - \alpha_{s,offshore}$ (Camenen and Larson, 2006b) with:

$$\alpha_{s,i} = 0.7\left(\frac{U_{cw,i}}{W_s}\right)^{0.5}\left(\frac{H_r}{T_{wi}W_s}\right)^{0.25}\exp\left[-0.25\left(\frac{P_{WR,cr}}{P_{WR}}\right)^4\right] \tag{11}$$

where $P_{WR} = H_r / d_{50}$ (H_r is the ripple height) is the vortex suspension parameter proposed by Van der Werf and Ribberink (2004) to predict the direction of the net sediment transport. The critical value is reached for approximately $P_{WR} = 100$.

APPLICATION OF FORMULA

Transport by steady current and waves

The proposed formula (Eqs. 2 to 11) was compared to a large set of experimental data with prevailing bed load or suspended load for both field and laboratory measurements, with current only or with waves and current combined (Camenen and Larson, 2005a, b, 2006a, b, 2007). It generally yields the best results with respect to other relationships found in the literature when compared to the compiled data set (*cf.* Tab.1 and previous papers for the description of the data sets). As shown in Tab.1 where the prediction (in %) of the sediment transport within a factor two is presented, an improvement of the results was obtained using Eqs. 2 and 5, especially for the bed load cases and when phase-lag effects start to prevail. For the suspended load, a slightly larger dispersion of the results was observed, but the prediction results were still better for most of the cases. The proposed formula should thus improve the prediction of sediment transport rate in both the longshore and cross-shore directions.

Longshore sediment transport

The longshore sediment transport is in general current-related, and the waves act primarily as a stirring agent. As observed by Bayram *et al.* (2001), most of the existing formulas yield similar predictive results, *i.e.*, a cross-shore distribution of the longshore sediment transport that is closely related to the cross-shore distribution of the longshore current. The main difference concerns the magnitude of the sediment transport rate, which may be adjusted trough calibration coefficients. A remaining difficulty to describe in the surf zone is that the total sediment transport is often underestimated on the bar, where the waves break, whereas it is often overestimated in the following trough where the breaking waves change to bores. Also, the longshore sediment transport in the swash zone is often neglected although many observations (Wang *et al.*, 2002; *cf.* also Fig.2) have shown that the magnitude of the longshore sediment transport in the swash might be of the same order as magnitude (or even larger than) the longshore sediment transport over the longshore bar. Baba and Camenen (2007) proposed a simple hydrodynamic model for the swash zone to be able to use the formula presented in this paper. Results of comparison between predictions by the present formula (denoted as the Lund-CIRP formula) and measurements from an experimental case presented by Wang *et al*. (2002) are shown in Fig. 2.

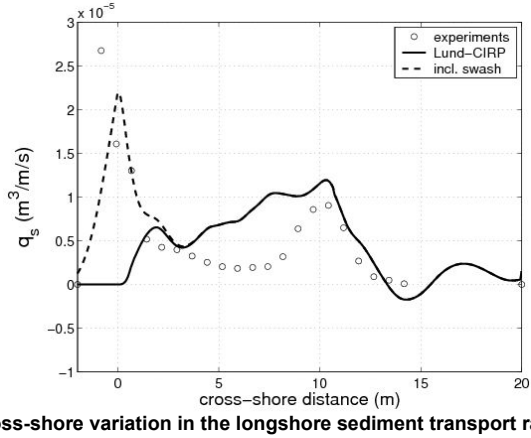

Fig. 2. Cross-shore variation in the longshore sediment transport rate from an experimental case by Wang *et al.* (2002; case 6 with plunging waves)

IMPORTANCE OF WAVE-RELATED TRANSPORT IN CROSS-SHORE DIRECTION

In the cross-shore direction, the current-related sediment transport induces a net transport towards the offshore only (in the direction of the undertow). Including the wave-related sediment transport allows for a possible transport in the onshore direction due to wave asymmetry. However, a complex interaction is obtained that is highly dependent on the bed regime. In case of ripples (offshore zone), the suspended load is prevailing and may be directed offshore due to phase-lag effects, even for strongly

asymmetric waves. In a similar manner, in the case of sheet flow (surf zone), the bed load often prevails and it may also be directed offshore due to the phase-lag effects. As a result the total net sediment transport rate along a cross-shore profile may change direction several times and thus induce a multiple bar system. As all these regimes are highly sensitive to ripple predictions and bed shear stress estimates, significant uncertainties in the calculations are expected.

In order to investigate the sensitivity of the formula in the nearshore, a simple model for the hydrodynamics was developed for a cross-shore line based on Larson and Kraus (2002). It includes the wave evolution and asymmetry (Dibajnia *et al.*, 2001), longshore and cross-shore (mean undertow) depth-averaged currents, bed form characteristics (Van Rijn, 1993; or Soulsby and Whitehouse, 2005; assuming wave ripples prevail), induced current and wave-related bed shear stresses, and total sediment load. In Fig.3, results of the hydrodynamic and sediment transport models are presented for a barred beach and estimates of the total load including (d) or not (c) the phase-lag effects, using the Van Rijn formulas (1993) for the ripple characteristics. The roughness height in presence of ripples was calculated with the Kim (2004) formula.

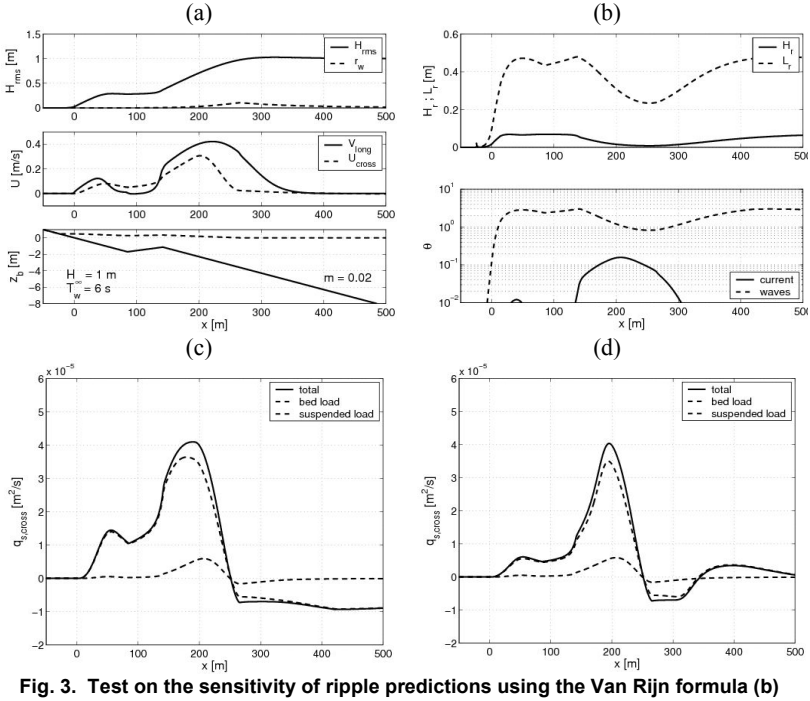

Fig. 3. Test on the sensitivity of ripple predictions using the Van Rijn formula (b) and the induced total load formula with (d) and without (c) the phase-lag effects for typical beach and hydrodynamic conditions (a)

When no phase-lag effects are included, the sediment transport is controlled by the balance between the undertow (which leads to offshore sediment transport) and the wave asymmetry (which leads to onshore sediment transport). If the undertow effects prevail in the surf zone, the wave asymmetry prevails in the offshore zone (cf. Fig.3(c)). A second observation is that the suspended load dominates over the bed load everywhere on a cross-shore line, even in the zone where the ripples are washed out. Fig.3(c) and (d) show how significant the influence of the phase-lag is on the suspended load. Two phenomena occur: First, a reduction of the total sediment flux is observed in the surf zone. Some phase-lag effects are observed since the offshore velocity is larger than the onshore velocity (because of the undertow). This phenomenon may, however, be unrealistic and only an artifact of Eq.11 which allows negative values on $\alpha_{pl,s}$. Second, strong phase-lag occurs in the offshore zone due to the ripples which leads to an opposite direction for the net sediment transport compared to the case when no phase-lag effects are included.

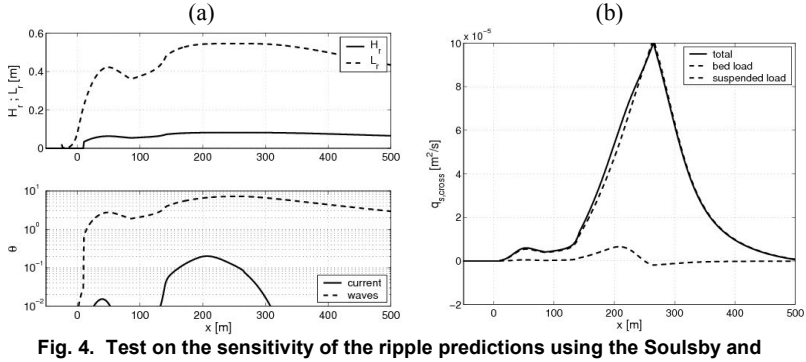

Fig. 4. Test on the sensitivity of the ripple predictions using the Soulsby and Whitehouse formula (a) and the induced total load formula with the phase-lag effects (b) for the same conditions as in Fig.3.

Using the Soulsby and Whitehouse (2005) formulas for the prediction of the ripple characteristics, the results are similar as for the Van Rijn (1993) formula, if the phase-lag effects are not included. However, the presence of ripples on the bar as predicted by the Soulsby and Whitehouse (2005) formula seems unrealistic and induces larger values for the Shields parameter and the suspended load over the bar (cf. Fig. 4(a)). When the phase-lag effects are included, since the Soulsby and Whitehouse formula predicts larger ripple heights on the seaward side of the bar, the phase-lag effects on the suspended load is also stronger. The direction of the net sediment transport is now offshore everywhere on the cross-shore profile. Thus, it seems that the estimate of the ripple characteristics strongly affects the prediction of the net suspended load (and then total load), especially when phase-lag effects are included. The predictors for the ripples characteristics over the domain have to be carefully chosen. Estimation of ripple washout appears to be one of the key issues to improve the prediction of sediment transport in the cross-shore direction.

IMPROVEMENT AND APPLICATION OF FORMULA IN INNER SURF ZONE AND SWASH ZONE

Because of the wave transformation in the surf zone, the wave change to a bore which induces a different velocity profile in the inner surf zone and swash zone (saw-tooth shaped). The asymmetry in the amplitude of the onshore and offshore parts of the velocity may be negligible ($r_w = 0$), but an asymmetry appears in the acceleration profile due the saw-tooth shaped velocity profile (cf. Fig. 5). This asymmetry may be defined with the coefficient $R_{ac} = T_{cu} / T_{cd}$ (for relatively simple wave velocity profile where $r_w = 0$, $R_{at} = T_{tu} / T_{td} = R_{ac}$). On the contrary to T_{wc} and T_{wt}, T_{cu}, T_{cd} T_{tu}, and T_{td} are not function of the steady current U_c and $T_{cu} + T_{cd} + T_{tu} + T_{td} = T_w$. In that sense, the proposed definition slightly differs from the definition proposed by Watanabe and Sato (2004). Watanabe and Sato (2004) observed that an increase in the acceleration asymmetry yields an increase in the suspension at the maximum velocity. They attributed this effect to an increase in the effective near-bed velocity. To treat this problem, Nielsen (2002, 2006) introduced a phase shift between the free stream velocity and the bed shear stress at the peak frequency. This so called "time domain filter method" yields an increase in the instantaneous bottom shear stress for the accelerated part of the flow.

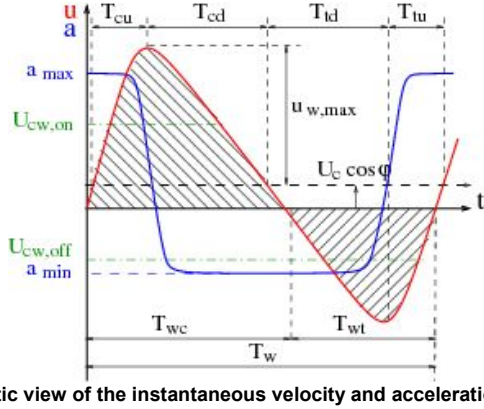

Fig. 5. Schematic view of the instantaneous velocity and acceleration variation for a bore over a wave period and in the direction of the waves

To introduce the effects of the acceleration asymmetry in the bed load formula (Eq. 2), the friction coefficient for wave-current interaction f_{cw} (used for the calculation of the mean shear stress $\theta_{cw,on}$ and $\theta_{cw,off}$) may be modified, assuming that f_{cw} is time-dependent. This modification relies on the assumption that an accelerated flow combined with an increasing velocity yields an increase in the instantaneous friction coefficient (compared to its time-averaged value); an accelerated flow combined with an decreasing velocity yields a decrease in the instantaneous friction coefficient. Eq.3 is thus rewritten:

$$\theta_{cw,net} = (1-\alpha_{pl,b})(1+\alpha_a)\theta_{cw,on} + (1+\alpha_{pl,b})(1-\alpha_a)\theta_{cw,off} \tag{12}$$

where α_a is a coefficient that is a function of R_{ac}. Using the data provided by Watanabe and Sato (2004), the following relationship is proposed:

$$\alpha_a = \frac{1-R_{ac}}{1+R_{ac}} \tag{13}$$

In Fig. 6 is a comparison between the predicted and measured values presented using Eqs.12 and 13 and the experimental data by Watanabe and Sato (2004). About 65% of the data are correctly predicted within a factor two allowed. Even if α_a may also be a function of the medium grain size and the wave period, Eq.13 already yields improved results.

As observed by Nielsen (2006), such an approach requires wave-by-wave analysis for irregular waves which is not very convenient for a simple nearshore model. As a first approximation, a constant value for R_{ac} may be employed also for the case of irregular waves.

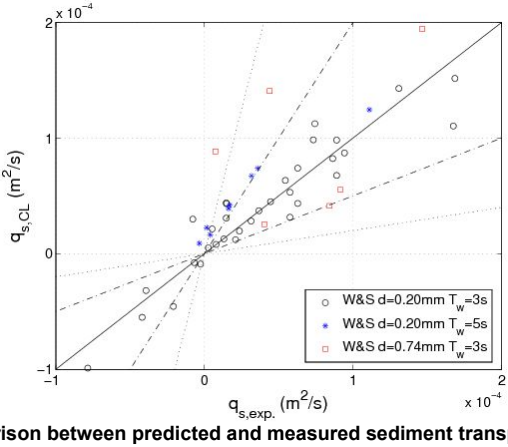

Fig. 6. Comparison between predicted and measured sediment transport rate using Eqs. 2, 12 and 13, and the experimental data from Watanabe and Sato (2004), which illustrates the influence of the acceleration asymmetry

In the same manner as Dibania *et al.* (2001) proposed an empirical relationship for the wave asymmetry across the surf zone (based on a large experimental data set), there is a need of a relationship to estimate the acceleration asymmetry across the surf zone and the swash zone. This latter quantity may be estimated using experimental data and numerical Boussinesq-type wave models.

CONCLUSIONS

A total load sediment transport formula is presented based on recent studies on the bed load and suspended load transports for the nearshore. Phase-lag in the sheet-flow layer or due to ripples, as well as acceleration effects, is included in the formula. This total load formula yields the best results among the studied formulas using a large data set of laboratory and field measurements for various regimes where bed load or suspended load prevails and with possible phase-lag effects in the sheet-flow layer or over the ripples. The formula also appeared to be applicable in the swash zone thanks to a simple hydrodynamic model.

A sensitivity analysis was performed to better qualify and quantify the current-related and wave-related sediment transport. It appeared that the prediction of the ripple characteristics (and the phase-lag effects over the ripples) is fundamental for a proper estimation of the suspended load in the direction of the waves. The ripple washout criterion may be one of the key issues. For the longshore sediment transport where the current-related total load prevails, the formulas are not as sensitive. Some improvement may be made for the effects of the breaking waves and rollers on the suspension.

Finally, the formula was improved to include the effects of a possible acceleration asymmetry in the wave velocity profile. The formula yields correct results compared to the experimental data by Watanabe and Sato (2004). There is however a need of a simple model to estimate the acceleration asymmetry across the surf zone and the swash zone.

Abstract: Small-scale laboratory experiments were conducted to investigate the total and the cross-shore distribution of longshore sand transport rate on long straight beaches of uniform grain size under monochromatic waves. An efficient trap system was introduced to collect the sediments transported alongshore. Substantial peak in the distribution of longshore sand transport rate was observed in the swash zone, in addition to the peak at the breaker zone under relatively strong plunging breakers. The cross-shore distribution of longshore sand transport rate was found to be dependent on the profile of the beach and the period of the waves, which controlled the breaker type.

INTRODUCTION

The breaking waves in nearshore combined with various nearshore currents transport beach sediments. Under certain conditions, it is only a local rearrangement of sediments in cross-shore direction, *e.g*., normal and storm beach profiles. The sand transport, which is found to occur parallel to the coast within the surf zone is defined as longshore sand transport. Cross-shore gradient of the longshore momentum flux generated by wave breaking process sets up longshore current and considered to be the major driving force of the longshore sand transport (hereafter LST).

If the LST rate is uniform in the longshore direction, the beach should become stable and fall into dynamic equilibrium state, i.e., beach profile will not change, while sediments

are still transported in longshore direction; hence any variation of LST rate could be a major factor, which governs erosion or accretion along a coast. In this sense, it is essential to obtain a better understanding of LST process in both qualitative and quantitative terms for most of the coastal engineering applications such as shoreline evolution behind structures, dredging of navigation channels etc. Not only the prediction of total transport rate but also its cross-shore distribution is desired to describe the morphological change in the vicinity of coastal structures and shoreline response behind them accurately.

The primary objective of this study is to investigate the sensitivity of beach profile and incident wave period to cross-shore structure of LST rate and to describe sediment movement mechanism on beaches, where the bed load dominates the suspended load.

EXPERIMENTAL METHODS

Experimental set-up

Experiments were performed in a wave basin with dimensions 11m x 6.5m x 0.3m using obliquely incident monochromatic waves. The wave basin was equipped with wave paddles capable of generating multi-directional random waves. The system could be run with the "reflection absorption mode" that was designed to cancel reflection from the wave generating boards. To minimize wave reflection from the downdrift end boundary of the wave basin, a "sponge layer" with 0.5m in width was provided as sketched in Fig. 1 (not drawn to scale).

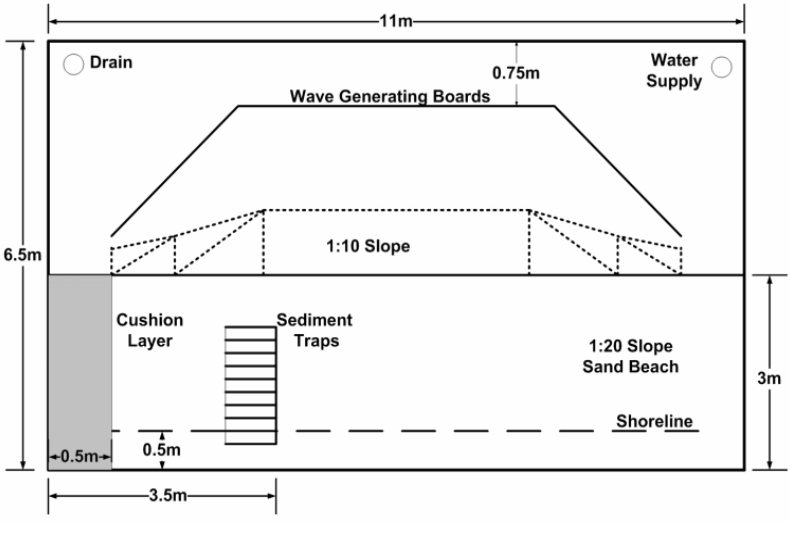

Fig. 1 Wave basin set-up

Each experiment was divided into three 15-minute segments. During the first segment, waves were generated without any measurement being taken, to allow the beach to reach a stable profile. Then wave heights and current velocities were measured during next two segments, respectively. No sand recharge was carried out during the experiments as no significant alongshore variation in the beach profile was observed during these experiments.

Beach profile preparation

To obtain the rate of LST and its cross-shore distribution accurately, it was necessary to maintain straight and parallel depth contours throughout the model beach, as beaches having three-dimensionality tend to change nearshore waves and longshore currents, and subsequently sediment transport.

Material used in the experiments was well-sorted fine quartz sand of $D_{50} = 0.2$ mm. The area of 10m x 3m was filled with sand to an average depth of 4cm over the 1/20 uniform slope. The beach slope was 1/20 for the entire area except for the foreshore portion of swash motion, which was kept at 1/7.5. The height of the berm was selected so that the maximum excursion of wave run-up in the swash zone would not reach the highest elevation of the berm. It was desirable to introduce a 2-D berm artificially to the beach, in order to avoid three-dimensional evolution of topography. On the other hand, it was also necessary to reduce the time for the beach to reach a realistic profile (concave shape). The foreshore slope (1:7.5) was evaluated after several tests for 2-3 hours of wave action starting with an initial plane beach of 1:20 slope (preliminary movable bed experiments).

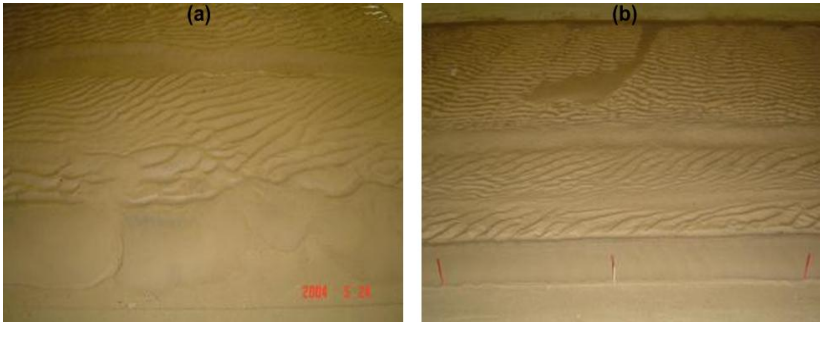

Fig. 2 Resulted bottom topography (a) without an initial berm after 2 hours (3-Dimensional beach) (b) with an initial berm behind the foreshore portion after 45 minutes.

Wave height and longshore current velocity measurements

Wave heights were recorded using capacitance type wave gauges (two gauges were mounted on the bridge with 25cm interval in the alongshore direction) and the cross-shore distribution of longshore current was measured using electromagnetic current meters (EMC). The current meter was located at one third of the water depth from the

bottom, which was near the elevation of the depth-averaged current velocity in the case of a logarithmic velocity profile.

Wave direction at the breaking point was estimated from the phase lag between the two wave gauges and compared with that obtained using EMC meter, in which wave direction was determined from linear regression of cross-shore water particle velocity vs. longshore water particle velocity plot.

Sediment collection

It was important to introduce a reliable technique to measure the cross-shore distribution of LST rate. Three standard techniques are used worldwide in field namely, sand tracers, long and short time impoundments and streamer traps. However, a buried type of trap system was found to be the only feasible technique to serve this purpose, having evaluated the available laboratory conditions and resources. The best geometry and the structure of the trap were determined through a laborious trial and error method.

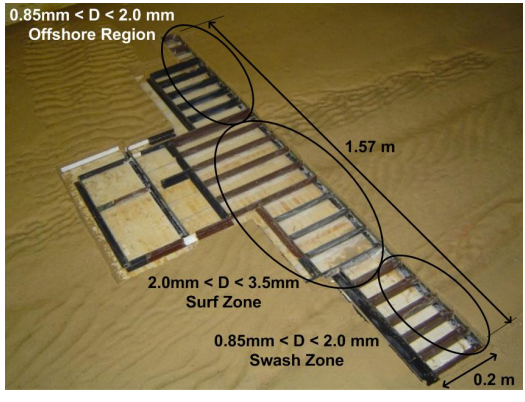

Fig. 3 Buried type of trap system.

The trap system (see Fig. 3) was installed in the centre of the wave basin, as it was impossible to keep it at the furthest point of downdrift side, due to the boundary effect of the wave basin. The boundary between the trap and the sand bed was found to be highly sensitive to the sand movement. If the trap boundary was higher than the sand bed level, it would underestimate sand volume due to the obstruction caused by the boundary. It could even divert the current offshore and at the same time caused scour at the boundary. On the other hand, if the trap boundary was lower than the bed level, it might over-predict sand movement. Therefore, the rigid boundary of the trap had to be lower than the lowest level of the sand bed, while the remaining portion was covered with a flexible material.

First, the trap was emptied prior to sediment collection. The offshore portion of the trap was then filled with a coarser material (0.85mm< D_{50} <2.0mm) to eliminate any over-

prediction due to orbital motion of sand particles. Here the minimum diameter of the coarser material needed to be larger than the maximum diameter of the fine sand. Sediment of similar size (0.85mm< D_{50} <2.0mm) was used within the trap situated in the swash zone, as swash motion was highly sensitive to the sediment size due to the relatively smaller scale fluid motion there. The remaining area of the trap was covered with an aluminum mesh to allow sufficient space for the sand to get collected and was leveled with a much coarser material of mean diameter (2.0mm< D_{50} <3.5mm), leaving sufficient space for the sand to be trapped without being bypassed over the trap. Materials inside each trap cell were sieved and fine sand was separated from coarse sand after the action of waves over a known sampling period. This fine sand was then dried and weighed to calculate the sand transport rate.

Repeatability of test results

It was necessary to reproduce the results under the same wave condition to confirm the reliability of sand transport rate measurements. Fig. 4 shows the average beach profile and cross-shore distribution of LST rate for wave condition SW4E (see Table 1) in two different tests. Only minor differences could be observed in average beach profiles and sand transport rates confirming the repeatability of the tests and the reliability of the buried trap system for sediment collection.

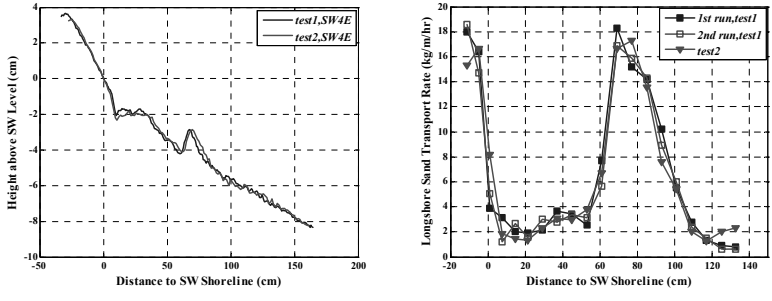

Fig. 4 Repeatability of test results.

RESULTS & DISCUSSION

Introduction

In LST, sand grains are set in motion mainly by wave action and carried by longshore current. Despite many research outputs are available on total LST rate, only few are reliable on the cross-shore distribution. In this study, monochromatic incident waves were used to obtain LST rates and its distributions for different wave conditions (see Table 1, in which wave conditions with subscript *board* stands for the condition at wave generating boards, *b* for breaking condition and 0 for deepwater condition). Each test was conducted with a water depth of 0.24m at the wave generating boards. In the present

study, bottom slope at the breaking point (m_b) is defined as the slope between the breaker line and the still water shoreline.

Wave height distribution and the average beach profile associated with all the tests are shown in Fig. 5, where SW1E, SW2E, SW4E, SW7E, SW8E were conducted on barred concave beach profiles with steep foreshore slope and SW4U on uniform beach profile of 1/18 slope.

Table 1. Longshore Sand Transport Experiment Wave Conditions

Experiment		SW1E	SW2E	SW4E	SW4U	SW7E	SW8E
Wave Height (cm)	H_{board}	3.8	3.4	3.4	3.4	3.4	4.0
	H_0	4.2	3.7	3.6	3.6	3.7	4.3
	H_b	5.4	5.0	5.6	5.7	4.8	6.6
Wave Period (s)	T	1.0	1.0	1.25	1.25	1.0	1.25
Water Depth (m)	h	0.24	0.24	0.24	0.24	0.24	0.24
Wave Angle (deg)	θ_{board}	20	15	20	20	30	16
	θ_b	13.4	6.7	11.8	13.1	15.0	9.9
Breaker Index	γ_b	0.83	0.98	0.98	1.00	0.99	1.02
Breaker Slope	m_b	0.054	0.054	0.057	0.055	0.053	0.055
Surf Similarity Parameter	ξ_0	0.33	0.35	0.47	0.45	0.34	0.41
	ξ_b	0.29	0.30	0.38	0.36	0.30	0.33
Breaker Type		WPL	WPL	PL	PL	WPL	PL

* WPL – Weakly Plunging; PL – Plunging.

In test cases SW1E, SW2E and SW7E, wave breaking was weakly plunging as it could be seen by the formation of mild bars. At the incipient breaking point, energy dissipation was found to be less dynamic. However, secondary wave breaking occurred in the mid surf zone particularly in SW1E and SW2E, creating prominent intermediate bars. In SW4E, SW4U and SW8E, waves broke by plunging as evident by the formation of substantial alongshore bars and troughs (except SW4U). In addition, bar type formations were observed in the mid surf zone in all cases, which resulted by the induced mass transport cells under partial standing waves (significant wave reflection was observed in all the tests, which led to node/anti-node phenomenon across the surf zone, see Fig 6).

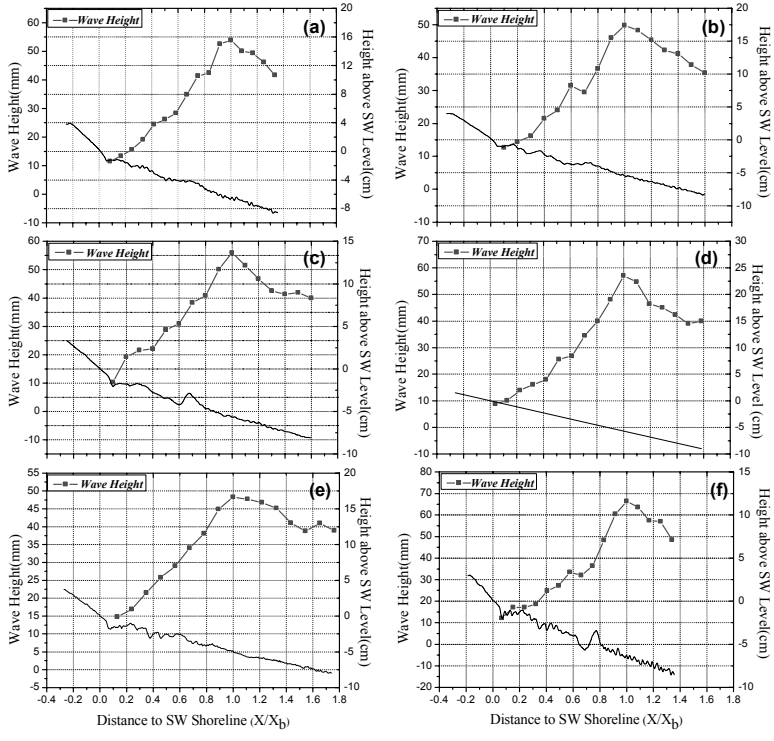

Fig. 5 Wave height distribution and the beach profile across the surf zone associated with (a) SW1E (b) SW2E (c) SW4E (d) SW4U (e) SW7E (f) SW8E

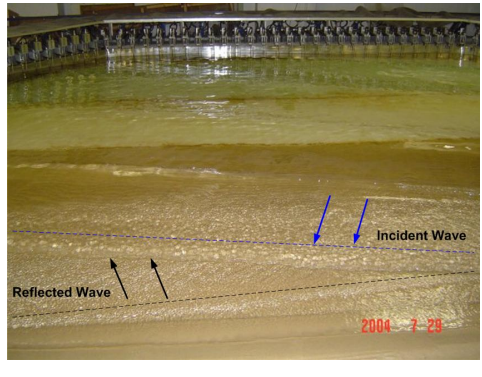

Fig. 6 Wave reflection from the steep foreshore

Cross-shore distribution of longshore sand transport rate

The cross-shore distributions of longshore current velocity for all the tests except SW8E (unexpected error occurred during the measurement of longshore current) are shown in Fig. 7. Interestingly peaks were observed just shoreward of the incipient breaker point bars in all the tests and prominent secondary peaks were observed shoreward of intermediate bars in SW1E and SW2E.

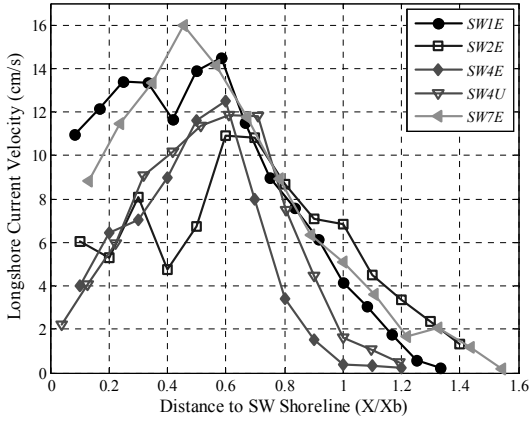

Fig. 7 Cross-shore distributions of longshore current velocity

Generally, the cross-shore gradient of the radiation stress and that of the longshore momentum flux due to the surface roller are thought to be the driving forces of the longshore current. The energy of the wave motion is first transferred to the surface roller energy, and then the energy is dissipated. Accordingly, the peak of the cross-shore gradient of the momentum flux due to the surface roller is located shoreward of the peak of the gradient of the radiation stress. As a result, when the cross-shore gradient of the momentum flux due to the surface roller is comparable to that of the radiation stress, the peak of the longshore current velocity is shifted shoreward. However, Reniers and Battjes (1997) suggested that surface roller effect can at most cause a relatively minor shift of the longshore current velocity maximum away from the bar crest. Further they concluded that longshore inhomogeneities in the bathymetry and wave field might result in longshore pressure gradients, which leads to this shoreward shift of longshore current velocity peak (Putrevu et al., 1995).

The cross-shore distribution of measured LST rates for all the tests are shown in Fig. 8. At incipient breaking, a substantial peak in the distribution of LST rate was found for SW4E, SW4U and SW8E, which were the plunging breaker wave cases. The turbulence associated with the plunging waves (due to the curl of water) penetrated deep into the water column, impacted the bed, and caused sand to be suspended and transported by the longshore current. In SW1E, SW2E and SW7E, the main breaker type was found to be

weakly plunging and some turbulence associated with this breaking caused relatively small peaks in the cross-shore distribution of LST rate at the incipient breaking.

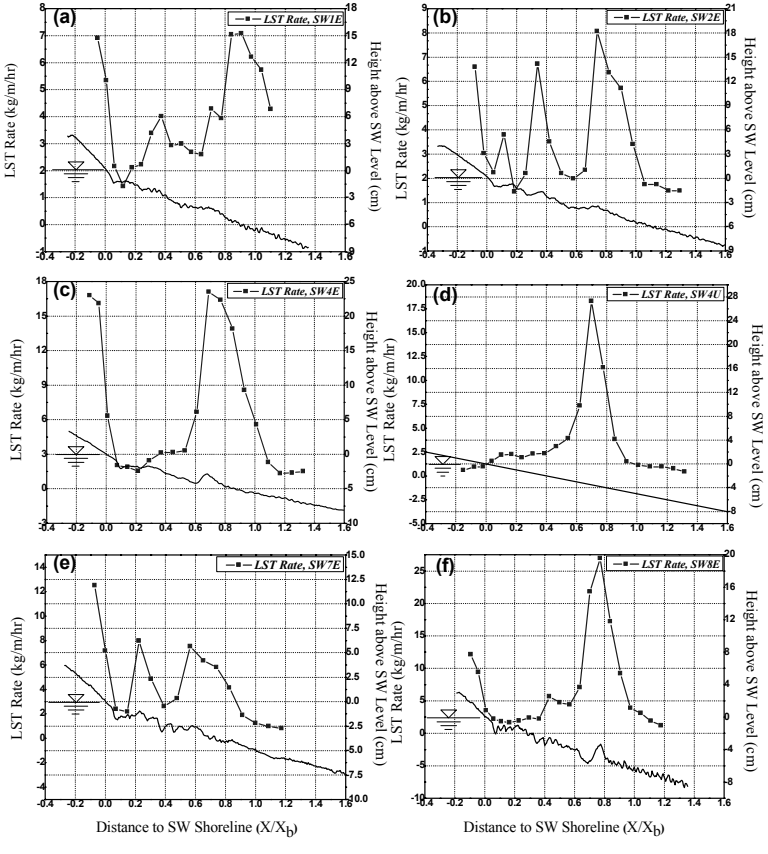

Fig. 8 Cross-shore distribution of longshore sand transport rate in cases (a) SW1E (b) SW2E (c) SW4E (d) SW4U (e) SW7E (f) SW8E

It is often believed that the sediment flux in mid surf zone is mainly controlled by the water depth; hence, wave height is the dominant parameter over wave period. In that sense, if a gradual decay of wave height is observed, less sediment flux can be expected in mid surf zone. However due to the secondary breaking, peaks were found in the cross-shore distribution of LST rate in mid surf zone for SW1E and SW2E (peak just shoreward of the peak at incipient breaking) and the secondary peaks in the longshore current velocity distribution complimented them. In addition, another peak of LST rate was found offshoreward of the peak in swash zone for SW2E and SW7E, apparently at

the bar (which formed under partial standing waves) due to the sediment mobility at the bar (anti-node) and low water depth. It is interesting to note that, substantial peak in the distribution of LST rate was observed at the swash zone (the region where run-up & run-down of waves are observed) in all the cases except SW4U.

No significant difference was observed in the wave height and longshore current distributions between SW4E (concave beach profile with steep foreshore slope) and SW4U (uniform beach slope). However prominent differences were noticed in the longshore sand transport distribution at the swash zone and the breaker zone. Substantial peak in the LST rate distribution was not observed in SW4U compared to SW4E at swash zone. This was mainly due to the mild foreshore slope in SW4U. Peak of the distribution in LST rate around the breaker point for SW4U was found to be slightly higher than that of SW4E, possibly due to the intensive cross-shore sand transport at the plunging point until it reached some near equilibrium to a bar and trough formation. On the other hand, the peak of the LST rate distribution of SW4E was found to be broader (offshoreward of breaker zone peak) than that of SW4U due to the difference of bed forms, as the suspended sediments over ripple bed, which were carried by longshore current, enhanced the sand transport rate in SW4E.

Total longshore sand transport rate

The total LST rates (dry mass rate) were calculated by summing up the sediment fluxes measured in all the trap cells and are listed in Table 2.

Table 2 Measured and Computed LST Rates

	SW1E	SW2E	SW4E	SW4U	SW7E	SW8E
Measured total LST rate (kg/hr)	5.98	5.00	9.66	5.36	5.34	10.96
Calculated total LST rate (kg/hr) by Kamphuis (1991) formula (dry mass rate)	22.38	14.46	30.66	34.89	17.74	37.06

Among the numerous formulae for predicting longshore sediment transport (derived using energetic, force balance or dimensional analysis method), the one derived by Kamphuis (1991) was used to compare the results obtained in the present study. This formula was developed after extensive model studies and has been applicable to prototype sandy beaches (see Fig. 9).

The Kamphuis (1991) formula in dimensionless form is expressed as follows:

$$\left(\frac{Q_u}{\rho H_{sb}^3 / T_p}\right) = 1.3x10^{-3}\left(\frac{H_{sb}}{L_{op}}\right)^{-1.25} m_b^{0.75}\left(\frac{H_{sb}}{D_{50}}\right)^{0.25} \sin^{0.6}(2\alpha_b) \qquad (1)$$

where Q_u is the underwater mass of transported sand, ρ is the density of fluid, H_{sb} is

the significant breaking wave height, T_p is the peak wave period, D_{50} is the median grain diameter, m_b is the beach slope at wave breaking, and θ_b is the breaking wave angle.

Wang et al. (2002) carried out large-scale laboratory experiments at CHL, US Army Corps of Engineers, Vicksberg, USA, to investigate the effect of breaker type on longshore sand transport rate with equilibrium beach concept (concave shape). The average deep-water wave height was around 0.2m and mean diameter of the sand used was 0.15mm. In their study, the final equilibrium beach profiles were obtained with the initial preparation of 1:5.5 slope for foreshore and 1:27 slope for surf zone. These results also showed that the Kamphuis (1991) formula provided consistent and fairly accurate predictions for the total rate of longshore sand transport under different wave conditions (see Fig. 9).

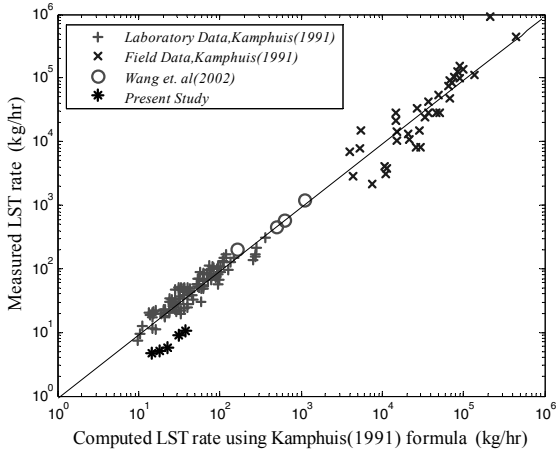

Fig. 9 Comparison of measured LST rates with Kamphuis(1991) formula

Generally, beach profile in field conditions exhibits remarkably concave shape under equilibrium conditions, which can be expressed by Dean (1977) model; i.e. $h(y) = Ay^{2/3}$, in which $h(y)$ is the water depth at a distance y offshore, A is a function of sediment size, D_{50}. Dean proposed a simple relationship between A and fall velocity, $w_f (= f(D_{50}))$.

$$A = 0.5 w_f^{0.44} \tag{2}$$

where A has the dimensions of $\mathrm{m}^{1/3}$ and w_f is in m/s, in which,

$$w_f = \left[(\rho_s/\rho - 1)g\right]^{0.7} \frac{D_{50}^{1.1}}{6\nu^{0.4}} \quad \text{for} \quad 0.13x10^{-3} \le D_{50} \le 1.6x10^{-3} \text{ m} \tag{3}$$

and for coarser material

$$w_f = 1.05\left[(\rho_s/\rho - 1)gD_{50}\right]^{0.5} \quad \text{for} \quad 1.6x10^{-3} \le D_{50} \le 8.0x10^{-3} \text{ m} \tag{4}$$

where ρ_s is the density of sediments, ρ is the density of fluid in kg/m^3, g is the gravitational acceleration in m/s^2 and ν is the kinematic viscosity of fluid in m^2/s.

At the same time, it is essential to describe the beach slopes with respect to the mobility number (H_b / D_{50}), as an equilibrium beach profile occurs when constructive and destructive forces acting on seabed are balanced. In that sense, if a beach is not fully modeled (wave height and periods are modeled but not the sand grain size) in the laboratory, the model beach will have a steeper slope than the prototype beach.

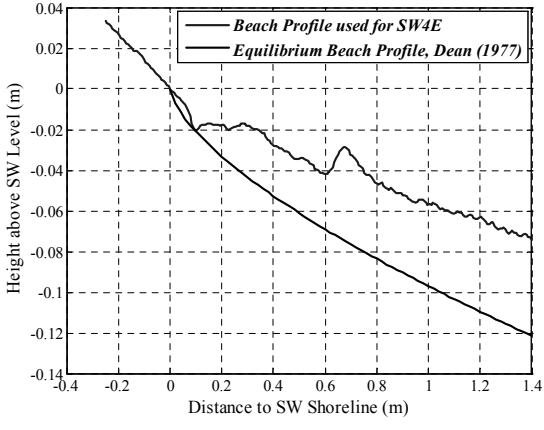

Fig. 10 Comparison of beach profiles used in present experiments.

As Kamphuis (1991) experiments were also carried out under small-scale laboratory conditions (slightly larger scale than the present study), his experiments certainly suffered the scale effect. However average beach slope was around 1:10 at equilibrium under the given wave conditions due to small H_b / D_{50} value. The direct scale effect (not scaling the sediment size) decreased the sand transport rate, while the increase in beach slope (the smaller the ratio H_b / D_{50}, the steeper the beach slope) increased the sand transport rate, *e.g.*, spilling breaker condition in the field might become plunging breaker in a model beach (given that the sediments were not scaled) under laboratory conditions; hence leading to the increase in sand transport rate due to change in breaker

type as the energy dissipation through wave breaking is concentrated over a much narrower region. The other important consequence of this narrow, energetic breaker zone was that the swash zone had been of similar width to the surf zone and accordingly the sediment transport within swash zone was more significant. Moreover, in those steep model beaches refraction of waves could have easily been incomplete, making the waves to arrive at the beach face with a considerable angle. Kamphuis (1991) showed that under these conditions, scale effect for sand transport rate appeared to be small, since the effects of distorted beach slope and grain size tended to cancel. Kamphuis also investigated the applicability of Eq. (1) to beaches with coarse-grains by comparing its predictions with the experimental results of Van Hijum and Pilarczyk (1982). He found that his formula over-predicted their results by a factor 2-5, concluding that this was to be expected, since gravel beaches will absorb substantial wave energy by percolation and the motion of the larger grains is much closer to the critical mobility numbers. Neither of these factors was included in his dimensional analysis leading to Eq. (1).

Kamphuis (1991) experiments were conducted in a slightly larger scale than the present experiments and the suspended load was found to be 0.7 times the bed load on average. However in physical models of present study (which can be considered as representative scaled models to coarse-grained beaches, irrespective of the beach slope and hydraulic conductivity) bed load was found to be more dominant over suspended load due to the relatively low stresses exerted, where in certain portions of the mid surf zone, the sand transport rate was found to be as low as 2 kg/m/hr. On the other hand, as it is evident from Fig. 10, longshore sediment transport rates were not measured on equilibrium beach slopes (the beach slopes were milder than the equilibrium beach slopes for the given wave condition and sediment size) in the present experiments, hence no substantial increase in sand transport rate was expected due to the effect of beach slope. This incompatibility in equilibrium beach slope further increased the difference between the measured sand transport rates and those predicted using Kamphuis (1991) formula (see Fig. 9).

CONCLUSION

A series of laboratory experiments were performed to investigate the cross-shore distribution of longshore sand transport rate under different wave conditions. An improved buried-type trap system was developed to measure the cross-shore distribution of longshore sediment transport.

The total LST rate and its distribution were found to be dependent on wave period and beach profile. Significant amounts of sand transport were measured for all the cases in the swash zone. Under relatively strong plunging breaker conditions substantial peaks were observed at the plunging point and swash zone. The dynamic behavior of the plunging breakers stirred the sand to be suspended and carried by longshore current at the plunging point. High energy of the run-up and run-down process in long period waves made the difference in the distribution of LST rate at swash zone compared to relatively short period waves. Alongshore bars were observed in mid surf zone for all the tests. Secondary breaking or induced mass transport cells under partially standing waves

or a combination of those two was found to be the reason for the formations of intermediate bars. Interestingly peaks in the cross-shore distribution of LST rate were noticed apparently at these bars including the one at the main breaking point.

Kamphuis (1991) formula overpredicted total LST rates obtained from these small-scale physical models as the critical shear parameters were not included in the dimensional analysis leading to his expression (the motion of sediment grains was much closer to critical mobility numbers in the present experiments). On the other hand, beach slopes were not modeled to match the equilibrium under the wave condition and the sediment size used in present experiments; hence, surf zone was found to be relatively broader and less energetic, which is inconsistent with Kamphuis (1991) experiments. This resulted less sediment suspension in both surf zone and swash zone, which further increased the difference between measured and predicted LST rates by Kamphuis (1991) formula.

Despite the shortcomings of scale effect, data from physical model tests conducted here can be utilized to calibrate and validate formulae for predicting total longshore sand transport rate and its distribution, particularly for coarse-grained beaches.

PRESSURE-INDUCED SUBSURFACE SEDIMENT TRANSPORT IN THE SURF ZONE

Ole Secher Madsen and William McKinney Durham

Abstract: The horizontal pressure gradient associated with the steep front of forward-leaning breaking waves is transmitted into the porous bottom to depths far exceeding the depth of the shear-stress-induced surficial transport sheet flow layer. The horizontal pressure gradient induces a flow within the bed which exerts a seepage force on the soil-skeleton. If sufficiently large the seepage force will cause a failure of the soil matrix and displace subsurface sediment grains, i.e. result in a subsurface sediment transport. This paper investigates the pressure-induced subsurface transport mechanism experimentally by photographically recording the displacement profile of subsurface lightweight sediment grains during passage of the steep front of breaking waves. A simple theoretical model for the dynamic response of subsurface sediments in failure is developed and provides predicted displacement profiles in reasonable agreement with measurements. The potential importance of the subsurface sediment transport mechanism is discussed.

INTRODUCTION

The pressure distribution on the bottom underneath forward-leaning near-breaking or broken waves is transmitted into the porous bed, where it induces a flow. This pressure-induced porous media flow extends to depths into the bed scaled by the horizontal scale of the pressure distribution and exerts a seepage force on the sediment grains within the bed. The horizontal component of this seepage force is related to the horizontal pressure gradient of the pressure distribution on the bottom and is therefore particularly pronounced under the steep front of a forward-leaning breaking wave and may, if sufficiently large, cause a soil-mechanics-type failure of the bed. This mechanism of a

pressure-induced subsurface failure during passage of breaking waves was first identified by Madsen (1974) who, based on a simple model akin to models used for the prediction of slope stability in geotechnical engineering, hypothesized that this failure mechanism could explain the burial of tracer particles to considerable depths below the sediment-fluid interface in the surf zone. He argued, however, that this failure mechanism would have an insignificant effect on sediment transport rates in the surf zone because it would merely reduce the critical shear stress for initiation of motion from τ_{cr} to 0 with τ_{cr} reasonably expected to be far smaller than the bottom shear stress, τ_b, under breaking waves, i.e. $\tau_b - \tau_{cr} \approx \tau_b$, and hence an insignificant effect on surficial shear-stress-induced sheet flow transport.

Drake and Calantoni (2001) developed a sophisticated granular flow model for the bottom-shear-stress-induced surficial sediment transport, referred to as sheet flow transport, under forward-leaning breaking waves. They found that inclusion of a forcing term related to the pressure gradient under the steep front of a breaking wave had a pronounced effect on the surficial sediment transport rates predicted by their model. Following their lead, Hoefel and Elgar (2003) subsequently succeeded in predicting on-shore bar migration by including a pressure gradient transport term in their empirical sediment transport formulation.

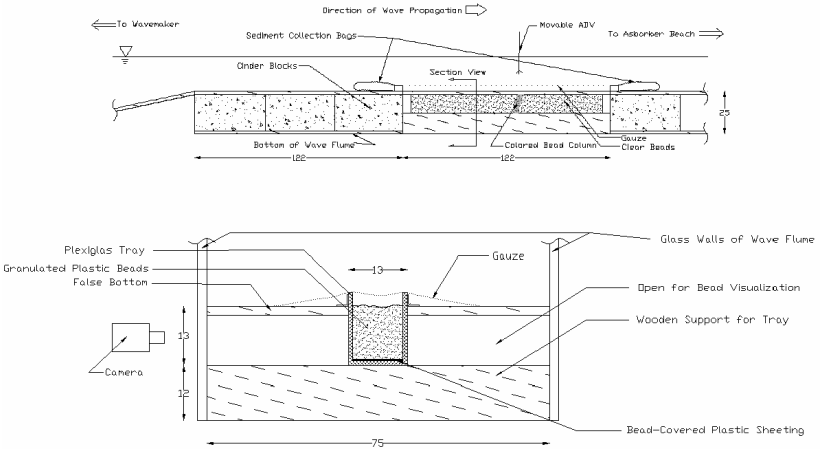
The renewed interest in pressure-gradient-associated sediment transport processes in the surf zone and the delicate balance between on- and off-shore transport rates for equilibrium beach profile predictions, prompted us to revisit the subsurface pressure-induced failure mechanism and its potential contribution to sediment transport rates in the surf zone. This time, however, a more extensive experimental investigation is carried out, as described in the first section of this paper. Also, the simple soil mechanics subsurface failure analysis, presented by Madsen (1974), is extended to include the dynamic response of the subsurface sediment in failure. This model is described in the subsequent section and affords an approximate prediction of the displacement of subsurface sediment grains caused by the passage of the steep front of a forward-leaning breaking wave. Finally, we show that the simple approximate model is capable of predicting experimentally observed displacements reasonably well; and we conclude with a discussion of the potential importance of the subsurface pressure-gradient-induced sediment transport rate relative to the shear-stress-induced surficial sheet flow transport rate in the surf zone. The reader interested in more details of this study than the page-limitation allows us to present here, is referred to Durham (2007).

EXPERIMENTAL INVESTIGATION

Experiments were conducted in the 30m-long, 0.9m-deep and 0.76m-wide wave flume in the J. Robert Gunther Environmental Fluid Mechanics Laboratory in the Ralph M. Parsons Laboratory. The wave flume is equipped with a programmable piston-type wave maker and has a 1 on 10 sloping absorber beach. An instrument carriage runs along the length of the flume on rails that are mounted on top of the frames that support the flume's glass sidewalls.

The Experimental Set-up

The experimental set-up, show in Figure 1, consists of a horizontal shelf made of marine plywood that forms a "false bottom" 25 cm above the actual flume bottom. Waves climb a 1 on 6 sloping ramp and enter the shelf where breaking is triggered. The breaking wave travels over the first section of the shelf before it enters the test section, which consists of a 10cm-wide, 100cm-long and 15cm-deep Lucite tray installed into the false bottom along the centerline of the flume. To prevent lateral loss of sediment during experiments the tray is covered by gauze, and to allow determination of longitudinal transport, sediment collection bags are installed at each end of the tray.



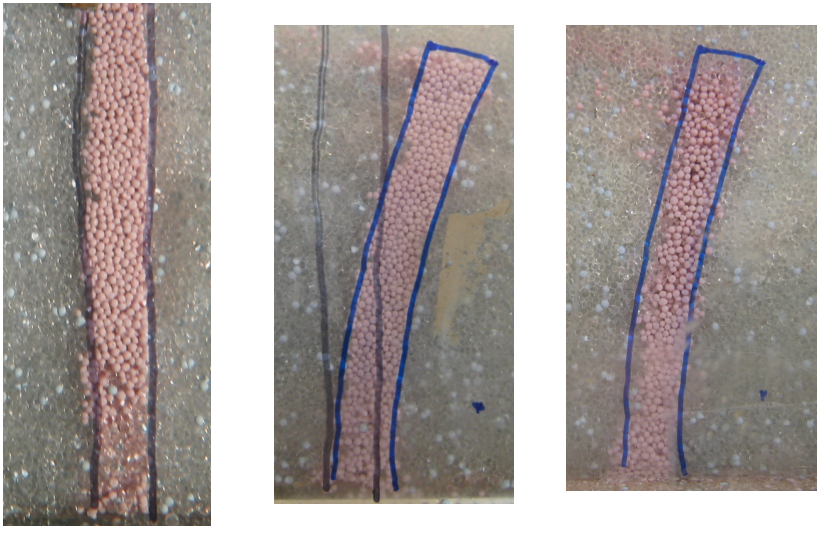


Fig. 1. Experimental Set-up (all dimensions in cm)

The Lucite tray protrudes below the false bottom and contains the sediment, making the sediment bed directly observable through the flume's glass sidewalls. The subsurface movement of a ~2cm-long column of colored sediment inserted in the sediment bed, at the midpoint of the test section, is recorded photographically using a Canon PowerShot S230 digital camera for both stills and video (with a frame rate of 15 frames per second). From the videos, shot during passage of a breaking wave, frame by frame analysis determines when the sediment column starts to move, when it reaches its maximum forward deflection, and when it comes to rest after the wave has passed. Since we are recording the displacement of the column of colored beads along the sidewalls of the Lucite tray, we cut a slice along the centerline of the Lucite tray, by inserting a thin Lucite sheet into the bed, to see if the observed displacements along the sidewall were representative of the displacements over the entire width of the column of colored beads. As evidenced by the still photos shown in Figure 2, we have in this manner verified the validity of our experimental procedure for the determination of subsurface, pressure-gradient-induced movements of a sediment bed.

Since the experimental conditions simulate two-dimensional conditions, the smooth sidewalls of the Lucite tray allow a near-frictionless movement of the sediment grains in contact with the sidewalls, i.e. reproduce two-dimensional conditions. The bottom of the Lucite tray is covered by sediment grains glued to the surface of a thin plastic sheet. Preliminary experiments showed that the entire sediment bed would slide along the bottom when this was left smooth. With the roughened bottom, the near-bottom sediments in the Lucite tray remained immobile during the experiments (see Figure 2).

The initial "top" of the column of colored sediments coincides with initial sediment fluid interface and is covered from view by the false plywood bottom. However, after passage of several waves a sharp interface between the top of the column of colored sediments, now covered by plain sediment, is clearly visible (Figure 2(b) and (c)). Thus, as conjectured previously in the Abstract, the pressure-gradient-induced subsurface transport, represented by the displacement of the column of colored sediments, extends to much greater depth within the bed than the thickness of the sheer-stress-induced surficial sheet flow, which is responsible for the shaving off of the top portion of the column of colored sediments.

(a) (b) (c)

Fig. 2. Still Photos of the Colored Sediment Column Inserted in the Sediment Bed. (a) Before; (b) After waves (along sidewall); (c) After waves (along centerline)

The Sediment

Madsen (1974) showed that pressure-induced bed failure would occur if the bottom pressure gradient exceeded a critical value given by

$$\left|\frac{\partial p}{\partial x}\right|_{crit} = \left(\rho_s(1-n) - \rho(1-n)\right) g \tan\varphi = \left(\rho_b - \rho\right) g \tan\varphi \qquad (1)$$

where ρ_s and ρ are the sediment and fluid densities, respectively, n is the porosity, g is gravity, φ is the internal friction angle of the sediment which is assumed cohesionless, and ρ_b is the density of the saturated bed. To maximize the subsurface pressure-gradient-inducing displacements and make these detectable in our small scale laboratory experiments, a light-weight "sediment", Polyethylene Terephthalate (PET), was chosen. The relevant physical characteristics of this sediment were determined to be: diameter = d = 1.1 ± 0.1 mm, density = ρ_s = 1.27 ± 0.01 g/cm^3, porosity = n = 0.37 ± 0.02, so ρ_b = 1.17 ± 0.01 g/cm^3 and angle of internal friction φ = 34°.8 ± 1° and 39°.2 ± 1°.1 for loosely and densely packed deposits, respectively. The characteristics of the colored PET beads were determined to be essentially identical to those listed above, and a surfactant (Windex) was added to the water to prevent the beads from sticking together.

The Waves

To maximize our ability to stop the experiment after any number of waves, the experiments were performed programming the wave maker to generate solitary waves. The near-bottom orbital velocity as the breaking waves pass over the test section was measured with a Sontek ADV system sampling at a rate of 25Hz. Assuming the breaking waves to be of near-permanent form, i.e. taking $\partial/\partial t \cong -c\partial/\partial x$ with c denoting the phase velocity of the wave, the smoothed time-series of near-bottom horizontal velocity, $u(t)$, provides an estimate of the associated bottom pressure gradient, since we have

$$-\frac{\partial p}{\partial x} = \rho\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x}\right) \cong \rho\frac{\partial u}{\partial t}\left(1 - \frac{u}{c}\right) \qquad (2)$$

Furthermore, by replacing $-\partial p/\partial x$ by $c^{-1}\partial p/\partial t$, (2) may be integrated to obtain the temporal bottom pressure variation $p(t)$ from which the spatial variation of the bottom pressure, $p(x)$, is obtained by replacing t by $-x/c$. Figure 3 shows the smoothed record of the measured near-bottom horizontal velocity $u(t)$ and the corresponding temporal variation of bottom pressure and pressure gradient obtained from (2) by ensemble averaging 10 wave realizations. For the phase velocity we took c = 1.5 m/s, the average of the measured speed of the crest (1.6 m/s) and the predicted phase velocity for our solitary wave (1.4 m/s). It is noted that the maximum experimental pressure gradient shown in Figure 3, ~180 dynes/cm, exceeds the critical pressure gradients predicted from (1), 116 dynes/cm and 136 dynes/cm for φ = 34.°8 and 39.°2, respectively. Thus, bed failure should occur and, as evidenced by the photos in Figure 2, it obviously did.

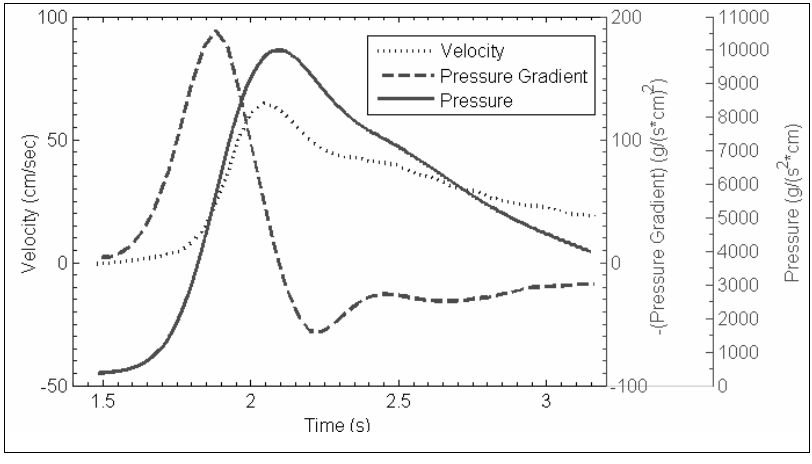

Fig. 3. Experimental Wave Characteristics.

THEORETICAL MODEL

The theoretical model is based on the principles adopted by Madsen (1974), i.e. pressure-induced subsurface failure is assumed to take place along circular arcs, slip circles, as shown in Figure 4.

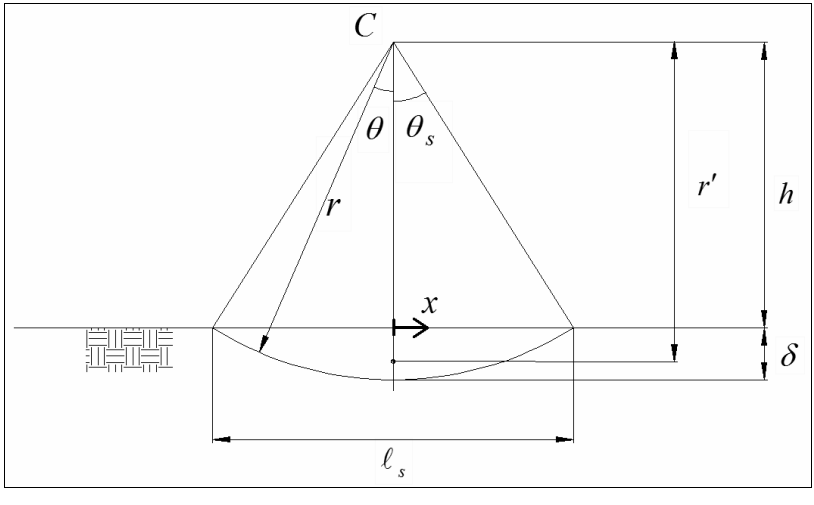

Fig. 4. Slip Circle Characteristics

From Madsen's (1974) analysis of effective stresses along the slip circle, it follows that

the maximum moment around the slip circle's center, C, due to shear stresses corresponding to failure along the slip circle (the "stabilizing" moment) is approximately

$$M_s = 2(\rho_b - \rho)gr^3 \sin\theta_s (1 - \theta_s \cot\theta_s)\tan\varphi \tag{3}$$

where the slip circle's radius = $r = h + \delta$, h being the distance of C above the bottom and δ the maximum depth of the slip circle below the bottom, and the angle

$$\theta_s = Arc\cos\left(\frac{h}{r}\right) \tag{4}$$

The length of the bottom segment within the slip circle is

$$l_s = \frac{2\delta \sin\theta_s}{1 - \cos\theta_s} \tag{5}$$

and it is over this distance, l_s, that the wave-associated bottom pressure acts and produces a moment around C as the bottom pressure distribution $p(x)$ translates past l_s at speed c. This moment, the "driving" moment, is a function of time and is given by

$$M_d(t) = \int_{-l_s/2}^{l_s/2} p(x)x\,dx = \int_{t+l_s/2c}^{t-l_s/2c} p(t')(ct')c\,dt' \tag{6}$$

with $p(t)$ as show in Figure 3.

Madsen (1974) determined the characteristics of the limiting slip circle by equating the maximum driving moment obtained from (6) for a specified value of $l_s = l_{smax}$ to the stabilizing moment given by (3), Madsen (1974, Eq. (15)). Here we obtain $l_{smax} = c\Delta t$ where Δt, the time interval during which the pressure gradient exceeds its critical value given by (1), is obtained from Figure 3. With this value of $l_s = l_{smax}$ balancing M_{dmax} and M_s produces the limiting slip circle along which the sediment just reaches failure at the instant when $M_d(t) = M_{dmaz}$. With all slip circles being concentric, for kinematic reasons, any slip circle contained within the limiting slip circle will experience failure for some short period during passage of the pressure distribution associated with the breaking wave.

Figure 5 shows the temporal variation of M_d, the driving moment, and the corresponding value of the maximum realizable stabilizing moment, M_s, for slip circles identified by their depth of penetration into the bed, δ, relative to that of the limiting slip circle, δ_{smax}.

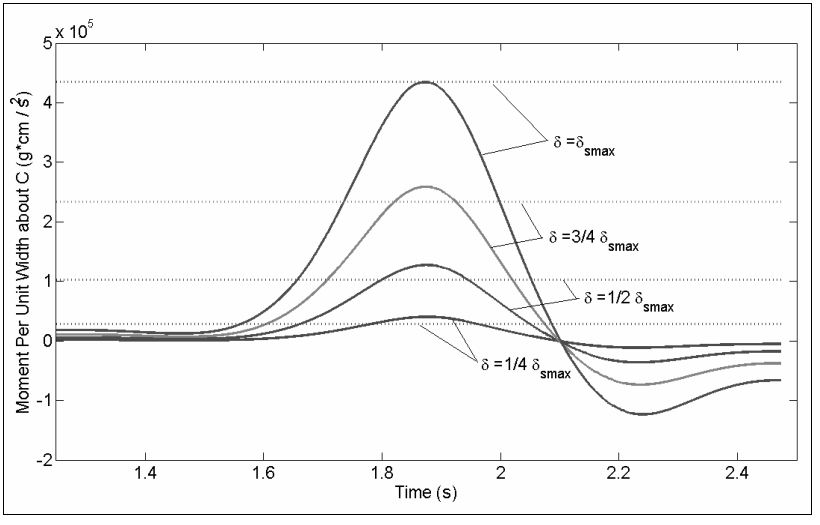

Fig. 5. Temporal Variation of Driving Moments (full lines) and Corresponding Stabilizing Moments (dotted lines) for Different Slip Circles

For the time interval during which $M_d > M_s$ for a particular slip circle, no static moment balance is possible and the bed material above the slip circle responds by rotating around C. As a simple approximate model for the dynamic response of the bed material above a slip circle when $M_d > M_s$ we take

$$I\frac{d^2\theta}{dt^2} + mgr'\theta = M_d(t) - M_s \tag{7}$$

where I is the radial moment of inertia of the bed material above the slip circle of radius r around C

$$I = \frac{r^4}{4}\left(2\theta_s - \sin 2\theta_s + \frac{2}{3}\sin 2\theta_s \sin^2\theta_s\right)\rho_b \tag{8}$$

The mass of the bed material above the slip circle is

$$m = \frac{r^2}{2}(2\theta_s - \sin 2\theta_s)\rho_b \tag{9}$$

and the distance from its center of gravity to C is

$$r' = \frac{4}{3}\frac{\sin^3\theta_s}{2\theta_s - \sin 2\theta_s} r \tag{10}$$

Finally, θ is the rotation angle around C of the material above the slip circle.

With $M_d(t)$ and M_s given for a particular slip circle of radius r, (7) may be solved subject to the initial condition of $\theta = d\theta/dt = 0$ at $t = 0$, and the computation proceeds until $d\theta/dt$ changes sign, i.e. $d\theta/dt = 0$ or $\theta = \theta_{max}$, signifying a change in the sense of rotation and hence a sudden change in the sign of M_s, which always must act in the direction opposite the sense of rotation of the material above. Having solved (7) for a particular value of r, the horizontal displacements of the subsurface sediment a distance of $\delta = r - h$ below the bottom is obtained from

$$\xi = r\theta \le \xi_{\max} = r\theta_{\max} \tag{11}$$

The salient features of this simple model are conceptualized by its graphical representation in Figure 6.

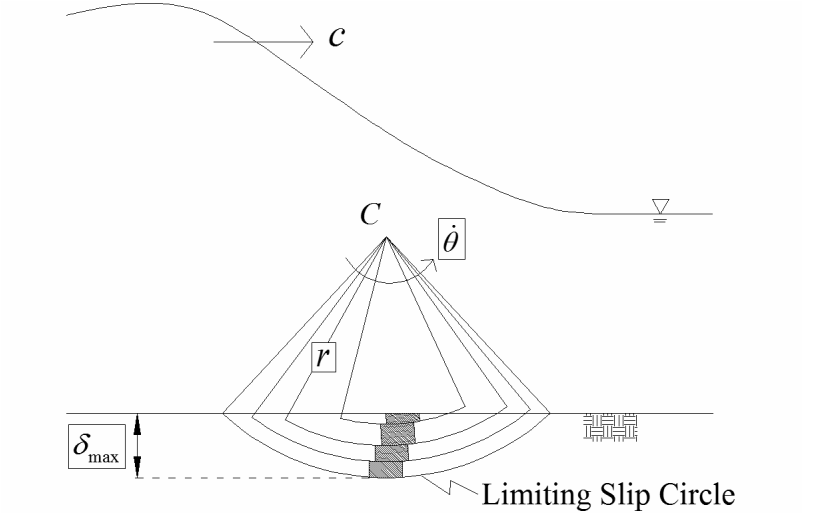

Fig. 6. Conceptual Illustration of the Theoretical Model of Subsurface Sediment Displacements during Failure

RESULTS

From the frame by frame analysis of the videos shot during passage of the steep front face of a forward-leaning breaking wave the displacements of subsurface sediment grains

during the period of pronounced bottom pressure gradients are obtained. Ensemble averaged subsurface displacement profiles (from four realizations) are plotted in Figure 7 as a function of number of waves that have passed over an initial "deposited" bed. A striking reduction in the magnitude of the displacement with number of waves is noticed. We conjecture that this reduction is associated with a strengthening of the bed as this is being reworked by the preceding waves, e.g. causing initially weak spots within the soil matrix to become stronger by rearranging individual grains into more stable configurations.

Also shown in Figure 7 are the predicted displacement profiles afforded by our simple theoretical model for the pressure-induced subsurface failure mechanism. The predicted results are shown for various friction angles, φ, which is the only "free parameter" in our model. It is clearly demonstrated that our model predicts a dramatic decrease in displacement as φ, i.e. the strength of the bed material, increases. This lends credence to our conjecture that the observed dramatic decrease in displacements with number of waves is associated with the accumulated reworking and strengthening of the bed material caused by previous waves.

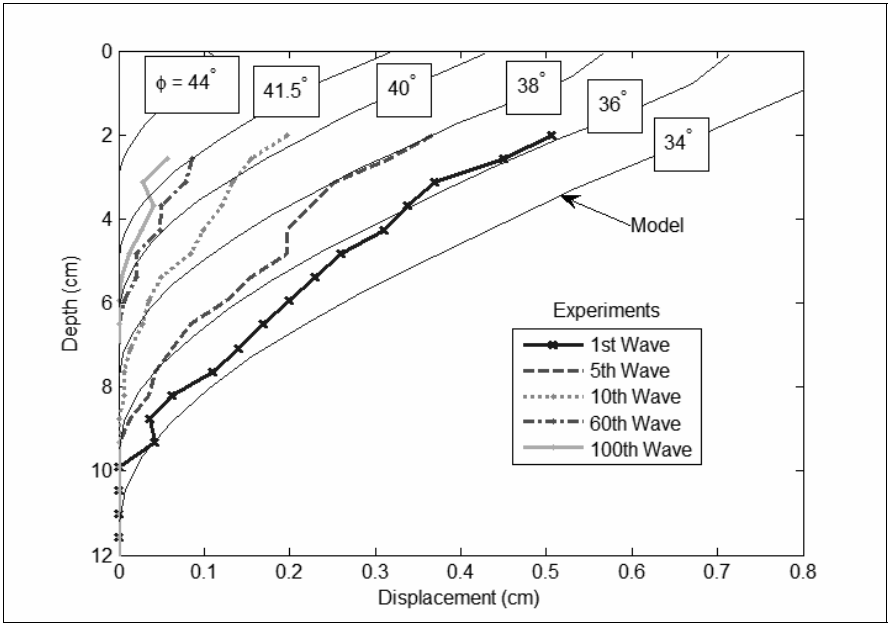

Fig. 7. Subsurface Displacement Profiles Caused by the Passage of the Steep Front Face of a Breaking Solitary Wave

It is particularly encouraging that the predicted displacement profiles are in reasonable

agreement with observations for values of the friction angle φ corresponding to those obtained for our sediment, i.e. $\varphi = 34.°8 \pm 1°$ for loosely packed sediments corresponding to passage of the first wave and $\varphi = 39.°2 \pm 1.°1$ for densely packed sediments corresponding to heavily reworked bed conditions.

A Reality Check

Before getting carried away by the apparent success of our simple model's ability to predict the observed subsurface displacement profiles in Figure 7, it must be emphasized that the observed displacement profiles shown in Figure 7 correspond to the forward subsurface displacements associated with the steep front, i.e. the large pressure gradient peak seen in Figure 3, of the breaking solitary wave passing overhead. Once this pressure gradient "pulse" has passed, the pressure gradient changes sign and drops to values well below the critical value of ~120 dynes/cm^2 predicted by (1). Thus, our simple model would predict that there should be no subsurface failure and hence no backward displacement after the crest of the breaking wave has passed.

But the experiments do not corroborate this prediction! In fact, following the strong forward displacement observed during passage of the steep wave front, the column of colored sediment rebounds, i.e. moves backwards, despite the negligible magnitude of the pressure gradient and comes to rest at a position suggesting the permanent displacement caused by the passage of the entire solitary wave to be but a mere fraction (of the order of one fifth) of the displacement experienced during the passage of the steep front, i.e. the observed displacement shown in Figure 7.

A clue to why this rebound takes place may be found in Figure 2(b) which shows the column of colored beads after the passage of several (~50) solitary waves. Clearly the column, while displaced, is still intact, i.e. individual beads have not been sliding across each other but stayed in contact with their neighbors throughout the experiment. Thus, an actual failure, in the soil mechanics sense, of the subsurface sediments really has not taken place during passage of a breaking wave overhead. If we stipulate that a relative displacement of $\Delta\xi > d$ between adjacent horizontal "layers" of thickness ~d signifies bed failure, since this would allow adjacent sediment grains to change neighbor, we may express a "failure" condition as $\left|\partial\xi/\partial z\right| > 1$, where z is the vertical coordinate. From the displacement profiles shown in Figure 7 we see that $\partial\xi_{max}/\partial z \leq\sim 0.1$ which supports our conclusion of "no real failure" reached from inspection of the still photos is Figure 2. This need to an angular displacement to exceed a critical value in order for actual failure to take place, appears related to the critical shear condition for irreversibility and the appearance of chaos mentioned by Gollub and Pine (2006).

Thus, the strong pressure gradient under the steep front of the wave has forced the column to deflect in the forward direction but not sufficiently to cause an actual failure. After passage of the wave front the column is left in an unstable state and rebounds in a nearly elastic manner once the force that caused its original deflection is removed. The integrity of the column of colored beads, as it appears along the sidewall of the Lucite tray in Figure 2(b), is somewhat broken up in the middle of the Lucite tray (Figure 2(c)).

However, the mixing of beads in the center of the tray may well have been caused by the insertion of the Lucite sheets into the bed during preparation of the center cut.

CONCLUSIONS

Experiments that demonstrate conclusively the existence of a subsurface sediment transport mode under breaking waves were conducted. A simple theoretical model based on soil mechanics principles for failure along slip circles was developed and was capable of predicting, with some success, the observed subsurface displacements caused by the passage of the pressure gradient "pulse" associated with the steep front of a forward-leaning breaking wave. However, the theoretical model did not predict the observed rebound of the subsurface sediments after passage of the crest of the breaking wave. This flaw is believed to be associated with the fact that an actual failure, in the soil mechanics sense, did not take place within the subsurface sediments. Nevertheless, we are confident that the observed (and predicted) subsurface displacements are pressure-gradient-induced. Since a large pressure gradient in the fluid corresponds to large fluid accelerations, this subsurface sediment transport mechanism is indirectly evidence of one of potentially many effects of fluid accelerations in sediment transport processes in the surf zone.

This leaves the all-important question of the importance of this subsurface sediment transport mode relative to the conventional surficial sheet flow transport mode to be answered. To shed some light on this issue, the total sediment transport rate in our experiments was measured by using the ADV system as a bottom profiler. After passage of two solitary waves over an initially plane bed the bottom elevation change (divided by 2 to obtain the value corresponding to passage of a single wave) was measured at 1 cm intervals along three transects for the entire 100cm-length of the Lucite flume. Denoting the measured bottom elevation change associated with passage of a single solitary wave by $\zeta(x)$, the sediment continuity equation

$$q_T(x) = q_{T0} - (1-n)\int_0^x \zeta(x)dx \qquad (12)$$

can be used to obtain the total sediment volume transport q_T [cm^3 of sediment per cm width of the tray per solitary wave] by using the amount of sediment captured by the upwave collection bag to determine q_{T0}, the transport at $x = 0$.

The results from ensemble averaging three such experiments for $q_T(x)$ are shown in Figure 8 including the standard deviations of $q_T(x)$. As one would expect $q_{T0} \approx 0$, since the orbital velocity of a solitary wave is purely positive, and q_T increases from $x = 0$ until it reaches a near-constant value of $q_T \approx 3.0$ cm^3/cm for $x > \approx 40$ cm, which is approximately the value of the excursion, $\int_0^\infty u(t)dt$, for our wave. It is noticed that the predicted transport at the end of the tray is in (remarkably) good agreement with the transport inferred from the sediment volume captured in the down-wave collection bag

at x = 100 cm (indicated by a tick-mark in Figure 8). Thus, we have confidence in our estimate of the total, i.e. surficial as well as subsurface, sediment volume transport per solitary wave being 3.0 cm^3/cm.

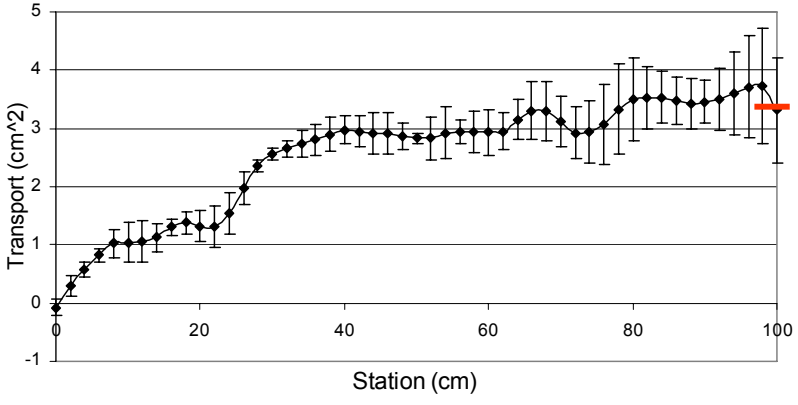

Fig. 8. Measured Total Sediment Volume Transport per Solitary Wave along the Test Section

For comparison, the subsurface sediment transport rate, inferred from the forward displacements during passage of the steep front of the breaking solitary wave (Figure 7), amounts to ~1.3 cm^3/cm for the first and ~0.1 cm^3/cm for the 100^{th} wave. Given the fact that the net subsurface transport rate, i.e. accounting for the "rebound", is lower than the values obtained from Figure 7, by a factor of ~5, it would appear that the subsurface transport rate is at most ~10% of the total. However, this estimate of the relative importance of surficial and subsurface transport rates is obtained for a solitary wave. For a periodic wave the forward velocity (and surficial transport) is followed by a backward velocity (and surficial transport), i.e. a net transport that is a potentially small difference between the forward and backward transport. In contrast, the subsurface transport is exclusively associated with the passage of the steep front of the breaking wave and this should not be significantly different for periodic and solitary waves. We therefore need further experiments involving periodic waves and including the effect of bottom slope, as well as investigations of the behavior of denser sediments (natural sands) during repeated wave-loading, in order to make a final conclusion regarding the potential significance of the contribution of the subsurface sediment transport mechanisms to the total net cross-shore sediment transport rate in the surf zone.

ACKNOWLEDGEMENTS

The support of the Office of Navel Research, Coastal Geosciences Program under Grant Number: N00014-6-1-0318 is gratefully acknowledged as is the assistance of Ms. Lizzie Lundgren who, as a UROP student, conducted some of the experiments and tirelessly analyzed videos, frame by frame, to obtain displacement profiles.

Abstract: Predictive skills to track the discharged sand grains are essential to design optimum sand-recycling system. This paper develops a new numerical model which focuses on the movement of a group of sand grains discharged at arbitrary locations in the near-shore area. While particles in a group of discharged sands may be transported with the group, spatial distribution of the group may be dispersed due to certain random effects such as near-bottom turbulence and wave motions. The present model follows the concept of existing process-based bedload sediment transport model to represent the former "mean" movement of sand particles. In addition, the model introduces random walk theory to account for the latter dispersive characteristics of discharged sand grains. The model shows excellent predictive skills of both mean and dispersive movement of dyed sand grains observed in the newly performed field survey.

INTRODUCTION

Sand-recycling or sand-bypassing system, which artificially transports sand from certain deposited area to the other eroded area, is one of environmentally sustainable, and thus preferable, sand-controlling systems that have relatively low impacts on

coastal environments. In order to propose the optimum design of such systems, predictive skills of the movement of discharged sand is essentially important. A field sand-tracking survey using dyed sand grains as a tracer is often applied to capture the feature of sediment movement around the possible dumping site of collected sand. However, the longer the observation period and the wider the spatial distributions of deposited sand grains, such field survey may become less reliable because the number of tracer particles in the sampled sands decreases.

As complement of such sand-tracking field survey, a numerical model, which traces Lagrangian movement of single sand grain, is often applied in Japan. Since these models focus on the movement of single sand particle, however, the model does not account for the features based on the movement of multiple sand grains, e.g., sediment transport rate and dispersive characteristics of discharged sand grains. These features are of great importance to determine the most effective sand-dumping locations and volumes in the actual sand-recycling project. For instance, dispersive feature of a certain group of sand grains is necessary to estimate how much sand grains out of initial total volume of dumped sand grains are transported to the target site where one aims to deposit these sand grains. Dispersive feature of sand grains are also important for us to examine the model validity by directly comparing the predicted sand distributions with field sand-tracking survey observations. The goal of this study is therefore to develop a new numerical model which is capable of predicting these features which are readily applicable to design the optimum sand-recycling or sand-bypassing systems. The newly developed model should accommodate various predictions such as volume of total sand grains in motion, mean movement of representative sand grains, and the dispersive characteristics of the group of dumped sand grains.

In this paper, we first develop a new numerical model which tracks certain groups of sand grains deposited on the sea bed. We then outline newly performed field survey, in which we monitored spatial distributions of tracer particles of dyed sand. Finally, we apply the developed model to the present field survey conditions and examine the model applicability by comparing predicted and measured spatial distributions of tracer particles.

NUMERICAL MODEL DEVELOPMENT

In this section, we develop a new numerical model to track a group of discharged sand grains. The model should account for both mean and dispersive movement of multiple sand grains. Sand-dumping site may be arbitrarily selected on a sea bed with various geometry where periodic or random waves and wave-induced near-shore mean currents may coexist.

Model Outline

Fig. 1 shows the flowchart of the present model. In the figure, $\mathbf{x}_i^t$ is a position vector of i-th sand particle (i=1,2, ... N) at time, t ($t=\Delta t, 2\Delta t, \ldots T_{end}$), and z_i^t is a depth of the same sand particle located below the sand bed surface at the initial dumping location.

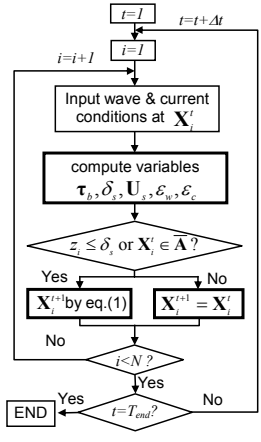

Fig. 1. Flow chart of the present model

As shown in the flowchart, the model consists of two iteration loops that proceed with time and number of particles, respectively, i.e., the model computes position vectors of different N sand grains at every time step, t. The same procedure is iterated until the time, t, reaches the designed computation time, T_{end}. In each iteration time step, the model first determines wave and current conditions at locations of each sand grain, $\mathbf{X}_i^t$. Based on the local wave and current conditions, the model determines following variables that govern the movement of sand grains: τ_b, bottom shear stress; δ_s, thickness of the moving sand grains layer; U_s, mean velocity of the moving sand grains; and ε_w and ε_c, dispersion coefficients of moving sand grains due to wave motion and mean current, respectively. In the present model, we applied energy balance equations to compute wave field with incident wave conditions specified from the measured wave data. Near-shore mean current field is then computed by non-linear shallow water equation with radiation stress determined from the computed wave field.

If the depth of the computing sand grain below the bed surface, z_i^t, is smaller than δ_s, then the model computes a new location of the sand grain, $\mathbf{X}_i^{t+\Delta t}$, by following equation.

$$\mathbf{X}_i^{t+\Delta t} = \mathbf{X}_i^t + \mathbf{U}_s \Delta t + \mathbf{R} \tag{1}$$

Here, $\mathbf{R}$ is a horizontal vector of random walk step for time step, Δt. Note that z_i^t decreases as the other surface sand grains are washed out and the remaining sand grains located in the deeper portion at the initial dumping site eventually begin to move. In this manner, the model accounts for the instantaneous volume of moving sand grains. Note that the present model applied this procedure only at the initial sand dumping site based on the assumption that sand grains remain on the surface once they are initiated to move. Computation of the movement of multiple sand

grains in (1) enables the model to estimate dispersive characteristics of discharged sand. The total number of sand grains, N, do not need to be the actual number of sand grains but should be sufficiently large so that the computed results well represent the dispersive feature of discharged sands. Determinations of all these variables are discussed in the following sections.

Velocity of Moving Sand Grains

Based on the number of field sand-tracking survey (e.g., Komar and Inman, 1970), Nadaoka et al. (1981) proposed that the time-averaged velocity of the moving sand grains, $\mathbf{U_s}$, under wave and current coexisting field is proportional to the depth-averaged mean current velocity, $\mathbf{U_c}$, and the ratio of these velocities, $|\mathbf{U_s}|/|\mathbf{U_c}|$, is about one or two percents. While this empirical relationship is simple, it does not account for various physical processes such as influence of waves, sizes and density of sand grains and the local bottom geography conditions. The present model introduces Madsen's (1991) bedload sediment transport model to determine the velocity of moving sand grains. Since Madsen's (1991) bedload sediment transport model is based on the physical mechanisms of the movement of sand grains, the model can accommodate various physical phenomena stated above.

Assuming that the near-bottom current velocity, u_{cr}, is just large enough to initiate the movement of sand particle at bottom, Madsen (1991) expressed the force balance equation on this single sand particle as

$$\frac{1}{2}\rho C_{DS} a_s u_{cr}^2 = (s-1)\rho g v_s (\cos\beta \tan\phi_s + \sin\beta) \tag{2}$$

Here ρ is density of the surrounding sea water, C_{DS} is a drag coefficient of static sand particle, a_s is surface area of the particle, $s=\rho_s/\rho$ with ρ_s, the density of the particle, v_s is a volume of the particle, g is gravity, $\tan\beta$ is a bottom slope in the current flow direction and ϕ_s is a friction angle of static sand grain. Critical current velocity to initiate the movement of a sand particle is thus expressed as

$$\frac{u_{cr}^2}{(s-1)g(v_s/a_s)} = \frac{2}{C_{DS}} \tan\phi_s \cos\beta \left(1 + \frac{\tan\beta}{\tan\phi_s}\right) \tag{3}$$

When the arbitrary current velocity, u_f, is greater than this critical velocity, u_{cr}, and the sand particle is moving in the direction of the current velocity with speed, u_s, the force balance equation acting on this moving particle is expressed as

$$\frac{1}{2}\rho C_{DM} S_s (u_f - u_s)^2 = (s-1)\rho g v_s (\cos\beta \tan\phi_m + \sin\beta) \tag{4}$$

with C_{DM}, a drag coefficient and ϕ_m, a friction angle of moving sand grain. Representing (4), difference of u_f and u_s is expressed in a similar form of (3) as

$$\frac{(u_f - u_s)^2}{(s-1)g(v_s/a_s)} = \frac{2}{C_{DM}} \tan\phi_m \cos\beta \left(1 + \frac{\tan\beta}{\tan\phi_m}\right) \tag{5}$$

From (3) and (5), relationship among current and moving sand grain velocities are expressed as

$$u_s = u_f - \beta_s u_{cr0} \tag{6}$$

Here u_{cr0} is the critical velocity on a horizontal plane bed, obtained by substituting β=0 in (3), and β_s is a coefficient which accounts for the influence of the bottom slope. Note that (6) is valid only when $u_f > \beta_s u_{cr0}$ and u_s=0 otherwise. If one takes $C_{DM} \sim C_{DS}$ and $\tan\phi_m / \tan\phi_s \sim 0.5$, β_s is derived from (3) and (5) as

$$\beta_s^2 = \frac{1}{2}\cos\beta\left(1+\frac{\tan\beta}{\tan\phi_m}\right) \tag{7}$$

From equations (6) and (7), the velocity of moving sand grain is expressed as functions of current velocity around the grain, critical current velocity, and the bottom slope in the direction of current flow. If one applies law of the wall, u_f, the fluid velocity at $z=z_d$, elevation of a particle from the bottom, is determined as

$$u_f = \alpha u_{*b} \qquad \alpha = \frac{1}{\kappa}\ln\frac{z_d}{z_0} \tag{8}$$

Here $u_{*b} = \sqrt{\tau_b / \rho}$ is shear velocity at the bottom with bottom shear stress, τ_b, κ(=0.4) is von Karman's constant and $z_0 = k_N$ /30 with k_N, Nikuradse's (1933) equivalent bottom roughness which is of the order of bottom sediment diameter, d. The value of α in (8) is explicitly determined as functions of k_N and z_d. For example, if one takes $k_N = d$ and $z_d = 0.8d$, equation (8) leads $\alpha \sim 8$. Taking similar procedure to (8), the critical fluid velocity, u_{cr0} is also expressed in terms of critical shear velocity, $u_{*cr} = \sqrt{\tau_{cr} / \rho}$ as

$$u_{cr0} \sim \alpha\, u_{*cr} \tag{9}$$

Substituting (9) and (10) into (6), instantaneous velocity of the moving particle, u_s, is determined as functions of bottom shear velocity,

$$u_s = \alpha\left(u_{*b} - \beta_s u_{*cr}\right) \tag{10}$$

Note again that (10) is valid only when $u_{*b} > \beta_s u_{*cr}$ and u_s=0 otherwise.

Moving Sand Layer Thickness and Bedload Sediment Transport Rate

As shown in the field sand-tracking survey discussed in the later section, a certain fraction of dyed sand grains tends to stay where they were initially placed for a certain period of time. This feature may be simply because some of these dyed sand grains were placed below the bed surface and thus did not "feel" the shear force due to near-bottom current velocity. The similar feature should occur in the actual sand recycling project especially when a relatively large amount of recycled sand is dumped in a relatively small area and thus the thickness of the dumped sand is relatively large. In this sense, it is important for the model to capture this time-difference of the initial movement of each sand grain. The model accounts for this feature by introducing the concept of the thickness of moving sand layer based on Madsen's (1991) conceptual bedload sediment transport model. By applying Madsen's bedload sediment transport mode to determine both velocity and thickness of the moving sand grains, we can ensure that the instantaneous sand volumes which moves away from the initial sand discharged area are also consistent with the well-known bedload sediment transport rate.

Following Madsen (1991), thickness of the moving sand layer, δ_s, is derived from the horizontal force balance equation for entire moving sand grains. Since the sand grain does not move just below the lower boundary of the moving sand grain layer, the shear stress acting on this boundary should be the critical shear stress, τ_{cr}. Taking V_s to be a total volume of sand moving across unit width, horizontal force balance equation acting on all the moving sand grains leads

$$\tau_b - \tau_{cr} = \rho(s-1)gV_s \cos\beta(\tan\phi_m - \tan\beta) \tag{11}$$

Taking a porosity of the moving sand as n, thickness of the moving sand layer, δ_s, is obtained from (11) as

$$\begin{aligned}\delta_s = \frac{V_s}{1-n} &= \frac{\tau_b - \tau_{cr}}{(1-n)\rho(s-1)g\cos\beta(\tan\phi_m - \tan\beta)} \\ &= \frac{(\psi_b - \psi_{cr})d}{(1-n)\cos\beta(\tan\phi_m - \tan\beta)}\end{aligned} \tag{12}$$

where $\psi = |\tau| / \rho(s-1)gd$ is Shields number with subscripts b and cr corresponding to the values based on bottom shear stress and critical shear stress, respectively. Finally, the product of (10) and (12) yields following Madsen's (1991) conceptual bedload sediment transport model with effect of the bottom slope,

$$q_{SB} = u_s V = u_s \delta_s (1-n) = \frac{8(u_{*b} - \beta_s u_{*cr})(\psi_b - \psi_{cr})d}{\cos\beta(\tan\phi_m - \tan\beta)} \tag{13}$$

Here α=8 was applied in (10). According to Madsen (1991), the bed load sediment transport rate obtained from (13) agrees with well-known Meyer-Peter and Muller's (1948) (referred as MPM hereafter) bedload formula within an error of around 10% on the horizontal bed (β=0). It should again be stressed that (13) is applicable only when $u_{*b} > \beta_s u_{*cr}$ and $\psi_b > \psi_{cr}$ and q_{SB}=0 otherwise.

Model Extension to Actual Field Problems

In this section, we extend the present model to actual field problems, in which waves and mean current may coexist and the sandy movable bed may form ripples or sheet flow. Especially in the near-shore area, where we put more focus on as sand recycling site, wave-induced near-shore mean current and waves coexist and relatively intensive wave orbital velocity often causes sheet flow bed conditions. Wave-current coexisting field yields time-varying bottom shear stress and sheet flow bed, which has larger equivalent bottom roughness, increases the sediment transport rates.

According to Wilson (1987), MPM bedload sediment transport formula yields reasonable sediment transport rate even on the sheet flow bed if one were to apply the total shear stress on the movable bed, i.e., the shear stress based on the movable bed roughness. The present model therefore applies the following Herrmann and Madsen's (2006) sheet flow bed roughness to determine the bottom shear stress. Using obtained total bottom shear stress, the model then determines the bedload sediment transport rate from (13), which is known to yield nearly the same sediment transport rate as MPM formula.

$$k_N = [2 + 4.5(\psi_b - \psi_{cr})]d \tag{14}$$

If the local Shields number, ψ_b, nears the critical Shields number, ψ_{cr}, i.e., there is no sand grains moving on the surface, equation (14) becomes $k_N=2d$, which is equivalent to well-known Jonson's friction model on a fixed sandy bed. In this study, therefore, we simply apply (14) to determine the equivalent bottom roughness whether or not the bed forms sheet flow conditions.

Applying Madsen's (1994) bottom boundary layer model under wave-current coexisting field, instantaneous bottom shear stress vector, $\boldsymbol{\tau}_\mathbf{b}$, is expressed as

$$\boldsymbol{\tau}_\mathbf{b} = \boldsymbol{\tau}_\mathbf{c} + \frac{f_{cw}}{2} u_{wm} \mathbf{u}_\mathbf{w}(t) \tag{15}$$

Here, $\boldsymbol{\tau}_\mathbf{c}$ is a bottom shear stress vector due to mean current velocity, f_{cw} is a friction factor, and $\mathbf{u}_\mathbf{w}(t)$ and u_{wm} are wave orbital velocity vector and its amplitude, respectively. Bedload sediment transport rate under wave-current coexisting field with sheet flow bed condition is thus determined by

$$\mathbf{q}_\mathbf{SB} = \frac{8\left(|\boldsymbol{\tau}_\mathbf{b}| / \rho u_{*m} - \beta_s u_{*cr}\right)(\psi_b - \psi_{cr})d}{\cos\beta(\tan\phi_m + \tan\beta)} \frac{\boldsymbol{\tau}_\mathbf{b}}{|\boldsymbol{\tau}_\mathbf{b}|} \tag{16}$$

Note that β is also a function of time because the flow direction varies with time and equation (16) is applicable only when $u_{*b} > \beta_s u_{*cr}$ and $\psi_b > \psi_{cr}$ as stated before.

On the sheet flow bed, the fraction of moving particle velocity, $\mathbf{u}_\mathbf{s}$, and thickness of the moving particles, δ_s, may be different because the different structures of movable bed roughness should affect the flow velocity near the bottom. In order to ensure that the present model yields the same bedload sediment transport rate as Madsen's (1991) model even on the sheet flow bed, we first assume that following relationship among $\mathbf{U}_\mathbf{s}$, δ_s and bedload sediment transport rate, $\mathbf{q}_\mathbf{SB}$, obtained by (16) holds.

$$\mathbf{q}_\mathbf{SB} = \mathbf{u}_\mathbf{s} V_s = \mathbf{u}_\mathbf{s} \delta_s (1 - n) \tag{17}$$

Based on this assumption, the present model first determine $\mathbf{u}_\mathbf{s}$ on arbitrary movable bed conditions and then inversely estimate δ_s from (16) and (17) with obtained $\mathbf{u}_\mathbf{s}$. As discussed previously, $\mathbf{u}_\mathbf{s}$ can be determined from (6) as functions of the fluid velocity vector around the sand grain, $\mathbf{u}_\mathbf{f}$. Following Madsen's (1994) wave-current bottom boundary layer model, the instantaneous current velocity, $\mathbf{u}_\mathbf{f}$, near the bottom, $z=z_d$, is expressed as

$$\mathbf{u}_\mathbf{f} = \frac{\boldsymbol{\tau}_\mathbf{b}}{\rho \kappa u_{*m}} \ln \frac{z_d}{z_0} = \alpha \frac{\boldsymbol{\tau}_\mathbf{b}}{\rho u_{*m}} \tag{18}$$

Here, u_{*m} is a maximum shear velocity under wave-current coexisting field and it should be stressed that (18) is valid only when z_d is below the outer-edge of wave-current bottom boundary layer thickness, δ_{cw}. As seen in (18), the value of α and corresponding $|\mathbf{u}_\mathbf{f}|$ decrease as the movable bed roughness, k_N, and thus $z_0=k_N/30$ increase. This feature is consistent with Wilson's (1987) experimental study in which he suggested that a part of the total shear stress on a sheet flow bed balances with friction forces among moving sediment particles and thus the current velocity within the sheet flow layer should be smaller than the current velocity on the fixed bed with

the equivalent bottom roughness of the order of sediment diameter, d. Based on a number of experimental data, Wilson (1987) proposed the current velocity in the sheet flow layer in the following form.

$$u_f = \frac{2u_{*b}}{\kappa}\sqrt{\frac{z}{\delta_{sf}}} \tag{19}$$

Here, δ_{sf} is thickness of the sheet flow layer. Averaging (19) over the sheet flow layer thickness, δ_{sf}, we obtain the "layer-averaged" flow velocity within the sheet flow layer. Under the steady current, i.e., $u_{*m} = u_{*b} = \sqrt{|\boldsymbol{\tau}_b|/\rho}$, equation (18) corresponds to this average flow velocity within the sheet flow layer if one takes α~3.3. To obtain α=3.3, equation (18) requires z_d/k_N to be around 0.12, which seems somewhat reasonable since the sheet flow roughness is about the order of magnitude greater than the sand diameter. Following these discussions, we simply estimate $\mathbf{u_f}$ from (18) with equivalent bottom roughness obtained by (14). This enables us to have smoothly varying α as functions of movable bed roughness. The instantaneous velocity of the moving sand grain, $\mathbf{u_s}$, is then obtained by the following vector form of (10).

$$\mathbf{u}_s = \max\left\{0,\ \alpha\left(\left|\frac{\boldsymbol{\tau}_b}{\rho u_{*m}}\right| - \beta_s u_{*cr0}\right)\right\}\frac{\boldsymbol{\tau}_b}{|\boldsymbol{\tau}_b|} \tag{20}$$

Thickness of the moving sand grain layer, δ_s, is then determined by substituting above $\mathbf{u_s}$ into (17) as

$$\delta_s = \frac{8(\psi_b - \psi_{cr})d}{\alpha(1-n)\cos\beta(1+\tan\beta/\tan\phi_m)} \tag{21}$$

Since the shear stress varies with time due to wave motion, δ_s and $\mathbf{u_s}$ should also vary with time. For computational efficiency, the model applies the mean velocity and thickness of the moving sand grain, $\mathbf{U_s}$ and $<\delta_s>$, which are obtained by time-averaging (20) and (21) over one wave period, respectively.

Fig. 2 shows $|\mathbf{U_s}|/|\mathbf{U_c}|$ predicted by the present model as functions of $|\mathbf{U_c}|/u_{wm}$ and ψ_w/ψ_{cr} with ψ_w, maximum Shields parameter under wave orbital velocity. As seen in the figure, predicted $|\mathbf{U_s}|/|\mathbf{U_c}|$ falls within the range of 0.01 to 0.05 and these predictions are surely consistent with the empirical relationship, $|\mathbf{U_s}|/|\mathbf{U_c}|$~O($10^{-2}$), proposed by Nadaoka et al. (1981). In contrast to this empirical relationship that assumed $|\mathbf{U_s}|/|\mathbf{U_c}|$ to be uniform, the present model shows that $|\mathbf{U_s}|/|\mathbf{U_c}|$ increases as $|\mathbf{U_c}|/u_{wm}$ or ψ_w/ψ_{cr} increases. If $|\mathbf{U_c}|/u_{wm}$ increases, the relative intensity of the wave-induced turbulence decreases and hence the relative magnitude of the mean shear current velocity becomes larger. If ψ_w/ψ_{cr} increases, the influence of critical shear stress decreases and thus $|\mathbf{U_s}|/|\mathbf{U_c}|$ should increase. The present model reasonably explains these phenomena.

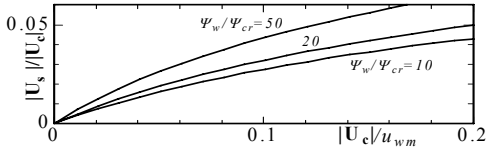

Fig. 2. $|\mathbf{U}_s|/|\mathbf{U}_c|$ as functions of $|\mathbf{U}_c|/u_{wm}$ and ψ_w/ψ_{cr}.

Modeling Dispersive Characteristics Based on Random Walk Theory

As seen in equation (1), the present model accounts for dispersive characteristics of the group of discharged sand grains by introducing the concept of random walk theory. In the field sand-tracking survey of dyed sand grains, as is introduced in the following section, we found that sand particles are more dispersed in the wave-propagation direction rather than the other direction. In order to represent this anisotropic dispersion feature, the model introduces anisotropic dispersion coefficients to determine horizontal random walk step vector, **R**.

The present model applies two different dispersion coefficients, ε_w, and ε_c, i.e., the dispersion due to wave motion acting in the wave-propagation direction and the dispersion due to mean current acting in the mean current flow direction, respectively. Applying the random walk theory, relationship between random walk step vector for computation time step, Δt, is expressed by

$$\mathbf{R} = c_w \mathbf{r_w} \sqrt{2\varepsilon_w \Delta t} + c_c \mathbf{r_c} \sqrt{2\varepsilon_c \Delta t} \tag{22}$$

Here, $\mathbf{r_w}$ and $\mathbf{r_c}$ are unit vectors in wave-propagation and mean current flow directions, respectively, and coefficients c_w and c_c are 1 or -1 whose sign changes randomly with every computational iteration. Finally, the dispersion coefficients may be determined as near-bottom turbulent eddy diffusivity due to the bottom shear stress, i.e.,

$$(\varepsilon_w,\ \varepsilon_c) = \kappa l (u_{*wm},\ u_{*c}) \tag{23}$$

In (23), l is length scale of the near-bottom turbulence, κ (=0.4) is von Karman's constant, and u_{*wm} and u_{*c} are components of bottom shear velocity due to wave orbital velocity and mean current flow, respectively. The length scale l may be δ_s or the bottom boundary layer thickness δ_{cw}. If one assumes that the characteristic velocity and mixing length may be scaled by velocity of the moving particle, U_{sw}, and the excursion amplitude of the sediment particle grain, $A_{bms}=U_{sw}\omega$, the dispersion coefficient due to wave, ε_w, may be determined as

$$\varepsilon_w = \lambda U_{sw} A_{bms} \tag{24}$$

with λ, proportional constant. In this study, we apply these dispersion coefficients and compare the predicted results with the newly conducted field survey results.

FIELD SAND-TRACKING SURVEY

In order to capture the movement of the discharged sand grains, we newly conducted field sand-tracking survey using dyed fluorescent sand grains on the Pacific Coast of

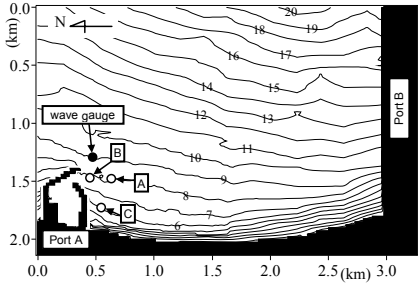

Fig. 3 Geometry of the field survey area and locations of sand-dumping point.

Japan. Fig. 3 shows geography of the field survey site with three different locations where we dumped sand particles dyed with different fluorescent paints. As seen in the figure, the survey site has about 2.5km-long sandy pocket beach between Ports A and B. In the middle of this sandy beach, the shoreline has been severely deteriorated. The beach has well-sorted quarts sand grains with median diameters , d=0.13 mm. The yearly-averaged significant wave height and wave period are 1.1m and 8.6s, respectively, at water depth in the offshore deep water area of this site. About 90% of waves are incident from ENE, E or ESE and dominant wave direction changes with seasons, i.e., most waves are incident from ENE to E in winter and waves from E to ESE are predominant in summer. During the survey, we had measured time-varying wave and current conditions at h=9m as shown in Fig. 3.

At each dumping location A, B and C, we placed around 0.63m^3 of dyed sand grains with diameter of 0.13mm on November 8th, 2004. This volume of sand placed at each point is estimated to be around 6.8×10^{10} sand grains. We then sampled bottom surface sand at 65 different sampling points 40 days after the placement of dyed sand grains. The volume and the surface area of the sampled sand at each sampling point were 300cm^3 and 120cm^2, respectively. These 65 sampling points around the dumping site were selected at grid points of 50m×50m square mesh in the on-offshore and along shore directions. From each of these 65 sand samples, we counted the number of dyed sand grains which were located within unit surface area, A=120cm^2.

MODEL APPLICATION

In order to investigate predictive skills of the present model, we applied the model to the present field sand-tracking survey conditions and compared predicted and sampled spatial distribution of dyed sand grains. Based on the actual wave data measured at the offshore of the survey site, we specified the incident wave conditions for every 12 hours during the entire field survey. These incident waves were determined so that the wave conditions represent the time-average of measured wave energy and radiation stress during each 12-hour period. In the numerical model, we first computed spatial distributions of wave and current conditions for every 12 hours and used the computed results to specify the local wave and current conditions where

and when the computing sand particle is located. We set the number of total sand grains to be N=10^5 at each of three sand-dumping sites, A, B and C. Since the actual number of placed dyed sand grains at each site is about 6.8×10^{10}, each of imaginary particle in the numerical computation represents about 6.8×10^5 of actual dyed sand grains, which correspond to the volume of about 6.3cm^3 of sand. Considering the fact that our focus is to capture the movement of a group of sand grains whose volume is of the order of cubic meters, the total number of N=10^5 seems sufficiently large to capture the features of our focus. Finally, the predicted number of sand particles at each sampling area was multiplied by 6.8×10^5 to estimate the actual number of dyed sand grains. In this manner, we can examine the quantitative predictive skills of the model by simply comparing the spatial distributions of measured and predicted number of dyed sand particles.

Fig. 4 compares observed and predicted significant wave heights, wave directions, near-shore mean current components in the eastward and northward directions at the wave gauge near the harbor mouth of Port A. The data are shown as functions of time during the entire period of the field sand-tracking survey. Note that the incident wave conditions used in the numerical model are not obtained from these measured data but are specified from the other wave gauge installed in the offshore area. Reasonable agreement between measured and predicted wave conditions at this wave gauge near the harbor mouth thus supports the validity of the present computation method. The near-bottom mean current velocity was measured by the electromagnetic flow meter attached on the same wave gauge, which was installed on the sea bed of still water depth, h=9m. Although the measured near-bottom current velocity is relatively small and may not be the suitable data to test the model, predicted near-bottom mean current velocities reasonably agreed with the observed data.

Fig. 5 compares predicted and measured spatial distributions of the number of tracer sand grains, K, sampled from the unit sampling area of 120cm^2. The comparison is when the dyed sand grains were placed at dumping site, A. Note that the numbers, K, in these figures are expressed in logarithmic numbers, i.e., $\log_{10}K$. The first three

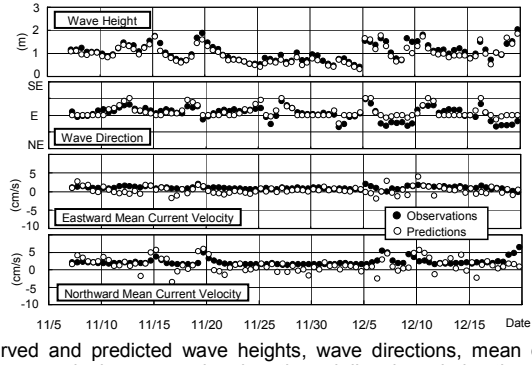

Fig. 4 Observed and predicted wave heights, wave directions, mean current velocity components in the eastward and northward directions during the survey period.

computed results compare different predictions when we applied the following three different dispersion coefficients, respectively: (i) both ε_w and ε_c determined by (20) with turbulent length scale represented by moving sand layer thickness, i.e., $l=\delta_s$; (ii) the same definitions as (i) except the turbulent length scale represented by wave-current bottom boundary thickness, i.e., $l=\delta_{cw}$; and (iii) ε_c identical to (ii) and ε_w determined by (21) with λ=0.4. While these length scales change with the wave and current conditions, the thickness of moving sand layer, δ_s, is generally greater than δ, the thickness of wave-current bottom boundary layer. For example on November 19th 2006, when we observed relatively large waves, H_s=1.87m at point B with h=8m, these layer thicknesses were estimated as δ_s=0.38mm, and δ_{cw}=3.1cm, respectively. As seen in the figures, predictions with dispersion coefficients (i) apparently underestimate the dispersive characteristics of the sand grains. While predictions with dispersion coefficients (ii) significantly improve the predictive skills of the dispersive characteristics, the predictions with dispersion coefficients (iii) showed the best agreement with the observed data. These comparisons clearly suggest that dispersions due to wave motions is greater than the one based on the turbulence caused by the bottom shear stress.

The computed result (iv) shown in Fig. 5 is the prediction when the model applied the same dispersion coefficients as (iii) but $\mathbf{U_s}$, were determined by the simple

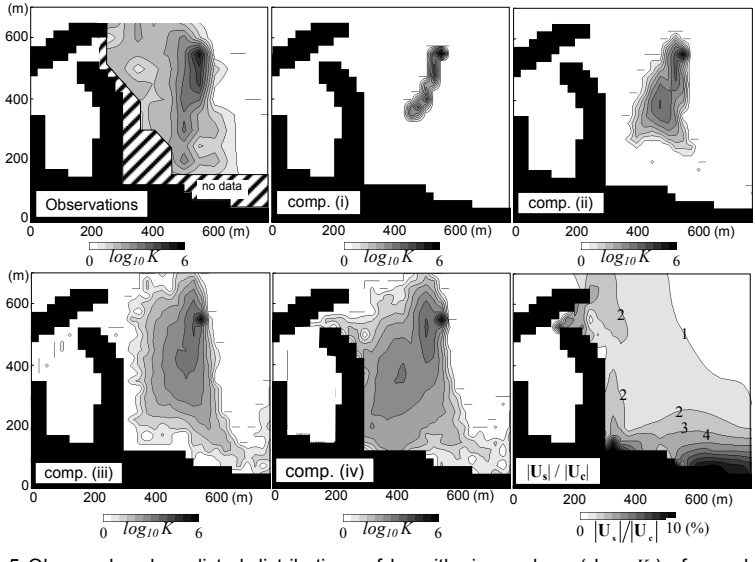

Fig. 5 Observed and predicted distributions of logarithmic numbers ($\log_{10}K$) of sampled dyed sand grains dumped at station A. The first three computations are the results with different dispersion coefficients. The forth computation result is the same as (iii) except $\mathbf{U_s}$ replaced by $\mathbf{U_s}$=0.01$\mathbf{U_c}$. The last figure shows $|\mathbf{U_s}|/|\mathbf{U_c}|$ predicted by the present model with incident wave conditions on Nov. 19th.

empirical formula, $\mathbf{U_s}=0.01\mathbf{U_c}$. For comparisons, Fig. 5 also shows $|\mathbf{U_s}|/|\mathbf{U_c}|$ estimated by the present model with incident wave conditions on November 19th. As seen in this figure, predicted $|\mathbf{U_s}|/|\mathbf{U_c}|$ falls into the range of one or two percents in deeper water where dyed sand grains were initially placed but it increases up to around 5 percents as the wave shoals near the surf zone where both wave-induced current velocity and near-bottom wave orbital velocity become larger. Comparing computed results (iii) and (iv), the present model (iii) predicts more sand transported in the longshore southward direction (rightward direction in the figure) due to the relatively large $|\mathbf{U_s}|$ in the near-shore area and thus predicts less sand grains left around Port A. This feature clearly improves the predictive skills of the spatial distribution of sand grains and thus somehow supports the validity of the present model which accounts for the varying $|\mathbf{U_s}|/|\mathbf{U_c}|$ based on Madsen's (1991) process-based bedload sediment transport model.

Fig. 6 shows the similar comparisons to Fig. 5 but for cases when dyed sand grains were placed at different locations, B and C, respectively. As seen in these observed spatial distributions of dyed sand grains, characteristics of sand grains movement are remarkably dependent upon the initial sand-dumping locations. Locations A and B, for example, are located nearly on the same water depth and at the same distance from the shoreline but B is about 200m away from A in the longshore direction toward the harbor mouth. Due to this alongshore difference of the initial dumping location, sand grains placed at B appears to have less movement than those at A and tend to stay around the harbor mouth. The present model reasonably captures this

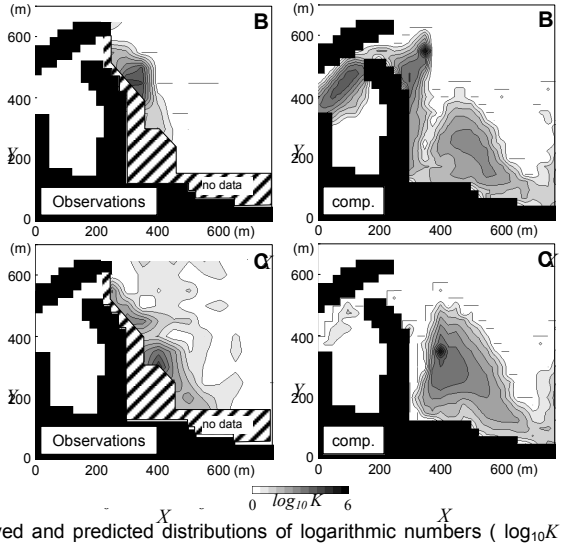

Fig. 6 Observed and predicted distributions of logarithmic numbers ($\log_{10}K$) of sampled dyed sand grains dumped at station B and C.

feature, i.e., the model surely represented that most of dyed sand placed at B stayed around the harbor mouth and had less dispersion compared to the one located at A. In the model predictions for B, certain amount sand grains are also deposited in relatively shallow area whose peak is around X=500m and Y=300m. Due to the lack of field data in this area where the water depth was too shallow to sample the bottom sand, model verification in the shallow water including the surf zone is left as future research. Dumping site C is located in the shallower area and, as seen in the figure, less sand is left at the initial dumping site compared with the other two cases. Although the number of sand grains left at C was over-predicted, the model successfully represented the overall spatial distributions of dyed sand grains along the coast.

CONCLUSION

A numerical model to track the movement of certain specific groups of discharged sand grains was newly developed. The model accommodates predictions of movement of group sand grains due to sediment transport processes as well as the dispersive characteristics of the discharged sand group. Introducing the same concept as Madsen's (1991) process-based bedload sediment transport model, the present model determined the velocity and layer-thickness of moving sand particles, whose product is consistent with Madsedn's (1991) bedload sediment transport rate. Introducing random walk concept, the model also accounts for the dispersive effects. The present model showed excellent predictive skills of the movement of dyed sand grains observed in the newly performed field survey.

Abstract: Suspended sediment transport dynamics occurring at relatively short time scales under super-critical wave groups created by moving high speed vessels are investigated by means of field measurements and the application of numerical models. Examples are provided from a variety of different environments, including predominately sandy beaches in low energy estuarine and fluvial settings. Model simulations combining the hydrodynamics of the wakes with steady currents and a sand transport model provide results that are largely consistent with field measurements and observations of the suspended load fraction. Wakes re-suspend sand in the nearshore that would otherwise be immobile and move it incrementally offshore and alongshore, eventually into deeper water where stronger ambient flows (tidal or fluvial) can transport the sediment. Super-critical wakes from high speed vessels have a tendency to cause offshore transport of sand-sized sediment leading to beach flattening while their sub-critical counterparts often lead to beach steepening.

INTRODUCTION

Wave-induced erosion associated with ship traffic in confined waterways has been widely reported including locations in San Francisco Bay, California, Puget Sound, Washington, Georgia Strait, British Columbia, Saint Lawrence River, Quebec, Waitemata Harbor and Marlborough Sounds, New Zealand, Loch Ryan, Scotland and Kattegatt, Denmark (see review by Parnell and Kofoed-Hansen, 2001). Because of their size and speed, many commercial and recreational vessels are capable of producing

sizable wakes that can be damaging to the adjacent shoreline and dangerous to other craft. Unfortunately, there is little design information and few unified design tools are available to scientists and engineers needing to predict the sediment transport and associated morphological effects on shorelines resulting from vessel wakes. This paper examines the details of the fluid and suspended sand dynamics that occur at medium (hours) and short (seconds) time scales on beaches with a range of grain sizes (sand-pebble) present in response to super-critical wave groups created by moving high speed vessels. Examples are provided from Snake River, Idaho and Auckland, NZ. The purpose is to gain insight into the differing modes of transport for coarse- and fine-grained sediments under wakes produced by high speed vessels.

SUPER-CRITICAL AND SUB-CRITICAL WAKES

A vessel wake observed at the shoreline in a coastal, estuarine, or fluvial environment occurs as a sequence or group of waves. The characteristics of the wave group observed at the shoreline depend on a large number of variables related to the moving vessel including position, heading, and distance from shore, speed, hull geometry, trim and displacement, as well as the properties of the ambient water body including depth contours, presence of currents, or wind waves. The term *super-critical* is sometimes used to describe high-speed vessels while the term *sub-critical* is used to describe displacement vessels traveling at slow speed. Super-critical refers to the state where the vessel is moving faster than the speed at which a wave of the same length can travel in that depth of water. The super-critical condition depends on the speed of the vessel and the depth of the water. The wake produced by a super-critical vessel is different from that produced by a vessel moving at sub-critical speed (see Osborne et al., 2006 for examples). In the latter case, the wake produced has both diverging and transverse components. The transverse component is monochromatic and its wavelength is determined from the linkage between the speed of the vessel and the celerity of the wake for the given depth of water. Whereas the spectrum of a super-critical wake shows peaks in energy at a number of frequencies and the wake passing a point shows a steady decline in wave period through time.

Figure 1a illustrates the classical wake pattern generated by a sub-critical vessel. The wake is composed of two types of waves; diverging wakes that move away from the vessel at an angle of 35.27^{o} and transverse wakes that move in the vessel's direction. Both types of wakes theoretically exist only within a cone set at 19.47^{o} from the vessel. This pattern, first described mathematically by Lord Kelvin in 1887, can be derived from simple geometry. The wavelength and speed of the wake can be found from linear wave theory. As the vessel speed increases, so does the celerity of the wake. A point will be reached where the vessel is moving faster than its transverse wake and this part of the wake is shed. From this point on (i.e. if the vessel maintains a speed equal to or greater than this speed and the depth remains the same or decreases) the wake will assume a new form; the super-critical wake pattern is composed only of diverging wakes (Figure 1b). The super-critical wakes cannot exist as free gravity waves in a classical Kelvin wake pattern. Super-critical vessels produce a wake pattern in which the period of the waves appears, to a stationary observer, to decrease in an approximately exponential manner.

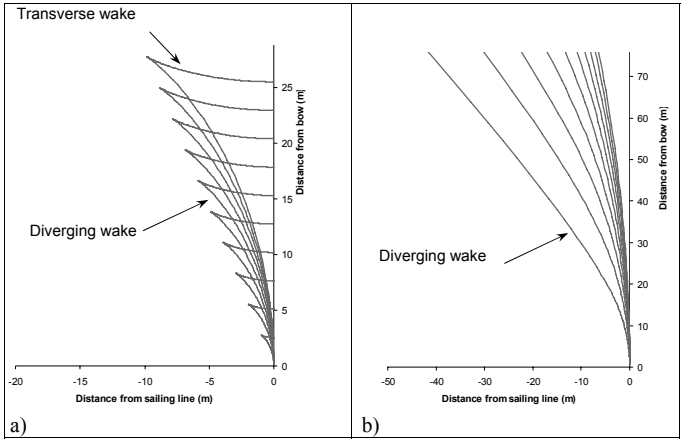

Figure 1. Wake patterns: a) sub-critical vessel; and b) super-critical vessel

METHODS

The approach in this paper involves a combination of detailed and direct field measurements and numerical modeling of the relevant processes. Field measurements were obtained from three different environments:

- a mixed sand and gravel beach exposed to wind waves, wakes from both conventional and high speed commercial and recreational vessels, and strong tidal currents in Puget Sound, Washington (see Osborne et al., in press),
- sand and gravel bars exposed to wakes from jetboats and river flows in the Hells Canyon Reach of Snake River, Idaho and
- a sandy foreshore exposed to wakes and wind waves in the Waitemata Harbor Auckland, NZ.

The approach to modeling is demonstrated with examples from a sand bar in the Snake River, Idaho.

Field Measurements

Field measurements collected and analyzed for this paper include time series of wakes and water surface elevations measured with pressure sensors or capacitance wires, 3D orbital velocities measured with Acoustic Doppler Velocimeter (ADV), and suspended sand concentrations (*ssc*) measured with Optical Backscatter Sensors (OBS). The ADV was integrated with other sensors as part a Sontek HYDRA system (Figure 2).

The sediment dynamic response under wakes and ambient conditions was determined by direct visual observation of sediment motion and recording of *ssc* time series with OBS. Calibration of the OBS to determine *ssc* was achieved using local sediment in a laboratory calibration facility following typical procedures for sandy sediments.

Wakes from a variety of different high speed vessels including recreational jet boats, conventional catamarans, and foil-assisted catamarans are considered. Measured wake time series were analyzed to compute wake wave characteristics using zero-crossing analysis and spectral analysis methods. The measurements allow validation of numerical models, but also provide valuable insights on processes occurring under boat wakes that lead to improvements in modeling.

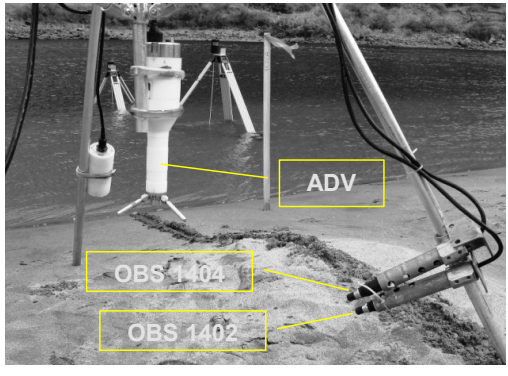

Figure 2. Sontek HYDRA system consisting of ADV and 2 OBS

Numerical modeling

Computer model application in the study includes tidal and river circulation models, wind wave models, a new wake prediction model for high speed vessels, and a Lagrangian sediment transport model. The approach to modeling is demonstrated in this paper with an example from the Fish Trap sand bar in the Snake River, Idaho. The general approach of the modeling exercise is as follows:

- Computer modeling with the Lagrangian Super critical Vessel (LSV) model, an enhanced 2D wake prediction model (MacDonald, 2005), is used to predict the spatially- and temporally-varying wake train produced by a powerboat as it passes a sand bar.
- The wake data is combined with flow data from a large-scale hydrodynamic model (MIKE 21C, IPC) of the river to predict the potential sediment transport caused by this single boat passage (i.e. the sediment put into suspension).
- A medium-term particle tracking simulation (48 hours) is performed with a Lagrangian Particle Tracking Model (PTM, MacDonald et al., 2006) to determine the transport of this sediment. This stage is performed with and without subsequent boat passes. PTM is used to simulate the pattern and magnitude of net sediment transport on the sand bars under the combined influence of boat wakes and river flows.

- An assessment of the fate (i.e. the percentage of material no longer in the vicinity of the sand bar) is made for both the river-only and river plus powerboat simulations to identify the impact of boating on the movement of sediment at the sand bar.

The preceding bullets identify an approach for the quantitative determination of the impact of boating on a select mass of sediments – those put into suspension by the first boat passage in the 48 hour period. The purpose of the modeling is to develop quantitative estimates of the relative role of boat wakes and river flows in causing mobilization of sediment on sand bars with the possibility of developing preliminary estimates of the potential for net transport from the bars. The approach does not consider the fate of any new sediment put into suspension by subsequent wake events, but there is no reason to believe that these new sediments would behave in a different manner. As well, the approach does not consider delivery of fine sediments to the sand bar by the river during high-flow events.

To better account for wave action, especially wave breaking in the nearshore, a new potential sediment transport equation developed by Camenen and Larsen (in press) was added to PTM. The Camenen and Larsen formula is a total load (i.e. bed load and suspended load) potential transport formula. The total transport rate is given by:

$$q_t = \frac{u_* a}{g(\rho_s - \rho)} \frac{\tau_{cw}}{\left(1 + \tan\beta \big/ \tan\Phi_m\right)} \exp\left(-b\frac{\tau_{cr}}{\tau_{cw}}\right)\left[1 + K_T \frac{h}{d_{50}} \frac{U_c}{u_* w} \sqrt[3]{D_t \big/ \rho}\right]$$

where q_t is the volumetric, depth-integrated sediment transport rate [units of m^2/s], θ_{cr} is the critical Shields parameter, w is the sediment fall velocity, τ_c is the current-induced shear stress, τ_{wc} is the combined wave-current shear stress, ρ is the fluid density, ρ_s is the sediment density, g is gravitational acceleration, β is the bed slope, Φ_m is the moving friction angle (≈30°), D_t is the total energy dissipation, d_{50} is the median grain size, U_c is the current speed, $u_* = \sqrt{\tau_c/\rho}$ and:

$$K_T = \frac{2\gamma_o c_B k_d}{a\pi\theta_{cr}}$$

The coefficients in the above equations are a=12, b=4.5, c_B=0.65 and γ_o=2×10^{-5}.

RESULTS

Offshore mean flow during super-critical wakes

Analysis of a large number of velocity records from several locations reveals that as well as introducing an oscillatory component to the nearshore current, the super-critical boat wakes also modify the local steady current by producing an offshore-directed flow. Figure 3 shows a plot of time-averaged nearshore east and north velocity components, V_E and V_N respectively, measured during wake and no-wake intervals at Fish Trap Bar on the Snake River. The shoreline in this case runs approximately north-south and is on the west river bank; therefore positive V_E indicates an offshore directed flow. In general, the

mean flows during the wakes are more easterly and larger than during the no-wake intervals. This pattern of enhanced offshore flow was consistent at all locations.

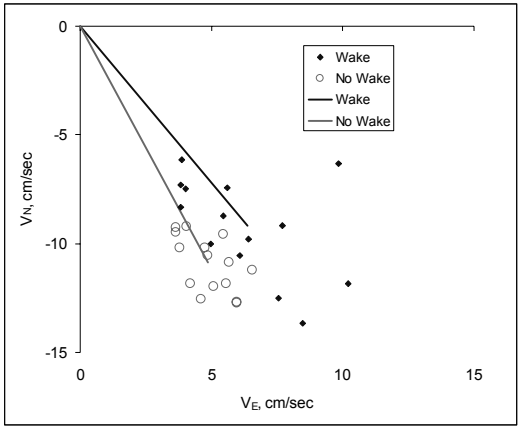

Figure 3. Time-averaged nearshore velocity components (V_E, V_N) measured during wake and no-wake intervals at Fish Trap Bar on the Snake River

The offshore-directed flow has not been previously documented in the context of vessel wakes though it appears to be analogous to a group-forced second-order flow and set-up driven undertow (e.g. Longuet-Higgins and Stewart, 1962, 1964; Doering, 1988). Figure 4 shows a time series of instantaneous near bed wave normal velocity, V_x, measured during a boat wake at Fish Trap Bar. Also shown in Figure 4 is the time variation of the velocities averaged over two to three wave periods (10 sec), $V_{x\text{-}Avg}$. A relatively simple undertow model Grasmeijer and Ruessink (2003) was found to be in good agreement with the measured flows.

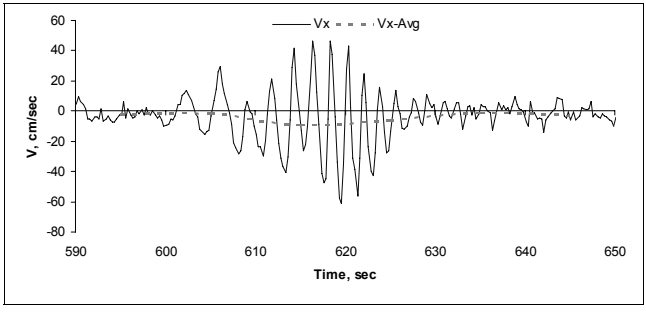

Figure 4. Instantaneous V_x under a wake and 10-sec average velocity, $V_{x\text{-}avg}$, measured at Fish Trap Bar, Snake River

Suspension of sand by super-critical wakes

Figure 5 provides examples of time series of V_x and *ssc* measured during the passage of super-critical wakes produced by different vessels over a variety of different substrates. The relevant conditions are summarized in Table 1. The V_x velocities were determined by rotation of the V_N and V_E velocities such that V_x is the principle component of flow and V_x is positive under the wave crests (approximately onshore in each case); V_y is the secondary flow and is orthogonal to V_x. Peak to peak velocities of +/- 0.40-1.0 m/sec occur under the largest waves in the wakes. The wakes produced by QuickCat result in maximum velocities which are approximately a factor of two larger than those observed in Snake River and correspondingly larger *ssc*. The wave-induced velocities in the wake train are distinctly asymmetric (nonlinear) with short, sharp-peaks under the crests and broader flatter troughs. The high velocities under the wave crests produce the largest peaks in *ssc*. The peaks in *ssc* are relatively low under the long period waves during the first half of the wake, whereas, large peaks in *ssc* occur during the higher, shorter-period waves in the middle of the wake. In most cases *ssc* remains elevated for several waves following the peak velocities.

Table 1. Summary of vessel operating conditions for selected super-critical wakes

Location	*Vessel Name*	*Date*	*TPass*	*Speed (knots)*	*Fr (depth)*	*Fr (length)*	*Distance (m)*	*Boat Length (m)*

To illustrate the relationships between wave forcing and near-bed sediment suspension on a wave-by-wave basis, phase diagrams of wave-averaged *ssc* as a function of wave-by-wave estimates of the skin friction Shields parameter (θ'_w) are shown in Figure 6 for each of the consecutive waves in the wake trains shown in Figure 5. Waves were identified by zero up-crossing analysis of time-series of V_x. Wave-by-wave estimates of θ'_w are based on U_{sig} (the average of the highest 1/3 velocity measurements under the crest of the wave), and the median sediment diameter representative of the local sediments. Measured *ssc* was averaged through each wave period.

A distinct counter-clockwise hysteresis is apparent in the phase diagrams (Figure 6). All of the phase diagrams exhibit a region of low and steady *ssc* through the first several waves while θ'_w increases well above the threshold for motion and for suspension. As θ'_w approaches a maximum under the largest waves in the wake train, *ssc* increases rapidly. The maximum *ssc* is reached during the wave following the maximum θ'_w and

then begins to decline. Despite a decline in both *ssc* and θ'_w following the maximum *ssc*, the *ssc* is significantly higher while θ'_w is decreasing after the peak than that measured under waves with similar values of θ'_w during the increase before the peak. The pattern is more pronounced at higher elevations above the bed (compare green line with blue line in Figure 6 b,c) indicating a significant temporal phase lag in *ssc* with elevation.

Simulation of sediment transport by combined wakes and currents

The sediment modeling methodology used in the present work consists of a multi-stage approach:

- development of a detailed daily wake climate using the LSV wake model;
- development of a 48-hour flow hydrograph using MIKE 21C data;

- application of the PTM model to predict the sediment put into suspension on a typical boat passage;
- application of the PTM model to predict the transport of the sediment for a 48-hour period, and;
- analysis of the sediment fate to determine percentage retention/loss of sediment caused by the boat wakes.

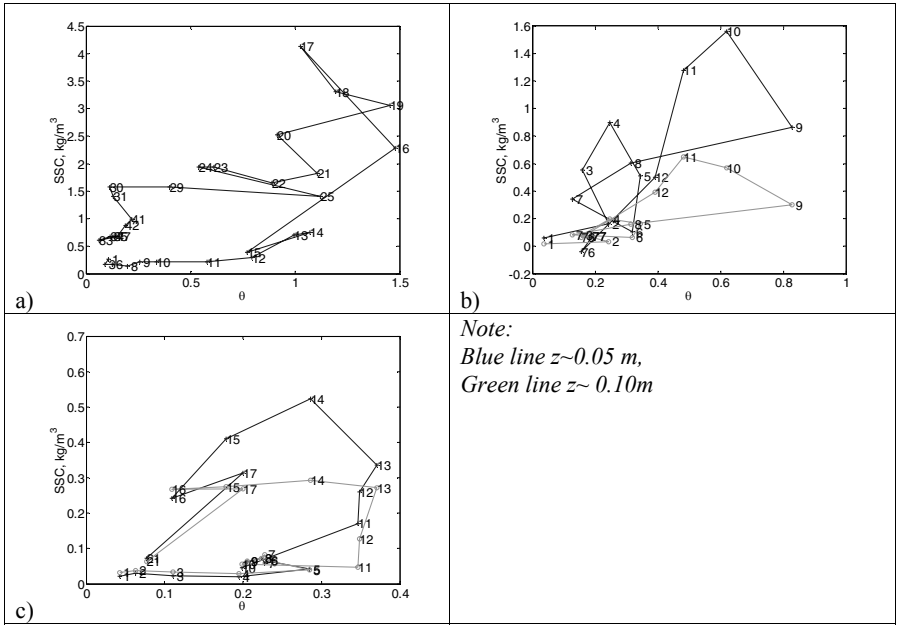

Figure 6. Phase diagrams of wave-by-wave θ'_w and *ssc* during high speed super-critical wakes: a) Torpedo Bay, Auckland, *QuickCat*; b) Tin Shed Bar, Snake River, *Hells Canyon Dream*; c) Salt Creek Bar, Snake River, *Happy Hour*

The LSV model was calibrated for two powerboats, a 26-ft workboat and a 44-ft tour boat, using wake data collected at Fish Trap Bar on the Snake River (Figures 7 and 8). A wave climate for the site was constructed from the number of boat passes measured and by running the LSV model a total of four times at each site (2 boats × 2 directions). Data manipulation programs were used to convert the LSV data into individual standard wave time series files. A wake time series for the 48-hour period was constructed by distributing the appropriate number of wake events, between the hours of 06:00 and 18:00 of each day. The periods between were taken as river-only periods.

A flow time series file for Fish Trap Bar was developed in an analogous manner to that of wake climate. Recorded discharges were used to estimate local discharges at the sand

bar site. Instantaneous hourly flows were interpolated from steady-state MIKE 21C results (5,000 cfs, 10,000 cfs, 20,000 cfs, 30,000 cfs, 50,000 cfs, 75,000 cfs, and 100,000 cfs). The discharge hydrograph for the Fish Trap bar site from 8-27-2005 to 8-29-2005 is shown in Figure 9; time is represented in hours since start of the simulation. Also shown in Figure 9 are the periods of boating activity.

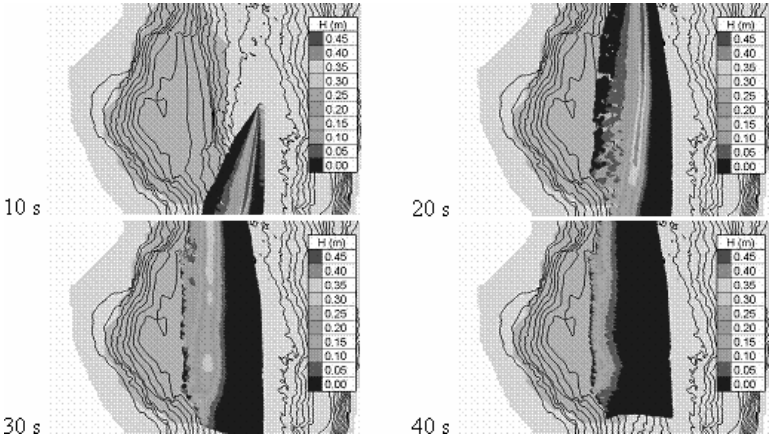

Figure 7. Time sequence of wake height at Fish Trap Bar on the Snake River produced by a 44-ft tour boat at 25 knots headed downstream

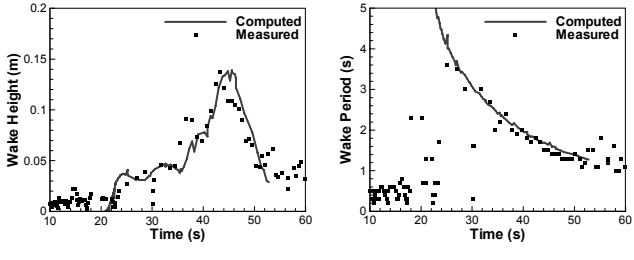

Figure 8. Comparison of measured and computed wake height (left) and period (right) for a 26.ft workboat headed downstream at Fish Trap Bar

The potential sediment transport rate predicted by the Camenen and Larson total load sediment transport formula was calibrated using optical backscatter *ssc* data collected at the study site. The calibration procedure involved operating PTM for a single boat passage and computing the instantaneous sediment load (i.e. the mass of sediment in the water column per unit area). Calibration of the model was obtained by adjusting the value of k_d in the Camenen and Larson formula until the measured and computed values

of the sediment load in the water column agreed. A value of k_d =0.015 was found to provide the best calibration. This value falls within the range of values suggested by Camenen and Larson.

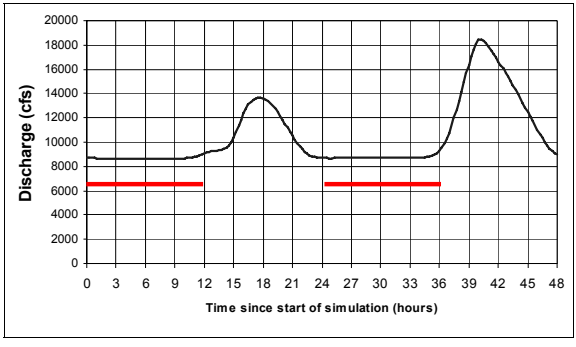

Figure 9. Discharge hydrograph at Fish Trap Bar over 48 hour simulation period. Red bars indicate periods of boating activity

In order to compare the measured results with the computed, they must first be time-averaged and depth-integrated. A two-second time-averaging window was used. Depth integration was performed using an assumed two-part concentration distribution. The concentration was assumed to be uniform over the lower 4 cm and to vary in a parabolic fashion above that point to the surface. Using this distribution a time series of the total suspended sediment load, M is computed (expressed in kg/m^2). Figure 10 shows the generally good agreement obtained between the estimated mass load of sediment in suspension based on field measurements at the study site and that predicted from the preliminary PTM run. The model tends to overpredict the suspended load in the early part of the wake and underpredict it later in the wake; this reflects the "wave group-induced" hysteresis observed in the measurements which is not accounted for in the sediment transport formula (Figure 6).

The results of the PTM simulation for the 48-hour period are presented in Figure 11. A general pattern of movement was observed in the results:

- boat wakes caused bed material to be brought into suspension;
- while in suspension, the ambient river currents and small wake-induced undertow caused a small, but important advection of the suspended material;
- the alongshore and offshore directed advection caused by multiple boat passages (35 on the first day and 23 on the second) and the river flow moved the material into deeper water, and;
- the larger discharge during the evening hours transported the material away from the site. This can be observed in the results at hours 18 and 39.

The general pattern of movement described above was observed at each of the sand bar sites studied on the Snake River. The river flows alone are not sufficient to

mobilize sand sized material in the nearshore zone. Boat wakes do put material into suspension. While in suspension, river flows and the wake-induced undertow gradually move the material along and across the nearshore zone. Often the material was moved into deeper water, where it was later removed when larger flows occurred.

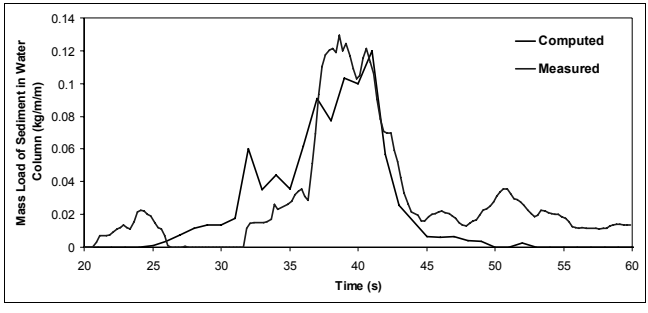

Figure 10. Comparison of measured and computed sediment load in the water column per unit bed area

CONCLUSION

Analysis of a large number of velocity records from several sites reveals that as well as introducing an oscillatory component to the nearshore current, the boat wakes also modify the local steady current by producing an offshore-directed flow. The offshore-directed flow has not been previously documented in the context of vessel wakes though it appears to be analogous to a group-forced second-order flow and set-up driven undertow. A relatively simple undertow model Grasmeijer and Ruessink (2003) is found to be in good agreement with the measured flow.

Suspended load and bedload modes appear to respond differently to waves of varying frequency in a super-critical wake group sequence. Osborne et al. (in press) describe how the longer period motions at the start of a super-critical boat wake result in net offshore transport of gravel and cobble on mixed beaches in Puget Sound. In this paper, the time varying suspension patterns under super-critical wakes are shown to exhibit properties similar to the suspension patterns under conventional wave groups produced by ocean waves (e.g. Villard et al., 2000). The *ssc* remains elevated for a number of waves following the peak velocities under the higher frequency waves in a wake group resulting in a hysteresis between the maximum wave component of bed shear stress and the ssc.

Model simulations combining the hydrodynamics of super-critical wakes with steady currents and a sand transport model provide results that are consistent with the field measurements and observations of the suspended load fraction. The wakes re-suspend sand in the nearshore that would otherwise be immobile. The sand is transported both alongshore and offshore incrementally away from the shoreline eventually reaching deeper water where stronger ambient flows can transport the sediment.

Although the model incorporates some of the elements of the wake induced mean flows, the approach does not fully account for the wave group-induced hysteresis on the suspended sediment load or the differential effects of wave frequency and shape (nonlinearity) effects on the suspended load and bedload. More work is also needed to model the tendency for offshore transport of sand, gravel, and cobble-sized sediment on mixed sediment beaches under super-critical wakes, that leads to beach flattening, while their sub-critical counterparts often lead to beach steepening.

ACKNOWLEDGEMENTS

This work would not have been possible without the cooperation and assistance of many people: past and present PI Engineering staff assisted with data collection and

processing; the waterfront property owners of Rich Passage continue to provide access to beaches, and the vessel operators have provided the wakes and vessel performance information. Their contributions are gratefully acknowledged. The development of LSV was funded by a federal grant program administered by the Federal Transportation Administration (FTA-WA-26-7007-2005), designed to support research and investigations of emerging transportation systems. Idaho Power Company (IPC) funded the studies on the Snake River; IPC staff also assisted with data collection and kindly granted permission to publish the results.

Abstract: X-Ray computed tomography (CAT scanning) has enabled the measurement of the relative density of sand ripples inside the sediment column during ripple migration. A sand ripple produced by stationary flow inside a vertical water tunnel reveals different internal density stratification on CAT-scan profiles. CAT-scan measurements provide a very precise integrated measurement of sediment transport inside the sand ripple, both at the water-sediment interface and in the water column. Results give the total sediment transport (suspended load column concentration and bed load) and illustrate the contribution of each type of sediment transport and their relative magnitude along sand ripples.

INTRODUCTION

The density of a sediment bed provides information on the different phases of the genesis of the internal architecture of sand ripples. The aim of this study is to analyze the evolution of the relative density of a sand ripple during its migration under a stationary flow regime inside a vertical sediment water tunnel on the way to determine the sand ripple characteristics under sediment transport.

Computed axial tomography (CAT) scanning, originally a medical technique which has been adapted to many uses in geosciences (Duliu 1999, Ketcham and Carlson 2001, Mees *et al.* 2003), may be used to measure the relative density of materials such as that of sand layers in sedimentological studies. Density values measured vary from -1024 to +3071 Hounsfield units (HU; Kak and Slaney 1999). Air and water values are respectively -1000 HU and 0 HU (Ketcham and Carlson 2001). For this study, as a first approximation, the conversion factor between density measurements in HU and g/cm³ is considered to be given by

$$Value\ in\ \frac{g}{cm^3} \cong \frac{(Value\ in\ HU + 1024)}{1000} \quad (1)$$

The scanographic research facility at Quebec City dedicated to non-medical use with applications in civil engineering and sedimentology fields, is built around a Siemens Somatom Volume Access CAT-Scan, (Fig. 1).

Fig. 1 CAT-scan facility and the vertical sediment water tunnel. The vertical sediment water flume (VSWF) is fixed on the examination table and the CAT-scan gantry moves along the flume on four parallel rails

The flume used in this study designed by Teeter and Pankow (1989) is 3048 mm long and 1219 mm height. The inner rectangular section 152 mm by 304 mm passes trough the mobile gantry of the CAT scanner. The lower part of the tunnel is filled with a 30 mm thick layer of C-109 Ottawa sand (0,37 mm in grain size with a 1,56 g/cm³ bulk dry density). The flow regime is adjusted by an electrical motor and controlled by a Doppler flow meter (Controltron 1010N). For more details of this apparatus see Montreuil (2006). In this experiment the voxel chosen is 0,391 mm by 0,602 mm and in each slice 512 profiles has been produced.

DEFINITIONS

The internal variation of layer densities in sand ripples agrees with the simple sand ripple model of Reineck and Singh (1975). But some terminology must be defined. The succinct approach of this terminology and the knowledge of the answer is presented in Long and Montreuil (in prep). A typical curve (Fig. 2) of the sediment column density variation is given by the vertical profile 149 of 512, located at H of the stoss-side of a sand ripple. On these profiles different sediment transport layers of the sand ripple body are defined as:

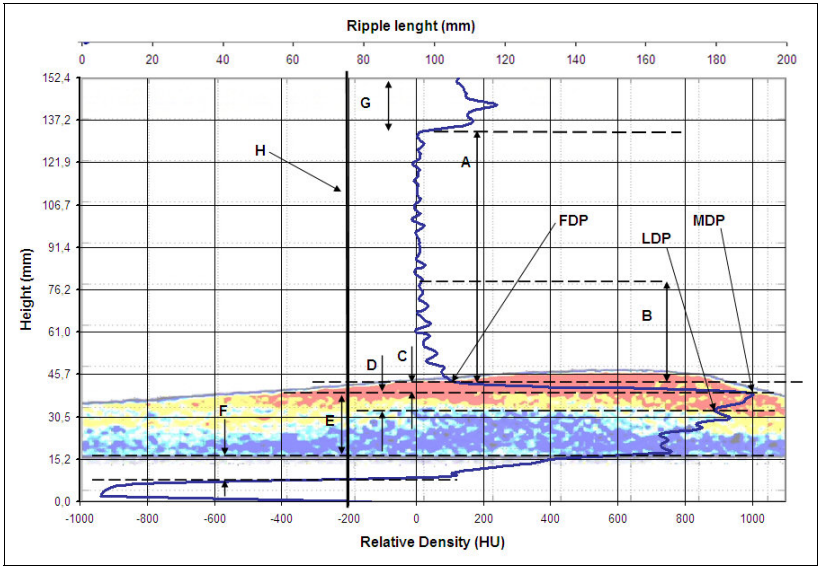

Fig. 2 Density profile, CAT-scan image of a sand ripple and definition of the different transport zone

- The water column (A) includes a free sediment water zone and, in B, the suspended transport zone (STZ). In this STZ, the variations of density over zero indicate the intensity of the sediment transported concentration in the water column. The STZ is separated from the lower unit by the frontier density point (FDP). This point corresponds to the passage between STZ and BTZ.

- The upper part of the solid sediment column (C) called the upper bedload transport zone (UBTZ) is limited at the top by the FDP and at the base by maximum density point (MDP). In this UBTZ, water penetrates more intensely between sediment grains during transport, but friction exists between the grains. This varies from a maximum value when the water concentration is at its minimum and the limit of the friction when the sediments leaves the bedload transport zone and passes into the suspended

load transport zone. After a period of time a new significant point appears close or distant to the maximum density point: the inflection density point (IDP). This point is due probably to the variation of the mechanical characteristics between grains during traction.

- This zone (D) corresponds to the middle bedload transport zone (MBTZ) and is limited at its top by the MDP and at its base by lower density point (LDP). This latter point corresponds to the passage between the MBTZ and the lower bedload transport zone (LBTZ). The thickness of this zone varies along the surface of the ripples. It attains its maximum value on the lee-side of the ripple when the avalanching process is active.

- The zone E. This zone corresponds to the lower bedload transport zone (LBTZ) and is limited at its top by the LDP. This point corresponds to an erosional transition due to the passage of the transgressive bedload transport layer over the discrete transport layer. It is a temporarily inactive transport zone, however it is included as part of the transport zone because it correspond to the upper part of the foreset laminae developed on the lee-side of the ripple. Below this sequence, the inactive transport zone corresponds to the sediment layer not affected by the passage of the sand ripple nor disturbed by the gyres in front of the lee-side.

- The bottom of acrylic flume F and the access port of the flume G were not analyzed.

RESULTS

In this paper, the evolution of the density from the base of the stoss-side of a sand ripple until the end of the lee-side of the ripple is presented. At the beginning of the experiment, the relative density of the dry sand bed was 1,57 g/cm³ (550 HU). Filling with water at 24°C increased the surface density of the sand to 1,91 g/cm³ (890 HU) by the replacement of air by water. Compaction of the sediment column is however not significant.

When the current is over the threshold limit for sediment transport, it was decided, by convention, that the upper limit of the suspended transport zone starts when the water density is greater than 1,02 g/cm³ (0 HU); the lower limit is taken as the density profile frontier point (Tab. 1), located at the intersection of the STZ and the UBTZ. During 3D CAT-scan measurements, the vertical flume creates some artifacts (e.g. beam hardening) near the acrylic wall. The fluid also generates eddy cell wall effects. For this reason, the effective measurement area is reduced from 152 mm by 304mm to 137,3 mm by 284,8 mm.

Table 1. Density of the Frontier point

All measurements are in g/cm³

Surface Density of the Sand Ripple

During ripple migration (flow = 25 cm/s), the surface density (Fig. 3) of the reworked layer increases from the beginning to the upper part of the stoss-side of the ripple (1,59 g/cm³ or 570 HU to 2,32 g/cm³ or 1300 HU). This relates to a decrease of the surface erosion of lower sediment layers (old prograding lee-side layers) due to a decrease in the backflow intensity and an increase thickness of the stoss-side laminae (Reineck and Singh 1975) with increasing pressure.

This phenomenon has been described from a sedimentological point of view by Reineck and Singh (1975) and from a hydrodynamic point of view by Middelton and Southard (1977). The evolution of the maximum density, measured on the surface of the sand ripple (Fig. 3), shows increasing density from 2,00 g/cm³ (975 HU) at the bottom of the stoss-side to a maximum of 2,32 g/cm³ (1297 HU) at a new point call maximumpoint located at profile 217 (Fig. 5). Past the maximumpoint, the density decreases to 1,87 g/cm³ (862 HU) at the brinkpoint (Fig. 3). Between the brinkpoint and the toepoint the density increases again to 2,09 g/cm³ (1062 HU) and decreases past the toepoint to 1,89 g/cm³ (864 HU).

The fluctuations noted along the stoss-side are probably related to micro turbulence due to extraction (passage) of transported grains from the bedload layer to the suspended load layer. Turbulence increases in intensity along the stoss-side and has its maximum amplitude just before the maximum density point. After this point the amplitude of the turbulences decreases in intensity.

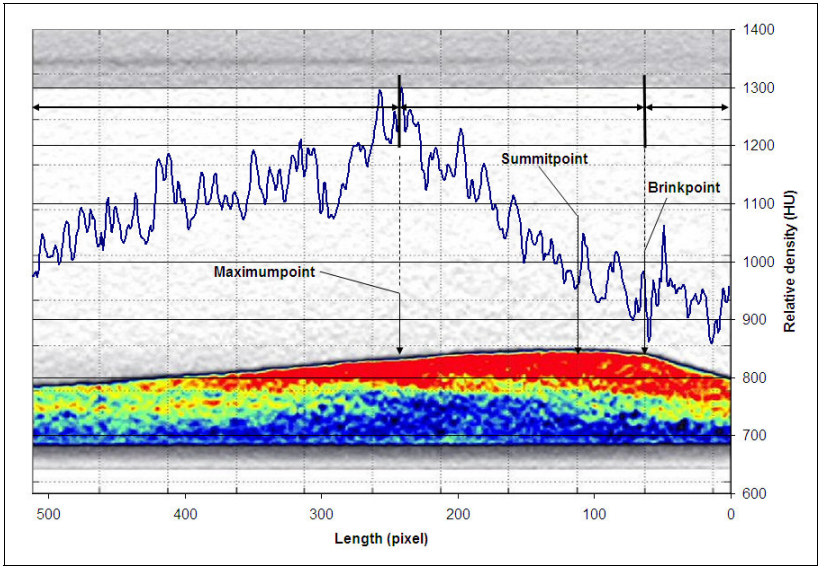

Fig. 3 Maximum surface density and CAT-scan image of the sand ripple (1 pixel = 0,391 mm for a ripple of 200 mm of length)

Lower Stoss-side of the Sand Ripple

To illustrate the evolution of the variations in the vertical density profile the most significant example of each specific zone is illustrated. For the lower stoss-side zone three profiles are presented: profiles 451, 475 and 501 (Fig. 4).

On the density profile 451, the STZ extends 16 mm over two vortexes. The negative HU density zone 1,08 g/cm³ (-56 HU) located at the base of the STZ indicates the presence of captive air inside a vortex, just over the UBTZ. Profile 475, slightly higher on the stoss-side, shows the presence of three vortices but a reduction in vortex intensity. On profile 501 only two vortexes are present and a smooth transition appears between STZ and UBTZ.

Inside the bedload transport zone, profile 451 presents a inflection density point (IDP) where the density of the lower part of the UBTZ passes from 1,80 g/cm³ to 1,97 g/cm³ (774 HU to 949 HU) in 5,4 mm. This limit indicates a deeper penetration of water inside the UBTZ, and consequently the thickness of the limited consolidation zone of the sediments. On profiles 475 and 501, the density of MDTZ increases from1,97 g/cm³ to 2,11 g/cm³, (945 HU to 1087 HU**).** The LBTZ remain similar on the two profiles with a density near 1,97 g/cm³ (950 HU), because sediments are not transported at this level.

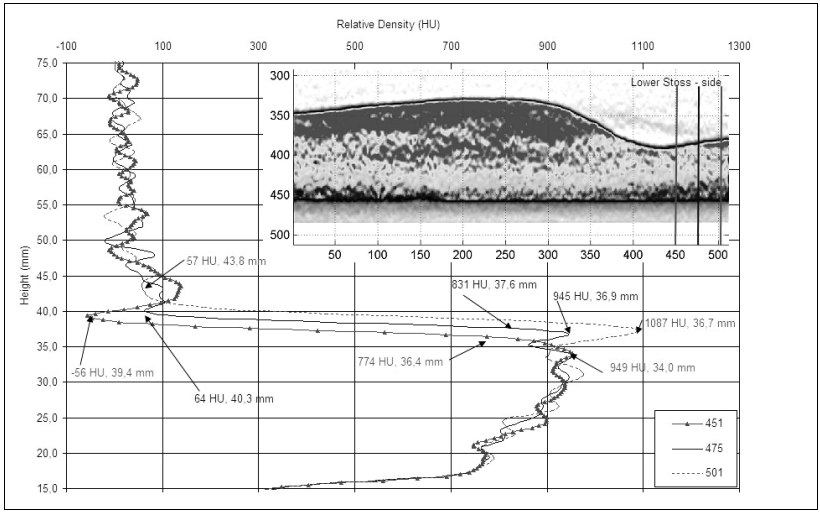

Fig. 4 Profiles of the lower stoss-side and CT-scan image of the sand ripple

Evolution along the Stoss-side of the Sand Ripple

Four profiles have been selected to represent this part of the ripple (profiles 11, 135, 271, and 375; Fig. 5). This selection of profiles presents the evolution of density profiles along the stoss-side. Profile 11, located at the base of the stoss-side (just after the lower part described above) indicates a large suspended sediment transport 19,7 mm thick increasing near the surface of the UBTZ to 1,15 g/cm³ (123 HU) at the interface STZ and UBTZ. Four small pulses appear on the profile.

The profile 135 presents similar results to that of profile 11, with a maximum peak concentration of 1,11 g/cm³ (90 HU) and an extension of the suspended zone of 11 mm with four peaks. On the profile 271, this maximum concentration increases to 1,18 g/cm³ (1152 HU), but the suspended zone is only 15,7 mm thick (This point will be discussed later.) On the summitpoint, the STZ is minimal (14,9 mm thick) and the density is only 0,99 g/cm³ (-32 HU). This value indicates the presence of vortices or eddies.

At the limit of the UBTZ, the frontier density point (FDP) on the density slope changes along the stoss-side. On profile 11, the break on the slope varies from 1,87 to 1,91 g/cm³ (844 HU to 883 HU), within 2,73 mm. On the profile 135, the intensity of the inflection density point (IDP) varies from 2,03 to 1,95 g/cm³ (1002 to 924 HU), within 2,34 mm, and on the profile 271, the slope of the UBTZ is continuous. The profile 375 gives a MDTZ of 6,64 mm and a density of 2,04 g/cm³ (1011 HU).

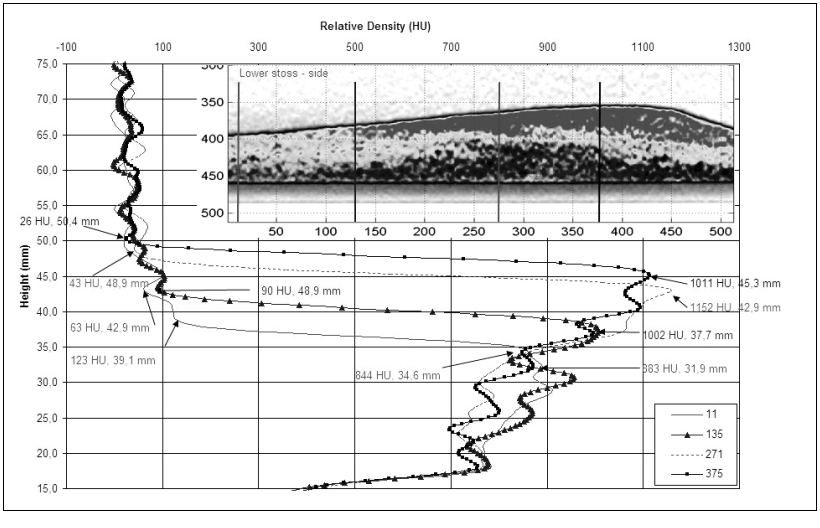

Fig. 5 Density profile along the stoss-side and a CT-scan image of the sand ripple

Summit of the Sand Ripple

Along the summit of the sand ripple, three profiles have been analyzed (profiles 229. 275 and 325; Fig. 6). At the summitpoint, the STZ presents the same aspect for all the profiles 205, 229 and 275 with density of 1,02 g/cm³ (-1 HU) on a thin layer. For the profile 325, located on the upper side of the lee-side, the STZ increases in concentration by 1,05 g/cm³ (23 HU) at the interface STZ and UBTZ.

On the UBTZ, the profiles 205 and 229 remains similar but the density is reduced from 2,16 to 2,13 g/cm³ (1133 HU to 1095 HU). Past the summitpoint, the density of the UBTZ presents an inflection density point (profile 275) where avalanching begins. The thickness of the area affected by avalanching increases on profile 325 and the density decreases to 2,04 g/cm³ (1012 HU).

On the LBTZ, profile 325, the density is reduced to 1,91 g/cm³ (884 HU) indicating the presence of an air bubble trapped inside the bedload zone. A series of prograding layers is observed on the density profiles. As demonstrated by Crémer and al (2002), each prograding layer is represented by a sinusoidal signal corresponding at the geneses of the layer. During an avalanching phase at the beginning of the processes sediment arrives in high concentration and non-compaction or grain organization appears. The signature of this episode is a lower concentration signal. Progressively sediments arrive in a more gentle process and grains are more ordered; the resulting signature of this phenomenon is an increasing of the density signal.

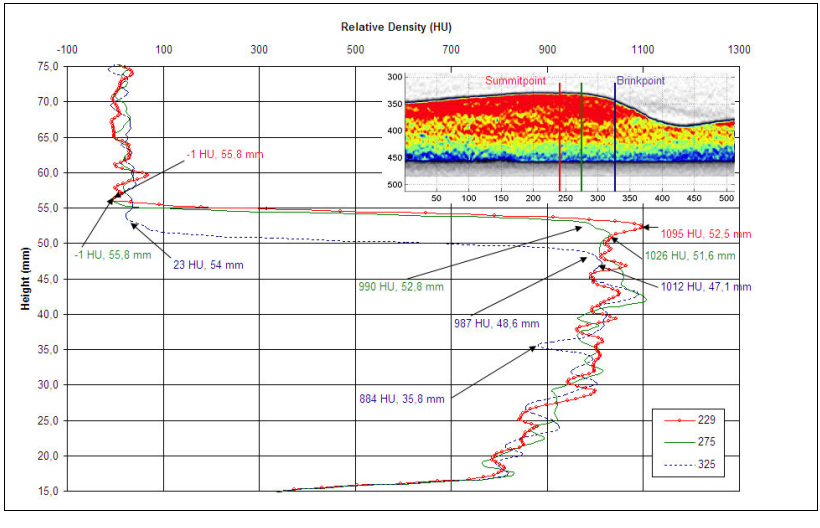

Fig. 6 Density profile over the summit of the sand ripple and a CAT-scan image

Lee Side of the Sand Ripple

Along the lee-side, four profiles located successively at the brinkpoint (profile 325, fig. 6), at the mid distance between the brinkpoint and the toepoint (profile 355, Fig. 7), at the toepoint (profile 397, Fig. 7), and at the troughpoint (profile 431, Fig. 7), have been analyzed. On the upper part of the lee-side on profile 325, the frontier point value increased in comparison to the frontier point located at the summitpoint (profile 275). The concentration varies from 1,02 versus 1,05 g/cm³ (-1 versus 23 HU). Also the vortex zone begins here but it is only discerned on profile 397 (Fig. 7) where the vortex zone is well developed, indicating suspended sediment transport and a vortex zone with a density variation of 1,18 g/cm³ (152 HU). At the toepoint, the high intensity vortex attains a density of 0,96 g/cm³ (-67 HU) and at the troughpoint the vortex intensity is 1,01 g/cm³ (-12 HU), but the thickness of STZ increases from 14,2 mm to 15,1 mm. The IDP present on each profile of the lee-side increases along the avalanching zone to the depositional zone.

The maximum density of the UBTZ on the profiles 325 (fig. 6), 355 (fig. 7) and 431 (Fig. 7) respectively presents a IDP with a MDTZ of 2,04 g/cm³ and 2,07 g/cm³ (1012 and 1044 HU). The profile 355 (Fig. 7) located at middle distance between the toepoint and the troughpoint has a MDTZ with a thickness of 7,1 mm. The profile 431 (Fig. 7) located at the troughpoint, presents a MDTZ of 2,00 g/cm³ (981 HU) and a inflection in the slope from 37,6 mm to 35,2 mm for a thick of 2,4 mm. The troughpoint presents a MDTZ of 1,99 g/cm³ (966 HU) and no inflection in slope.
The LBTZ of profiles 355 and 397 show similarities; the inflection in the slope of profile 397 is present on the LBTZ of the profile 355, indicating previous formation of the foreset laminae.

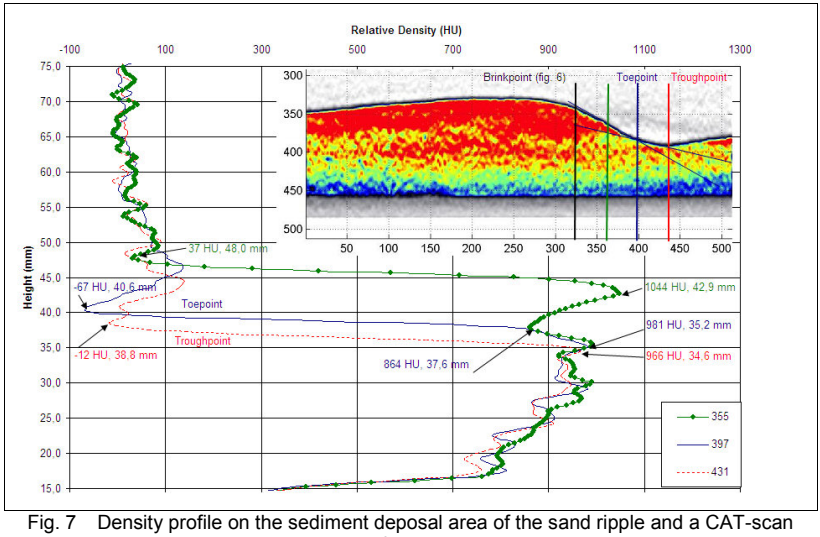

Fig. 7 Density profile on the sediment deposal area of the sand ripple and a CAT-scan image

Evolution of the STZ and UBTZ along the Sand Ripple

Along the sand ripple, the thickness of the STZ of the lower stoss-side lies between 3,4 mm and 5,7 mm (Tab. 2). Its thickness fluctuates on the summit of the sand ripple, increasing from 3,3 mm to 6,9 mm. Approaching the lee-side, the STZ increase rapidly to value near 15 mm.

The thickness of UBTZ of the lower stoss-side lies between 14,3 mm and 16,4 mm. The thickness along the stoss-side decrease until the summit of the sand ripple is approached. Its increases again past the summitpoint, on the lee-side from 10 mm to 25 mm, and decreases to 17,9 mm after the troughpoint.

Table 2. Thickness of the STZ and UBTZ for each profile

Figure number	4			5				6			7

DISCUSSION

The sedimentological characteristics of Reineck and Singh (1975) provide the basis for the characterisation of sediment transport zones. During this experiment, several zones along the ripple surface have been distinguished from CAT-scan density variations. Four zones have been defined in vertical sections: the STZ, the UBTZ, the MDTZ and the LBTZ. The passage between the STZ and the UBTZ is continuous and is determined by a frontier point on the curve of vertical density concentration. The density related to this frontier point changes along the surface of the ripple. Such changes are probably due to the intensity of the turbulence at the surface of the ripple.

Lower Stoss-side of the Sand Ripple

The top of the STZ (Fig. 4) is created by shear flow over the sediment bed. The concentration of the suspended sediment along the STZ is very great and the thickness of this zone varies from 14,3 mm to 16 mm. The curve in the profile at the transition between STZ and UBTZ indicates the presence of significant vortices which decrease in intensity when rising along the stoss-side. A large quantity of sediment is present in the STZ. To quantify sediment transport, it is essential to use a PIV system. Planned future use of PIV will confirm the exact masses of sediment in suspension in the STZ and on the UBTZ.

The UBTZ located between the lower limit of the STZ and the upper limit of the MDTZ is a transition zone in the bedload transport mechanism. At this stage, water penetrates more and more inside the sediment matrix and has transformed the traction movement of the MDTZ to a pseudo-traction movement where the cohesion between grains decreases dramatically to reach the limit of the cohesion between two grains (frontier density point on the curve). The increasing density of the material in the MDTZ (Fig. 4) indicates a consolidation of the sediment when raising the stoss-side of the sand ripple.

Slope Inflection
The inflection in the slope (profile 451, Fig. 4) indicates deeper penetration of water inside the UBTZ.

Evolution along the Stoss-side of the Sand Ripple
Along the stoss-side, the thickness of the STZ (Fig. 5) is reduced and the size of the UBTZ increased. This co-evolution indicates a change of sediment transport mechanism: suspended sediment transport decrease in intensity in favor of bedload sediment transport. On profile 374, located at the summitpoint of the ripple, the thickness of the MDTZ is maximal (6,64 mm) and this MDTZ passes across the total set of laminae and shows the variation of the architecture of one isolated lamina.
In the STZ and UBTZ, the density profiles distribution is not uniform. Close to the summitpoint the turbulence level is reduced. The STZ gets thinner from the lower stoss-side to the summitpoint.

Maximumpoint
The major parts of the ripples present a point of maximum density (peak). The positions of this maximumpoint vary along the ripple in function of the ripple's form and the flow velocity. The profile 271 (Fig. 5) presents a maximum surface density and MDTZ of 2,18 g/cm³ (1152 HU). This maximumpoint is located on the stoss-side of the sand ripple and represent the maximum pressure of the water column over the bedload (Middleton and Southard 1977).

Summit of the Sand Ripple
The size of the STZ increases past the summit of the sand ripple and simultaneously the gravitational depositional processes begins (profile 275, Fig. 6). The form of the UBTZ indicates avalanching processes and the creation of foreset laminae. The density of MDP is reduced from 2,16 to 2,04 g/cm³ (1133 HU to 1012 HU).

Lee Side of the Sand Ripple
The lower part of the lee-side presents a reduction of STZ (Fig. 6 and Fig. 7). This is related to the form of the sand ripple and by the amplitude of eddies. The reduction of the STZ could also be caused by air trapped inside eddies. The thickness of the STZ is not constant along the deposition zone. During the formation of the foreset laminae, sediments leave the water column and are trapped inside the foreset laminae in formation.
The presence of the UBTZ and the inflection in the slope phenomena are significant of bedload transport. The density of the toepoint is 1,09 g/cm³ (67 HU) due to the high intensity of the vortex over a UBTZ and create the foreset laminae with a large bedload sediment movement indicated by the inflection in the slope.
The UBTZ of the brinkpoint profile presents a inflection in slope indicating a MDTZ of 1044 HU (2,07 g/cm³) and the presence of avalanching processes.
The profile 431 (Fig. 8) with a break in the slope of 3,13 mm indicates deposition of sediment transported by avalanching phenomena.

The troughpoint presents a MDTZ of 1,99 g/cm³ (966 HU) but no inflection in slope, indicating a depositional (avalanching) process with the presence of a vortex over UBTZ indicating the approach of erosional process.

CONCLUSION

In conclusion, the use of Computed axial tomography provides a new perspective for the study of bed forms by providing a means of internal examination of sand ripples. The density variation model obtained during the migration under a stationary flow regime reveals the architecture of the internal part of the ripple and the action of the different phases of sediment transport inside the sand ripple.

The sedimentologique characteristic of Reineck and Singh (1975) gives the base vocabulary for the elaboration of the characteristics of sediments transport zones.

This preliminary work opens the possibility for characterization of sediment transport in 3D. In vertical profiles of the sand ripple, four zones were defined: the STZ, the UBTZ, the MDTZ and the LBTZ. The passage between the STZ and the UBTZ is continuous and is determined by a frontier density point on the curve of vertical density concentration. The density related to this frontier point changes along the surface of the ripple. This is probably due to the intensity of the turbulence at the ripple surface. The MDTZ thickness is determined by the inflection in the slope how indicates an activity in the lower part of the UBTZ. The different stages of transport have been measured successfully for a single grain size and flow velocity.

For the first time, the X-ray gives a look inside the sand ripple without interference on the middle.

X-ray densities define a field between 0 and 4,10 g/cm³ (-1024 and 3071 HU) at 0.001 g/cm³ resolution (with 90% confidence at 0,002 g/cm³) with an image size of 512 by 512 densimetrics value. In the near future, a new CAT-scan to be installed in the Québec scanning laboratory will provide a resolution of 1024 by 1024 for the same span and the possibility for modification of the span for a high density range. PIV techniques will also be used to compute suspended load and bedload sediment transport volumes.

Abstract: The potential relevance of wave skewness and sloping beds on morphodynamic predictions is investigated. Based on a comparison with measurements it was shown that the phase lag is potentially important for modeling nearshore bar dynamics as it influences the suspended wave related transports (magnitude and direction). Velocity skewness results in a phase shift between the orbital motion and the instantaneous bed shear stress increasing onshore bed load transport. It was seen that its influence is relatively small but does affect bar migration and helps to predict the observed asymmetric bar shape. The bed slope affecting the initiation of motion and sediment bed-load transport magnitude and direction are investigated by comparing scour hole predictions. The initiation of motion, which is also included on the suspended transports, only has an effect for somewhat steeper slopes. The modifications of bed-load direction and magnitude significantly affect the horizontal and vertical scour hole equilibrium dimensions.

INTRODUCTION

As part of the implementation of the TR2004 transport formulations (Van Rijn, 2006a,b) in the Delft3D-Online model (Lesser et al., 2004) a number of additional processes were included or updated. Here we are focusing on processes of which the relative importance in morphodynamic simulations is not well known. The investigated processes are the phase lag effects on the wave related suspended transport, the role of orbital velocity skewness on the bed shear stress and the effect of sloping beds on bed-load and suspended sediment transport. First, a brief description of the considered processes is given, followed by a limited number of morphodyamic simulations to illustrate their potential relevance. Finally, some concluding remarks and recommendations for further research are given.

PHASE LAG EFFECTS

The wave-induced suspended transports are based on an intra-wave approach, which consists of a parameterized description of the instantaneous response of the suspended sand concentration to the near-bed orbital wave motion (Houwman and Ruessink, 1996):

$$q_{s,w} = \lambda f_p \left(\frac{U_{on}^4 - U_{off}^4}{U_{on}^3 + U_{off}^3} \right) \int_a^{3\delta_s} c\,dz \qquad (1)$$

in which U_{on} is the near-bed peak orbital velocity in onshore direction (in wave direction), U_{off} is the near-bed peak orbital velocity in offshore direction, c the vertical distribution of the time-averaged sediment concentration, λ is a coefficient (0.1), δ_s is the thickness of the wave boundary layer, an extension of the original formulation is the function (f_p) which represents the phase-lag effects.

Phase lag effects may occur when sediment is stirred up and does not respond directly to the orbital wave motion as it takes time to fall back to the bed (Dohmen-Janssen, 1999). The phase lag can result in a decreased transport of sediment in the wave direction or can, in cases of fine sediment and relative short wave periods, result in sediment being transported against the wave propagation direction. Van Rijn (2006b) accounted for this phase-lag effect by including a f_p-phase function ($-1 < f_p < 1$) which depends on the bed characteristics (form roughness, grain size) and the strength of the asymmetric wave motion:

$$f_p = -\tanh\left[100\left(P - P_{cr}\right)\right] \qquad (2)$$

with $P = \dfrac{k_s}{w_s T_p}$, in which k_s is the wave-related bed roughness height, w_s is the settling velocity, T_p is the peak wave period, and P_{cr} is the critical phase lag number which is set to 0.1.

WAVE SKEWNESS

Nielsen (1992, 2002, 2006) and Nielsen and Callaghan (2003) have shown that fluid accelerations in strongly asymmetric wave motion lead to an increase and phase lead of the bed-shear stresses. This is partly due to the presence of boundary layer streaming and

partly to the saw-tooth asymmetry, i.e. the front of the waves being steeper than the back. Moreover, Watanabe and Sato (2004) have shown that the fluid acceleration effects on the bed shear stresses leads to a small net transport in the case of forward leaning waves, even if the peak onshore and offshore orbital velocities are equal, because of the more abrupt acceleration under the steep front. More abrupt accelerations are associated with thinner boundary layers and greater pressure gradients for a given velocity magnitude.

Nielsen and Callaghan (2003) proposed a simple method to deal with these processes, by expressing the transport rate in terms of an instantaneous Shields parameter rather than in terms of a free stream velocity, and accounting for both streaming and accelerations in the Shields parameter calculations. The instantaneous bed-shear stress under asymmetric wave motion including enhanced acceleration effects in saw-tooth waves reads as:

$$\tau_{b,t}^{'} = 0.5\rho_w f_w^{'} \left| u_{w,t}\cos\xi_\tau + \frac{1}{\omega}\frac{du_{w,t}}{dt}\sin\xi_\tau \right| \left(u_{w,t}\cos\xi_\tau + \frac{1}{\omega}\frac{du_{w,t}}{dt}\sin\xi_\tau \right) \quad (3)$$

in which ρ_w is the fluid density, $f_w^{'}$ is the grain-related wave friction factor, $u_{w,t}$ the instantaneous orbital velocity at the edge of the wave boundary layer, ω is the angular wave frequency and ξ_τ is the phase lead.

Consequently the instantaneous bed shear stress values shifts forward and the peak bed-shear stress increases with the phase lead-value, leading to an increase of the onshore net transport. Based on comparison with the Watanabe and Sato (2004) experiments, Nielsen (2006) recommends using a phase lead-value of 51°. However, the range of the optimal values is relatively large for considered experiments (average values for ξ_τ in the range of 40° to 62°). Here we are driving the Nielsen and Callaghan (2003) model with a velocity signal derived from a non-linear wave model based on Isobe and Horikawa (1982) which only describes velocity skewness. Acceleration skewness which is associated with saw-tooth waves (or pitched-forward waves) is not accounted for.

BED SLOPE EFFECTS

Most transport formulas are only valid for (nearly) horizontal beds (bed slope=tan $\beta \leq 10^{-3}$ (positive values of β refer to down sloping beds). Based on the results of experimental work, it appears that the bed slope may affect the transport rate in three ways:

1. the bed slope will influence the local near-bed flow velocity (hydrodynamic effect not considered here);
2. the bed slope will change the threshold conditions for initiation of motion;
3. the bed slope may change the transport rate and/or direction, once the sediment is in motion.

Here we will discuss expressions dealing with the initiation of motion and the change of transport rate and/or direction and how they are implemented in Delft3D.

Threshold conditions

Dey (2001, 2003) studied the critical bed-shear stress on both longitudinal and transverse

(lateral) bed slopes. Experiments were conducted in two different, transparent (perspex) semi-circular ducts for three sizes (600, 940 and 1350 μm with angles of repose of 32°, 34° and 35°) of uniform sediments. Based on these experiments Dey (2003) derived a rather complicated expression to describe the critical bed-shear stress along combined longitudinal and transverse bed slopes, which reads as:

$$\frac{\tau_{b,cr}}{\tau_{b,cr,o}} = a\left(-b + \left(b^2 + c\right)^{0.5}\right) \tag{4}$$

with $a = \left(\left(1 - \eta \tan\phi\right)\tan\phi\right)^{-1}$, $b = \sin\beta + \eta\left(\tan\phi\right)^2\left(\left(\cos\phi\right)^2 - \left(\sin\phi\right)^2\right)^{0.5}$, $c = \left(1 - \left(\eta\tan\phi\right)^2\right)\left(\left(\cos\phi\tan\phi\right)^2 - \left(\sin\phi\tan\phi\right)^2 - \left(\sin\beta\right)^2 - \left(\sin\gamma\right)^2\right)$, η is the ratio of lift and drag forces on a particle, $\tau_{b,cr}$ is the critical bed-shear stress, $\tau_{b,cr,o}$ is the critical bed-shear stress along the horizontal bed, β is the longitudinal slope angle (positive values refer to down sloping beds), γ is the lateral (transverse) slope angle and ϕ is the angle of repose.

Assuming a horizontal bed in normal to the flow direction ($\gamma = \eta = 0$), Eq. (4) reduces to the Schoklitsch equation. When assuming a horizontal bed in longitudinal direction ($\beta = \eta = 0$) Eq. (4) reduces to the Leitner equation (see e.g. Van Rijn, 1993). Dey showed that Eq. (4) is in reasonable agreement with his experimental values. However, it significantly over-predicts the critical bed shear stress for relatively large longitudinal adverse slopes. Here we are using an empirical expression proposed by Dey (2001) which was modified slightly to improve the agreement with measured data (see Fig. 1):

$$\frac{\tau_{b,cr}}{\tau_{b,cr,o}} = \left(1 - \frac{\tan\beta}{\tan\phi}\right)^{0.75}\left(1 - \frac{\tan\gamma}{\tan\phi}\right)^{0.37} \tag{5}$$

The instantaneous bed load transport due to the combined action of waves and currents is based on Van Rijn (2006a) and reads in simplified form:

$$S_{b,t} = A\left(\frac{\tau_{b,cw,t}}{\rho_w}\right)^{0.5}\left(\frac{\tau_{b,cw,t} - \tau_{b,cr}}{\tau_{b,cr}}\right) \tag{6}$$

in which A is a factor (see Van Rijn; 2006a), $\tau_{b,cw,t}$ is the instantaneous grain-related bed-shear stress due to both currents and waves.

From Eq. **Error! Reference source not found.**(6) it becomes clear that the threshold condition, Eq. (5), will result in a linear scaling of the bed load transports.

The modification of the critical bed shear is also applied on the reference concentration, c_a, (Van Rijn, 2006b):

$$c_a = B\left(\frac{\overline{\tau}_{b,cw} - \tau_{b,cr}}{\tau_{b,cr}}\right)^{1..5} \tag{7}$$

in which B is a factor (see Van Rijn, 2006b), $\overline{\tau}_{b,cw}$ is the time-averaged effective bed-shear stress and $\tau_{b,cr}$ is the critical bed-shear stress according to Shields including the

modification of the threshold condition according to Eq. (5).

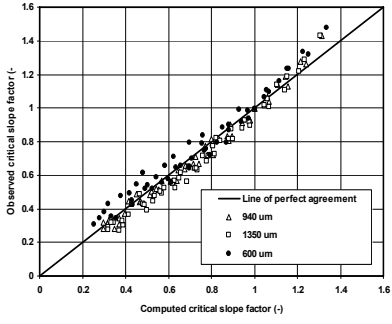

Fig. 1 Observed and computed critical slope factor for combined longitudinal and transverse bed slopes based on Eq. (5) modified expression of Dey (2001).

Bed load transport on sloping beds

Two methods are considered which describe the transverse transports on a sloping bed. The first method, originating from Van Bendegom (1947), determines the angle of the transverse transports based on the forces acting on a particle along a sloping bottom. The second method (Ikeda, 1988) is based on the equation of motion and results in a correction of the transport magnitude. Both transverse correction methods are combined with longitudinal corrections which are mentioned for completeness sake, but are not the focus of this paper.

Direction based transverse transport correction

Van Bendegom (1947) gives the following expression for the direction of sediment moving on a sloping bed:

$$\tan\alpha = \frac{S_{b,n}}{S_{b,s}} = \frac{\sin\delta - \dfrac{1}{f(\theta)}\tan\gamma}{\cos\delta - \dfrac{1}{f(\theta)}\tan\beta} \tag{8}$$

in which $S_{b,n}$ and $S_{b,s}$ are the bed load transports in transverse and longitudinal direction respectively, $f(\theta)$ is a transverse bed-slope coefficient, being a function of the shields number, θ; z_b is the bed elevation, x and y are the horizontal coordinates, δ is the angle of the flow near the bed.

Ignoring the longitudinal bed slope effects ($\delta = 0$ and $\tan\beta = 0$) reduces Eq. (8) to:

$$\tan\alpha = -\frac{1}{f(\theta)}\tan\gamma \tag{9}$$

Talmon (1992) and Talmon et al. (1995) studied the direction of sediment transport (bed load and suspended load) on transverse alluvial bed-slopes based on Eq. (9). Laboratory experiments with transverse bed slopes in a straight flume were performed. Various sand sizes were used (d_{50} of 90, 160 and 790 μm). Suspended load transport was dominant in

the tests with the finer sediments (90 and 160 μm). The initial bed was placed under a transverse slope in the (straight) flume. The bed level difference between the left and right sides of the bed in the flume was observed to be smoothed out (leveled) by the flow as a function of time by transverse sediment transport processes. The observed bed development in the experiments with coarse sand (790 μm) can be represented quite well by a relatively simple mathematical model for the transverse sediment transport processes, in which the *f(θ)*-coefficient is represented as (Koch and Flokstra, 1981):

$$f(\theta) = 1.7\theta^{0.5} \tag{10}$$

In the modeling of the bed slope effects in the presence of suspended load transport, it was assumed that only the bed-load transport part of the sediment transport is affected by the transverse sloping bed. In the experiments with fine sediment (90 and 160 μm) the *f(θ)*-values derived from the experimental results are significantly lower (a factor 1.4 for 90 μm sand to 3.5 for 160 μm sand) than the values predicted by Eq. (10). Considering measured data and numerical simulation results of both natural rivers and laboratory flumes, Talmon et al. (1995) have found a distinct influence of the bed forms which differ in both situations (scale effects, particle size and flow depth). This effect can be expressed through the relative particle size (d_{50}/h) as:

$$f\left(\theta, \frac{d_{50}}{h}\right) = 9\left(\frac{d_{50}}{h}\right)^{0.3} \theta^{0.5} \tag{11}$$

This expression suggests that, at the same θ, the transverse slope effect (i.e. *1/f(θ)*) on the bed load transport particles is stronger (smaller *f(θ)*) in situations with finer sediment (dominant suspended load transport) than with dominant bed-load transport, as found in the laboratory experiments with 790 μm. However, the transverse slope effect may also be acting on the suspended particles (at least those close to the bed). This latter approach yields a larger effect in the case of dominant suspended load transport. Talmon (1992) has also studied the morphological behavior of river bends in the case of dominant suspended load transport (>50%). His mathematical model was formulated in terms of the depth-averaged equations using an asymptotic approximation to represent the horizontal and vertical adjustment of the depth-averaged sediment concentration to changing flow conditions (Galappatti-method). Experiments in a curved laboratory flume have been conducted to provide verification data for the mathematical model. The effect of transverse bed slopes is assumed to act on the bed load transport fraction only. Using this approach, the transverse bed slopes are under-predicted by the model. This suggests that either the *f(θ)*-value acting on the bed load transport fraction is too small or it should also be applied to the suspended load particles.

The approaches described by Eqs. (10) and (11) are combined with a longitudinal slope effect based on Koch and Flokstra (1981) which reads:

$$\alpha_s = 1 + \varepsilon_s \tan\beta \tag{12}$$

in which ε_s is a user-specified tuning parameter (default value: 0.05)

Talmon (1992) used this parameter in various comparisons with experiments and used values for ε_s in the range of 0.15 to 0.3.

Magnitude based transverse transport correction

An alternative approach is based on the equation of motion of a particle moving over a sloping bed, suggested by Ikeda (1988) for transverse sloping beds:

$$\alpha_n = \varepsilon_n \left(\frac{\tau_{b,cr}}{\tau_b} \right)^{0.5} \tan\gamma \tag{13}$$

in which ε_n is a user-specified tuning parameter (default value: 1.5, range between 1.5 and 3).

Lesser et al. (2004) used Ikeda (1988) to model the morphological development (dominant bed load transport; sediment of 450 μm; mean velocity of 0.4 m/s) of a river bend in a laboratory flume. Good results were obtained by using ε=2.

The Ikeda (1988) method is combined with the Bagnold (1956) approach for longitudinal sloping beds:

$$\alpha_s = 1 + \varepsilon_s \left(\frac{\tan\phi}{\cos\left(\tan^{-1}\beta\right)\left(\tan\phi - \tan\beta\right)} - 1 \right) \tag{14}$$

in which ε_s is a user-specified tuning parameters (default value: 1).

Implementation in Delft3D

Both methods to account for sloping beds (van Bendegom and Ikeda) in the bed load transport are included in Delft3D. In both methods first the *magnitude* of the transport is determined or modified by applying the longitudinal bed slope correction factor, next the *direction* of the transport is modified by applying the transverse bed slope correction factor. However, due to the way how the bed slope adjustment factors have been derived, the implementations in Delft3D differ slightly for both methods. The description given here is based on a vectoral description of transports in the horizontal plane.

For the Ikeda/Bagnold method the implementation is based on:

$$\begin{aligned} S'_{b,x} &= \alpha_s S_{b,s} \cos\alpha - S_{b,n} \sin\alpha \\ S'_{b,y} &= \alpha_s S_{b,s} \sin\alpha + S_{b,n} \cos\alpha \end{aligned} \tag{15}$$

in which $S'_{b,x}$ and $S'_{b,y}$ are the adjusted bed-load transport components based on the unadjusted transports $S_{b,s\ or\ n}$ and α_s is determined according to Eq. (14).

By using $S_{b,n} = \alpha_n |S_b|$, $\sin\alpha = \frac{S_{b,y}}{|S_b|}$ and $\cos\alpha = \frac{S_{b,x}}{|S_b|}$, Eq. (15) can be written as:

$$\begin{aligned} S'_{b,x} &= \alpha_s S_{b,x} - \alpha_n \alpha_s S_{b,y} \\ S'_{b,y} &= \alpha_s S_{b,y} + \alpha_n \alpha_s S_{b,x} \end{aligned} \tag{16}$$

For the van Bendegom based methods the bed slope factors are taken into account by

first adjusting the magnitude of the bed load transport:

$$S_b^{'} = \alpha_s S_b \tag{17}$$

with α_s according to Eq.(12).

The adjusted transport is subsequently decomposed by using:

$$S_{b,x}^{'} = S_b^{'}\left(\frac{\alpha_{n,x}}{\left(\left(\alpha_{n,x}\right)^2+\left(\alpha_{n,y}\right)^2\right)^{0.5}}\right) \; and \; S_{b,y}^{'} = S_b^{'}\left(\frac{\alpha_{n,y}}{\left(\left(\alpha_{n,x}\right)^2+\left(\alpha_{n,y}\right)^2\right)^{0.5}}\right) \tag{18}$$

where $\alpha_{n,x}$ and $\alpha_{n,y}$ are the decomposed transverse bed slope factors:

$$\alpha_{n,x} = f(\theta)\frac{S_{b,x}}{S_b}+\frac{dz_b}{dx} \; and \; \alpha_{n,y} = f(\theta)\frac{S_{b,y}}{S_b}+\frac{dz_b}{dy} \tag{19}$$

with $f(\theta)$ being determined according to Eqs. (10) or (11), note that in the above equation the unadjusted transports are used.

MORPHODYNAMIC APPLICATIONS

The aim of this section is to illustrate the relevance of the discussed modifications rather than claiming to provide a comprehensive overview. The selected test cases have the characteristics for which the discussed extensions are potentially important. The phase lag and wave skewness are investigated for the LIP11D experiments carried out in WL | Delft Hydraulics' Delta flume (Arcilla et al., 1994). Using a water depth of 4.1 m, the length of the constructed bottom profile was approximately 180 m. Here both the erosive (Test 1B: H_{m0} = 1.4 m, T_p = 5 s) and accretive (Test 1C: H_{m0} = 0.6 m, T_p = 8 s) test are considered. The predicted and measured profile development are compared after 18 (Test 1B) and 13 hours (Test 1C), with a focus on the bar at x=138 m.

Phase lag effects

Three runs were carried out: f_p was determined using Eq. (2) and setting it to -1 and +1, representing its maximum offshore and onshore limits. The profile developments are compared in Fig. 2 for both tests. It is clear that the wave suspended transport is able to change the direction of the bar migration. The value for f_p according to Eq. (2) is close to +1 which correctly predicts the shoreward or seaward bar migration. However, for Test 1B the λ was set to 0.03 (compared to 0.1 for Test 1C) in Eq. (1).

Wave skewness

A sensitivity analysis was performed by varying the phase lead, ξ_τ, in the range of [0°, 10°, 25°, 40°, 51°]. The results are shown in Fig. 3, from which is becomes apparent that ξ_τ only results in a visible influence when it is 25° or larger. The higher ξ_τ-values enhance the bed-shear stress, increasing of the onshore net transport. The best agreement is obtained for the ξ_τ ranging from 25° to 40°. The observed onshore bar migration which is accompanied with enhanced asymmetry bar shape is qualitatively reproduced by the model using the higher ξ_τ-values for Test 1C. Furthermore, ξ_τ mainly affects the bar regions. The inner bars that are predicted in both tests are not realistic and are mainly

due to the applied relatively simple orbital motion model which does not account for the fact that waves evolve from peaked waves (shoaling) to asymmetric pitched-forward shapes with steep front faces after breaking (Hoefel and Elgar, 2003). This essentially results in a transition from velocity skewness to acceleration skewness being dominant. This is also relevant for the phase lag results discussed in the previous section.

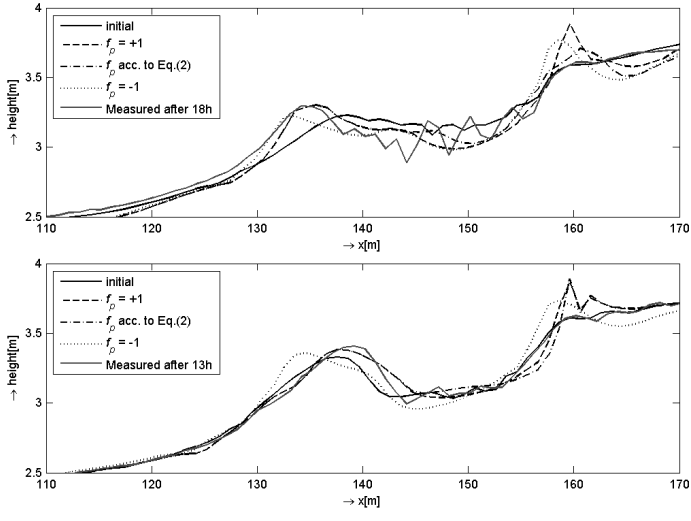

Fig. 2 Profile development induced by various settings of the f_p phase-factor for LIP11D Test 1B (top) and Test 1C (bottom).

Bed slope effects

To illustrate the influence of the discussed slope corrections, transverse and longitudinal transports are compared as a function of the shields parameter for a horizontal bed and two transverse bed slopes ($\tan\gamma = 0.05$ and $\tan\gamma = 0.2$) at 5 m water depth and d_{50} is 0.2 mm. Only transverse bed slopes are considered (i.e. horizontal longitudinal bed). Furthermore, their influence is investigated by comparing the morphodynamic predictions for a schematic case in which, due to current contraction, a scour hole develops.

First the modification of the initiation of motion (Dey, 2001) is investigated by comparing the resulting transports including and excluding Dey (2001) in combination with Ikeda (1988). The transverse bed-load transports are shown in Fig. 4, from which it can be seen that Dey (2001) results in an overall transport increase for the large slope case (compare the blue and the dashed-black lines). For the mild slope Dey (2001) has no visible influence (compare red and solid-black lines). Similar trends are visible for the longitudinal transports shown in Fig. 5.

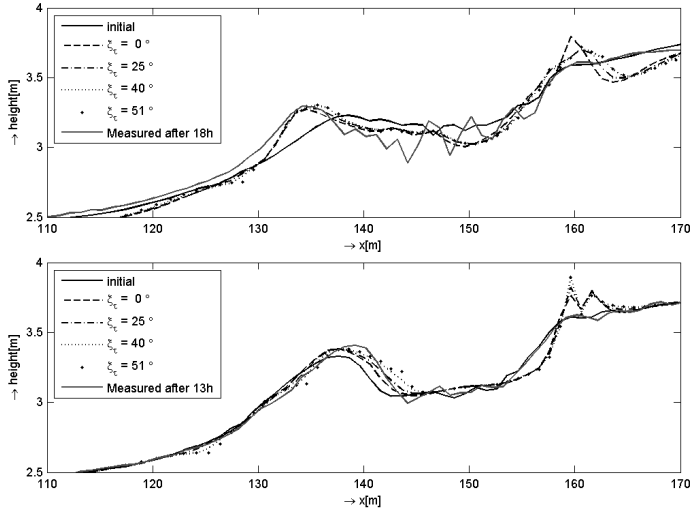

Fig. 3 Profile development induced by various settings of the phase lead for LIP11D Test 1B (top) and Test 1C (bottom).

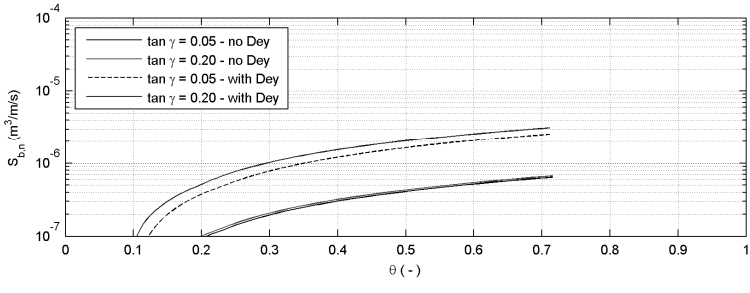

Fig. 4 Transverse bed-load transport as a function of the shields parameter for various transverse sloping beds.

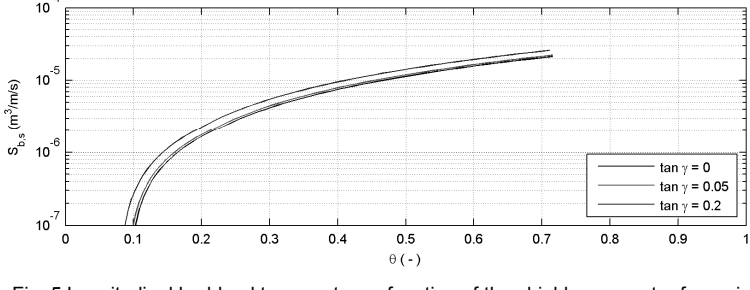

Fig. 5 Longitudinal bed-load transport as a function of the shields parameter for various transverse sloping beds.

The effects on the longitudinal suspended transport are shown in Fig. 6. As could be expected the same trend is found again. However, these results also indicate the potential relevance for including slope effects in the suspended transports. This could especially be the case for areas where suspended sediment is dominant (e.g. ebb tidal deltas and estuaries). Although this approach requires further justification and validation, experimental data (Talmon, 1992) seem to justify this method.

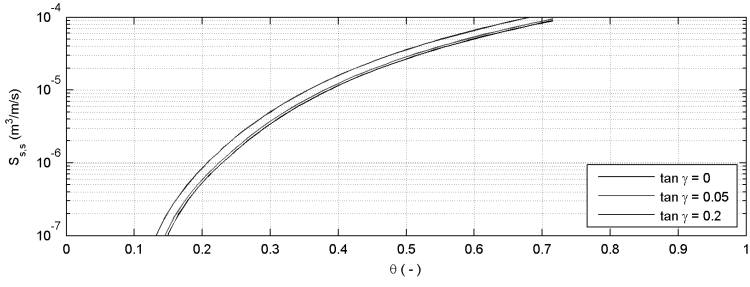

Fig. 6 Longitudinal suspended transport as a function of the shields parameter for various transverse sloping beds.

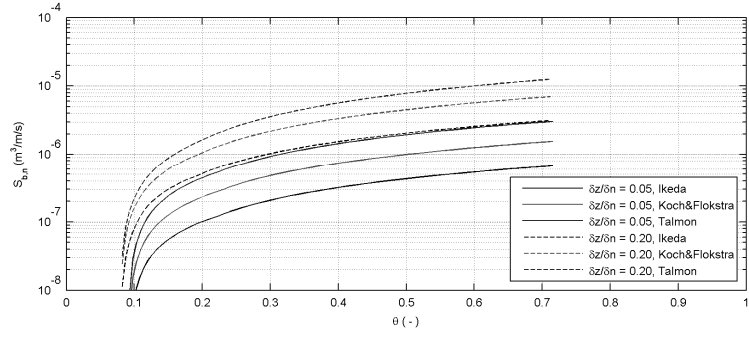

Fig. 7 Transverse bed-load transport as a function of the shields parameter for various transverse sloping bed correction methods.

The transverse bed slope correction methods are compared for the same transverse bed slopes in Fig. 7. The differences between the mild and steep slope transports are of the same order as the differences between the three bed slope correction factors. The behavior of the formulations is very similar, which is somewhat surprising for Ikeda (1988). It was expected for Koch and Flokstra (1981) and Talmon et al. (1995) as they are based on the same approach.

The morphodynamic effects of the different bed slope formulations are investigated by comparing the predictions of a scour hole which is in (near) equilibrium state. The computational grid of the model is 100 m long and 20 m wide with a grid spacing of 1 m in both directions (see Fig. 8) and has an initial uniform water depth of 5 m. Two 4 m

long groynes perpendicular to the flow are situated at x = 20 m from the upstream boundary. A stationary current of 0.5 m/s is imposed at the upstream (left) boundary. Flow contraction results in an initial increase of current velocities up to 0.9 m/s in between the two groynes. The morphodynamic simulations are carried out with the sediment transport relations of Van Rijn (2006a,b) applying a uniform grain size of 0.2 mm. The simulations cover a 100 day period which is sufficiently long to obtain a bathymetry in approximate equilibrium. Three combinations of bed slope formulations are considered, the influence of the initiation of motion (Dey, 2001) is compared in combination with Ikeda (1988) and Talmon et al. (1995) including Dey (2001).

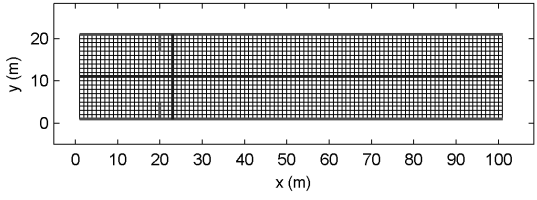

Fig. 8 Grid schematisation including groynes (red) and output transects (blue).

Due to the increased current velocities, a scour hole develops with a depth in the range 6.5 m to 7.2 m depending on the applied bed slope correction formulation as can be seen in Fig. 9. The predicted transverse profiles show a marked difference. Especially the difference between Ikeda (1988) and Talmon et al. (1995) is relatively large.

CONCLUSIONS

The wave-related suspended transport contribution is usually directed in the wave propagation direction, but may, depending on local wave and ripple characteristics, change sign. This transport can be of great importance when modeling morphodynamics in the surf zone, as it can alter the bar migration direction. However, the f_p-phase lag function was not tested extensively and will require further research to assess the robustness of the suggested approach.

Application of the Nielsen and Callaghan (2003) model to account for velocity acceleration in the bed shear stress showed that its effect is relatively small for the considered cases. However, the qualitative trends in bar shape improved with this expression. The best agreement between the model and the observations is obtained for a phase angle, ξ_τ, ranging from 25° to 40°. Including acceleration skewness in the orbital velocity signal may improve predictions in the inner (or saturated) surf zone as acceleration skewness tends to be dominant compared to the velocities skewness in this region. This will not only influence the bed-load transports, but may also affect the wave-related suspended transport.

The applied bed slope effects show the expected trends, but the differences between the considered transverse bed slope correction factors is relatively large and results in distinctly different equilibrium bathymetries for the considered case. In combination

with recently acquired data on 250 and 960 μm sand, Talmon and Wiesemann (2006) focused on the mechanical balance of moving bed-load particles. In that approach the shear stress-to-the-grains θ' is the governing variable, instead of θ. Further research will include this new data and the suggested alternative approach. The inclusion of the initiation of motion in both the bed-load and suspended load transport seems conceptually correct, but requires further research. This is emphasized in view of its importance in the predicted equilibrium bathymetries.

Abstract: The highly active Atlantic Ocean hurricane seasons of 2004 and 2005 produced unique morphological changes outside of the surf zone. This paper focuses on two northeast Florida areas — St. Johns County and Volusia County. These morphological changes, as determined by bathymetric surveys, revealed net sediment accretion in greater than 30-foot water depths after the 2004 storms just offshore of the St. Johns County Shore Protection Project and net sediment erosion on sand shoals located in 60-foot water depths, about seven miles offshore of Volusia County after the 2005 storms. Analyses of beach profiles and borrow area survey data revealed significant sediment transport at large depths, greater than those associated with typical wave conditions. Application of depth of closure and near bottom velocity methods showed wave conditions in 2004 and 2005 capable of sediment transport at these large depths.

INTRODUCTION

Many beach fill projects exist around the state of Florida. Project permit requirements include nearshore beach profile monitoring to assess project performance. Issuance of permits require offshore borrow surveys to quantify the availability of beach compatible sand for proposed beach nourishment projects. The highly active Atlantic Ocean hurricane seasons of 2004 and 2005 produced unique morphological changes outside of the surf zone. The availability of the above types of surveys provides an opportunity to assess sediment transport as a result of the active storm seasons. This paper focuses on

two northeast Florida areas — St. Johns County and Volusia County.

ST. JOHNS COUNTY ANALYSIS

Background

St. Johns County lies in northeast Florida about 35 miles south of the Florida/Georgia border. The initial nourishment (referred to as the 2003 project) of the St. Johns County Shore Protection Project (SPP), completed in January 2003, extended approximately 2.9 miles (mi) from approximately 600 feet (ft) north of Florida Department of Environmental Protection (FDEP) monument R-137A (approximately 2.7 mi south of St. Augustine Inlet in Anastasia State Park) south to approximately 600 ft south of FDEP monument R-151 in the City of St. Augustine Beach in St. Johns County, Florida. The State of Florida, piggybacking the federal nourishment project, extended the beach nourishment project approximately 0.9 mi north into Anastasia State Park to FDEP monument T-132. The first renourishment (referred to as the 2005 project) also extended approximately 2.9 mi from monument R-137A to R-151. The 2004 hurricane season forced an expedited schedule of the renourishment project — backed with emergency remediation money appropriated from the U.S. Congress.

Tropical storm Bonnie, a strong northeast storm, and four hurricanes (Charley, Frances, Ivan, and Jeanne) affected the State of Florida during the six-week period from August 12 through September 26, 2004. Each of these significant storms adversely affected the SPP. The occurrence of storms in rapid succession caused erosion and damages beyond those expected from an isolated, individual storm because recovery of nearshore material lost from previous storms did not occur before subsequent storms.

2004 Hurricane Season

Figure 1 contains wave and wind data generated by the National Oceanic and Atmospheric Administration's (NOAA) GFDL and WAVEWATCH III models for location 29.75°N, 81.0°W, offshore of the SPP (USACE, 2005). Wind speeds correspond to outlying winds a few miles from the hurricane's center. National Weather Service estimates of "sustained winds" or "maximum sustained winds" — which refer to eyewall wind speeds recorded by aircraft reconnaissance — will exceed the wind speed values in Figure 1. The following paragraphs provide details for each of the major storms that affected St. Johns County in 2004 — information compiled from FDEP (2004a, b, c) and USACE (2005).

Tropical Storm Bonnie: Tropical Storm Bonnie made landfall near Apalachicola in western Florida at 1200 Eastern Daylight Time (EDT) on August 12th with sustained winds near 50 miles per hour (mph). The storm moved northeast across Florida and caused slightly increased wave heights and wind speeds in the SPP.

Hurricane Charley: Hurricane Charley made landfall at 1700 EDT on August 13th on the southwest coast of Florida just north of Captiva Island in Lee County. A Category 4 hurricane at landfall, Charley contained maximum sustained winds estimated at 145 mph with a storm surge estimated at over 10 ft (FDEP, 2004a). Hurricane Charley featured a

tight radius which allowed the storm to maintain hurricane force winds along a north-northeast trajectory across central Florida (USACE, 2005). Still of hurricane intensity, Hurricane Charley exited the east coast of Florida near Daytona Beach in Volusia County at 0200 EDT on August 14th with maximum sustained winds near 85 mph and higher gusts. Hurricane force winds extended outward up to 25 mi from Charley's center and tropical storm force winds extended outward up to 85 mi. As Hurricane Charley exited the state on August 14th, approximately 50 mi south of the project site. Offshore waves peaked at seven feet with winds reaching 28 knots.

Hurricane Frances: At 0100 EDT on September 5th Hurricane Frances made landfall in northern Martin County on Florida's east coast. A Category 2 storm at landfall, Hurricane Frances had maximum sustained winds near 105 mph and higher gusts. Hurricane force winds extended outward up to 85 mi from the storms' center and tropical storm force winds extended outward up to 200 mi. High waves also affected much of Florida's east coast for a relatively long duration — affecting much of central and south Florida for up to 30 hours — because of the storm's slow pace. As Hurricane Frances made landfall on September 5th, the NOAA Crescent Beach, FL water level station (29°46.1' N, 81°15.5' W) recorded a level of 4.5 ft-National Geodetic Vertical Datum (NGVD), which approaches the 10-year storm water level (combination of astronomical tide and storm surge) return period of 4.8 ft for the St. Johns County project area (USACE, 1990; as referenced in USACE, 2005). Offshore wave heights, peaking at 19.7 ft, approached 15 ft for 33 hours. This peak height falls between the 2-year return period wave height of 18.8 ft and the 5-year height of 21.5 ft (Brooks and Brandon, 1995; as referenced in USACE, 2005). Average wind speeds (peaking at 44 knots) during this time exceeded 25 knots for 54 hours. Hurricane Frances became a tropical storm as the storm continued west-northwest across the Florida peninsula.

Hurricane Ivan: Near 0300 EDT on September 16th Hurricane Ivan made landfall as a Category 3 hurricane in Baldwin County, AL (just west of the Florida Panhandle region). Maximum sustained winds equaled 130 mph and NOAA recorded storm surge elevations of five feet. Wave heights reached 53 ft as recorded by NOAA buoy 42040 (located 62 nautical miles south of Dauphin Island, AL, in 780 ft of water). Hurricane Ivan maintained southerly wave heights near five feet in St John's County.

Unnamed Nor'easter: One week before Hurricane Jeanne's landfall, a strong nor'easter affected Florida's east coast with waves in excess of 10 ft in St. Johns County. During this storm, wave heights remained above eight feet (peaking at 12.4 ft) for nearly three days. Wind speeds reached 25 knots and exceeded 20 knots for nearly 39 hours. Combined tide and storm surge arriving just ahead of the nor'easter reached 4.6 ft-NGVD — approaching a 10-year storm surge event. The extended duration — nearly four days — of high wave and water level conditions caused significant erosion to the SPP.

Hurricane Jeanne: Hurricane Jeanne made landfall at 0000 EDT on September 26th as a Category 3 storm on Florida's east coast in northern Martin County. Maximum sustained

winds equaled 120 mph with storm surge estimates near levels experienced during Hurricane Frances (8-10 ft). The landfall location, near Stuart, nearly matched the landfall location of Hurricane Frances only 20 days earlier. The National Hurricane Center reported that the landfall points came an unprecedented 2 mi apart. Tropical storm force winds extended outward up to 175 mi from the storm's center. Offshore wave heights peaked at 17 ft (and remained above 15 ft for 21 hours) as Hurricane Jeanne augmented waves created by the nor'easter. Offshore wind speeds during this time reached 35 knots and exceeded 28 knots for 39 hours. A Crescent Beach water level station near the SPP measured a maximum water level of 4.9 ft-NGVD; this water level corresponds to a 10-year storm surge event.

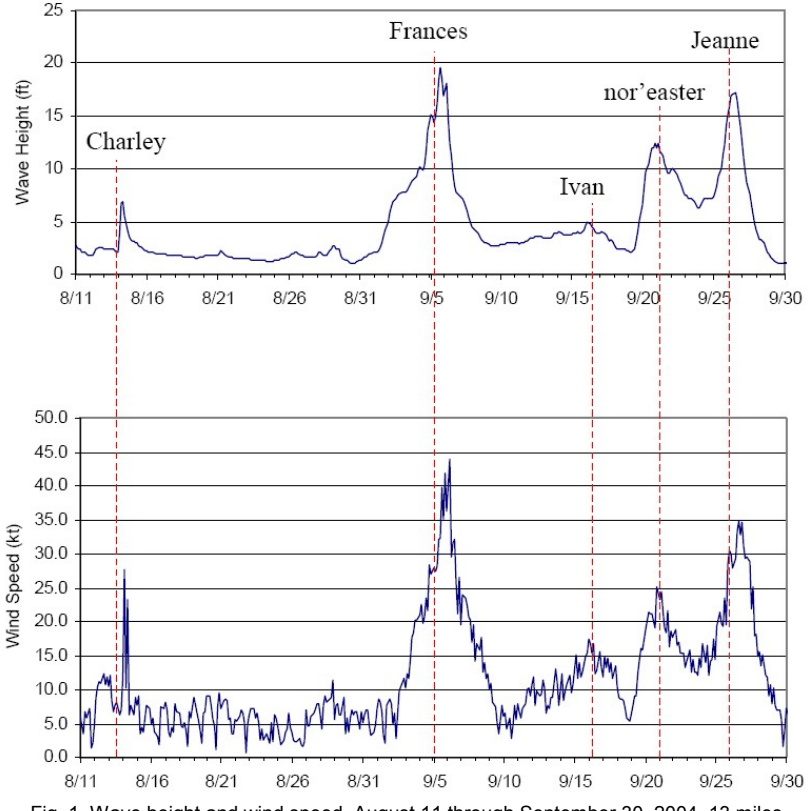

Fig. 1. Wave height and wind speed, August 11 through September 30, 2004, 13 miles offshore of Crescent Beach, St. Johns County, FL; 29.75° N, 81.0° W (USACE, 2005)

Nearshore Data Analysis

Regular monitoring of beach profile surveys in the St. Johns County SPP tracked the beach response to, and recovery after, the 2004 hurricane season. Analysis of the survey

data allows insights into the project performance and sediment dynamics offshore of the surf zone related to the major storms of 2004. This section describes major features of the survey data from pre-hurricanes 2004 to spring 2006. An analysis of wave data from 2002 to 2005 allows estimation of the depth of closure variability offshore of the SPP. Notably, bathymetric changes offshore of the survey extents hamper the analysis of the sediment transport pathways.

A comparison of 2004 pre-hurricanes to 2004 post-hurricanes survey data indicates the impact of the 2004 hurricane season on the SPP. This analysis represents conditions from 36 days before Hurricane Francis to 36 days following Hurricane Jeanne. The intensive forces of the hurricanes affected the beaches tremendously. All profiles in the SPP show erosion above -10 ft and accretion below -10 ft. Unless otherwise stated, all elevations in this section refer to the North American Vertical Datum (NAVD) vertical reference. The beach profile evolution at R-148 demonstrates the dramatic offshore accretion with a large shoal forming below -15 ft (Figure 2). However, longshore sediment transport also contributed to the erosion during the hurricanes. Across the nearshore profile, the fill placement eroded while both North and South control areas accreted — evidence of lateral transport.

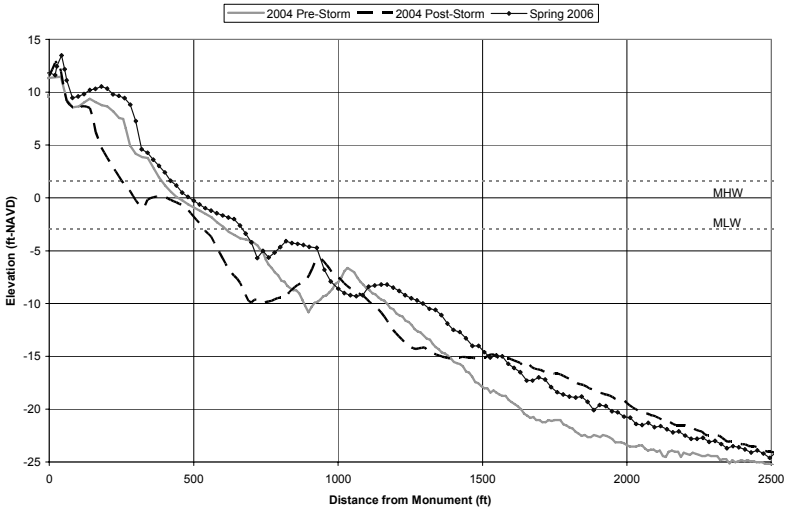

Fig. 2. Survey data for FDEP Monument R-148 in St. Johns County for 2004 pre- and post-hurricane and spring 2006 conditions

The 2004 post-hurricanes to 2005 pre-fill comparison provides an example of the beaches' natural recovery from episodic hurricane events. This analysis represents conditions 190 days following the 2004 post-hurricanes survey. Notably, several winter

storms in late 2004 and early 2005 affected the SPP. In the SPP, erosion continues both above and below MHW following the 2004 hurricane season and winter 2004/05 storms.

To replace sediment lost from recent storms, a beach nourishment project completed in the fall of 2005 placed approximately 2.8 million cy of material in the St. Johns County SPP area (Taylor Engineering, 2006). Comparison of 2005 post-fill to Spring 2006 surveys offers insight on the effect of six months of regular beach processes on beach volumes. This analysis indicates the manner in which beach fill redistributes naturally over time. The SPP eroded above MHW and accreted below MHW, resulting in a net beach volume gain. Erosion onshore and accretion offshore represent normal behavior subsequent to a nourishment project as beach fill diffuses offshore. The few profiles showing net erosion from dune to -20 ft occur at R-142 (St. Augustine Pier) and R-140 to R-141 (just north of the pier) and R-143T to R-143A (just south of the pier). Previous studies have demonstrated increased erosion near R-142, a known erosional hotspot.

Table 1 presents volume changes in the SPP across four nearshore compartments — dune to MHW, MHW to -10 ft, -10 ft to -20 ft, and -20 ft to -30 ft. The table indicates large volume changes below -10 ft, especially below -20 ft. Notably, many surveys did not extend to -30 ft and in these cases the profile analysis terminated at the end of the shortest survey or 3,000 ft from the control monument. The 2004 pre- to post-hurricanes comparison indicates over 1.3 million cy of accretion in the project area between -20 ft and -30 ft. The volume losses above -10 ft do not offset this volume gain. Assuming that longshore processes do not contribute the majority of the excess material requires movement of material from offshore to produce the large accretion below -20 ft. The 2004 post-hurricanes to 2005 pre-project and 2005 pre- to post-project time intervals in Table 1 suggest erosion below -20 ft. The 2005 post-project to spring 2006 analysis indicates accretion between -20 ft and -30 ft.

Table 1. Nearshore Volume Changes between Recent Surveys in the St. Johns County SPP

	2004 Pre-Hurricanes to 2004 Post-Hurricanes	2004 Post-Hurricanes to 2005 Pre-Project	2005 Pre-Project to 2005 Post-Project	2005 Post-Project to Spring 2006
	Volume Change (cy)			
Dune to MHW	-483,900	-72,500	956,000	-31,400
MHW to -10 ft-NAVD	-571,400	-167,400	1,399,700	12,500
-10 ft to -20 ft-NAVD	697,100	-277,500	474,800	244,500
-20 ft to -30 ft-NAVD	1,343,400	-381,500	-355,500	338,300
Dune to -30 ft-NAVD	985,200	-898,900	2,475,000	563,900
Most surveys do not reach -30 ft-NAVD				

The depth of closure represents the theoretical offshore depth beyond which sediment transport does not occur. Under normal conditions, the depth of closure provides a convenient offshore extent for the volume calculations with all volume change landward of that point. Profiles that do not converge in the offshore region cause difficulty for volume change calculations as erosion or accretion extends offshore of the available data. Analysis of wave data offshore of the St. Johns County SPP allows insight into wave-

induced sediment motion outside of the surf zone. The National Data Buoy Center (NDBC) buoy 41012 (30.0 N 80.6 W) contains wave and meteorological information offshore of the SPP from 2002 to 2005.

The Hallermeier (1978, 1981) and Birkemeier (1985) methods allow estimation of the depth of closure (h_c) offshore of the St. Johns County SPP. Hallermeier defined conditions for sediment motion for relatively rare conditions — effective wave height (H_e) and period (T_e) conditions exceeded only 12 hours per year.

$$h_c = 2.28H_e - 68.5\left(\frac{H_e^2}{gT_e^2}\right) \quad (1)$$

Birkemeier (1985) applied high-quality field measurements from the USACE Field Research Facility at Duck, NC to evaluate Hallermeier's relationship. Birkemeier developed a simplified expression for h_c based on the effective wave height.

$$h_c = 1.57H_e \quad (2)$$

Kraus et al. (1998) contains examples and a reference that demonstrate the Hallermeier formulation produce more conservative estimates of h_c than the Birkemeier formulation.

Application of linear wave theory shoaled the NDBC data (2002 to 2005) from the buoy location (~160 ft depth) to a depth of 35 ft. Sorting of the wave data and application of the Hallermeier and Birkemeier methods calculated the depth of closure for each year from 2002 to 2005. Table 2 presents the results of the depth of closure analysis. In all instances (and by an average of almost six feet), the Hallermeier method produces larger h_c values than the Birkemeier method.

Table 2 indicates that the depth of closure varies significantly from year to year with a depth of closure in 2004 that approaches 38 ft with the method of Hallermeier. The 2004 depth of closure nearly doubles the 2002 estimate. Closer analysis of the 2004 wave data revealed, as expected, Hurricanes Frances and Jeanne produced the wave events responsible for the large depth of closure in 2004.

Table 2. Depth of Closure Estimates for St. Johns County SPP with Hallermeier and Birkemeier Methods and NDBC Data

	Depth of Closure--h_c (ft-MLW)	
	Wave Height Transformed to 35 ft depth	
	Hallermeier CEM (III-3-9)	Birkemeier CEM (III-3-12)
2002	17.3	13.8
2003	28.1	20.7
2004	34.9	28.0
2005	27.9	22.1

The values in Table 2 confirm the 2004 hurricane season contained wave events capable of moving sediment at depths greater than typical closure values. Lack of survey data

offshore of -30 ft removes the possibility to evaluate bathymetric changes near the estimated depth of closure. This situation demonstrates that — to capture sediment transport limits in extreme events — survey operations need to extend seaward of typical transport limits.

VOLUSIA COUNTY ANALYSIS

Background

Volusia County lies in northeast Florida about 95 miles from the Florida/Georgia border. As part of an ongoing beach and dune restoration permitting, engineering, and design project for approximately 5.5 mi of beach, Volusia County identified many candidate sand shoals about 5 to 15 mi offshore during a reconnaissance-level study, which consisted of a literature review and bathymetric survey (collected in November 2004). Further refinement of the borrow areas needed for the proposed beach and dune restoration project focused on two sand shoals (B11-3 and B12-1) about 5 to 7 mi offshore in about 60-ft water depths. Note that borrow area B12-1 lies just seaward of borrow area B11-3. Boundaries for the proposed B11-3 borrow area run about 3,000 ft and 6,000 ft in the shore-normal and shore-parallel directions (413 acres). Boundaries for the proposed B12-1 borrow area run about 4,000 ft and 6,000 ft in the shore-normal and shore-parallel directions (551 acres). The long axes of both borrow areas primarily orient along the north-south axis with the greatest shoal relief features primarily orienting along the northeast-southwest axis (Figure 3). Based on the plans & specs-level sand search investigation, Coastal Technology Corporation (2006) analyzed the borrow areas' sediment size characteristics of several vibracores with the B11-3 and B12-1. Mean grain size diameters ranged from 0.21 to 0.22 mm. The median grain sizes equal 0.19 and 0.20 mm for B11-3 and B12-1.

Another bathymetric survey (collected in December 2005), performed as part of the refined work, revealed altered shoal bathymetries (Figure 4). Negative (red) contours indicate areas of erosion and positive (green) contours indicate areas of accretion. Local relief changes showed erosive and accretive patterns on the order of five feet. Over the entire survey extents, the shoal gained 468,000 cy near borrow B11-3. Near borrow area B12-1, the shoal lost 952,000 cy over the entire survey extents. Because of the relative proximity of borrow areas, some of the sand may have moved eroded from near borrow area B12-1 and deposited near borrow area B11-3. The passage of five tropical events (Katrina, Rita, Ophelia, Tammy, and Wilma) and several nor'easters between the two surveys may have affected shoal relief.

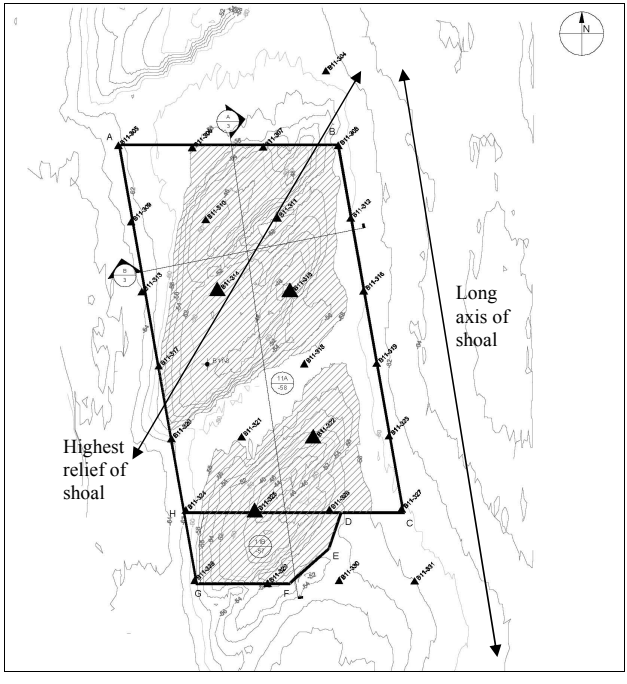

Fig. 3. December 2005 conditions at borrow area B11-3

2005 Storm Season

Several nor'easters and tropical events occurred near Volusia County in 2005. Nor'easters generally form quickly and last about two to three days but may last longer (7 to 10 days). During these storms, northeasterly winds blowing across the Atlantic Ocean over a large fetch (hundreds of miles) produce wind setup and large waves that affect the area. Severe storms occurred in 1925, 1932, 1947, 1956, 1958, 1960, 1962, 1964 – 1966, 1969, 1972 – 1975, 1981, 1984, 1986, 1987, 1989, and 1992 – 1995 (USACE, 1991; USACE, 1982; Taylor and Yáñez, 1994). Taylor Engineering (2003) reports from 1956 – 1975 and 1981 – 1995, the area averaged about 5 – 6 storms per year. From 1976 – 1980, an especially stormy period, the study area averaged 12 storms per year.

Annual frequencies of events reaching tropical storm or hurricane strength vary widely from year to year. The main tropical hurricane season runs from June through November with significant hurricane activity occurring between August and October. NOAA provides historical hurricane data via the Internet. Presented on annual maps, the data include hurricane track, maximum winds, and central pressure. Taylor Engineering (2003) supplemented this information with data from a hurricane database (Pesek, 1991), which includes hurricane forward velocity. On average, tropical storms or hurricanes pass near the area about once every three years.

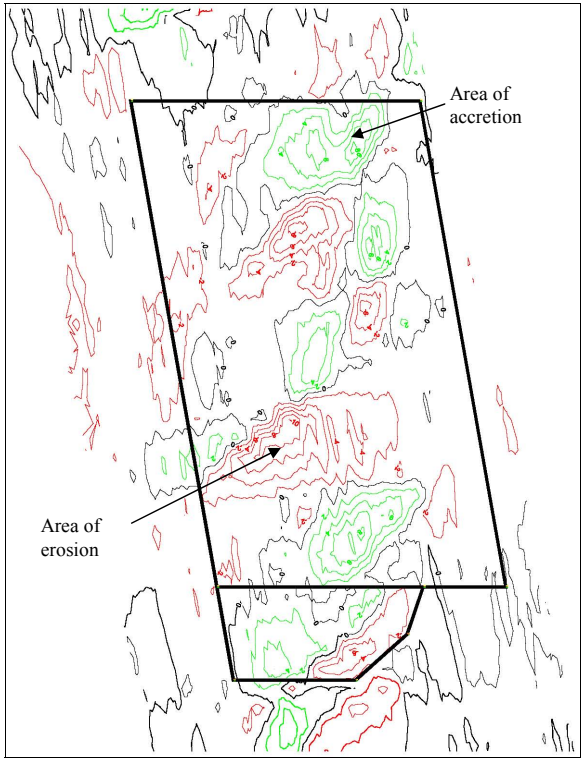

Fig. 4. Comparison of borrow area B11-3 survey data for November 2004 and December 2005 conditions

The NDBC buoy 41009 (28.50 N 80.17 W), about 20 nautical miles east of Cape Canaveral, Florida, contains wave and meteorological information during 2005. Application of linear wave theory shoaled the NDBC data from the buoy location (~136 ft depth) to a depth of 60 ft. Following methodologies presented in Goda (1988, 2000), a peak-over-threshold extreme wave analysis identified storms and their associated largest waves and return periods. In addition to the five tropical events, this analysis revealed nine nor'easter storms. The number of nor'easters and hurricanes exceeded the historical averages.

Six nor'easters occurred in January and February 2005. The maximum wave heights and associated wave periods ranged from about 9 to 14 ft and 6.3 to 13.8 seconds (sec); the storm durations, ranged from two to eight days. Another nor'easter occurred in April and lasted about five days. The maximum wave height and associated wave period equaled about 15 ft and 12.9 sec. Two more nor'easters occurred in November and early

December. These storms produced maximum wave heights of 10 and 15 ft and associated wave periods of 10 and 8.3 sec. The November storm lasted 10 days and the December storm lasted four days.

Five tropical events also passed near the area. These events included Hurricane Katrina (August 25, 2005; Category 1), Ophelia (September 6 to 9, 2005; Tropical Storm, Category 1), Tropical Storm Tammy (October 5 to 6, 2005), and Hurricane Wilma (October 24, 2005; Category 3). The maximum wave heights and associated wave periods ranged from 9 to 19 ft and 6.7 to 10 sec. Storm durations varied from 2 to 11 days. Note Hurricane Wilma produced the largest wave condition but had the shortest duration of the five tropical events. Ophelia had the longest duration. Wind speeds for the tropical events ranged from 25 (Ophelia) to 110 knots (Wilma) at the NDBC buoy.

Offshore Data Analysis

Employing the Willis-Ackers-White method, based on the Ackers and White (1973) method for unidirectional flow and modified by Willis (1979) for waves, can quantify the potential for sediment transport outside of the surf zone. Ackers and White developed their method to calculate total sediment load, including both bed and suspended loads, in unidirectional flow over an alluvial bed. This technique, based on a transport power approach whereby the work exerted to move sediment equals the product of the power available to move sediment and the efficiency of the system, includes a criterion for the inception of sediment motion. Willis defines the threshold of movement criterion due to waves only as

$$F_{grc}^2 = \frac{\left(\frac{0.23}{\sqrt{D_{gr}}} + 0.14\right)^2}{0.04141 D_{gr} + 0.20354} \tag{3}$$

where F_{grc} = the critical mobility number and D_{gr} = the dimensionless grain diameter defined as

$$D_{gr} = \left(\frac{\gamma_s}{\gamma}\frac{gD^3}{\nu}\right)^{\frac{1}{3}} \tag{4}$$

where γ= the specific weight of seawater, γ_s = the specific weight of the sediment, γ= the specific weight of seawater, g = the acceleration due to gravity, D = the sand grain diameter, ν = the kinematic viscosity of water (1.4×10^{-5} square feet per second). Given the wave conditions and sediment characteristics, one calculates D_{gr} from Eq. 4, estimates the bottom shear stress from empirical friction coefficient data from Jonsson (1966; as cited in Willis, 1979) and determines the Ackers and White mobility number, defined as

$$F_{gr}^2 = \left(\frac{u_{*fg}^n u_{*cg}^{1-n}}{\sqrt{gD\left(\frac{\gamma_s}{\gamma} - 1\right)}} \right) \quad (5)$$

where F_{gr} = the Ackers and White mobility number, u_{*fg} and u_{*cg} = shear velocities for material moved as suspended and bed load, and n = an empirical coefficient. If the mobility number at a particular location and depth falls above the critical value, then sediment transport at that depth may occur.

The method defines sediment load as

$$X = C\left(\frac{F_{gr}}{F_{grc}} - 1\right)^m \frac{\rho_s}{\rho}\frac{D}{d}\left(\frac{\rho^{\frac{1}{2}} P_{fg}}{\tau_{fg}^{\frac{3}{2}}}\right)^n \left(\frac{P_{cg}}{\tau_{cg} V}\right)^{1-n} \quad (6)$$

where X = the sediment load, ρ = the seawater density (64 pound per cubic foot), d = the water depth, P = the power per unit area available to move sediment, τ = bottom shear stress, and V = mass transport velocity due to waves (from linear wave theory). The subscripts, *fg* and *cg*, denote fine grains and coarse grains. Multiplying Eq. 6 by the appropriate values yields the sediment transport at a point in units of cy/s/ft.

Analysis of offshore wave data near the borrow areas allows insight into wave-induced sediment motion outside of the surf zone. Based on application of the Willis-Ackers-White method, Ophelia and Tammy generated the most transport (Table 3). Calculated transport rates also revealed that two nor'easters (January No.1 and November) may have contributed to observed bathymetric changes. Relative to Ophelia, Tammy and the two nor'easters generated 5, 16, and 54% less transport.

For comparison purposes, Table 3 also shows the relative rank of the maximum wave heights and storm durations to assess if any trends exist between these characteristics and sediment transport. Although weak, sediment transport and duration ranks showed better correlation than did sediment transport and maximum storm wave heights. This means that storms with longer durations may lead to more sediment transport.

The December 2005 borrow area survey indicates significant sediment movement in the Volusia County project borrow areas compared to November 2004 conditions. The bathymetric changes observed suggest completion of a pre-project survey to obtain existing sediment quantities and locations in the borrow areas.

Table 3. Sediment Transport Estimates Derived from Willis-Ackers-White Method and NDBC Data

Number	Name	WAW transport (cy/s/ft)	Max H (ft)	Rank Transport	% Difference from Rank 1 Transport	Rank Max H	Rank Duration
1	Jan No.1	3.57E-03	13.7	4	-54%	6	4
2	Jan No.2	1.05E-03	9.5	14	-426%	11	9
3	Jan No.3	1.19E-03	10.6	10	-363%	9	9
4	Feb No.1	2.88E-03	13.8	6	-91%	5	3
5	Feb No.2	1.17E-03	8.8	12	-373%	13	14
6	Feb No.3	1.07E-03	8.9	13	-413%	12	11
7	Apr	2.60E-03	14.9	8	-112%	3	6

11	Tammy	5.27E-03	15.2	2	-5%	2	5
12	Wilma	2.63E-03	18.8	7	-110%	1	13
13	Nov	4.74E-03	9.8	3	-16%	10	2
14	Dec	2.89E-03	14.9	5	-91%	3	8

CONCLUSION

The highly active Atlantic Ocean hurricane seasons of 2004 and 2005 produced unique morphological changes outside of the surf zone. Bathymetric surveys revealed net sediment accretion in greater than 30-ft water depths after the 2004 storms just offshore of the St. Johns County Shore Protection Project and net sediment erosion on sand shoals located in 60-ft water depths, about five to seven miles offshore of Volusia County after the 2005 storms. Analyses of beach profiles and borrow area survey data revealed significant sediment transport at large depths, greater than those associated with typical wave conditions. Application of depth of closure and near bottom velocity methods showed wave conditions in 2004 and 2005 capable of sediment transport at these large depths.

GEOMORPHIC AND SEDIMENTOLOGIC EVIDENCE FOR NET LITTORAL DRIFT – A REVIEW

Terry Healy
Coastal Marine Group, Dept of Earth and Ocean Sciences,
University of Waikato, New Zealand
trh@waikato.ac.nz

Abstract: Some 24 different indicators of the net littoral or alongshore drift are identified. Most of these relate to the geomorphic and sedimentologic properties of the littoral system, but also include deductions from wind data and wave properties. Not all indicators can be accorded equal confidence as definitive indicators.

INTRODUCTION

For many of the worlds' coastlines the net direction of wave generated alongshore sediment transport, the "littoral drift", is well known, but along some coastal sectors the evidence is not always so clear, for example, in cases of large coastal compartments. Komar (1998) illustrates 6 schematic cases representing the net direction of the littoral drift (Figure 1). Basically 5 of these are variations of sediment impoundment by structures such as groynes, jetties, or breakwaters, and natural structures such as headlands, and the other is long term migration of large tidal inlets or river mouths. However, there are numerous additional geomorphic and sedimentologic indicators of the direction of the net littoral drift. In this paper some 24 separate littoral drift direction indicators are recognised, not all of which can be regarded with the same confidence as definitive indicators.

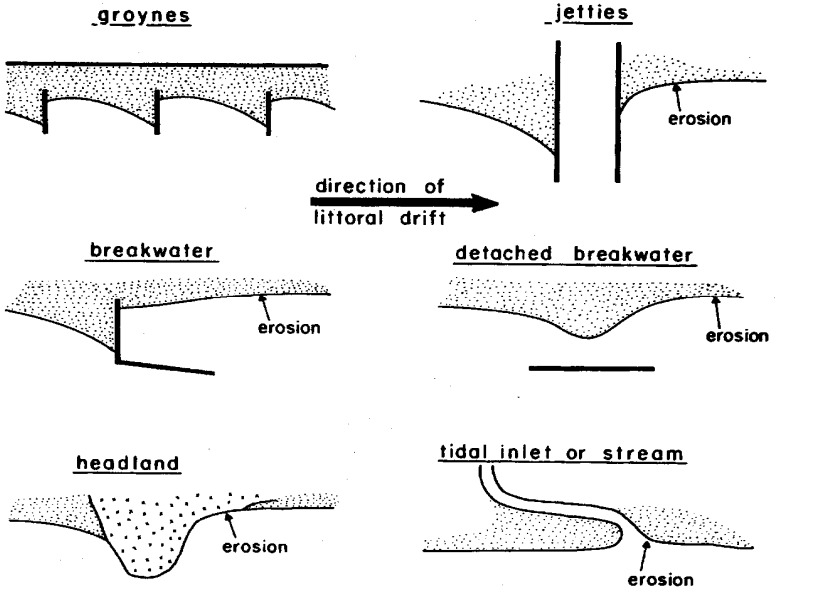

Figure 1. Geomorphic indicators of net littoral drift (From P.D. Komar (1998): *Beach Processes and Sedimentation 2nd Edition)* With permission.

SOME FUNDAMENTAL DEFINITIONS

Waves and currents in the nearshore wave shoaling zone interact to produce transport of sediment on the sea floor which may be onshore–offshore (diabathic) transfer or alongshore (parabathic). "*Littoral or longshore drift*" is the term given to the alongshore transport of material from the nearshore sea floor under the combined action of waves and currents (Muir-Wood 1969; Kidson 1982).

It is axiomatic that alongshore transport or littoral drift on a sandy coastline is primarily wave driven. Waves approaching from one direction, imperfectly refracting and breaking at an angle to the shoreline, will drive sediment in the breaking wave zone alongshore, but at other times waves breaking from the opposing direction will drive sediment in the opposite direction. There is thus a large difference between the ***total*** littoral drift up and down the beach (the sum total of wave generated drift from all of the directions of wave approach up and down the beach on an annual basis) and the ***net*** littoral drift (the difference between the total drift toward one direction along the beach compared to the total drift in the opposing direction).

The net longshore transport rate "*refers to the summation of the amounts of sediment passing a given point during a certain amount of time, usually a year, with a positive quantity applied to transport in one direction, and a negative quantity in the opposite direction. Zero net transport refers to an equilibrium position of a beach where the*

amount of material eroded is balanced by the amount supplied" (Herbich and Handy 1982).

The littoral drift along sandy beaches is considered as comprising two parts, namely, transport in the breaking wave (surf) zone, and transport in the swash zone along the beach face (Komar 1976). Most sediment transport occurs in the surf zone where "*due to the turbulence of the breaking and surging waves, large volumes of sediment are placed in suspension or rolled along the bed in the surf zone*" (Silvester 1974).

LITTORAL CURRENTS AND SEDIMENT TRANSPORT

The fundamental reason that particles comprising the beach sediments move alongshore relates to the physical forcing processes, which when of sufficient magnitude, generate bottom shear stresses that move the individual sediment particles. Mechanisms for generating the shear stresses include the orbital motion beneath the passage of a wave, or from turbulence in the broken wave bore. These processes induce uplift so that the sediment particles are moved along the bottom or become suspended into the water body, at which point they may be transported by any superimposed current.

At least four types of littoral zone current are important for driving sediment transport on beaches, *viz*.: (i) longshore currents, (ii) wave bore currents, (iii) rip currents, and (iv) undertow, downwelling and upwelling currents. In addition, tidal currents interacting with waves may be important in restricted locations such as tidal inlets.

Longshore Currents

These are the most important for driving the alongshore sediment transport or littoral drift that may involve hundreds of kilometers of sediment displacement along the coast. Basically longshore currents are generated when breaking waves are not fully refracted and break at an angle to the alignment of the beach face When there is perfect refraction the wave breaks simultaneously at all points along the beach; and there is no longshore current generated. It is now generally accepted that the generation of longshore currents results from forces associated with the breaking wave on a sloping beach, and in particular the radiation stress, a momentum flux associated with the breaking waves. The radiation stress has two components, onshore (S_{xx}) and alongshore (S_{yy}). When waves approach the coast at an angle with respect to the shoreline, the combined radiation stress is given by:

$$S_{xy} = En \sin\alpha \cos\alpha \qquad (1)$$

where E is the wave energy density {= ⅛ρgH^2 where H is the wave height, ρ is the sea water density}, n is the ratio of the wave group and phase velocities (1 in the surf zone), and α is the angle between the breaking wave crests and the shoreline alignment. As explained by Komar (1998), when the waves approach the shoreline obliquely, S_{xy} is the longshore directed (y component) of the radiation stress that is moving towards the shoreline (in the x direction directly onshore). The 'thrust" that actually drives the longshore current is derived from the dissipation of S_{xy} in the

nearshore surf zone, being a maximum at the breaker zone and decreasing to 0 at the shoreline. Komar (1998) notes that the longshore current is proportional to the parameter $u_m \sin\alpha_b \cos\alpha_b$ (where u_m is the maximum bottom orbital velocity, and α_b is the angle of the wave front with the shoreline at the point of breaking). Komar and Inman (1970) obtained a relationship for the longshore current, V_ℓ, measured at the mid-surf position half way between the breaker zone and the shoreline – the zone of maximum current across the width of the surf zone:

$$V_\ell = 2.7\, u_m \sin\alpha_b \cos\alpha_b \qquad (2)$$

where α_b. is the angle of the breaking wave relative to the beach alignment. When dealing with wave spectra, the relationship of the longshore current to the significant height at breaking, $H_{bs,}$ is given approximately (Komar 1998) as

$$V_\ell = 1.0 \sqrt{gH_{bs}} \quad \sin\alpha_b \cos\alpha_b \qquad (3)$$

From the above it is evident that the prime driver of the longshore current is the breaking wave, and that other factors, such as beach slope, appear to have little influence on the strength of the longshore current.

Wave Bore Currents.

Upon breaking, the oscillatory property of the wave is largely lost and the energy transformed into a wave of mass translation, known as a bore. A wave bore presents as an abrupt change in water height with the front of the advancing bore a mass of white water foaming fluid turbulence as it propagates across the surf zone at about half the speed of the swell wave prior to breaking, and finally runs up the beach face as swash. As the spent wave recedes and runs down the beach face as backwash, it recreates a reduced wave form moving back to the surf zone, inducing a vortex at the base of the beach face where the backwash meets the incoming bore. This vortex can be important in localized erosion of the sediment bed at the base of the beach face.

Rip Currents

When the shoaling waves break with their crests effectively parallel to the shoreline, the currents generated take the form of a cell circulation, the most obvious part of which is the rip current. These strong, spatially restricted, currents flow seaward to beyond the surf zone. Rip currents occur where there are systematic longshore variations in the height of the breaking waves: larger waves have associated larger wave set-up from radiation stress (an excess flow of momentum) in the onshore direction which is converted to localised generation of longshore currents, which in turn feed the rip currents. In simple terms the longshore currents flow “downhill” from alternating areas of greater wave heights and set up to areas of lower waves and set-up where the converging longshore currents turn seaward as rip currents (Komar 1998; Aagaard and Masselink, 1999). Such conditions tend to be more frequently associated with a steeper or “reflective” morphodynamic beach face.

Downwelling (undertow) and Upwelling Currents.

The mass of water carried shoreward by breaking waves and wave bores may be compensated for by a seaward return flow known sometimes as “undertow”. Komar (1998) notes that laboratory and field measurements tend to confirm theoretical

analyses of a net landward flow of water in the wave crests with a compensating return flow beneath the wave troughs. Typically superimposed on this theoretical mechanism is the effect of wind stress on the water surface. Onshore winds significantly enhance the shoreward flow of water as wind stress set-up, and therefore enhance the seaward bottom return flow (down-welling). Conversely offshore winds carry surface water offshore and induce set-down in the surf zone, for which there is a compensatory shoreward bottom return flow (up-welling). Both mechanisms are important for the understanding of both diabathic and parabathic sediment transport as part of the littoral drift system.

Tidal Currents.
Tidal currents normally play no essential role in transporting littoral sediment transport on the open coast long beaches. However they are important at tidal inlets and harbour entrances, (and arguably major large scale topographic constrictions such as the English Channel and large re-entrant embayments such as Hangzhou Bay in China). Here they may sequester sediment transported in the wave generated nearshore littoral drift and transport the sediment into the tidal inlet. Typically the tidal currents accelerate as they converge toward the tidal inlet on the flooding tide and decelerate upon the passing through the inlet. The acceleration generates intense turbulence and large scale bedforms toward the inlet gorge. The converse is true for the ebbing tidal condition.

SEDIMENT TRANSPORT IN THE LITTORAL ZONE

As is evident from the discussion above, the prime driver of the littoral drift along sandy shorelines is the wave generated longshore currents due to obliquely breaking waves. The major driver of the sediment transport is the directed wave power (i.e. wave energy x time in a given direction). The alongshore component of wave power, or wave energy flux in the longshore direction, P_ℓ , is given by:

$$P_\ell = (ECn)_b \sin\alpha_b \cos\alpha_b \quad (4)$$

where $(ECn)_b$ is the wave energy flux at the breaker zone, and α_b is the wave breaker angle. Here $(Ecn)_b$ is the wave power or wave energy flux per wave crest length, and is converted to a unit shoreline quantity by inclusion of the $\cos\alpha_b$, while the longshore component assumed to be available for transporting sediment in the longshore direction derives from $\sin\alpha_b$.

The sand transport rate may be expressed either as a volume transport rate, Q_ℓ, or more usually as an immersed weight transport rate, I_ℓ, given by:

$$I_\ell = (\rho_s - \rho) g\, a\, Q_\ell \quad (5)$$

where ρ_s is the sediment and ρ the water density, and a is a pore space factor (normally taken as 0.6), such that $a\, Q_\ell$ represents the volume of solid sand. The use of I_ℓ is based upon the Bagnold (1963) sediment transport model, and it possesses the same units as P_ℓ so that the relationship becomes:

$$I_\ell = K\, P_\ell \quad (6)$$

where K is a dimensionless proportionality coefficient. Based upon plotting of considerable field data, K ~ 0.7 (Komar 1998) when wave energy calculations are based upon root mean square wave heights for H_{bs}. Note that these equations are based upon empirical data of variable quality from various sand beaches. Komar (1998, p.401 and following pages), in a wide ranging discussion concludes that the dependence of the longshore sediment transport rate on environmental factors such as grain size, beach slope, and wave steepness remains poorly established and requires further research.

Table 1 presents a selection of littoral sediment transport formulae commonly used in the past few decades, and specifically lists the parameters used in each. While most use the obvious parameters of breaking wave height (H_b), breaking wave celerity (C), breaking wave angle (α_b), sediment grain size diameter (D), wave steepness and beach slope, and bottom roughness (both form drag and skin friction) are rarely included.

Table 1. Various Formulae for Longshore Transport/Littoral Drift

Name	Date	Paramaters
Longshore Sediment Transport		
Kalinske - Krijlink formula	1952	$D, g, S_b, V_l, \mu, \rho, \rho_s$
Inman and Bagnold	1963, 1966	$\rho, g, H_b, C_b, \alpha_b$

V_l - average longshore current		C_b - wave-celerity at the breaker line
H_b - breaker height		h - water depth
L, T - wave length and period		D - sediment grain size diameter (median)
n - wave number at breaker line (~1)		ω - sediment fall velocity
S_b - bed load transport		μ - so-called " ripple factor"

Sediment Transport from Broken Wave Bores

The intense turbulence in the broken wave bore picks up sediment from the lower beach and transports it up the beach face as swash. As the swash loses momentum these particles become deposited. At the maximum point of wave run up the momentum is spent, some water percolates into the beach sand, which is highly porous, and subsequently the spent wave recedes down the beach face, gathering speed and discharge, at which time many surface particles are re-entrained and transported back toward the surf zone.

When waves break obliquely to the alignment of the beach the swash run-up tends also to travel obliquely up the beach face. Likewise the return swash run-down often continues an oblique pathway rather than normal to the beach profile. In this way particles are transported along the beach face as a component of the overall littoral drift.

Sediment Transport in Rip currents

The cellular circulation associated with rip currents generates its own morphodynamics. Rip currents tend to occur mainly with fully refracted waves, especially on reflective beach morphodynamic states, and under such conditions the overall longshore sediment transport is minimal. In general it can be concluded that rip currents redistribute sediment across, and even seawards of the broad surf zone, but it is not clear that they otherwise impact on the overall magnitude of net littoral drift. However, the onshore component of the cellular circulation assists with the shoreward drift of the nearshore sediment.

Diabathic or Cross Shore Sediment Transport

Sediment transport does not only occur within the breaking wave zone in the along shore direction, but also in given circumstances in an onshore-offshore direction, i.e. as diabathic transport. Sediment may be transported offshore from the beach face by steep waves, often in storms, and replaced on the beach face at times of long waves with low steepness.

But it is being increasingly recognised that onshore or offshore wind stress effects inducing mean water level set-up or set-down at the shoreline markedly enhances cross shore sediment transfer. In principle the stress created by the wind blowing over the water surface, say onshore, generates a wind forced surface water current in the wind direction. This causes a set-up at the coast above water level. For reasons of continuity, a bottom return flow, or down-welling current is generated. Sediment that is uplifted into suspension by the normal oscillatory movements from wave orbital motions, and turbulence generated by passing waves, is acted upon by the downwelling current as it falls back to the sea floor. In this way the downwelling current transports sediment offshore, and this is thought to be the dominant process across the lower shoreface (Cowell et al. 1999). Niederoda et al. (1985) review work in which downwelling velocities of 60 cm/s were measured, but more commonly the downwelling veolocites are around 8-15 cm /s.

Conversely, for offshore winds, the offshore directed wind stress causes surface water from the shoreline to be removed offshore, causing a set-down at the shoreline, and a compensatory bottom return flow, or upwelling current in the onshore direction. In addition onshore transport of sand is assisted by effects of long wave asymmetry, which induces onshore-directed bottom water mass transfer for Stokesian type waves under fair-weather conditions. Under these conditions sediments from the inner shelf and shore face move onshore and even on to the beach[1].

It is evident that maximum diabathic sediment transfer occurs with constant strong onshore or offshore winds, associated with high waves of long period waves, e.g. T ~ 14s, for these long period waves have greater bottom orbital velocities, and therefore induce greater sediment movement at a given depth.

Wind driven, sometimes termed “Ekman”, currents can drive diabathic sediment transport on the shelf, but depending upon wind direction may also generate parabathic (shore parallel) sediment transport along the shelf and obliquely over the shelf. This phenomenon has been well researched in New Zealand’s Bay of Plenty in relation to monitoring of sandy dredge spoil dispersion off Tauranga (Harms, 1989, Healy, Harms and de Lange 1991, Mathews 1995) and also the very detailed work by Bradshaw et al. (1989, 1994) off the Waihi Beach shelf and north along the Coromandel shelf. These studies showed that parabathic (along shelf and presumably obliquely-across-shelf) sediment transport occurs seawards of the surf zone driven by winds and also tidal shelf currents which are exclusive of tidal inlet effects. In particular, side scan sonar mapping off Tauranga (Harms 1989; Healy et al. 1991) and

over the inner shelf off Waihi Beach demonstrated zones of coarse grained ripples, normally referred to as megaripples (Black and Healy 1988) which are identified as scour zones. For the Bay of Plenty shelf these scour zones are frequently being overridden by sheets of fine sand moving toward the northwest. However the rates and volumes of sediment moving over the inner shelf are not known and this is necessary future research for a better understanding of the Bay of Plenty beach systems.

Viewed in relation to instantaneous deterministic processes, sediment transport on the shoreface – inner shelf is the result of time dependent advection of sediments by residual currents. For the most part the sediment flux involves agitation by waves, with other flows responsible for the net drift of the sediments.

INDICATORS OF NET LITTORAL DRIFT

Multiple lines of geomorphic and sedimentologic evidence exist, usually several in combination, which point to the direction of net littoral drift. Some of these are illustrated in Komar (1998, Figure 1).

(i) ***Sand impoundment by artificial structures, and down-drift erosion***. Structures such as "jetties", breakwaters and groynes can provide some of the clearest evidence of the net direction of littoral drift. While beach groynes may be relatively small structures and be subject to seasonal drift reversals, large jetties extending across the surf zone interrupt the net drift in the surf zone, and the resultant pattern of sediment trapped reflects the long term sediment transport direction. In such cases there is impoundment of sand from the up-drift, and compensatory erosion down-drift of the structure.

(ii) ***Sand impoundment by natural headlands, and down-drift erosion***, is the analogue in nature, of the blockage by jetties. Sometimes this feature is difficult to distinguish because of the topographic irregularity of the headland acting as a groyne in nature. For the New Zealand case where there are often headlands adjacent to a tidal inlet system, the down-drift erosion occurs on the barrier spit or island

(iii) ***Offset of sand salient impoundment due to offshore structures*** such as detached breakwaters. Typically in the lee of detached breakwaters a sand salient occurs. Where refraction patterns around the offshore structure are dominant over littoral drift, a symmetrical shaped salient occurs. However on a net littoral drift beach, the sand salient acts as a partial barrier to the littoral drift, resulting in a wider beach up-drift and a narrower, tending to eroded, beach down-drift. The salient apex becomes offset, with a longer tail in the down-drift direction.

(iv) ***Offset natural salients or cuspate forelands in the lee of islands***. Long wave refraction patterns around natural islands induce the formation of cuspate

forelands, and where a littoral drift is superimposed, the salient becomes offset with a longer flank or tail in the direction of net littoral drift.

(v) ***Alongshore increase in width of subaerial beach and dune height***. This condition indicates an increase in sand budget availability in the alongshore direction with an increase in sediment budget. Such a situation occurs up-drift of a major interruption to the littoral drift, and there may often be a change toward a more reflective morphodynamic beach state with increase in sand availability.

(vi) ***Alongshore increase in the width and number of the nearshore beach bars***. The beach bar may act as a reservoir of sediment in the beach system, depending upon the controlling morphodynamic conditions. Occurrence of multiple bars indicates a sediment surplus in the beach system. A trend alongshore from lack of a bar , to vestigial bar, to well formed bar, to multiple bars is indicative of a trend of increasing sediment budget as a result of the littoral drift. Examples occur on the eastern Baltic coast of Lituania and Latvia with an increase in bar size Klaipeda to the foreland peninsula at Mazirbe, and also in Port Phillip Bay (Australia) from Martha Point to Rosebud.

(vii) ***Alongshore decrease in width of subaerial beach and dune height***. This condition occurs where there is a decrease in beach sand availability in the net longshore direction. This may be induced by a major interruption to the littoral drift, for example, sediment starvation from a structure, a dredging operation, or loss offshore to a submarine canyon. The beach morphodynamic state trends toward a dissipative condition. Usually this geomorphic trend occurs over relatively short distances.

(viii) ***Deflection of sizeable river mouths.*** The long term action of wave resultant power from a dominant direction provides sediment from up-drift forcing the river mouth to migrate in the direction of the net littoral drift.

(ix) ***Maintenance of river mouth locational stability by retaining structures.*** Often rivers on a littoral drift coast are maintained in position by moles or a groyne in the down-drift side.

(x) ***Deflection of small streams crossing the beach, and cutting out the frontal dunes.*** Small streams crossing the beach are also influenced by the beach wave processes and driven in the direction of the littoral drift. During storm wave events with elevated water levels from storm surge and set-ups, often accompanied by heavy rainfall events increasing the stream discharge, at high tide especially the streams are diverted and cut out the adjacent frontal dunes. Drainage culverts discharging on the beach may behave similarly. The asymmetry of the embayment in the frontal dunes adjacent to the stream indicates the net direction of the littoral drift.

(xi) ***Deflection of a large stable tidal inlet gorge and tidal discharge jet crossing an ebb tidal delta***. At tidally dominated large tidal inlets with marked ebb tidal delta, more sediment arrives from the net up-drift direction. This typically moves along the ebb tidal delta terminal lobe and over the shoals, forcing sediment into the main tidal discharge channel. This causes the channel and the main discharge jet to be deflected in the direction of the net littoral drift.

(xii) ***Sand deposition on a consistent side of a major tidal inlet navigation channe requiring dredging***. As noted above, along littoral drift coasts sediment migrating in the net littoral drift may frequently spill into a navigation channel of a tidal inlet, requiring dredging. More deposition will be evident on the 'up drift' channel side of the net drift direction.

(xiii) ***Asymmetrical ebb tidal delta from up-drift deposition..*** The deep inlet channel of large tidal inlets acts as a partial barrier to the littoral drift, and thus sediment arriving from the up-drift direction tends to accumulate on the up-drift side resulting in larger and shallower shoals on the up-drift side of the ebb-tidal delta.

(xiv) ***Erosion on the up-drift extremity of a barrier island, (or barrier spit) and***. This arises because the up-drift tidal inlet acting as a partial barrier to the littoral drift, thus promoting down-drift erosion on the adjacent downdrift barrier system and accretion on the downdrift corner. The accretion may take the form of a re-curved spit.

(xv) ***Sand accumulation and extension on the down drift distal end of a barrier island.*** Likewise on the down-drift end of the barrier island there is sand accumulation, which due to the inlet may evolve as a re-curved spit into the inlet.

(xvi) ***Growth of a spit in the direction of littoral drift***. The formation of a spit usually indicates the direction net longshore transport, towards the end of the spit, and causes it to become distended in the direction of littoral drift. Note however that on occasions counter-net drift spits can develop.

(xvii) ***Evolution of sequential re-curved frontal dunes on a prograding spit***. A series of dune ridges on a barrier spit which show sequential re-curving and longshore growth at the distal end of the spit, is a classic indicator of net littoral drift over the time of evolution of the spit. In such a situation the innermost dunes are the older, and wave refraction around the tip of the spit causes the frontal dune to evolve around the re-curved shoreline towards a bay or an inlet. As sediment accumulation and progradation progresses the more recent dunes accrete seawards and also progressively alongshore as the spit grows, creating a sequence of re-curved dune ridges toward the distal end of the spit.

(xviii) ***Alignment of parabolic dune axis and frontal dune blowouts behind the beach.*** Parabolic and dune blowout axis alignment is a function of the resultant of winds of sufficient strength to move sand grains. Thus in environments where local coastal winds influence the littoral drift (from generation of local wind forced waves as distinct from distantly generated swell waves) the axis alignment of the parabolic dunes relative to the shoreline alignment may indicate the direction of net littoral drift, at least the local wind generated waves.

(xix) ***Resultant direction of alongshore wave power (ECn)***. Long term data recorded from a continuous recording directional wave height and period instrument, such as an S4 or similar, deployed beyond but close to the surf zone, provides evidence of the net littoral drift based upon the direction of the wave power (ECn) resultant. A wave power resultant for locally generated wind waves may also be constructed from a wind rose based upon long term wind records.

(xx) ***Mineral species tracing alongshore from an input source.*** Beach sand samples demonstrating alongshore trends of the concentrations of a specific mineral or component sediment type from an identifiable input source such as a river or industry, may indicate the direction of net littoral drift. Samples are typically collected from the beach berm on the basis that this is the most energetic part of the beach face where sorting processes are maximised. Mineral tracing is especially pertinent if there is one exclusive source of a specific mineral, and one input point – e.g. a specific river or erosion of a particular cliff. Concentration trends of a specific heavy mineral, or ratio of minerals typically produce consistent interpretations of longshore drift directions.

(xxi) ***Alongshore trends in beach sediment Mean Grain Size (Mz).*** Alongshore progressive variation in mean grain size can indicate the direction of the net littoral drift. This is particularly evident for gravel sized beach sediments and is based upon larger particles possessing a greater fall velocity. Typically one assumes that a reduction in Mz indicates the direction of the littoral drift, but for sand sized particles this is only true for beach sediments that are near spherical and of closely uniform particle density, such as quartz. Where the beach sands consist of heterogeneous grain size, density and possibly angularity, the opposite occurs. That is the larger more angular lighter particles are transported in preference, so that the trend is for increasing Mz sand size in the direction of net littoral drift.

(xxii) ***Alongshore trends in beach sediment Sorting Parameter.*** Typically for beach sediments of uniform density the direction of net littoral drift is indicated by an improvement in the sorting, i.e. a narrower size range. This feature is most apparent for sediments sampled from the beach berm crest.

(xxiii) ***Alongshore trends in beach sediment particle shape.*** Particularly for gravel beach sediments, the gravels at source will possess a greater angularity. Alongshore in the net drift direction the particles become more rounded and spherical. For gravels the discoidal clasts travel preferentially along the beach face, and thus measures of dioscoidal clasts also can indicate the net littoral drift direction.

(xxiv) ***Alongshore trends in particle "rollabilty".*** Rollability is the ability of a particle to move under the action of waves. Thus an along shore trend from less rollable to more rollable particles indicated the direction of the net littoral drift.

DISCUSSION: CONCLUSIONS AND ENIGMAS FROM LITTORAL DRIFT INDICATORS

Not all of the above indicators possess equal confidence as indicators of littoral drift. Some such, as a sequence of distal recurved prograding frontal dune ridges on a Holocene barrier spit, are indisputable evidence of the direction of net littoral drift; as the spit has evolved each sequential dune ridge has been moved further in the direction of net littoral drift. However, not all indicators are so incontrovertible, and we have more confidence in some of the indicators than others. For example, the directional alignment of a spit, while often indicating littoral drift does not universally do so. For example the spits on the strong littoral drift, but microtidal coast of southeast Australia are counter to the direction of the net littoral drift.

Likewise, typically groynes act to capture the sand from the net updrift direction and cause sand starvation leading to erosion downdrift. They are therefore a good indicator of the net direction of the littoral drift. However if the groynes are short and do not extend across most of the beach, during periods of drift reversal the opposite effect may be seen, so that instantaneously the drift net drift direction may appear to come from the wrong direction. For the case of headlands, especially when associated with tidal inlets, the sand entrapment may not be so clear cut as an artificial groyne constructed across the littoral pathway.

Of these indicators there is strongest confidence for sequential re-curved frontal dunes on barrier spits, sediment impoundment by headlands and large groynes, breaking wave directional power based upon long term wave records, migration of large river mouths, and deflection of large ebb tidal jets. There is only weak confidence in the indicators that are based upon beach sediment textural data alone, upon spit direction alone, or upon parabolic dune axes.

Occasionally paradoxes of the net littoral drift directions occur, such as spits aligned counter to the direction of the regional drift (as on the southeast Australian coast), spits aligned in opposite directions either side of a headland or tombolo (as at Orbithello, Italy), or counter drift sediment transport pathways induced by eddy currents, as may occur at large tidal inlets. Ideally establishment of the net regional littoral drift direction should be based upon several lines of evidence which are

consistent, and where net drift hypotheses are tested by numerical simulation of wave induced sediment transport based upon long term wave data.

Abstract: The cross-shore variation of long-term average longshore sediment transport rate was examined on the basis of longshore sediment transport rates at the Hasaki coast in Japan for 15 years estimated using a one-dimensional numerical model of longshore current velocity. The model was calibrated with longshore current velocities measured once a day at about 50-m intervals along a 427-meter-long pier at the study site for the same period. Numerical simulations showed that the average longshore sediment transport rate was northward near the shore, but southward away from the shore, where the seaward distance from the shore is larger than 150 m.

INTRODUCTION

The predominant longshore sediment transport rates, which are the transport rates averaged over long-term periods, cause long-term morphological changes, and hence understanding the predominant longshore sediment transport is essential for sediment budget analysis and for effective coastal zone management.

The direction of the predominant longshore sediment transport near the shore can be detected from the long-term shoreline changes around coastal structures because the predominant longshore sediment transport induces accumulation on the updrift side of a coastal structure and erosion on the downdrift side. However, because of the lack of field data and numerical simulation results of longshore sediment transport rate away from the shore over long-term periods, the cross-shore variation of the long-term average longshore sediment transport rate is poorly understood although Sato

(1996) has suggested on the basis of longshore current field data that on the Kanazawa coast of Japan, the direction of the long-term average longshore sediment transport offshore may be the opposite to that near the shore.

The objective of this study was to investigate the cross-shore variation of long-term average longshore sediment transport rate using a one-dimensional numerical model developed for the estimation of longshore current velocity. We calibrated the model with longshore current velocities measured along a 427-meter-long pier for 15 years. Using this model, we estimated the cross-shore variations of the longshore sediment transport rate for the 15 years and obtained the cross-shore variation of the long-term average longshore sediment transport rate.

FIELD MEASUREMENT OF LONGSHORE CURRENT VELOCITY

Field measurements of longshore current velocity were conducted once a day from 1987 to 2001 at intervals of about 50 m along a 427-meter-long pier of the Hazaki Oceanographical Research Station (HORS), located on the Hasaki coast of Japan facing the Pacific Ocean (Figure 1).

Nearshore current velocities 1 m below the water surface were measured with a spherical float that had a diameter of 0.2 m and was connected with an identification buoy by a 1-meter-long rope (Figure 2). The float attached to a 30-m-long line was released from the pier, and the time for full extension of the line was measured with a stopwatch (Figure 2). The current velocity was calculated from the time and the length of the line. The transport direction of the float due to the nearshore current was observed with a protractor. At each measurement point, currents were measured three times and the averaged value was used for the analysis.

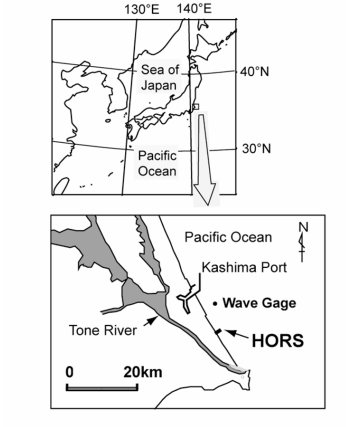

Fig. 1. Locations of the study site and offshore wave gage.

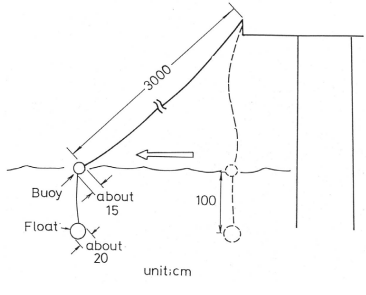

Fig. 2. Float for the measurement of longshore current velocity.

The validity of this measurement method was confirmed with longshore current velocities 1 m below the water surface simultaneously measured with the present method and an electro-magnetic current meter (Kuriyama and Ozaki 1993; Kuriyama 1995). The relationship between the time-averaged longshore current velocities measured with the float U_{FLOAT} and those measured with the current meter U (Figure 3) showed a very strong correlation with only a small influence of the wind. The correlation coefficient r was 0.97, and the standard deviation was 0.086 m/s. The relationship between them was expressed as

$$U = 0.81 U_{FLOAT}. \quad (1)$$

In the following analysis, the values of U were used.

The measurement points were located where the seaward distance relative to the reference point, located close to the entrance of the pier, was 115, 145, 190, 245, 280, 330 and 380 m. Each position along the pier is referred to as the seaward distance and designated as "P." For example, P115m denotes a position 115 m seaward from the reference point.

Besides the longshore current velocities, the beach profiles along the pier were measured at 5-m intervals every day, except for weekends and holidays, with a 5-kg lead from the pier, and with a level and a staff shoreward of the pier. Moreover, the bathymetry near HORS was surveyed once or twice a year in an area 600 m wide in the alongshore direction and about 700 m long in the cross-shore direction. The median sediment diameter along the profile is 0.18 mm and remains almost uniform along the profile (Katoh and Yanagishima 1995). Based on the datum level at Hasaki (Tokyo Peil -0.687 m), the high, mean and low water levels are 1.252 m, 0.651 m, and -0.196 m, respectively.

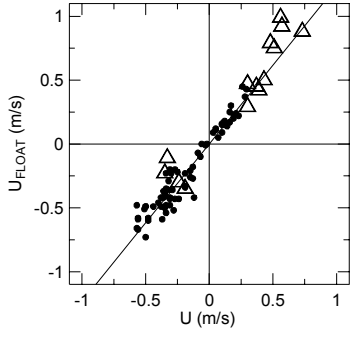

Fig. 3. Relationship between the longshore current velocities measured with the electro-magnetic current meter U and those with the float U_{FLOAT}. Open triangles represent data obtained when the absolute value of the wind velocity exceeded 8 m/s.

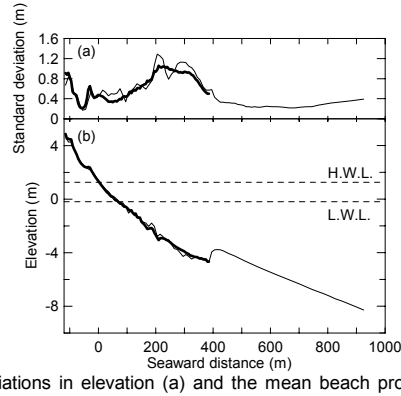

Fig. 4. Standard deviations in elevation (a) and the mean beach profiles (b) based on the daily profile measurements along the HORS pier (thick lines) and yearly bathymetry surveys around HORS (thin lines) (Kuriyama 2002). The elevation is based on the Hasaki datum level.

The averaged beach profiles show that the beach slope during the measurement period decreased gradually in the offshore direction (Figure 4). It was about 1/40 near the shoreline, about 1/100 at P300m and about 1/120 seaward of the tip of the pier. In the region between P200m and P400m, longshore bars emerged, migrated seaward and decayed. Although local scours were observed in trough regions and the discontinuity of the averaged beach profile at P400m was probably caused by these local scours, the locations and elevations of bar crests and the locations of toughs were almost uniform alongshore (Kuriyama 2002).

Deepwater waves were measured at a water depth of about 24 m with an ultrasonic wave gage for 20 minutes every 2 hours (Figure 1). Wave angles were visually observed at the tip of the pier once a day. However, because the time interval and the accuracy of the visual observation were not thought to be sufficient as input data for numerical simulations of longshore sediment transport rate, the offshore wave angles every 2 hours were estimated using the WAM model, a third generation wave prediction model (e.g., Hashimoto et al. 2000). Wind angles and velocities were measured at the tip of the pier for 10 minutes every hour.

The coordinate system used in this study is shown in Figure 5. The positive direction for the longshore current velocity and sediment transport rate was defined as being southward. The wave and wind angles were defined relative to the shoreward direction and were positive in the counterclockwise one.

The seasonal change of the deepwater wave height was large from January to March and from September to October, but small from June to August (Figure 6 (a)). On the other hand, the wave period was almost constant at 8 s (b). Waves mainly came from the north in December to February, and from the south in May to August (c).

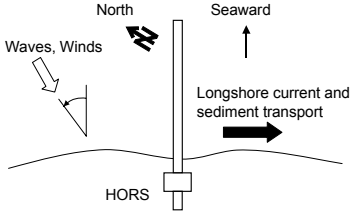

Fig. 5. The coordinate system at HORS.

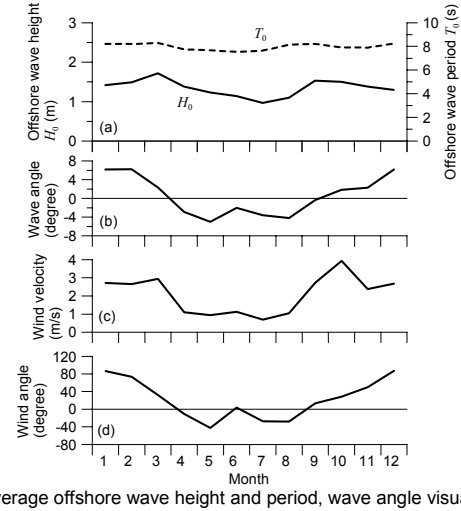

Fig. 6. Monthly average offshore wave height and period, wave angle visually observed at the tip of the HORS pier, and wind velocity and angle.

Strong winds came from the north in October to February, whereas weak winds came from the south in May to August (d). Compared with the seasonal changes, yearly changes were small.

NUMERICAL SIMULATION OF LONGSHORE CURRENT VELOCITY

The 1-D numerical model of longshore current velocity developed by Kuriyama and Nakatsukasa (2000) was utilized to estimate the longshore sediment transport rate. Although it was calibrated with longshore current velocities obtained in the field including HORS, the model was modified and recalibrated with the longshore current data obtained for 15 years from 1987 to 2001 at HORS. The model consists of a wave transformation model and a longshore current model, and adopts a wave-by-wave approach, in which wave heights and longshore current velocities are calculated for individual waves.

Wave Transformation Model

The wave transformation model is based on the model developed by Kuriyama (1996), which calculates the shoaling, breaking and reforming of individual waves. The shoaling of a wave was estimated using the shoaling coefficient proposed by Shuto (1974) with consideration for wave nonlinearity.

The criterion on wave breaking was based on a formula proposed by Seyama and Kimura (1988), who modified Goda's formula (1970). In the formula, the wave height-water depth ratio at wave breaking is expressed as a function of beach slope, offshore wavelength and water depth at wave breaking.

Energy dissipation of the organized wave motion in the surf zone, which is the source of the energy of the surface roller, was estimated with a periodic bore model used by Thornton and Guza (1983). The model is expressed by

$$\frac{\partial E_w C_g}{\partial y} = \frac{1}{4}\rho_w g \frac{1}{T}\frac{(BH)^3}{h}, \tag{2}$$

where E_w is the energy of the organized wave motion ($=\rho_w g H^2/8$), C_g is the group velocity, y is the seaward distance, ρ_w is the sea water density, g is the acceleration of gravity, T is the wave period, H is the wave height, h is the water depth, and B is a dimensionless coefficient determining the amount of energy dissipation. Kuriyama and Ozaki (1996) examined coefficient B with the experimental data of Seyama and Kimura (1988), and proposed the following formula:

$$B = C_B\{1.6 - 0.12\ln(H_0 / L_0) + 0.28\ln(\tan\beta)\}, \tag{3}$$

where C_B is a dimensionless coefficient, H_0 is the offshore wave height, L_0 is the offshore wavelength and $\tan\beta$ is the beach slope.

The location of wave reforming, where the wave energy dissipation stops and a broken wave returns to the unbroken wave, was judged from the wave height-water depth ratio. Based on field data obtained by Kuriyama and Ozaki (1996), the wave height-water depth ratio at the wave reforming point was set at 0.35.

With a significant wave height and a period set at an offshore boundary, a time series of water surface elevation for 10 minutes having the JONSWAP type spectrum at the offshore boundary was numerically simulated. The peak enhancement factor γ was set at 3.3. Next, with the zero-down crossing method, the time series was divided into individual waves, which were used in the calculation.

The incident directions of individual waves at the offshore boundary were determined with the given principal wave direction, the directional spreading function of the Mitsuyasu type and the spreading parameter estimated using the method of Goda and

Suzuki (1975). When the spreading parameter exceeded 100, the individual waves were treated as uni-directional waves.

Longshore Current Model

The time- and depth-averaged longshore current velocity of an individual wave U_{ind} was estimated on the basis of the balance among the bottom friction F_x, the lateral mixing force L_x, the gradient of the radiation stress R_x, the wind stress W_x, and the gradient of the momentum flux due to the surface roller M_x. The balance is expressed by

$$F_x - L_x + R_x + W_x + M_x = 0. \tag{4}$$

The bottom friction was estimated with the following equation proposed by Nishimura (1988).

$$\begin{aligned} &F_x = \frac{C_f}{h}(W + \frac{w_b}{W}^2 \sin^2\theta)U_{ind}, \\ &W = \left(\sqrt{U_{ind}^2 + w_b^2 + 2U_{ind}w_b\sin\theta} + \sqrt{U_{ind}^2 + w_b^2 - 2U_{ind}w_b\sin\theta}\right)/2, \\ &w_b = 2\nu_m/\pi, \nu_m = \pi H/(T\sinh(2\pi h/L)), \end{aligned} \tag{5}$$

where C_f is a friction coefficient, θ is the wave angle and L is the wavelength. Although Kuriyama and Nakatsukasa (2000) showed that numerical simulations with a constant C_f of 0.005 fitted well with the measurements, we expressed C_f as a function of water depth. The modification of the model will be given in the **Modification of the Model** section.

The lateral mixing term L_x was estimated on the basis of the energy dissipation of organized wave motion and the surface roller. In the estimation of the radiation stress term R_x, the small amplitude theory was used.

The wind stress was estimated using

$$W_x = C_d \rho_a W^2 \sin\theta_w. \tag{6}$$

where C_d is a nondimensional coefficient, ρ_a is the air density, W is the wind velocity and θ_w is the wind angle. The coefficient C_d was set at 0.0022, which was estimated on the basis of the data obtained at the tip of the pier when the wave height was small and the bottom friction F_x was assumed to be balanced with the wind stress W_x (Kuriyama and Yanagishima 2006).

The gradient of the momentum flux M_x is expressed by

$$M_x = \frac{1}{\rho_w h}\left(\frac{\partial M_r}{\partial y}\right), \quad M_r = -\frac{1}{3}\rho_w C^2 \frac{A_r}{L}\cos\theta \sin\theta, \tag{7}$$

where M_r is the momentum flux due to the surface roller having a triangle-shaped distribution of time-averaged velocity, in which the velocities at the tip and bottom of the roller are celerity, C, and 0, respectively, (Kuriyama and Nakatsukasa 2000). The value of A_r is the area of the roller.

Kuriyama and Nakatsukasa (2000) proposed the triangle-shaped velocity distribution in the roller because the cross-shore velocity of the roller is thought to change gradually from the top to the wave trough level owing to large eddies reported by Nadaoka et al. (1989), which have shoreward velocity near the surface and seaward velocity near the wave trough.

The area of the surface roller A_r was estimated on the basis of the assumptions given below.

(a) The area of the surface roller is basically assumed to be proportional to the square of the wave height. The area A_{r1} is estimated with a dimensionless coefficient C_A from

$$A_{r1} = C_A H^2. \tag{8}$$

(b) The energy of the surface roller, however, should not exceed the energy transferred from the organized wave motion. The roller area therefore is determined not to exceed the roller area A_{r2} estimated without energy dissipation of the surface roller from the following equation.

$$\begin{aligned} &\frac{\partial (E_w C_g)}{\partial y} + \frac{\partial (W_r C)}{\partial y} = 0, \\ &W_r = \frac{1}{8}\rho_w C^2 \frac{A_{r2}}{L}, \end{aligned} \tag{9}$$

where W_r is the energy of the roller having the triangle-shaped distribution of the time-averaged velocity above the wave trough level.

As for C_A, Kuriyama and Nakatsukasa (2000) showed that numerical simulations with C_A expressed as Eq. (10), which is a function of the surf similarity parameter at the wave breaking position, agreed with longshore current velocities in the field.

$$\begin{aligned} &C_A = 17.0 \log \xi_b + 24.7, \\ &\xi_b = \tan\beta / (H_{1/3,b} / L_{1/3,0})^{1/2}, \end{aligned} \tag{10}$$

where $H_{1/3,b}$ is the significant wave height at the wave breaking position and $L_{1/3,0}$ is the offshore wavelength corresponding to the significant wave period. The value of $H_{1/3,b}$ was defined as a local maximum of the significant wave height.

Modification of the Model

Kuriyama and Nakatsukasa (2000) used a constant C_f of 0.005 to estimate longshore current velocity and showed that estimated longshore current velocities agreed well with the measured values on barred beaches. However, because Garcez Faria et al. (1998) showed that the friction coefficient is not constant in the cross-shore direction, we assumed that C_f would be a function of the water depth as shown by Garcez Faria et al. (1998). It is expressed by

$$C_f = 0.011\left(\frac{k_a}{h}\right)^{\alpha}, \tag{11}$$

where k_a is the apparent bed roughness length scale and α is a coefficient. Although k_a varies according to the bottom and wave conditions (e.g., Garcez Faria et al. 1998), we assumed it to be constant as done by Ruessink et al. (2001). The values of k_a and α were determined so that the overall error between the predicted and measured longshore current velocities defined by Eq. 12 would be minimal.

$$\varepsilon = \sqrt{\frac{\sum\left(U_{mes} - U_{pred}\right)^2}{N}}, \tag{12}$$

where ε is the error, U_{mes} and U_{perd} are longshore current velocities measured and predicted, and N is the data number.

In addition to k_a and α, because the accuracy of the offshore wave angle estimated by the method of Hashimoto et al. (2000) had not been confirmed, we adjusted the estimated offshore wave angles by shifting them with an angle θ_a and minimizing the overall error.

The best parameters were k_a = 1.09 m, α = 1.4 and θ_a = -3 degrees. The correlations between the predicted and measured values at P115m and P380m are shown in Figures 7 (a) and (b). The overall error estimated with Eq. 12 is 0.22 m/s and the error at each measurement point ranged from 0.17 to 0.26 m/s.

Figure 8 shows the cross-shore variations of the estimated and measured longshore current velocities averaged for 15 years. The measured one was based on the values measured once a day, and the estimated one on the longshore current velocities predicted every 2 hours. The beach profile seaward of P445m used in the estimation was the mean beach profile shown in Figure 2. The profiles shoreward of P385m every 2 hours were temporarily interpolated with the ones measured once a day along

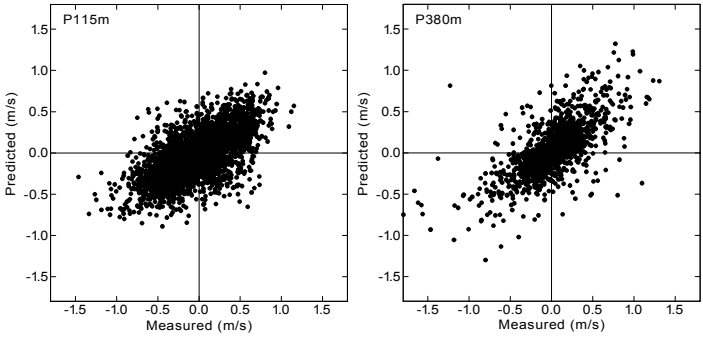

Fig. 7. Comparisons between measured and predicted longshore current velocities at P115m (left) and P380m (right).

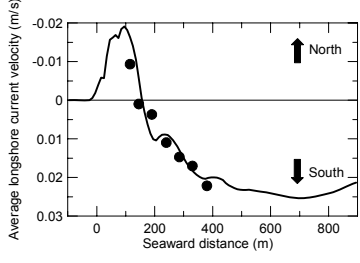

Fig. 8. Cross-shore variations of long-term average longshore current velocities measured (solid circles) and predicted (solid line).

the pier, and the profiles between P385m and P445m were spatially interpolated with the elevations at P385m and P445m. The coefficient C_B in Eq. 4 was set at 0.95 as in Kuriyama and Yanagishima (2006). The grid interval was 10 m, and the seaward boundary was set at P925m, where the elevation of the beach profile is -8.28 m and waves seldom break.

The average value of the predicted longshore current velocity agreed well with that of the measured one, which is northward near the shore and southward away from the shore. The cross-shore variation of the long-term average longshore current velocity was formed owing to the difference between the wave and wind conditions when the northward and southward currents developed (Kuriyama and Yanagishima 2006). When the northward current developed, the deepwater wave height was relatively small and the frequency of the wind from the north was almost equal to that from the south. As a result, the northward current developed only near the shore and decayed outside the narrow surf zone. On the other hand, when the southward current

developed, the deepwater wave height was relatively large and the wind from the north was predominant, which resulted in the southward current developing not only in the wide surf zone but also outside the surf zone. The superposition of the two cross-shore variations produced the cross-shore variation of the long-term average longshore current velocity with a northward velocity near the shore and a southward velocity away from the shore.

ESTIMATION OF LONGSHORE SEDIMENT TRANSPORT RATE

The longshore sediment transport rates Q were estimated using Eq. 13, which is based on Watanabe's formula (1992).

$$\begin{aligned} Q &= A(\tau_b - \tau_{cr})U/(\rho_w g), \\ \tau_b &= \rho_w h F_x, \\ \tau_{cr} &= (\rho_s - \rho_w) g d \psi_{cr}, \end{aligned} \tag{13}$$

where A is a nondimensional coefficient, τ_b is the bottom shear stress, F_x is the bottom friction expressed by Eq. 5, τ_{cr} is the critical shear stress for incipient motion, U is the time-averaged longshore current velocity, ρ_s is the sediment density, d is the sediment diameter and ψ_{cr} is the critical Shields parameter for incipient motion. The sediment diameter was set at 0.2 mm. The value of A was set at 2.0 according to Watanabe (1992), and ψ_{cr} was 0.06 according to Madsen and Grant (1976) and Tsuchiya (1986).

To estimate the longshore sediment transport rates for the 15 years, the longshore current velocities were estimated every 2 hours with the simulation model of longshore current velocity. Next, using Eq. 14, the longshore sediment transport rates were estimated every 2 hours.

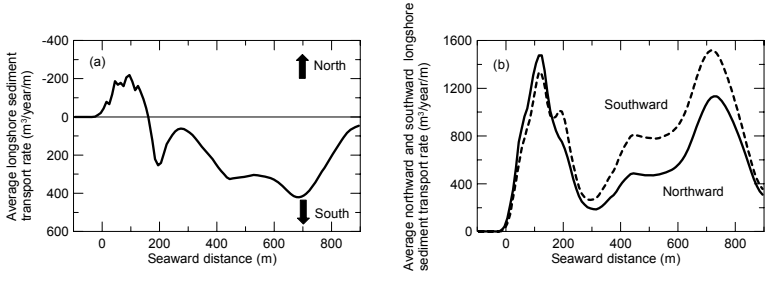

Fig. 9. (a) Cross-shore variation of the average longshore sediment transport rate. (b) Cross-shore variations of the absolute values of the northward and southward average longshore sediment transport rates.

The cross-shore variation of the average longshore sediment transport rate and those of the absolute values of the average northward and southward longshore sediment transport rates are shown in Figure 9. The average northward and southward longshore sediment transport rates at a certain point are defined as the average values of the sediment transport rates when the northward and southward sediment transports developed at the point, respectively. As suggested by the cross-shore variation of the average longshore current velocity (Figure 8), the average longshore sediment transport rate is northward near the shore, and southward away from the shore, seaward of P165m.

DISCUSSION

Sato and Tanaka (1966) analyzed bathymetry data from the shore to a water depth of about 7 m around breakwaters and groins constructed about 10 km north of the study site, and showed that the northward and southward gross longshore sediment transport rates are about 600,000 m^3/year. The integrated values of the average northward and southward longshore sediment transport rates (Figure 9 (b)) from the shore to a water depth of about 7 m, where the seaward distance is 735 m, are 469,000 and 596,000 m^3/year, respectively. These values are consistent with those reported by Sato and Tanaka (1966).

The northward direction of the average longshore sediment transport rate near the shore is identical to that of the predominant longshore sediment transport on the Hasaki coast derived from the shoreline changes (e.g., Tanaka et al. 1980). Thus, these results show that the estimated longshore sediment transport rates were reasonable.

Although the southward average sediment transport away from the shore is not supported by direct evidence, it is most likely to occur because the long-term average longshore current velocity is southward away from the shore (Figure 8). However, the southward average longshore sediment transport rate integrated from P165m to P735m is about 149,000 m^3/year and much larger than the northward one near the shore, 22,000 m^3/year. Further quantitative investigation on the southward average sediment transport rate away from the shore is required.

The finding that the direction of the average longshore sediment transport offshore can be opposite to that near the shore indicates that careful consideration should be given to bathymetry changes around a large-scale port or coastal structure induced by the average longshore sediment transport not only near the shore but also away from the shore.

CONCLUSION

We conducted numerical simulations of the cross-shore variation of longshore sediment transport rate for 15 years using a 1-D model for longshore current velocity in order to investigate the cross-shore variation of the long-term average longshore sediment transport rate. The model was calibrated with longshore current velocity

data obtained with a float once a day at about 50-m intervals along a 427-meter-long pier at the study site for the same period. The accuracy of the measurement method was confirmed with longshore current velocities simultaneously measured with the float and an electro-magnetic current meter.

The simulation results show that the average longshore sediment transport was northward near the shore, but southward away from the shore, where the seaward distance from the shore is larger than 150 m. The direction of the average longshore sediment transport near the shore is identical to that of the predominant longshore sediment transport derived from shoreline changes, and the estimated gross longshore sediment transport rates from the shore to a water depth of about 7 m are consistent with the values shown by a previous study. These results indicate that the estimated longshore sediment transport rates are reasonable. Our findings show the need to consider bathymetry changes near large-scale ports or coastal structures both near and away from the shore because sediment transport movements can occur in opposite directions.

ACKNOWLEDGEMENTS

The offshore data were provided by the Kashima Port Construction Office of the Ministry of Land, Infrastructure and Transport and the Marine Information Division of the Port and Airport Research Institute. We thank all the staff members at HORS, who conducted the field measurements.

LONGSHORE SAND TRANSPORT CALCULATED BY TIME-DEPENDENT SHEAR STRESS

Ernest R. Smith[1] and Nicholas C. Kraus[1]

1. U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA. Ernest.R.Smith@erdc.usace.army.mil; Nicholas.C.Kraus@erdc.usace.army.mil.

Abstract: Based on longshore sand transport experiments performed in a large basin, measured sand transport rates obtained for spilling and plunging waves are compared to the Bodge and Dean (1987) and Watanabe (1992) distributed load formulas, representative of typical formulas applied in engineering practice. Neither formula estimates the measurements satisfactorily. The Bodge and Dean formula is sensitive to changes in energy flux and does not include threshold shear. The Watanabe formula includes critical shear, but transport estimates are made from time-averaged values of bottom shear stress, which did not exceed critical shear stress at most cross-shore locations. A new transport formula is introduced based on time-dependent shear stress calculated from the total velocity that includes the wave orbital velocity. The new formula gives reasonable estimates for both spilling and plunging breaker types. A conclusion is that it is essential to represent the time-dependent, or fluctuating, component of fluid motion in predictive equations of the longshore sand transport rate.

INTRODUCTION

Many studies have been conducted to relate longshore sand transport rates to wave and current processes for developing predictive capability in terms of variables that are relatively easy to measure or hindcast. Total, or bulk, load transport refers to the total amount of sand transported along the coast in the surf zone. Distributed transport refers to the cross-shore distribution of longshore transport with a varying local rate across the surf zone. Despite the many studies that have been performed worldwide to develop accurate estimates for the longshore sand transport rate, there are limitations for quantitative applications. The purpose of this paper is to compare the existing distributed

load models of Bodge and Dean (1987) and Watanabe (1992) to high quality mid-scale laboratory data, and to introduce a new distributed load model based on the time-dependent shear stress that more reliably reproduces the measurements.

LABORATORY EXPERIMENTS

Mid-scale laboratory experiments were performed to measure the longshore sand transport and nearshore hydrodynamics in a controlled environment. Mid-scale denotes wave and current conditions that commonly occur on coasts such as the Gulf of Mexico and the Great Lakes. "Midscale" contrasts with much smaller wave heights and shorter wave periods typically generated in three-dimensional laboratory basin facilities. For example, mid-scale wave height and period might be on order of 0.25 m and 3 sec, respectively, as opposed to small-scale laboratory conditions on the order of 0.1 m and 1 sec. Because wave energy is proportional to the square of wave height and energy flux to the 5/2 power of wave height, more than doubling the wave height capable in mid-scale experiments as compared to traditional small-scale laboratory experiments greatly increases mean energy and associated turbulence in the surf zone. Longer wave period increases the extent of the area considered as shallow water.

Numerous laboratory and field studies have found that suspended sand concentration at the breaker line is strongly influenced by breaker type. Sand concentrations measured under plunging breakers are significantly greater than concentrations measured under spilling breakers of similar wave height (Kana 1977; Wang et al. 2002). Because longshore sand flux is the product of sand concentration and longshore current velocity, greater concentration would result in greater sand transport given similar longshore current velocity. The laboratory experiments were designed to include both spilling and plunging breaker types.

LSTF Facility and Experiment Design

The Longshore Sediment Transport Facility (LSTF) is a large-scale laboratory facility capable of simulating conditions comparable to low-wave energy coasts. The sand beach consists of 150 m^3 of fine quartz sand having a mean diameter d_{50} of 0.15 mm. An external recirculation system can maintain a steady and uniform wave-generated longshore current along the beach to minimize boundary effects. The LSTF includes instruments to measure water surface elevation, 3-D current velocity, and sand concentration simultaneously at several cross-shore locations. Wave gauges and acoustic Doppler velocimeters (ADV's) are mounted on a movable bridge that can be positioned at any location along the shore. Twenty sand traps at the downstream boundary of the model are instrumented with load cells to weigh trapped sand and are used to measure total cross-shore distribution of the total longshore sand transport rate generated under obliquely incident waves. Hamilton et al. (2001) discuss LSTF features and capabilities.

Four irregular wave signals with relatively broad spectral shape representative of sea conditions were generated in these LSTF tests. They were designed to obtain and compare transport rates for different breaker types through varying incident wave height and period. Four conditions generated in the LSTF are listed in Table 1, where H_{mo} is

energy-based significant wave height measured near the wave generators, H_{mob} is wave height at breaking, T_p is peak wave period, h is water depth at the wave generators, θ_b is incident wave angle at the generators, and m is the average slope of the beach from the breaker line to the shoreline. The wave conditions can be grouped by energy level. Tests 1 and 3 had similar incident wave height and are referred to as higher energy conditions, and Tests 5 and 6 are referred to as lower energy conditions. Each test was conducted with an h = 0.9 m and θ = 10 deg at the wave generators.

Table 1. LSTF test wave conditions

Test Number	Breaker Type	H_{mo} m	H_{mob} m	T_p sec	h m	θ_b deg
1	Spilling	0.25	0.26	1.5	0.9	6.5
3	Plunging	0.23	0.27	3.0	0.9	6.4
5	Spilling	0.16	0.18	1.5	0.9	6.7
6	Plunging	0.19	0.21	3.0	0.9	6.4

LSTF Results

The cross-shore distribution of wave height of each test is shown in Fig. 1. Test 3 and Test 6 waves shoaled prior to breaking and decreased in height sharply directly shoreward of breaking, typical of plunging waves. Test 1, a spilling case, also showed a sharp decrease in height directly shoreward of breaking. Test 1 had a surf similarity parameter on the upper end of spilling waves, 0.34 (Smith and Kraus 1991), and some plunging waves were observed within the time series; however, waves were observed to break predominately by spilling. Wave height in Test 5 decayed through the surf zone, typical of spilling breakers.

Measured longshore sand flux is plotted as a function of cross-shore location in Fig. 2. Three distinct zones of transport are evident; the incipient breaking zone, inner surf zone, and swash zone. At incipient breaking, a substantial peak in transport occurs for the plunging-waves (Tests 3 and 6), but is not observed in the spilling-waves (Tests 1 and 5). Shoreward of breaking, in the inner surf, wave energy is saturated, and wave height is strongly controlled by depth, independent of wave period. Fig. 2 implies that longshore sand flux in the inner surf zone is dominated by wave height, independent of period. A peak in transport occurs in the swash zone for all tests. For waves having similar incident wave height, but different period, i.e., Tests 1 and 3, and Tests 5 and 6, swash zone transport is much greater for the longer period tests. This result is consistent with elevation of wave runup (Hunt 1959), in which runup is directly proportional to wave period.

COMPARISON OF LSTF DATA TO SELECTED PREDICTIVE FORMULAS

Smith et al. (2006) compared LSTF results to distributed load formulas of Bodge and Dean (1987) (B&D) and Watanabe (1992), summarized here. B&D examined forms of energetics and stress models and developed several alternative formulas based on laboratory experiments and short-term impoundment of sand under moderate wave conditions in the field. The recommended equation from their study, which predicts longshore transport based on wave energy dissipation and is valid only inside the surf zone where wave energy is expected to dissipate by depth-limited breaking, is given as:

$$i_y = \frac{k_q}{h}\frac{\partial F}{\partial x} V \left[\frac{dh}{dx}\right]^r \tag{1}$$

where i_y is the local immersed weight sand transport rate (force/time) per unit offshore length, k_q is a dimensional coefficient found equal to 0.057 sec for laboratory data and 0.48 sec for field data, h is local water depth, x is cross-shore position, F is average wave energy flux per unit surface area, V is the mean local longshore current, and r is a dimensionless constant, where $r = 0.5$ gave the best agreement with the B&D data set. However, Bodge (1989) stated that scaling effects in the B&D movable-bed laboratory experiments may have exaggerated the apparent relationship between local transport and bottom slope, and that r may equal 0, eliminating the last factor of Eq. 1. In shallow water, average wave energy flux per unit surface area in linear wave theory is the product of wave energy per unit surface area, E, and wave group celerity, C_g:

$$F = EC_g = \left(\frac{\rho g H^2}{8}\right)\sqrt{gh} \tag{2}$$

where ρ is fluid density, g is acceleration due to gravity, and H is local wave height.

Fig. 3 shows that the B&D formula follows the general trend of the Test 1 measurements and predictions vary greatly for the spilling wave condition. Test 3 measurements were underestimated and no transport is calculated in the trough of the breakpoint bar, because dh/dx is negative. The model is based on energy dissipated and will not predict transport where no dissipation theoretically occurs, i.e., regions of increasing wave height or increasing depth, such as from a bar crest to bar trough. Wave gauges were not located in the swash zone, so transport estimates in the swash zone could not be made.

The B&D formula with $r = 0$ is compared to the LSTF measurements in Fig. 4. The B&D formula significantly over-predicts Test 1 measurements. Dropping the slope term produced a transport estimate near the Test 3 breakpoint, but the model greatly over-predicted transport shoreward of breaking. Estimates can be improved by adjusting k_q, but a different coefficient would be required to give optimal results for each breaker type.

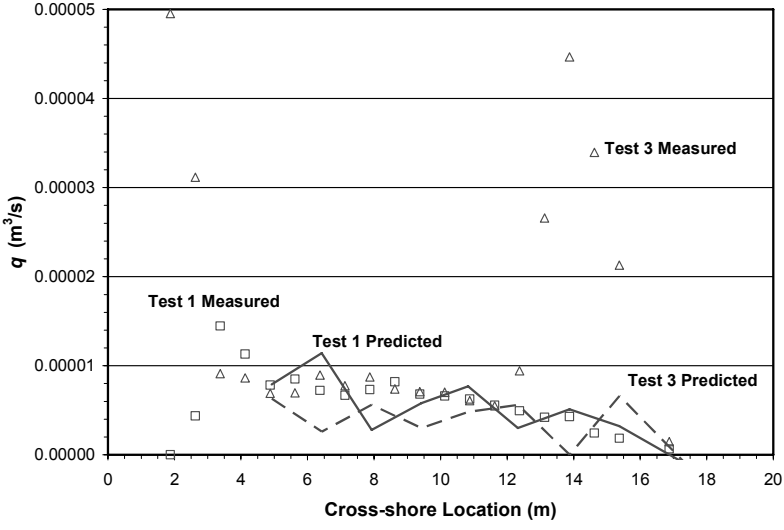

Fig. 3. Bodge and Dean (1987) estimates compared to Test 1 and Test 3 (r = 0.5)

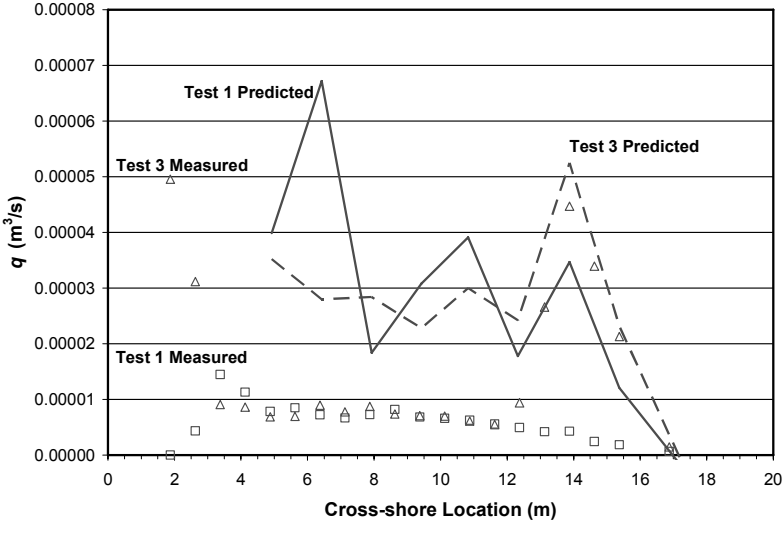

Fig. 4. Bodge and Dean (1987) estimates compared to Test 1 and Test 3 (r = 0)

Watanabe (1992) (W92) proposed a Meyer-Peter and Muller-type equation to calculate longshore sand transport as combined bed and suspended load of the form:

$$q_y = A\left[\frac{(\tau - \tau_{cr})V}{\rho g}\right] \tag{3}$$

where τ_{cr} is the critical shear stress for inception of sediment motion, and A is an empirical coefficient approximately equal to 2 for irregular waves. The magnitude of the total bottom shear stress under waves and currents is represented here as:

$$\tau = \frac{\rho c_f}{2}\sqrt{U^4 + V^4} \tag{4}$$

in which c_f is the bottom friction coefficient for combined waves and quasi-steady current and was calculated as in Buttolph et al. (2006), and U and V are the mean cross-shore and longshore velocities, respectively. Critical shear stress is calculated as:

$$\tau_{cr} = (\rho_s - \rho_w) g d_{50} \theta_{cr} \tag{5}$$

where ρ_s is the density of the sediment, d_{50} is expressed in meters, and θ_{cr} is the critical Shields parameter for sediment motion, taken to be 0.05 for 0.15-mm diameter sand.

The difference in shear stresses in Eq. 3 can be interpreted as representing a stirring function, and the velocity term represents a transport function. This formula has received wide-spread application for its simplicity, while incorporating several physical processes.

The W92 formula is applied to the LSTF Tests 1 and 3 (Fig. 5). Transport is not predicted at several cross-shore locations for both the plunging and spilling breaker conditions because the time-averaged bottom shear stress did not exceed the critical shear at those locations. The formula fails for low-wave conditions because it only estimates transport where the time-averaged bottom shear stress exceeds the critical shear, true for virtually all the smaller wave test locations (Tests 5 and 6).

The two predictive formulas evaluated did not perform well in comparisons to high-quality LSTF data. The B&D model either greatly underestimated the transport at the plunging wave breakpoint or over estimated the spilling wave case, depending on whether the slope term was included. The formula was sensitive to changes in energy flux, and it does not include threshold shear or differentiate between breaker types. The W92 formula includes threshold shear, but estimates longshore sand transport from only the time-averaged values of current. The time-averaged bottom shear stress exceeded critical shear stress at only a few cross-shore locations in the laboratory. Additionally, breaker type is not represented, nor is the wave orbital velocity in the surf zone. These results motivated examination of sand transport mechanics from a more basic approach.

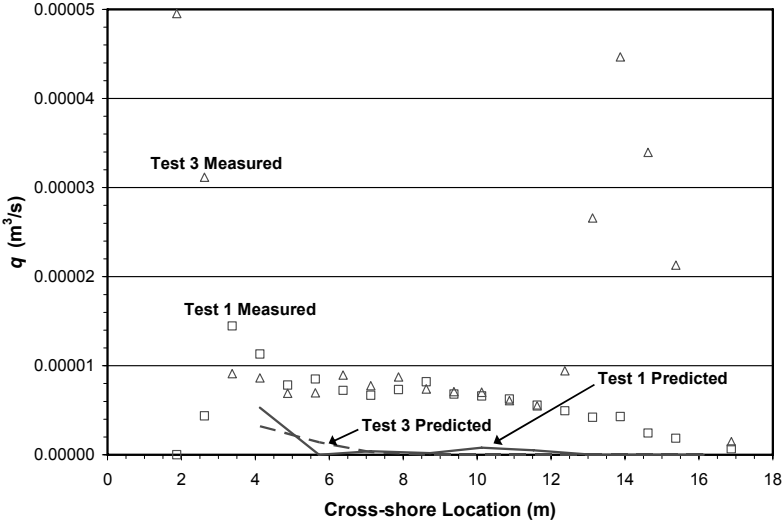

Fig. 5. Watanabe (1992) estimates compared to Test 1 and Test 3

PREDICTIVE FORMULA BASED ON TIME-DEPENDENT SHEAR STRESS

Madsen (1991) states that any model of sediment response to fluid forces that relies on the mean turbulent flow characteristics is limited to being conceptual. The necessity of including the fluctuating component of fluid motion was motivated by the findings of Madsen and Grant (1976), who noted that a sediment grain at point of incipient motion reacts to the fluctuations rather than to the mean value of the entraining force. Kraus et al. (1988) demonstrate that trends in prediction of the local longshore sand transport rate in the surf zone is improved by including the dissipation of waves and standard deviation in the longshore current velocity, both of which represent variations in fluid motion.

The shear stress, including the fluctuating component together with the mean value, can be calculated from the wave orbital velocity measured with the ADV's installed in the LSTF. The total cross-shore component of velocity is written:

$$u(t) = U + u'(t) \tag{6}$$

where U is the time-mean of $u(t)$, and $u'(t)$ is the fluctuating component that includes wave orbital velocity and turbulence. Similarly, the total longshore current velocity can be written as:

$$v(t) = V + v'(t) \tag{7}$$

where V is the time mean of $v(t)$, and $v'(t)$ is the fluctuating component and is typically small compared to V. The total shear stress exerted by the water on the sand bottom is:

$$\vec{\tau}(t) = \hat{x}\,\tau_x + \hat{y}\,\tau_y \tag{8}$$

the magnitude of which is:

$$\tau(t) = \sqrt{\tau_x(t)^2 + \tau_y(t)^2} = \frac{\rho_w c_f}{2}\sqrt{u(t)^4 + v(t)^4} \tag{9}$$

The time series of τ was calculated via Eq. 9 for Test 1, spilling waves at four ADV's having cross-shore locations X = 18.6, 13.1, 8.7, and 4.1 m (Fig. 6). At the most offshore ADV (X = 18.6 m), shear stress sometimes exceeded τ_{cr}, but often did not (Fig. 6a). This result indicates that the sand in the LSTF for this location was only occasionally mobilized for transport, so the transport rate is expected to be small. The magnitudes of total shear stress were much greater at ADV's located at X = 13.1 m and X = 8.7 m (Figs. 6b and 6c, respectively), and transport rates are expected to be greater at these cross-shore locations. Fig. 6d shows that shear stress magnitudes decrease at the most onshore ADV located at X = 4.1 m, but τ_{cr} was exceeded more frequently, i.e., sand was mobilized for transport more frequently at the most onshore ADV than at the other locations shown. The greater mobilization calculated correlates to the cross-shore distribution of sand transport rate observed for this case (Fig. 2).

The original W92 formula (Eq. 3) includes only the mean shear stress and predicted no transport at many LSTF cross-shore locations because the shear stress based on mean velocity did not exceed the critical shear (Fig. 5). In contrast, Fig. 6 shows that the total velocity components, which include the fluctuating components u' and v', produce a shear stress that frequently exceeds the critical shear. Therefore, accounting for the fluctuating component is essential for reproducing longshore sand transport under different types of breaking waves for smaller wave conditions.

Several transport formulas were investigated in this study based on the concept of:

$$q(t) = ST(t) \times TR(t) \tag{10}$$

where $q(t)$ is the time-dependent transport rate per unit length perpendicular to the transport, ST is a stirring function that mobilizes the sand, and TR is a transporting function that moves the sediment (Kraus and Horikawa 1990).

Equation 10 must be averaged over the time record, with the average taken of the full expression, although the averages of each factor on the right-hand side may be of interest in examining the physical processes of sand stirring and transport. A new formula was developed based on the time-mean of longshore sand transport rate:

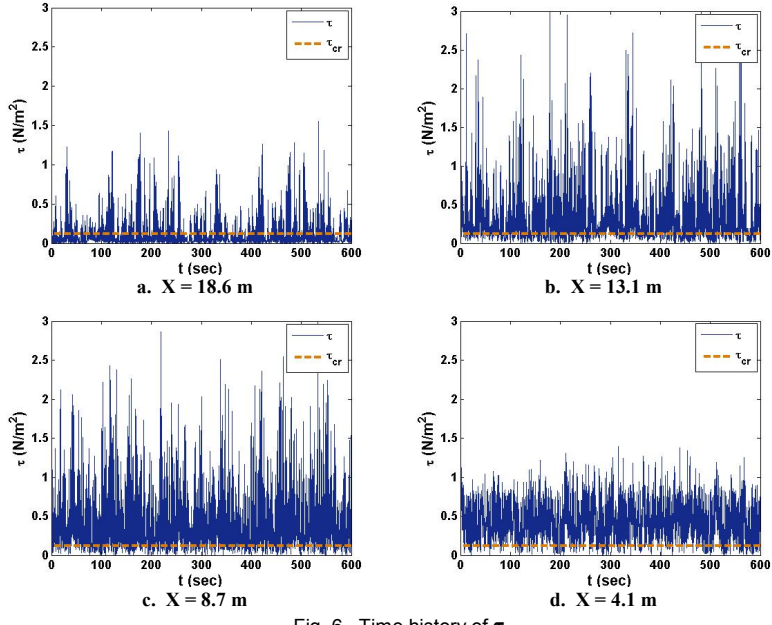

Fig. 6. Time history of **τ**

$$q_y = K\left\langle \left(ST(t) - \tau_{cr}\right)\left(TR_y(t)\right)\right\rangle \tag{11}$$

where K is an empirical parameter that may involve several dimensional quantities, depending on the stirring function $ST(t)$ and transporting function $TR_y(t)$, and <-> represents the time-average operation.

The stirring function $ST(t)$ is the time-average of τ:

$$\langle ST\rangle = \langle \tau(t)\rangle = \frac{1}{N}\sum_{1}^{N}\tau(t) \tag{12}$$

where N is the number of calculation points. For calculating the longshore transport rate, the transporting function $TR_y(t)$ is $v(t)$, Eq. 7, and the time-average is V.

It was observed during the LSTF plunging wave experiments that sand remained in suspension at the trough of the break-point bar for the duration of the tests. The plunging waves distributed sand through the water column, and sand entrained in the upper water column had a greater distance to settle to the bed, requiring a time interval longer than several wave periods. Subsequent waves would redistribute the suspended sand through

the water column. Therefore, sand entrained into the water column by a single plunging wave would continue to be transported during several subsequent waves. An additional term to account for events that cause sand to be suspended through the water column and increase the transport rate near the break point of plunging waves is included in the model. This suspension term $s(t)$ is as defined as:

$$s(t) = \left(u'(t)^2 + v'(t)^2 \right)^k \tag{13}$$

where k is an empirical exponent set to 2 based on numerical comparison to the LSTF data.

The new predictive longshore sand transport rate formula based on time-dependent shear stress is then given as:

$$\begin{gathered} q_y(t) = \left(f_b K \left(\tau(t) - \tau_{cr} \right) + f_s s(t) \right) V \quad \text{for } \tau(t) > \tau_{cr} \\ \text{and} \\ q_y(t) = 0 \quad \text{for } \tau(t) < \tau_{cr} \end{gathered} \tag{14}$$

where $f_b = 10$ and $f_s = 0.014$ are empirical coefficients determined by comparisons to the LSTF results. The time-averaged transport rate over the record was calculated by:

$$q_y = \frac{1}{N} \sum_{1}^{N} q_y(t) \tag{15}$$

Estimates of Test 1 longshore sand transport rates were improved using the time dependent formula (Eq. 15), as shown in Fig. 7. The equation modeled the trend and general magnitude of measured transport rates. Transport rates for Test 3 also are estimated well, especially near breaking and in the surf zone onshore of X = 6 m.

The time-dependent formula was compared to the smaller waves of Test 5 and Test 6 (Fig. 8). Estimates followed the trend of the measured distribution, although slightly high, and were good onshore of X = 6 m. Estimates with Test 6 conditions gave good agreement with measurements. Eq. 15 predicts a peak in transport near breaking with Test 6 waves, although lower than measured, and estimates surf zone transport rates well.

The same values of the empirical coefficients were used for all LSTF test conditions. Eq. 15 estimated the trend and magnitude of cross-shore distributed longshore sand transport rates for both spilling and plunging breakers. Although ADV's were not present throughout the swash zone, the formula presented is capable of estimating swash zone transport if the swash zone hydrodynamics are available for input.

CONCLUDING DISCUSSION

A key finding of the present study is that it is essential to include the fluctuating component of the wave orbital velocity in predictive sand transport rate equations for the surf zone. Bottom shear stress calculated from the mean velocity rarely exceeds the critical shear for sand motion for small waves or for sediment with a large grain size. Figure 5 illustrates that the original Watanabe (1992) equation, which is based on mean bottom shear stress, predicts zero sand transport for several of the LSTF cross-shore locations. Also, mean values of the longshore current and cross-shore current do not contain significant information on the wave breaking process, which determine in great part the intensity and vertical extent of fluctuations produced. Therefore, it is concluded that the fluctuating component of shear stress must be included in future hydrodynamic simulations aimed at providing forcing for calculating longshore sand transport.

Additionally, breaker type was found to be a central variable in the amount of sand transport that occurs at a location, which agrees with the findings of Kana 1977 and Wang et al. 2002. Plunging breakers produce greater turbulence throughout the water column whereas turbulence associated with spilling breakers remains near the surface in the bore. Mean values of the longshore and cross-shore current do not provide information on the wave breaking process, which determines the amount of turbulence produced.

A new formula was developed that yielded improved estimates of longshore sand transport and includes the fluctuating component of wave orbital velocity. For engineering purposes, the fluctuating component can be related to the mean wave orbital velocity, which is a function of wave height and period. As a result, an accurate wave transformation model is necessary to give reliable estimates of distributed longshore sand transport rates. Comparison of the new predictive transport formula and field measurements is underway, the results are so far favorable.

Abstract: Reservoirs, dams and barrages regulating the discharges of the Danube river, cut-offs of meanders and the jetties at Sulina mouth have disrupted the natural discharge and circulation of sediment on the coastal zone of Danube Delta. The aim of our research is to quantify the alongshore sediment transport and use this as a prime input to construct a sediment budget. Based on regional wind (1991 - 2000) data and a nearshore state-of-the-art wave model a morphologically representative wave climate along the representative depth contours of the Danube Delta was determined. This forms the basic input for a one-line model approach deriving the alongshore sediment transport and resulting coastline changes. The closure depth was computed and used, along with alongshore sediment transport gradients, to obtain the sediment budget.

1. INTRODUCTION

In modern times, especially the XX century, deltas all over the world were subject to a strong human pressure due to industrialization, Danube Delta being one of these. The circulation of the sediments in its coastal zone was disturbed by human activities such as the prolongation of the Sulina jetties into the sea, decreasing the amount of the sediment reaching the coast due to the damming upstream on the river (Panin 1997; Giosan et al. 1999; Ungureanu et al. 2000; Stanica 2003).

To assess the present day status of the coastal zone in front of the Danube Delta we especially need information on the nearshore wave energy distribution and sediment circulation. Several steps were necessary in order to reach our objectives: the wave

climate, the closure depth, the longshore transport and the sediment budget. These steps will be described and discussed further in this paper.

2. GEOGRAPHICAL SETTING AND DESCRIPTION OF THE STUDY AREA

The Danube River starts its course in the Schwartzwald Mountains in Germany and ends, after 2,857 km, in Romania forming the Danube Delta. This delta is situated the Northwestern part of the Black Sea, between 44°25' and 45°30' Northern latitude and between 28°45' and 29°46' Eastern longitude. The Danube River discharges into Black Sea through three arms (from north to south): Kilia, which transports approximately 52% of the water discharge, Sulina, the major waterway, 20% and Sfantu Gheorghe, 24.5%, the rest of the water being discharged through Razelm-Sinoe lagoon system (Stanica 2003). The distribution of the discharge of the sediments is slightly different: Kilia - approximately 54.5%, Sulina - 6%, Sfantu Gheorghe - 22%, the rest being deposited in the Danube Delta (Stanica 2003).
Southward from the Sf. Gheorghe Branch the Razim-Sinoe lagoon system is situated. Our study zone is bordered by the Sulina jetties northward and Portita inlet southward (figure 1).

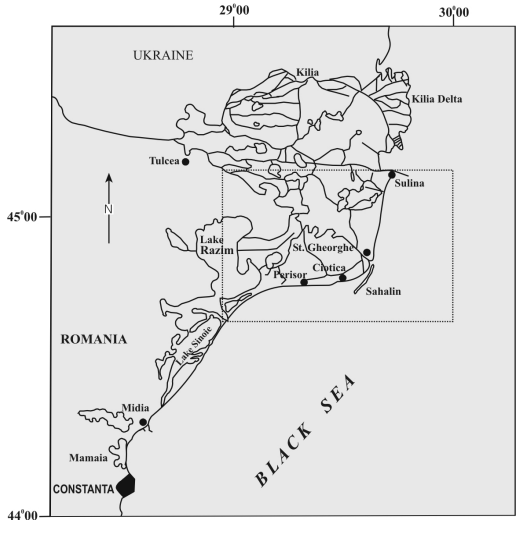

Fig.1 Location of the study zone (dotted lined box).

The human interventions disrupted the natural equilibrium of the coastal zone of the Danube Delta. Among these interventions, two induced major changes: the barrages build along the Danube River and its tributaries, and the Sulina jetties. After the building of two barrages Iron Gates I (943km from the Black Sea) in 1970 and Iron Gates II dam (864 km) in 1983, the sediment discharge decreased with 35% to 50% compared to the mean value of the pre-barrage sediment discharge regime (Panin

1996). The Sulina jetties construction started in 1858 as part of the plan transforming Sulina branch into a navigational channel. Today, the jetties extend 8 km into the Black Sea. The structure, acting like a barrage, blocks the alongshore drift from secondary delta Kilia towards south completely, resulting in the clogging of the Musura Bay and causing "beach starvation" downdrift.
An important role in the historical evolution of the coastal zone of the Danube Delta is played by the changes of mean sea level. The tide regime in the study area has average amplitudes of 7 – 11 cm (Bondar et al. 1973). The relative sea level rise consists of eustatic sea level rise, estimated for the past century at about 1.3 mm/year (Malciu 2000), and natural subsidence, with average values of 1.5 – 1.8 mm/year (Panin 1999).

3. WAVE CLIMATE

The first step in our approach was to obtain a reliable nearshore wave climate. The wave data available in Romania are based on visual observation and the records are not continuous, with blackouts occurring especially during extreme events, which are the most important for coastal changes. Therefore, we took the decision to construct the wave climate from the wind measurements, which we consider more reliable and which are more complete.

Wind data available cover a 10 years period (1991 - 2000) from Sulina (Danube Delta) meteorological station and from 2002 recorded simultaneously at Sulina and the Gloria Oil Rig (offshore). Records were taken four times per day containing speed (m/s) and direction (nautical convention, 16 directions). At Sulina the records were made at a height of 10 m above the mean sea level, but at Gloria Oil Rig at 36 m height. The Sulina meteorological station is situated at the landward end of the Sulina jetties which extend the channel into the sea. Therefore, the station can be considered, as located, on the shoreline. First correction needed was to transform the wind speed of the Gloria data set to a wind speed at the standard elevation of 10 m above the mean sea level ($U_{10} \approx U_{36}/1.2$) (Shore Protection Manual 1984).
The important question was whether the Sulina station is representative for the offshore wind conditions. To answer this a comparison was made between the Sulina 2002 data set and the Gloria 2002 data set (situated offshore). It turned out that almost 70% of the records were similar, which can be considered a good correlation.

A second correction was to apply a land vicinity correction. An empirical method was used, obtained from a study of winds in the Great Lakes area, USA, (Shore Protection Manual 1984), resulting in a dimensionless coefficient of 1.2 as a multiplication factor for the recorded wind speed. Then, the data were split in the 16 directions for each set. For the wind directions, which are crossing land, the corrected data correlate better with those from Gloria. For the directions crossing only water the correlation is better for uncorrected data. Nevertheless, the directions starting from WSW to NNW, clockwise, were not taken in account for wave computations because these only cross land and generate offshore directed waves only.

For the computation of the wave climate using the state-of-the-art wave model SWAN (Simulating WAve Nearshore) (Booij 1999) two kind of data were used as input: a bathymetric map and wind records. The bathymetric survey was carried out in 1995 by GeoEcoMar Bucharest and covers an area between the Sulina jetties in the North and Portita inlet in the South. It covers, also, a range of water depths from the shoreline (East) to 30 – 55 m offshore (West).

Based on the spatial extent of the storm systems in the northwestern part of the Black Sea (Ginzburg et al. 2002) the fetch was chosen to be 100 km from Sahalin Island towards North, West and South. Each directional and speed class corresponds to two runs of the model, one for the large grid and one for the small one. After elimination of the wind directions which are crossing only land (from W to NNW) and the smallest wind speeds (below 5 m/s), considering their insignificant weight in the wave climate, the number of wind conditions that remained was 66. The next step was to simulate the generation and propagation of the waves for each wind direction and speed class. Because the simulation area was rather large the first computation is coarse (2 km each cell). The second computation was a so-called nested grid containing only the littoral area with a finer resolution of computation (200 m each cell). The obtained results were considered representative for one year, being, in fact, an average of the ten years of wind records (Dan et al. 2006).

4. CLOSURE DEPTH

In previous studies on the circulation of sediment in the Danube Delta coastal zone (Giosan et al. 1999) the closure depth was estimated between 6 and 12 m water depth. Since there are no systematic measurements of the submerged beach profile in the studied zone, we have employed the method proposed by Sabatier et al. (2004) to determine the closure depth.

The method is based on a characteristic extreme wave condition which occurs at least 12 hours per year. In our case, the larger waves were produced by winds from N, NE and SW at wind speeds of 40, 28 and 30 m/s, respectively. We took in account ten years of wind records at Sulina, the same used as a base for computing the wave climate. The next step in the procedure was to choose an arbitrary closure depth offshore for the first computation based on Hallermeier's formula (Hallermeier 1980). These depths range between 16 and 20 m. The locations and depths were chosen to be as much as possible representative for the local wave climate. After applying this procedure again a new closure depth resulted. Then, the formula was applied at this new closure depth, obtaining the final value. The resulting values ranged from 5 m depth at Portita area (point 1), 6 m close to Sulina jetties (point 32) to 8.5 in the central part of the Sahalin island (point 19) (point locations in figure 3). The values of the closure depth obtained using the method of Sabatier et al. (2004) proved, in our case, to be heavily dependent on the depths choose to start the computation. Another concern was the relative small values of the closure depth taking in account the extreme wave conditions use for the computation.

Therefore, we decided to use the original method proposed by Hallermeier (1980) in order to check the obtained values. Based on laboratory experiments with regular

waves Hallermeier (1980) determined the transition between motion and no motion as:

$$\frac{A}{D} = \left(\frac{8(s-1)g}{\omega^2 D} \right)^{0.5} \quad (1)$$

where A is the wave excursion, D the diameter of the spherical grains, s is the relative density (ρ_s / ρ), g the acceleration of gravity, and ω is the angular frequency ($2\pi/T$). The density of the sediments ρ_s=2,65 $\cdot 10^3$ kg/m^3, density of the water ρ=1 $\cdot 10^3$ kg/m^3, g=9,81 m/s^2 and the grain size D=0.16 mm were used for the computation. The wave height and period were extracted from the wave climate for every location. We keep the same rule of the list 12 hours per year of extreme wave condition. Waves generated by winds from North at 40 m/s and from South-West at 30 m/s were used for this second method. The locations chosen to extract the wave data coincides with the locations of the 25 profiles used in UNIBEST CL+ longshore sediment transport computation. In table 1 the values for each location are listed.

Table 1 - The closure depth computed using Hallermeier formula. The italic values were determined by the south-west waves and the normal values by the north waves. For location of the profiles see figure 3.

Profile	Closure Depth (m)	Profile	Closure Depth (m)	Profile	Closure depth (m)
Profile 1	*6.9*	Profile 10	10.5	*Profile 19*	*5.1*
Profile 2	*6.8*	Profile 11	11.6	*Profile 20*	*5.0*
Profile 3	6.7	Profile 12	10.8	*Profile 21*	*5.3*
Profile 4	8.4	*Profile 13*	*9.0*	*Profile 22*	*5.6*
Profile 5	8.7	*Profile 14*	*8.0*	*Profile 23*	*5.6*
Profile 6	8.4	*Profile 15*	*5.9*	*Profile 24*	*6.4*
Profile 7	9.6	*Profile 16*	*5.5*	*Profile 25*	*6.6*
Profile 8	9.4	*Profile 17*	*5.6*		
Profile 9	10.0	*Profile 18*	*5.4*		

The computed values for closure depth vary strongly along the studied area. The smallest values occur in the northern and southern parts. This is due to the sheltering of these areas against northern direction waves. The maximum values are reached in the front of Sahalin spit island due to the full exposure to both the main wave directions: northern and southern. This large range of closure depth proves that for an accurate sediment transport computation over a large zone a single (or averaged) value of the closure depth cannot be used.

5. ALONGSHORE SEDIMENT TRANSPORT CAPACITY

The alongshore sediment transport capacity was obtained using the coastline model UNIBEST CL+ (UNiform Beach Sediment Transport Coast Line) (Szmytkiewicz et al. 2000) to obtain a continuous and precise alongshore transport capacity. We use 25 profiles (for location see Figure 3) to compute the sediment transport capacity along the coastal zone between Sulina jetties (north) and Portita (south). The profiles are located where local information is specified. Each of these profiles was placed in

locations considered representative and each of these used a different cross-shore profile determined from the bathymetric map. The closure depths from Table 1 were used. At the offshore extremity of every profile a local wave climate was extracted from the wave climate file. The formulas used for the sediment transport computation were CERC (Shore Protection Manual 1984) and Bijker (Bijker 1971).
The general direction of the alongshore sediment transport, on Sulina – Sfantu Gheorghe segment, is from north to south. An exception from this rule is the sector between the Sulina jetties and profile 1 where the transport is towards north. Because of the influence of the jetties the waves from northern directions have small heights the waves from eastern and southern directions induce the alongshore current here, reversing the general direction. Downdrift, to the Sfantu Gheorghe mouth the alongshore transport is oriented towards south and it is continuously increasing. Between profile 2 and profile 4 the transport is increasing with a very steep gradient, suggesting intense erosion. The next sector (profile 4 - profile 9) is keeping the same trend, but with a milder gradient.

Around the Sf. Gheorghe mouth (profile 9 - profile 11) the transport gradient gets very mild showing almost the same values at the beginning and the end of the sector. Nevertheless, this is the sector where the maximum amplitude of the longshore sediment transport from the whole studied area, is reached, 1,080,000 m^3/yr, according to the CERC formula and 775,000 m^3/yr, according to the Bijker formula. This is also the location where, to this maximal transported sediment quantity is added the contribution of the Sf. Gheorghe branch. By adding this contribution, 350,000 - 500,000 m3/yr (Panin, 1997), a total of 1,200,000 - 1,500,000 m^3 sandy sediment is entering in the Sahalin domain each year.

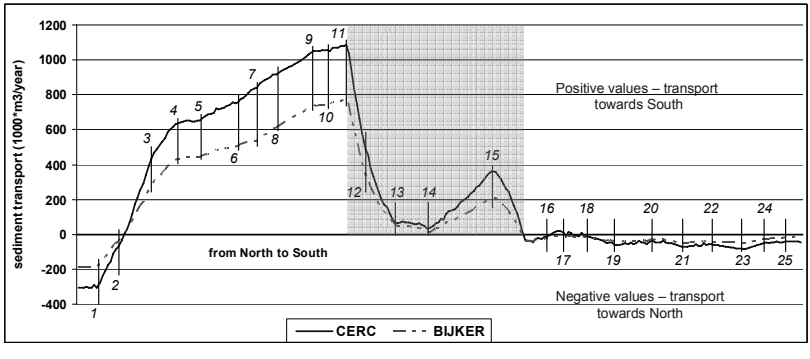

Fig. 2. The alongshore sediment transport capacity computed with UNIBEST CL+. The gray rectangle contains the sediment transport in the Sahalin spit island domain. For location of the profiles see figure 3.

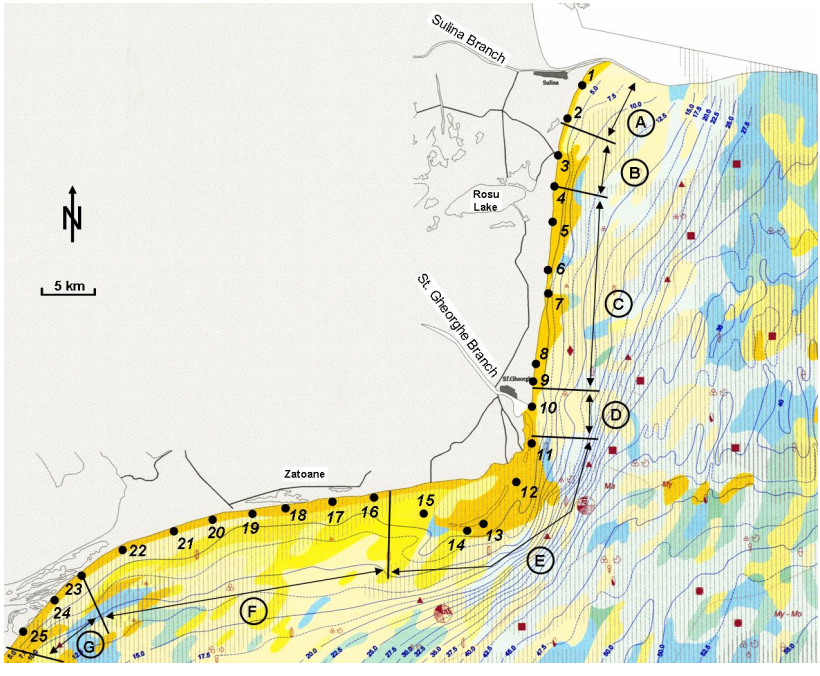

Fig. 3. The location of the profiles used in computation (black dots). Capital letters in circles are the sectors used to compute the sediment budget.

Immediately after the shoreline orientation is changing (profile 11), the transport is decreasing with a strong gradient reaching almost zero at the end of the island domain (profile 16). In front of the Sahalin spit island the wave climate is the strongest from the whole area, both predominant winds sectors (northern and south-western) exerting wave action there. The longshore transport gradient is suggesting here an intense accretion along the island. However, the measurements show an erosion of the island on the eastern side simultaneously with migration towards mainland and elongation in the southern end (Panin, 1998; Giosan et al., 1999). The processes which control the erosion/accretion here are more complex than a coastline model can handle. A special discussion will be paid to this region in the sediment budget chapter.
Around profile 15 a new peak is reached in the sediment transport. Sand is eroded from the end of the spit and, probably "pushed" into the golf, formed between the island and the mainland, by the waves from south and south-west directions.

The sector between profile 16 and profile 25 is characterized by a low sediment transport from south-west toward north-east, the maximum being 55,000 - 85,000 m^3/yr (profile 23). This sector, with a mild slope of the submerged beach, is

controlled by the waves from southern direction, which attack the shores at low incidence angles, explaining the rather small values of the sediment transport.

6. THE SEDIMENT BUDGET

The sediment budget was computed taking into account the longshore sediment transport, closure depth and additional sources of sediment as delivered by Sf. Gheorghe branch. Starting from the northern boundary we describe 9 sectors (figure 3) defined according to the longshore transport gradients and morphological particularities of the coastal zone. The erosion/accretion values are expressed with a minimum (corresponding to Bijker formula) and a maximum value (corresponding to CERC formula). The whole coastal zone can be split into three sections, corresponding with the characteristics of the sediment budget.

Section Sulina - Sfantu Gheorghe

This section is delimited northward by the Sulina jetties. Since these jetties extend into the sea for some 8 km, up to a depth of 7-8 m, we assume there is no sediment input from the northern boundary. Next to the jetties, southward, (sector A) the average advance of the shoreline is ranging, according to our calculation, from 4.5 to 7.5 m/yr. This sector has been described (Panin, 1996; Stanica 2003) as the place where due to the jetties an eddy-like current is forming, reversing the normal direction of the longshore drift. The same authors mention a mean annual shoreline advancement rate ranging between 8 and 10 m. In sector B the largest erosion rate of the whole study area is computed, from 9 to 13 m/yr. From literature, the observed erosion rate here is 6 - 11 m/yr (Panin, 1996; Stanica, 2003). In figure 4, shoreline positions are plotted at different times. In the periods 1952 - 1985 and 1960 - 1985 the average erosion rate is 11 m/yr. This segment is corresponding to the segment profile 30 - profile 26 where, according to our computation, the erosion rate is 5 - 7 m/yr.

The erosion rates decrease in sector C at 2 - 2.5 m/yr reaching values of 0.5 m/yr in the sector D. Sector D coincides with the segment described (Ungureanu at al., 1996; Stanica, 2003) as stable.

Sahalin spit island

The domain of Sahalin island is corresponding to the sectors E in figure 3 and the associated sediment transport is contained in a gray rectangle in figure 2. Here, the longshore transport is just one of the factors controlling the evolution of the island, but other processes, like overwash, migration towards the mainland and the continuous elongation to south-west (Panin, 1999; Giosan et al., 1999) are also important. Although, our computation suggests accretion, according to the same authors the eastern side of the island is strongly eroding. In the Sahalin domain the sand input has two main contributors: the longshore transport which brings here 775,000 - 1,080,000 m^3/yr and the input from Sf. Gheorghe arm which is 350,000 - 500,000 m3/yr.

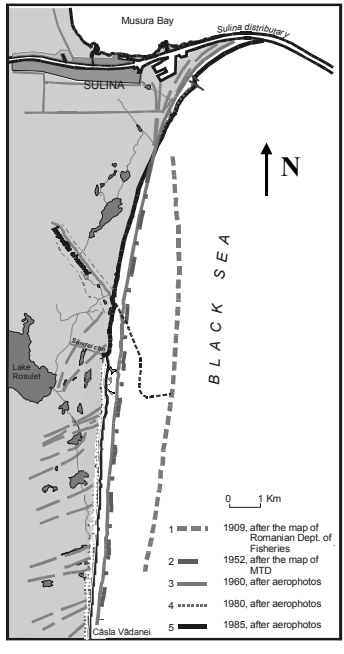

Fig. 4. The evolution of the coastline of the Danube Delta Front in the Sulina - Sfantu Gheorghe section during the last century (modified after Panin, 1996).

Observing the evolution of Sahalin island, the obvious conclusion is that much of the sand brought by the river and the longshore transport is deposited at the southern tip of the island. From figure 5 it can be noticed that the length of the island is increasing with a rate of 85 - 100 m/yr. Obviously, not only the emerged part of the islands is growing, but also the submerged associated domain, both landward and seaward are moving towards south-west with the previous mentioned rate. Based on the evolution of the island in the last decades, the assumption was made that the active domain is confined by the 3 m depth isobaths northward (the largest depth from the bay) and the 8 m depth isobaths southward (the closure depth in that area).

The cross-section chosen for quantification is shown in figure 6. The general direction for the elongation of the island is towards south-west, but the tip of the island is moving toward west, so the cross-section is oriented almost north – south. The result is a surprisingly well match between the sediment entering in the system (1.2 - 1.5 million m^3/yr) and the deposited sediment (1.25 - 1.4 million m^3/yr).
The erosion of the island on the eastern side of the island is, most probably, caused by overwash. This same process explains an important part the accumulation of sediments in the Sahalin bay.

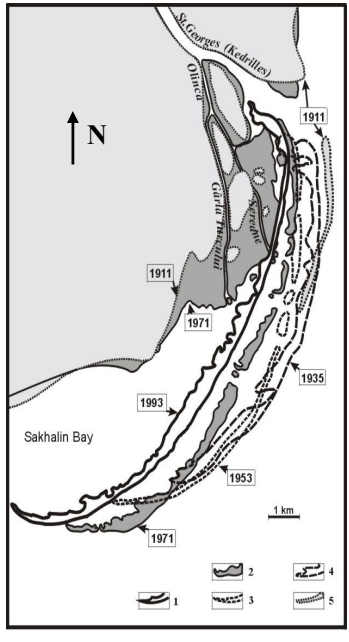

Fig. 5. Evolution of the modern St. George Delta and Sakhalin barrier island (modified after Giosan et al., 1999) 1: coastline in 1993; 2: coastline in 1971; 3: coastline in 1953; 4: coastline in 1935; 5: coastline in 1911.

The sediment accumulated behind the island (Sahalin Bay) has three main sources. The first source is the Sf. Gheorghe arm (with its sub-branches Garla Turcului and Seredne - figure 5). Due to the sheltered environment the grain size of the sediment settled here is, in major proportion, finer than sand (Panin 1998). The second source is the overwash. The overwash processes are stimulated by the elevation of the island which is rather low especially in the central and southern parts (1.5 - 2 m) and the steep slope of the submerged domain eastward. Finally, the third source is "felt" during the storms from southern direction when the sediment (accumulated between profiles 15 and 16 in our computation) is reworked by the waves and transported into the gulf.

The explanation that we propose for the evolution of the Sahalin spit island is taking in account the fact that longshore sediment transport is just one of the factors involved in this process. Observing the evolution of the island (figure 5) it can be noticed that the length of the island is growing constantly since it is formed, so erosion produced by the longshore transport is not responsible for the continuous migration toward land of the island. A significant erosion of the island due to the longshore transport will lead, eventually, to the disappearance of the island, since there is no accumulation on the landwards side of the island. The only process that can be hold responsible for this migration is the overwash. However, the longshore

transport and the Sfantu Gheorghe branch sediment input are the main source for continuous elongation towards south-west of the island.

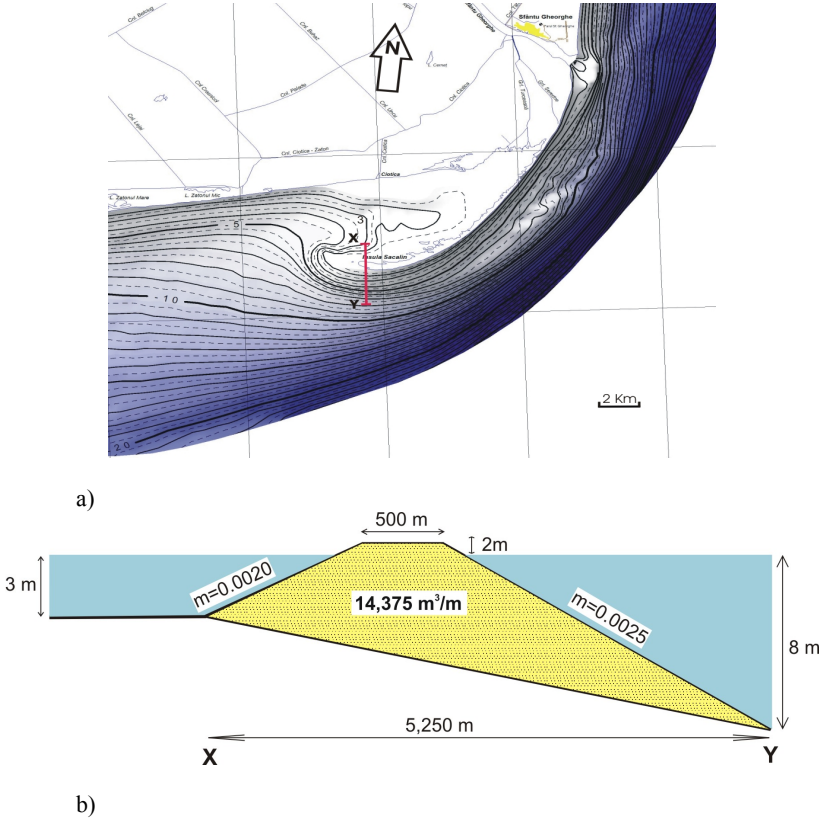

Fig. 6. The cross section used to compute the volume of sand accreting every year in the southern part of the Sahalin island; a) location; b) cross section, m is the slope (not to scale).

A strong argument for this is the good correlation between the quantity of sediment brought into island domain by the longshore drift and the river with the quantity stored every year at the southern tip of the island domain.

The longshore transport gradients in the figure 2 (gray rectangle), especially between profiles 11 and 14 show an ideal situation, since we computed the net alongshore transport capacity. The longshore current from northern direction is having an important source of sediment to erode (area between profiles 2 and 11), but the longshore drift caused by the southern waves is virtually unsaturated with sediments

when it is reaching the Sahalin island. Then, it starts to erode, but very soon (between profiles 12 and 13) the longshore drift loses its transport capacity due to the change in the coastal orientation. When the direction of the longshore drift is changing again (to northern direction) the sediment moved previously by the southern drift along with a new quantity brought by the river and northern drift is transported and deposited at the southern tip of the island. The explanation for the accumulation of the sediment in this area is the fact that the northern longshore drift is losing the transport capacity due to the change of the shoreline orientation (profiles 12 - 14).
The sediment transport between profiles 14 and 16 (figure 2) is not reliable in terms of quantity since UNIBEST CL+ was not designed to model spit islands. However, the trend of the sediment transport seems realistically, since this zone is one of the sediment sources for the clogging of the Sahalin bay.

Section Sahalin - Portita inlet
There are two sectors here: F, with a rate of erosion of 0.4 m/yr and G, with a rate of accretion of 0.6 m/yr. The area corresponding to the eastern half of the sector H and the sector I is described to be erosive, but the western half of the sector H the shoreline is, on average, stable (Panin, 1998). The erosion rate described for eastern half of the H sector is big (10 m/yr) (Panin, 1998), but it seems to be rather a local feature since the neighboring sectors are stable.

7. Discussion and conclusions

The sediment circulation in the studied area is mainly controlled by two wave directions sectors: one from north to north east and the other one from south to south west. However, waves from the northern directions occur more frequently and are associated with larger energy.

The most "energetic" area is the Sahalin spit island domain, in correspondence with the computed closure depths (up to 11.6 m), but also with the maximum quantity of sand transported by the longshore current. The two important factors contributing to this are the full exposure of the western side of the island to both important wave directions (northern and southern) and the rather steep slope of the submerged beach.

The majority of the computed erosion and accretion matches very well with the direct observations. An exception is the position of the shoreline in 1909 from figure 4. According to this map an average erosion rate for the Garla Imputita - Casla Vadanei was over 30 m/yr, three times larger than the computed one. A possible explanation could be the flooding of a large part of the aerial beach, a situation which often occurs in low lying sediment starved coastal zones.

The Sahalin spit island domain is able to store large quantities of sediment, brought by the longshore current and Sfantu Gheorghe branch, through the continuous elongation towards south-west. Cross-shore processes like overwash are responsible for the movement of the island towards the mainland by erosion at the more exposed side, the eastern one, and accumulating on the western side in the quieter

environment of Sahalin Bay. In the case of the elongation of the Sahalin spit we were able to quantify the volumes of sediment moved, but for the Sahalin bay only qualitative explanations were given. In order to quantify also here the volumes of sediment more measurements are required, especially on overwash processes and the input of the fine sediment into the bay through Garla Turcului and Seredne branches. Nevertheless the authors do not exclude the hypothesis that some of the sediment is lost from the system being carried to larger depths than the closure depth. Further, to the south west, longshore transport plays a more important role in the shoreline evolution. According to our computations the net transport is towards south and of small amplitudes. This is not matching with all the descriptions of the area. A possible explanation is the link with the moment when the observations were made. For example, the Perisor - Periteasca (between profiles 8 and 12 in figure 3) is described by Panin (1996), as stable, but with back and forth movements, depending on the energy level of the considered year. Since the data used for derivation of the wave climate and, subsequently, the longshore transport cover ten years (1991 - 2000) we conclude that, over all, a good match was achieved between the computation and the measurements.

Abstract: Measurements of suspended sediment concentration profiles, *C-Profiles*, and hydrodynamic conditions were obtained in the surf zone on a barred beach composed of fine sand using streamer traps. A simple model was used to estimate the total longshore sediment flux. *C-Profiles* predicted for wave-current conditions were found to compare favorably with the field data. In some cases the cross-shore distribution of LST exhibited two peaks associated with wave shoaling and breaking over the bars. Comparisons between present results and predictions from well-known longshore transport formula and a formulae for sediment transport in combined wave-current conditions generally show good agreement. The results indicates that sediment transport processes in the surf zone are not markedly different from those operating in unidirectional and combined wave-current flows under non-breaking wave conditions. The work contributes to the body of published field data by documenting the rates and cross-shore distribution of LST at a previously unstudied field site.

INTRODUCTION

The quantification of hydrodynamic conditions and sediment flux in the surf zone is required in a range of practical engineering applications (e.g. beach nourishment, design of offshore breakwaters and other coastal defence structures). In this zone, sediment is mobilised primarily by oscillatory wave-induced flows. If the wave angle relative to the shoreline is less than 90^{o} sediment is transported by a longshore wave-induced current. Sediment can be also transported onshore and offshore by the combined action of

asymmetric wave-induced flows, undertow and infragravity waves which together give rise to the formation of a range of familiar beach features. Here we focus only on longshore sediment transport (LST) and exclude swash processes.

The measurement of LST in the field presents many challenges. In the surf zone, air bubbles preclude the use of the acoustic instruments and optical techniques are better suited to fine sediments. Furthermore, instruments designed for work in deeper water are relatively delicate and unable to withstand breaking wave conditions. Methods employed in the past to measure LST include interception and tracer techniques. However, there are considerable discrepancies between measured and predicted LST and much of the available field data is subject to considerable errors (Greer and Madsen, 1979).

This paper makes use of time-averaged vertical suspended sediment concentration profiles, *C-Profiles*, measured across the surf zone using streamer traps. The most suitable method for prediction of the measured *C-Profiles* based on available hydrodynamic information is identified. A semi-empirical modeling approach based on well-established formulae is then used to calculate the rate of LST. By necessity, the model makes a number of simplifying assumptions about wave transformation across the surf zone, bedform morphology and the cross-shore profile of the longshore current. Where possible the model is validated with field data. Cross-shore variability in LST and its relationship to surf zone morphology are examined and comparisons are made between predicted LST from the present model with LST predicted by other well-known approaches.

FIELD SITE, EQUIPMENT AND MEASUREMENTS

The measurements of LST were obtained at Cassino, Rio Grande do Sul, Brazil (Fig. 1) on a very long, open ocean dissipative beach composed of fine sand. The site has a mean semidiurnal tidal range $O(0.5$ m) and waves typically have mean annual significant height (H_s) of 1.4 m and peak period (T_p) of 7 s to 9 s. Samples of suspended sediment transported by the longshore current were obtained at a range of heights above the bed using streamer traps (STs, Fig. 1a). These followed the design of Kraus (1987) and comprise a series of 10 nets made from polyester monofilament sieve cloth with a mesh size of 63 μm arranged in an equally spaced vertical array on a steel sampling frame. On the ST, nets are held open to the flow using a metal frame 9 cm high and 14.5 cm wide. Beach profiles and frame locations were measured using a total station. ST frames were deployed to face into the longshore current in the surf zone by two operators standing clear of the trap openings. Surficial bed sediment samples were also obtained at the deployment site and STs were removed after a sampling period of 10 minutes (Fig. 1b). Ripples were observed to be locally present but were not measured.

The local longshore current speed, U_L, was measured in two ways: by timing a drogue float between two fixed points 200 m apart, equidistant from a given ST location and at the same offshore location; and by tracking approximately neutrally buoyant floats using a mm wave radar (*c.f.* Bell et al., 2004). The average wave height H, the average breaking wave height, H_b, and wave period, T, for approximately 150 incident waves

were estimated visually. The wave approach angle relative to the shoreline in the breaker zone, α, was measured using a compass bearing or measured directly from the radar images.

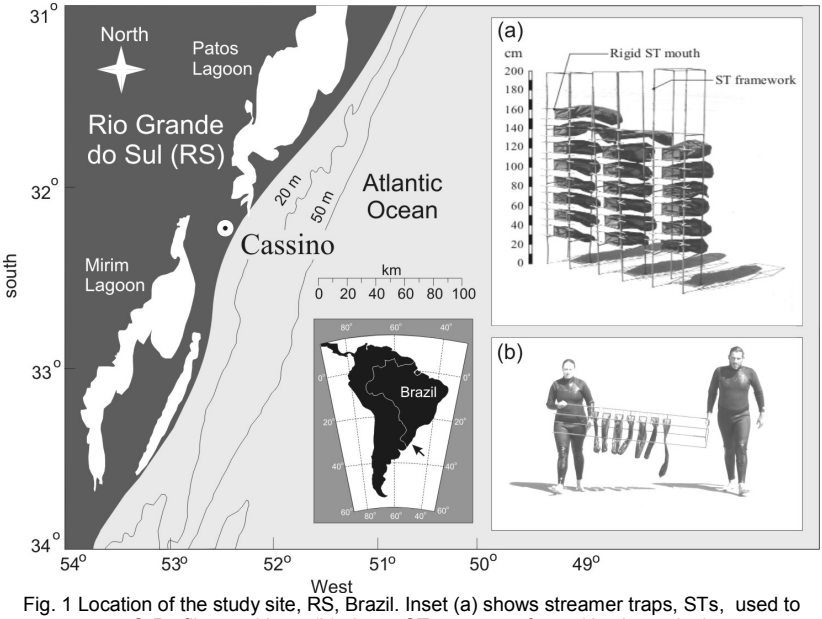

Fig. 1 Location of the study site, RS, Brazil. Inset (a) shows streamer traps, STs, used to measure *C-Profiles*; and inset (b) shows ST recovery after a 10 minute deployment.

Field measurements were undertaken at Cassino on 7/12/2004, 12/3/2005, 27-28/5/2005 and 23/10/2005. Although **all** ST data have been used to study *C-Profiles*, here for brevity we only present modelling results from **three** experiments on 12/3/2005, 28/5/2005 and 23/10/2004, hereafter referred to as Case 1, 2 and 3, respectively. These studies span the range of conditions pertaining during the other experiments. The measured beach profiles and ST locations are shown in Fig. 2 and the measured hydrodynamic conditions are summarized in Table 1. During May and June 2005, further useful data related to the cross-shore distribution of wave height and longshore currents were obtained[1]. By choosing periods when hydrodynamic and meteorological conditions were closely similar to those pertaining during the ST campaigns it was possible to approximate cross-shore profiles of wave height, $H(x)$ and longshore current speed, $U_L(x)$ for modeling studies of Cases 1 to 3.

DATA ANALYSIS

Hydrodynamic measurements obtained by individual observers were cross-checked for

Table 1. Measured hydrodynamic conditions during ST measurement campaigns at Cassino, RS, Brazil. (Gaps indicate where measurements were not made as conditions were not observed to change). Modelling test cases 1, 2 and 3 are identified here.

is reported in Williams et al, (2007). In the laboratory, ST and surficial bed sediment samples were washed from the nets and oven dried at 110°C before being weighed, sieved at 0.25 phi intervals and analysed for $CaCo_3$ content. Since ST data are an integrated measure of the total suspended sediment flux at a given height above the bed, $M(z)$, determination of the *C-profile* requires knowledge of the vertical longshore current profile. In the absence of current profile data it is necessary here to assume that in water

depth, h, in the range $0h < z < 0.5h$, the vertical current profile takes a logarithmic form (Wang et al., 2002) defined as

$$U_L(z) = \frac{U_*}{\kappa} ln\left(\frac{z}{z_o}\right) \quad (1)$$

where $U_L(z)$ is the measured longshore current speed at height z above the bed, U_* is the bed friction velocity, κ is von Kármáns constant (0.4) and z_o is the total bed roughness (see below). U_* is defined in terms of the skin friction bed shear stress τ_c as $\sqrt{\tau_c/\rho}$ where $\tau_c = \rho Cd U^2$, ρ is the fluid density (1023 kg/m^3 for sea water and salinity of 35ppt), and the drag coefficient, Cd, is given by

$$Cd = \left[\frac{\kappa}{1 + ln(z_0/h)}\right]^2 . \quad (2)$$

For $z > 0.5h$, $U_L(z)$ is assumed to be constant with depth up to the water surface. This type of vertical velocity profile is a reasonable approximation to longshore current profiles measured in the laboratory (e.g. Wang et al., 2002) and in the field (e.g. Garcez Faria et al., 1998). The suspended sediment concentration in g/l, C, was then computed at each sampling height using $C(z) = M(z)/[U_L(z)$ x 0.145 x 0.09 x 600].

MODELLING

The modeling outlined here is used to predict the total LST across the width of the surf zone. In the model, cross-shore distributions of U_L and H (Williams et al., 2007) are imposed on the measured bathymetry and wave period is held constant. A measured cross-shore gradient in D_{50} ranging from 0.18 mm at the shoreline to 0.1 mm at the seaward boundary defines the bed sediments. Although suspended sediment grain size variations with height were measured (Esteves et al., 2007), these are not included in the present model. Interactions between the waves and the longshore current, the resulting bedforms and resuspension and transport of sediments is then simulated at 2 m intervals across the surf zone using some well-know approaches outline below. Each model simulation point along the cross-shore profiles is hereafter referred to as a node.

Sediments

The physical and dynamic properties of the sediments, expressed as settling velocity and entrainment threshold, determine the sediments response to hydrodynamic forcing and are critical parameters governing sediment behavior irrespective of the transport mode. Here the threshold bed shear stress, τ_{crit}, for incipient grain motion is given by $\tau_{crit} = \theta_{crit} g(\rho_s - \rho) D_{50}$ where the critical Shields parameter, θ_{crit}, is defined by the dimensionless grain size parameter D_* so that

$$\theta_{crit} = \frac{0.3}{1 + 1.2D_*} + 0.055\left[1 - exp(-0.02D_*)\right] \quad (3)$$

and $$D_* = \left[\frac{g(s-1)}{\nu^2}\right]^{1/3} D_{50} \quad (4)$$

(Soulsby, 1997). Here s is the ratio of grain to fluid density (ρ_s/ρ) and ν is the kinematic viscosity of the water. Here we use: $g = 9.81$ m^2/s, ρ_s for quartz grains = 2650 kg/m^3 and $\nu = 1.36 \times 10^{-6}$ m^2/s. Estimates of the settling velocity of grains in suspension was calculated using the optimised formula

$$w_s = \frac{\nu}{D_{50S}}\left[\left(10.36^2 + 1.049 D_{*S}^3\right)^{1/2} - 10.36\right] \quad (5)$$

(Soulsby, 1997), where D_{50s} is the **measured** suspended sediment grain diameter (Esteves et al, 2007) and D_{*s} is the D_* values for that sediment. The threshold depth-mean current speed, U_{crit}, for $D_* > 0.1$ is given by Soulsby (1992)

$$U_{crit} = 7\left(\frac{h}{D_{50}}\right)^{1/7}\left[g(s-1)D_{50}\theta_{crit}\right]^{1/2} \quad (6)$$

Bed roughness

Establishing accurately the hydrodynamic roughness of the bed is pivotal in all approaches to estimating bed shear stresses and associated cohesive sediment responses. In the surf zone, where there may be bedforms and active sediment transport, the total bed roughness, z_0, has three components: roughness due to the bed sediments, z_{0G}, defined a $D_{50}/12$, roughness due bedforms (form drag), z_{0R}; and roughness due to sediment transport, z_{0Q}. z_{0R} can be defined as

$$z_{0R} = \Theta\frac{\eta^2}{\lambda} \quad (7)$$

(Soulsby, 1992),where Θ is a scaling parameter in the range 0.3 to 3.0 and λ and η are the wavelength and height of bed ripples, respectively. A widely used equation for z_{0Q} that does not require knowledge of z_0 is *a priori* is $z_{0Q} = 0.00533 U_w^{2.25}$ (Raudkivi, 1990), where U_w is the wave orbital velocity (see below). Thus

$$z_o = z_{0G} + z_{0R} + z_{0Q} = \frac{D_{50}}{12} + \Theta\frac{\eta^2}{\lambda} + 0.00533 U_w^{2.25} \quad . \quad (8)$$

Although the cross-shore distribution of D_{50} was measured, Eq. 8 still relies on estimates of bed morphology coming either from existing equations that predict the dimensions of bedforms or from field observations of bedforms in the surf zone. Since it was not possible in the study to measure bedforms, and surf zone roughness in weak to moderate wave conditions is likely to be dominated by wave-generated bedforms, estimates of η and λ were obtained using the approach of Grant & Madsen (1982) as detailed in Appendix 1.

Waves

Analysis of cross-shore wave properties was undertaken primarily to obtain estimates of the wave-induced bed shear stresses required by formulae given below. Although wave shoaling and breaking processes in the surf zone are highly non-linear and complex Deigaard et al. (1991) show that wave induced stresses under breaking and shoaling waves are not **on average** significantly different from unbroken waves and thus application of conventional approaches to estimation of wave-induced bed shear stresses are possible. Using the appropriate $H(x)$ distribution, estimates of $U_w(x)$, were obtained

at model nodes using Deans stream function wave theory (Dean et al., 1983)[2]. Estimates of the peak wave-induced bed shear stress, $\hat{\tau}_{ws}(x)$, were then obtained using $\hat{\tau}_{ws} = 0.5 f_w U_w^2$, where the wave friction factor, f_w, is defined in terms of the relative roughness, r, by Swart (1974) as $f_w = 0.3$ for $r \leq 1.57$ and $f_w = 0.00251 exp\left(5.21 r^{-0.19}\right)$ for $r > 1.57$. Here $r = A_o / k_s$ where A_o is the orbital amplitude of the waves ($U_w T / 2\pi$). For rough turbulent, flat bed conditions, the Nikuradse equivalent sand grain roughness, k_s, is given by $2.5D_{50}$ and $\hat{\tau}_{ws}$ relates to the **skin friction only**. However, in cases where ripples are present on the bed, and sediment is transported as bedload, k_s is defined by the **total bed roughness** z_0 so that $k_s = 30z_0$ (see below).

Longshore currents

Estimates of the longshore current-related bed shear stress profile, $\tau_C(x)$, are required at locations across the surf zone in order to estimate the combined W+C shear stress responsible for mobilization, suspension and transport of sediment. Although longshore currents were only measured at a few locations during the experiments and very few supporting field data exist related to the spatial or temporal characteristics of U_T, most studies indicate that that the cross-shore distribution of U_T is approximately parabolic and vertical velocity distribution conforms to a logarithmic law (Wang et al., 2002; Reniers and Battjes, 1997). Both these characteristics were confirmed by the cross-shore PUV array and by drogue floats (Williams et al., 2007). These measurements showed that in the case of purely wave-driven longshore currents, the maximum current velocities occur close to areas where wave breaking is most intense (Reniers and Battjes, 1997). Estimates of the τ_C were obtained using $\tau_c = \rho C d \hat{U}_L$, where Cd is the total drag coefficient and $\hat{U}_L$ is the depth-mean longshore currents velocity.

W+C interactions and *C-Profiles*

In order to estimate the total suspended load carried by the longshore current it is essential to model *C-Profiles* at all cross-shore locations accurately. In the surf zone, where longshore currents can exceed 0.5 m/s, it is unclear if the characteristics of the *C-profile* are controlled by the current, by the waves or by a combination of the two. Following investigation of *C-Profiles* predictors for current-only, wave-only and combined wave-current, W+C, conditions, the simple single layer model proposed by Williams et al., (1997) was found to give good agreement with *C-Profiles* measured by the STs and was relatively easy to implement in the model. This takes the form

$$\overline{C}(z) = \overline{C}(a)\left(\frac{z + L\alpha_{wc}}{a + L\alpha_{wc}}\right)^{-\alpha_{wc}} \qquad (9)$$

where $\overline{C}(a)$ is the reference $\overline{C}$ value at height a, L is a vertical length-scale parameterising the vortex ejection process in oscillatory flow over ripples, and α_{wc} is a Rouse-type parameter = $w_s / \kappa(U_{*mean} + U_{*max})$. Here the time-averaged W+C shear velocity, U_{*mean}, defines an apparent sediment mixing coefficient and is used to parameterise the quasi-periodic vortex ejection process over ripples and the peak W+C

[2] Matlab routines from http://faculty.gg.uwyo.edu/DSF

shear velocity, U_{*max}, is analogous to the standard turbulent diffusion mechanism. Here we use the algebraic approximation to the W+C model of Fredøe (1984) from Soulsby et al., (1993) to estimate U_{*max} and U_{*mean} at cross-shore nodes. Estimate of *C(a)* were obtained using

$$C_a = \rho_s \left[\frac{0.331(\theta_s - 0.045)^{1.75}}{1 + 0.720(\theta_s - 0.045)^{1.75}} \right] \quad (10)$$

where θ_S is the skin-friction Shields parameter (Zyserman and Fredsøe, 1994). Following Nielsen, (1992) L is defined by the ripple height, η, and grain settling velocity w_s as

$$L = 0.075 \frac{U_w}{w_s} \eta \quad for \quad \frac{U_w}{w_s} < 18 \quad (11), \qquad \text{and } L = 1.4\eta \quad for \quad \frac{U_w}{w_s} < 18 \quad (12)$$

Bedload and total load transport in W+C conditions

Since we have no absolute measure of LST from the present site, it is useful to compare results from the present model with established predictive formulae. Most formulae used to quantify LST make simple assumptions regarding hydrodynamics and sediment processes, and do not consider factors such as barred topography and/or the cross-shore sediment exchanges. The CERC formula is used widely to predict the LST rate Q and is believed in ideal conditions to have an accuracy of ± 30% to 50%. The CERC formula states

$$Q_{CERC} = \frac{K}{16(s-1)(1-p)} \sqrt{\frac{g}{\xi}} H_b^{2.5} \sin(2\alpha) \quad (13)$$

where Q_{CERC} is the volumetric LST rate (m^3/s) integrated across the width of the surf zone, K is the CERC coefficient, p is the sediment porosity (0.32) and ξ is a wave breaker index (0.78). Here we use the expression $K = 1.4\,exp^{(-2.5 D_{50})}$ from Komar (1988). The Kamphuis (1991) LST formula includes the influence of T, beach slope, m, and D_{50} in the form

$$Q_{K91} = 7.9x10^{-4} \left(\frac{1}{(1-p)} \right) \left(\frac{g}{2\pi} \right) H_b^2 T^{1.5} m^{0.75} D_{50}^{-0.25} \sin^{0.6}(2\alpha) \quad (14)$$

A method designed specifically for estimating sediment transport in W+C conditions is given by Soulsby (1997). It applies **only** to rippled beds and in conditions where $U_w < U_L$ and is expressed as

$$Q = A_s U \left[\left(U^2 + \frac{\xi}{Cd_6} . U_w \right)^{0.5} - U_{crit} \right]^{2.4} \left(1 - 1.6 \tan\phi \right) \quad (15)$$

where ξ is an empirical coefficient (= 0.018), Cd_6 is the recommended drag coefficient for a rippled bed (z_0 = 6 mm). The coefficient A_s is defined as $A_{ss} + A_{sb}$, where

$$A_{sb} = \frac{0.005h(D_{50}/h)^{1.2}}{[gD_{50}(S-1)]^{1.2}} \quad (16)$$

for bedload, and for suspended load.

$$A_{ss} = \frac{0.012 D_{50} D_*^{-0.6}}{\left[g D_{50} (S-1) \right]^{1.2}} \tag{17}$$

RESULTS AND DISCUSSION

All measured *C-Profiles* are shown in Fig. 3. Profiles have been grouped based on the shape of the illustrated best-fit line into concave, convex and irregular profiles. In all cases, concave profiles predominate with convex and irregular profiles being associated with location on top of and just landward of an offshore bar, respectively.

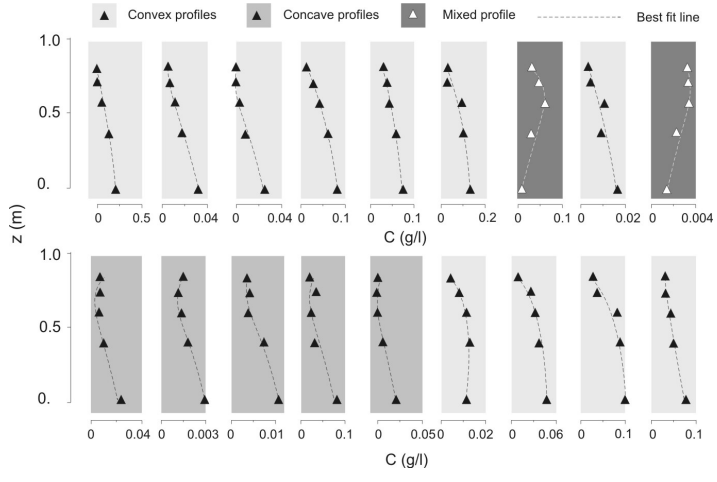

Fig. 3. All *C-Profiles* measured by STs in Cases 1 to 3 with a best-fit line

The shape of *C-Profiles* in Fig. 3 exhibit a good degree of consistency at locations across the surf zone. The principal exceptions to this concern *C-Profiles* measured inshore from the main region of breaking waves in the deepest locations between the shore and the first bar. Here *C-Profiles* show sediment concentrations initially increasing from the bed to approximately 0.5 m and thereafter declining in the expected way. It is thought that at these locations, sediment entrained by breaking waves over the bars is swept into the trough region where wave resuspension is less effective, and where the longshore current is only competent to transport sediment already in suspension. A combination of suppressed sediment entrainment at the bed and the periodic supply of suspended material from above may have resulted in these distorted *C-Profiles*. The exact mechanism remains the subject of further investigation.

A comparison shown in Fig. 4 between all measured *C-Profiles* and *C-Profiles* predicted by Eq. 9 in the range 0.1 m < z < 1 m generally shows good agreement (typically, R^2 = 0.85 or better). Here ST values exhibiting the largest degree of scatter are shown using gray squares. These data values show no systematic trend and are thought to reflect both

the inherent inaccuracy of the ST sampling devices and natural variability of suspended sediment behavior in the surf zone. A reduction in predicted C values by around 4 orders of magnitude between Ca and C at $z = 0.5$ m is typical. Although there is no independent way of verifying the validity of predicted Ca values, the reduction of C with z is predicted independently of the measured *C-Profiles* and thus support the view that predicted Ca values are realistic. As expected from results in Fig. 3, Fig. 4 shows also that some measured *C-Profiles* do not conform to expected behavior. If this was attributable simply to measurement errors, one would expect such profiles to be found at locations other than in the tough behind the inner bar. This is not the case and thus their properties must be considered if a more refined analysis of cross-shore suspended sediment distributions is to be attempted.

The selected model results for cases 1 to 3 in Fig. 5 depict a complicated, but consistent picture of suspended sediment in the surf zone. $H(x)$, $U_L(x)$ and $U_W(x)$ distributions in Fig. 5b shows some modulation of these parameters due to the barred topography of the surf zone (Fig. 5a). Taking into account the various hydrodynamic roughness components described above, including predicted bedforms shown in Fig. 5d, the resulting cross-shore distributions of U_{*mean} and U_{*max} in W+C conditions are shown in Fig. 5c. The bottom 3 panels (Fig. 5e) show predicted $Q(x)$ from the present model and $Q_T(x)$, $Q_S(x)$ and $Q_B(x)$ derived from Eq. 15. In general there is broad agreement between the present model $Q_T(x)$ and $Q_S(x)$. Predictions indicate that $Q_B(x)$ makes only a relatively small contribution to $Q_T(x)$. This might be expected in the present conditions where the longshore current in not greatly in excess of the entrainment threshold, and sediment dynamics are dominated by wave resuspension. Both Case 1 and 3 exhibit similar characteristics with maximum LST predicted between the inner trough and the swash zone, thus reflecting surf zone bathymetry.

In Case 2, wave conditions allowed ST measurements to be obtained at a greater distance from the shoreline. In this case the influence of the second bar is evident and gives rise to two peaks in LST rate, both in the zone displaced shoreward from the outer and inner bar trough regions. In Case 2 we also see less agreement between $Q(x)$ from the present model and $Q_T(x)$ and $Q_S(x)$ predicted by Eq. 15. Reductions in predicted η values correspond to higher shear stresses over the bars and lead to a predicted reduction in bed roughness at suspended sediment. In contrast Eq. 15 utilizes a constant drag coefficient and thus remains unresponsive to possible changes in bed roughness associated with changing hydrodynamic conditions. In this case, peak $Q_T(x)$ and $Q_S(x)$ are correlated with the approximate cross-shore location of maximum U_w and U_L values. The small second peaks in Q_T and Q_S values close to the shore are thought to be an artifact of the imposed $H(x)$ and $U_L(X)$ profiles.

Fig. 6 shows measured and predicted *C-Profiles* from the locations indicated on three upper panels in Fig. 5. Good agreement is shown in all cases supporting the view that the present model is providing reliable predictions of the sediment concentration field across the surf zone.

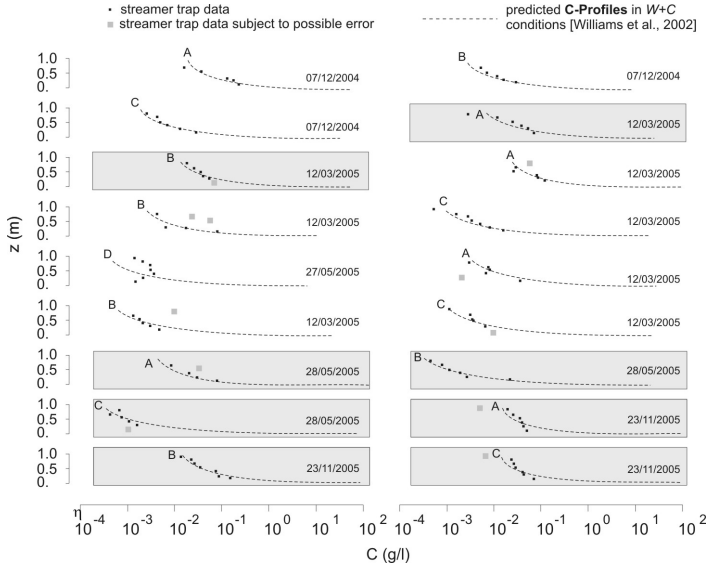

Fig. 4 Comparisons between measured and predicted *C-Profiles* (Eq. 9) for all measured ST profiles. Test cases 1 to 3 are highlighted in gray.

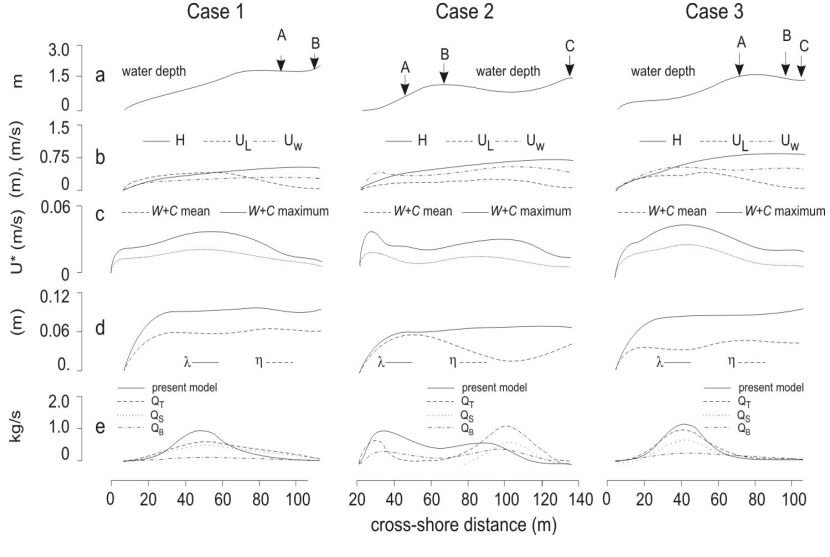

Fig. 5 Predicted ripples morphology, $Q_T(x)$, $Q_S(x)$ and $Q_B(x)$ values and associated hydrodynamic forcing across the surf zone for test cases 1 to 3.

Table 2. Predicted LST rates across the surf zone for Cases 1 to 3, Cassino, RS, Brazil

Case	Date	CERC	K_{91}	Q_T	Q_S	Q_B	$Q_{Present}$
1	12/03/2005	11.09	11.55	12.50	10.49	2.01	10.19
2	28/05/2005	5.11	5.06	4.09	0.93	3.16	4.83
3	23/10/2005	26.03	10.98	13.55	8.64	4.91	12.69

Table 2 summarises predicted values of the total flux, Q_T, from the CERC, Kamphius (1991) and Soulsby (1997) formulae, and from the present model. It shows also the integrated values for Qs and QB predicted by the Soulsby (1997) formula. The largest discrepancy (a factor of approximately two) is found between CERC and present model predictions for case 3.

CONCLUSIONS

New measurements of *C-Profiles* have been obtained across a barred surf zone and add to the body of published field data pertaining to longshore sediment transport. The ability of the present model to predict with reasonable accuracy *C-Profiles* at a number of different cross-shore locations has been verified with field data. Although shear velocity values and bedform dimension obtained from imposed hydrodynamic gradients across the model domain are at best approximations and may not be accurate across the whole model domain, the use of more advanced approaches cannot be supported by the present sparse field data. Although not presented in the paper, model sensitivity studies showed that predicted *C-Profiles* and estimates of the total LST were very sensitive to subtle changes in bed roughness.

The present model is based on formulae primarily developed for wave-only, uni-directional flows or weakly interacting W+C situations. It is therefore interesting to find that even in the complex hydrodynamics of the surf zone, the relationships they define between the applied bed shear stress and sediment mobility remain reasonably robust and the predicted rate of sediment transported across the width of the surf zone by a longshore current is in fair agreement with some well-established bulk formulae. With this in mind it may now be possible with further refinements to investigate the temporal and spatial behavior of LST and thereby improve our present ability to predict accurately LST over extended periods of time.

Abstract: Experiments were carried out in a flume 36 m long and 55 cm wide equipped with a piston wave generator. The sloping bottom consists of a loose material of low density (1.19 kg L^{-1}) with a median diameter d_{50}=0.6 mm in order that Shields and Rouse numbers are of the same magnitude as those of natural environments. Irregular waves are generated according to a JONSWAP spectrum. The waves are measured along the flume and bottom profiles are recorded in between repeated wave sequences. The infragravity modes amplitudes along the flumeare obtained for different wave climates. The correlation between the incident short wave envelope and the infragravity waves clearly indicates that the latter is the consequence of both a break point and a bound long wave release mechanisms.

INTRODUCTION

Field measurements indicate that waves in the infragravity range play a role on beach morphology. The generation of such long period waves can be explained by two different mechanisms. On one hand the breaking is thought to release bound long waves due to wave grouping (Longuet-Higgins & Stewart, 1962). On the other hand wave grouping produces a break point and set-up oscillation that acts as a piston at the wave group period (Symonds *et al.*, 1982). In both cases these incident long period waves reflect on the beach face, interfere with the incident waves to produce long period standing waves known as surf-beats.

Recently, Wang *et al.* (2002) performed velocity and concentration measurements over a beach that was shaped by breaking irregular waves in laboratory flume. A similar topography was obtained in a wave flume and allowed turbulent measurements in the surf zone suspension by Hurther *et al*. (2007). They also observed sediment suspension

concentrations fluctuations at the frequency of a free standing wave. Such laboratory experiments in wave tanks with beaches made of loose material are rare (Dette *et al.*, 2002). Most experimental studies were performed with a rigid bottom topography. Janssen *et al*. (2003) evaluated the long waves generation for a mild slope topography (1:70) molded in sand with a smooth concrete surface. They concluded that the mechanism of bound wave release is dominant. Baldock and Huntley (2002) and Baldock *et al*. (2004) observed breaking forced waves for a steeper uniform slope (1:10) and a barred beach profile. Moreover, the maximum long wave radiation occurs when the mean breakpoint closely coincides with a nodal point of the free standing long wave. The aim of the present paper is to investigate the characteristics of such surf-beats in small-scale mobile bed experiments. We will evaluate their relation to the bottom profile under controlled conditions. More specifically we will compare surf-beat characteristics for a beach at equilibrium and a barred beach in evolution.

EXPERIMENTAL SET-UP

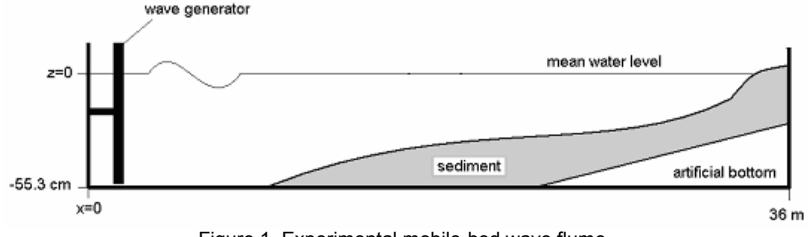

Figure 1. Experimental mobile-bed wave flume.

Our experiments were carried out in a flume 36 m long and 55 cm wide equipped with a piston wave generator (Figure 1). The still water depth is 55.3 cm. The mean overall slope is approximately 1:40. The sloping bottom consists of a loose material of low density (1.19 g cm^{-3}) with a median diameter d_{50}=0.6 mm. In the experiments, the Froude number, the Shields number in the shoaling part and the Rouse number in the breaking zone (ratio of turbulent agitation to the settling velocity of the sediment) are of the same magnitude as those of natural environments. Time and length scales are roughly 1/3 and 1/10. Irregular waves are generated according to a JONSWAP spectrum (peak enhancement factor γ=3.3). For each simulation, we check that these waves conform to the expected spectrum and that they follow a Rayleigh distribution at 2 m downstream of the wave maker. Twelve wave gages mounted on trolleys measure instantaneous water elevations. Records are at least 30 mn long in order to achieve statistical convergence. Bottom profiles are recorded in between wave series.

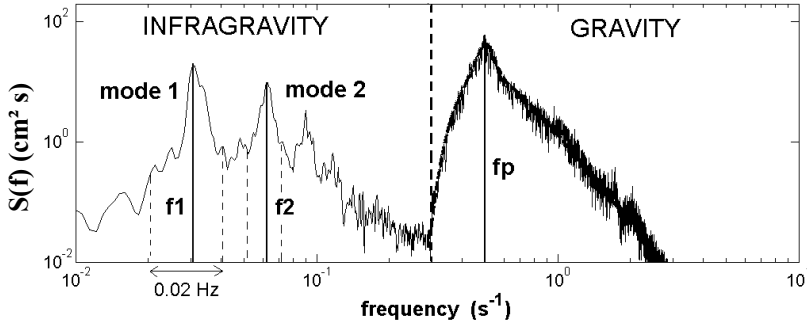

Figure 2. Surface elevation energy spectrum at x=2 m in the flume on the equilibrium beach plotted in Figure 3d (–). Wave parameters: H_{rms0}=7.5 cm, f_p=0.5 Hz, h_0=55.3 cm. First infragravity frequency peak f_1=0.03 Hz.

Spectral estimates *S(f)* were obtained from Fourier transforms of five 50% overlapping data segments, each comprising 32768 points sampled at 50 Hz. A wave spectrum measured at x = 2 m is plotted in Figure 2. Frequencies above $3/5\times f_p$, correspond to the generated JONSWAP spectrum and fall in the "gravity" domain. The generation of low frequency waves – resulting of gravity waves breaking – is clearly visible in the spectral power density below $3/5\times f_p$ (this is the "infragravity" domain). A closer inspection of the low frequency range shows a broad peak at a frequency f_1 around 0.03 Hz. The first harmonic (f_2) of this peak is also clearly visible. The amplitude of the long wave motion associated with both frequencies is evaluated by estimating the energy contained in finite frequency bands of 0.02 Hz centred on peak frequencies. We choose a 0.02 Hz band cutting in order to include the main energy part of the considered peaks.

LONG WAVES STRUCTURE

Comparison for equilibrium profile, transient profile and theory

A wave climate characterized by its peak frequency (f_p=0.5 Hz) and the root mean square wave height at 2 m downstream the wave maker (H_{rms0}=7.1 cm) was run for several tens of hours. Evolutions of H_{rms} and infragravity modes amplitudes (H_{ig}) along the flume are plotted in Figure 3 for two different bottom profiles. These (plotted in Figure 3d) correspond to two different stages. One is a transient stage characterized by a bar that travels onshore at about 1 m/h. This profile shows interesting similarity with the rigid bottom profile in the experiments of Baldock *et al*. (2004). The other profile is at equilibrium in the sense that it changes very little (at plotting precision) over several hours. Note that the barred profile data is more scattered than the equilibrium profile data. The bottom changes between two sets of measurements are not entirely negligible in this case.

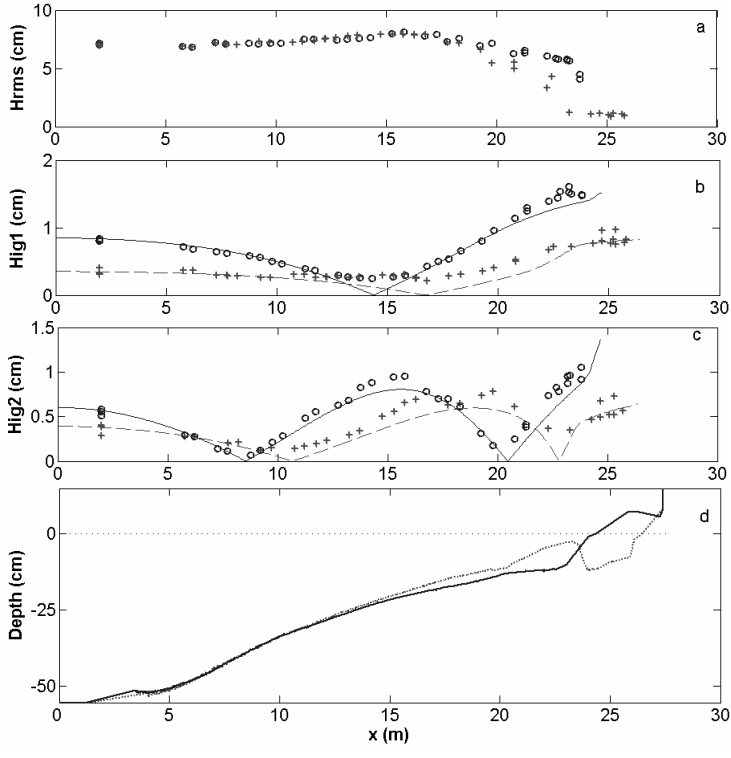

Figure 3. Wave and bottom characteristics along the flume axis for equilibrium profile (o) and transient profile (+): a) root mean square wave height, b) First mode infragravity wave amplitude, c) Second mode infragravity wave amplitude and d) equilibrium bottom profile (–) and transient bottom profile (--).

The infragravity wave energy is plotted in terms of significant amplitude in Figure 3b-c. The first mode amplitude (H_{ig1}) is maximum at the berm, minimum close to x=15 m and large again close to the wave maker. This indicates that a low frequency standing wave with a node somewhere around x=15 m is generated in the flume. Despite the fact that the equilibrium profile is far from being a plane beach, the Wilson formula for a uninodal seiche in a rectangular flume with a plane beach reported by Dean and Dalrymple (1984, p.149) gives a very good estimate of f_1 (*i.e.* 0.03 Hz). In addition, the data are compared with an analytical solution for small amplitude free standing long wave of the linearized Saint-Venant equations (plotted in Figure 3b-c as a solid line for equilibrium profile and a dashed line for the transient profile). The solution yields the modes frequencies, the nodal structure and normalized amplitudes. The overall agreement of the nodal structure is good and the peak frequencies are remarkably well

predicted (*i.e.* f_1=0.031 Hz and f_2=0.063 Hz for the equilibrium profile and f_1=0.024 Hz and f_2=0.047 Hz for the transient profile).

We note on Figure 3b-c that the infragravity significant amplitudes are clearly more important for the equilibrium bottom profile. This difference may be firstly explained by the steep bar of the transient bottom profile, causing a partial waves reflection and decreasing the resonance phenomenon along the flume. . Besides, we note an important decrease of H_{rms} in Figure 3a for the transient profile (+), it corresponds to a large dissipation. Nevertheless this energy is not transferred in the infragravity domain. Figure 4 shows the mean set-up measured for the equilibrium and transient profiles. The waves breaking localised on the bar seems to enhance the time-varying breakpoint mechanism and reinforce the set-up. The energy contained in the set-up could be dissipated through an enhanced undertow current. We emphasize that those observations are only possible in our special configuration of mobile-bed experiments.

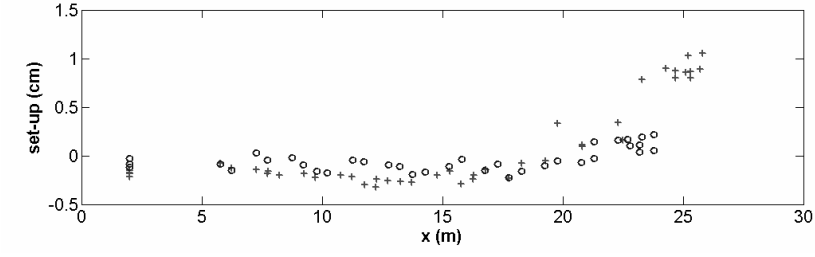

Figure 4. Mean water level along the flume axis for equilibrium profile (o) and transient profile (+) plotted in Figure 3d.

Our results in the barred case exhibit the same features, in terms of long waves amplitudes and node positions, as the results of Baldock *et al*. (2004). Their experiments were performed on a rigid bottom with a barred shape. The generated waves are similar (H_{rms0}=5 cm; 7.5 cm and 10 cm, for f_p=0.6 Hz) to our case, but the mean slope (1:10) is steeper than our transient profile mean slope (1:35). By changing the incoming wave amplitude, they might conclude that a maximum long wave radiation occurs when the mean breakpoint closely coincides with the nodal point of the long wave. In our experiments, the long waves are more energetic on the equilibrium bottom profile for which the breaking point and first mode node position are a few meters apart.

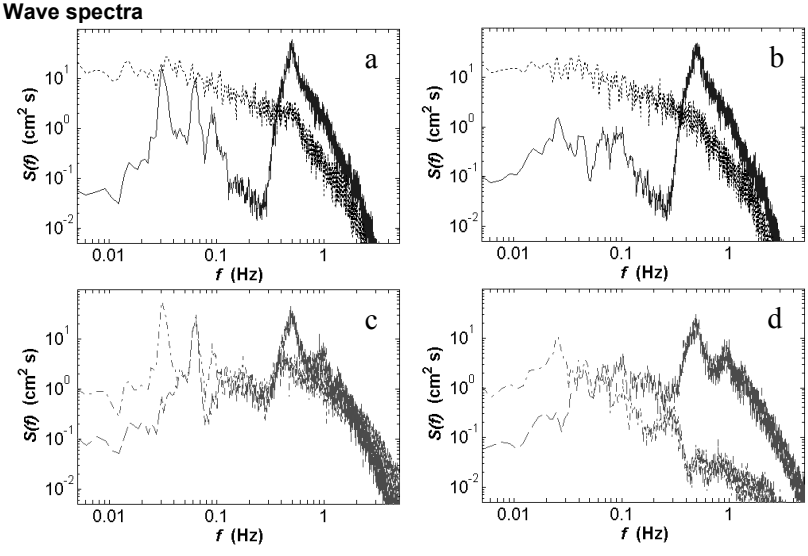

Figure 5. Total wave energy spectra at x = 2 m (—), x = 15.3 m (– –), x = 23.3 m (- . -) and spectrum of the short wave envelope at x = 2 m (.....); for an equilibrium bottom profile (a,c); for a transient bottom profile (b,d).

Surface elevation energy spectra for the two different topographies are plotted in Figure 5.They are presented for three positions along the flume that correspond to the deep region, the breaking region and close to shoreline. The location of the breaking region (maximum of H_{rms} in Figure 3a) is close to the node of the first mode (Figure 3b) and the anti-node of the second mode (Figure 3c). The spectra confirm that the energy in the infragravity domain is a lot larger and the peaks more clearly defined in the case of the equilibrium profile. In the case of the transient profile, we may note that the energy in the gravity domain is very low close to shoreline. Indeed, the short waves have dissipated almost all their energy passing the bar, as indicated by the estimate of H_{rms} for x>23 m in Figure 3a.

In addition, the spectrum of the short wave envelope, obtained via a Hilbert transform of the measured surface elevation data, is plotted in dotted line in Figure 5a,b. This does not account for real energy in surface elevation but as energy possibly contained in the wave packets that could be released in the breaking region. It is important to emphasize that there is no dominant frequency in the wave grouping. This confirms that the frequency peaks of the infragravity waves depend on the beach profile only.

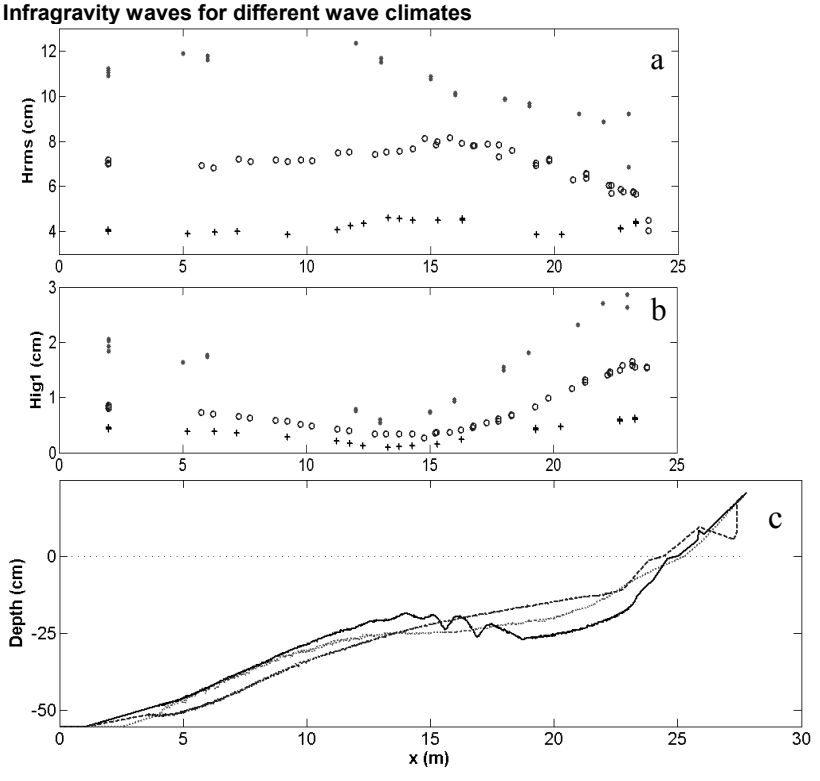

Figure 6. a) Root mean square wave height, b) First mode infragravity wave amplitude and c) bottom profile, for different wave climate: (• ; ...) H_{rms}=11.1 cm, f_p=0.33 Hz; (o ; --) H_{rms}=7.1 cm, f_p=0.5 Hz and (+ ; —) H_{rms}=4 cm, f_p=0.5 Hz.

Different wave climates were generated (varying H_{rms} and peak frequency f_p), that reproduce storms, mild summer climates and very gentle climates. The Figure 6 synthesises the H_{rms} and H_{ig1} data for these three different climates. We note that incident short waves have a direct influence on the long waves amplitude. H_{ig1} is clearly more important for the storm type of climate (•). The maximum of the H_{rms} corresponds to the beginning of the wave breaking location and its decrease is linked to the wave energy dissipation. We observe in Figure 6 a clear distinction between break point positions of the different climates: 12 m for H_{rms}=11.1 cm (.); 16 m for H_{rms}=7.1 cm (o) and 24 m for H_{rms}=4 cm (+). In contrast, the first mode infragravity node position is almost the same in the three cases (13-14 m). Note that the bottom profiles corresponding to the three wave climates are similar in term of length (from the wave-maker to the shoreline) (Figure 6c). We can conclude that the long wave structure mainly depends on the beach morphology rather on the generated wave characteristics.

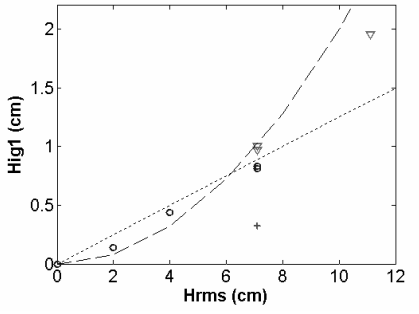

Figure 7. First mode infragravity wave amplitude versus root mean square wave height for different wave climates. (o) equilibrium bottom profile; (▽) quasi-equilibrium bottom profile; (+) transient bottom profile. Linear approximation (…) and quadratic approximation (--).

The first mode infragravity wave amplitudes for different wave climates are plotted on Figure 7 and classified in three categories that depend on the corresponding bottom profile evolution speed. This is estimated by the vertical evolution of the bottom profile ($z(x)$), averaged along the flume, during a time lap ($\Delta t = t_{i+1} - t_i$):

$$V = \frac{\int_{i=1}^{L_{flume}} |z_{i+1} - z_i| dx}{L_{flume} \times \Delta t}. \quad (1)$$

We define that an evolution speed V less than 1.5 mm/h corresponds to an "equilibrium" bottom profile (o); V between 1.5 mm/h and 4 mm/ h is related to a "quasi-equilibrium" (▽) and a "transient" bottom profile is for an evolution speed V larger than 4 mm/h (+). We note again that for a same wave climate (H_{rms}=7.1 cm) the value of H_{ig1} is twice smaller for a transient bottom profile (the cross in Figure 8) compared to equilibrium conditions. The dependency of H_{ig1} to H_{rms} should characterize the long wave generation mechanism. A quadratic relation would correspond to the bound waves release, whereas a linear relation would characterize the break point oscillation mechanism (Baldock & Huntley, 2002). According to the experiments performed by Baldock *et al.* (2004) on a barred rigid bottom (slope 1:10), long waves are shown to be linearly dependent on the incident short wave amplitude both offshore and shoreward of the breakpoint at all frequencies. In our case, the number of different wave climates simulated is too weak to determine a clear tendency in Figure 7

LONG WAVE MOTION CORRELATION WITH THE SHORT WAVE ENVELOPE

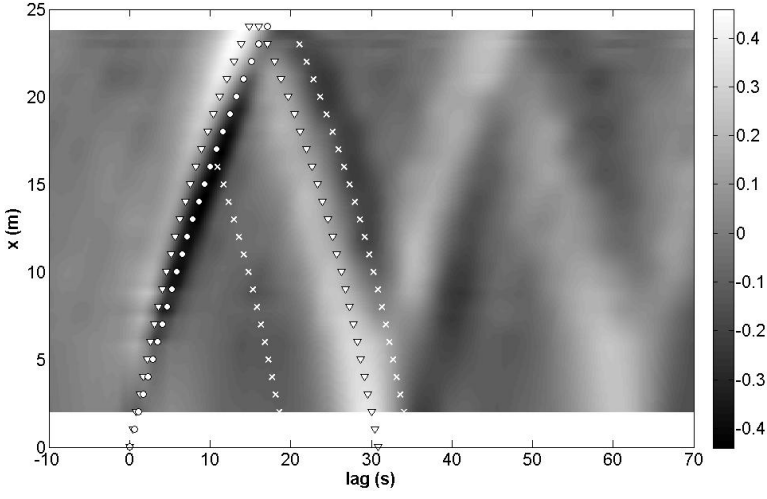

Figure 8. Cross-correlation between the infragravity waves and the short wave envelope at x=2 m, equilibrium bottom profile. Group celerity (for f_p=0.5 Hz): (o); phase celerity (= $\sqrt{gh}$) for positive correlation (▽) and negative correlation (x).

Figure 8 shows the cross-correlation between the short wave envelope in the constant depth region of the flume (x=2 m) and the total low pass filtered surface motion (f<0.3 Hz) along the flume axis. The high spatial resolution of the experimental data allows, using an interpolation function, a presentation of the sequence of correlation functions as quasi-continuous in space. A black ridge corresponds to a negative correlation and a white ridge represents a positive correlation. There is a negative correlation for lags close to zero at x=2 m. This corresponds to the locally forced incident bound long wave, which is out of phase with the short wave envelope (Longuet-Higgins & Stewart, 1962). This black ridge matches the phase-plane trajectory at the group celerity (represented by circular markers on Figure 8). The lag is increasing and the correlation becomes stronger further shoreward as the bound wave amplitude increases due to the shoaling of the short wave and represents a larger proportion of the total long wave energy (at $\tau\approx$10 s and x=15 m). This bound wave is released during breaking and still negatively correlated to the wave envelope at lags $\tau\approx$18 s at x=2 m and $\tau\approx$20 s at x=23 m. The free waves resulting of the bound wave released move to the phase celerity, which is equal to $\sqrt{gh}$ in shallow water (cross markers). We may discern a light black ridge under the white crosses which may correspond to the free wave released close to x=15 m at $\tau\approx$10 s, moving offshore to reach x=2 m at $\tau\approx$18 s.

On the other hand, a positive correlation is present for $\tau \approx 2$ s at x=5 m. It may correspond to a dynamic set-up generated by the breaking of the larger wave packets. The correlation becomes very strong at the shoreline ($\tau \approx 13$ s). We notice that the triangle markers (celerity $\sqrt{gh}$) match the white ridge from $\tau \approx 2$ s to $\tau \approx 16$ s. This is in agreement with Symonds *et al.* (1982) who showed that the long waves generated by breakpoint oscillations propagate freely at the phase celerity. The position and intensity representations of long waves peaks can be distorted due to the overlapping between the long wave resulting of breakpoint oscillations (positive correlation) and the bound long wave released (negative correlation).

Next, the long waves are reflected and propagate offshore (from x=24.5 m to 0) as seen on the correlation signature: a white ridge from $\tau \approx 17$ s to 31 s; and a black ridge from $\tau \approx 21$ s to 35 s. According to the theory, the reflected long waves travel at the phase celerity (plotted with triangle and cross markers). At larger lags, both negative and positive correlation peaks are still present but damped. This indicates that the long waves reflect on both ends of the flume but are not amplified. We recall that Janssen *et al*. (2003) concluded that the bound wave release in their mild slopes laboratory experiments (~1:70) was dominant, while Baldock *et al*. (2004) observed breaking point forced waves for stronger slopes (~1:10). Both mechanisms are clearly observed in our case of an equilibrium beach profile (~1:45).

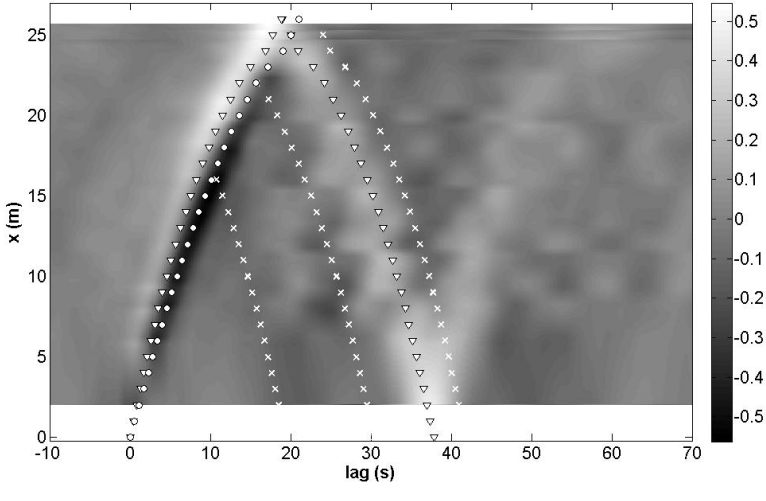

Figure 9. Cross-correlation between the infragravity waves and the short wave envelope at x=2 m, transient bottom profile. Group celerity (for f_p=0.5 Hz): (o); phase celerity (= $\sqrt{gh}$) for positive correlation (▽) and negative correlation (x).

For the transient bottom profile, the correlation picture shown in Figure 9 is in marked contrast. After reflection the correlation peaks have weaker values and we note a quicker and greater damping compared to the equilibrium case. The bound long wave signature (black ridge) is seen from $\tau \approx 0$ s at x=2 m to $\tau \approx 18$ s at x=23 m but not really at the shoreline (x=25.8 m). It may be due to reflection and dissipation of long waves over the bar positioned at x=23 m. We notice again that the bound long wave travels at the group celerity (circular markers).

Clearly, the dynamic set-up induces again a positive correlation (white ridge) evolving at phase celerity (triangle markers), starting for $\tau \approx 2$ s at x=5 m and becoming stronger close to $\tau \approx 18$ s at x=25.8 m. The break point mechanism is apparently dominant for this topography that is closer to Baldock *et al*. (2004)'s experiments. We also note that the bound long wave releases a free wave offshore at nearly $\tau \approx 12$ s and x=15 m (light black ridge under cross markers). We observe two negative correlations (under cross markers): from $\tau \approx 17$ s at x=23 m to $\tau \approx 30$ s at x=2 m; and from $\tau \approx 22$ s at x=25 m to $\tau \approx 38$ s at x=10 m. Those correspond to released bound long waves, partially reflected by the bar (x=23 m) and the berm (x=25.8 m). This probably leads to the weak correlation for larger time lags ($\tau > 60$ s). Bound wave release and breakpoint forcing do not reinforce the generation of the infragravity waves as for the equilibrium beach profile.

BEGINNING OF THE WAVE SEQUENCE

The presence of significant infragravity waves spectral peaks at the shoreline does not necessarily imply resonant amplification. The generated wave packets are not necessarily in phase with the radiated long waves since the incident short wave groups do not have a dominant frequency (as shown by the short waves envelope spectra in Figure 5). In that sense, seiching is not really stationary in the flume. To illustrate this point, we plot in Figure 10 the beginning of the wave sequence. In Figure 10a, the short wave packets in the deep region are visible. They induce a modulation of the mean level close to shoreline. Resulting low frequency motions are shown in Figure 10d. The main period of about 32 s, corresponding to f_1, is sometimes observed. For instance, at x=23.8 m, the peak for $t \approx 34$ s is enhanced for $t \approx 66$ s. In that case, a large waves packet has arrived in the breaking region in phase with the return of the generated long wave. This is not a general feature. The signature of a long wave is generally not seen after a couple of flume travel lengths. The main period of 32 s is not visible in the infragravity wave signal corresponding to the deep region for $t > 130$ s in Figure 10d. In that sense, we do not notice any amplification in the long wave generation process.

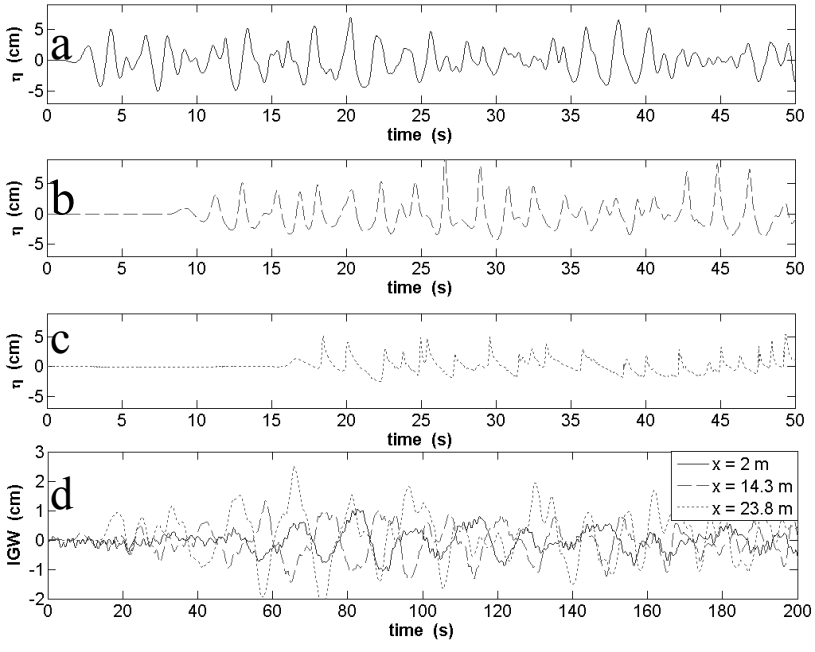

Figure 10. Surface elevation in the deep (a), breaking (b), shoreline (c) regions; and infragravity waves (d) for the equilibrium bottom profile.

CONCLUSION

The experiments show that the long wave structure strongly depends on the beach morphology rather than on the generated short wave characteristics. The nodal structure of the infragravity waves is determined by the beach shape that is, mainly the distance between the wave-maker and the shoreline.

Increasing the incoming wave amplitude increases the long wave amplitude but too few experiments were conducted for precisely determining a dependency in between linear and quadratic.

The experiments of Baldock et al. (2004) and Janssen et al. (2003) indicate that the breakpoint oscillation mechanism is prevailing and could be the result of a steep beach slope (~1:10), while the bound wave release mechanism could be dominant for a weak beach slope (~1:70). In our case, the loose bottom has a beach slope of about 1:40 and both mechanisms are clearly observed as shown by the correlation between the short waves envelope and the long waves.

The infragravity waves are more energetic on the equilibrium bottom profile compared to the transient barred profile. It is suggested that the beach topography evolves as to reinforce both the bound long wave release and the dynamic set-up generation.

Abstract: The paper describes large-scale laboratory experiments performed with simultaneous measurements of suspended sand concentrations, free surface elevations and three-component velocities (including turbulent fluctuations) at several levels above the sea bed. The data from these experiments are used to develop a more correct description of the contribution of vertical velocity to the convective sand flux and the relationships between fluctuations of turbulent kinetic energy and wave energy dissipation for the estimation of local sand suspending and advection to the temporal variation of suspended sediment concentration.

INTRODUCTION

In traditional models only the time averaged characteristics of water circulation, sediment and pollutant transport processes are considered, without taking into account the group structure of waves, their transformation within the coastal zone and contribution of phase shifts between sediments and the fluid at different frequencies of an irregular wave spectrum. Some advances have been achieved as a result of field research in the last years, which show that the group structure of waves and infragravity waves have considerable influence upon the sediment transport in the

zone of the wave transformation and breaking. Such investigations need to be continued with the emphasis on precise laboratory experiment using a broad range of parameters.

The hypothesis is that a physical model of temporal-spatial fluctuations of sand suspension and transport is possible on the basis of the mechanisms of convective suspension, determination of phase and amplitude ratios between the suspended sediment concentration (SSC), turbulent kinetic energy (TKE) and losses of wave energy due to wave breaking, allowing the estimation of the contribution of local convection, diffusion and advection of sediments to form the concentration field over rippled and plane beds.

Existing data allow neither the correct discrimination of the contribution of vertical velocity to the convective sand flux nor the relationships between fluctuations of turbulent kinetic energy and wave energy dissipation, to the estimation of local sand suspending and advection to the temporal variations of SSC (Kos'yan et al, 2001). Therefore in 2006 new large-scale laboratory experiments ("Hannover-2006") were performed in the LARGE WAVE CHANNEL (GWK) of the Coastal Research Centre (FZK) in Hannover. Simultaneous measurements of SSC, free surface elevations and three-component velocities (including turbulent fluctuations) were carried out at several levels above the sea bed.

LARGE – SCALE EXPERIMENTS

The physical simulation of dynamic processes in the coastal zone at prototype scale is extremely important to keep the similarity of both hydrodynamic and lithodynamic processes. The LARGE WAVE CHANNEL (GWK) of the Coastal Research Centre (FZK) in Hannover has a total length of 303 m, a width of 5 m, a total depth of 7 m and the maximum water depth is 5 m. For the experiments a sand bed was installed (Fig. 1). The wave generator is absorption controlled and allows waves up to 2 m depending of the local water depth along the channel. The measuring equipment used for the experiments consists of:

- Wave gauges (resistance wire type) for measurement of surface elevation along the wave channel (Fig.1)
- Optical turbidimeters for measurement of suspended sediment concentration at 4 different levels above the sea bottom (Fig. 2A);
- 3-component acoustic velocity sensors (type Vector) for measurement of wave induced currents at 2 different levels above sea bottom (Fig. 2 B);
- Sediment accumulators at different levels (Fig. 2E)

The analog sensor signals were sampled by a parallel 80-channel analog-to-digital converter (ADC) with a frequency of 40 Hz and recorded on a computer. A sample and hold modus guaranteed synchronization of all measured signals.

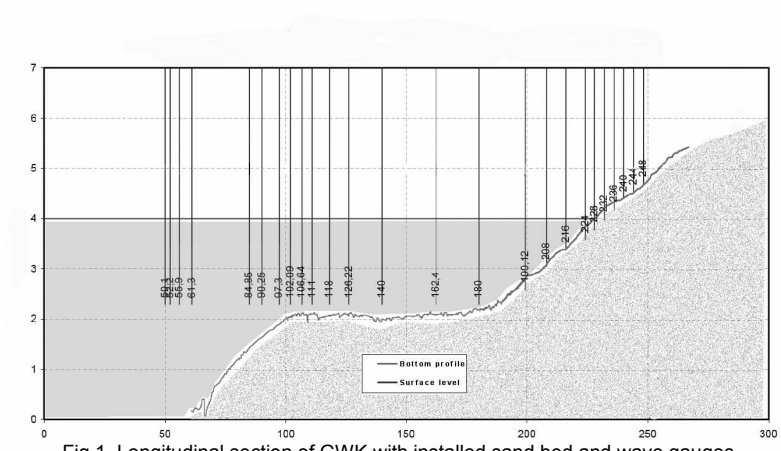

Fig.1. Longitudinal section of GWK with installed sand bed and wave gauges

Fig. 2. Installed turbidimeters, velocity sensors (Nortek-Vector) and sediment accumulators (left hand photo). Positioning of turbidimeters (upper right photo) and velocity sensors (Nortek-Vector) (lower right photo)

Two main test series were performed with respect to the simulated wave spectra:

- Irregular waves with spectra characteristics occurring at the Black Sea
- Irregular waves with artificial spectra where the peak periods were kept constant (Tp = 5 s) and the significant wave heights and spectral steepnesses were changed consecutively (H_{sig} = 0.9 to1.1m, wave spectrum steepness index γ =1.0 to 10.0).

RESULTS

In the following some first results from the ongoing analysis are described. In Fig. 3 examples of synchronously recorded time histories for some sensor signals are plotted. The time histories in Fig. 3 show the suspended sediment concentration fluctuations measured at distances of 7, 15, 25 and 40cm above sea bottom (1 – 4), the surface elevation H (5) and the wave induced velocities, where v_x is the horizontal cross-shore component (6) and v_y the vertical component (7).

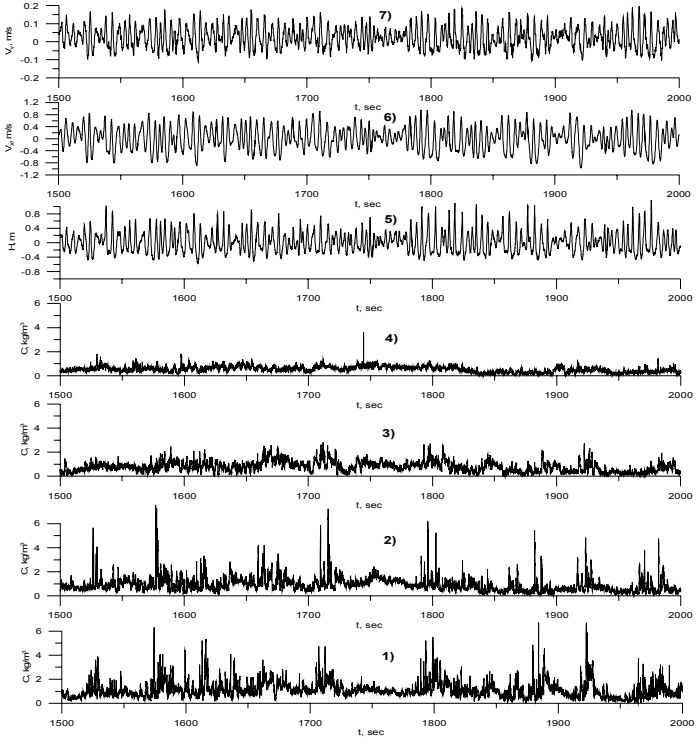

Fig. 3. Fragments of the recorded suspended sediment concentration fluctuations (turbidimeters 1-4 from 7, 15, 25, 40cm above sea bottom), the synchronous free surface elevation H (5) and the water velocities from the Vector sensor, where v_x is the cross-shore (6) and v_y the vertical component (7) of velocity.

The shapes of vertical profiles of suspended sediment concentration (some examples are shown in Fig. 4) vary quickly with time and deviate significantly from the mean values of suspended sediment concentration. When analyzing high-frequency fluctuations of vertical profile of suspended sediment concentration, several characteristic types of vertical concentration distribution were found as plotted in Fig. 5.

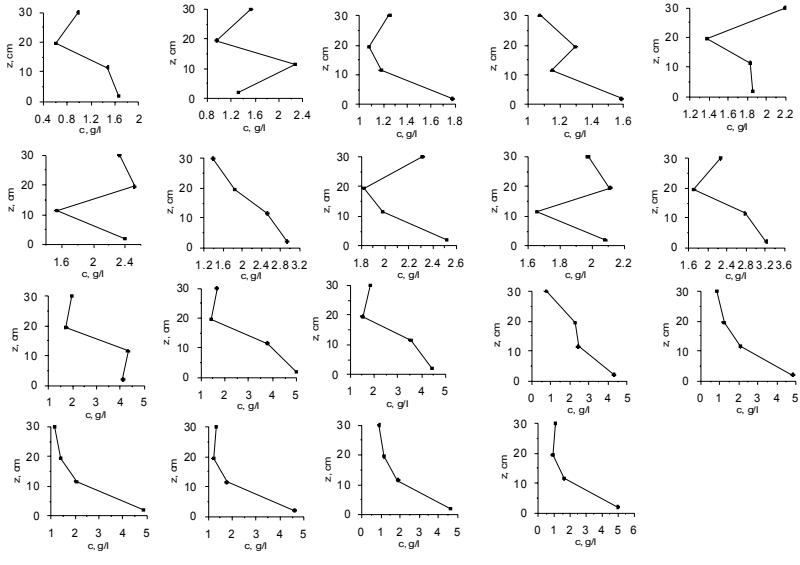

Fig. 4. High-frequency fluctuations of vertical profiles of suspended sediment concentration, each analyzed for a one second time segment from the time histories.

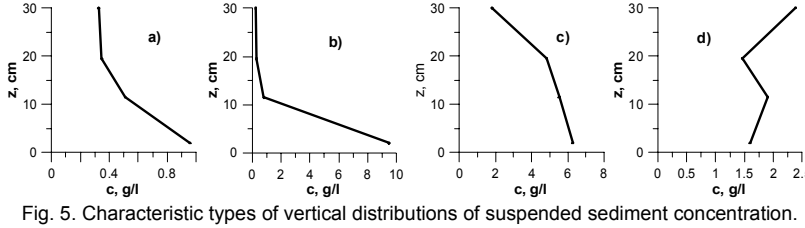

Fig. 5. Characteristic types of vertical distributions of suspended sediment concentration.

In general a vertical profile close to a logarithmic curve (Fig. 5a) is present under small waves between groups of large waves, when wave induced velocities are small and diffusion processes prevail in the formation of suspended sediment field. In the second case (Fig. 5b) high values of suspended sediment concentration are observed at the level of 4 cm over sea bed. They decrease sharply towards the surface. The

concentration gradient decreases by ~1g/l per cm in vertical height. Suspended sand is restricted to near-bottom layer and does not penetrate into higher layers. A third type of vertical concentration distribution (Fig. 5c) is observed during the passage of large waves or during wave collapse when the vertical profile is nearly linear. Sand suspended from the bottom can rise to heights of several tens of centimetres above the bottom with maximum vertical gradients of concentration 20-30 cm above the bottom.

Another type of vertical distribution is an irregular profile (Fig. 5d). Concentration of suspended sediment further away from the bottom layer may be higher than near to the bottom. Alternation of layers with high and low values of suspended sediment concentration is typical. Such vertical profiles of concentration prevail after the passage of high waves when a cloud of suspended sand separates from the bottom, is transported by the flow and gradually disperses and settles. In Fig. 6 a cloud of suspended sediments of about one second duration is shown between 307 and 308 on the time axis, which occurs under the wave trough at the distance of 15 cm from sea bed. At this moment there is no sand suspension from the bottom. Advection processes play a major role in formation of such a vertical distribution of sediments.

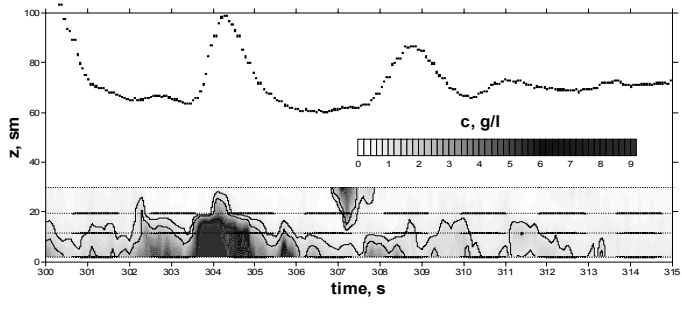

Fig.6. Chronogram of temporal fluctuations of the field of suspended sediment concentration and surface elevation

The analyzed data show that fluctuations of vertical distribution of suspended sediment concentration near the bottom is initiated by individual waves particularly under crests where water velocity is rather high. Penetration of clouds of suspended sand into the water column is not connected statistically with the passage of individual waves. In this case hydro-dynamical processes at the frequency of group waves and features of a group wave structure are determining factors. Thus, high-frequency fluctuations of the vertical distribution of suspended sediment concentration is determined both by the parameters of individual waves and by low-frequency characteristics of the waves. The fluctuations of the vertical profiles of SSC described in detail in Kos'yan et al. (2007).

A model of the fluctuations of suspended sand concentration above a flat bottom under waves with pronounced group structure was constructed and checked against the results of our laboratory experiments "HANNOVER-2006" and those of

"SISTEX'99" (Ribberink et al., 2000). Series of synchronous recording of suspended sediment concentration, components of water velocity and elevation of free surface of waves with group structure were selected for modeling and verification of the model. The model is based on one-dimensional diffusion equation for suspended sediment concentration

$$\frac{\partial C}{\partial t} = w_s \cdot \frac{\partial C}{\partial z} + \frac{\partial}{\partial z}\left(\varepsilon_s \cdot \frac{\partial C}{\partial z}\right) \tag{1}$$

where C(z,t) is suspended sediment concentration, ε_s is a coefficient of turbulent diffusion of suspended particles, w_s is settling velocity, t is time and z is the vertical coordinate.

According to this equation a change of concentration in time at any horizon from the bottom is defined by the change of balance of suspended sediment flow in vertical direction owing to the particle settling (the first term on the right hand side of equation 1) and due to the suspended sediment flux from the bottom (the second term on the right hand side).

At the free water surface suspended sediment flow is considered to be equal to zero:

$$\varepsilon_s \cdot \frac{\partial C}{\partial z} + w_s \cdot C = 0 \tag{2}$$

Near the bottom suspended sediment concentration is described by:

$$C(0,t)=A\ p(t), \tag{3}$$

where p(t) is a function of local ejection of suspended sediment (pick-up function). When individual waves are passing, sediment suspension takes place not during the whole period, but as a quick ejection of a cloud of suspended sediment. The analysis of field data has shown that only one ejection happens during the phase of decrease from maximum to zero of the horizontal component of velocity. This fact is taken into consideration by coefficient A, that changes within $0 \le A \le 1$, and is equal to 1 during the suspension phase and is zero at other times. It applies to both single waves and to group of waves in terms of their envelope.

The results of measurements of the velocity profile, the elevation of the level and suspended sediment concentration under waves with a pronounced group structure were taken as input data. The convective sediment flux is described by formula based on the field and laboratory data. The sediment entrainment from the bottom is represented by a pick-up function that takes into account the phase shift between the suspended sand concentration and the flow velocity.

Mean parameters of the waves, necessary for calculation, were found from the spectral characteristics of waves. An even grid pitch in depth and in time, was used for calculation with $\Delta z = 0.005$ m and $\Delta t = 0.228$ s.

Fig 7 shows a comparison of concentration chronograms calculated using the model, with those measured at 5.5 cm from the bottom. Discrepancy in absolute values of the concentration peaks obtained by experiment and model can be explained by the fact that the model assumes a constant granulometric composition of suspended sediment in vertical direction and median diameter of suspended particles. This effects the particle settling velocity. In the course of our experiments it was confirmed that median diameter of suspended particles becomes smaller when moving away from the bottom, and consequently the value of settling velocity decreases. This fact will be taken into account in the future modelling. Six regions of suspension are clearly seen in Fig. 7, corresponding to the passage of groups of waves (labelled 1-6 in Fig. 7).

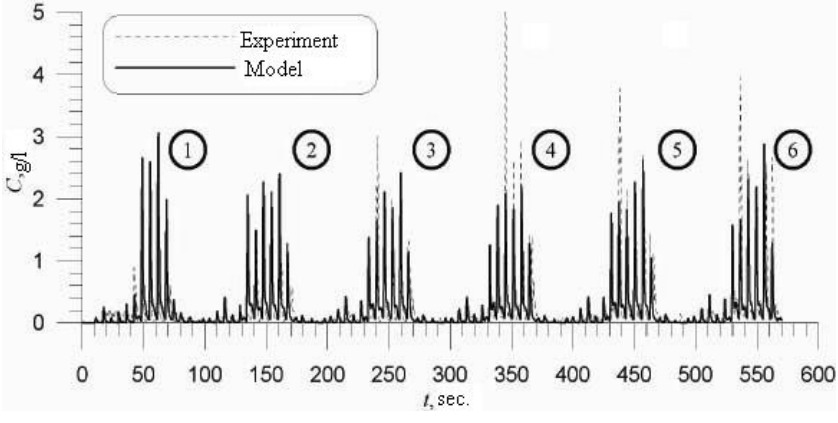

Fig.7. Comparison of concentration chronograms calculated on the model with those measured at 5.5 cm above sea bottom

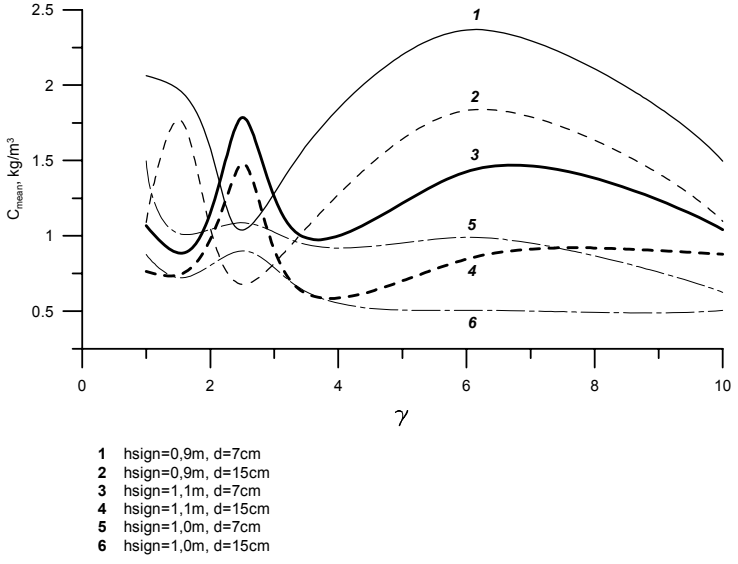
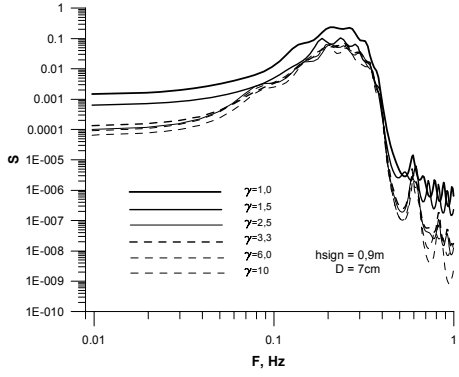
The results obtained demonstrate a rather high coherence between modelled and observed suspended sand both at low frequencies and frequencies of the maximum of spectral density. This modelled time series of suspended sediment concentration agrees statistically with the experimental one so we can conclude that the model has been successfully elaborated for calculation of the fluctuations of suspended sediment concentration above a flat bottom under the influence of groups of waves. It takes into account the influence of group structure of waves and phases of individual waves upon the sediment suspension which is very important for modelling of fluctuations of suspended sediment concentration. The model demonstrates very well all qualitative peculiarities of sediment suspension in these given conditions. The predicted and measured concentrations coincide satisfactorily in time. The peaks coincide with the inflexion points on the vertical profile of velocity in the bottom boundary layer. This model is described more fully in Kos'yan et al, (2006).

Real processes of sediment suspension are more complex than the mechanisms which are put into the model. The present model of suspension of bottom sediments will be improved as a result of further observations from both experimental and theoretical investigations.





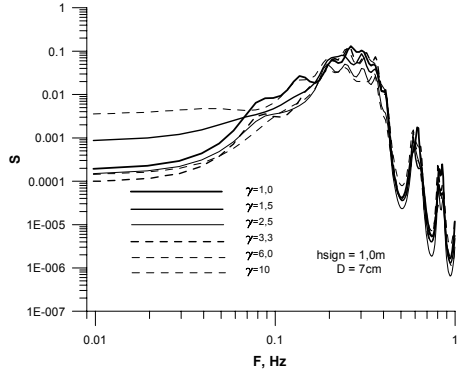


Fig. 8. Dependence of time averaged concentrations at two horizons (7 and 15 cm from sea bottom) for three significant waves heights (H_{sig} = 0.9, 1.0 and 1.1m) on spectral steepness.

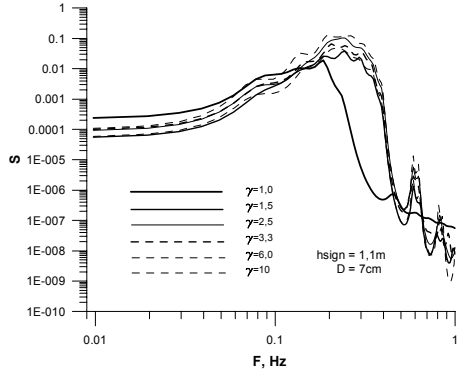
One of the tasks of these experiments was to identify any dependence between values of suspended sediment concentration and the form of wave spectrum. Fig. 8 shows the dependence of averaged concentrations at two horizons (7 and 15 cm from the bottom) for three values of significant waves height (H_{sig}= 0.9, 1.0 and 1.1m) on spectral steepness. Fig. 9 shows spectra of suspended sediment concentration for different steepness (γ), and wave heights at the distance 7cm from the bottom.



From the figures it is seen that the form of wave spectrum greatly influences on the SSC values. With the same wave parameters the spectral steepness can alter the concentration by 2.5 times. There are some peaks of SSC values which occur at different steepnesses. Spectra of suspended sediment concentration also greatly depend on the wave spectra steepness. To explain and formulate any dependence we have to have many more new data.

CONCLUSION

A series of investigations were conducted in the Large Wave Channel (GWK) of the Coastal Research Centre (FZK) in Hannover which afforded an opportunity to model storm dynamic processes in the coastal zone at almost full-scale. This is most important because it turns out not to be possible to simultaneously similarity of hydrodynamic and lithodynamic processes under any scale of modelling. A data bank of unique experiments, modelling processes of an intensive storm was collected during a short experiment period. The analysis of this data bank gave the possibility of significantly advancing our understanding of storm dynamics and sediment flux in the coastal zone.

In the first stage of analysis of these observations we a) investigated the high-frequency fluctuations of the vertical profile of suspended sediment concentration; b) construct a model of which predicted the fluctuations of suspended sand concentration above a flat sandy bottom under waves with pronounced group structure and c) determined the dependence between values of suspended sediment concentration and the form of wave spectrum.

Abstract: A contour-line-change model considering the sorting effect of grain size was applied to the prediction of the changes in longitudinal profile of a model beach composed of sand of mixed grain size. The results were compared with the experimental results using a large wave tank. The experimental results that sand of mixed grain size is sorted into fine and coarse sand, and that coarse sand is transported shoreward, forming a berm, whereas fine sand sinks into a zone deeper than the depth of closure h_c were accurately reproduced by the numerical simulation. Furthermore, the result that the formation of the berm is rapid, whereas seabed changes in the offshore zone are slow, was also reproduced by the numerical model. The results of the calculation of changes in the content rate indicated that an increase in the volume of coarse sand contributes to the shoreline advance as a result of berm formation, whereas an increase in the volume of fine sand accelerates the outflow of fine sand into a zone deeper than h_c.

INTRODUCTION

When a model beach composed of fine sand is created in a relatively small-scale wave tank and waves are generated, the model beach deforms because of wave

action, resulting in changes similar to that of beach deformation observed on real coasts. This phenomenon has been recognized for a long time, and on the basis of the results of model experiments, a method predicting shoreline recession and advance by introducing a parameter C depending on wave characteristics and grain size has been proposed (for example, Horikawa, 1985).

This method has been extensively used in Japan, but its applicability to real coasts is still questionable. The most important issue is that the dynamic similitude of sand transport has not yet been established, and therefore, the relationship between the phenomena observed in experiments and those observed on real coasts is obscure. To reduce the difficulty to some extent, experiments using a large-scale wave tank have been carried out in recent years, but the mechanisms of the phenomena have not yet been clarified. In solving the problem, studies on the mechanism with which a longitudinal profile tends to approach a stable form are required with respect to changes in longitudinal profile. Furthermore, movable-bed experiments using sand of mixed grain size in a large wave tank have also been carried out, but the interpretation of the phenomena is still insufficient (Meguro *et al*., 2005).

Uda *et al*. (2004) developed a model for predicting changes in beach topography and grain size of seabed materials. In their model, equilibrium slopes for each grain size and the mixing of bed materials in a mixing layer were assumed, and they successfully explained the selective movement of coarse and fine sand. However, the physical evaluation of the model was insufficient. In this study, we aim to investigate the applicability of this model to experiments using sand of mixed grain size, in which the changes in longitudinal profile and cross-shore distribution of the grain size are investigated in detail in a large wave tank.

EXPERIMENT USING LARGE WAVE TANK AND SAND OF MIXED GRAIN SIZE

A movable bed experiment using sand of mixed grain size, which ranges widely from medium sand to silt, was carried out using a 135-m-long, 2-m-wide and 5-m deep wave tank to study the formative processes of an equilibrium beach and grain size distribution (Meguro *et al*., 2005). The median diameter of grain size used was d_{50} =0.62 mm and the initial uniform slope was 1/20. Regular waves with a height of 0.6 m and a period of 3.5 s were generated for 78 hours.

Figure 1 shows the change in longitudinal profile and the cross-shore distribution of d_{50} on the seabed. A flat seabed was formed by erosion at a depth of h_c=1.3 m on the initial uniform slope, and a steep foreshore of slope 1/6 was formed. The flat seabed in the vicinity of the depth h_c was covered with fine sand, whereas coarse sand selectively accumulated on the foreshore. From these facts, it is clear that sand of mixed grain size undergoes a sorting effect by wave action, with coarse sand deposited on the foreshore, forming a berm with a steep slope, and fine sand transported offshore and deposited to form a gentle slope on the offshore bed.

Figure 2 shows the cumulative grain size distributions on the foreshore at x=0.4 m and on the offshore bed at x=30.4 m. The grains in the foreshore and offshore zones are clearly separated into the grains larger and smaller than 1 mm, respectively. On the basis of this result, hereafter we simply refer to grains smaller than 1 mm, as 'fine sand', and larger than 1 mm as 'coarse sand'.

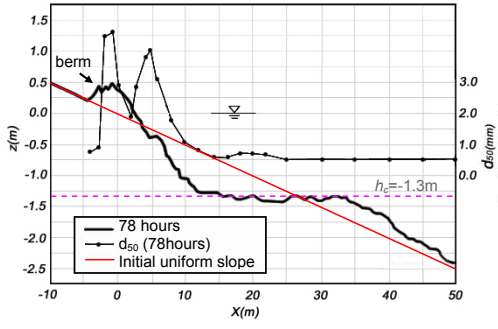

Fig. 1. Change in longitudinal profile and cross-shore distribution of d_{50} in experiment using large wave tank based on work of Meguro *et al.* (2005)

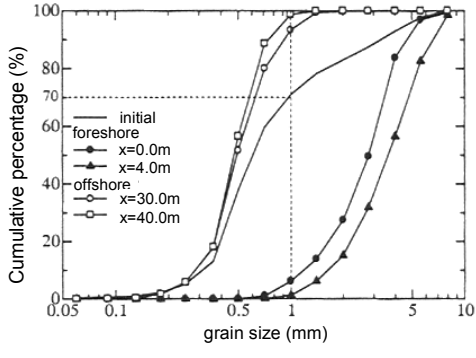

Fig. 2. Cumulative grain size distributions on foreshore at x=0.4 m and on offshore bed at x=30.4 m in experiment

SUMMARY OF EXPERIMENTAL RESULTS

(1) Erosion occurred only in a zone shallower than h_c=1.3 m, which is equal to the depth of closure.

(2) Coarse sand was transported shoreward, forming a 0.5-m-high berm and a foreshore of slope 1/6.

(3) The volume of coarse sand contained in the erosion zone is limited, and the development of a berm depends on this volume of coarse sand. Although the berm

height depends on wave characteristics, a minimum volume of coarse sand is required for the development of a berm.
(4) Fine sand was transported to a zone deeper than h_c, and a slope of 1/10, which was larger than the initial slope, was formed on the offshore bed.
(5) After a berm developed sufficiently, the beach profile became stable, because the grain size on the foreshore matched the slope. The offshore flat bed in the vicinity of h_c also became stable because further erosion did not occur, resulting in the cessation of the offshore discharge of fine sand. Thus, the equilibrium condition is only assumed to result, when a berm develops sufficiently.

NUMERICAL MODEL

A result of a contour-line-change model considering the effect of the change in grain size of seabed materials proposed by Uda *et al*. (2004) was compared with the results of the above-mentioned experiment using sand of mixed grain size. This model can predict not only the beach changes, but also grain-size changes due to the difference in the sorting effect corresponding to grain size.

The fundamental concept was described in Uda *et al*. (2004), but the comparison between the experimental results of the change in longitudinal profile in a wave tank and the numerical model has not yet carried out, requiring the verification of the applicability of the numerical model by physical experiments. In this study, beach changes caused by only cross-shore sand transport are reproduced by the numerical simulation, neglecting the action of longshore sand transport, because the changes in longitudinal profile were obtained in the previously described wave flume test.

The fundamental equations of the simulation are the cross-shore sand transport equations of Eqs. (1)-(3), the mass conservation equations for each grain size of Eqs. (4) and (5), and Eqs. (6) and (7), which calculate the content rate of each grain size.

Cross-shore sand transport

$$q_z^{(k)} = \mu^{(k)} \cdot \varepsilon_z(z) \cdot K_z^{(k)} \cdot (EC_g)_b \sin\overline{\beta} \cdot \left(\frac{\cot\beta}{\cot\beta_c^{(k)}} - 1 \right) \tag{1}$$

$$K_z^{(k)} = \frac{\gamma \cdot A}{\sqrt{d^{(k)}}} \tag{2}$$

$$\varepsilon_z(z) = \begin{cases} = \dfrac{2}{h_c^3}\left(\dfrac{h_c}{2} - z \right)(z + h_c)^2 \quad .....(-h_c \le z \le h_R) \\ = 0 \quad .....(z < -h_c \ , h_R < z) \end{cases} \tag{3}$$

Mass conservation for each grain size

$$\frac{\partial y^{(k)}}{\partial t} = -\frac{\partial q_z^{(k)}}{\partial z} \qquad (k = 1, 2, \cdots, N) \tag{4}$$

$$\frac{\partial Y}{\partial t} = \sum_{k=1}^{N} \frac{\partial y^{(k)}}{\partial t} \tag{5}$$

Change in content rate of each grain size

$$\frac{\partial \mu^{(k)}}{\partial t} = \frac{1}{B}\left\{\frac{\partial y^{(k)}}{\partial t} - \frac{\partial Y}{\partial t}\cdot \mu^{(k)}\right\} \quad (k = 1, 2, \cdots, N) \quad \text{for erosion} \tag{6}$$

$$\frac{\partial \mu^{(k)}}{\partial t} = \frac{1}{B}\left\{\frac{\partial y^{(k)}}{\partial t} - \frac{\partial Y}{\partial t}\cdot \mu_B^{(k)}\right\} \quad (k = 1, 2, \cdots, N) \quad \text{for accretion} \tag{7}$$

Here, N is the number of grain sizes, and k is the number of each grain size (k=1, 2$\cdots$, N), $\mu^{(k)}$ (k=1, 2,$\cdots$, N) is the content rate of grain size k in the exchange layer of sand. z is the depth, t is the time, Y is the location of a specific contour line, and $(EC_g)_b$ is the wave energy flux at breaking point. $\beta_c^{(k)}$ is the equilibrium beach slope angle corresponding to each grain size, $\overline{\beta}$ is the average beach slope angle between the berm height h_R and the depth of closure h_c, and β is the beach slope angle at each contour line. $\varepsilon_z(z)$ is the depth distribution of the cross-shore sand transport given by Eq. (3) (Uda and Kawano, 1996) and $q_z^{(k)}$(k=1, 2,$\cdots$, N) is the cross-shore sand transport of each grain size. $d^{(k)}$ is the grain size (mm), $K_z^{(k)}$ is the coefficient of the cross-shore sand transport for each grain size, and γ is the ratio between the coefficients of sand transport, which expresses the mobility of cross-shore sand transport compared with longshore sand transport. B is the thickness of the exchange layer, and is assumed to be 3% of the breaker height, after Kraus (1985). A is a coefficient that depends on the physical conditions of the beach, and α_{bs} is the angle between the wave-crest line at the breaking point and the contour lines (in this study, α_{bs} = 0). $\mu_B^{(k)}$ is the content rate shoreward of the exchange layer, which is the content rate before the beach changes.

The cross-shore sand transport of each grain size q_z is calculated first, using Eqs. (1)-(3), and then the change in the contour lines is calculated by solving the continuity equation of sand given by Eqs. (4) and (5). Furthermore, the change in content rate in the exchange layer is calculated using Eqs. (6) and (7). The same procedure is recurrently carried out to predict both beach changes and time change in content rate in the exchange layer.

The sinking of sand in a zone deeper than the depth of closure due to gravity and the formation of a scarp on the shore face were predicted using the method proposed by Uda *et al*. (2004). The seabed slope of fine sand in a zone deeper than h_c was assumed to be the value obtained experimentally, considering that the sand movement was due to the effect of gravity. The numerical simulation was carried out by the explicit finite difference method using staggered meshes.

For the calculation condition, the number of grain sizes is assumed to be 2, since the sorting of grains occurred at a critical grain size of 1 mm in the experiment, and two grain sizes of $d^{(1)}$=0.45 mm and $d^{(2)}$=3 mm, which typically represent fine and coarse sand, respectively, are selected. These grain sizes were determined on the basis of the cumulative grain size distribution of the sand of mixed grain sizes used in the experiment, so that $d^{(1)}$ and $d^{(2)}$ are approximately equal to d_{50} calculated from the entire samples of fine and coarse sand, respectively, and so that the mean grain size of the entire sample d_m used in the experiment becomes equal to 1.21 mm.

The initial content rate of sand was assumed to be $\mu^{(1)}$=0.7 for fine sand and $\mu^{(2)}$=0.3 for coarse sand, the same condition as in the experiment. The initial beach profile is given a uniform slope of 1/20, and h_R and h_c are set as h_R=0.5 m and h_c=1.3 m, on the basis of the experimental results.

For the equilibrium slopes, the gentle seabed slope composed of fine sand in the offshore zone and the steep seabed slope composed of coarse sand are given as $tan\beta_c^{(1)}$=1/100 and $tan\beta_c^{(2)}$=1/6, respectively, referring to the experimental results. The width of the exchange layer B is given by the thickness of the exchange layer divided by the slope. Since the experiment had large scale, the thickness is given by 0.02 m, which is 3% of the breaker height (H_b =0.75 m), based on the results obtained from the field observation by Kraus (1985), and B is set to be 0.4 m, dividing the exchange-layer thickness by the initial slope of 1/20.

The critical slope of sinking for sand of each grain size is separately given for on land and on the seabed, similar to that in Uda *et al*. (2004). In this study, the sinking of fine sand into the zone deeper than h_c is considered to be caused by the effect of gravity and is given by a slope of 1/10, which occurred in the experiment. In the other zone, the critical slopes are set to be 1/2 and 1/3 on the land and seabed, respectively, as in Uda *et al*. (2004).

The coefficient of sediment transport A, which defines the rate of beach change, was determined as A=0.2 by a trail calculation, so that the numerical simulation can reproduce the development of a berm in 20 hours as in the case of the experiment, assuming γ =1 in Eq. (2) for simplicity, since longshore sand transport is not related to the phenomenon. For the depth distribution of cross-shore sand transport, the same depth distribution of longshore sand transport as that in Eq. (3) given by Uda and Kawano (1996) was assumed. For the wave condition, the time-averaged breaker height of the observation results, H_b=0.75 m was given. Other calculation conditions such as mesh size and time step are shown in **Table 1**.

Table 1. Calculation conditions

Cases	Reproduction: $\mu^{(1)}$=0.7 and $\mu^{(2)}$=0.3 Prediction: Case 1: $\mu^{(1)}$=0.1 and $\mu^{(2)}$=0.9 Case 2: $\mu^{(1)}$=0.3 and $\mu^{(2)}$=0.7 Case 3: $\mu^{(1)}$=0.5 and $\mu^{(2)}$=0.5 Case 4: $\mu^{(1)}$=0.9 and $\mu^{(2)}$=0.1
Initial topography	Uniform slope of tanβ=1/20
Grain size	Number of grain sizes: N=2 Fine sand: $d^{(1)}$=0.45 mm Coarse sand: $d^{(2)}$=3 mm Initial content rate: $\mu^{(1)}$=0.7 and $\mu^{(2)}$=0.3
Width of exchange layer	B=0.4 m
Wave conditions	Breaker height: H_b=0.75 m (H_0=0.6 m, T=3.5 s) Breaker angle: α_{bs}=0 deg. Tide level: mean sea level
Depth of closure	h_c=1.3 m
Berm height	h_R=0.5 m
Coefficients of sand transport	A=0.2 and γ =1.0
Depth distribution of sand transport rate	Cubic equation given by Uda and Kawano (1996)
Equilibrium slope	$tan\beta_c^{(1)}$ =1/100 (fine sand) $tan\beta_c^{(2)}$ =1/6 (coarse sand)
Critical slope	Fine sand: 1/2 on land and 1/10 on seabed Coarse sand: 1/2 on land and 1/3 on seabed
Calculation domain	z=+1.0 m to -3.0 m
Mesh size	Δz=0.1 m
Time interval	Δt=0.01 h
Total time of calculation	t=200 h (20,000 steps)
Boundary conditions	q_z=0 at landward and offshore boundaries
Calculation method	Explicit finite difference method

RESULTS OF NUMERICAL SIMULATION

4.1 Case of initial content rates of fine and coarse sand : $\mu^{(1)}$=0.7 and $\mu^{(2)}$=0.3

First, numerical simulation was carried out in the case with the same conditions as that of the experiment. **Figure 3** shows the change with time of the longitudinal profile when the content rates of fine and coarse sand are $\mu^{(1)}$=0.7 and $\mu^{(2)}$=0.3, respectively. Erosion starts from a shallow zone in the vicinity of the shoreline, and part of the sand is transported landward forming a berm on the foreshore. Sand is also transported offshore, forming a small hump in the offshore zone.

Figure 4 shows a comparison between the measured and the predicted longitudinal profiles after wave action. The results are in a good agreement in terms of the formation of a berm, the flat offshore sea bottom and offshore deposition of sand. Furthermore, it is realized from **Fig. 3** that the formation of the berm is relatively rapid compared with the change in the offshore topography in establishing a stable condition.

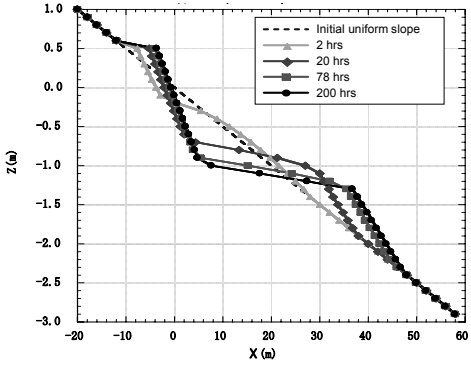

Fig. 3. Change with time of longitudinal profile in case that content rates of fine and coarse sand are $\mu^{(1)}$=0.7 and $\mu^{(2)}$=0.3, respectively

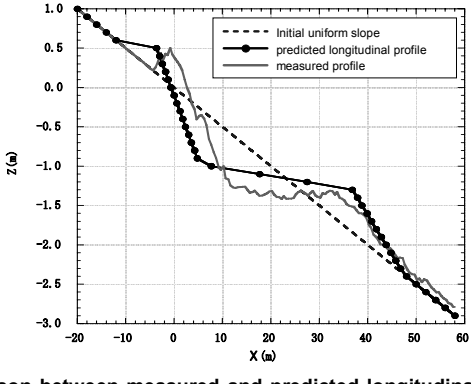

Fig. 4. Comparison between measured and predicted longitudinal profiles after wave action

Figures 5(a) and **5(b)** show the cross-shore distributions of the content rates $\mu^{(1)}$ and $\mu^{(2)}$ corresponding to the profile changes shown in **Fig. 3**. The foreshore materials become only coarse sand ($\mu^{(1)}$=0, $\mu^{(2)}$=1.0), whereas the offshore seabed with a gentle slope becomes covered with only fine sand ($\mu^{(1)}$=1.0, $\mu^{(2)}$=0). **Figure 6** shows the cross-shore distribution of the mean grain size. The grain size is large at 3.0 mm on the steep slope of the foreshore and on the berm, whereas on the offshore seabed it becomes as small as 0.5 mm. These results correspond well to the cross-shore distribution of d_{50} as shown in **Fig. 1**.

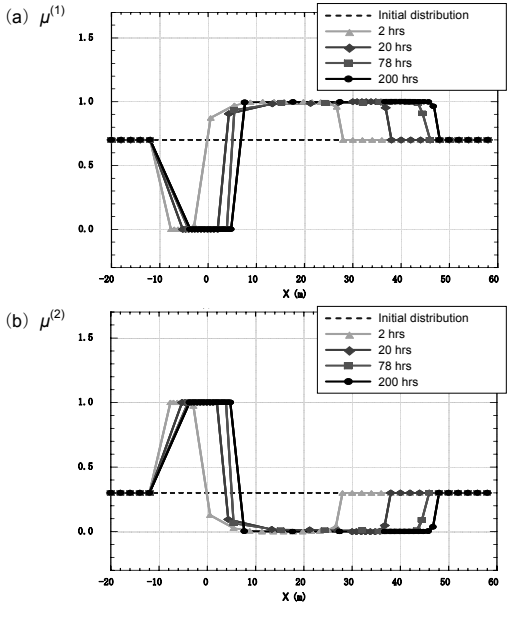

Fig. 5. Cross-shore distribution of content rate $\mu^{(1)}$ and $\mu^{(2)}$ of fine and coarse sand, respectively

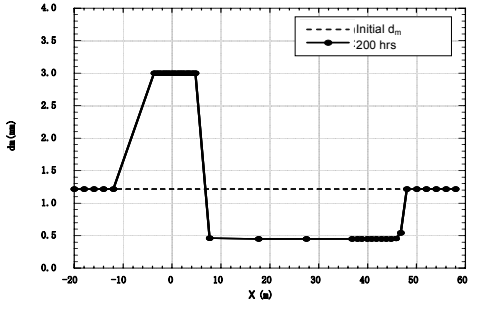

Fig. 6. Cross-shore distribution of mean grain size

In conclusion, the changes in longitudinal profile in the experiment were accurately reproduced in the numerical model, taking into account the five findings described in the 'summary of experimental results' section. It was found that fine and coarse sand are sorted on model beaches composed of sand of mixed grain size, and that coarse sand is transported shoreward, whereas fine sand is transported offshore, finally approaching the equilibrium slope corresponding to each grain size.

4.2 Case of initial content rates of fine and coarse sand : $\mu^{(1)}$=0.3 and $\mu^{(2)}$=0.7

In the experiment, the changes in longitudinal profile were investigated in the case that the initial content rates of fine and coarse sand are inversely $\mu^{(1)}$=0.3 and $\mu^{(2)}$=0.7, respectively, to investigate the effect of the difference in the initial content rates on the final, stable profile. **Figure 7** shows the results.

As a result of the increase in the content rate of coarse sand, sand volume transported shoreward increased compared with the case as shown in **Fig. 3**, and a berm predominantly developed. In contrast, a smaller volume of sand was transported offshore. **Figures 8(a)** and **8(b)** show the change with time of the content rates of fine and coarse sand $\mu^{(1)}$ and $\mu^{(2)}$ in the same manner as shown in **Figs. 5(a)** and **5(b)**. The distributions of $\mu^{(1)}$ and $\mu^{(2)}$ are similar to each other, but shoreward sand movement predominated as a result of the increase in the content rate of coarse sand, and therefore, beach changes became active in a relatively shallow zone.

4.3 Change in initial content rate and equilibrium profile

Figure 9 shows the final, stable profiles in the cases that the initial content rates ($\mu^{(1)}$, $\mu^{(2)}$) are altered to (0.9, 0.1), (0.5, 0.5), (0.3, 0.7) and (0.1, 0.9), as well as the result of the reproduction case with the content rates (0.7, 0.3). The berm develops more with the increase in content rate of coarse sand, $\mu^{(2)}$. In contrast, the berm develops less with the increase in content rate of fine sand, $\mu^{(1)}$, and offshore sand transport becomes dominant, accelerating the deposition of fine sand in the offshore zone.

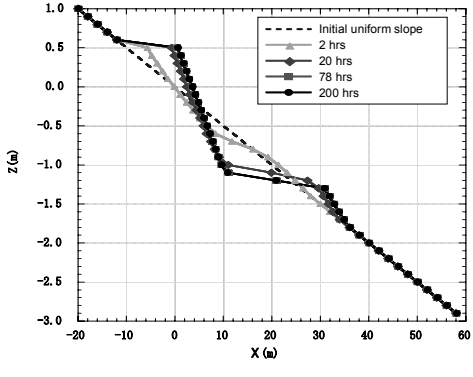

Fig. 7. Predicted changes in longitudinal profile when content rates $\mu^{(1)}$ and $\mu^{(2)}$ are 0.3 and 0.7, respectively

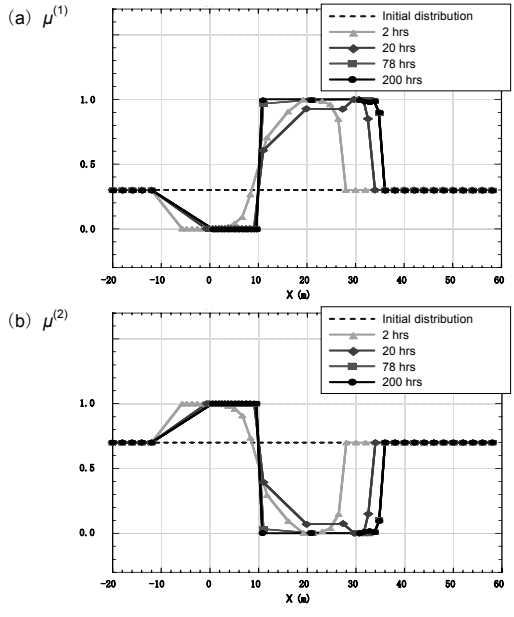

Fig. 8. Change with time of content rate of fine and coarse sand $\mu^{(1)}$ and $\mu^{(2)}$

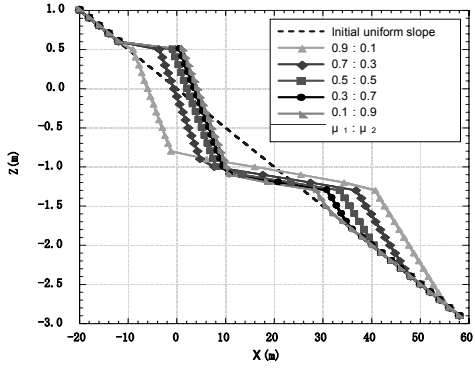

Fig. 9. Final, stable profiles in cases that initial content rates ($\mu^{(1)}$, $\mu^{(2)}$) are altered to (0.9, 0.1), (0.5, 0.5), (0.3, 0.7) and (0.1, 0.9), as well as result of reproduction case with content rates (0.7, 0.3)

Thus, the grain size has a decisive effect on the changes in longitudinal profile. On a beach composed of only fine sand, offshore sand transport from the initial stage never converges and an equilibrium profile cannot ever be attained. The equilibrium

profile in the wave flume experiment is formed only when sufficient volume of coarse sand is available to cover the foreshore and to form a berm.

CONCLUDING REMARKS

The present model accurately reproduced the characteristics that sand of mixed grain size undergoes a sorting effect, coarse sand is transported shoreward to form a berm and fine sand is transported offshore to a zone deeper than h_c. The formation of a berm is very rapid, whereas the time scale of change for the offshore topography to approach a stable condition by the movement of fine sand is much longer. From the calculations when the content rate of coarse sand increases, the foreshore becomes wide owing to the formation of a berm, and it contributes to the shoreline advance. In contrast, with an increase in the content rate of fine sand, the outflow of sand toward a zone deeper than h_c increases.

There are cases that the volume of coarse sand, which accumulates near the shoreline forming a berm with a steep slope, is limited, depending on the initial content rate of sand. This condition often occurs in beach nourishment rather than in natural beach processes. In such a case, the sand used for nourishment is transported offshoreward and a stable profile cannot ever be attained. This means that we must be very careful in selecting the grain size of sand for beach nourishment.

In addition, the most important parameter in determining changes in longitudinal profile is the equilibrium slope, which depends on the grain size. Since the changes in longitudinal profile depend on the combination of the equilibrium slope and the content rate of sand, the parameter such as the shoreline position has less physical meaning.

Since this study focused on reproducing the experimental results using a large wave tank, various parameters of this study must be reconsidered in the application to other experimental results and field data. In particular, in the application to field data, the berm height, depth of closure and equilibrium slope of each grain size of each coast must be determined on the basis of bathymetric survey data and the depth distribution of grain size of the seabed materials. In addition, in the contour-line-change model, in principle, the contour line is defined only as single-valued function of the ground elevation, and therefore, the bar-trough topography is difficult to express because of the necessity of multiple contour lines. In this area, future studies are required.

Finally, a movable-bed experiment using a large wave tank was realized in this study, and a model for predicting the longitudinal profile using sand of mixed grain size was successfully developed. This model will become a useful tool for predicting beach changes during beach nourishment using sand of mixed grain size, because the remaining rate of nourished sand in a shoreline zone corresponds to the grain size.

Abstract: A probabilistic-deterministic model for swash zone sediment transport is presented and applied to predict cross-shore beach profile change under random waves. For accretionary conditions, inclusion of a random wave approach is essential for accurate representation of berm building processes. The model provides good estimates of beach volume changes for small scale laboratory experiments and sediment overwash volumes on a natural beach. Future modeling improvements are discussed, notably the inclusion of pre-suspended sediment, sediment pickup and long wave influences. Field and laboratory data show that sediment is advected into the swash zone from much further offshore than predicted by the classical swash solution, which increases uprush suspended sediment flux. Conversely, backwash suspended sediment flux may be limited by hindered pickup which may occur when the thickness of the backwash sheet flow layer becomes large relative to the flow depth.

INTRODUCTION

Despite recent advances in both analytical (Pritchard and Hogg, 2005) and numerical modelling (e.g. Kobayashi and Johnson, 2001; Karambas, 2006), predictions of morphological evolution in the swash zone remains a challenge, particularly over longer time-scales. As a result, few or no broad scale parametric-deterministic models attempt to model sediment transport in the swash zone. This paper addresses this point and presents a framework for including the influence of random wave runup and sediment transport in deterministic, parametric or empirical hydro-morphodynamic models (e.g.

COSMOS (Nairn, 1990), SBEACH, DELFT3-D, MIKE21 etc.). As a result of the intermittent nature of the swash flow, an event-based model is developed, as opposed to a time-averaged model. The model is compared to laboratory data for both eroding and accreting beaches. Other applications of the model are also discussed, including swash overwash, for which an event-based modeling process is also more appropriate than a time-averaged approach.

The basis for model presented here was reported by Holmes and Baldock (1997). The original approach utilised, and was embedded within a version of the COSMOS profile model developed by Nairn (1990) at Imperial College, UK. At that time, Holmes and Baldock had reservations about the sediment transport routines in the swash model, notably the application of the Bagnold Energetics approach and the use of an equilibrium beach face concept as a predictive tool, and the model was not published further. However, validation of the Energetics approach for swash transport by Masselink and Hughes (1998) and the adoption of Shields type u^3 models by Nielsen (2002) and Pritchard and Hogg (2005) addresses some of these concerns. In addition, further validation of the original swash hydrodynamics model (Baldock and Holmes, 1997) by Hughes and Baldock (2004) and its application to calculate swash overtopping and sediment overwash suggested that revisiting and updating the model would be beneficial.

Section 2 of this paper outlines the original model, together with the revisions and updates based on recent international swash research. Section 3 describes the laboratory setup and wave conditions. Model-data comparisons for beach profile evolution are given in section 4, together with some results of applying the model to field conditions and sediment deposition on the crest of beach berms. A critical evaluation of the model is presented in section 5, together with a discussion of where recent advances could be incorporated. In addition, a caveat concerning the use of representative monochromatic wave conditions to simulate random wave conditions is discussed on the basis of experiments illustrating the influence of surf beat and wave groups on beach profile evolution. Final conclusions follow.

MODEL FORMULATION

Surf zone and swash zone hydrodynamics

The hydrodynamics within the model are predicted using a cross-shore wave transformation model formulated on a full Rayleigh probability density function for the nearshore wave heights and by abandoning the usual depth limitation (Baldock et al., 1998). This model was extensively tested and calibrated by Ruessink et al. (2003) for a wide range of field data. This wave transformation model provides the bore height at the run-down position for subsequent use in the swash hydrodynamics module. The surf zone wave heights govern the remainder of the surf hydrodynamics used in the original ANPM.

The intermittent nature of the swash flow means that the parametric time-averaging approach adopted for the surf zone is inappropriate. For example, a representative

monochromatic wave may provide a good description of the wave energy and sediment stirring in the surf zone, but will under-estimate the maximum run-up under random wave conditions. In the simplest case, this may result in no predicted overtopping or sediment overwash when in reality it would occur. Further, the smoothing effect of the random wave run-up is ignored. However, adopting the parametric approach offshore and in the surf zone prohibits the use of full numerical solutions (e.g. Kobayashi et al., 1989; Masselink and Li, 2001) for the swash. The swash hydrodynamics are calculated using the swash model of Baldock and Holmes (1997), recently extended and applied to field conditions by Hughes and Baldock (2004) and Hughes et al. (2007). The input to the model is the height of the incident bore at the seaward limit of the swash zone, available from the cross-shore wave transformation routine, and a friction coefficient, which can be calculated internally if necessary following Hughes (1995).

Swash zone sediment transport

Holmes and Baldock (1997) adopted an Energetics approach for the swash sediment transport model, following the Energetics approach (e.g. Bagnold, 1966) utilised elsewhere within the ANPM. However, the Energetics approach has some inconsistencies which have not been closely examined. For example, the efficiency factor for the bed load transport rate is usually assumed to be of order 0.1 (Bagnold, 1966; Nairn, 1990). However, for shallow water, Bagnold (1966) suggests that the overall bed load efficiency may approach 0.3, a result of the boundary transport efficiency approaching 1. Consequently, since the power available for suspended load transport depends on the power expended transporting the bed load (Bagnold, 1966), there must be also a corresponding change in the suspended load efficiency factor. In addition, the predicted net transport was always offshore as a result of the predicted flow asymmetry in the swash zone (Baldock and Holmes, 1997). While Holmes and Baldock (1997) found that the Energetics approach gave reasonable results, the model has since been revised to use a Shields type model (e.g. Nielsen, 1992; 2002) in order to adress the first two concerns.

To address the problem of achieving net shoreward transport with negatively skewed asymmetric swash flows, Holmes and Baldock (1997) adopted Turner's (1995) equilibrium beach face concept, where the direction of the net transport on the beach face is determined by whether the beach face gradient is greater or smaller than an equilibrium value. In more recent work, it has been shown that the uprush transports a greater sediment load for a given free stream velocity, or is twice as "efficient" (e.g. Masselink and Hughes, 1998). A number of reasons have been given for this, including infiltration/exfiltration effects (e.g. Turner and Masselink 1998; Masselink and Li, 2001) and flow acceleration (Nielsen, 2002; Puleo et al., 2003), but neither have been conclusively demonstrated. Pre-suspended sediment advected from the inner surf zone (e.g. Pritchard and Hogg, 2005) is potentially a very important contribution to net sediment fluxes and has been incorporated within a parametric framework (Alsina et al., 2005). Nevertheless, correct *a priori* prediction of the direction of sediment transport probably remains beyond the state of the art. Therefore, at present, the model retains the

equilibrium beach face concept. Possible future improvements to overcome this issue are discussed later below.

The sediment transport model is a standard sheet flow Shields model (Nielsen, 1992) where Q is:

$$Q = \Phi d\sqrt{(s-1)gd} \tag{1}$$

with

$$\Phi = C(\theta - 0.05)\sqrt{\theta} \tag{2}$$

and

$$\theta = \frac{1/2\, f_w u|u|}{(s-1)gd} \tag{3}$$

where d is the median grain diameter, s is the specific gravity of the sediment, u is the free stream horizontal velocity, f_w is the wave friction factor and C is an empirical transport coefficient. Here, C= 8 for θ<1 and C=12 for $\theta \geq 1$, which are recommended values (Nielsen, 1992). A standard expression for f_w is (Nielsen, 1992; 2002):

$$f_w = \exp\left[5.5\left(\frac{2d_{50}}{A_{rms}}\right)^{0.2} - 6.3\right] \tag{4}$$

where A_{rms} is based on the free stream velocity variance and the swash frequency $\omega=2\pi/T_s$.

$$A_{rms} = \frac{\sqrt{2}}{\omega}\sqrt{Var\{u(t)\}} \tag{5}$$

A_{rms} and f_w therefore vary across the swash zone. Nielsen (2002) modified (3) for the case where a significant positive local temporal flow acceleration or landward directed pressure gradient occurs. Puleo et al. (2003) proposed that these conditions may occur during uprush and to a lesser extent during the backwash. However, Baldock and Hughes (2006) present field data that indicates that this is not the case, and that the local and total fluid acceleration in the swash is nearly always directed seaward. Consequently, the original formulation is retained.

In the model, (4) and (5) vary across the swash zone, depending on the velocity variance any fixed position. The bed slope was also accounted for by modifying the Shields parameter according to

$$\theta_s = \theta\left(1 - \frac{\tan\beta}{\tan\phi}\right)\cos\beta \tag{6}$$

where ϕ is the friction angle ($\tan\phi$=0.63). The values of f_w are in the range $0.02<f_w<0.05$ of local swash friction factors inferred by Cox et al. (2000) and Raubenheimer et al. (2004). For application to a beach profile model, the net transport per swash, Q_{net}, is determined following Turner (1995) as

$$Q_{net} = Q\frac{\tan\beta_{eq} - \tan\beta}{\tan\beta_{eq} + \tan\beta} \tag{7}$$

where β is the local beach slope and β_{eq} is the user-defined global equilibrium beach slope in the swash zone. (7) therefore controls both the magnitude and direction of the net transport. The choice of β_{eq} is discussed below. Q_{net} may be time-averaged, or retained as a discrete transport volume, depending on the overall modeling framework.

Probabilistic modeling

Application of the model with monochromatic waves leads to an under-estimation of the extent of morphological change for both accretionary and erosive conditions (see section 3 below). Consequently, Holmes and Baldock (1997) adopted a probabilistic-deterministic approach, which has since been utilised to model sediment overwashing natural beach berms. Bore heights in the inner surf zone are well described by a Rayleigh distribution (Baldock et al., 1998), which is consistent with Rayleigh distributed run-up under random waves (e.g. Nielsen and Hanslow, 1991). In the model, the total transport is determined for a series of Rayleigh distributed bore heights, H_b, ranging from H_{bmin} to H_{bmax}, with the net transport at any location weighted by the respective probability of occurrence for that bore height. Hence,

$$Q_{total} = \int_{Hb\min}^{Hb\max} Q_{net}\, p\left(\frac{H_b}{H_{brms}}\right) d\left(\frac{H_b}{H_{brms}}\right) \tag{8}$$

where

$$p\left(\frac{H_b}{H_{brms}}\right) = 2\frac{H_b}{H_{brms}}\exp\left[-\left(\frac{H_b}{H_{brms}}\right)^2\right] \tag{9}$$

H_{brms} is the rms bore height at the run-down position determined by the surf zone wave transformation model. For steep beaches, the maximum run-down below the MWL (setup) intersection with the beach was estimated to be about $0.3R$, where R is the runup obtained from Hunt's (1959) formula. The mean seaward boundary of the swash is assumed to be the MWL (setup) intersection with the beach face. Here, H_{bmin} was set to $H_{brms}/5$, with $H_{bmax}=2.4H_{brms}$, but a finer representation of the wave height distribution could be used. For overtopping and overwash calculations, the runup elevation, z_P,

exceeded by any fraction, P, of the N incident waves can be estimated from Nielsen and Hanslow (1991) as:

$$z_P = R\sqrt{-\ln(P)} \tag{10}$$

Hence, both the number of overwashes and the beach freeboard varies with tide level and wave conditions. Overtopping and overwash is summed for a series of Rayleigh distributed runup events, with P varied from 0.05-0.95 in steps of 0.1, corresponding to runup elevations exceeded by each decile of the incident waves (i.e. z_{95}, z_{85}, …z_5). A finer distribution of runup events (e.g., 1% intervals) can also be adopted.

EXPERIMENTAL SETUP

In 1995-1997 mobile bed experiments were carried out in the large wave flume in the Civil Engineering Department at Imperial College (figure 1). A flat bottom-hinged wave paddle was used to generate regular or random waves up to frequencies of 2Hz, with simultaneous absorption of short waves reflected from the far end of the flume. A slope (β) of gradient 0.05 starts 32m from the paddle, rising to 0.1 in the surf and swash zones. The last 6m of the flume are subdivided into three sections, providing two working sections of width 0.9m and a central section for access to instrumentation. Within the swash zone, fixed and mobile beds of sediment (d_{50}=0.5mm; d_{50}=1.5mm, thickness 0.1m) were used to investigate frictional effects on run-up and beach profile evolution. Further description of the experimental setup is given by Baldock and Holmes (1997). Three sets of Jonswap random wave conditions were used for each sediment size, but only the case with the largest waves is discussed here. Each run started with an initially plane beach, with profile measurements at 30min, 60min, 120min, 240 and 360min run times. Profile measurements were made with a simple drop stick, with accuracy ±1mm in the vertical and ±1cm horizontally. The fine sand beach evolved to a longshore bar-trough system with erosion in the swash zone, whereas the coarse sand beach evolved with the formation of a large swash berm and onshore transport in the surf zone. Both beaches extended sufficiently far landward and seaward to minimise any influence of insufficient sediment supply at the boundaries.

Table 1. Wave conditions

Case	Wave period (s)	H_{rmso} (m)	Offshore wave steepness	Surf similarity, ζ
J1	1.5	90	0.033	.55
J2	1.5	74	0.027	.61
J3	1.0	46	0.031	.57

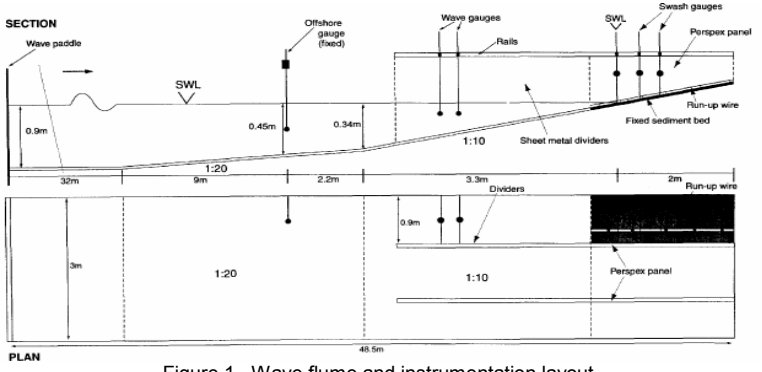

Figure 1. Wave flume and instrumentation layout.

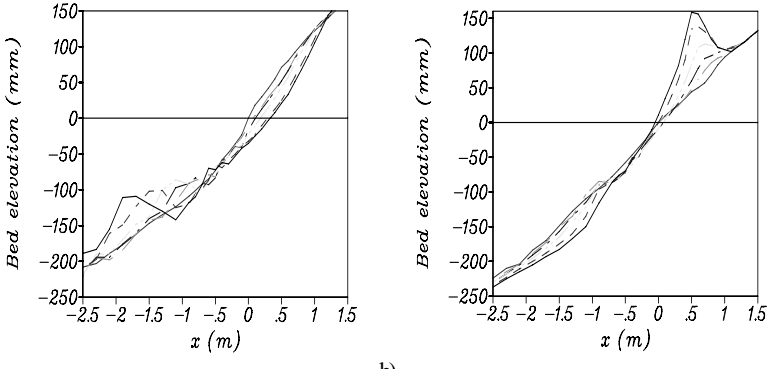
RESULTS

Figures 2a-d illustrates the profile evolution over 360 minutes for both the fine and coarse sand for case J1, indicating a gradual evolution toward equilibrium.



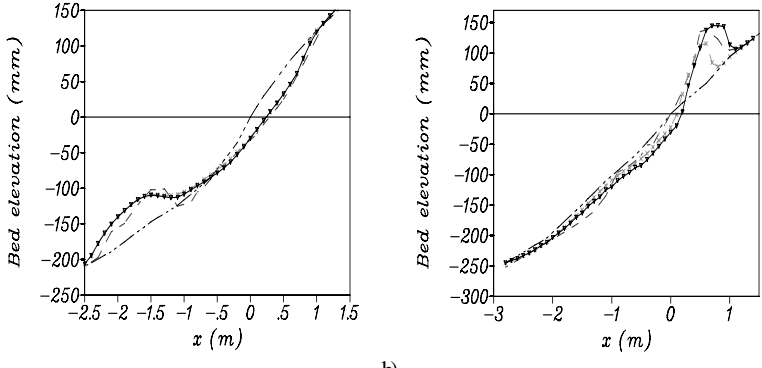


Figure 2. Beach profile at t=0 (red) 30 (green), 60 (blue), 120 (yellow), 240 (magenta) and 360 (black) minutes for fine and coarse sand beaches. a) fine, J1; b) coarse, J1.

Model-data comparisons for t=240min are illustrated in figure 3. The model is run for identical input parameters in both cases, with the exception of grain size and that the suspended load efficiency is set to zero for the coarse sand case and the user-defined equilibrium slope is different. The hydrodynamic and morphodynamic time-step is 6 minutes, but the incident "deep water" wave conditions are constant. For the fine sand, the best fit was obtained with an equilibrium slope of tanβ=0.12. This corresponds closely with the gradient of the model beach at the SWL at all time steps. The optimum

equilibrium gradient for the coarse sand beach was tanβ=0.45, which corresponds to the maximum gradient observed on the model beaches, in this instance in the middle of the seaward face of the swash berm. For the eroding beach, the model results do not differ significantly between the monochromatic and probabilistic approaches, except at the very upper limit of the swash. This is a result of only weak transport in the upper swash, the dominant effect of the offshore bar in controlling the beach morphology at later times and profile smoothing. In contrast, for the accretionary event, it is very important to account for the variable runup in order to predict both the berm position and the total berm volume (figure 3b).

a) b)

Figure 3. Model-data comparisons for a) eroding beach and b) accreting beach. —·· — Initial profile; — — measured profile —∇—, probabilistic model, —×—, monochromatic model. Case J1..

Cumulative eroded/accreted volumes within the swash zone (above the SWL intersection on the beach face) are compared with the model predictions at the different time intervals in figure 4. In conjunction with the equilibrium model, the swash sediment transport routine appears to provide good overall description of the variation in beach face sediment volume. Note that in both cases the trend to morphological equilibrium is quite slow, and may not in fact occur at all for the accreting beach, where the (constant) incident wave conditions continually drive sediment onshore.

The probabilistic approach has also been adopted to calculate swash sediment transport overwashing beach berms, the first step in developing a deterministic parametric model for berm growth. In this case, field data was obtained during sub-aerial berm growth following closure of a coastal lagoon entrance at Belongil Beach, NSW, Australia (see Weir et al., 2005 for details). Overwash volumes were obtained from survey data and compared to sediment transport rates calculated at the berm crest using the probabilistic model. The wave run-up was determined using Hunt's (1954) formula and offshore wave conditions, from which the bore height in the hydrodynamics model is determined. In addition, a constant friction factor was used in Eq. (3). Cumulative overwash volumes

compare well with measured volumes (figure 5) for friction factors in the range f_w=0.024-0.3, which are in the middle of the range suggested by field measurements (e.g. Raubenheimer et al., 2004).

DISCUSSION

While the model works well for predicting overtopping flows, i.e. uprush transport only, it is not yet a good predictive tool for beach morphology, since the equilibrium slope is required as input to the model. In some respects this is not a major shortcoming, since

many models require calibration or ad hoc fitting, and the equilibrium slope may be a parameter that can be robustly defined for particular beaches or grain sizes. However, the model also neglects some sediment transport dynamics that are likely to play an important role, at least in the lower swash zone. Firstly, the advection of pre-suspended sediment is not considered. The Lagrangian model proposed by Pritchard and Hogg (2005) and Alsina et al. (2005) is promising, but the present hydrodynamic routine is not particularly efficient and does not allow for morphological-hydrodynamic feedback.

The importance of pre-suspended sediment on reflective sand beaches is illustrated in figure 6, which shows a significant sediment load in the inner surf zone just prior to bore collapse. How much sediment enters the swash zone then depends on from how far offshore sediment is advected across the swash boundary following bore collapse (figure 7). The classical swash solution predicts that this distance is very small, $1/16^{th}$ of the run-up length (see Pritchard and Hogg, 2005). However, field and laboratory measurements suggest the advection length is approximately $1/4$-$1/3^{rd}$ of the runup length (figure 8). Consequently, sediment can be advected into the swash from further offshore and the total sediment flux into the swash zone is much greater for a given concentration of pre-suspended sediment. Correct representation of this flux will again require a probabilistic approach, with the flux for different bore heights similarly weighted according to the probability of that bore height occurring.

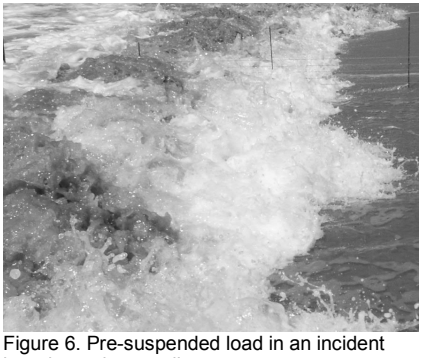

Figure 6. Pre-suspended load in an incident bore just prior to collapse.

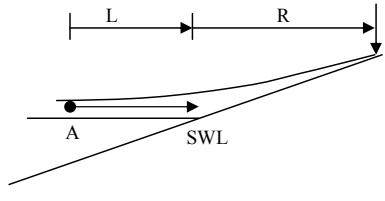

Figure 7. Definition sketch of advection ratio, L/R. Particle at A at time of bore collapse just crosses the SWL during uprush.

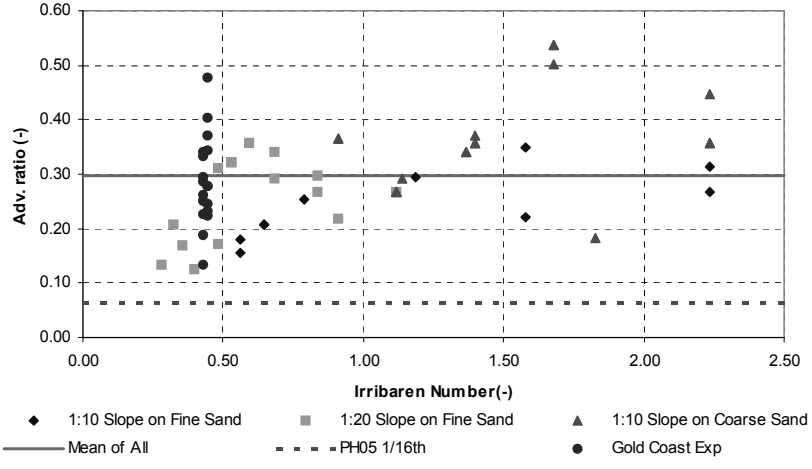
An unresolved issue remains the prediction of the net sediment transport in the swash zone, together with the correct cross-shore variation of the net transport (Q(x)). The latter controls the morphological change. The gradients in the net transport rate are therefore very important. However, particularly for accreting beaches, u^3 type models perform poorly in this respect. For example, the important solutions of Pritchard and Hogg (2005) show that quasi-equilibrium u^3 models with maximum asymmetry at the SWL result in maximum morphological change close to the SWL (their figure 12).



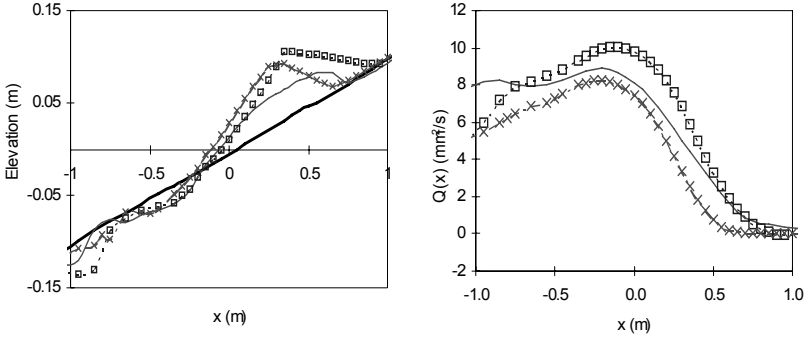


Figure 8. Advection ratio for monochromatic laboratory waves and random waves on a natural beach. After Kudo (1995).

While this is perhaps realistic for net erosion in the swash zone, it is unrealistic for net accretion. However, in the absence of tide, experimental data show that maximum accretion (the berm crest) tends to occur in the mid-upper swash (figure 9a). This requires that Q(x) is initially a downward convex function, with an inflexion point at the berm crest position (figure 9b). For a quasi-intantaneous transport model ($q \propto f(u^n)$), inviscid swash solutions give Q(x) as a monotonic concave function decreasing shoreward, resulting in morphological change that also shows a monotonic concave shape, again decreasing shoreward. Increasing the concentration of the pre-suspended load entering the swash does not change the predicted pattern if a simple suspended load settling model is used in the uprush (see Pritchard and Hogg, 2005). However, a downward convex pattern in Q(x) is possible if an advection-diffusion model is adopted, even for a quasi-intantaneous transport model, provided that the suspended load is the dominant transport mode (see Alsina et al., 2005). Data from Hughes et al. (2007) indicates that during the uprush sediment is maintained in suspension across a large region of the runup zone, well above the mid-swash position, which is consistent with significant morphological change in the upper swash.

Hughes et al. (2007) also note that the concentration in the latter stages of the backwash is lower than might be expected on the basis of the high flow velocity. A possible explanation for the latter may be "hindered pickup" at high bed load transport rates. During the backwash, the concentrated thin sheet flow layer may reduce the relative effectiveness of turbulent bursts in picking up sediment from the immobile bed, in comparison to pickup at lower transport regimes.

a) b)

Figure 9. Profile evolution and sediment transport rates in the inner surf and swash zone. — ·×· — monochromatic wave; —— monochromatic wave with small amplitude long wave; – –□– – monochromatic wave with large amplitude long wave.

An alternative view of this hindered pickup of suspended sediment can be developed from the Energetics approach. Bagnold (1966) suggested that the bed load efficiency factor, e_c, increases as the flow depth reduces in comparison to the thickness of the moving granular layer. In the backwash, the depth is reducing while the thickness of the mobile layer is increasing, so an increase in e_c may be important. The total bed load efficiency factor, e_b, also increases. An increase in e_c consequently reduces the power available to maintain a suspended load. Indeed, Bagnold (1966) suggests e_c may approach unity. If that was the case, little fluid power would remain available for suspended sediment transport.

Finally, the parametric approach involves the fundamental assumption that a representative H_{rms} wave height can provide a sufficient description of the nearshore processes, with wave grouping and surf beat effects neglected. Limited work has considered the role of surf beat in modifying nearshore wave heights and how long waves may alter sediment transport rates outside the surf zone. Nairn (1990) and Roelvink (1993) investigated the influence of surf beat on beach morphology, but few specific experiments have been reported. Baldock et al. (2007) compare beach profile response for a monochromatic wave and bichromatic wave with the same mean surface variance (energy) and the same mean wave period. The beach profile response was in complete contrast, accretion versus erosion, respectively. Further work is ongoing to determine if this is a direct result of wave grouping or the influence of long waves. For the latter, Baldock et al. (2007) found that free surf beat (free long waves in the presence of monochromatic short waves) generally promoted a trend toward a more reflective beach state, and was particularly important in controlling the morphology in the upper swash zone (see figure 9 above). Including both long wave effects and swash-swash interactions in parametric models requires further work, but is also likely to require a probabilistic approach.

CONCLUSIONS

A probabilistic framework has been presented to include random wave runup and swash sediment transport in parametric swash sediment transport models. Runup elevations and swash hydrodynamics are based on established parametric models. Sediment transport calculations are based on well-established total load transport formula. The magnitude and relative weighting of the swash transport are obtained for a random wave field by assuming Rayleigh distributed runup and nearshore bore heights. The model provides good estimates of uprush sediment transport over a natural beach berm. The model is incorporated within a beach profile model, but is not yet a full predictive tool as a result of the difficulties in predicting net transport in the swash zone. An equilibrium type approach is therefore adopted, with reasonable success. The inclusion of pre-suspended sediment and long waves in these form of models is also discussed.

ACKNOWLEDGEMENTS

The present swash model is embedded within the original COSMOS model developed by Rob Nairn at Imperial College in 1990. The authors gratefully acknowledge the continued use of that model.

Abstract: Existing simple, practical models used to predict the transport rate of cohesionless sediment in the sheet flow regime have obvious shortcomings. They generally relate the transport rate directly to the velocity just outside the boundary layer or to an estimate of the instantaneous bed shear stress. Such models neglect important unsteady flow effects such as phase lags between the flow forcing and the bed shear stress and between the bed shear stress and the transport rate. Most also fail to account for the influence of the acceleration time history on the magnitude of the bed shear stress. In this paper a new simple, practical model is developed that aims to provide similar prediction accuracy as more complex process-based models without the computational expense. Convolution integrals are employed to obtain solutions for the governing differential equations in the time domain while accounting for the important unsteady flow effects.

INTRODUCTION

Simple, practical models for sheet flow sediment transport in the coastal environment have evolved from those developed for steady flows in riverine environments. The simplest of these express the transport rate as a function of the near-bed orbital velocity (e.g. Bailard, 1981; Ribberink, 1998). Such models operate under the assumption that the transport rate responds instantaneously to changes in the near-bed wave induced velocity (i.e. that the process is quasi-steady). However, in the coastal environment this assumption is often invalid due to the unsteady and non-uniform nature of the hydrodynamics. Within the wave boundary layer substantial phase differences may exist between the free stream velocity and bed shear stress, and between bed shear stress and sediment transport rate. Also, for a given free stream velocity, the bed shear stress depends on the time taken to accelerate to that velocity. Models that relate the transport rate directly to the near-bed velocity do not account for these unsteady flow effects.

Sediment transport models at an intermediate level of complexity express the instantaneous transport rate as a function of an estimated bed shear stress or Shields parameter. The calculation of the Shields parameter $\theta(t)$ in an oscillating flow generally requires the use of a boundary-layer model. Simple formulae that attempt to bring in the influence of acceleration on the magnitude and phase of the bed shear stress have been proposed. Nielsen (2006) developed a model of this type that accounts for both acceleration skewness and boundary layer streaming present under real waves. However, such models fail to account for suspension hysteresis, where the amount of mobilised sediment depends on the past history of $\theta(t)$, which is important for finer sands and shorter wave periods.

At a higher level of complexity, process-based models have been developed that solve the continuity and momentum equations for both the fluid and sediment phases down into the mobile bed (e.g. Hsu, 2002; Teakle, 2006). These 1DV models resolve the instantaneous velocity and concentration profiles, which enables calculation of both instantaneous and net sediment flux. However, at present these models are too computationally expensive for practical use in engineering applications.

There is therefore a need for simple, practical sediment transport models that include sufficient physics to account for unsteady flow effects and suspension hysteresis. Teakle (2006) proposed a model framework based on the use of convolution integrals. This approach allows solution of the governing differential equations in the time domain for an arbitrary forcing function. This idea is developed further in this paper and the model is parameterised using results from a detailed two phase process-based model developed by Teakle (2006). The objective is to predict the net transport rate with a similar accuracy to the more detailed process-based model without the computational expense.

MODEL DESCRIPTION

A flowchart outlining the model structure is presented in Figure 1. The near-bed velocity time series is the primary input for the model. The instantaneous bed shear stress (and non-dimensional Shields parameter) is estimated by solving the linearised boundary layer equations in the time domain using a convolution integral technique. The Shields parameter is used as the driver for a pickup function. Assuming a particular sediment entrainment mechanism, solutions for the vertical sediment distribution were presented by Nielsen (1992). These solutions are used as the basis for a convolution integral formulation that calculates the vertically integrated amount of mobilised sediment. Finally, the instantaneous sediment transport rate q_s is determined by multiplying the amount of mobilised sediment by an effective transport velocity. The effective transport velocity is estimated by another convolution integral formulation.

The formulae used in the model were parameterised using results from a detailed process-based model developed by Teakle (2006). This model has achieved success in representing much of the important physics in mobile bed boundary layers. The process-based model was used for the parameterisation because laboratory measurements of sheet flow velocity and concentration profiles are limited in detail and accuracy. The process-based model results can be analysed to reveal the instantaneous value of the important terms in the momentum and mass balances at any phase of the flow.

Overall model performance was assessed by comparing the net transport rates predicted by the model to the measured net transport rates in 104 test cases from European and Japanese oscillatory flow tunnel and wave flume experiments (Dohmen-Janssen et al., 2002; O'Donoghue and Wright, 2004; Ribberink and Al-Salem, 1995; Ribberink and Chen, 1993; Ribberink et al., 2000; Watanabe and Sato, 2004). The experimental parameters of the test cases are shown in Table 1. The Japanese data is from tunnel experiments with velocity time-series representing forward-leaning "saw-tooth" wave profiles with non-zero acceleration skewness. The wave shape was characterised by

$$\beta = 1 - T_{cu} / T_c = T_{cd} / T_c \qquad (1)$$

as illustrated in Figure 2. Three of the test cases (W&S test 28, Ribberink B8 and Aberdeen LS915) are used to illustrate examples of the model output in this paper.

Bed Shear Stress

The equation of motion within the boundary layer (assuming horizontal uniformity) is

$$\rho \frac{\partial u}{\partial t} = -\frac{\partial P}{\partial x} + \frac{\partial \tau}{\partial z} \tag{2}$$

where u is the horizontal velocity, P is pressure and τ is shear stress. With the assumption of hydrostatic pressure and adopting the Boussinesq eddy viscosity assumption describing the turbulent diffusion of momentum, equation (2) becomes

$$\frac{\partial u}{\partial t} = \frac{\partial u_\infty}{\partial t} + \nu_t \frac{\partial^2 u}{\partial z^2} \tag{3}$$

For the simplest case of constant and uniform eddy viscosity, the velocity profile and bed shear stress for a simple harmonic driver $u_\infty(t) = \mathrm{Re}\left\{Ae^{i\omega t}\right\}$ are given by

$$u(z,t) = \mathrm{Re}\left\{ A\omega \left(1 - e^{-(1+i)\frac{z}{\sqrt{2\nu_t/\omega}}} \right) e^{i\omega t} \right\} \tag{4}$$

$$\tau(0,t) = \mathrm{Re}\left\{ \rho(1+i)\sqrt{\frac{\nu_t \omega}{2}} A\omega e^{i\omega t} \right\} \tag{5}$$

Nielsen (1992) found that a constant, uniform eddy viscosity is a reasonable assumption for flows in the natural roughness range.

The frequency response function for the bed shear stress from input $\frac{\partial u_\infty}{\partial t}$ is then

$$F(\omega) = \rho(1-i)\sqrt{\frac{\nu_t}{2\omega}} \tag{6}$$

The bed shear stress for arbitrary $u_\infty(t)$ can be found by obtaining the Fourier transform of $\frac{\partial u_\infty}{\partial t}$, multiplying by the frequency response function (6), and obtaining the inverse Fourier transform of the result. Alternatively, the equivalent calculation can be carried out in the time domain by convolution of $\frac{\partial u_\infty}{\partial t}$ with an appropriate impulse response function $f(t)$:

$$\tau(0,t) = \int_{t'=0}^{t} f(t-t') \frac{\partial u_\infty}{\partial t'} dt' \tag{7}$$

The impulse response function is found by inverse Fourier transform of the frequency response function. The appropriate convolution integral for calculation of bed shear stress based on the free stream acceleration time series is

$$\tau(0,t) = \rho\sqrt{\frac{\nu_t}{\pi}} \int_{t'=0}^{t} \frac{\frac{\partial u_\infty}{\partial t'}}{\sqrt{t-t'}} dt' \tag{8}$$

This is a useful expression for the estimation of bed shear stress based on the history of the free stream acceleration. Past values of the free stream acceleration are weighted according to the time elapsed. In practice the integral may be used in discrete form and the limit truncated (typically to within a few wave periods), since the magnitude of the impulse response function decays as (t-t') increases.

A convolution integral formula for the calculation of $\tau(0,t)$ can also be derived where the eddy viscosity is a function of distance from the bed. For an eddy viscosity prescribed by

$$\nu_t(z) = C_1\, u_* z^p \tag{9}$$

where C_1 is a dimensional constant, u_* a representative friction velocity and power $0 \le p < 1$, Liu (2006) showed that the leading-order expression for the bed shear stress is

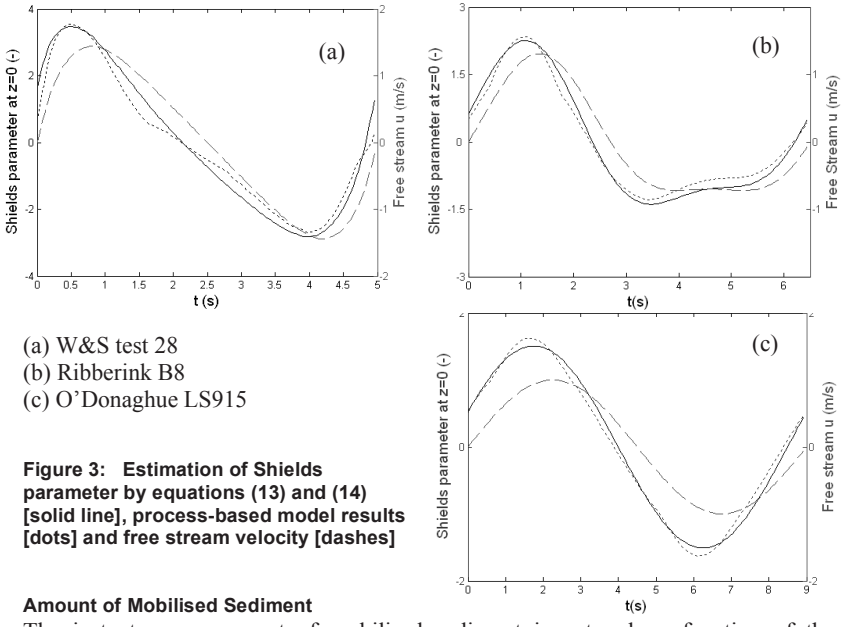
$$\tau(0,t) = C_2 \frac{(1-q)^{2q-1}}{\Gamma(q)} \int_{t'=0}^{t} \frac{\frac{\partial u_\infty}{\partial t'}}{(t-t')^q} dt' \quad \text{where} \quad q = \frac{1-p}{2-p} \tag{10}$$

In terms of Liu's scaling parameters, the dimensional C_2 constant is

$$C_2 = \rho \sqrt{\nu_t(z_0) A^{2q-1} g^{0.5-q} h^{0.5-q}} \tag{11}$$

where A is a horizontal length scale (here taken to be the typical near-bed orbital amplitude), and h is depth. Replacing Liu's velocity scale $\sqrt{gh}$ by $A\omega$ and adopting Nielsen's (1992) empirical expression for the eddy viscosity at the bed $\nu_t(z_0) \sim rA\omega$ where r is the bed roughness, we obtain

$$\tau(0,t) = C_3 \rho \sqrt{rA}\, \omega^{1-q} \int_{t'=0}^{t} \frac{\frac{\partial u_\infty}{\partial t'}}{(t-t')^q} dt' \tag{12}$$



The solution for constant, uniform eddy viscosity is recovered for q=1/2, p=0.
The convolution technique is only useful for the prediction of the bed shear stress due to unsteady components of the forcing signal. In the derivation of (10) the velocity was assumed to be zero at time t=0 and therefore any bed shear stress due to a mean component of the velocity signal must be considered separately. Various ways of incorporating the steady component of the forcing were trialled, and it was found that

$$\tau(0,t) = C_4 \rho \sqrt{rA}\, \omega \left(\int_{t'=0}^{t} \frac{\frac{\partial u_\infty}{\partial t'}}{(t-t')^q \omega^q} dt' + C_5 U_0 \right) \tag{13}$$

performed well with C_5=0.35, where U_0 is the steady component of the forcing. This can be rationalised by considering that the two terms in the bracket on the right hand side of equation (13) have units of velocity, and the appropriate scaling is provided by the terms outside the brackets. A C_4 value of 0.043 was found to lead to successful predictions for the magnitude of maximum shear stress at the initial bed level compared to the process-based model. A value of q=1/8 was found to accurately predict the phase of the maximum shear stress. Considerable uncertainty surrounds the appropriate value for an equivalent roughness height r for mobile beds. A value of $100d_{50}$ was used in this parameterisation based on energy dissipation data (see Nielsen, 1992 p.155). The Shields parameter is

$$\theta(t) = \frac{\tau(0,t)}{\rho(s-1)g d_{50}} \tag{14}$$

For each of the test cases considered, the results from equations (13) and (14) were compared to the Teakle (2006) process-based model results for the total shear stress at the initial bed level. Examples of the predictions of the two models for the three sample test cases are shown in Figure 3.

Amount of Mobilised Sediment

The instantaneous amount of mobilised sediment is not only a function of the instantaneous value of the bed shear stress but also its immediate past values, since sediment will remain entrained in the flow for some time once it has been picked up. Nielsen and Callaghan (2003) found that for fine sands with $d_{50} < 0.2$mm and wave periods $T < 6$s, phase lags between bed shear stress and the amount of mobilized sediment become important. The use of a convolution integral is an obvious way to bring in the influence of the history of $\theta(t)$.

For a horizontally uniform situation, the sediment conservation equation can be written as a balance between a gravitational settling flux $-w_0 c$ and an upward flux q_z:

$$\frac{\partial c}{\partial t} = w_0 \frac{\partial c}{\partial z} - \frac{\partial q_z}{\partial z} \tag{15}$$

Nielsen (1992) presented two alternative solutions to this equation based on whether the upward flux is due to turbulent convection or diffusion. In each case a pickup function prescribed on the bottom boundary is used to drive the model. For an arbitrary pickup function $p(t)$, Fourier analysis can be used to calculate the overall concentration profile $c(z,t)$ by linear superposition of each harmonic component. The alternative is to use a convolution integral, which enables solution in the time domain. The Shields parameter is used as the driver in a pickup function $p(t)$. The amount of entrained sediment is then

$$\Omega(t) = \int_{z=0}^{\infty} c(z,t)\, dz = \int_{t'=0}^{t} p\left(t'\right) f\left(t - t'\right) dt' \tag{16}$$

where $f(t)$ is an appropriate impulse response function corresponding to the vertically integrated sediment distribution model.

For the convective model with an exponentially decaying distribution function $e^{-\frac{z}{L_c}}$, the impulse response function for the total amount of sediment entrained based on input *p(t)* is (Teakle, 2006):

$$f_C(t) = \frac{w_c}{w_0 + w_c} e^{-\frac{w_0 w_c}{L_c(w_0 + w_c)}t} \tag{17}$$

where L_c is a convective distribution length scale and w_c is a vertical convection velocity. For the diffusive model with constant, uniform sediment diffusivity K_s, the impulse response function is (Teakle, 2006):

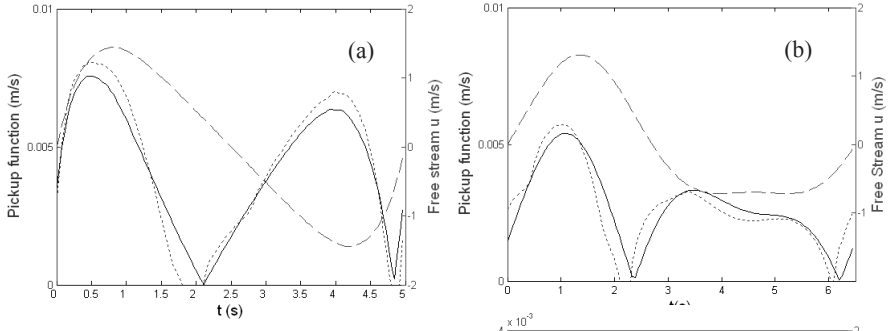
$$f_D(t) = \left(1 + \frac{\zeta}{2}\right) - \left(1 + \frac{\zeta}{2}\right) \mathrm{erf}\left(\frac{\sqrt{\zeta}}{2}\right) - \sqrt{\frac{\zeta}{\pi}} e^{-\frac{\zeta}{4}} \tag{18}$$

where

$$\zeta = \frac{w_0^2 t}{K_s} \tag{19}$$

The form of the pickup function needed in the new model framework was determined by back-calculation using Fourier analysis of the Teakle (2006) process-based model results. The required pickup function was found to be of the form

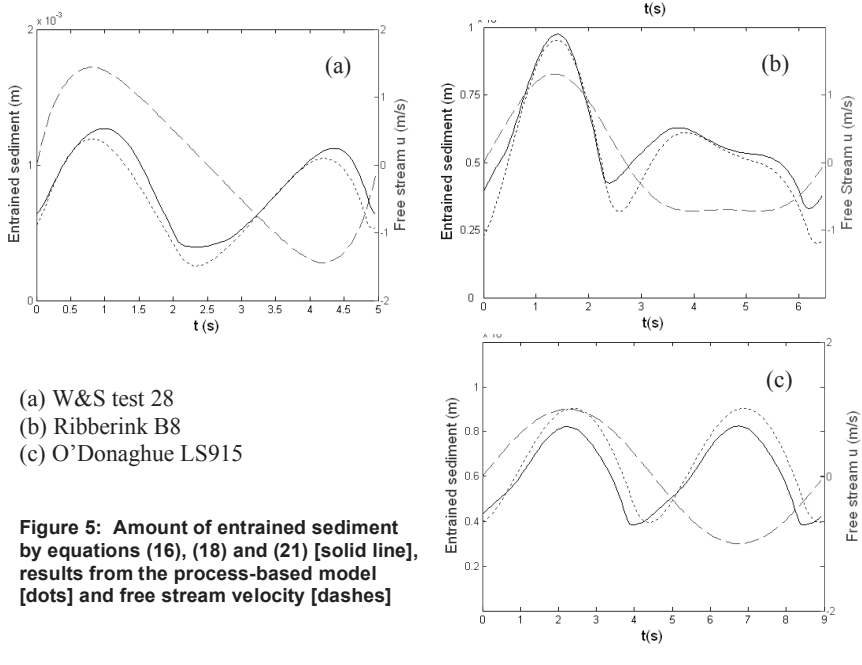
$$p(t) = C_6 w_0 \left|\theta(t) - 0.05\right| \tag{20}$$



where dimensionless coefficient C_6 was found to be approximately 0.1. This expression resembles the pickup function recommended by Nielsen (1992) p.226 except that the Shields parameter is raised to a power of 1 instead of 1.5. A comparison of the pickup function back-calculated from the Teakle (2006) model and from equation (20) for the example test cases is shown in Figure 4. The pickup is seen to occur ahead of the free stream velocity and has a greater magnitude where the free stream acceleration is greater.

The amount of sediment entrained in the flow is calculated using equations (16) and either (17) or (18). Here, an example is given for the diffusive model with constant, uniform sediment diffusivity K_s. The sediment diffusivity K_s was empirically parameterised by analysing results from the process-based model. The following expression was found to perform well:

$$K_s = C_7 \, g \frac{r^{1.5}}{A^{0.5}\omega} \tag{21}$$



where C_7=0.005. The inverse relationship with ω is interesting, since we might have expected the sediment diffusivity to decrease with increasing wave period, as does the eddy viscosity $\nu_t \sim rA\omega$. However, Nielsen (1992) noted on the basis of flume data that the sediment diffusivity needs to be an increasing function of w_0/u_*, which may account for the form of equation (21). In addition, analysis of sheet flow experimental data by Dohmen-Janssen (1999) revealed that the sediment diffusivity derived from the time-averaged concentration profiles increased with increasing period.

Examples of the model output compared to the process-based model results are shown in Figure 5. More sediment is mobilised where the acceleration magnitude is greater.

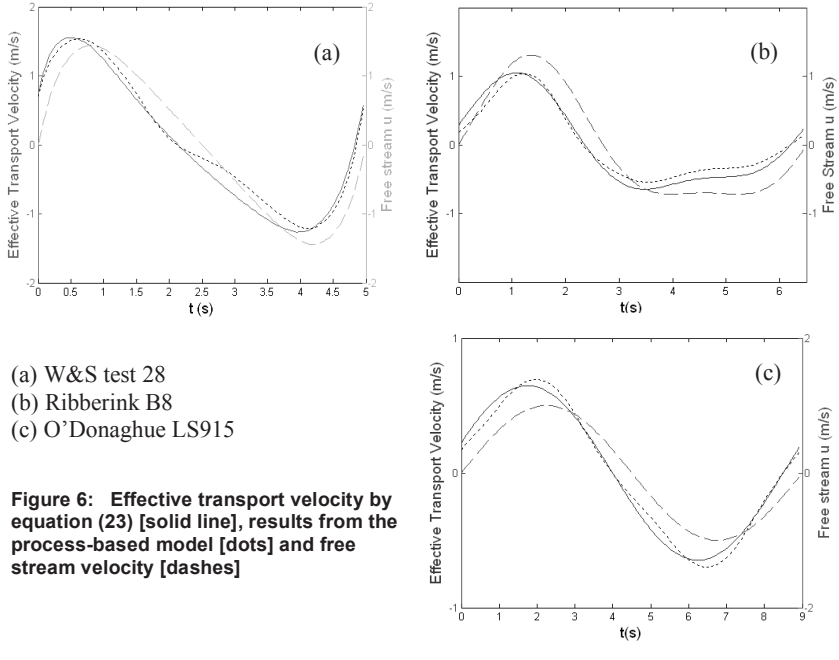
Figure 5: Amount of entrained sediment by equations (16), (18) and (21) [solid line], results from the process-based model [dots] and free stream velocity [dashes]

The Effective Transport Velocity



The effective transport velocity was also parameterised by analysing the results of the process-based model. The target effective transport velocity was found by dividing the instantaneous horizontal sediment flux from the process-based model results by the vertically integrated amount of entrained sediment:

$$u'(t)_{\text{target}} = \frac{\int_{z=z_0}^{\infty} c(z,t)\,u_s(z,t)\,dz}{\int_{z=0}^{\infty} c(z,t)\,dz} \tag{22}$$

where z_0 is the instantaneous bed elevation. It was found that for the majority of the test cases considered, the phase and magnitude of the effective transport velocity was accurately predicted by

$$u'(t) = C_6 \frac{A^{0.7}}{r^{0.2} g^{0.5}} \omega^{1-q} \int_0^t \frac{\dfrac{\partial u}{\partial t'}}{(t-t')^q}\,dt' \tag{23}$$

with q=1/8 and C_6=1.16. Examples of the equation (23) results compared to the process-based model are shown in Figure 6. The effective transport velocity is in phase with the bed friction velocity and is enhanced where the acceleration is greater.

(b) Ribberink B8
(c) O'Donaghue LS915

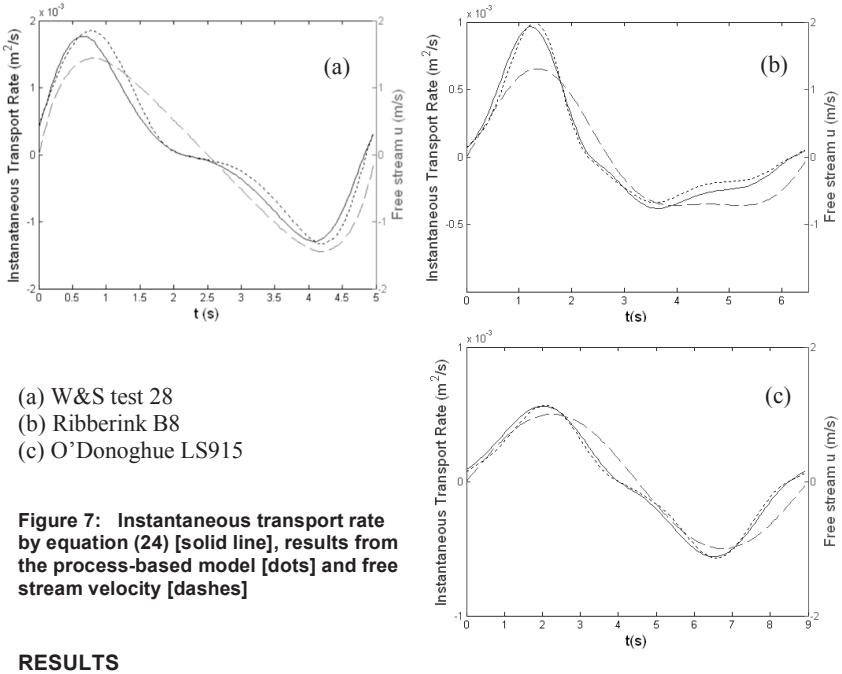

Figure 6: Effective transport velocity by equation (23) [solid line], results from the process-based model [dots] and free stream velocity [dashes]

The Instantaneous Transport Rate

The instantaneous transport rate is found by multiplying the instantaneous amount of entrained sediment from (16) by the effective transport velocity from (23).

$$q_s(t) = \Omega(t)u'(t) \tag{24}$$

An example of results from (24) compared to the process-based model results is shown in Figure 7. It is clear that the magnitude of the onshore transport is enhanced by acceleration effects.

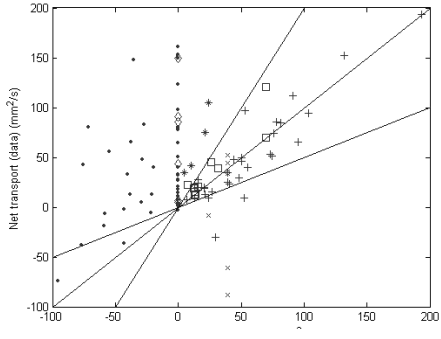
Figure 7: Instantaneous transport rate by equation (24) [solid line], results from the process-based model [dots] and free stream velocity [dashes]

RESULTS

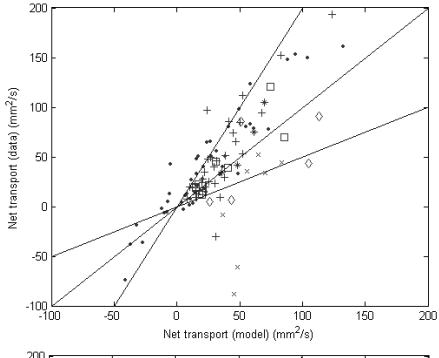
The fully parameterised model was run for the 104 test cases listed in Table 1. The net sediment transport predictions of three simple models compared to the measured net transport rates are plotted in Figure 8.



The first model is the simplest, based on a net transport rate directly proportional to the mean of the velocity cubed and ($q_s \sim \overline{u^3}$). Note the poor performance, particularly for the Watanabe and Sato tests where positive net transport was observed for $\overline{u^3} \le 0$.

The second model presented is that of Nielsen (2006) calibrated with a phase angle $\phi_\tau = 47°$. The inclusion of acceleration effects is seen to produce a considerable improvement in model prediction skill compared to the velocity moment model, since the sum of squares of normalised errors is considerably reduced.

The third model presented is the current convolution integral formulation. Note that the agreement is generally within a factor of 2, which is considered to be good performance for a relatively simple model. The sum of squares of normalised errors was further reduced compared to the Nielsen model, demonstrating improved model prediction skill. An area for future improvement is grain size dependence, since the model performance was poorer for the coarser sediment (d_{50}>0.5mm) and finer sediment (d_{50}<0.15mm).



(a) Velocity moment model $q_s \sim \overline{u^3}$

$$\sum \left(\frac{q_{\text{model}} - q_{\text{meas}}}{q_{\text{meas}}} \right)^2 = 25$$

(b) Calibrated Nielsen (2006) model with $\phi_\tau = 47°$

$$\sum \left(\frac{q_{\text{model}} - q_{\text{meas}}}{q_{\text{meas}}} \right)^2 = 13$$

(c) New convolution integral model

$$\sum \left(\frac{q_{\text{model}} - q_{\text{meas}}}{q_{\text{meas}}} \right)^2 = 9$$

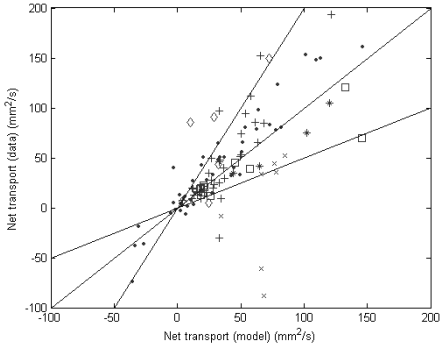


Figure 8: Model results for the net transport rate compared to laboratory data. Watanabe and Sato (0.2mm sand, dots; 0.74mm sand, diamonds), Ribberink and coworkers (Series B, squares; Others, plusses), O'Donoghue and Wright (crosses). The lines indicate a factor 2 difference between model results and data

DISCUSSION

Employing the detailed process-based model of Teakle (2006) to parameterise the new model is justified by the good performance of the new model in predicting net transport rates from tunnel experiments. Although improvements have been made in the measurement of instantaneous velocity and concentration profiles in laboratory experiments, the data is still not of sufficient quality or quantity to effectively enable model parameterisation directly from the measurements.

The effects of acceleration on the bed shear stress and hence the pickup of sediment have been captured by the adopted convolution integral formulation equation (12). The direct action of the pressure gradient on sediment grains may also become important for lightweight sediments and coarse particles, as noted by Sleath (1999). This effect could be included in the model by an extra term in the pickup function related directly to the instantaneous free stream acceleration.

The phenomenon of secondary entrainment of sediment at flow reversal may also be treated by modifying the pickup function. Inclusion of this effect would improve the convolution model performance shown in Figure 8, particularly where $d_{50} < 0.2$ mm.

Suspension hysteresis is particularly important where substantial amounts of sediment remain in suspension through flow reversal, reducing the net transport rate. The use of a convolution integral to solve the sediment conservation equation automatically includes such effects.

Real wave effects such as the boundary layer streaming identified by Longuet-Higgins (1957) can be easily accommodated in the model by addition of a steady component to the equation for the effective transport velocity. The offshore-directed streaming that occurs in wave tunnels simulating 2nd-order Stokes waves (due to the asymmetry of turbulence production) may be treated in a similar manner. Consideration of this process would improve the convolution model performance for many of the outliers in Figure 8.

It is hoped that the model can be extended to other sediment transport regimes such as rippled beds by modifying the form of the pickup function.

Application of the model to a horizontally non-uniform situation, e.g. the swash zone, would in general require a Lagrangian implementation since the convective terms have been neglected in the governing equations.

CONCLUSION

The simple model framework presented in this paper predicts instantaneous sediment transport rates based on simple flow parameters in a computationally efficient manner. Sufficient physics is included to represent the most important boundary layer processes, including phase lags between the flow forcing and the bed shear stress, and between the bed shear stress and the sediment transport rate. Further work will improve the model performance for fine sands ($d_{50} < 0.2$mm) and extend the model to other sediment transport regimes and non-horizontally uniform flows.

Abstract: A new middle-long term beach evolution model is proposed. This model is based on an analytically integrated sediment conservation equation (without assuming any hypothesis regarding the beach profile) and on a beach profile evolution model. The sediment conservation equation provides the long-shore sediment contributions and the beach profile evolution model combines the cross-shore sediment redistribution associated to seasonal process with this long-shore supplies. The model achieves the prediction of the shoreline position and the profile shape along a beach, from middle to long term scale. Furthermore, in this beach profile evolution model, the definition of the complete profile is incorporated (breaking zone, transition zone, exterior zone and geological zone). The proposed middle-long term beach evolution model has been applied in some test cases and it has also been compared to similar models showing a good capability to predict beach evolution in plan form and profile.

INTRODUCTION

As beach erosion problems have become serious in many countries, necessary measures against erosion are being considered. In this context, the capability to predict beach evolution due to changes in natural conditions or caused by human activities is needed and the development of some tools to predict beach evolution (specifically to determine the shoreline evolution) is required.

Processes involved in beach evolution are complex, occurring at different scales and being three dimensional (3D). At present there is no model to be used in the complete scale range, from the short-term (hours) to the long-term (decades). Therefore, beach evolution models for different temporal and spatial scales are necessary. Beach evolution models can be classified depending on different aspects, perhaps one of the most prominent aspects is the temporal scale (short term: hours-days, middle term: days-years, long term: years-decades). According to the temporal scale, these models can be classified in: short-term, middle-term and long-term beach evolution models. Short-term beach evolution models are usually used for small scales (storms, hours to days). These models require a detailed data base for the calibration, validation and sensibility analysis. However, these models provide reasonably good capability to predict beach hydrodynamic and morphology on this short time scale.

Long-term beach evolution models are applied to predict beach morphology for long scales (years to decades). The classical long-term beach evolution model is the "*one-line model*" or "*shoreline model*" (e.g. GENESIS model, Hanson and Kraus 1989 and ONELINE model, Dabees and Kamphuis 1998). In this type of models, beach evolution is represented by means of the shoreline evolution, which can be well predicted based on a previous calibration and validation of the model with local data. Beach profile variation is negated and the cross-shore transport is not taken into account either. Thus, seasonal shoreline changes (summer-winter variations) and shoreline changes associated to storm events, cannot be predicted by using this type of models. Some process-based morphodynamic models applied to long-term scales have been developed in the last decades. However, as expressed by De Vriend et al. (1993), these kinds of models are not the best approach of long-term modelling. Since the natural system is nonlinear, and the validity of long-term model predictions does not follow straightforwardly from model's validity at the hydrodynamic time scale.

Middle-term beach evolution models try to predict the plan and profile variability presented by a beach in a seasonal cycle (summer-winter). The evaluation of the phenomena that occurs in this time scale presents serious difficulties given that their scale is too great to be able to use process models (wave to wave), and yet is too small to assume that it has reached an equilibrium in certain phenomena (De Vriend et al. 1993). *S*everal models have been developed trying to introduce the beach profile variation to the "*one-line models*". Three different models can be recognized: "*one-line models with a cross-shore transport term",* "*N-line models*" and "*hybrid models*". In "*one-line models with a cross-shore transport term*", a cross-shore transport term is introduced into the simplified sediment conservation equation used by "*one-line models*". However, the beach profile variation is not considered. "*N-line models*" can be defined as several "*one-line models*" connected by cross-shore transport (e.g. INLINE model, Hanson and Larson 2000 and NLINE model, Dabees and Kamphuis 2000). However, the expressions available to calculate this transport are not very reliable and by using the cross-shore transport the involved physical process is not taken into account. Furthermore, "*N-line models*", compared to the "*one-line models*", need longer computer time. Finally, "*hybrid models*" link a "*one-line model*" and a "*beach profile evolution model*". There

are different "*hybrid models*", as for example: 3DBEACH model (Larson et al. 1990), in which the GENESIS model (one-line model) is connected to the SBEACH evolution model (cross-shore model), 3D-SHORE model (Shimizu et al. 1996) and LITLINE module in the LITPACK package (DHI 2001). These kinds of models can be a tool for the middle-term. However, there are important limitations, regarding its calibration (several hydrodynamic and sediment transport parameters) and a high consuming computer time. The limitations for these kinds of models are also more critical in order to predict the combined middle-long term scales.

In this work, a behaviour-oriented beach profile evolution model in the same line as the 3DBEACH is considered the most adequate model to develop a tool for the middle-long term. Thus, following this approach, in this paper a new middle-long term beach evolution model is proposed, which is based on an analytically integrated sediment conservation equation (without assuming any hypothesis regarding the beach profile) and on a beach profile evolution model. The model is able to predict the shoreline position and the profile shape along a beach, in the middle to long term scale. It also incorporates the definition of the extended beach profile (breaking zone, transition zone, exterior zone and geological zone), which is not a process-based model, reducing the computer effort in the long-term.

INTEGRATED SEDIMENT CONSERVATION EQUATION

As most of the classical long-term beach evolution models use a simplified sediment conservation equation, in order to propose a middle-long term beach evolution model, the general sediment conservation equation has to be derived, without assuming any hypothesis regarding the beach profile.

Following Abbott and Price (1994), the sediment conservation equation is determined by using Eq. (1), indicating that the temporal variation of the sediment concentration is due to advection, diffusion and potential sources/sinks.

$$\frac{\partial c}{\partial t}+\frac{\partial}{\partial x}\left(cu_{sed}\right)+\frac{\partial}{\partial y}\left(cv_{sed}\right)+\frac{\partial}{\partial z}\left(cw_{sed}\right)=\frac{\partial}{\partial x}\left(\varepsilon_x\frac{\partial c}{\partial x}\right)+\frac{\partial}{\partial y}\left(\varepsilon_y\frac{\partial c}{\partial y}\right)+\frac{\partial}{\partial z}\left(\varepsilon_z\frac{\partial c}{\partial z}\right)+FS \quad (1)$$

where c = the sediment concentration (kg/m^3); t = time (s); (x, y, z) = spatial coordinates (m), with x the longshore coordinate, y the cross-shore coordinate and z the vertical coordinate (positive upward); $(u_{sed}, v_{sed}, w_{sed})$ = sediment velocity components (m/s); $(\varepsilon_x, \varepsilon_y, \varepsilon_z)$ = diffusion coefficient components (m^2/s) and FS = sediment concentration per unit time due to potential sources/sinks (kg/m^3/s).

In order to get the corresponding equation in two dimensions, Eq. (1) is integrated in vertical and cross-shore coordinates. In the vertical coordinate it is integrated between the bottom position (z_b) and the water surface position (z_η), in the cross-shore coordinate, it is integrated between the shoreline position (y_s) and a time-independent offshore limit position (y_e). The following considerations are taken into account: the bottom sediment

velocity is null, the cinematic condition in the water surface is introduced, the diffusive mass flux perpendicular to the contour is null on the bottom and also on the water surface, the total sediment (sand) concentration along the water column does not change over time and the bottom sediment concentration is uniform along the spatial coordinates x and y. After that, Eq. (2) is obtained.

$$\frac{\partial A_y}{\partial t} + \frac{\partial Q_x}{\partial x} + q_{x_{y_s}} \frac{\partial y_s}{\partial x} - q_{y_{y_s}} = q_{FS} \tag{2}$$

where A_y = the transversal section (m^2) between the bottom elevation and the z axis and from the y_s limit to the y_e limit and is defined by Eq. (3); Q_x = the total longshore sediment transport (m^3/s) integrated between the y_s limit and the y_e limit and is defined by Eq. (4); $q_{x\,ys}$ = the longshore transport (m^2/s) in the shoreline position; $q_{y\,ys}$ = the cross-shore transport in the shoreline position (m^2/s) and q_{FS} the sediment supply or sediment loss (m^2/s) due to potential sources/sinks expressed by Eq. (5). In Eq. (4) and Eq. (5) ρ_s= the sediment density (kg/m^3) and p = the porosity (non-dimensional).

$$A_y = \int_{y_s}^{y_e} z_b dy \tag{3}$$

$$Q_x = \int_{y_s}^{y_e} q_x dy = \frac{\int_{z_b}^{z_n} \left(cu_{sed} - \varepsilon_x \frac{\partial c}{\partial x} \right) dz}{\rho_s (1-p)} \tag{4}$$

$$q_{FS} = \int_{y_s}^{y_e} \left(\frac{1}{\rho_s (1-p)} \int_{z_b}^{z_n} FS dz \right) dy \tag{5}$$

However, A_y and Q_x only have physical meaning if the "x, y" components correspond to the "longshore, cross-shore" components regarding the beach profile. This is why working with a similar equation but set in these local coordinates (x_l, y_l) is recommended. Following O'Rourke and LeBlond (1972), if the curvature radius of the beach is large compared to the surf zone, then Eq. (2) can be represented in local coordinates by using Eq. (6).

$$\frac{\partial A}{\partial t} + \frac{\partial Q_{x_l}}{\partial x_l} - q_{y_{l\,y_{ls}}} = q_{FS} \tag{6}$$

where A = the transversal section of the beach profile (m^2) between the bottom elevation and the z axis and from the y_{ls} limit to the y_{le} limit and the remaining terms have the same meaning as in Eq. (2) but referring to the local coordinates, that is, x_l = longshore

component regarding to the beach profile and y_l = cross-shore component regarding to the beach profile.

Eq. (6) only has information of the sediment variation in the studied area in terms of the temporal variation of the transversal section. Notice that to determine the temporal variation of the shoreline position the dependence between the temporal variation of the transversal section and the temporal variation of the shoreline position must be introduced. Furthermore, as the sediment conservation equation only indicates the temporal variation of the transversal section, even when providing this dependence, the temporal variation of the shoreline position not associated to variations of the transversal section could not be determined at all. The latter variation is usually associated to sediment redistribution along the profile by cross-shore transport, which can generate shoreline position changes without transversal section modifications and it is especially important in the middle-term. That is the case of the seasonal variations of the shoreline position (summer-winter).

Therefore, in order to predict shoreline position in the middle-long term a beach profile evolution model is necessary. This model evolves taking into account the temporal variation of the transversal section imposed by the general conservation equation derived previously (long-shore sediment contributions) combined with cross-shore sediment redistribution associated to middle term forces.

EXTENDED BEACH PROFILE MODEL

Traditionally, the beach profile has been defined taking into account only the breaking-zone (e.g. Dean 1987; Gonzalez et al. 1999), other authors have included a transition zone associated to the shoaling zone (Medina et al. 2000). The beach profile model proposed in this work has been denominated extended beach profile, because it includes different cross-shore zones: breaking zone, transition zone, exterior zone and geological zone (see figure 1).

Extended beach profile zones

The complete beach profile is composed of the following zones: breaking zone, transition zone, exterior zone and geological zone. These zones can be observed in figure 1 and are described next:

Breaking zone. The breaking zone is assumed to be in equilibrium with the incident wave conditions. This zone goes from the high tide level to the breaking point of the low tide level, h_{rt}.

Transition zone. The transition zone is extended from the breaking point of the low tide level (h_{rt}) to the local exterior depth of the low tide level, $h_{e\,loc}$. To calculate this depth, an expression is going to be proposed later.

Exterior zone. The exterior zone is the beach profile zone which remains unchangeable between two successive moments. This zone goes from the local exterior depth of the

low tide level ($h_{e\ loc}$) to the exterior or geological depth of the low tide level, h_e. This exterior limit is time-independent and an expression to estimate this depth will be proposed later.

Geological zone. The geological zone is defined in deeper waters from the exterior geological depth (h_e).

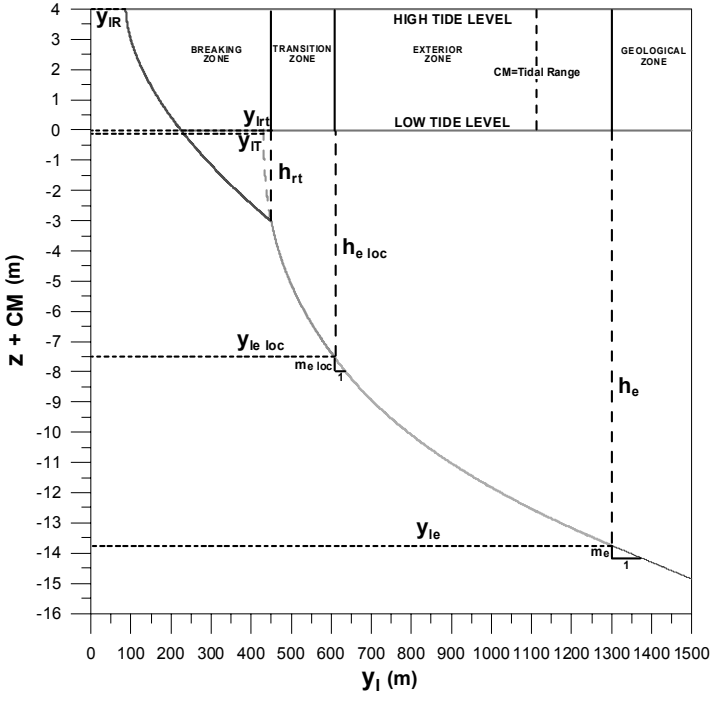

Fig. 1. Zones of the complete beach profile

In figure 1, the vertical z axis begins in the high tide level and is positive above this level. *CM* is the tidal range. Notice that the horizontal axis y_l represents the local axis, but the origin is displaced from the shoreline position.

Extended beach profile formulation

In the following expressions, which are going to be proposed to define every zone along the beach profile, the water depth h (h_R for the breaking zone and h_T for the transition zone) is defined as beginning in the high tide level (as the z axis) and is positive below this level (just the opposed to the z axis). The horizontal cross-shore axis y_l represents the local axis, but the origin is displaced from the shoreline position.

Breaking zone profile. As the breaking zone is assumed to be in equilibrium with the incident wave conditions, any of the formulations existing in the literature for the equilibrium beach profile existing in the literature can be applied to define the profile for this zone. Following, beach profiles similar to Vellinga (1984), Dean (1987), Boon and Green (1989) or Larson et al. (1999), a potential expression is used, as it is indicated in Eq. (7).

$$h_R = A_R \left(y_l - y_{lR} \right)^{m_R} \Rightarrow y_{lR} \le y_l \le y_{lrt} \quad 0 \le h_R \le h_{rt} + CM \tag{7}$$

In Eq. (7) the origin of the potential expression is located in the high tide level, A_R is the shape parameter, m_R is the exponent of the potential expression and y_{lR} is the origin position of the potential expression regarding the origin of the local axis y_l. Therefore, y_{lR} is the shoreline position.

Transition zone profile. This beach profile zone is in constant evolution and is the transition between the breaking zone and the exterior zone. In order to define this profile, a potential expression is also used, as it is presented in Eq. (8).

$$h_T = B_T \left(y_l - y_{lT} \right)^{m_T} + CM \Rightarrow y_{lrt} < y_l \le y_{le\,loc} \quad h_{rt} + CM < h_T \le h_{e\,loc} + CM \tag{8}$$

In Eq. (8) the origin of the potential expression is located in the low tide level. B_T is the shape parameter, m_T is the exponent of the potential expression and y_{lT} is the origin position of the potential expression regarding to the origin of the local axis y_l.

Exterior zone profile. The profile in this zone has to be defined initially at time (t=0) for the evolution model. From this moment on, this zone is automatically determined as the zone which remains unchanging between two successive moments. The definition of this initial profile can be established directly using the real profile or, similarly as in the previous zones, by using a potential expression.

MIDDLE-LONG TERM EVOLUTION MODEL

The proposed middle-long term beach evolution model is based on the analytically integrated sediment conservation equation (without assuming any hypothesis regarding the beach profile) and on a beach profile evolution model. The temporal variation of the transversal section (forced by the long-shore sediment contributions) is imposed by the conservation equation in local coordinates integrated to the exterior limit (time-independent offshore limit) and which was established in Eq. (6). On the other hand, the beach profile evolution model combines the cross-shore sediment redistribution associated to the seasonal processes with this long-shore constributions. The model achieves to predict the shoreline position and the profile shape along a beach, from middle to long term scale.

Model formulation and initial conditions

In order to establish the temporal evolution of the model, the same terminology utilized in the previous section will be used to define the different zones of the beach profile, and a new temporal coefficient will be added to the parameters associated to the beach profile zones, indicating the time at any time step as (1 for t_1) or the time at the next time step as (2 for t_2). The parameters A_R, y_{lR}, m_R, h_{rt}, B_T, y_{lT}, m_T and $h_{e\,loc}$ will be input data for the initial time (t=0) in the evolution model. The parameters A_{R1}, m_{R1}, h_{rt1} and $h_{e\,loc1}$ will be always input data at time t_1. Therefore, the unknown parameters which define the shoreline position and the shape of the profile in the transition zone at the next time step (y_{lR2}, B_{T2}, y_{lT2} and m_{T2}) will be found by matching at the interfaces, as follows.

1. *Continuity of the beach profile in the breaking point* (y_{lrt2}, h_{rt2}). This point belongs to the breaking zone and to the transition zone (see figure 1).

2. *Continuity of the beach profile in the point with associated depth* $h_{e\,loc2}$ ($y_{le\,loc2}$, $h_{e\,loc2}$). This point belongs to the transition zone and to the exterior zone (see figure 1).

3. *Continuity of the beach slope* $m_{e\,loc2}$ *in the point with associated depth* $h_{e\,loc2}$ ($y_{le\,loc2}$, $h_{e\,loc2}$). This is the second condition that the exterior zone imposes on the transition zone.

4. *Sediment conservation* imposed by Eq. (6) on the beach profile evolution model.

Finally, using the previous four conditions, the four unknown parameters y_{lR2}, B_{T2}, y_{lT2} and m_{T2} are obtained. Notice that y_{lR2} is just the shoreline position.

Input parameters determination

Local waves are the forcing dynamic on the system. These waves keep the information regarding the middle term (seasonal) and long term (yearly) variations. Local waves define at each time step and beach location, the sediment longshore flux (Q_{x1}) and the water depth limits h_{rt}, h_{eloc}.

The sediment longshore transport can be calculated applying an expression similar to the Osaza and Brampton (1980) formulation, which includes the transport associated to the wave incident obliquity and the longshore wave height gradients (e.g. Hanson and Kraus 1989; Dabees and Kamphuis 1998).

The expression proposed by Bernabeu et al. (2003) can be used to determine the breaking point of the low tide level, h_{rt}.

The expressions proposed by Requejo (2005) can be utilized to calculate the local exterior depth of the low tide level ($h_{e\,loc}$).

The exterior or geological limit of the low tide level is imposed by the peculiar geology of every particular place. However, a tentative expression to determine the depth h_e associated to this limit was found by Requejo (2005).

APPLICATION CASES

In order to illustrate the advantages of using the proposed model, two comparison examples are going to be presented. The first case is a situation with no temporal variation of the transversal section of the beach profile associated to the longshore sediment transport. The second case is a situation with temporal variation of the transversal section of the beach profile associated to longshore variation of the longshore sediment transport.

Case 1

This case is a rectilinear coast of 1200 m. Boundary conditions correspond to null longshore sediment transport in both contours. Waves reach the coast perpendicularly and the temporal sequence of the significant wave heights are the following: 4 m, 3.5 m, 6 m, 5 m, 5.5 m and 6.5 m. This is a typical case of temporal variation of the shoreline position due to variable wave height, as occurs with the easonal variations of the shoreline position (summer-winter) or middle term variations.

In the proposed model for defining the different zones of the beach profile, the following considerations have been taken into account:

In the *breaking zone*, a potential expression with an exponent value of 2/3 (Dean´s profile) and a shape parameter established with Dean´s formulation (see Dean 1987) for a grain size of 0.0002 m has been used (A_R=0.0975 $m^{1/3}$).

In the *transition zone* a potential expression has also been considered. To calculate $h_{e\,loc}$ depth, expressions proposed by Requejo (2005) have been utilized.

In the *exterior zone*, the exterior geological limit has been defined by a horizontal distance of 1300 m and an exterior or geological depth of 14 m. Additionally, to defining the initial exterior zone, in this limit the beach slope has been determined (m_e=0.006) and the initial transition zone has been extended to a horizontal distance of 650 m. The tidal range (CM) has been established at 2 m.

On the other hand, in classical one-line models, the beach is defined by a unique profile. To define this profile, a potential expression with an exponent value of 2/3 (Dean´s profile) and a shape parameter A_d, established to balance the cross-shore sediment mass, has been used (A_d=0.133 $m^{1/3}$). To be consistent with the values for the sum of the exterior or geological depth (h_e=14 m) and the tidal range (CM=2 m) used in the proposed model, in the classical one-line model the value for the sum of the berm height D_B and the depth of closure D_C is assumed to be the same ($D_B + D_C$=16 m).

In this example, as the wave incidence is normal and there is no longshore variation of the wave height, there is no longshore variation of the longshore sediment transport. Consequently, the temporal variation of the transversal section of the beach profile is null. As classical one-line models can only predict temporal variation of the shoreline

position associated to longshore variations of the longshore sediment transport, in these types of models the shoreline position remains invariable, as it is depicted in figure 2. For this situation the proposed model is especially valuable because this model is not only able to predict temporal variations of the shoreline position related to temporal variations of the transversal section but also is capable to determine the temporal variation of the shoreline position associated to sediment redistribution due to cross-shore transport, as in the present case. Additionally, the estimated shoreline position using the proposed model is represented in figure 2.

For this example, the beach profile evolution is depicted using the proposed model in figure 3. In this figure the beach profile is also presented for classical one-line models, in this case the beach profile is invariable. Therefore, Dean´s profile is extended from the invariable shoreline position.

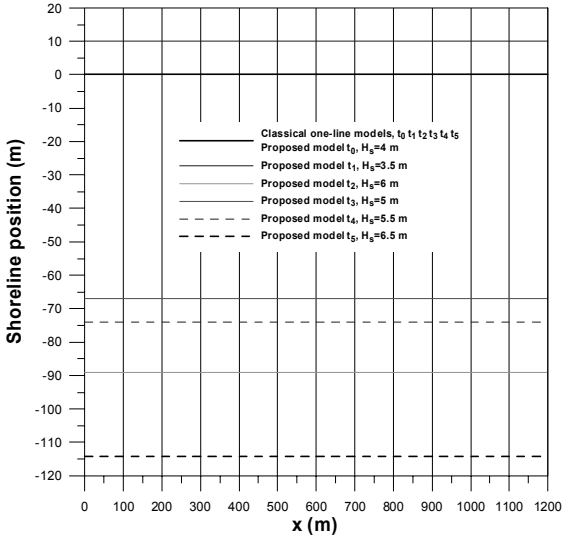

Fig. 2. Plan view of the shoreline position determined with the proposed model and with classical one-line models for Case 1.

Case 2

This case is a rectilinear coast of 1200 m. Boundary conditions correspond to two infinitely long jetties, which is equivalent to the sediment longshore transport is null in both contours. In this case wave conditions are constant, deep water wave conditions are: 3 m for the significant wave height, 10 s for the peak period and 10 degrees for the incidence angle.

This example is the opposite of the previous one because the temporal variation of the shoreline position is associated to the longshore variation of the sediment longshore

transport due to the oblique incidence of waves. In consequence, temporal variation of the transversal section of the beach profile is generated.

Both models, the proposed model and the classical one-line model, have been executed using the following parameters: 25 cells to define the shoreline position, 50 m for the cell width, 12 hours for the execution time interval. To calculate the sediment longshore transport the formula proposed by Ozasa and Brampton (1989) has been used.

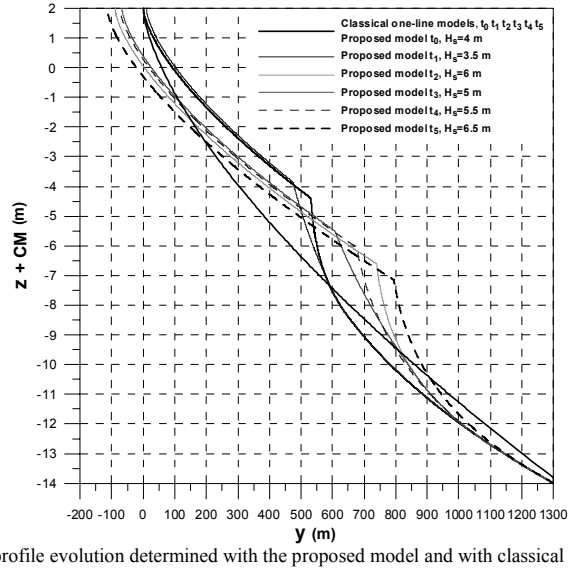

Fig. 3. Beach profile evolution determined with the proposed model and with classical one-line models for Case 1.

Regarding the specific parameters of the model, in the proposed model for defining the different zones of the beach profile, the following considerations have been taken into account:

In the *breaking zone*, a potential expression with an exponent value of 2/3 (Dean´s profile) and a shape parameter established with Dean´s formulation (see Dean 1987) for a grain size of 0.0003 m has been used (A_R=0.119 $m^{1/3}$).

In the *transition zone* a potential expression has also been considered. To calculate $h_{e\,loc}$ depth, expressions proposed by Requejo (2005) have been utilized.
In the *exterior zone*, the exterior or geological limit has been defined by a horizontal distance of 1300 m and an exterior or geological depth of 13.75 m. Additionally, to define the initial exterior zone, in the previous limit the beach slope has been determined (m_e=0.00555) and the initial transition zone has been extended to a horizontal distance of 650 m. The tidal range (*CM*) has been established at 4 m.

On the other hand, in classical one-line models the beach is defined by a unique profile. To define this profile, a potential expression with an exponent value of 2/3 (Dean´s profile) and a shape parameter A_d established with Dean´s formulation (see Dean, 1987) for a grain size of 0.0003 m has been used (A_d=0.119 $m^{1/3}$). To be consistent with the values for the sum of the exterior or geological depth (h_e=13.75 m) and the tidal range (CM=4 m) used in the proposed model, in the classical one-line model the value for the sum of the berm height D_B and the depth of closure D_C is assumed to be the same (D_B + D_C=17.75 m). However, a different value for the sum of the berm height and the depth of closure in the classical one-line model would change the temporal scales of the shoreline evolution. Additionally, in an ordinary case using classical one-line models the beach profile is extended to a smaller depth.

In figure 4 the shoreline evolution determined with both models are presented. For this case, to attain the equilibrium shoreline position in the classical one-line model 105 days are required. Otherwise, in the proposed model 42 days are needed. Therefore, the temporal scales of the beach evolution are different comparing both models.

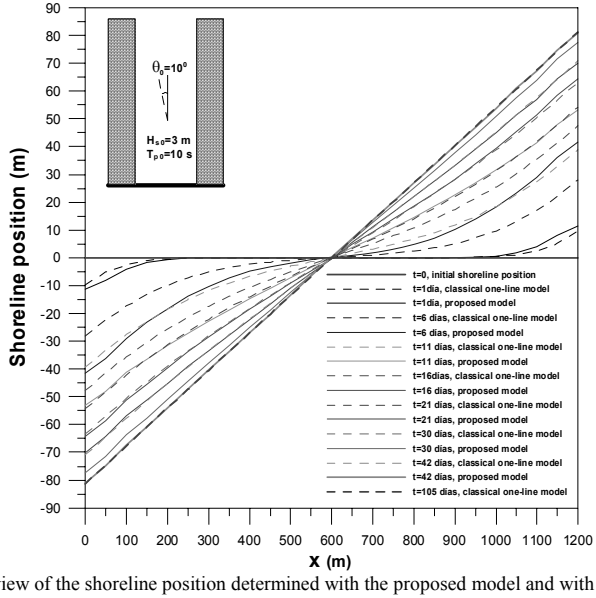

Fig. 4. Plan view of the shoreline position determined with the proposed model and with classical one-line models for Case 2.

CONCLUSIONS

A new middle-long term beach evolution model has been proposed. This model has been established based on an analytically integrated sediment conservation equation (without assuming any hypothesis regarding the beach profile) and on a beach profile evolution

model. The model is able to predict the shoreline position and the profile shape along a beach, from middle to long term scales.

The sediment conservation equation only has information of the sediment variation in the studied area in terms of the temporal variation of the transversal section. However, in order to determine the temporal variation of the shoreline position, the introduction of the temporal variation of the cross-shore profile is required.

The temporal variation of the transversal section (forced by the long-shore sediment contributions) is imposed by the conservation equation integrated to the exterior limit (time-independent offshore limit). On the other hand, the beach profile evolution model combines the cross-shore sediment redistribution associated to seasonal processes with the long-shore contributions.

Traditionally, the beach profile has been defined taking into account only the breaking-zone, other authors have included a transition zone associated to the shoaling zone (Medina et al. 2000). The beach profile model proposed in this work has been denominated extended beach profile, because it includes different cross-shore zones: breaking zone, transition zone, exterior zone and geological zone.

Finally, the advantages of using the proposed model compared to classical one-line models have been determined. A more thorough field validation is also necessary. However, in this work a lack of high quality field measurements of hydrodynamics, sediment samples, shorelines and cross-shore profiles in beaches, at an appropriated time and space scale taking into account seasonal changes throughout several years has been identified.

Abstract: Returning to the starting point of Bagnold's basic study, sand transport equations were derived. A model for predicting beach changes by applying the concept of the equilibrium slope introduced by Inman and Bagnold (1963) and the energetics approach of Bagnold (1963) was developed. As a result, the physical rationality of the predictive model was enhanced compared with the original model. Typical beach changes caused by the obstruction of longshore sand transport and associated changes in grain size could be predicted. This becomes a practical tool for predicting three-dimensional beach changes on coasts composed of sand of mixed grain size.

INTRODUCTION

Artificial alteration of coasts not only gives rise to beach changes, but also often affects the ecosystem in the shallow zone of the sea through changes in the grain size of seabed materials. Because of this, several models for predicting not only beach changes, but also quantitative changes in seabed materials, or grain size, have been developed in recent years. Uda *et al*. (2004) and Kumada *et al*. (2006) have developed models for predicting both beach changes and grain size changes, applying the contour-line-change model (Serizawa *et al*., 2003). Although the applicability of these models to real cases is high, the sand transport equations used have been derived not

by a theoretically rigorous method but rather by an intuitive method. In this study, we return to the starting point of Bagnold's study and sand transport equations are derived. A model for predicting beach changes by applying the concept of the equilibrium slope introduced by Inman and Bagnold (1963) and the energetics approach of Bagnold (1963) is developed.

PREDICTIVE MODEL

Sand Transport Equation Based on Bagnold's Concept

The fluid motion near the seabed due to waves is oscillatory, changing the direction alternately shoreward and seaward, and a sand particle moves back and forth in the cross-shore direction. Inman and Bagnold (1963) derived their fundamental equations on the basis of energy conservation, using the sand transport equation explicitly including the seabed slope (Bagnold, 1963), and assuming that sand transport in a wave field is the sum of the components caused by shoreward flow during the motion of incoming waves and seaward flow during the motion of outgoing waves. In this study, in accordance with this concept, a simple equation of sand transport flux is derived first, using only the wave conditions at the breaking point for the sediment of a single grain size (Serizawa *et al.*, 2006).

Consider Cartesian coordinates (x, y), and that the elevation at a point Z (x, y, t) is a variable to be solved. Assume that waves are obliquely incident on a coast with a uniform slope of $\tan\beta$. Sand transport in a wave field is assumed to be the sum of the components caused by shoreward flow during the motion of incoming waves and seaward flow during the motion of outgoing waves as suggested by Inman and Bagnold (1963), and the sand transport equation for a unidirectional steady flow introduced by Bagnold (1963) is applied to each component.

Assuming that $\tan\beta$ is infinitesimal, that the flow causes a sand particle to move in the direction of flow and that gravity causes the downslope action, then the sand transport flux of a unidirectional flow is expressed by Eq. (1) as a linear approximation in terms of $\tan\beta$ (Bagnold, 1963; Bailard and Inman, 1981). The first term represents the action produced by the flow and the second term represents the downslope action due to gravity. The sign of the coefficients a_0 and a_1 is always positive.

$$\vec{q_u} = a_0 \vec{e_u} - a_1 \nabla Z \qquad (a_0 > 0, \quad a_1 > 0) \tag{1}$$

Here, $\vec{e_u}$ is the unit vector in the direction of the flow, $\nabla Z = (\partial Z/\partial x, \partial Z/\partial y)$ is the gradient vector of Z, the direction and magnitude of which give shoreward normal to the contour line and $\tan\beta$, respectively. Assume that the sand transport caused by shoreward and seaward flow during the motion of incoming and outgoing waves is expressed by Eq. (1), when the sand transport is averaged over a period. Then, the net sand transport flux due to waves is expressed as Eq. (2) by the summation of the components due to incoming and outgoing waves as shown in Eqs. (3) and (4), respectively. The sign of the coefficients a_0^+, a_0^-, a_1^+ and a_1^- is always positive.

$$\vec{q} = \vec{q^+} + \vec{q^-} \tag{2}$$

$$\vec{q^+} = a_0^+ \vec{e_w^+} - a_1^+ \nabla Z \quad \left(a_0^+ > 0,\ a_1^+ > 0\right) \tag{3}$$

$$\vec{q^-} = a_0^- \vec{e_w^-} - a_1^- \nabla Z \quad \left(a_0^- > 0,\ a_1^- > 0\right) \tag{4}$$

Here, the superscripts + and – show the values corresponding to incoming and outgoing waves, respectively, and $\vec{e_w^+}$ and $\vec{e_w^-}$ are the unit vectors in the directions of shoreward and seaward flow of waves, respectively. Modifying Eq. (2) under the assumption that the directions of waves propagating shoreward and seaward are exactly opposite, as given by Eq. (5), defining the slope satisfying zero net on-offshore sand transport when waves are incident from the direction normal to the shoreline as the equilibrium slope, $\tan\beta_c$ (Eq. (6)), and defining the coefficient A by Eq. (7), sand transport flux can be written as Eq. (8).

$$\vec{e_w^-} = -\vec{e_w^+} \tag{5}$$

$$\tan\beta_c = \left(\frac{a_0^+ - a_0^-}{a_1^+ + a_1^-}\right) \tag{6}$$

$$A = \left(a_1^+ + a_1^-\right) \tag{7}$$

$$\vec{q} = A\left[\tan\beta_c \vec{e_w} - \nabla Z\right] \tag{8}$$

Applying the energetics approach (Bagnold, 1963), in which a part of the dissipating wave energy is used for the work of sand transport and the rate of sand transport is related to the dissipation of wave energy, and assuming that the coefficient A in Eq. (8) is proportional to the wave energy dissipation rate Φ, then total longshore sand transport rate is obtained by integrating the longshore component of Eq. (8) over the depth. This has the same form as the CERC formula of Eq. (9) (Komar and Inman, 1970), and the coefficient A is determined by Eq. (10) from the equivalence of both results. Finally, the sand transport flux due to waves can be written as Eq. (12).

$$Q_s = C_0 K_1 \left(EC_g\right)_b \cos\alpha_b \sin\alpha_b \tag{9}$$

$$A = C_0 \frac{K_1 \Phi}{\tan\beta_c} \tag{10}$$

$$C_0 = \frac{1}{(\rho_s - \rho)g(1-p)} \tag{11}$$

$$\vec{q} = C_0 \frac{K_1 \Phi}{\tan\beta_c}\left[\tan\beta_c \vec{e_w} - \nabla Z\right] \tag{12}$$

Here, $\vec{e_w} = \vec{e_w^+}$ is the unit vector in the wave direction, θ_w, K_1 is the coefficient of

longshore sand transport, a_b is the angle between the wave direction at the breaking point and the direction normal to the contour line, C_0 is the coefficient through which the sand transport rate, expressed by the immersed weight, is related to the volumetric sand transport rate, ρ_s and ρ are the sand and water densities, respectively, g is the acceleration due to gravity, and p is the porosity of the sand.

The equilibrium slope defined by Eq. (6) is equal to the slope for which cross-shore sand transport reduces to zero, when waves are incident from the direction normal to the shoreline, as deduced from Eq. (12). This represents the balance between upslope flow asymmetry and the downslope component of gravity (Inman and Bagnold, 1963; Bowen, 1980; Bailard and Inman, 1981 and Bailard, 1981). Equation (12) has the characteristics that cross-shore sand transport diminishes when waves are incident from the direction normal to the shoreline and the local slope is equal to the equilibrium slope. Shoreward transport is generated when the local slope is smaller than the equilibrium slope, and vice versa.

A sandy beach approaches a statically stable condition, only if the contour lines at each point are orthogonal to the wave direction and the local slope at each point is in agreement with the equilibrium slope. Sand transport is generated if there is a discrepancy from the equilibrium state. These characteristics are the same as those of the contour-line-change model proposed by Serizawa *et al.* (2003).

For a numerical simulation, it is necessary to formulate Φ. In this study, the energy dissipation ratio Φ is simply evaluated by the energy flux of waves at the breaking point, as is the case in the ordinary contour-line-change model (Serizawa *et al.*, 2003), considering the ease of practical use.

Assume that the beach changes occur in a depth zone between the depth of closure $-h_c$ and the berm height h_R corresponding to the wave run-up height. Assuming that Φ is given by the wave energy flux at the breaking point divided by the cross-shore distance between two points, the elevations of which are equal to $Z = -h_c$ and $Z = h_R$, and introducing the depth distribution of the intensity of sand transport $\varepsilon(Z)$, the coefficient A in Eq. (10) can be expressed by the energy flux at the breaking point $(EC_g)_b$. Sand transport flux can thus be written as Eq. (13), which is the fundamental sand transport equation for predicting beach changes on a coast composed of sand of a single grain size.

$$\vec{q} = \frac{G}{\tan\beta_c}\left[\tan\beta_c \vec{e_w} - \nabla Z\right] \tag{13}$$

$$G = C_0 K_1 \varepsilon(Z)\left(EC_g\right)_b \cos^2\alpha_b \tan\beta_c \tag{14}$$

Here, $\varepsilon(Z)$ is defined so that the integral over the depth between $Z = -h_c$ and h_R is equal to 1, and in this study, the depth distribution of longshore sand transport given by Uda *et al.* (1996) is used in the same manner as that of the ordinary contour-line-change

model. In the numerical simulation, the mean beach slope of the coast before the construction of artificial structures is given as the equilibrium slope when considering the long-term prediction of beach changes; the same as in the model of Serizawa *et al.* (2003).

Model for Predicting Beach Changes on Coast Composed of Sand of Mixed Grain Size

A model for predicting not only beach changes, but also grain size changes on a coast composed of sand of mixed grain size was developed by expanding Eq. (13) to include the effect of mixed grain size (N grain sizes) based on the same method as that used by Uda *et al.* (2004) and Kuroiwa *et al.* (2006).

N is set to be the number of grain sizes, and introducing the concept of the exchange layer in the same manner as Hirano (1971), the volume content rate $\mu^{(k)}$ of each grain size $d^{(k)}$ (k=1, 2, $\cdots\cdots$, N) in the exchange layer is added to the variable to be solved. The sand transport for each grain size is expressed by Eqs. (15) and (16), obtained when Eqs. (13) and (14) are multiplied by the content rate to evaluate the distribution of the energy dissipation of waves, and the equilibrium slope for each grain size is introduced.

$$\vec{q}^{(k)} = \frac{G^{(k)}}{\tan\beta_c^{(k)}}\left[\tan\beta_c^{(k)}\vec{e}_w - \nabla Z\right] \quad (k=1,2,\cdots,N) \tag{15}$$

$$G^{(k)} = \mu^{(k)} \cdot C_0 K_1^{(k)} \varepsilon(Z)\left(EC_g\right)_b \cos^2\alpha_b \tan\overline{\beta} \quad (k=1,2,\cdots,N) \tag{16}$$

The coefficient of sand transport for each grain size is assumed to be inversely proportional to the square root of the grain size after Kamphuis *et al.* (1986), as Eq. (17), and in the same manner as assumed by Kumada *et al.* (2006). Beach changes are expressed by Eq. (19) as the summation of components for each grain size obtained from the continuity equation, Eq. (18), for each grain size. Finally, the content rate is calculated from the continuity equation for each content rate in the exchange layer as Eq. (20).

$$K_1^{(k)} = \frac{A_1}{\sqrt{d^{(k)}}} \quad (k=1,2,\cdots,N) \tag{17}$$

$$\frac{\partial Z^{(k)}}{\partial t} = -\nabla\cdot\vec{q}^{(k)} \quad (k=1,2,\cdots,N) \tag{18}$$

$$\frac{\partial Z}{\partial t} = \sum_{k=1}^{N}\frac{\partial Z^{(k)}}{\partial t} \tag{19}$$

$$\frac{\partial \mu^{(k)}}{\partial t} = \begin{cases} \dfrac{1}{B_h}\left(\dfrac{\partial Z^{(k)}}{\partial t} - \mu^{(k)}\dfrac{\partial Z}{\partial t}\right) & \dfrac{\partial Z}{\partial t} \geq 0 \\ \dfrac{1}{B_h}\left(\dfrac{\partial Z^{(k)}}{\partial t} - \mu_B^{(k)}\dfrac{\partial Z}{\partial t}\right) & \dfrac{\partial Z}{\partial t} < 0 \end{cases} \quad (k=1,2,\cdots,N) \tag{20}$$

Here, N is the number of grain sizes, B_h is the thickness of the exchange layer, $\mu^{(k)}$ is the volume content rate of each grain size in the exchange layer, $\mu_B^{(k)}$ is the volume content rate in the layer underneath the exchange layer, $\tan\beta_c^{(k)}$ is the equilibrium slope for each grain size, $K_1^{(k)}$ is the coefficient of longshore sand transport rate for each grain size, $\tan\overline{\beta}$ is the mean slope between $Z = -h_c$ and h_R, and A_1 is a constant depending on the deformation process of the coast. In addition, the unit of grain size $d^{(k)}$ is mm. For B_h, Hirano (1971) chose the maximum grain size, which Kraus (1985) determined to be 3% of the breaker height on the basis of field observation. In this study, B_h was selected to be the larger of the values determined by these two methods, and in this case, was given by the maximum grain size.

Numerical simulation was carried out using in staggered meshes on the x-y plane. The sand transport flux for each grain size is calculated from Eqs. (15)-(17). The mass continuity equations of Eqs. (18) and (19) are solved using an explicit finite difference method to obtain the beach changes. The change in the content rate in the exchange layer is calculated from Eq. (20). These procedures are repeated recursively, and beach changes and the change in content rate are obtained.

For the boundary conditions, sand transport is set to be 0 along the outer boundaries of the calculation domain and along the boundaries of structures. Methods considering the sinking of sand due to gravity in a zone deeper than h_c and on land, the evaluation of the wave field in the wave-shelter zone of the offshore breakwaters, and the extra term to include additional longshore sand transport developed by Ozasa and Brampton (1980) are omitted here (Serizawa *et al.*, 2006).

RESULTS

Beach Changes between Groins under Oblique Wave Incidence

The model was applied to the experimental results of beach changes between groins under oblique wave incidence using sand of mixed grain size by Kumada *et al.* (2003). In their experiment, a 4-m-wide movable bed with a uniform slope of 1/10 using sand of mixed grain size was produced in a wave tank, and waves were obliquely incident to the initial shoreline making a breaker angle of 10 degrees to cause longshore sand transport. Groins were placed at both ends of the wave tank. Regular waves with an equivalent wave height of 4 cm and wave period of 0.8 s were generated.

The bed material used in the experiment was a mixture of two types of sand, the median diameters of which were 0.2 mm and 2 mm, with a volume ratio of 1:1. For the calculation conditions, the beach material is assumed to be composed of sand with two grain sizes of 0.2 mm and 2 mm, and the initial content rate is given by 50 %. The breaker height and angle are given by constant values which are determined by an average of the measured values in the longshore direction. The width of the exchange layer is assumed to 2 mm, equal to the maximum grain size. **Table 1** shows the calculation conditions.

Table 1. Calculation Conditions

Structural condition	Groins	Detached breakwaters
Initial seabed slope	1/10	1/10
Number of grain sizes N Grain size d Initial volume content rate μ Equilibrium slope $\tan\beta_c$	N=2 $d^{(1)}$=0.2 mm, $\mu^{(1)}$=0.5 and $\tan\beta_c$=1/10 $d^{(1)}$=2 mm, $\mu^{(1)}$=0.5 and $\tan\beta_c$=1/10	N=4 $d^{(1)}$=0.1 mm, $\mu^{(1)}$=0.25 and $\tan\beta_c$=1/20 $d^{(1)}$=0.2 mm, $\mu^{(1)}$=0.25 and $\tan\beta_c$=1/20 $d^{(1)}$=0.3 mm, $\mu^{(1)}$=0.25 and $\tan\beta_c$=1/5 $d^{(1)}$=0.4 mm, $\mu^{(1)}$=0.25 and $\tan\beta_c$=1/5
Thickness of exchange layer B_h	2 mm	0.4 mm
Breaker height H_b and breaker angle α_b	H_b=3.6 cm and α_b=6.3°	H_b=5.2 cm and α_b=10°
Depth of closure h_c and berm height h_R	h_c=6 cm and h_R=2 cm	h_c=11 cm and h_R=5 cm
Critical slope	1/2	1/2
Coefficient A_1	0.5	0.1
Ratio of coefficients of littoral drift K_2/K_1	0	1.62
Mesh size $\Delta x = \Delta y$	0.1 m	0.1 m
Time step Δt	0.0002 hr	0.0001 hr
Total time t	10 hrs	2 hrs
Boundary conditions	$q_x = 0$ at both ends	$q_x = 0$ at both ends

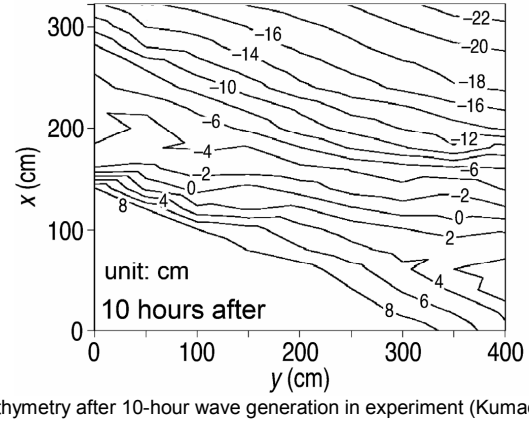

Figure 1. Bathymetry after 10-hour wave generation in experiment (Kumada *et al.*, 2003)

Figure 1 shows the bathymetry obtained after 10 hours of wave action. The initial parallel contours were deformed by obliquely incident waves. Sand was mainly transported downcoast by the longshore sand transport, accumulating on the updrift side of the groin. **Figure 2** shows the calculated bathymetry corresponding to **Fig. 1**. In

the eroded zone, a gentle slope was formed owing to erosion in the zone shallower than h_c = 6 cm, whereas in the accretion zone, sand was deposited forming a flat foreshore on land as well as the formation of a steep slope in the zone deeper than h_c due to the sinking of sand. These results are in agreement with those of the experiment.

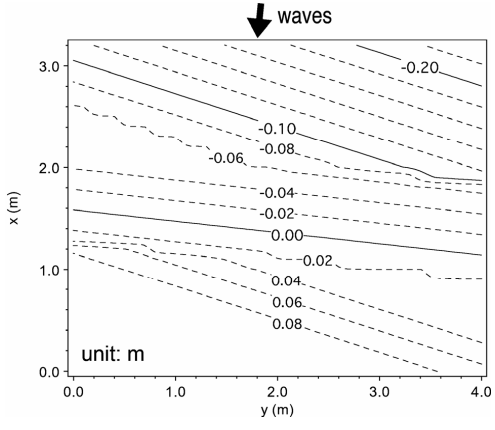

Figure 2. Calculated bathymetry under oblique wave incidence

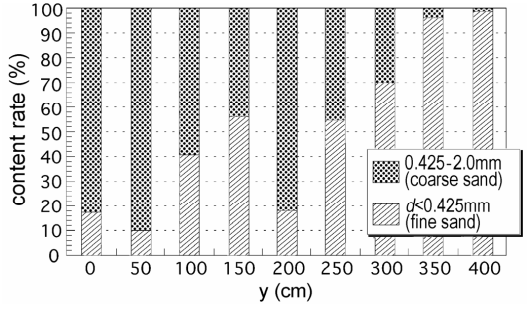

Figure 3. Content rates of coarse and fine sand in experiment (Kumada *et al*., 2003)

Figure 3 shows the longshore distribution of the measured composition of the grain size of bed materials on the shoreline after the beach changes. This figure clearly shows the occurrence of predominant longshore sorting due to longshore sand transport, which is often observed on coasts; in the erosion zone, the content rate of coarse sand increases with the removal of fine sand, whereas fine sand selectively removed from the erosion zone accumulates in the accretion zone.

Figure 4 shows the results of the calculation corresponding to **Fig. 3**, and shows the plane distribution of mean grain size with the initial shoreline and the shoreline after the beach changes. Furthermore, **Fig. 5** shows the predicted composition of the grain size of bed materials along the shoreline after the beach changes. The sorting due to longshore sand transport resulting in coarse sand being left behind in the erosion zone and fine sand selectively accumulating was accurately predicted by the numerical simulation.

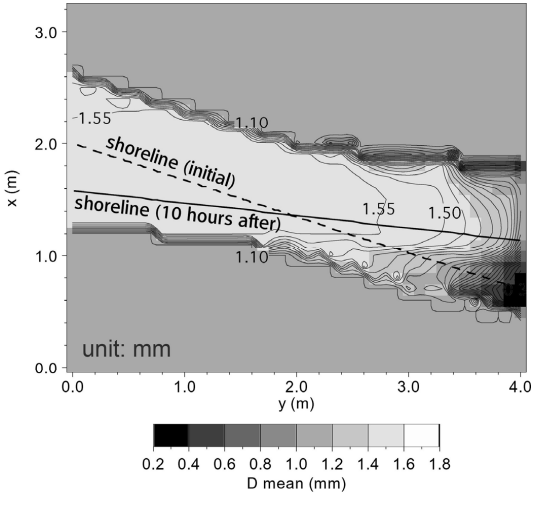

Figure 4. Calculated distribution of mean grain size under oblique wave incidence

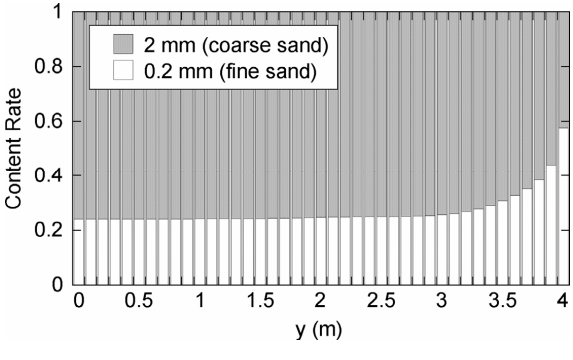

Figure 5. Calculated content rates of coarse and fine sand

Application to Prediction of Beach Changes around Detached Breakwaters

Consider the case when detached breakwaters are built for coastal protection. Uda *et al.* (1987) carried out a movable-bed experiment using a plane wave tank to investigate beach changes around three detached breakwaters subjected to obliquely incident waves. The initial topography in the experiment was a straight beach with a uniform slope of 1/10, and for the wave conditions, the incident wave height was $H_0 = 3$ cm and the breaker angle was 10 degrees. In the experiment, the median diameter of sand used was $d_{50} = 0.28$ mm, but strictly speaking, it was composed of grains of mixed size. In the calculation, a mixture of sand composed of sand of grain sizes 0.1, 0.2, 0.3 and 0.4 mm with the same content rate and the same initial median diameter was assumed. The sorting effect was investigated using this mixture of sand. Assuming that sand of 0.1 and 0.2 mm grain size has an equilibrium slope of 1/20 and sand of 0.3 and 0.4 mm grain size has an equilibrium slope of 1/5 on the basis of the experimental results, the sorting effect of sand was investigated in the model, with the assumption of the width of the exchange layer being 0.4 mm.

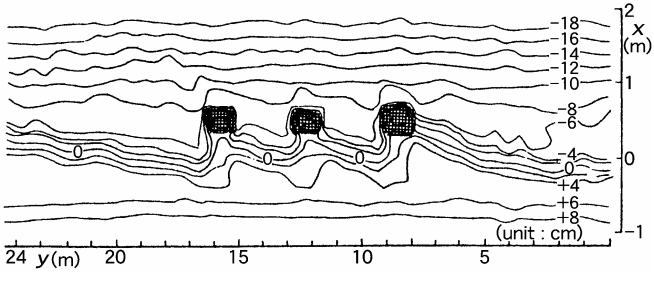

Figure 6. Bathymetry after constructing detached breakwaters in experiment (Uda *et al.*, 1987).

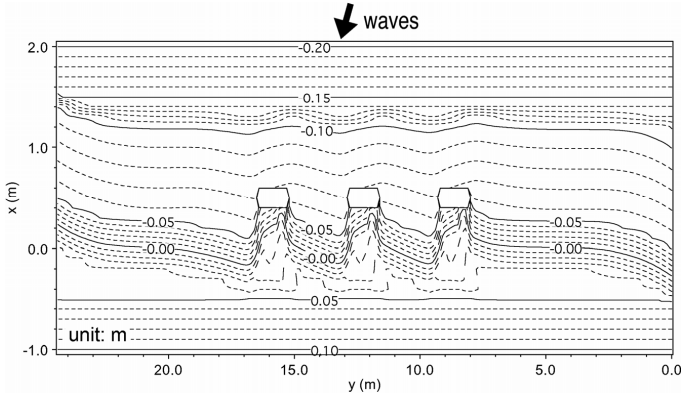

Figure 7. Calculated bathymetry after constructing detached breakwaters

Figures 6 and **7** show the measured and predicted beach topography after 2 hours of wave action when detached breakwaters were installed on the seabed with parallel contours. The calculated results accurately explain the results obtained in the experiment, such as the formation of a salient behind the detached breakwaters, the formation of a steep foreshore slope, a relatively gentle slope off the shoreline and the meandering of contours off the detached breakwaters.

Figure 8 shows the calculated distribution of the mean grain size. Although the direct comparison of predicted values with the experiment is difficult because of the lack of experimental data, the sorting of grain size due to cross-shore sand transport, often observed in real cases, was accurately predicted; coarse sand accumulated in the vicinity of the shoreline and fine sand was transported offshore. Furthermore, the fact that fine sand accumulated behind the detached breakwaters was accurately predicted.

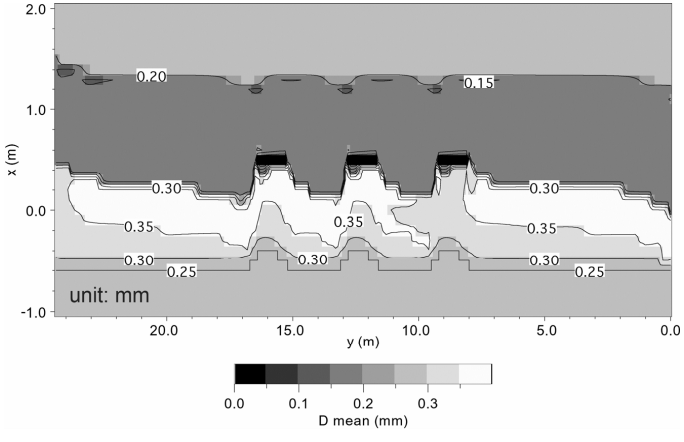

Figure 8. Calculated mean grain size after constructing detached breakwaters

CONCLUSION

Simple equations for evaluating sand transport flux under a wave field were derived based on Bagnold's concept, and a new model for predicting not only beach changes but also grain size changes was developed. As a result of this study, the physical rationality of the predictive model was enhanced compared with those of the models of Uda *et al.* (2004) and Kumada *et al.* (2006). Many examples of typical beach changes caused by the obstruction of longshore sand transport and the changes in grain size described by Uda (2004) are capable of being predicted by the model. Finally, a practical tool for predicting three-dimensional beach changes on coasts composed of sand of mixed grain size was developed.

Abstract: Analytical models predict the growth (instability) of shoreline salients when deep-water waves approach the coast from highly oblique angles, contrary to classical shoreline change models in which shoreline salients can only dissipate. Using the process-based wave, circulation, and sediment transport model Delft3D, we test this prediction for simulated bathymetric and wave characteristics approximating the open-ocean conditions at Duck, North Carolina. We consider two cases: a uniform coast with a varying wave approach angle, and a bathymetry with coastal salients and a single high-angle boundary wave condition. Incident wave conditions include a swell case with no wind and a wind-wave case with active local wave regeneration by wind. The uniform-coast tests predict transport maxima at oblique wave angles for both wave cases, indicating the potential for shoreline instabilities, similar to the analytical models. However, the critical angle for instability is much higher in the wind-wave case. Our tests with coastal salients agree with previous findings that a minimum salient length scale may be required for the instability effect to be active. Here, a salient with a longshore scale of 4 km results in transport divergence (erosion; no instability) at the salient crest while an 8 km salient results in transport convergence (accretion; instability) at the crest.

INTRODUCTION

Since the initial formulation by Pelnard-Considere (1956), the most common approach for modeling shoreline evolution has been the "one-line model," in which shoreline change is related to gradients in longshore transport through a continuity equation. Typically, longshore transport is found using empirical equations relating wave

characteristics at the breakpoint to the total longshore transport in the surf zone. In the U.S. coastal engineering community, a frequently-used model that employs this approach is GENESIS (Hansen and Kraus, 1989), a one-line model that utilizes the "CERC formula" (Komar and Inman, 1970; Rosati et al., 2002) for longshore transport.

Ashton et al. (2001), in an innovative application of the one-line approach, predict that when waves approach the coast from high angles (i.e., highly-oblique or non-normal wave incidence), the diffusive, coast-smoothing, nature of the Pelnard-Considere equation can be reversed, resulting in the growth of coastal salients (referred to as "negative diffusion"). Although breaking wave angles are generally much lower than the critical angle for the instability effect (45° in the CERC formula), Ashton et al. (2001) demonstrate that due to the energy-spreading effect of waves refracting towards the coast, only the deep-water wave angle needs to exceed a critical angle (about 42°) for shoreline instabilities to occur. Using a simple cellular modeling approach and Snell's law for wave transformation over shore-parallel contours, Ashton et al., (2001), Ashton and Murray (2006a), and Ashton and Murray (2006b) simulate many realistic-appearing coastal morphologies that spontaneously grow from small, random perturbations to a uniform coast.

Falqués and Calvete (2005) explored potential limits to the shoreline instability effect using a linear stability analysis and an analytical wave transformation model, and suggest that under certain conditions even very high-angle waves will not result in the growth of coastal salients. In general, they found that the longshore wavelength of the coastal undulations, the depth to which undulations are reflected in bathymetric contours, and the incident wave period control the degree to which the shoreline experiences instabilities. In a similar stability analysis, Uguccioni et al. (in press) employ a simple flow and sediment transport model to assess the effect of flow convective terms on shoreline stability, showing that this has only a moderate impact on the preferred wavelength and growth rate of the instabilities.

In all previous modeling and analytical work on the shoreline instability problem, many simplifying assumptions have been employed, especially in the transformation of wave characteristics from deep water to the surf zone (e.g., limiting wave transformation processes to Snell's law over parallel contours). Our objective here is to employ a much less simplified process-based model to evaluate the potential for shoreline instabilities in a situation approximating an open-ocean beach. We use the circulation and sediment transport model Delft3D (Lesser et al., 2004) in conjunction with the wave model SWAN (Booij et al., 1999) in test cases designed to roughly approximate the bathymetric and wave conditions for a moderate storm on a U.S. east coast beach at Duck, North Carolina. We first evaluate the potential for the instability effect using an (effectively) infinite uniform coast, in which only the deep-water incident wave angle is varied. We then place coastal salients of varying longshore scales on the coast, and apply waves with angles high enough to be within the instability range as indicated by the uniform-coast tests. We derive longshore sediment transport gradients through both the CERC equation and the cross-shore integration of Delft3D-predicted longshore transport through the surf

zone. The patterns of transport convergences and divergences relative to the salient morphology are used to asses the potential for the instability effect. Morphological evolution is not simulated here.

METHODOLOGY

Bathymetric Grids

We use two types of simplified bathymetries for our Delft3D model runs: a uniform coast with a longshore-uniform cross-shore profile, and a coast with salients constructed by superimposing a 3D Gaussian surface on the uniform-coast bathymetry.

The uniform-coast bathymetry consists of a composite plane beach profile, scaled roughly after the coastal profile from the beach to the shelf slope at Duck, North Carolina, at the U.S. Army Corps of Engineers Field Research Facility. Plane beach segments (and their slopes; depth maxima) include the beach/nearshore (0.0125; 8 m), the shoreface (0.004; 17 m), the shelf (0.00003; 40 m), and the shelf slope (0.006; 100 m). While this coastal profile has the advantage of simplicity of bottom grid construction, the slope discontinuities between plane segments produce some minor discontinuities in the model results presented below; for future work it would be advantageous to employ a more smoothly varying profile.

The objective for our uniform-coast model runs was to investigate the effect of variations in incoming wave direction through all angles relevant for generating longshore flow and sediment transport, from normally incident (wave crests 0° relative to the shoreline) to coast following (wave crests 90° relative to the shoreline). Such a range of wave directions presents a significant challenge for applying any wave model (including SWAN) due to the specification of the wave conditions on the "lateral" boundaries (Fig. 1), which encompass depths ranging from dry land to deep water. Although iterative methods exist for establishing such boundary conditions, we follow a simple approach of nesting the wave model, starting with a regional grid that covers an area sufficiently large that lateral boundary effects are absent where boundary conditions are provided to a nested wave grid. Our tests show that this procedure was effective even for waves propagating directly alongshore. An example is given in Fig. 1, in which predicted wave heights near the up-wave lateral boundary are highly affected by boundary effects, yet become uniform in the region of the nested wave grid.

For each uniform-coast model run, three rectilinear grids were constructed over the coastal profile described above. The regional wave grid (Fig. 1) has longshore by cross-shore dimensions of 300,000 by 90,000 m, grid spacings of 2,000 by 500 m, and extends to 100 m water depth. The nested wave grid (Fig. 1) has dimensions of 8,000 by 3,000 m, spacings of 80 m by 20 m, and extends to 16.5 m depth. The grid used for Delft3D circulation and sediment transport is identical to the nested wave grid, except that the longshore dimension is reduced to 6,400 m so that flows are unaffected by boundary problems in the nested wave grid (which still exist despite receiving their boundary conditions from the regional wave grid).

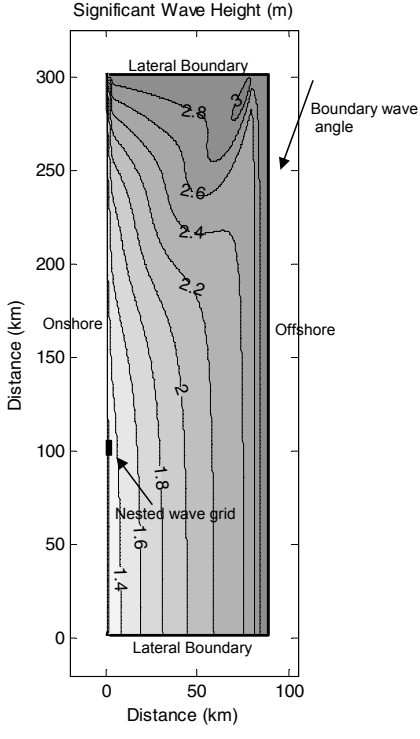

Figure 1. Regional and nested wave grid domains used in the uniform-coast tests. Contours shows the significant wave height for the swell wave case with the angle of incidence on the lateral and offshore boundaries set to 70° relative to normal incidence.

Model grids for the coastal salient tests were constructed similarly, except that the nested wave and flow grids had to be significantly expanded to accommodate the non-uniform bathymetry. The nested wave grid has dimensions of 32,000 by 13,000 m and spacings of 200 m by 50 m. The circulation grid has dimensions of 20,000 m by 13,000 m, and spacings of 100 m by 25 m. Both extend to a water depth of 20 m. Although a curvilinear, coast-following grid with variable spacing (finer closer to shore) would be more efficient and likely provide less noisy results for these tests, our need to construct bathymetric grids for coastal salients at many scales dictated the use of a rectilinear grid for this exploratory work. Coastal salients varying between 1 and 8 km in length were constructed by adding a 3D Gaussian surface to the composite-plane surface used in the

uniform-coast tests. The salient length scale is defined as the distance encompassing 95% of the Gaussian height distribution. The water depth to which bathymetric contours are perturbed by the salient depends on the salient length scale. For our 1 km salient depth contours are modified to a depth of about 2 m, while for the 8 km bump this depth is about 16 m.

All grids for Delft3D flow computations were constructed with one vertical layer, providing flow predictions in a vertically-averaged or 2DH mode.

Delft3D Model Runs

Waves, currents, and sediment transport were simulated by the Delft3D modeling system (Lesser et al., 2004), version 3.25.02. Delft3D employs the wave model SWAN (Booij et al., 1999), a spectral wave action-balance model accounting for the modification of waves by currents. In the mode applied here, SWAN simulations include the effects of refraction (both bathymetry and current-related), depth-induced breaking, dissipation due to bed friction, and the local regeneration by wind (for tests in which wind is present). Two wave conditions were applied uniformly to the lateral and offshore boundaries of the regional wave grid (Fig. 1): swell waves with significant wave height H_s=3.0, peak period T_p=10.0 seconds, directional spread 10°, and no wind; and a wind-wave case with H_s=3.0, T_p=7.0 seconds, directional spread 20°, and a steady, uniform wind of 15 m/s in the same direction as the boundary waves. These conditions roughly approximate moderate storm conditions on the North Carolina coast. It is important to note that the "wind wave" cases examined by Falqués and Calvete (2005) and Ashton and Murray (2006a) included no local regeneration of waves by wind.

For the uniform-coast tests, the boundary wave crest angle relative to the shoreline angle was varied in 5° increments from -5° to 100° (Fig. 2), where 0° is normally incident and 90° is directly alongshore. For the coastal salient tests, boundary wave directions were chosen to maximize the potential for the instability effect.

The Delft3D flow model is driven by gradients in wave-induced radiation stresses which are computed by the SWAN model. In our tests, flows are driven only by wave forces, neglecting tides, density stratification, wind, or other processes that could also generate flows in the coastal zone. Lateral flow boundaries are of the Neumann type (Roelvink and Walstra, 2004), which prescribes a water level gradient at the boundary. The offshore boundary has a fixed, still water level condition. We used the default Delft3D sediment grain size of 0.20 mm, as only patterns of transport gradients, not absolute magnitudes of transport, are relevant here and any grain size that would produce mainly suspended sediment transport would give essentially the same results. Bedload and suspended load sediment transport were predicted using the default Delft3D transport formulations of van Rijn (1993).

The flow model and wave model interact through flow requests for updated wave information every 30 minutes, with the flow model providing fields of sea-surface elevations and depth-averaged currents to the wave model. After each wave model

update, the flow model continues for 30 minutes (model time) using an unchanging field of wave forcing. Because we employ steady wave boundary conditions, the wave/flow solution reaches a steady-state solution after about 17 hours of model time (in the absence of morphological evolution). Only results from the final, steady-state solution are of interest here.

The sensitively of model results was tested in response to many, but far from all, combinations of free model parameters in the flow component of Delft3D. It is believed that the results presented here are qualitatively robust to reasonable ranges of free model parameters, but the possibility that certain combinations of parameters would give substantially different results cannot be discounted.

Longshore Transport and Transport Gradients

We derive longshore transport gradients for our test cases using two methods, both of which utilize the same Delft3D model runs. First, we apply the empirical CERC equation (Komar and Inman, 1970; Rosati et al., 2002) employing SWAN-modeled wave characteristics at the breakpoint. Second we directly use Delft3D predictions of longshore sediment transport within the surf zone.

The CERC equation (also known in similar forms as the Scripps or Komar equations) predicts the volumetric longshore sediment transport rate, Q_x, as

$$Q_x = K_1 a_1 H_b^{5/2} \sin(2\phi_b) \qquad (1)$$

where K_1 is an empirical coefficient (set to 0.6 here), H_b is the root mean square wave height (H_{rms}) at the breakpoint, ϕ_b is the relative angle between the shoreline and the wave crest angle at the breakpoint, and

$$a_1 = \frac{1}{16\left(\frac{\rho_s}{\rho} - 1\right)(1-p)}$$

where ρ_s is the density of sand, ρ is the density of water, and p is the sand porosity. In some studies, including the shoreline instability analysis of Falqués and Calvete (2005), a less tested "second CERC term," accounting for the effects of beach slope and longshore gradients in wave height (Ozasa and Brampton, 1980) is added to Eqn. 1. For our tests, this term's contribution is an order of magnitude less than predicted by Eqn. 1, and is therefore neglected.

We extract H_b and ϕ_b from the nested SWAN wave model output through the procedure described by List et al. (in press). In brief, H_b and ϕ_b are derived independently at each longshore grid node where the breaking wave height to depth ratio, γ_{rms}, equals 0.3.

Note that this γ_{rms} is much lower than typically employed for identifying the breakpoint in applications of the CERC equation in which monochromatic wave models are used (SWAN is a spectral model). Sensitivity tests demonstrated that varying γ_{rms} from 0.2 to 0.4 had no qualitative affect on the results presented here. For the uniform beach tests, ϕ_b is simply the wave crest angle because the shoreline orientation is constant. For the coastal salient tests, ϕ_b is found as the difference between the wave crest angle and the angle of the shoreline defined at the still water level of the flow model (z=0).

Delft3D calculates sediment transport at grid node locations, and can optionally evolve the seabed morphology by translating the gradients in sediment transport between grid nodes into vertical seabed changes. However, in order to obtain estimates of the longshore transport comparable to what is obtained through the CERC approach, we adopt a method for extracting the cross-shore integrated longshore transport from the Delft3D output similar to the approach of Haas and Hanes (2004), with no morphologic evolution permitted. At each longshore location, we integrate the predicted longshore component of the total (suspended and bedload) transport from the shoreline to the offshore extent of the grid to give a Delft3D-predicted Q_x comparable to Q_x in Eqn. 1. No attempt was made to limit the integration to the seaward limit of the surf zone, because minimal flow velocities and transport beyond the surf zone make this unnecessary. Because we are only considering the longshore component of the predicted sediment transport, the influence of cross-shore transport, and associated gradients, are not considered here. Our sign convention is that positive Q_x represents transport towards the right when facing offshore.

For the uniform-coast tests, we derive longshore transport at one representative location away from boundary disturbances. We extract longshore transport as a function of distance along the coast for the salient tests, but only use the component of transport in the alongshore direction of the rectilinear grid, i.e., we do not find the component of transport parallel to the changing orientation of the salient shoreline. We find the longshore transport gradient as $\partial Q_x / \partial x$, also using the rectilinear grid for the alongshore distance, x, thereby removing the problem associated with the curving coastline. A negative $\partial Q_x / \partial x$ indicates transport divergence and a positive $\partial Q_x / \partial x$ indicates transport convergence, assumed to indicate the potential for shoreline erosion and accretion, respectively. (For example, a negative transport gradient within any segment of coast indicates that more sediment is leaving that segment than entering it, indicating that that segment of coast would be erosional.)

RESULTS

Uniform-coast Tests

H_b, ϕ_b, and Q_x for both the CERC and Delft3D approaches are shown for the swell wave tests in Fig. 2 as a function of the wave crest angle specified on the lateral and offshore boundaries of the regional wave grid. All curves are very similar to results obtained

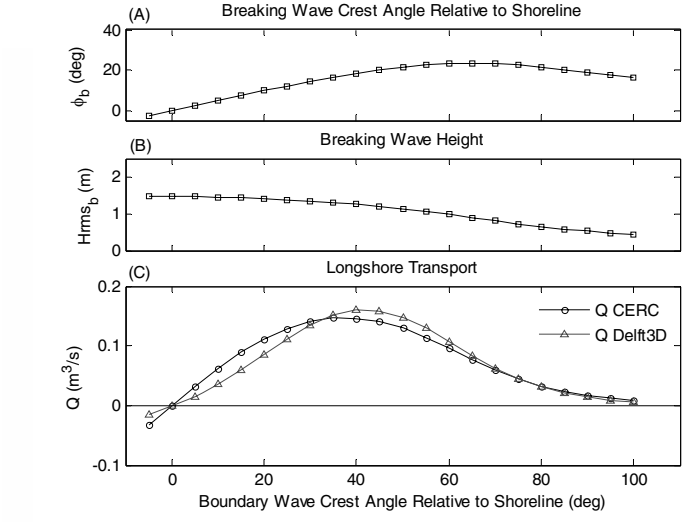

Figure 2. Uniform coast, swell wave tests: (A) breaking wave angle, (B) breaking wave height, (C) longshore transport as a function of wave angle specified at the lateral and offshore boundaries of the regional wave grid.

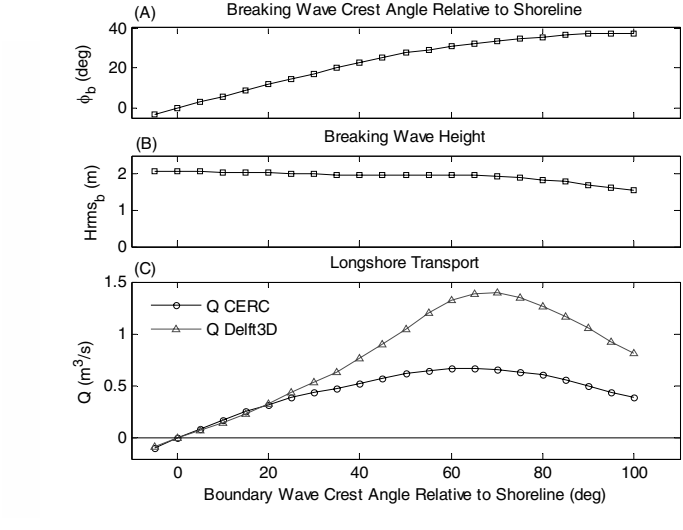

Figure 3. Uniform coast, wind-wave case: (A) breaking wave angle, (B) breaking wave height, (C) longshore transport as a function of wave angle specified at the later and offshore boundaries of the regional wave grid.

through analytical approaches (Falqués, 2003; Ashton and Murray, 2006a), confirming that although the wave crest angle at the breakpoint is always less than the 45° critical angle required for shoreline instabilities in the CERC equation, a Q_x maximum at a boundary wave crest angle of about 40° results from the reduction in wave height at higher angles due to higher refractive spreading. Shoreline instabilities would therefore be expected for these bathymetric and wave conditions when the deep-water wave angle exceeds approximately 40°, very close to the value predicted by Ashton et al. (2001).

Comparable information is shown in Fig. 3 for the wind-wave test case. Although a maximum in transport is still present, the critical boundary angle is shifted to about 65°, indicating that shoreline instabilities would only occur for very high deep water wave angles. The reason for this shift can be understood from the curve for H_b—the refraction-induced decrease in wave height is less strong at higher angles than for the swell case, presumably because of wave energy re-generation by local wind across the shelf and shoreface. In addition, because the wave height diminishes less with increasing deep-water wave angle, ϕ_b does not reduce at high boundary angles as in the swell case where smaller breaking waves are located in shallower water where waves have refracted more towards the coast.

Note that in both wave cases, Q_x does not reduce to zero at 90° (waves traveling directly alongshore), as would be expected from the CERC formula. This is due to the wave directional distribution in the SWAN model, set to 10° in the swell case and 20° in the wind-wave case. The effect is especially pronounced for the wind-wave case, with substantial longshore transport remaining for cases with offshore-directed winds.

Although secondary to the objectives of this paper, the comparison between the CERC-derived and Delft3D-derived Q_x is also of interest. We made no attempt to calibrate either method for a better match, and the close correspondence between the two approaches in Fig. 2 is probably fortuitous, as reflected in the much poorer correspondence in Fig. 3. No explanation for this difference between the swell case and wind-wave case is immediately evident, although the two methods agree on the important aspect of Figs. 2 and 3—the location of the Q_x maxima.

Coastal Salient Tests

The tests in Figs. 2 and 3 indicate the potential for shoreline instabilities occurring within the framework of a process-based model, but it is unclear if these results, based on a uniform coast with parallel bathymetric contours as assumed in the original model of Ashton et al. (2001), would apply to a non-uniform coast in which coastal salients have finite length scales. Falqués and Calvete (2005) address this issue with an analytical approach using a linear stability analysis, predicting that a minimum longshore length scale may be required for instability depending on the bathymetry and wave conditions. We test this result in a more natural situation here by adding coastal salients with finite amplitudes to the uniform bathymetry and evaluating the longshore transport gradients

under high wave angle conditions. A positive transport gradient (convergence) at the salient crest would indicate salient accretion (the instability or negative diffusion effect), while a negative transport gradient (divergence) at the salient crest would indicate salient erosion (diffusion). A gradient pattern of divergence (erosion) on the updrift side of the salient and convergence (accretion) on the downdrift side would indicate salient translation in the downdrift direction.

Coastal salients were constructed with longshore scales of 1, 2, 4, and 8 km for tests under both the swell and wind-wave conditions. The uniform-coast results of Figs. 2 and 3 were used to identify the wave angles with the highest potential for the instability effect. While all angles above the Q_x maxima have this potential, the steepest part of the curve is associated with the highest "negative diffusion," or tendency for the diffusional nature of the Pelnard-Considere formulation to be reversed (Ashton and Murray, 2006a). For the swell wave case we chose 70° and for the wind-wave case we chose 80° (although tests with similar wave angles gave very similar results).

All our salient tests indicate salient translation downdrift, as indicated by the transport gradient curves for both the CERC and Delft3D approaches. Examples are given in Figs. 4 and 5 for our swell and wind-waves tests with 4 and 8 km salients. This result is contrary to some previous shoreline modeling studies which required an arbitrary advection term to the shoreline diffusion equation to produce salient translation (e.g., Thevenot and Kraus, 1995).

However, the transport gradient patterns shown in Figs. 4 and 5 do not indicate pure translation, since the transport gradients at the salient crests (10 km) are not equal to zero. There is a clear tendency for divergence (negative gradient) at the salient crest in the 4 km case (Figs. 4DEF and 5DEF) to shift to convergence (positive gradient) at the crest in the 8 km case (Figs. 4ABC and 5ABC). This can also be seen in the longshore transport curves, with the peak transport appearing downdrift of the salient crest in the 4 km case and updrift in the 8 km case. These results suggest that as the salient scale increases from 4 to 8 km, the shoreline diffusion shifts from positive to negative and coastal salients become more likely to grow rather than being smoothed out.

For comparison, we add the curve "CERC-recast" to Figs. 4 and 5, representing the transport and transport gradients derived using the deep-water wave transformation approach of Ashton et al. (2001). For this approach the transport convergence is nearly centered on the salient crest for both the 4 and 8 km cases, indicating salient growth without translation.

A possible explanation for the difference between our 4 and 8 km salient tests, as well as the difference between the CERC/Delft3D and the CERC-recast results, is the limited water depth to which the salient-perturbed contours extend (about 10 m for the 4 km salient and 16 m for the 8 km salient). An examination of the wave angle field shows that the 4 km salient contours do not extend offshore into the zone where

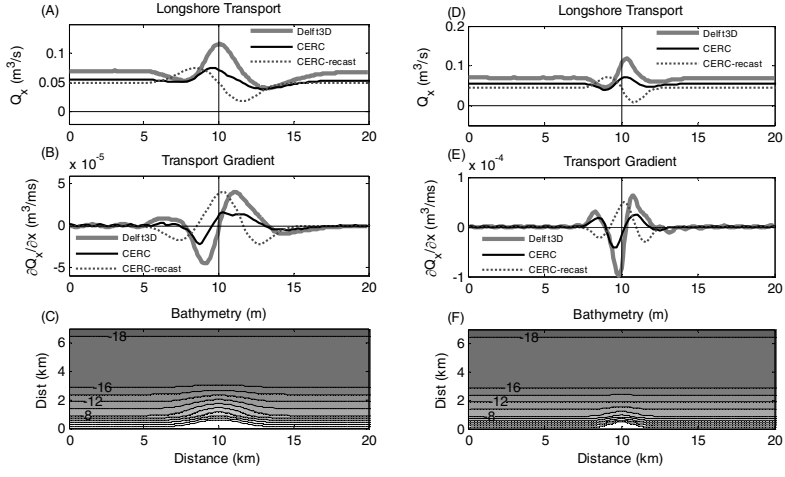

Figure 4. Swell wave case: (A,D) longshore transport (smoothed), (B,E) longshore transport gradient, and (C,F) salient bathymetry for 8 km (A,B,C) and 4 km (D,E,F) salients. The boundary wave crest angle is 70° relative to the overall coastal trend. The sign conventions for panels (A,B,D,E) are explained in the text. The magnitudes of the CERC-recast curves are scaled to match the D3D curves.

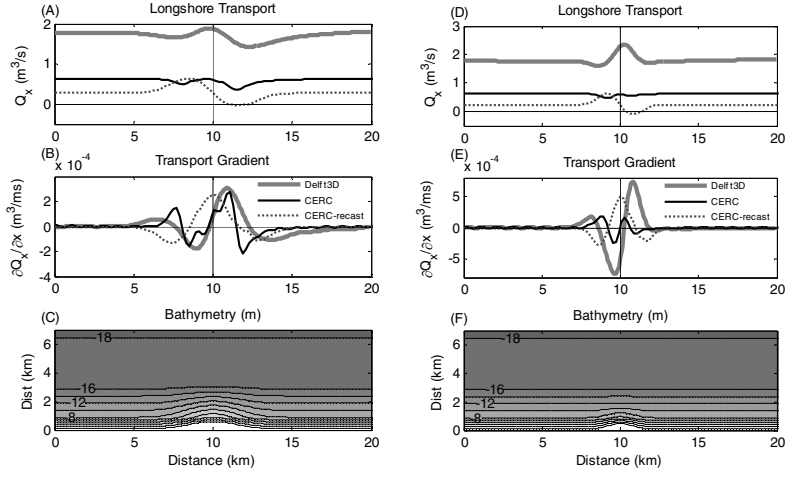

Figure 5. Wind-wave case: (A,D) longshore transport (smoothed), (B,E) longshore transport gradient, and (C,F) salient bathymetry for 8 km (A,B,C) and 4 km (D,E,F) salients. The boundary wave crest angle is 80° relative to the overall coastal trend. See Fig. 4 for more information.

wave angles exceed the critical angle for instability (>40° for the swell wave case, Fig. 2; and >65° for the wind-wave case, Fig. 3). If waves have already refracted below the critical angle before reaching the salient contours, it seems unlikely that any instability effect is possible. For the 8 km salient, swell wave case, the salient-perturbed contours extend a limited distance into the zone of high angle waves, suggesting that the instability mechanism could be active for this case. For the 8 km salient, wind-wave case, the salient-perturbed contours still don't extend into the zone of high wave angles, but it is possible that the very high angle criterion for instability (>65°) determined from the uniform-coast test does not really apply for the wind-wave case. More research is needed to examine the processes by which an increase in salient scale shifts the transport gradients patterns toward salient growth.

The close correspondence between the CERC and Delft3D transport gradients in these tests is noteworthy. This contrasts with the results of List et al. (in press), in which the CERC and Delft3D transport gradients diverged greatly in the case of shoreface pits disconnected from the shoreline. It is apparent that when bathymetric irregularities reflect the shoreline shape, the two approaches give much more similar results.

CONCLUSIONS AND DISCUSSION

We apply a process-based model for evaluating the conditions for shoreline instabilities induced by high angle waves under bathymetric and wave conditions roughly approximating the open-ocean coast at Duck, North Carolina. Tests with a uniform coast indicate the potential for the instability effect for both swell and wind-wave cases, although the critical wave angle required for instability in the wind-wave case was much higher due to the local regeneration of wave energy which balances the energy lost due to refractive spreading.

Tests with high wave angles and coastal salients at a range of scales from 1-8 km suggest a minimum alongshore length scale necessary to initiate the instability effect. While all tests indicate salient translation downdrift, the longshore transport gradients also indicate a shift from salient erosion at the 4 km salient scale to salient accretion at the 8 km scale. This contrasts with the transport gradients found through the approach of Ashton et al. (2001), for which salient growth is predicted independent of scale. The linear stability analysis of Falqués and Calvete (2005), however, also suggests the existence of a minimum salient scale for shoreline instability.

We must add the caveat that in this work we only derive static patterns of transport gradients—we do not simulate shoreline or morphological evolution including feedback between the evolving morphology and the transport gradients. It is possible that given such evolution, the morphological outcome might be very different from the initial transport gradient patterns we present here.

Our results suggest that small-amplitude, random perturbations to an otherwise straight coast might not grow and self-organize into larger scales under the open-ocean

conditions we approximate in our high wave angle tests. Even if such random perturbations contained length scales large enough for the instability effect to operate (apparently larger than 4 km in our tests), the transport gradients associated with these perturbations would be exceedingly small (small differences in longshore transport divided by large distance). On natural coasts, near-ubiquitous shelf and shoreface irregularities which are not associated with shoreline shape might generate much higher magnitude gradients in longshore transport and therefore control the initial shoreline evolution. However, if shoreline features generated in this manner (or through other processes such as geologic framework controls) were of the necessary length scale, the instability effect could then assume control of the subsequent coastal evolution. An example could be the large-scale "Carolina Capes"of the Southeast U.S., identified as a potential long-term result the instability effect (Ashton et al., 2001; Ashton and Murray, 2006b).

ACKNOWLEDGEMENTS

Amy Farris is thanked for writing parts of the post-processing code for analyzing model output. Giles Lesser and Jacco Groeneweg are thanked for expert training in the use of the Delft3D modeling system and SWAN, respectively. Bert Jagers is thanked for modifications to Delft3D needed to conduct the model runs presented here. Edwin Elias is thanked for support in the operation and application of Delft3D for coastal change studies. Guy Gelfenbaum and Chris Sherwood of the USGS are thanked for their efforts to make Delft3D available to all researchers in the USGS. Use of the Delft3D modeling system does not imply endorsement by the USGS. Peter Ruggiero and Chris Sherwood are thanked for reviewing this paper, resulting in substantial improvement.

Abstract: We present a simple numerical model capable of producing distinctive scalloped bays of a form found when a sandy coastline extends downdrift of a rocky headland. The shape of such bays can often be approximated by a log-spiral—a curve for which the radius of curvature increases logarithmically with distance from the headland or 'pinning point.' A considerable body of work has been published attributing this shape to the pattern of refraction and/or diffraction created as waves approaching from a dominant direction interact with the pinning point. Here, we present a fundamentally different explanation for these shapes. We use an existing one-line numerical model of wave-driven alongshore transport which includes shoaling and refraction over contours assumed to parallel local shoreline orientations. Rather than assuming a single wave angle, it generates new waves repeatedly according to an input wave climate. It does not include refraction or diffraction around the pinning point; thus, the log-spiral-like shape evolves as simply as a result of alongshore transport driven by a distribution of deep-water wave approach angles.

INTRODUCTION

When a sandy coast extends downdrift of a relatively inerodible rocky headland, a scalloped bay often forms. Such forms have been given many names, including headland-bay beaches, crenulate bays, hook-shaped bay beaches, half-heart-shaped beaches, and zetaform beaches (e.g. Yasso 1965, Finkelstein 1982. Yasso, the first to claim that the planform shape of these features tended to approach a logarithmic spiral, was responsible for another name, logarithmic- or log-spiral bays.

a) b)

Fig 1 a) Logarithmic spiral, given by $r = r_0 e^{\cot(\square)}$. b) Half Moon Bay, California (Yasso 1965) (Image courtesy of NASA).

Log spirals (Fig. 1), first described by Descartes, are curves having the property that a line drawn from the center to any point on the curve cuts a constant angle α. The radius of curvature of a log spiral increases logarithmically with the distance along the curve, and the width of successive whorls increases geometrically. Log spirals are found in nature in many other contexts, including the arrangement of seeds in a sunflower or pine cone and, famously, the coiled shell of the chambered nautilus.

It is generally thought that these bays erode according to alongshore-transport gradients controlled by the influence of the upwind headland, or pinning point, on the angle of waves reaching the beach. In this conceptual model, it is the pattern of refraction and/or diffraction created as waves approaching from a dominant direction interact with the headland which produces a bay decreasing in curvature away from the pinning point at the center of the spiral (e.g. Yasso 1965, LeBlond, 1979, Lavalle and Lakhan 1996, Moreno and Kraus 1999).

Several authors have predicted that refraction and/or diffraction ought to produce bays of this general form. The logarithmic spiral is an elegant hypothesis, although Komar and others (Phillips, 1985) argue that the theoretical ideal shape is less important than more general descriptors such as a downdrift decrease in curvature. Headland-bay beaches have been fit to other curves, sometimes more successfully than to logarithmic spirals (e.g. Moreno and Kraus 1999), but no mechanisms are generally accepted for these correspondences.

A prediction of the logarithmic-spiral model conceptual model is that the bay will reach

equilibrium once the orientation of the shoreline parallels the refracted wave crests approaching from the dominant direction, leading to a zero-alongshore-flux equilibrium configuration (Leblond 1979, Klein et al. 2003).

We here present modeling results that suggest a fundamentally different explanation for these coastline features. Using a simple one-line numerical coastline model, we generate headland-bay beaches that owe their existence not to the shape of diffracted or refracted wave crests, but to the presence of waves of many deep-water approach angles, not only one dominant angle. Shoreline protuberances such as a headland shadow downwind areas from some wave-approach angles, and any local wave climate is thus a nonlocal function of the nearby shoreline shape (Ashton and Murray, 2006a and 2006b).

METHODS

Numerical Model Overview

The modeling framework used has been described previously (Ashton et al. 2001, Ashton and Murray 2006a). The family of models described briefly here, including a version adapted to include the interactions between shoreline lithology and mobile sediment (Valvo, et al., 2006), features the random selection of a daily deep-water wave angle from a probability distribution function; it is therefore not necessary to assume one dominant wave approach angle.

These models fall in the class of 'one-line' models (Larson, et al. 1987, Komar 1998) of coastal evolution. They assume that over the time scales under consideration (years to decades and longer) the shoreface profile may be considered to be constant as the coastline position translates seaward or landward. One line of beach cells is therefore sufficient to specify the location of the shoreline.

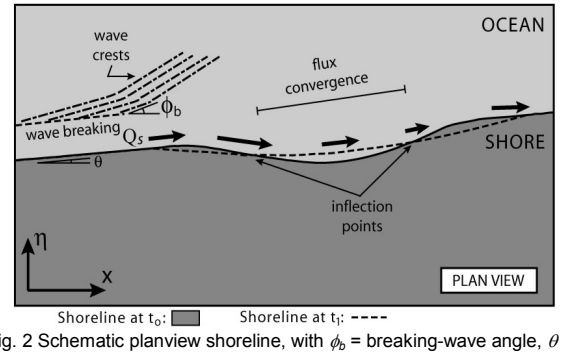

Fig. 2 Schematic planview shoreline, with ϕ_b = breaking-wave angle, θ = local shoreline angle. For low-angle wave climates, divergences from a straight coastline are smoothed away. (from Valvo et al., 2006)

Wave-driven alongshore transport can be related to deep-water wave approach angle relative to the global shoreline orientation with the commonly used CERC equation (Komar, 1998):

$$Q_s = KH_b^{5/2}\sin(\phi_b-\theta)\cos(\phi_b-\theta), \quad (1)$$

where H_b is breaking-wave height, ϕ_b is breaking-wave angle, θ is local shoreline angle relative to the global shoreline orientation, and K is an empirical constant. On a sandy coastline, alongshore gradients in the sediment flux, Q_s, tend to cause changes in the shoreline position, η (Fig. 2), and shoreline change for each cell is determined by the following mass-conservation equation:

$$\partial\eta/\partial t = -(1/D)\partial Q_s/\partial x, \quad (2)$$

where η represents shoreline position and D is the depth to which erosion and accumulation extend. It must be noted that simplified model physics and geometry preclude its application to phenomena at scales less than kilometers and years. Also, the large number of simplifying assumptions make this modeling framework inappropriate for the simulation of any given real coastline; rather, its aim is to explore the causes of poorly-understood phenomena that may arise from even such simplified representations of coastal processes.

The CERC equation predicts a maximum in alongshore sediment transport for deepwater wave-approach angles of about 45°, a prediction with important consequences for shoreline evolution. When deep-water wave angles below this maximum dominate in a wave climate (Ashton and Murray 2006b), diffusive conditions prevail, and planview shoreline features are reduced in amplitude. However, recent work (Ashton et al. 2001; Falques et al. 2005; Ashton and Murray 2006a) has revealed that, given a wave climate dominated by wave angles greater than approximately 45°, diffusivity actually becomes negative, resulting in an instability in planview shoreline shape: alongshore flux converges across the crest of a shoreline perturbation, causing accretion. As planview perturbations grow, regular shoreline features including spits and large capes tend to form (Ashton et al., 2001). In this paper, we consider only low-angle-dominated wave climates that tend to produce smooth coastlines.

Model Algorithm

The model domain consists of a two-dimensional grid of cells representing a planform coast. Shoreline cells are partly filled with water and partly with land; a coastline is defined at the interface. During a model run, deep-water waves are generated repeatedly from a probability distribution function representing a global deep-water wave climate. The input wave climate is parameterized with two variables, one representing the proportion of waves from the right side of the domain (the "asymmetry") and the other specifying the percentage of waves that are high-angle. Wave refraction and shoaling are calculated assuming shore-parallel contours, and breaking wave height and angle are used to calculate the alongshore sediment flux, Q_s, leaving each cell from Equation 1.

Equation 2 determines the erosion or accretion or she shoreline based on sediment-flux gradients.

Adaptation for Rocky Coasts

Initial investigations with this model focused on sandy coastlines, but work by Valvo et al. (2006) included the effect of underlying lithology (the 'geological framework'): in this version, land may consist of mobile sediment or of rock. We use this version of the model in some experiments reported below. Rock weathers into mobile sediment according to an exponential-decay function of the form $W = W_0 e^{-xd}$, where W is the weathering rate in m/yr, x is the amount of sediment cover in meters (Fig. 2), d is a decay constant, and W_0 is a coefficient representing the maximum weathering rate, that for bare rock. This simple parameterization is roughly consistent with observations of terrestrial bedrock weathering (Heimsath et al. 1997) and is appropriate given the lack of empirical data on shoreface weathering and the model's exploratory (Murray, 2003) goals.

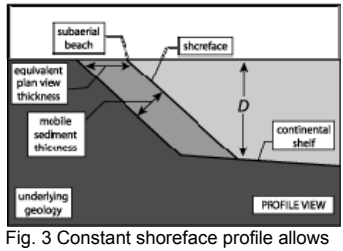

Fig. 3 Constant shoreface profile allows planview thickness to act as proxy for sediment cover (from Valvo et al., 2006)

The thickness of the sediment layer separating bedrock from water is used as a proxy for the degree to which the rock is protected from weathering (Fig. 3); it may be interpreted as representing the frequency with which bedrock is covered by shifting sediment. This simplification represents the assumption that if the time scales being modeled (years and longer) are great enough, intermittent sediment coverage may be reduced to a time-averaged parameter. The variable x is therefore a somewhat abstract quantity representing the ability of sediment cover to impede weathering.

Further, rock composition can vary spatially; this quantity specifies the proportion of the material that weathers into fine sediment (e.g. silt and clay) and will therefore be lost to the nearshore system when a unit of rock is weathered to mobile sediment.

Finally, a feature of the model we add here is the ability to specify sinks, locations on the shoreline that capture all sediment flux. These allow representation of rocky headlands that have steep and deep flanks, and which therefore act to remove sediment delivered by alongshore transport from the nearshore system. This model includes three ways for sediment to be lost from the system—sinks, the removal of weathered rock as fine-

grained sediment, and a globally imposed erosion rate representing sea level rise. Each can be toggled on and off.

Initial Conditions

We explored a range of initial conditions. The initial shoreline configuration consists of a stretch of beach with blocks of inerodible rock at the updrift and downdrift ends. The dry land behind the beach was either set to be rock or mobile sediment. Model experiments reported here involve an asymmetrical wave climate that will produce net sediment transport toward one end of the coast. The wave climate is also dominated by low-angle waves, and thus tends to smooth the shoreline shape.

RESULTS

Necessary conditions for the formation of a scalloped bay include: 1) the predominantly low-angle and asymmetric wave climate; and 2) some mechanism for sediment loss—sinks at the headlands, loss of fine-grained sediment, or simply a globally imposed erosion rate. The equilibrium bay shape was not markedly sensitive to the mechanism of sediment loss.

Figure 4 shows a time series of a sample model run that produced a hook-shaped bay. Near the updrift end of the model domain, an inerodible headland is associated with a sink that removes any sediment transported onto the headland. Downdrift of the pinning point (headland), the lack of sediment influx produces a divergence of sediment flux and therefore erosion; an indentation forms downdrift of the headland, and as more sediment moves downdrift and is not replaced, the indentation becomes a growing bay. As the bay deepens, any location on its coast is increasingly shadowed by the opposite side, and so local wave climates resemble the global deep-water wave climate less and less.

Figure 5 comes from the first years of the same model run and shows that the bay does not acquire an obviously spiraled shape until it has undercut the headland to a sufficient degree to become recurved. At the downdrift end of the new bay, the growing spiral-like shape has an inflection point as its angle approaches that of the undisturbed flat coastline. The bay continues to grow until the downdrift end is intercepted by an inerodible headland, which acts to trap the bay by removing the high-erosion inflection point. After this, the bay approaches a steady state, equilibrium shape. By contrast, Fig. 6 presents a new bay which is not yet influenced by the presence of the downdrift headland.

Figure 7 shows a model experiment in which rock progressively weathers into mobile sediment. As long as the maximum weathering rate exceeds the rate at which sediment transport removes material locally, the presence of rock near the surface does not alter the model behavior. The loss of fine-grained material upon weathering, however, removes the necessity to impose sediment sinks at the headlands.

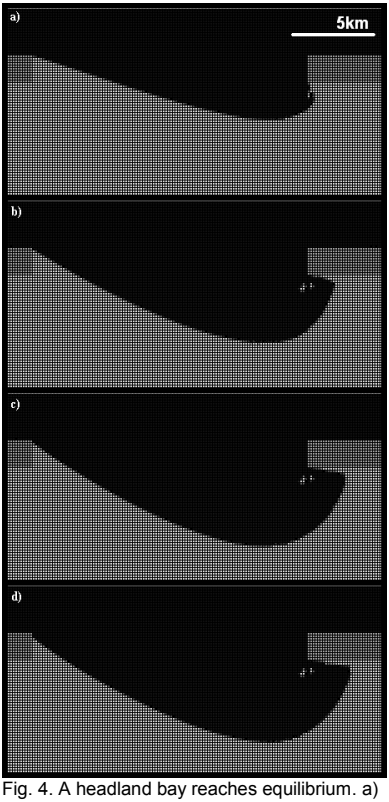

Fig. 4. A headland bay reaches equilibrium. a) t=200yrs. b) t=400yrs. c) t=800yrs. t=1600yrs.

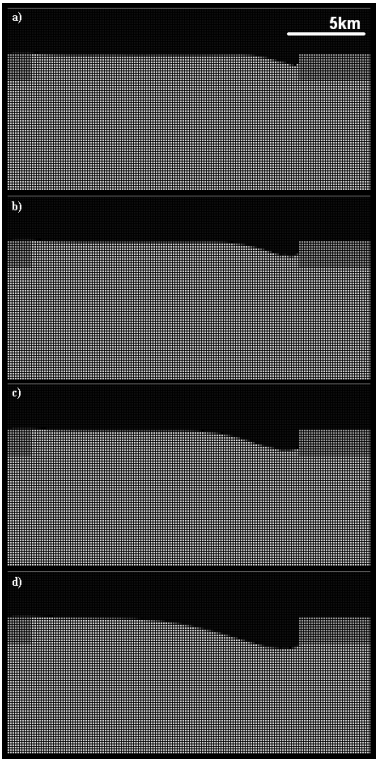

Fig. 5 The origin of the bay. a) t=2yrs. b) t=4yrs. c) t=8rs. d) t=16yrs

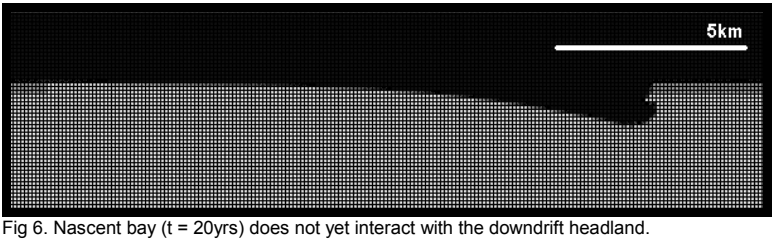

Fig 6. Nascent bay (t = 20yrs) does not yet interact with the downdrift headland.

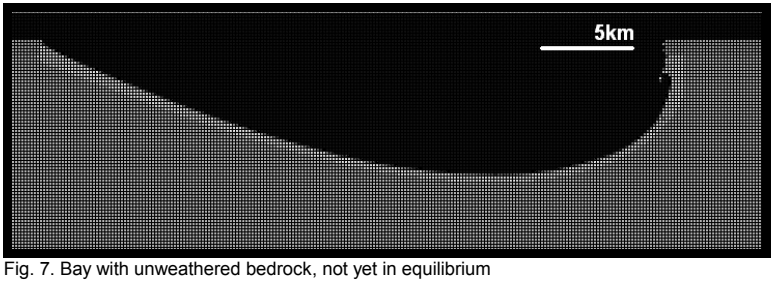

Fig. 7. Bay with unweathered bedrock, not yet in equilibrium

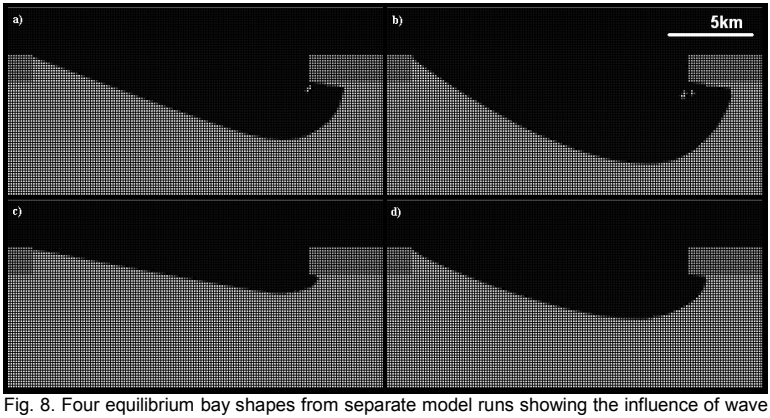

Fig. 8. Four equilibrium bay shapes from separate model runs showing the influence of wave climate. a) Asymmetry = 0.15, Low-angle proportion = 0.9. b) Asymmetry = 0. 15, Low-angle proportion = 0.6. c) Asymmetry = 0.35, Low-angle proportion = 0.9. d) Asymmetry 0.35, Low-angle proportion 0.6.

In Fig. 8, four equilibrium bays are shown. Different combinations of wave diffusivity and asymmetry affect the angle (α) of the spiral; a more-diffusive wave climate with a higher proportion of low-angle waves produces a flatter beach, and a greater proportion of waves from the right produces a deeper beach.

DISCUSSION

These initial modeling results suggest a mechanism for the formation of spiral-like bays that differs significantly from the conventional perception that they reflect patterns of refraction and diffraction of wave energy. In our model, it is the fact that waves come from many directions rather than a single one, combined with simple wave shadowing, that leads to the emergence of the bay shape. As the bay shape evolves, local wave climates change through shoreline reorientation and increasing wave shadowing. The shape ceases to evolve when local wave climates produce no net sediment flux and

therefore no shoreline change.

The evolution of the bay from growing indentation to equilibrium shape highlights the significance of the downdrift lithology: in these model results, a downdrift headland is not necessary for spiral bays to exist, as some previous authors have claimed (Finkelstein 1989), but it is required if the bay is to reach a steady state; if it does not impinge upon and become trapped by a headland, the downdrift end will erode indefinitely. The growing bay tends to evolve into a shape in which net sediment transport is locally minimized, but this is never possible at the inflection point. Only when the inflection point becomes coincident with an inerodible headland is the bay's progress halted. When the shoreline orientation adjacent to the downdrift headland approaches that for which no net sediment transport occurs, because of the deepening of the bay, the bay ceases to deepen, and a steady state results in which net sediment fluxes everywhere approach 0.

Some questions have been raised about the influence of underlying lithology on the morphology of headland-bay beaches. In the model, the presence of rock is not relevant if it weathers fast enough that erosion is controlled only by sediment-transport processes and not by weathering rates. If stretches of the coast are occasionally left bare of sediment, however, erosion will slow locally, limited by the rate at which new sediment is formed, and the bay's evolution will correspondingly be affected. In the long term, however, sediment flux divergences continue to expose the underlying rock to weathering until the bay achieves the shape that features no net sediment flux everywhere. After this, weathering produces a progressively thickening mantle of mobile sediment, and the weathering rate asymptotically approaches 0. Thus, the process of converting rock to sediment does not affect the long-term equilibrium shape.

CONCLUSION

Previous authors have outlined what may well be a sufficient explanation for the existence of spiral-like bays. Based on this initial work, it is not possible to claim that the mechanism proposed here is more likely to be the principal mechanism, particularly because the model used is intentionally simplified. However, because of the good agreement of our model with observed headland-bay morphology, it seems quite possible that the existing explanation is not necessary. If that is the case, the key interactions causing the basic log-spiral-like shape are very different than those commonly assumed. Future, more detailed modeling will be required to evaluate the relative importance of simple alongshore transport, treated as a function of local shoreline orientation, and the wave patterns caused by refraction and/or diffraction around a headland.

THE RESPONSE OF SPIT SHAPES TO WAVE-ANGLE CLIMATES

Abstract: We investigate spit formation and evolution in light of the high-wave-angle instability in shoreline shape arising from a maximizing angle for wave-driven alongshore sediment transport. Single spits emerge in a simple one-contour line numerical model that evolves the coast using morphodynamic feedbacks and a 'climate' of waves approaching the shore from variable directions. Analysis of sediment transport and shoreline stability metrics illustrate how spits can be generated, demonstrating how waves from all angles can play a role in spit formation and evolution. Simulations suggest that regardless of whether high- or low-angle waves dominate relative to the general shoreline trend, as spits extend offshore, they tend to orient themselves such that most of their coast barely experiences low-angle waves and alongshore sediment transport to the spit end is maximized. This 'graded' spit shape minimizes gradients in sediment flux, while the recurve at the spit end experiences larger gradients and a region of high-angle instability. Examining hindcast wave data, similar trends are seen along the natural example of Long Point, Lake Erie, Canada.

INTRODUCTION

Discussion of the presence and the morphological importance of a maximizing angle for alongshore sediment transport is not new (e.g. Bruun 1954; Grijm 1960, 1964); however, interest in the importance of this maximum has recently been reinvigorated by studies of a high-wave-angle instability in shoreline shape (Ashton et al. 2001; Falqués and Calvete 2005). Numerical simulations have demonstrated how 'high-angle' waves, with angles

between deep-water wave crests and the shore greater than this transport-maximizing angle, could cause the self-organization of a coast into quasi-periodic fields of flying spits, cuspate spits, and capes. Although many such series of capes and flying spits can be found in nature, frequently spits are found alone and in regions dominated by low-angle waves. Here, we extend recent developments in the understanding of shoreline evolution (Ashton and Murray 2006a) to study how the maximum in alongshore sediment transport affects the evolution of single spits. Using newly developed wave climate metrics (Ashton and Murray 2006b), numerical modeling results and comparisons with nature suggest that the transport maximum plays an important role in determining the orientation of spits.

BACKGROUND

Fed by an updrift source of littoral sediment, spits represent one of the most common depositional clastic coastal landforms. As the downdrift end of a spit is by definition untethered, primary driving forces, particularly alongshore sediment transport, help determine spit shape and orientation. Sometimes spits are considered to grow in the direction of the alongshore current; unfortunately, drift direction alone cannot be used to explain spit orientation as the alongshore current is by definition shore-parallel. Spits also recurve, or trend back towards the shore—even the high-energy, seaward-facing side of a spit faces many directions, experiencing waves from a variety of deep-water directions.

Spit Orientation

Bruun (1954), from quantitative and laboratory investigations, was one of the first to suggest that a maximizing angle for alongshore sediment may determine the angle of spit accumulation. Grijm (1960; 1964) theoretically explored the shoreline shapes that could result from waves approaching from any one angle greater or less than a suggested maximizing transport angle of 45º (not specifying whether this is a breaking or deeper-water angle). Zenkovich (1967) also studied the influence of wave angle on spit shapes, suggesting that for high-angle waves, spits should grow offshore at an angle of 45º to the shoreline trend.

More recently, Kraus (1999) developed a simple analytic mode of spit extension, although this model does not account for shoreline reorientation. Petersen et al. (2001) present a one-contour-line analytical model for spit accretion for an assumed ‘equilibrium’ spit shape, again emphasizing the importance of a maximizing angle in evolution. Results suggest that more detailed hydrodynamic models are required to give rise to recurved spit ends. Further laboratory experiments, similar to those of Bruun (1954), investigate the growth of a spit subjected to waves from a single high angle (Petersen et al. 2002). These investigations follow the research history of investigating the issue of spit orientation in terms of waves approaching from only one direction.

Other research, particularly studies focusing on the evolution of periglacial environments, suggests a distinction between ‘swash-aligned’ and ‘drift-aligned’ spits (Forbes et al. 1995). According to this distinction, ‘drift-aligned’ coasts tend to

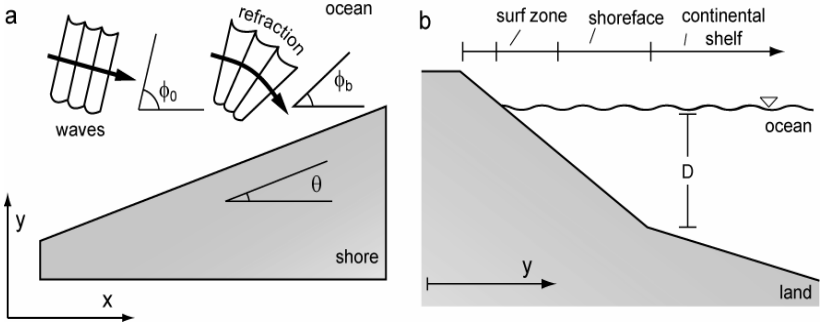

Fig. 1. a) Plan-view domain. b) Cross-shore profile.

experience waves with oblique approach, with strong gradients in wave heights and angles, whereas wave approach tends to be shore-normal for 'swash-aligned' coasts (Orford et al. 1991). The results of numerical modeling experiments presented below raise the question of whether a process distinction must be evoked to explain these different modes of shoreline behavior.

Shoreline Instability

Because wave refraction changes both wave angle and height, common breaking-wave formulations for alongshore sediment transport, such as the CERC formula (Komar 1971), cannot be used to properly understand gradients in alongshore sediment transport along an undulating coast (Ashton and Murray 2006a; 2006b). Instead, a deeper water reference frame is required. The CERC formula can be recast for fully deepwater waves assuming refraction over shore-parallel contours,

$$Q_s = KT^{1/5} H_0^{12/5} \cos^{6/5}(\phi_0 - \theta)\sin(\phi_0 - \theta), \quad (1)$$

where Q_s is the alongshore sediment flux (m^3/s deposited volume), K typically equals ~0.34 $m^{3/5}s^{-6/5}$, T is the wave period (s), H_0 is the root-mean-squared deep-water wave height (m), and $(\phi_0 - \theta)$ is the relative wave angle (Fig. 1). This formula exhibits a maximum for a relative deep-water angle of 42° (Fig. 2a). Recasting the CERC formula for non-breaking waves suggests that the shoreline instability can frequently occur, and does not require that waves break at uncommonly large angles (as previously thought).

The standard one-contour-line approach (Pelnard-Consideré 1956), where local surf-zone gradients in Q_s are assumed to be spread over a shoreface of depth D (Fig. 1b), yields a diffusion-like equation for the plan-view evolution of the shoreline,

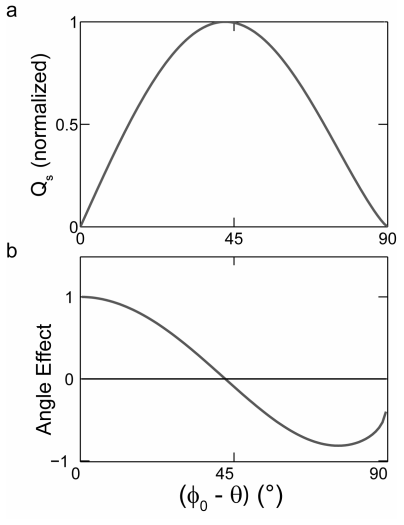

Fig. 2. a) Normalized alongshore sediment transport vs. deep-water angle.
b) The 'angle effect' upon diffusivity vs. deep-water angle.

$$\frac{\partial y}{\partial t} = -\mu \frac{\partial^2 y}{\partial x^2}. \tag{2}$$

For (1), the deep-water CERC formula, the diffusivity, μ (m/s^2), varies with the angle of wave approach,

$$\mu = \frac{K}{D} T^{1/5} H_0^{12/5} \left\{ \cos^{1/5}(\phi_0 - \theta) \left[\left(\frac{6}{5} \right) \sin^2(\phi_0 - \theta) - \cos^2(\phi_0 - \theta) \right] \right\}, \tag{3}$$

The term in the brackets {} represents the wave-angle dependence of the diffusivity. Fig. 2b shows a negative diffusivity for high-angle waves, representing the shoreline instability which causes perturbations to an otherwise straight coast to grow.

Recent research using more realistic treatments of wave refraction suggest that the growth of slight shoreline protuberances is damped at smaller alongshore scales (Falqués and Calvete 2005; List and Ashton 2007). However, the importance of the maximizing angle for Q_s extends far beyond initial instability. For example, simple analysis suggests that waves approaching from a single high angle will cause a finite-amplitude shoreline protuberance to eventually develop into an off-shore extending flying spit with an erosional updrift flank (Ashton and Murray 2006a). Numerical modeling shows that over

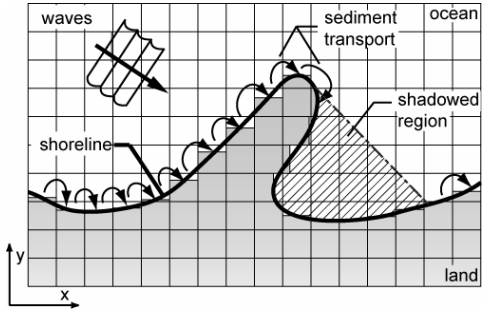

Fig. 3. Plan view model schematic

time, morphodynamic feedbacks and finite-amplitude effects occurring well beyond initial instability play increasingly important roles in high-wave-angle shoreline evolution; these effects, for example, can lead to emergent behaviors, such as the self-organization of alongshore sandwaves, flying spits, and capes (Ashton and Murray 2006a).

As terminal portions of littoral cells, spits elongate because of the gross alongshore delivery of sediment to the spit end (per (1)). Updrift of this point, evolution of the shoreline shape remains controlled by gradients in alongshore sediment transport (per (3)). Interestingly, the CERC formula predicts that such gradients in sediment transport are minimized when transport is at a maximum (diffusivity = 0 at the transport-maximizing angle, Fig. 2), suggesting that the waves that control spit elongation may be unimportant in the evolution of the spit shape, relative to other waves in the climate. Correspondingly, waves important in the evolution of the spit shape will not transport much sediment towards the spit end (large diffusivity when transport is small, Fig. 2). Therefore, it is unlikely that spit evolution can be sufficiently understood using waves approaching from just one presumed 'dominant' angle.

METHODS

Here we apply a previously developed numerical model that evolves the plan-view shape of the shoreline in response to gradients in alongshore sediment transport. Wave climate metrics, used to determine the long-term net, directional alongshore sediment transport and the long-term coastal stability are computed along the shore.

Numerical Modeling

Similar to other common 'one-contour-line' models (Hanson and Kraus 1989), we have developed a model evolving the shape of the shoreline due to gradients of alongshore sediment transport within the surf zone (assuming that the shoreface maintains a constant shape (Fig. 1b)). Discretizing the CERC formula, (1), the model contains a numerically stable solution scheme for the case of high-angle waves, and can accommodate a shoreline that becomes arbitrarily sinuous, even doubling back on itself (Fig. 3) (Ashton et al. 2001; Ashton and Murray 2006a). To simulate spit growth, the model contains a simplified representation of barrier overwash. Overwash is assumed to occur whenever a

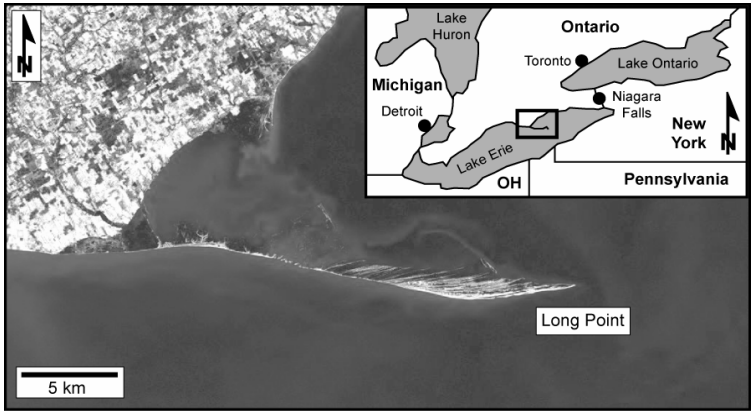

Fig. 4. Long Point, Lake Erie, Canada. Data are available from USGS/EROS (figure from Ashton and Murray 2006b).

barrier is below a minimum critical width (Leatherman 1979), and it will widen a barrier whenever backbarrier depths are less than the shoreface depth (Jiménez and Sánchez-Arcilla). Waves (with $H_0 = 2$ m, $T = 8$ s) approach from a new angle every day, with a direction selected from a probability distribution function determined by U, the fraction of unstable, high-angle waves, and A, the asymmetry, defined as the fraction of waves approaching from the left, looking offshore. Computations assume that all wave refraction occurs over shore-parallel contours.

Wave Climate Metrics

At a shore of a given orientation, the contributions to alongshore sediment transport from a long-term wave climate can be summed, leading to $Q_{S,net}$, the net alongshore sediment transport. Similarly, every approaching wave contributes to the evolution of the coastline, either diffusively or anti-diffusively. A dimensionless 'instability index', Γ, assesses the competition between diffusion and anti-diffusion,

$$\Gamma = \frac{\sum_{i=1}^{n} \mu_i \Delta t_i}{\sum_{i=1}^{n} |\mu_i| \Delta t_i}, \tag{4}$$

for each data point i, and data interval Δt. This normalized index, which represents the 'competition' between high- and low-angle waves, ranges between 1 for a wholly low-angle climate and –1 for a wholly high-angle climate. A Γ of zero would mean that a wave climate is on the verge of instability—low- and high-angle waves balance each other out. (Ashton and Murray 2006b)

RESULTS

First, the model and metrics will be used to build upon research into the effects of high-angle waves by studying in detail a single 'flying' spit, or 'ness'. Further simulations investigate spit growth in wave climates dominated by low-angle waves, and how spit reattachment to the mainland can result in dramatic shoreline reorientation.

Natural 'Flying' Spit: Long Point

Long Point is a large flying spit along the Canadian shore of Lake Erie (Figure 4). WIS hindcast covering 1956-1987 from Lake Erie WIS station 33 shows that the predominant westerly winds blowing along the long axis of the elongate lake result in a high-angle-dominated wave climate along the north and south shores of Lake Erie (Great Lakes WIS hindcast can be found at ftp://ftp.erdc.usace.army.mil/pub/PERM/wisftp/). Although there are other high-wave-angle features along these shores, such as Point Pelee, Rondeau Point, and Presque Isle, they are far from Long Point. This spit, which appears to have formed over the Holocene, is not part of an alongshore chain, likely because it began as a large glacial moraine perturbing to the shoreline trend (Coakley 1992).

Wave climate computations show although local wave climates are unstable at either end of Long Point, the spit is oriented such that the main stretch of the shore is marginally stable (Figure 5). Alongshore sediment transport is dominantly to the left (looking offshore), but it is slightly reduced along the middle of the spit, and maximized at the updrift and downdrift regions where the wave climate becomes unstable. Interestingly, another type of feature associated with high-angle waves, alongshore sand waves, appear along same portions of the spit that experience unstable wave climates (further discussed by Ashton and Murray (2006b)).

Modeled Single 'Flying' Spit

To determine if alongshore sediment transport and the high-angle instability can give rise to a feature similar to Long Point, the numerical model was run using a single initial shoreline protuberance added to an otherwise straight coast. Like the natural case, waves were high-angle ($U = 0.6$) and asymmetric (with more waves approaching from the right, looking offshore, $A = 0.2$). Not only does the simulated flying spit eventually attain a shape that generally resembles Long Point, perhaps more significantly, there are similar trends in wave metrics (Fig. 6). The simulated flying spit has reoriented itself such that the main stretch of the spit experiences predominantly low-angle waves, whereas predominantly high-angle waves affect the proximal and distal spit ends.

Modeled Headland-Extending Spits

As a corollary to the high-angle spit evolution, another simulation investigates how spits extend offshore even if the local wave climate is dominated by low-angle waves. Beginning with a large rectangular protuberance, waves that are regionally low-angle ($U = 0.2$) with an asymmetry (net drift to the right, looking offshore, $A = 0.7$) lead to the extension of spits in both the updrift and the downdrift direction (Fig. 7). As a result of the asymmetry in the wave climate, the spits attain different orientations on either side of the hump. In both cases the direction of spit growth is not parallel to the initial shoreline orientation.

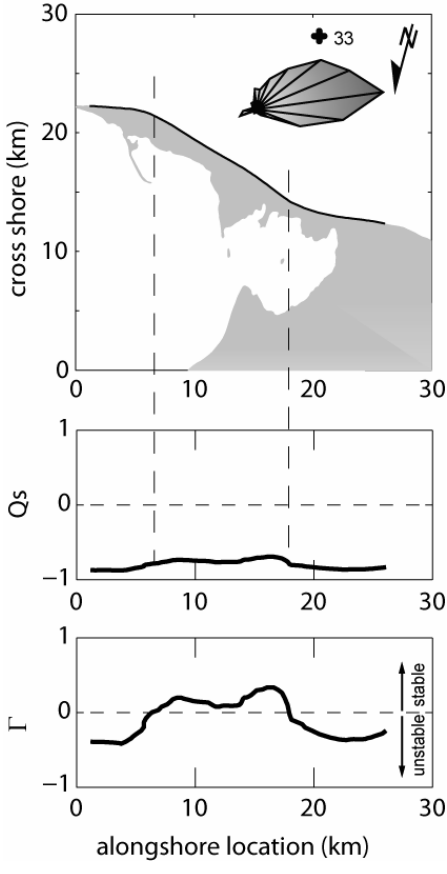

Figure 5. Long Pont rotated 195° clockwise, showing a) shoreline with b) relative Q_s and c) Γ along the shore. Inset rose of 'wave energy' and location of WIS station 33.

After the spits have extended offshore, wave climate metrics indicate that although the coast along most of the spit experiences a predominantly stable wave climate, there is a transition to instability at the end of the spit. For both spits, the transition to instability corresponds to the location of the maximum in net Q_s. This suggests that the instability and the maximizing angle for sediment transport play key roles in the orientation of the spit ends. Interestingly, spits extend in what would be described as a dynamically 'equilibrium' form even though the updrift shore is not dominated by high-angle waves as suggested by Petersen et al. (2001). Note that although for the updrift (left) spit, the maximum in Q_s and the transition to instability occurs at the spit end, for the downdrift

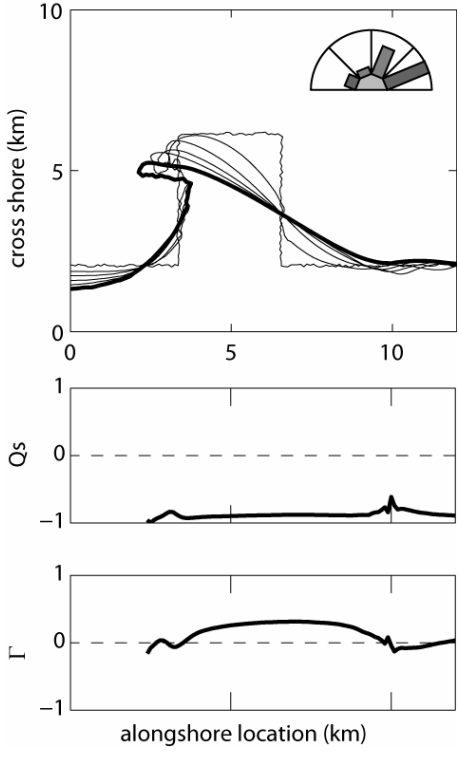

Figure 6. Simulated high-angle spit showing a) shoreline (analyzed shoreline in dark line with b) relative Q_s and c) Γ along the shore. Inset of PDF of wave-approach angle.

(right) spit, the Q_s maximum and instability transition occur updrift of the spit end. This effect is likely due to the wave 'climate' used to simulate shoreline evolution, such behavior would not be predicted by a one-contour-line model using only a single wave approach angle (Petersen et al. 2001).

As the spits continue to extend offshore, they eventually intersect the mainland coast (Fig. 8). After this intersection, shoreline orientation dramatically changes; new behavior occurs after the spit connects to the down drift beach. As the spit end extends offshore, the coastal changes at the spit end are controlled by the rate of sediment delivery, the alongshore flux to the tip. However, once the spit reconnects with the coast, sediment can be transported in both directions—like the rest of the coast, shoreline evolution is now controlled by gradients in alongshore sediment flux, not by the magnitude of flux.

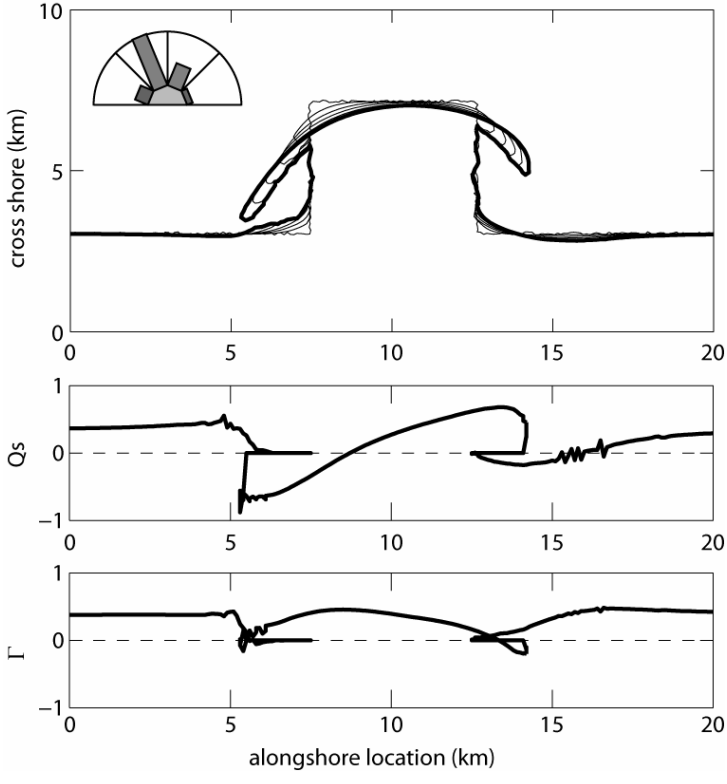

Fig.7. Low-angle spit simulation results showing a) shoreline (analyzed shoreline in dark line) with b) relative Q_s and c) Γ along the shore. Inset of PDF of wave-approach angle.

Because of the generally stable, diffusive wave climate, the simulated shore continues to smooth over time, eventually eliminating the initial hump.

DISCUSSION AND CONCLUSIONS

Although the exploratory model here appears to capture many essential elements of spit evolution, more attention should be paid to the controls upon the accretion rate of the spit end. For instance, if a spit is accreting into water significantly deeper than the shoreface depth, spit growth will be slowed dramatically, which would have a strong effect on spit shapes and orientation (the current numerical model assumes accretion onto a constant depth seabed). Also, the simple one-line approach assumes that a section of coast corresponds to a shoreface segment of the same alongshore width. Where the coastline curvature is extreme, such as at spit ends, this assumption breaks down, as a segment of the shore will correspond with a 'wedge' of shoreface of increasing width offshore.

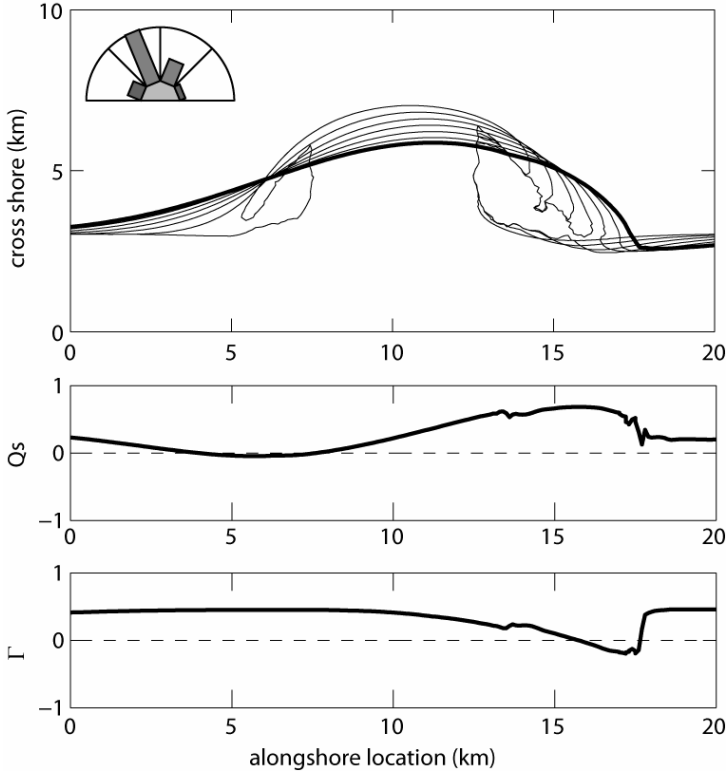

Fig.8. Low-angle spit simulation results showing a) shoreline (analyzed shoreline in dark line) with b) relative Q_s and c) Γ along the shore. Inset of PDF of wave-approach angle.

Rigorously studying spit-end phenomena would require a more spatially explicit model—a break from the one-contour-line approach. Although more explicit models may improve the numerical accuracy of simulations, they would likely be driven mainly by the same processes and feedbacks operating in the existing model.

We have studied shoreline evolution using a one-contour-line model, using sediment transport and stability metrics to better understand how spits can orient themselves in response to wave climates. In both high- and low-angle climates, simulations evolve a smooth spit shape, and along its flank: 1) gradients in net sediment flux are very low; 2) net alongshore sediment flux tends to be maximized; and 3) the effective local diffusivities are small but positive (stable). These three characteristics are intertwined. Net sediment flux for a given wave climate should be maximized when the shoreline orientation produces an effective diffusivity of 0 (Fig. 2). When the effective diffusivity

becomes small, shoreline curvatures do not produce strong gradients in alongshore flux—the shoreline will evolve slowly and its shape will persist. Although continued spit extension (caused by sediment delivery to the spit end) prevents a true static steady state from developing, evolution of the spit shape itself will be slow. In short, the orientation that produces the maximum sediment flux (for a give wave climate) along the flank dictates general spit orientation in this model. Trends along the Long Point coast are consistent with these model suggestions. (Future work should include more comparisons of the modeled wave climate trends with those found along natural coasts.)

These results present a unified model for spit extension, suggesting that distinctions such as 'drift-' and 'swash-aligned' may not be of fundamental importance. The results shown in Fig. 7 show that along a single coastline stretch, areas that would be called swash aligned (experiencing little to no net transport) grade into areas that would be called drift aligned (experiencing the maximum transport possible for the local wave climate). Fig. 8 further demonstrates that even in the same wave climate, alongshore sediment transport alone can result in a coast with spits to trend towards an orientation dramatically different than that of an open coast. These preliminary investigations suggest that the maximizing angle for alongshore sediment transport, combined with boundary conditions, may explain many observed spit behaviors.

ACKNOWLEDGEMENTS

We wish to acknowledge the contributions of Liviu Giosan to this research. Portions of this research were funded by WHOI and the USGS through the WHOI Postdoctoral Scholar program, the Andrew W. Mellon Foundation, and NSF grants DEB-05-07987 and EAR-04-44792.

Abstract: Using National Ocean Service topographic sheets and global positioning system shoreline position surveys, historical shoreline changes of Parramore Island, Virginia, are quantified between 1852 and 2006 to address long- and short-term trends in shoreline movement. Quantitative analyses of twelve high water line (shoreline) positions indicate the shoreline is retreating at increasing rates in the short term (decadal) when compared with long-term trends (centennial). In particular, the behavior of the outer shoreline changed from clockwise rotational instability to sustained retreat. Parramore's entire outer shoreline (Cells 3, 4, and 5) experienced a retreat rate of -3.6 m/yr over the long term (1852-2006) and -8.8 m/yr over the short term (1998-2006). The short-term rate changes indicate that the processes controlling shoreline trends, e.g., overwash to the south and inlet dynamics to the north, have intensified and/or changed relative to the long-term.

INTRODUCTION

Shoreline mapping and change studies that utilize geospatial data sets and technology have the ability to map coastal landforms and quantify shoreline processes at various spatial and temporal scales (e.g., Fenster and Dolan, 1993; Byrnes et al., 1995; McBride and Byrnes 1997; Morton et al., 2005). Barrier islands are dynamic geomorphic features, and studies of these coastal environments are hampered by the limited availability and inaccuracy of most historical data sources (Anders and Byrnes, 1991; Crowell et al., 1991; Byrnes et al., 2003; Leatherman, 2003; Boak and Turner, 2005). However, advancements in geospatial technology have surpassed conventional surveying methods in their ability to observe accurately, quickly, and affordably coastal features such as barrier islands. Specifically, the capacity to study

coastal changes was improved by the development of geographic information systems (GIS) and global positioning systems (GPS). In addition, aerial photography and satellite imagery inventories continue to expand and provide a rich source of geospatial data.

In recent years, the open-ocean shoreline of Parramore Island has retreated at a rapid rate as indicated by numerous qualitative factors, such as massive tree die-offs along interior dune ridges, numerous fallen trees across the foreshore, outcropping of relict marsh along the beachface, and exposure of an historical shipwreck on the beach. This study seeks to determine and compare long-term versus short-term change rates for a highly dynamic barrier island located within the Virginia Coast Reserve. In particular, we identify the magnitude and direction of shoreline migration trends, short-term reversals in those trends or rate increases, and investigate the causes of the observed trends. In turn, this approach provides a morphodynamic analysis of Parramore Island.

STUDY AREA

Parramore Island is an undeveloped, mixed-energy, tide-dominated barrier island located mid-way along the Virginia Eastern Shore of the Delmarva Peninsula (Figure 1). Parramore is the largest island of the Virginia Coast Reserve, which constitutes one of the longest stretches of coastal wilderness remaining along the U.S. Atlantic coast. With a mean spring tidal range of 1.7 m and an average significant wave height of ~0.6 m, the island has a classic ‘‘drumstick-shape’’ with large ebb-tidal deltas characterizing the tidal inlets at either end (McBride, 1999). Net longshore sediment transport is to the south. Parramore Island’s outer shoreline is about 12.7 km in length and may be segmented into three geomorphic zones: 1) the high-profile, inlet-influenced northern end; 2) the north-central segment characterized by the truncation of high-profile, tree-lined beach ridges; and 3) the southern portion, which is a low-profile, washover-dominated barrier and barrier spit (Figure 2). Wachapreague Inlet and Cedar Island are to the north and Quinby Inlet and Hog Island are to the south.

DATASETS & METHODS

NOS T-Sheets

Data sets used to reconstruct historical shoreline positions are National Ocean Service (NOS) topographic sheets (T-sheets) from 1852, 1871, 1910, 1914, 1942, and 1959/1962. The shoreline indicator on a T-sheet is typically the mean high water (MHW) line, which is equivalent to the high water line (HWL) as discussed by Leatherman (2003). Thus, the HWL enables the use of the longest possible record of shoreline position (~150 years) for determining change rates as opposed to any other shoreline indicator (Moore, 2000; Honeycutt et al., 2001; Pajak and Leatherman, 2002; Graham et al., 2003; Leatherman, 2003; Boak and Turner, 2005).

GPS Shoreline Position Surveys

GPS shoreline position surveys are a rapid, low-cost, large-scale, and highly accurate means to map a shoreline. The accuracy of a survey depends on the knowledge and competency of the instrument operator, the choice of HWL used in the field, and

Fig. 1. Parramore Island is located along the southern Delmarva Peninsula.

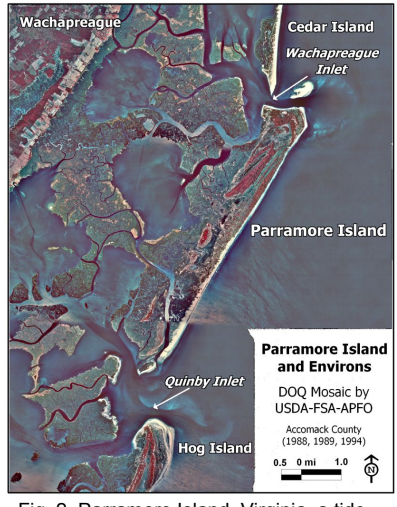

Fig. 2. Parramore Island, Virginia, a tide-dominated barrier island (image provided by the USDA Aerial Photography Field Office).

differential correction techniques. However, Pajak and Leatherman (2002) concluded that identifying a shoreline with GPS was more accurate than using aerial photography to delineate specific shoreline features. Our study uses seven GPS shoreline position surveys (Table 1) that were collected between 1998 and 2006 by visibly identifying the berm crest or the base of active dune scarps through on-the-ground beach surveys (i.e., walking). The GPS shorelines were differentially corrected through a post-processing procedure that used a Continuously Operating Reference Station (CORS) at the Virginia Institute of Marine Science (VIMS) facility in Wachapreague, Virginia, located about 7 km from Parramore Island. The 1998 and 1999 surveys utilized a CORS located in Dover, Delaware (178 km) because a base station was not installed yet at VIMS during these GPS shoreline surveys.

Shoreline Change Studies

The approach that we used to study coastal change requires comparing the areal position of shoreline positions through time. The proxy typically used to measure changes in shoreline position is the HWL. The GPS shoreline surveys map the position of the berm crest to delineate the HWL position. Transects are plotted perpendicular to the shoreline at 50-m intervals to measure and calculate the magnitude and rates of change. We used an ArcGIS software extension, the Digital Shoreline Analysis System (DSAS), to obtain both end point rates (EPR) and linear regression rates (LRR) at each transect (Thieler et al., 2005). The magnitude and rates of shoreline position change are evaluated to assess long- and short-term responses to natural coastal processes for the periods from 1852 to 2006 and from 1998 to 2006. Negative and positive signs indicate retreat and advance, respectively.

Table 1: Summary of Shoreline Data Sets for Study Area

NOS T-Sheets:	Shoreline Name	Date	Scale	Accuracy	RMS
	T-00512 (Va10a02)	1/1/1852	1:10000	8.9 m	x

* Accuracies based on Anders and Byrnes (1991), Byrnes et al. (1991), Crowell et al. (1991) and Byrnes et al. (1995).

** RMS = cumulative maximum root-mean-square potential error for the long-term shoreline change data analysis.

We segmented Parramore Island into five separate shoreline change cells based on differences among geomorphic characteristics and shoreline orientation: 1) the bayside, inlet-influenced shoreline; 2) the inlet throat shoreline; 3) the seaward, inlet-influenced shoreline; 4) the north-central, open-ocean shoreline; and 5) the southern, washover-dominated shoreline (Figure 3). An overlay of all shorelines revealed several areas of intersection that correlated to inherent morphodynamics. A linear mean of shoreline cells was then calculated to determine the orientations of the individual baselines used in the analysis. In places, the excessively dynamic and changing shoreline orientations caused us to create several sub-cells and associated baselines within larger cells: (1) the seaward, inlet-influenced shoreline (Cell 3) and (2) the southern, washover-dominated shoreline (Cell 5) (Figure 3).

RESULTS

Cell 1: Bayside, Inlet-Influenced Shoreline

Table 2 is a quantitative summary of the long- and short-term rates and magnitude of change for the bayside, inlet-influenced shoreline (Cell 1). The results demonstrate Cell 1 has retreated at a consistent pace over the long term with LRRs ranging from -0.6 m/yr between 1852 and 1942 to -0.7 m/yr between 1852 and 2006. In addition, the shoreline within this cell experienced only -129.9 m of total retreat for the entire period of record. Short-term results in Table 2 show a slightly higher retreat rate when compared to long-term trends. The shoreline retreated -1.5 m/yr for the period 05/1999 to 04/2006. The results also show that the Cell 1 shoreline has retreated at a slower rate when compared to the other shoreline cells (i.e., Tables 3, 4, 5, and 6).

Cell 2: Inlet Throat Shoreline

Cell 2, the inlet-throat shoreline, displays little variation in average change rates over

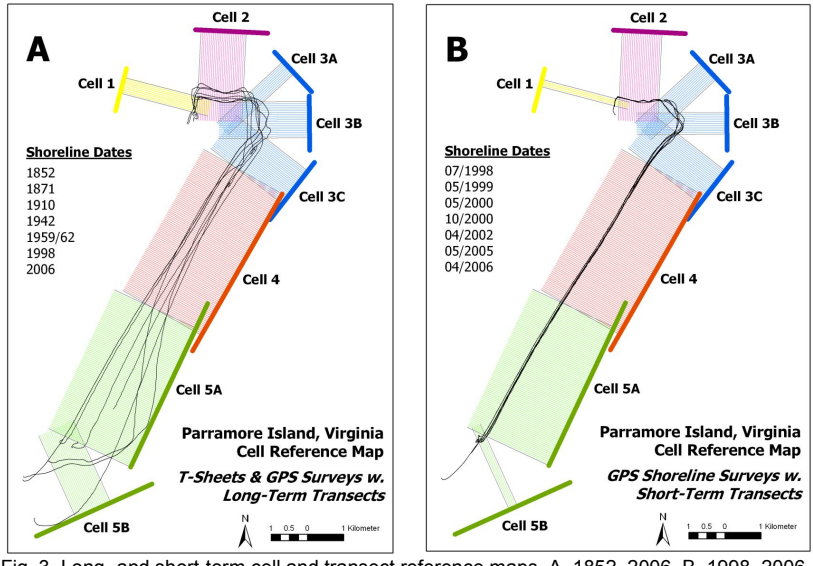

Fig. 3. Long- and short-term cell and transect reference maps. A. 1852–2006. B. 1998–2006. (*Baseline position, length, and orientation are identical for the two periods).

the long term but ranges from advance to retreat in the short term. The long-term LRR from 1852 to 1910 shows minor retreat at -0.3 m/yr, whereas rates for the periods 1852–1962, 1852–1998, and 1852–2006 are similar at -2.1 m/yr. In addition, the LRRs are supported by high R-squared measurements that demonstrate the strength of the linear relationship between shoreline position and time and explain the total variation in the data. The increase in the retreat rate may have occurred during the 1910–1942 timeframe as evidenced by the highest recorded EPR measurement of -4.5 m/yr from 1910 to 1942. The short-term LRR for Cell 2 is -3.5 m/yr (07/1998–04/2006) with an R-squared value of 0.65. Figure 4 clearly demonstrates the minimal spatial variability among rates within the Cell 2 shoreline over the long term as indicated by the LRRs. Essentially, the shoreline in this cell has migrated linearly through time and consistently in space. However, the graph also reflects short-term retreat along the eastern segment of the Cell 2 shoreline.

Cell 3: Seaward, Inlet-Influenced Shoreline

Table 4 shows that considerable temporal and spatial variations existed in shoreline trends for the seaward, inlet-influenced shoreline within Cell 3. Cell 3 is strongly influenced by tidal inlet processes (i.e., ebb-tidal delta of Wachapreague Inlet). The dynamics of the ebb-tidal delta produce substantial swings in shoreline position because of wave refraction, a local reversal in longshore sediment transport, and seasonal onshore/offshore sediment transport. The long-term LRR ranges from 3.7 m/yr between 1852 and 1910 to 0.8 m/yr between 1852 and 2006. However, the R-squared values decrease progressively from 0.70 to 0.36 for the same timeframes and

** EPR = End Point Rate (m/yr), LRR = Linear Regression Rate (m/yr), R2 = R-Squared of LRR, MAG = Magnitude of Change (m), and SLG = Shoreline Length (m).

x = shoreline survey for cell does not exist or at least three shorelines required to generate a LRR.

this reduces the confidence in using the measurement for prediction. Results from the short-term analysis show that Cell 3 is undergoing rapid retreat, but the degree of retreat is moderated through time with the inclusion of additional shorelines. Specifically, the LRR decreases progressively from -43.1 m/yr between 07/1998 and 05/2000 to -7.1 m/yr between 07/1998 and 04/2006. However, the modest R-squared numbers for both the long- and short-term rates show that Cell 3 undergoes variation in shoreline movement that the linear regression cannot explain. This phenomenon could result from nonlinear shoreline migration over time. Figure 5 demonstrates the

** EPR = End Point Rate (m/yr), LRR = Linear Regression Rate (m/yr), R2 = R-Squared of LRR, MAG = Magnitude of Change (m), and SLG = Shoreline Length (m).

spatial consistency of the long-term rates, whereas the short-term data reveal the spatial and temporal variability of shoreline change associated with a tidal inlet.

Cell 4: North-Central, Open-Ocean, Outer Shoreline

Table 5 summarizes the changes of the north-central, open-ocean, outer shoreline that exhibited the highest rates of shoreline advance and near-stability over the long term. However, the interior of the island within Cell 4 is currently experiencing massive tree die-offs along relict dune ridges and numerous large loblolly pines have fallen onto the foreshore. This field evidence validates both long- and short-term results

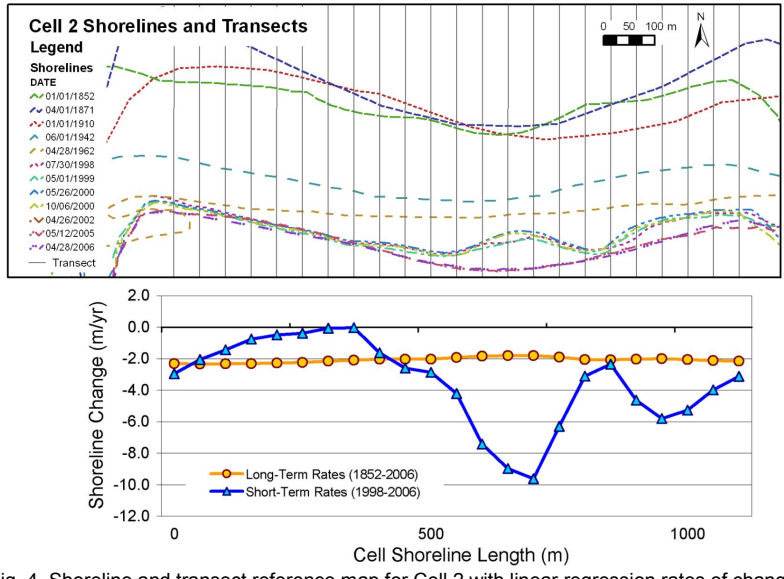

Fig. 4. Shoreline and transect reference map for Cell 2 with linear regression rates of change plotted below.

which demonstrate a switch from advance to retreat over the long term from 5.8 m/yr (1852–1910) to -1.1 m/yr (1852–2006) and an increasing retreat rate in the short term (-4.9 m/yr between 07/1998 and 05/2000 to -7.4 m/yr between 07/1998 and 04/2006). The ever-larger LRRs and associated R-squared values demonstrate the strength of the linear relationship between shoreline position and time and total variation in the data for the different periods of record—specifically, -2.9 m/yr and 0.57, respectively, for the period 1871–2006 to -4.9 m/yr and 0.83 for the period 1910–2006 to -6.7 and 1.00 for both the 1942–2006 and 1962–2006 timeframes. The short-term results also show an increase in the retreat rate. The LRRs for the short-term data illustrate accelerating retreat rates with high R-squared values extending from -7.6 m/yr and 0.82, respectively, for the period 05/1999–04/2006 to -12.9 m/yr and 0.95 for the period 04/2002–04/2006. Figure 6 portrays the smooth retreat rates over the long term and an overall increase with variability in retreat over the short term. Figure 6 also exhibits the increasing retreat rate along the southern segment of Cell 4.

Cell 5: Southern, Washover-Dominated, Outer Shoreline

Table 6 represents the change rates for the southern, washover-dominated, outer shoreline that is characterized by large magnitudes of change and high retreat rates because of extensive overwash processes. In fact, the magnitude of change includes more than a kilometer of landward movement (-1059.0 m between 1852 and 2006). The LRRs for Cell 5 are the highest retreat rates for any cell and the associated R-squared values are also high. Specifically, the long-term values range from -8.4 m/yr and 0.81, respectively, between 1852 and 2006 to -10.6 m/yr and 1.00 between 1962 and 2006. The short-term values range from -10.3 m/yr and 0.91, respectively,

for the period 07/1998–04/2006 and -13.8 m/yr and 0.94 for the period 04/2002–04/2006. Figure 7 demonstrates the change rate is not spatially uniform along Cell 5. Specifically, the shoreline change rates increase three-fold from north to south over the long term. The short-term rate also increases to the south, but this trend is less pronounced when compared to the long-term values.

DISCUSSION AND CONCLUSIONS

The bayside shoreline (Cell 1) retreated at the slowest rate of all shoreline segments because of its protection from open-ocean processes. However, the bayside shoreline

experienced a two-fold increase in its retreat rate from -0.7 m/yr (1852–2006) to -1.5 m/yr (05/1999–04/2006). The inlet-influenced shoreline (Cell 2) migrated more slowly than the open-ocean shoreline segments. Wachapreague Inlet migrated south at -2.1 m/yr (1852–2006) but increased its southern migration rate to -3.5 m/yr from 07/1998 to 04/2006. The seaward, inlet-influenced shoreline (Cell 3) is the only shoreline to show long-term advance at 0.8 m/yr (1852–2006), but the short-term rates reveal a high retreat rate at -7.1 m/yr (07/1998–04/2006). The long- and short-term trends of advance nearest the inlet demonstrate the role of swash bar attachment on mixed-energy barrier islands (Figure 5). However, the reversal to high retreat rates

beginning approximately 700 m south of the inlet (-22.0 m; -8.6 m on average) may indicate the control of shorter-term inlet dynamics, such as ebb-tidal delta breaching, outer channel shifting or sediment supply changes on the adjacent shorelines. The north-central, open ocean shoreline (Cell 4) exhibited moderate advance rates during a portion of its past (3.5 m/yr from 1852 to 1942 and 1.0 m/yr from 1871 to 1942), but the shoreline segment still demonstrated a relatively small long-term retreat rate at -1.1 m/yr (1852–2006). However, this reach experienced a higher retreat rate over the short term at -7.4 m/yr (07/1998–04/2006). This short- term result may help explain the extensive tree die-offs along interior relict dune ridges and the large

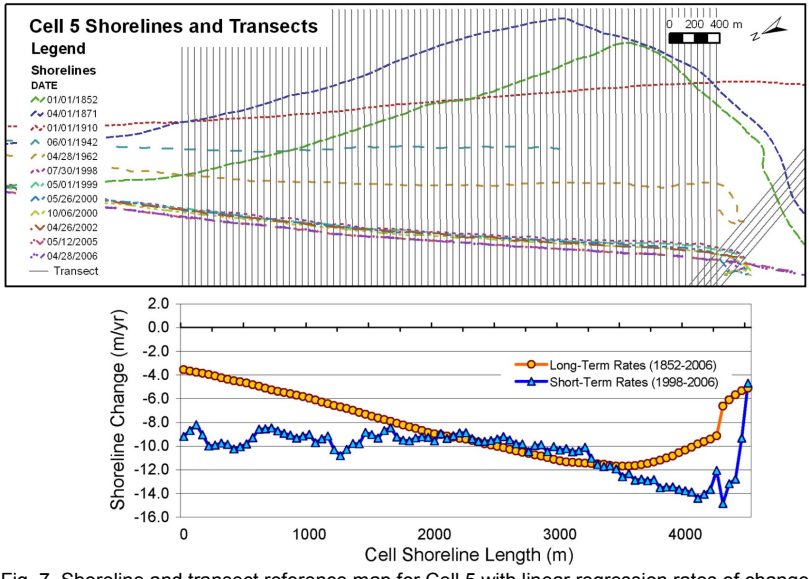

Fig. 7. Shoreline and transect reference map for Cell 5 with linear regression rates of change plotted below. (**90° transects are correlated to the graph, whereas angled transects require interpretation.)

number of fallen trees across the foreshore. Moreover, the parabolic shape of the spatial distribution of the retreat rates (Figure 6) may reveal the location of an inlet-influenced node and the southern-most extent of inlet-influenced processes. The southern, washover-dominated reach (Cell 5) experienced the highest retreat rates among all the shoreline segments with more than 1 km in net shoreline movement. The retreat rate along this reach increased from -8.4 m/yr (1852–2006) in the long term to -10.3 m/yr (07/1998–04/2006) over the short term.

Along the entire outer shoreline (Cells 3, 4, and 5), results indicate that shoreline behavior of Parramore Island has evolved from clockwise rotational instability over the long term as described by Leatherman et al. (1982) to continuous rapid retreat over the short term. Specifically, Parramore's outer shoreline (Cells 3, 4, & 5) experienced a retreat rate of -3.6 m/yr over the long term (1852-2006) and -8.8 m/yr over the short term (1998-2006). We conclude that Parramore Island has undergone a fundamental adjustment in its pattern of shoreline movement. Additional analyses are needed to determine why these shoreline changes are occurring so rapidly and to determine if the change patterns along Parramore Island exist along other barrier islands of the Virginia Coast Reserve and elsewhere.

ACKNOWLEDGEMENTS

Abstract: Weekly beach profiles, shoreline surveys, and nearshore wave measurements were collected before, during, and immediately after construction of the 1100-m Upham Beach nourishment project on the low-energy, west coast of Florida. Substantial planform diffusion occurred prior to construction completion via formation of a spit extending from the widest portion of the fill. Longshore spreading occurred abruptly, as opposed to gradual adjustment predicted by long-term models. Profile equilibration also occurred rapidly due to the passage of three hurricanes. Nine days after nourishment, Hurricane Frances generated high wave conditions (H_{sig} = 1.7 m) for this region, reducing the steep post-nourishment beach slope from 0.078 to 0.036, nearly the equilibrium slope (0.034). Hurricanes Ivan and Jeanne, which were nearly as energetic, resulted in much less slope change. This study indicated that profile equilibration was an event-driven process, contradicting the concept of long-term equilibration.

INTRODUCTION

This study examines two types of coastal change: gradual and episodic. Gradual change involves processes occurring over time causing a response. Cascading time scales, for example from the century to the daily scale, imply gradual change on various spatial scales. Another type of "temporal scale" that does not fit into the cascade is an event. A similar morphologic response may occur due to gradual change over time or it might occur relatively instantaneously as the result of an event. The magnitude of these event-driven changes will govern their spatial extent. It is

crucial to understand both types of change, gradual and episodic, because distinct processes drive changes at these different time scales.

Beach nourishment provides an excellent opportunity for the study of intensified sediment transport gradients and associated morphologic changes in a natural setting. Generally speaking, a beach nourishment project is a large nearshore perturbation that eventually equilibrates with the surrounding system via longshore and cross-shore sediment transport (Dean 1983). These forcing mechanisms influence the evolution of beach nourishment projects through planform adjustment, i.e. longshore spreading, and cross-shore evolution, i.e. profile equilibration (Fig. 1).

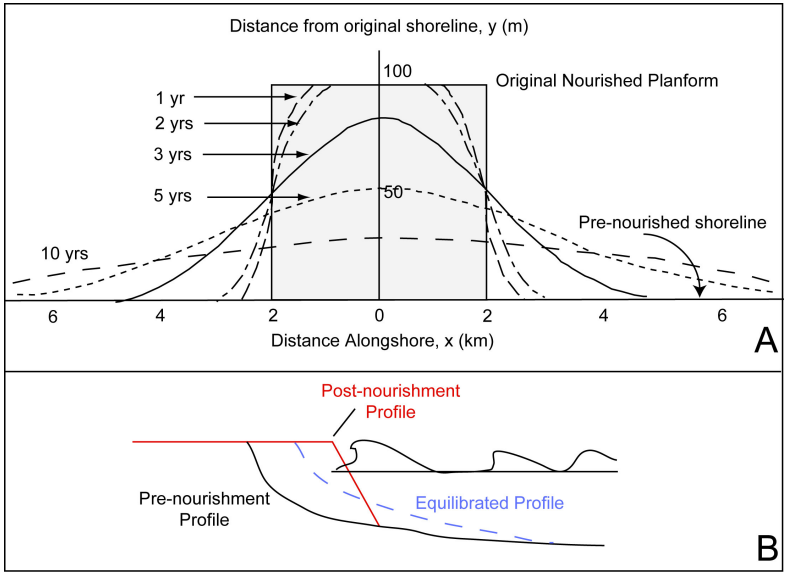

Fig. 1. Beach nourishment project evolution: A) planform adjustment via longshore transport; B) profile equilibration via cross-shore transport (modified from Dean (2002)).

One-line models that predict the long-term planform evolution of nourishment projects (Dean 1983; 1996; Hanson and Kraus 1989) have been developed from the Pelnard-Considére (1956) diffusion equation. Fig. 1A is a schematic of the gradual diffusion over time predicted by the long-term models. During the diffusion process, the post-nourishment shoreline perturbation is smoothed by incoming wave energy that drives longshore transport. The beach fill gradually diffuses from a rectangular planform to a bell-shaped curve that spreads out to a straight shoreline eventually over time (Fig. 1A). This generalization represents long-term and large-scale diffusion; therefore, immediate post-nourishment evolution at the end transitions may not be adequately described. Quantifying short-term, local project adjustment, such

as transport gradients at end transitions, is essential in improving the present state-of-the-art predictive capabilities.

Profile equilibration refers to the reduction of a steep nourished profile to a gentler characteristic, or equilibrium, profile (Fig. 1B). The equilibrium profile form that is frequently estimated with the simple model of Brunn (1954) and Dean (1991)

$$h = Ax^{2/3} \tag{1}$$

is dependent on sediment grain size. In Eq. (1), h is the water depth relative to mean sea level, x is the horizontal distance from the shoreline, and A is a scale parameter correlated with grain size (D). The A value can be determined graphically from Moore (1982), or according to Dean (1987).

Nourished beaches are typically constructed with sediment that differs from the grain size of the natural beach. Nourished beaches are also constructed on steeper slopes than natural profiles. During profile equilibration, most of the fill volume remains within the project area landward of the closure depth, and is redistributed across the profile. The dry beach width is usually reduced during this process (Fig. 1B). Profile equilibration is thought to continue for several years after nourishment (Browder and Dean 2000); however, design guidance for profile equilibration time is limited (Dean and Campbell 1999). Presently, no cross-shore sediment transport models accurately predict time scales of profile equilibration (Dean 2002).

This study analyzes detailed monitoring data collected before, during, and immediately after beach nourishment. The objective is to quantify and predict the immediate profile and planform response of nourishment. Specifically, the time scales and energy levels associated with initial project adjustment are examined.

Study Area

The project area, Upham Beach, is located on the west coast of Florida in southern Pinellas County (Fig. 3). This is a low-energy coastal system with annual average breaking wave heights of 0.3 m (Tanner 1960) and a mean tidal range of about 0.8 m (NOAA 2004). During the 2004 hurricane season, four strong hurricanes made landfall in Florida (Fig. 3). All four hurricanes affected the west-central Florida coast.

Upham Beach is located at the north end of the barrier island of Long Key, and is bordered on the north by Blind Pass. In this region, net annual littoral drift is from north to south (Davis 1994). Upham Beach is sediment starved due to the combined effect of sediment trapping by the Blind Pass jetties, a minimal ebb shoal, and periodic dredging of the inlet. Thus, sediment bypassing around Blind Pass to Upham Beach has been largely eliminated (Davis 1989; CPE 1992). The only sediment supplied to Upham Beach is through beach nourishment.

Prior to the 2004 project, Upham Beach had been nourished six times in 1975, 1980, 1986, 1991, 1996, and 2000. Based on results from the 1996 project, half of the plan area erodes in approximately one year (Elko et al. 2005). Longshore currents transport the nourished material to the downdrift beaches; thus, Upham Beach serves as a "feeder beach" for the rest of Long Key (USACE 1999). A feeder beach is a nourishment project where material is introduced at the updrift end of the area intended to receive fill.

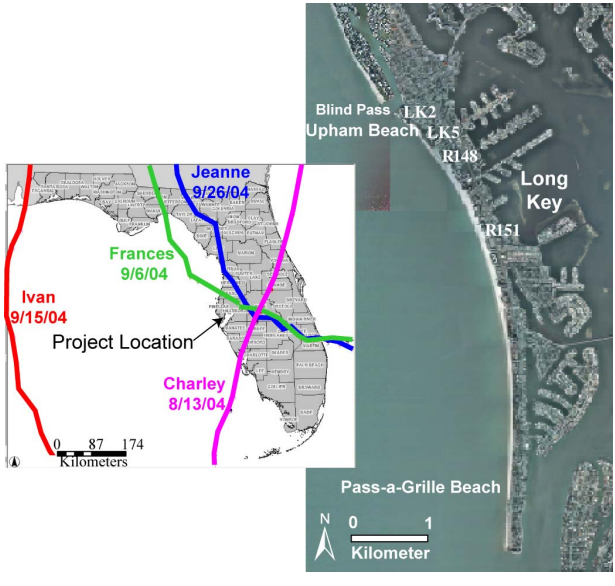

Fig. 2. Study area and the tracks of the four hurricanes that impacted Florida in 2004.

2004 Nourishment Project

The 2004 Upham Beach nourishment project had a total project length of 1100 m, a total volume of 294,000 m^3, and a design berm elevation (B) of 1.8 m. The 2004 project was designed with three distinct segments (Fig. 3): 1) the wide north segment, from Blind Pass to LK3A, 2) the central segment, from LK3A to LK5A, and 3) the south segment, from LK5A to R148, which was nourished for the first time in 2004. The nourishment volume density ranged from 95 m^3/m in the south segment to 360 m^3/m in the north segment. The fill was designed with two transitions: 1) the large transition in the central segment of fill that reduced the berm width from 140 m to 40 m over 260 m, and 2) the slight transition at the south end which tied in with the natural berm width of about 40 m.

Fill placement began on Upham Beach on July 28, 2004 (Table 1). Fill was placed from south to north (Fig. 3) in the opposite direction of net littoral drift. Due to the

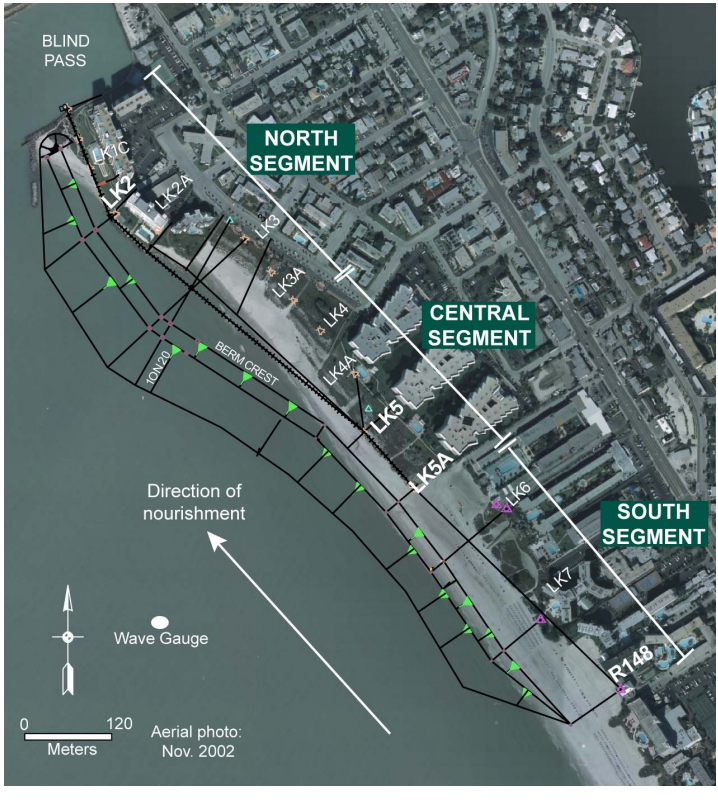

Fig. 3. The planform design template of the 2004 Upham Beach nourishment project.

passage of four hurricanes in August and September 2004, during and shortly after the completion of the project, a large amount of sediment eroded rapidly from the design template. A repair nourishment, authorized for Upham Beach following the storms (Elko 2005), was completed on October 28, 2004. This renourishment repaired a section from Blind Pass to LK4 (Fig. 3) to the original design template.

Table 1. Construction Schedule for the 2004 Upham Beach Nourishment Project.

Segment	Completion date (2004)	Completion to the passage of Hurricane Frances on September 5, 2004 (days)
South	July 22	45
Central	July 28	39
North	August 27	9
Repair	October 28	n/a

METHODOLOGY

A rigorous field-monitoring program was initiated prior to construction of the 2004 nourishment project. Beach profiles, offshore bathymetry, and offshore waves were measured from June to October 2004. Wading profiles, which are typically surveyed to approximately -1.5 m, were extended to capture nearshore changes and measure profile equilibration. The beach profile surveys extended offshore nearly to the depth of closure, which is approximately -3 m in southern Pinellas County (Wang and Davis 1999). These wading beach-profile surveys followed level-and-transit procedures using an electronic total survey station.

Thirteen surveys of the 21 profile lines were conducted during this field effort. Weekly beach profiles were surveyed before, during, and immediately after nourishment until October 1, 2004. The pre-construction beach survey was conducted on June 6, 2004, and the post-construction surveys were conducted at different times along different segments (Table 1). A PUV directional wave gauge was deployed about 600 m offshore of the center of the Upham Beach nourishment project in approximately 4 m of water (Fig. 3).

RESULTS

On August 13, Hurricane Charley made landfall approximately 110 km south of the project area (Fig. 2). Charley generated maximum wave periods (T_p) of about 8.3 s and significant wave heights (H_{sig}) of up to 0.92 m at the project area (Fig. 4). Following the passage of Charley, calm conditions that are commonly observed in the Gulf of Mexico prevailed. Hurricanes Frances, Ivan, and Jeanne made landfall on September 5, 15, and 26, respectively. Hurricane Frances passed by the project area nine days after nourishment was complete. Hurricanes Frances and Jeanne passed by the project area within 50 and 80 km, respectively. These storms generated steep storm waves with maximum wave heights of H_{sig} = 1.7 m (Fig. 4), roughly six times the annual average wave height along this low-energy coast. Waves generated by Hurricane Ivan (max: H_{sig}= 1.0 m, T_p = 15.9 s) approached the project area as a well-organized swell.

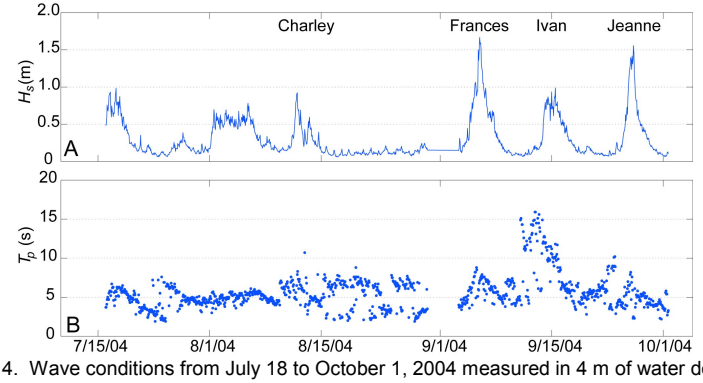

Fig. 4. Wave conditions from July 18 to October 1, 2004 measured in 4 m of water depth.

The mean sediment grain size of the fill material (D_F) was 0.51 mm. The fill material was similar but slightly coarser than the native sand (D_N = 0.45 mm) with the exception of the section from LK3 to LK5 (Fig. 3). The nourishment sediment grain sizes ranged from 0.3 to 0.9 mm. The use of relatively coarser sediments between LK3 and LK5 (mean D_F = 0.6 mm) was expected to improve nourishment performance in this rapidly eroding area.

PLANFORM ADJUSTMENT

During the 40 days between completion of nourishment in the central and south segments and the passage of Hurricane Frances, the beach in these segments prograded. Sediment that eroded from the north segment was deposited in the nearshore and intertidal zones (Fig. 5B and C). In the downdrift region, offshore sand bars accumulated sediment and migrated onshore (Fig. 5D).

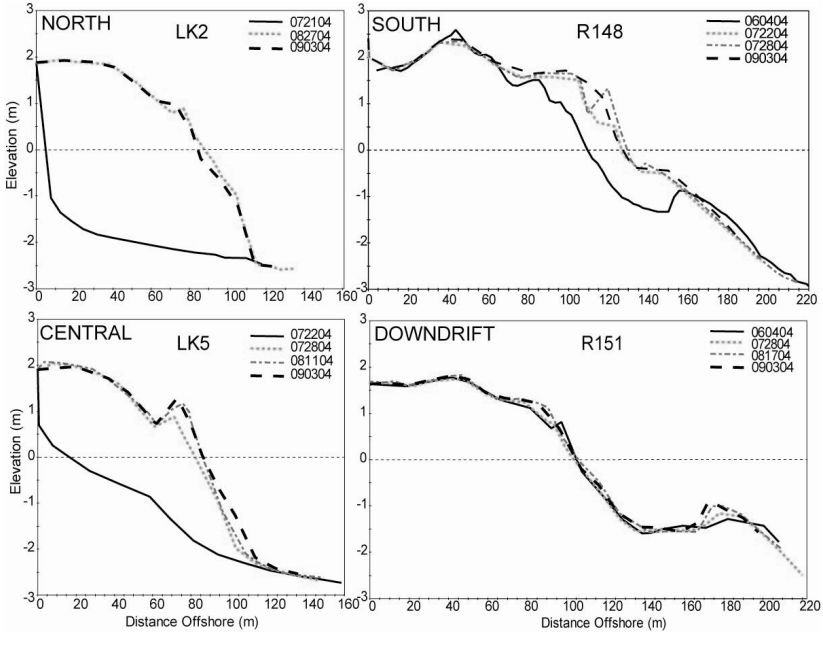

Fig. 5. Profile response after nourishment from the four project segments. See Fig. 2 for profile locations.

Deposition in the central segment was first measured on August 11, about two weeks after nourishment was complete in this segment. Weekly survey data indicated the formation of a large inter- to supra-tidal sediment body in this segment, resembling a spit spreading from the transition of the wide north segment of the planform. Systematic documentation of the formation of this "diffusion spit" is available in

Elko and Wang (2007). Coarse nourished grain size and local wave, tide, and weather conditions combined to promote spit formation. Post-nourishment spit formation is a common occurrence on the west coast of Florida. Diffusion is initiated immediately following nourishment, abruptly reducing the large shoreline orientation change at the end transitions. This immediate planform evolution does not adhere to the generalized model of Fig. 1A.

PROFILE EQUILIBRATION

Profile shape and slope were relatively constant until the passage of Hurricane Frances on September 5, 2004 resulted in remarkable beach profile changes.

Profile-shape adjustment

Beach profile changes resulting from the passage of Hurricane Frances differed in the three nourished segments. The same four profiles from Fig. 5 (except LK5A replaces LK5) are displayed in Fig. 6 to illustrate these changes.

North Segment In the north segment, beach profiles maintained a steep post-construction slope for nine days until the passage of Hurricane Frances on September 5 (Fig. 5A). The newly constructed, wide, north segment of Upham Beach lost over 25 m of shoreline during the week of Frances' passage (Fig. 6A). Net cross-shore transport, e.g., offshore transport and formation of sand bars, as is typical during storms, did not occur. The profile-shape change was largely caused by net longshore transport, resulting in substantial volume loss (60 m^3/m) over the entire profile. This segment typically exhibits a monotonic beach profile, unlike the other segments that contain a nearshore bar. The extreme seaward-advanced position of this segment and the large gradients in longshore transport appear to preclude bar formation.

Central/south Segments Nourishment was completed earlier in the central and south segments than in the north segment (Table 1). Here, the steep post-construction slope persisted for up to 40 days after nourishment (Fig. 5B and C). During this time, the passage of Hurricane Charley generated a brief 0.9 m swell (Fig. 4), but did not induce sufficient cross-shore sediment transport to reduce the beach slope. Due to the passage of Frances, net offshore transport resulted in deposition on the nearshore sand bars (Fig. 6B and C). As compared to the north segment, little berm erosion took place in these segments. In fact, along the central segment, up to 8 m of berm progradation was measured (Fig. 6B), apparently benefiting from the longshore sand supply from the north segment and dispersion of the diffusion spit, which was destroyed by the passage of Frances.

Overall, the morphologic changes within the fill area caused by Frances resulted in reduction of the steep post-nourishment slope. Downdrift of the fill, the sand bar migrated offshore in response to the passage of Hurricane Frances. Otherwise, the profile, which was likely already in an equilibrium form, changed little (Fig. 6D).

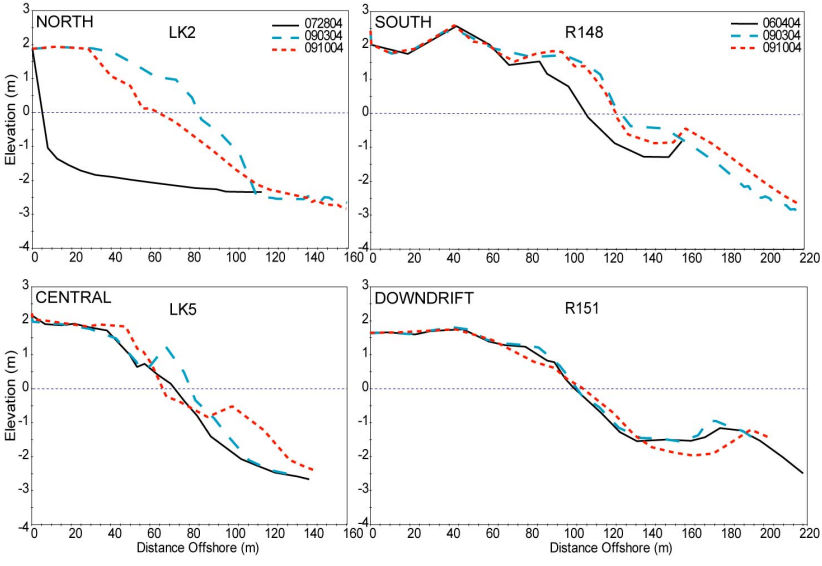

Fig. 6. Beach-profile changes induced by Hurricane Frances for the four segments of the project. See Fig. 2 for profile locations.

Beach slope

To further quantify this apparent rapid profile equilibration, beach slope (γ) was calculated for all of the 106 measured and equilibrium profiles. Beach slope was determined via linear regression from mean high water (MHW = 0.12 m) to the toe of fill (-2.5 m). The limit of this calculation extends seaward of the bar. Although not capable of representing the details of slope variations along the profile, the linear-regression slope represents the beach slope trend from the shoreline to the toe of fill.

The "measured equilibrium" beach slope was estimated from the slope of the pre-nourishment beach profiles, assuming the beach was in equilibrium before nourishment. Pre-nourishment profiles are typically used to represent the natural beach slope, unless scour in front of a seawall has occurred. The "calculated equilibrium" beach slope was estimated based on profiles calculated with Eq. (1).

Overall, the mean slope of the calculated equilibrium profiles (γ_{eq}) was 0.034 and the mean slope (γ_m) of the pre-nourishment profiles (measured equilibrium) was 0.025 (Table 2). The slightly gentler measured slope (γ_m) is influenced by the presence of a nearshore sand bar as discussed in the following sections.

When construction of the project was complete on August 27, the overall mean slope (γ_m) was 0.078 (Table 2), indicating a steep post-nourishment slope, as expected.

Nine days later, due to the passage of Hurricanes Frances, this γ_m was dramatically reduced to 0.036, or less than half of the post-construction slope. The γ_m decreased further due to the passage of Hurricanes Ivan and Jeanne, from 0.036 to 0.028; however, the slope reduction was much less than that induced by Frances. In fact, Hurricane Jeanne generated similar wave conditions to those generated by Frances (Fig. 4). The magnitude of beach change caused by these two events was quite different, with much more change induced by Frances.

Table 2. Calculated Beach Slope (γ) during the Study Period in 2004.

	Calc. Equilib. (γ_{eq})	Pre-nourish (Jun 4)	Post-constr. (Jul 22-Aug 27)	Post-Frances (Sep 10)	Post-Jeanne (Oct 1)	Repair post-constr. (Oct 29)	Winter (Dec 13)
North	0.033	0.026*	0.102	0.046	0.035	0.064	0.034
Central	0.032	0.023	0.075	0.035	0.027	0.055	0.031
South	0.037	0.026	0.041	0.023	0.020		
Mean (γ_m)	**0.034**	**0.025**	**0.078**	**0.036**	**0.028**	**0.063**	**0.033**

* Pre-nourishment slope of LK2 and LK2A was omitted from this calculation due to scour in front of the seawall.

North Segment When fill was placed in the north segment, a 1:20 (0.05) slope was constructed to about -1 m, within the range of the construction equipment. Pre-nourishment profiles were exceptionally steep due to scour in front of the seawall at LK2 and LK2A. Below -1 m (Fig. 5A), the fill settled at a slope of about 1:7 (0.14) resulting in an exceptionally steep post-construction γ_m of 0.102 for the north segment (Table 2). The impact of Hurricane Frances resulted in a sharp drop of γ_m from 0.102 to 0.046 (Fig. 7A). The post-Jeanne slope of 0.035 was similar to the equilibrium slope of 0.033.

Central/south Segments In the central segment of fill, the γ_m was relatively constant at 0.075 for about 40 days after nourishment was complete on July 28 until the passage of Frances on September 5, 2004 (Fig. 7B). The formation of the diffusion spit (Elko and Wang, 2007) and the resulting berm accretion are responsible for the slight increase of γ_m during this period of relatively calm weather. Similar to the north segment, a sharp decrease of γ_m, from 0.075 to 0.035, was measured following the passage of Hurricane Frances.

Fill was mainly placed between the berm and bar in the south segment (Fig. 5C). Consequently, the post-nourishment profile was not as steep (Fig. 7C) as in the north and central segments. The post-nourishment γ_m was constant at 0.041 for about 45 days, followed by a drop to 0.023 induced by the passage of Hurricane Frances. The slope decrease was not as dramatic as in the other segments due to the gentler post-nourishment (or pre-storm) γ_m. In both segments, the storms served to reduce γ_m to approximately the pre-nourishment slope.

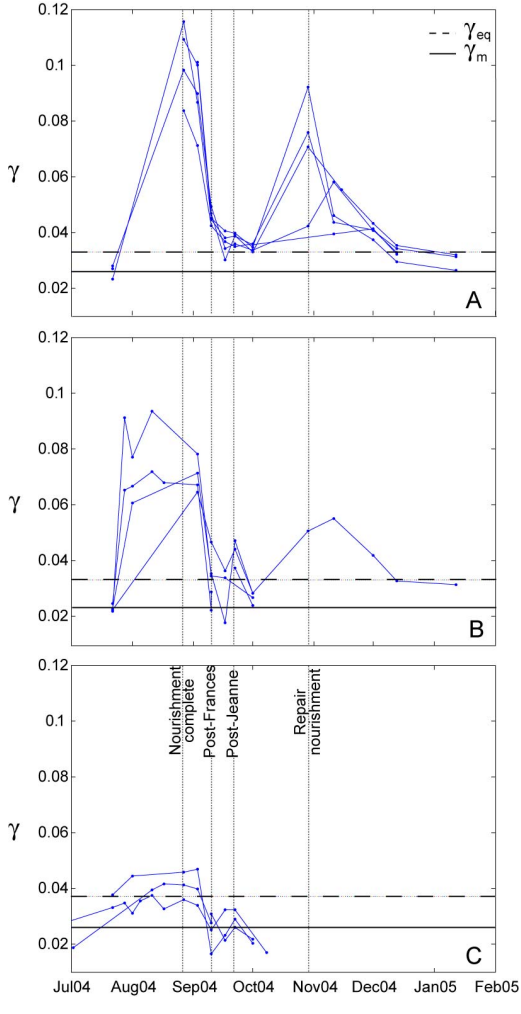

Fig. 7. Time series of measured beach slopes for 12 surveyed profiles. The calculated and measured equilibrium slopes are shown as dashed and solid horizontal lines, respectively.

Rapid Equilibration

The profile shape change shown in Fig. 6 indicates that profile equilibration was controlled by high-energy wave events. The steep nourished profile was flattened by the single event of the passage of Hurricane Frances, reducing the overall beach slope

to nearly the pre-nourishment slope. Based on this morphologic response and the calculated beach slopes (Table 2), it is reasonable to conclude that profile equilibration was largely complete by October 1, 2004, 35 days after nourishment was complete.

Rapid equilibration due to high-energy events is also supported by cross-shore profile adjustment during the winter season following the repair nourishment. When the repair nourishment was complete on October 28, 2004, the measured γ_m for the renourished profiles increased to 0.064 in the northern segment and 0.055 in the central segment (Table 2, Fig. 7). Within six weeks, γ_m decreased to 0.034 in the northern segment and 0.031 in the central segment, once again approaching the equilibrium slope. Several energetic cold fronts, capable of generating waves exceeding 1.2 m, impacted the study area during this time. Rapid slope reduction following the repair nourishment was apparently a result of these cold front events. This suggests that the event-driven equilibration that occurred following the initial nourishment was not simply an anomalous result influenced by the passage of three strong hurricanes. Event-driven profile equilibration also occurred during the winter.

This study documented rapid beach profile equilibration as a result of high-energy events following nourishment on two separate occasions. This result differs from the general understanding, which suggests that profile equilibration continues for several years after nourishment (Dean and Campbell 1999; Browder and Dean 2000; Dean 2002). The present study suggests that profile equilibration can be an event-driven process rather than a process that occurs gradually as the project evolves. The rate of equilibration may be a function of energy rather than time.

In addition, storm conditions may be required for profile equilibration to occur on a nourished beach, particularly in the offshore portion of the profile. Transport to the depth of closure is initiated during energetic conditions (e.g., Hallermeier 1981). For sediment redistribution from a steep post-construction slope to a gentler slope that is relatively constant from the shoreline to the depth of closure, high-energy conditions are necessary. In the case of Upham Beach, transport to a depth of 2.5 to 3 m was induced during the passage of Hurricanes Frances and Jeanne during the month following nourishment.

The duration between the completion of nourishment and the first high-energy event to impact the project area is likely an important factor governing the time scale of profile equilibration. The exponential decay model of Fig. 1A may not apply. This suggests that profile equilibration time is unpredictable. Rapid initial profile evolution toward dynamic equilibrium was also measured in both medium- and large-scale laboratory experiments (Wang et al., 2003; Wang and Kraus, 2005). Profile equilibration should be considered complete once the slope is reduced to near the equilibrium slope. Profile equilibration should demonstrate a clear trend of profile-shape changes (e.g., decreasing beach slope) and should not be confused with dynamic variations in profile shape without a distinctive trend.

CONCLUSION

A wide nourished planform, large gradients in longshore transport, and the impact of severe storms following nourishment were all complicating factors in analyzing profile and planform adjustment with the data presented in this study. However, it is clear that planform adjustment began immediately after nourishment and that the relatively high-energy wave events following both the initial and repair nourishments resulted in profile equilibration. Both profile and planform adjustment can occur rapidly given the appropriate site conditions and energy levels. Substantial planform diffusion occurred prior to construction completion via formation of a spit extending from the widest portion of the fill. Longshore spreading was initiated abruptly, as opposed to gradual adjustment predicted by long-term models.

Based on individual profile-shape analysis and calculated beach slopes, the steep post-nourishment slope equilibrated nearly to the equilibrium slope within weeks of construction. This equilibration was largely dominated by one high-energy event, Hurricane Frances. Subsequent storms completed the equilibration process. Profile equilibration may be an event-driven process rather than a process that occurs gradually as the project evolves. The duration between nourishment and the passage of the first high-energy event appears to be an important, yet unpredictable, factor controlling the time scale of profile equilibration.

ACKNOWLEDGEMENTS

We would like to thank the Pinellas County Board of County Commissioners for funding and encouraging this research. We would like to thank our surveyors, Dave Tidwell, Craig Tolliver, and Andy McManus, who performed the weekly field work.

Abstract: This paper summarizes the main findings from the investigations that were conducted, including GIS comparison of historic air photos, an 18-year wave hindcast, longshore sediment transport calculations, and extensive 2DH numerical modeling of hydrodynamics and sediment transport at Grand Marais Harbor. A sediment budget is presented based on geomorphic assessment and numerical modeling results. Future shoreline positions are also predicted.

INTRODUCTION

Grand Marais Harbor is located along the southern shore of Lake Superior, approximately 115 km east of Marquette, MI. The harbor was initially formed by three structures, consisting of two jetties and a pile dike breakwater, all of which were built in the late 1800s (see Figure 1). The jetties fix the opening to the harbor and the pile dike provided sheltered water for vessels in addition to retaining the prevailing west to east longshore sediment transport from the Grand Sable Dunes. The pile dike breakwater was placed approximately 85 degrees clockwise from centerline of the east jetty. It extended from the existing east jetty for approximately 1,740 m. The construction was of timber batter and soldier piles filled with stone. Since 1943, the breakwater has received no maintenance and has deteriorated to the point where little, if any, portion of the structure remains. The last remaining portions of the structure were destroyed in the mid-1970s during the same storm in which the ship known as the Edmund Fitzgerald sank in Lake

Superior. Consequently, Grand Marais Harbor has experienced substantial infilling and the available space with sufficient depth suitable for recreational and commercial vessels has significantly reduced. A breakwater oriented at an angle of 55 degrees to the shore has been proposed to prevent further migration of sediments into the West Bay.

In the present study, several investigations, including GIS comparison of historic air photos, 18-year wave hindcast, longshore sediment transport calculations, and extensive 2DH numerical modeling of hydrodynamics and sediment transport around the harbor were conducted. The analysis was aimed at establishing a sediment budget, evaluation of the morphodynamics at the area since the demise of the pile dike structure, and prediction of future morphology for different scenarios including a "do nothing" approach and structural alternatives.

Fig. 1. Grand Marais Harbor area

SITE DESCRIPTION

A general introduction to the Grand Marais Harbor area is given in Figure 1. Superior Beach is a fillet beach west of the harbor and consists of sand, pebbles and cobbles near the shore with a backbeach area consisting of embryo dunes and more mature dunes further inshore, both with vegetation (beach grass). The west end of this beach is covered by lots of pebbles and cobbles backed by vegetated low dunes. Town Beach is a sandy beach spanning the west end of the bay and backed by vegetation and beach grass. There are no pebbles or cobbles visible on this beach indicating that this is a deposition zone at the west end of the bay where only sand particles can reach.

The north shoreline of the West Bay area features vegetation right up to the water's edge owing to the sheltering from waves. Along the southwest shore of West Bay the shoreline is accreting in both lakeward and westward directions and the mouth of Carpenter Creek is shifting towards the west. Large waves due to NE storms reach this point from time to time and a beach scarp is visible.

Lonesome Beach is located between Lonesome Point bluffs (on the east of East Bay) and the Sucker River mouth. The east end of this beach is mature and features a relatively high beach berm, cobbles, beach grass, shrubs and driftwood. The central part of this beach features lots of pebbles and cobbles with little vegetation. This is currently the most visited nesting area for Piping Plovers in Grand Marais. As the west part of Lonesome Beach grows in the form of a low spit, the distal end of this split forces the migration of the Sucker River mouth toward the west. The west end of Lonesome Beach is sandy and low with no pebbles or cobbles and gets overwashed during storms.

South Beach is located between the Sucker River mouth and the Carpenter Creek area. It is mostly sandy and backed by rather high dunes with beach grass, all indications of a dynamic accretional environment with landward wind-blown transport. The Sucker River is cutting through the east end of this beach as it migrates westward.

GEOMORPHIC ASSESSMENT

Shoreline Comparison

A series of historic aerial photographs from 1939, 1953, 1974, 1983, 1992, 1993 and 1999, a USGS DRG map of 1967 and a satellite image of 2004 were used for GIS analysis and shoreline comparisons (see Figure 2). The timber pile breakwater failed sometime between 1939 and 1953, explaining the erosion of the barrier beach into small remnant islands by 1953. Comparison of the 1939 and 1953 shorelines indicates that the Superior Beach had reached its capacity by 1939, allowing any incoming sediment to bypass the harbor (and fill the channel or reach the downdrift shores). Extension of the west jetty in the 1960's resulted in further trapping of sediment by the new jetty and the subsequent growth of the Superior Beach to its present size. Comparison of the 1953 and 1999 shorelines indicates an infilling rate of 40,000 to 50,000 m^3/year. Comparison of the 1999 and 2004 shorelines indicates little change in the size of this beach and therefore, the Superior Beach has almost reached its capacity again. Sediment currently bypasses the jetties to the downdrift shores. Both the 1999 air photo and the 2004 satellite image show a bypassing path connecting the west jetty tip to the shoreline in the west vicinity of the Lonesome Point.

The monthly mean water level in Lake Superior at the time of the 1939, 1953, 1971, 1974, 1983, 1992 and 1993 photos were at comparable levels but were low (183.2 m) for the 1999 and 2004 photos. Therefore, the 1999 and 2004 shorelines are in slightly lakeward positions relative to other historic shorelines. Sand accumulation near the west

jetty between 1999 and 2004 is partly because of lower water levels in this period and shoreline developments at this area likely have slowed down.

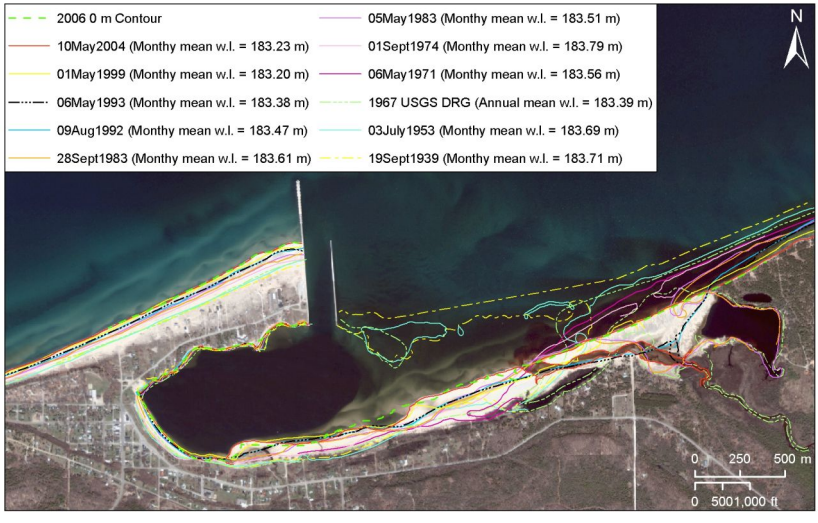

Fig. 2. Grand Marais area shoreline change between 1939 and 2006

On the east side of the harbor, the demise of the pile dike resulted in redistribution of the beach sediment, which it used to hold, towards inside the West Bay. GIS analysis of the visible edge of the underwater sand from the aerial photographs and satellite image shows how this redistribution has occurred. The lines are shown in Figure 3 and represent the changing position of the steep slope defining the boundary between deep (12 to15 m) and shallow (2 to 4 m) water that is no longer safely navigable. Beach sediments have in general moved towards the south to fill the old harbor basin. By 1999 the eastern half of the harbor basin was completely filled in.

With the ongoing infilling of the basin, more and more sediment could reach the south shores of the bay and from there alongshore to the west. Gull Island was also submerged into the basin while moving to the south and its existence closer to the shoreline caused the creation of a salient by 1999. Disappearance of this island and other remnants of the pile breakwater left the inner harbor more exposed to N and NE wave attacks. With burial of the east harbor basin, sediment is now encroaching to the west to fill the remaining part of the basin, the navigation channel of the harbor and southwest shores of the West Bay.

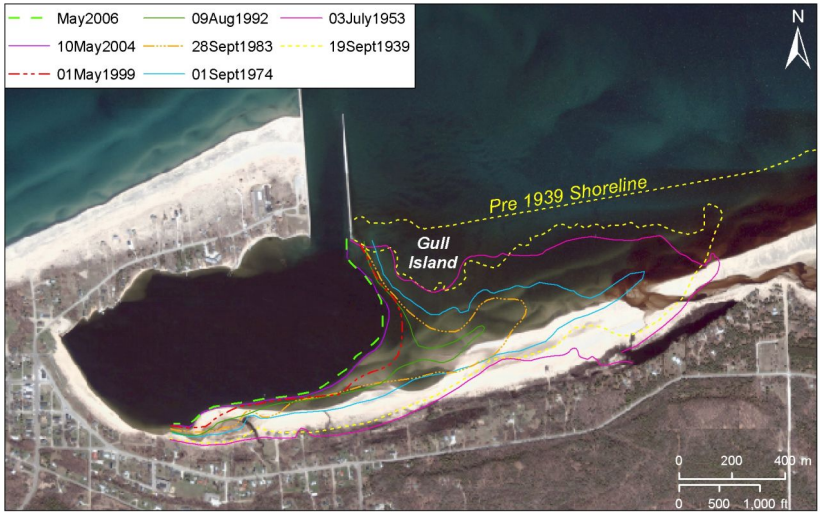

Fig. 3. Harbor basin change between 1939 and 2006

Comparison of the vegetation lines to the east of Sucker River and the East Bay indicates ongoing erosion of the bluffs in this area. The average bluff erosion rate in the area immediately east of Lonesome point was 3.6 m/year between 1939 and 1953, 2.6 m/year between 1953 and 1983 and 3.7 m/year between 1983 and 2004. Assuming that the bluffs are 100% made of sand and gravel, desktop calculations indicate that the bluffs over a 3 to 4 km reach east of Lonesome point could roughly provide up to 110,000 m^3/year of sand and gravel to the littoral system. Waves from north and northeast directions then transport part of this volume towards the west where it is trapped in the Grand Marais Bay area.

Figure 4 shows the geomorphic response of the Lonesome Point - Sucker River mouth zone. The river mouth was located at its most westerly location from 1939 (at that time emptying in the protected East Bay inshore of the timber pile breakwater) through 1953 and later from 1967 to 1971. In 1967 a small spit had extended across the mouth towards the east as a result of local eastward sand transport. Through a combination of the blockage of the mouth, erosion of the narrow barrier between East Bay and the lake, and the high lake levels of 1973, the river mouth switched its position back towards the east, as seen in the 1974 river mouth position. The 1974 condition consisted of a flooded estuary area inshore of an outer barrier beach and encompassing East Bay. Extension of the west jetty in the 1960's prevented the bypassing of sand to downdrift shores. In the meantime, lowering of the water levels resulted in less erosion of the bluffs to the east, such that between 1974 and 1983 the river mouth became wide open and the East Bay was connected to the lake. Since 1983 the inner East Bay area began to fill with sand (likely because of higher lake levels in the mid to late 1980's which caused more bluff

erosion), separating the bay from the lake and a wide river mouth was developed, as seen with the 1992 and 1993 shoreline positions. Since 1993, with the decline in water levels and the resumed sand bypassing, the wide river mouth area filled with sediment and a straight shoreline was created by 1999. Once the shoreline had been rendered relatively straight, the river mouth began to migrate towards the west at a rate of approximately 120 m/year between 1999 and 2004 and 60 m/year between 2004 and 2006. It is expected that the migration rate will slow with time, as the river approaches its full possible extension to the west.

Across the west end of the West Bay sediment has been accreting lakeward to create the Town Beach. Around the southwest corner of West Bay the shoreline has been accreting in both lakeward and westward directions. This process has recently shifted the mouth of Carpenter Creek toward the west. This depositional zone is likely a result of the longshore transport of sand along the south shores of the bay. The irregular outline of this shore is likely a result of temporally and spatially discrete pulses of sand arriving at the shore.

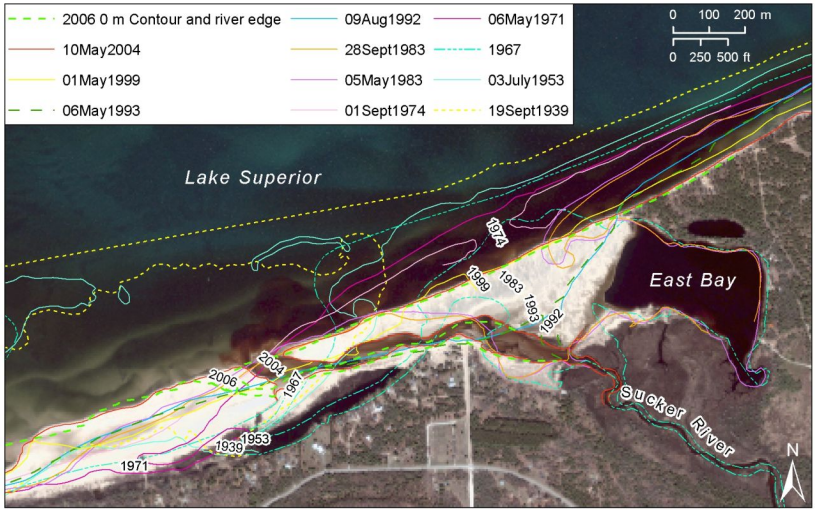

Fig. 4. Shoreline response at Lonesome Beach between 1939 and 2006

Bathymetry Comparison

A comprehensive hydrographic survey of the area was conducted in May 2006. This survey was compared to a number of previous surveys. Figure 5 shows the change in bottom elevation between 1967 and 2006. The 1967 contours were digitized from the 1967 USGS DRG map. It is observed that the old pile dike beach sediment has moved and deposited towards the south and west. Volume calculations within the comparison area (shown by the dashed line) indicate 1,900,000 m^3 of accretion of sediment in the old

harbor basin. This corresponds to an infilling rate of 48,000 m^3/year over the past 39-year period. A dash line dividing the comparison area into two sections on both sides of the proposed 55 degree breakwater is also shown in Figure 5. Accumulation rates to the east and west of this line are 21,000 and 27,000 m^3/year respectively. The bypassing shoal and some accumulation on the east side of the east jetty are also observed

.

Figure 6 shows the surface comparison results between 2003 and 2006 surveys. In this figure the survey data points are also shown as an indication of accuracy. The movement of sand along the bypassing shoal as a series of sand pulses is well captured in this figure. Total accumulation volume in the dash line comparison area is 354,000 m^3 over the 3 years. Accumulation rates to the east and west of the proposed breakwater line are 19,000 and 89,000 m^3/year, respectively. Comparison of the 2006 survey with a limited survey of the inner harbor basin conducted in 2002 by the Corps shows an accumulation rate of 48,000 m^3/year over the past 4 years in the inner harbor basin west of the proposed breakwater line. In either case, it is clear that the sediment infilling volume into the West Bay has increased significantly in recent years. This may be attributed to complete infilling of the eastern half of the harbor basin, disappearance of remnants of Gull/Lost Island, which has made the inner West Bay more exposed to the action of waves (in particular N and NE waves), and resumption of full sand bypassing around the harbor jetties to the downdrift east shores, making more sand available for transport. With the recent rates of accumulation, the whole West Bay will likely be filled in with sediment in less than 100 years and probably as soon as 50 to 60 years from now.

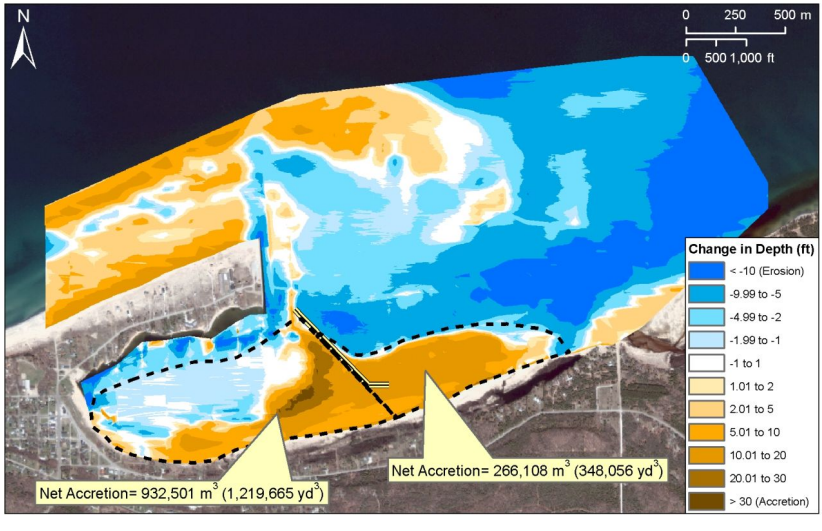

Fig. 5. Bathymetry comparison and volume calculations (1967-2006)

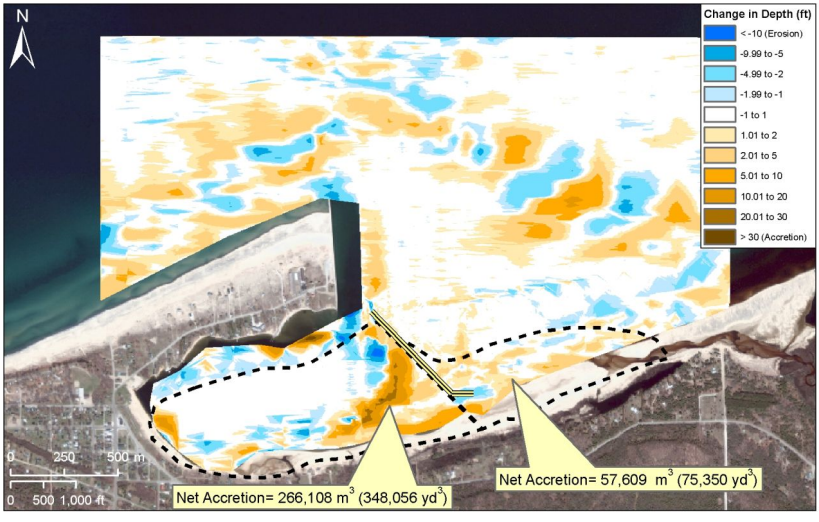

Fig. 6. Bathymetry comparison and volume calculations (2003-2006)

NUMERICAL MODELING

Offshore Waves

An 18-year (1984 to 2002) hindcast offshore wave climate at Grand Marais was generated in the using a 1D parametric model. The offshore wave rose is shown in Figure 7. The wave climate at Grand Marais is multidirectional with waves arriving from east to north and to west. N, NW and W waves, however, are predominant (53% of the time). The lake is calm (no waves) for 31% of the time. Wave heights greater than 3 m occur 2.1% of the time and have periods of 8 to 12 s. They mostly but not always come from the N to W quadrant. Wave height is less than 1 m and 2 m for 72% and 92% of the time (including calm periods), respectively. Ice conditions happen in January to March but are not considered in the present analysis because of uncertainties in climate change in upcoming years.

HYDROSED Modeling

Numerical modeling using *HYDROSED* was undertaken to transform offshore waves and calculate waves and their corresponding nearshore currents and sediment transport that occur in the harbor area. *HYDROSED* is a 2DH hydrodynamic and sediment transport state of the art model for coastal areas. It consists of a spectral wave transformation model (where the wave field is calculated by the spectral energy conservation equation of Karlsson 1969, with the breaking dissipation term of Isobe, 1987), a hydrodynamic model (Nishimura, 1988) to describe wave generated nearshore currents and circulations (driven by radiation stresses predicted with the spectral wave transformation model) and a sediment transport model presented by Dibajnia et al (2001). The sediment transport

model considers the influence of non-linear orbital velocities and undertow and is based on the sheet flow transport formula of Dibajnia and Watanabe (1992), which was extended by Dibajnia (1995) to consider suspended transport over ripples as well as the bedload transport. Dibajnia et al (2001) also conducted a sensitivity test of their model and showed that the model response under various actual nearshore wave environments is satisfactory. For a given wave condition, *HYDROSED* provides a full spatial description of nearshore currents in and around the harbor.

The nearshore wave transformation mesh had 477×675 grids (cross-shore × alongshore) with a constant grid spacing of 40 m in both directions. The depth at the offshore boundary of the calculation domain was approximately 150 m. The calculation domain for the harbor area, which used the 2006 bathymetry at a 0.2 m water level, featured a 662×692 mesh (cross-shore × alongshore) with grid size of 5 m. The depth at the offshore boundary of the inner calculation domain was approximately 16 m.

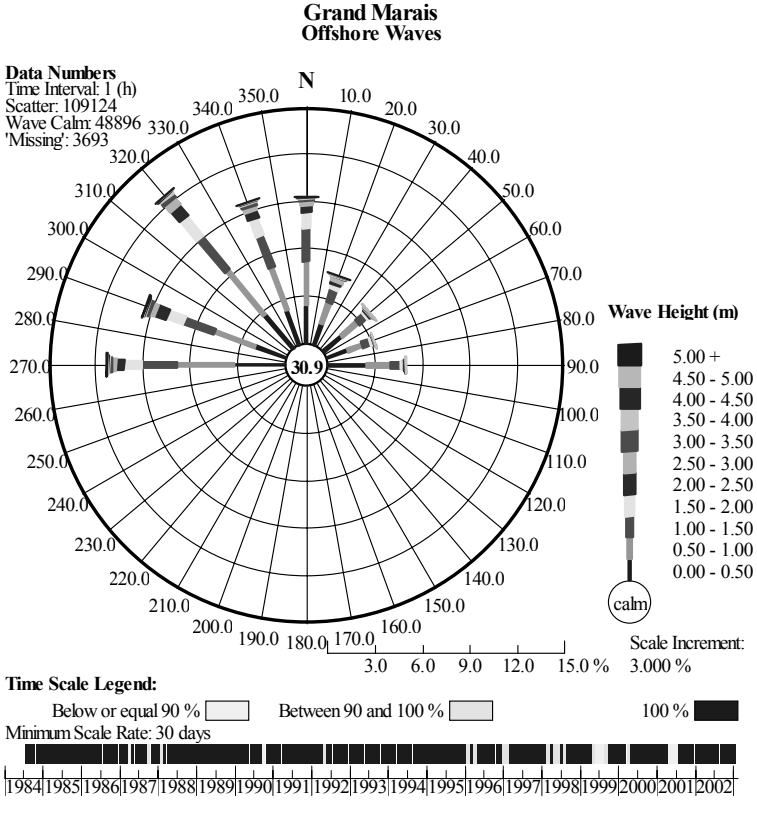

Fig. 7. Grand Marais Offshore Wave Rose

Existing Conditions

The model was run for 143 wave conditions with the existing bathymetry and harbor conditions. The selected wave conditions were representative of the predominant and extreme events of the 18-year hindcast dataset. Figure 8 shows sample results for nearshore currents under 3 m, 8 s waves from the NW direction. (a typical large wave condition at this site). The longshore current from this wave condition flows along the Superior Beach, bypasses the jetties and continues over the bypassing shoal towards the Sucker River mouth where it divides into separate eastward and westward components. A clockwise circulation is also created around the east jetty causing a northward outgoing current through the navigation channel. Although this current is not a very strong current, it is sufficient to counteract the movement of sediment by nonlinear wave orbital motions into the navigation channel. Under large NE waves, the westward longshore current partly bypasses the jetties, but mostly flows into the West Bay south shores as well as the harbor basin and again northward into the navigation channel. Therefore, under most large wave conditions there is a northward outgoing current through the navigation channel, which is likely helping to keep the channel clean and free of sediments.

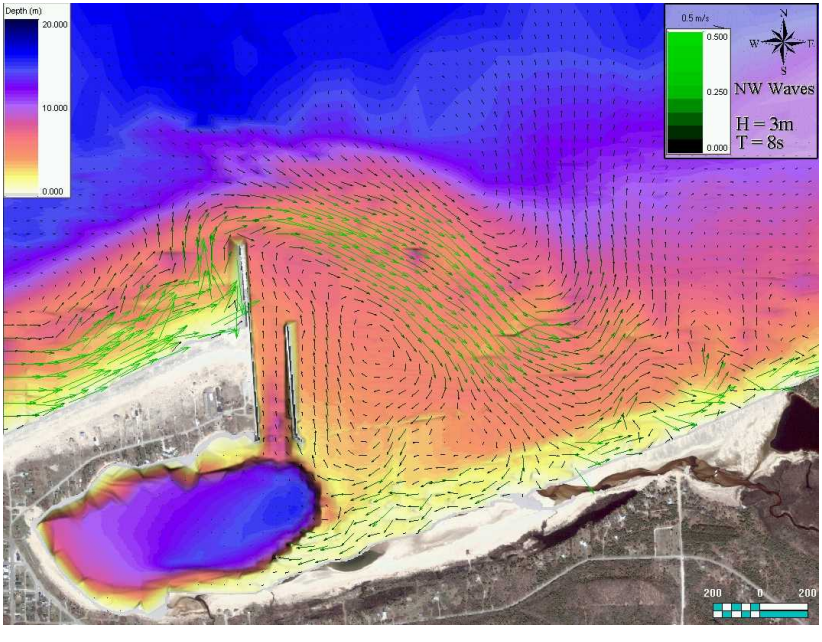

Fig. 8. Nearshore currents under 3 m, 8 s NW waves (existing conditions)

Model results for 143 representative wave conditions were tabulated as lookup tables for a simple numerical interpolation program that stepped through the 18-year time series of

hourly wave data to determine the long-term average sediment transport rate across several cross- sections in the calculation domain. The results are summarized in Figure 9. In summary, *HYDROSED* predicts a net eastward transport of 50,000 m^3/year that fully bypasses the jetties and reaches the downdrift shorelines. The bypassed sediment reaches the downdrift shores through the bypassing shoal (30,000 m^3/year) and over the shallow shelf between the bypassing shoal and the east jetty (20,000 m^3/year). The predicted eastward and westward components of transport are 70,000 and 20,000 m^3/year, respectively. The 20,000 m^3/year westward transport at Lonesome Point is also trapped in the study area. As a result, 70,000 m^3/year is available for accumulation in the harbor basin and on its south shores. The predicted transport rate into the West Bay area is 50,000 m^3/year and is in fair agreement with the estimated volumes through bathymetry comparisons. The remaining 20,000 m^3/year is accumulated in the South Beach area. Note that values in Figure 9 are long-term average figures and maybe different in individual years depending on wave conditions in each year.

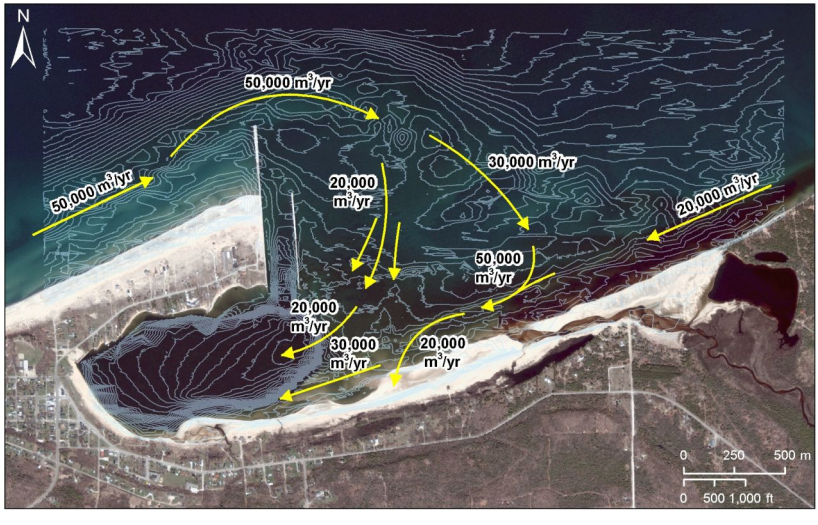

Fig. 9. Sediment budget predicted by *HYDROSED* for the existing conditions

55 degree Breakwater

Figure 10 shows the nearshore current results for 3 m, 8 s waves from the NW direction for the proposed 55 deg breakwater. The westward longshore current, west of the Sucker River mouth, is effectively blocked by the 55 degree breakwater. The clockwise circulation near the east jetty does not go through the navigation channel. Large NE waves and the resulting westward longshore current are partly blocked by the breakwater and partly diverted northward towards the entrance channel where it joins a small circulation entering into the navigation channel. Long-term analysis of *HYDROSED* results predicts accumulation rate against the breakwater of about 60,000 to 70,000 m^3.

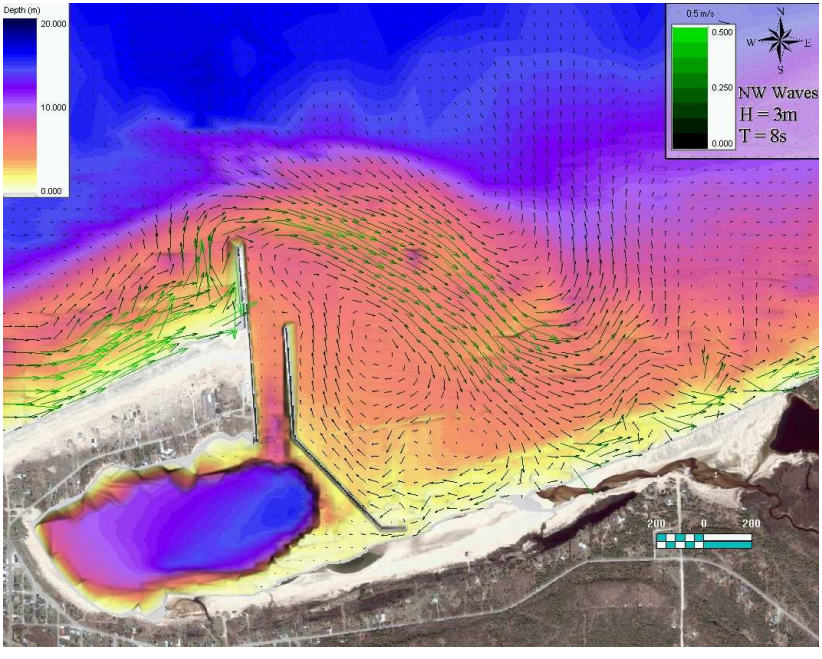

Fig. 10. Nearshore currents under 3 m, 8 s NW waves (55 degree breakwater)

CONCLUSIONS

Based on the numerical modeling results and the geomorphic analysis presented in the above sections, it is concluded that Figure 11 provides a reasonable sediment budget for the Grand Marais area. Based on our geomorphic assessment and numerical analysis, therefore, a net eastward transport of 40,000 to 60,000 m^3/year exists that fully bypasses the jetties and reaches the downdrift shorelines. There is also about 20,000 to 40,000 m^3/year supply from bluff erosion east of the Lonesome Point to the harbor area. As a result, 60,000 to 100,000 m^3/yr is available for accumulation in the harbor basin and on its south shores.

Projections of the future shorelines for the proposed alternative and the No Project condition were completed. An average accumulation rate of 80,000 m^3/yr was used in the calculations. Predictions of future shoreline conditions were made for 5, 10, 20 and 30 years out from the present. It is noted that these predictions are approximate and that the potential error of the prediction becomes larger as the duration of the prediction increases. The future water levels and frequency/intensity of storm events (both waves and river floods) have a significant influence on the Sucker River mouth location. Dramatic river switches (back to the east) are more likely to occur under high lake level and river flood conditions under all scenarios. After each switch, however, the river

mouth will start to migrate to the west once the water levels are back to normal or low levels.

Figures 11 and 12 show the predicted shorelines for the No Project condition and the 55 degree breakwater, respectively. With the No Project condition the historic trend of lakeward and westward advancement of the shoreline are projected to continue. Land-connected accumulation rates (for the beaches and basin) were 60,000 m^3/year and the remaining 20,000 m^3/year was considered to fill the deeper basin. Actual rates may be higher or lower than predictions, depending on the number and frequency of storm events that occur in the future. The West Bay basin will also continue to infill under the No Project condition.

With the 55 degree breakwater alternative (Figure 12) the main area of accumulation is offshore and to the east of the new breakwater structure. The volume of accumulation is greater than that of the No Project scenario because the basin is no longer infilled once the breakwater is constructed and this sediment is instead trapped next to the breakwater. With No Project and the 55 degree breakwater scenarios the bluff erosion to the east will continue resulting in erosion of the Lonesome Beach on the north side of the Sucker River. The 55 degree breakwater presents little or no restriction to the westward extent of migration compared to the No Project condition.

Abstract: A temporary construction harbour was built for the Egyptian Liquified Natural Gas (ELNG) facility in Abu Qir Bay on Egypt's Mediterranean Sea coast, west of the Rosetta Nile. A shoreline impact assessment was undertaken during the planning process which involved modelling the existing beach processes as well as shoreline development during construction, operation, decommissioning and recovery. Based on this assessment and modelling, a schedule of shoreline management and monitoring was proposed to ensure that the temporary harbour did not have a negative impact on the shoreline over its three year life. ELNG followed the proposed programme under scrutiny from the Egyptian Shoreline Protection Agency (SPA) and successfully restored the beach to its pre-construction state. This paper discusses the ELNG project, beach modelling, monitoring and the management programme as a case study, and assesses the beach modelling against the unique field data set

INTRODUCTION

The Egyptian LNG facility, located within Abu Qir Bay on the Mediterranean Sea coast (Figure 1), receives natural gas from wells offshore of the Nile Delta (West Delta Deep) and exports liquefied natural gas (LNG. The liquefaction plant and the associated marine facilities for tanker export were built between 2002 and 2005. A construction dock was required for the off-loading of plant from shallow draft barges directly to the site. Given the exposed nature of the site, the dock was protected within a small dredged harbour formed of rock breakwaters at the shoreline, with a dredged navigation channel connecting to deeper water. Tanker facilities for LNG export were built further offshore to minimise the need for maintaining a dredged channel across the shallow nearshore zone and LNG was piped to the tankers using a 3km long trestle (Figure 1).

As it was recognised that the harbour could have a significant impact on coastal processes, it was planned to be a temporary structure. The impact was to be monitored and managed

throughout its life, with the intention of reinstating the shoreline to its natural form following removal. This approach was intended to satisfy the regulating authorities, but also ensured that the LNG facilities would not be at risk from erosion or flooding as a result of the disruption to beach evolution processes. A management plan based on desk studies and numerical modelling was agreed and then implemented and scrutinized by the Egyptian Shoreline Protection Agency (SPA) over the period from construction in the spring of 2003 to removal of the harbour in the autumn of 2005.

The intensive management period resulted in an extensive beach data set from the pre-existing natural beach through construction, operation, removal and reinstatement. These data provided an opportunity to assess model predictions against measured shoreline changes, and the success of the proposed management plan.

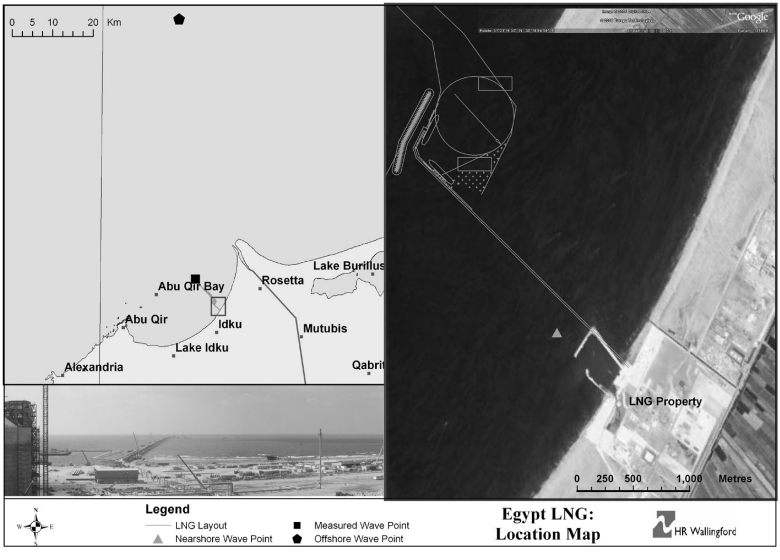

Fig. 1. Location Map

SITE DESCRIPTION

Abu Qir Bay is less than 20m deep and about 33km wide from the partially sheltered area in the lee of the reefs and islands off Ras Abu Qir in the west, to the rapidly eroding delta of the Rosetta Nile in the northeast. The shallow waters of Idku Lake lie just behind a barrier beach in the southern part of the Bay. The shore is exposed to dominant north-westerly waves, driving a strong easterly longshore drift along most of the Nile Delta coast (Fanos *et al*., 1995 and Frihy *et al*., 1991) but with a local south-westerly drift direction along the shore of Abu Qir Bay to the north of the ELNG plant location. The Bay has a small tidal range (typically ~0.2m), and the main driving forces for currents and sediment transport are wind and waves. Fresh water flows into the Bay via the Rosetta Nile and Idku Lake, although both sources are now low volume and considered to have little impact on coastal processes in relation to winds and waves.

Understanding of the coast and seabed evolution is based on information derived from historic maps and charts, satellite images, published research papers, unpublished reports, project specific field surveys and numerical modelling of sediment transport. In summary, the seabed and beaches are formed of fine sand and silt, subject to continuing change due to the dramatic reduction in sediment supply from the Rosetta Nile following construction of the Aswan dams, combined with the moderately high energy wave conditions typical of the Egyptian north coast. The net longshore shoreline drift is from northeast to southwest in the area of the ELNG plant, but is subject to short term reversals and a high level of annual variability. There is evidence, from sediment sampling, of offshore transport of silt and some fine sand to deeper water across the mouth of the Bay. At decadal timescales the shoreline is considered to be stable or slowly accreting in the area of the LNG facility, with a reasonable balance between sediment transport alongshore and losses offshore.

Previous beach and nearshore surveys carried out by CoRI (Coastal Research Institute, Egypt) over the 12 years prior to construction of the facility indicated that the natural shoreline and nearshore seabed levels were subject to substantial short term variability in response to seasonal conditions, up to ± 40m relative to a mean position, Fanos (2001).

It was anticipated that sand would accumulate to the north of the harbour, and that there would be areas of erosion to the south. An updrift accretion could potentially cause problems of infilling in the harbour and downdrift erosion could result in unacceptable loss of land to the LNG property or further along the coast. The nearshore bed was also expected to change both seasonally and over longer time periods, with some transport around the seaward face of the breakwaters, possibly causing infill of the dredged navigation channel.

SHORELINE IMPACT MODELLING

Potential impacts of the construction harbour on the shoreline were assessed using a suite of numerical models. Offshore wave conditions were defined and then transformed to create a time series of nearshore conditions as input to longshore drift predictions for the open coast and in the presence of the harbour breakwaters.

The wave climate offshore from the ELNG facility was evaluated by a combination of numerical modelling methods, with the offshore wave climate established using “Eurowaves”, which are model data based on the ECMWF (European Centre for Medium Range Weather Forecasts) hindcast model. At the time of this study seven years of sequential Eurowaves data (1992 – 1999) were available for the model point 30.5°E 32°N (Figure 1). The offshore wave predictions were calibrated against wave measurements made over a six-month period (November 2001 to April 2002) at the seaward end of the proposed approach channel (Figure 1).

Nearshore wave conditions over the seven year period were then modelled at a number of locations along the ELNG site on the 6m contour below Chart Datum (CD – approximately LAT at Alexandria). The time series of six-hourly predicted values of wave height, period and direction at a point just offshore from the northern harbour breakwater was used to model the likely changes to the shoreline.

The simplest measure of sand transport along a beach is the “potential mean annual transport rate”, denoted here as Q_{mean}. This single statistic allows an initial assessment of the scale and

pattern of any beach erosion / accretion following installation of coastal structures. It must be emphasised that Q_{mean} is:

- Subject to considerable uncertainty, because of the difficulties involved in calculation (i.e. it is extremely sensitive to the precise wave conditions and the beach orientation at any given point along the frontage;
- Averaged over a number of years and may be subject to substantial annual variability; and
- Dependent on the availability of suitable sediment to feed the drift.

The nearshore time series waves were transformed up to the breaking point of each condition. The values of wave height, period and direction at breaking were then used to derive the instantaneous longshore transport rate for sand for each six hour period using the CERC formula modified by Ozasa and Brampton (1980). The cumulative transport rates at the end of each month and year were defined. Finally, all the results were averaged over the seven years to produce the predicted mean annual nett transport rate, Q_{mean}. The best estimate prediction of Q_{mean} was approximately 480,000m^3/ year (south-westerly), as presented in Table 1, with a standard deviation of 196,000m^3/year. These figures give an indication of the potential variability in annual longshore drift, albeit from a small sample.

Table 1 provides a breakdown of the contributions to the drift rate produced by various categories of nearshore wave. Waves arriving from 310°N - 010°N produce a northeast to southwest drift (positive values), while waves arriving from 260°N - 300°N produce a southwest to northeast drift (negative values). The dominating effect of the waves between 1.5m to 2.5mH_s can be appreciated by considering the entries in the "Total" column, which show that these wave heights generate over 60% of the nett "positive" drift. The effect of the largest waves on drift direction is also important, indicating that very stormy periods are likely to be associated with drift reversals.

Table 1. Annual drift and % Wave height

Resultant wave height (m)	Direction sector (°N)									Total	% Wave Height
	275 - 285	285 - 295	295 - 305	305 - 315	315 - 325	325 - 335	335 - 345	345 - 355	355 - 005

4.0 +	..	-75,668	-86,721	71,009	7,612	..	..	..	..	-83,768	1.22
Total	-1,225	-212,901	-178,955	543,324	171,136	53,188	75,637	26,306	4,036	480,547	100

Table 1 also shows that about 60% of the mean annual drift rate is produced by waves with heights in excess of 1.5m. Such waves occur for less than 30% of the time (see Table 1), and hence it can be appreciated that a "calm" year, with fewer than average storms, will be likely to produce a very different drift rate to a "stormy" year with more storms.

Figure 2 shows the calculated variations in the nett longshore transport rate from month to month over the seven-year period. This indicates that transport is relatively constant in direction and rate during the summer months, at approximately 50,000m^3/month towards the southwest, but during the winter months the drifts can be much stronger, in one month alone the drift rate is equal to a years mean drift and in some cases there may be a reverse in drift direction. This had implications for the harbour entrance, since there was a danger that infill could occur by sand travelling from southeast to northwest.

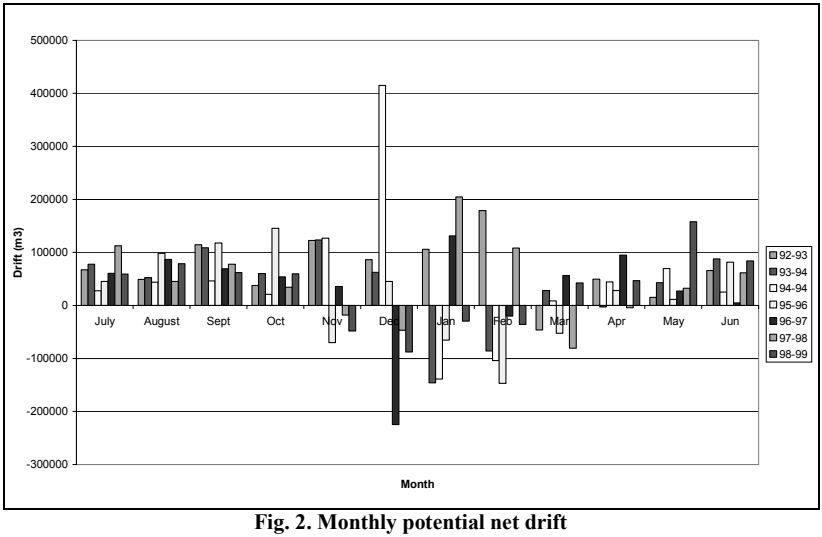

Fig. 2. Monthly potential net drift

The figure for Q_{mean} of 480,000m^3/ year at the north end of the harbour was considered to be a conservative prediction (i.e. overestimating) and the actual rate may be less due to the nearshore wave predictions not accounting for dissipation effects during storms from the shallow silty seabed. Furthermore the drift calculation is sensitive to the assumed beach orientation and sensitivity tests indicated that a change to the beach orientation of 1° gives a corresponding value of Q_{mean} altered by approximately 240,000m^3/ year. Therefore as the shoreline curves continuously, Q_{mean} will decrease significantly along the site towards the south, potentially even reversing immediately south of the LNG frontage. The sensitivity of drift predictions to small changes in wave direction is also similar. Since it is hardly possible to measure, let alone predict, nearshore wave directions to accuracies better than ±5°, then the uncertainty of the computed Q_{mean} value can be appreciated.

BEACH PLAN SHAPE EVOLUTION

Introduction

The changes in the plan shape of the beach around the temporary harbour were examined through the use of the HR Wallingford BEACHPLAN 1-line beach model, (HR Wallingford 2004 and Ozasa & Brampton 1980). This model uses the same wave conditions gathered at the LNG site as used in the drift calculations, in the form of a time series (from July 1992 to

June 1999). Ideally, when predicting shoreline evolution the model is calibrated against historical shoreline positions and detailed up to date beach and nearshore profiles are used to assess the active beach. A lack of suitable data for this study required the need for a conservative approach to predicting drift rates so that the potential for shoreline changes and subsequent mitigation measures would not be underestimated. Similarly, to be on the conservative side, no attempt was made at simulating the bypassing of sand around the seaward end of the harbour and although no nearshore survey data was available at this time it was assumed that the cross-shore extent of significant transported extended to at least the 5mCD contour. These and other model parameters were all chosen on a basis of experience and using a conservative approach in order to provide suitable guidance for the pattern and scale of beach changes and the subsequent mitigation requirements i.e. recycling.

The BEACHPLAN model was run for a number of different scenarios to provide initial assessment of the potential beach response to the proposed construction harbour. The model runs presented within this paper consider the following:

- Beach response to the harbour over 3 years, assuming no management measures.
- Beach recovery over 3 years following removal of the harbour.

Modelling runs: Natural response to the harbour

The model was first used to examine the potential changes in the shoreline following the construction of the harbour breakwaters. The model was run for three years to simulate the beach changes likely to develop over the life span of the harbour. Figure 3 shows the predicted beach plan-shape six months after the completion of the harbour. Substantial accretion of up to 150m is predicted, after 3 years, on the east side of the causeway, and a maximum of up to 100m of landward movement of the coastline to the west of the western breakwater. This figure also presents the predicted changes after 1, 2 and 3 years. The beach position after 1 year is very similar to the beach position after 6 months and it could be interpreted that the beach has not moved a great deal in this time period. However on examination of the results in more detail, on a monthly basis for example, it was predicted that the beach varies a great deal and as a result of storm activity, the drift rate is higher and more variable, often with periods of a reversal, as shown in Figure 2. The variations in the wave climate therefore resulted in a predicted beach position after 12 months similar to the one seen after 6 months. The longshore extent of predicted accretion and erosion was about 3km either side of the harbour. This is considered to be a qualitatively realistic though conservative scenario.

The model was not set up to indicate the potential volume of sand that may by-pass the breakwaters, which would largely be expected to be deposited within the dredged navigation channel leading to the dock, and would therefore result in more accretion on the updrift side. The results indicate that under conditions of “average annual” littoral drift substantial accretion was expected east of the temporary harbour with high rates of coastal erosion to the west.

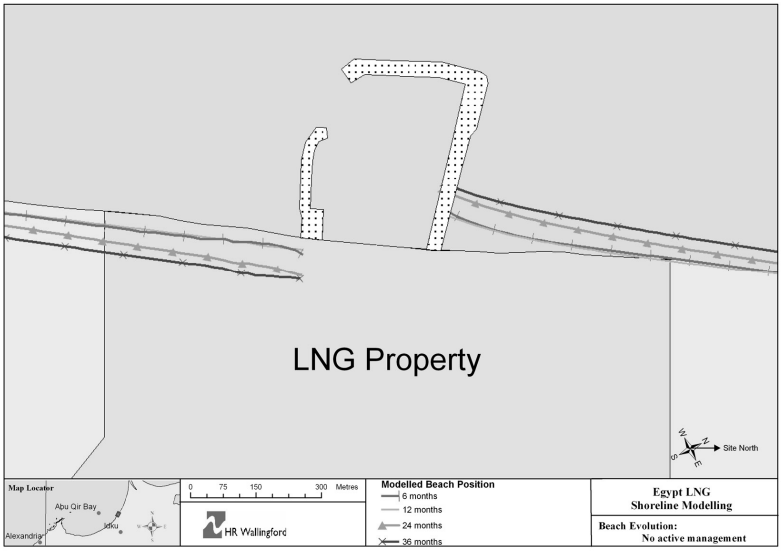

Fig. 3. Modelling of beach plan shape evolution

Modelling runs: Beach recovery

The model was also used to examine the changes in the shoreline after removal of the harbour. The initial situation was taken as the final shoreline position after three years with the harbour in place. The model demonstrated an initial rapid beach response followed by a gradual reorientation of the beach towards its original alignment over time. It is predicted that in less than three years from removal the beach would recover to its pre-construction state.

BEACH MANAGEMENT

A beach management plan was prepared for ELNG to minimise any impacts of the temporary harbour on the natural environment, as required by the Shoreline Protection Agency. The main aims and objectives of the management plan were to:

- Keep both the accumulation of beach material on the north-east side of the harbour and erosion south-west of the harbour to within agreed limits representing the envelope of beach variation under natural conditions;
- Minimise the rate of siltation of dredged areas in the harbour or its approach channel; and
- Return the shoreline to its pre-construction equilibrium state following removal of the harbour.

An envelope of acceptable shoreline movement was defined, based on the recorded movement of the shoreline over the previous decade, Fanos (2001) and the beach plan-shape modelling. The acceptable limits recognised that the beach would re-orient itself to a new position following the installation of the harbour and was considered not to be a problem as

the shoreline would rapidly return to its pre-construction position. Provided that the shoreline stayed within this envelope, no immediate management action was required. A further envelope of tolerable short-term erosion and accretion was defined allowing the contractor some leniency while undertaking bypassing operations. Variation outside this envelope was considered contractually unacceptable.

In order to maintain the beach within the agreed limits regular bypassing was proposed to move sand from areas of accumulation to areas of erosion. It was also proposed that any clean sand dredged from the navigation channel or the dock area would be deposited onshore for beach management purposes. A sand bypassing scheme using trucks was recommended as more efficient and flexible than any schemes involving pumps or dredging plant. It was anticipated that bypassing of up to 40,000m³ of sand might be required each month, but that this rate would vary in response to seasonal and storm conditions. The actual volumes of beach material moved are presented in Table 2.

A flexible management system was recommended because the beach and drift modelling highlighted that actual beach changes can occur very quickly (Figure 2) and are subject to the vagaries of the wave climate. It was not possible to determine the exact location of sand pick up and set down positions for sand bypassing and it was recommended that this would be determined by means of regular shoreline and nearshore monitoring.

A beach and nearshore survey programme was instigated to monitor the changes as a result of the temporary construction harbour and to facilitate in the management of the shoreline adjacent to the harbour.

The programme involved an assessment of the pre-construction shoreline and nearshore bathymetry, with frequent monitoring throughout the life of the facility. The survey programme comprised six-monthly bathymetric surveys out to about the 6mCD contour, two-monthly beach profile surveys accompanied by photographs and fortnightly waterline surveys. Furthermore volumes of any dredging and sand bypassing required to maintain the shoreline position were logged.

As shoreline data were recorded at frequent and regular intervals throughout the life of the harbour, an efficient data management and analysis system was set up. ArcMap GIS was used to store and analysis the data as it allowed efficient data management, a rapid analysis of shoreline changes and a cost effective method for monitoring contractor performance and compliance with SPA's requirements.

Table 2. Management Activities

Date	Activity	Volume Removed	Volume Added	comments
Feb-03	Construction of the temporary harbour begins			
Apr-03	Capital dredging begins	120,000m	10,700m	109,300 stored onsite
May-03	Temporary harbour complete			
Jun-03	Removal of sand from north beach	400m		Used to fill voids in breakwater
Aug-03	Maintenance dredging	38,200m	38,200m	
Nov-03	Sand Bypassing	22,000m	20,000m	
Jun-04	Maintenance dredging	15,200m	15,200m	
Apr to Oct-04	Sand Bypassing	44,750m	42,750m	
Jun-05	Removal of temporary harbour	Redistribution of sand		

ANALYSIS OF SURVEY DATA

Nearshore Surveys

The beach and nearshore surveys collected every six months, eight in total, illustrate clearly the response of the shoreline to the presence of the temporary construction harbour. Although these surveys only represent the situation on individual days they also show the patterns of accretion and erosion.

The February 2003 survey (Figure 4) was completed prior to any construction work. The contours are largely parallel, with a distinct nearshore channel/bar system typical of a "winter" beach condition. By the April 2003 survey (Figure 5) the harbour was part built, and was beginning to have an impact on the nearshore processes. The nearshore bar is still clearly present to the north of the breakwater, but to the south there is a channel, indicating a loss of about 2m elevation. There is also a deep scour hole (5m deeper than the surrounding seabed) near the end of the breakwater, which was thought to be caused by waves reflecting off the structure and possibly by longshore currents being turned offshore.

Over the summer of 2003 the bathymetry changed in a way that is often observed on sandy shorelines and by the October 2003 survey, the nearshore channel/bar system had flattened off, leaving a more even slope down from the beach typical of a "summer" profile i.e. the bars had migrated onshore. This indicated a continued loss of total sediment volume, despite the dumping of some 49,000m^3 of dredged sand onto the beach during the late summer 2003. There was also an accretion of sand to the north of the harbour, extending out to the contractual limit agreed with the SPA. As the harbour arm was extended for the completion of the harbour (Table 2), the scour hole migrated further offshore to form a stable but extensive feature off the northwest corner, Whitehouse (2005). This scour hole caused an instability of the trestle structure that runs alongside the temporary harbour and as a consequence a section of the northern arm of the harbour breakwater was realigned to a parallel orientation approximately 50m to the south, as shown in Figure 6.

By April 2004 the nearshore profile had again adopted a "summer" shape with a reduced nearshore bar, but there was still a clear build up to the north of the dock and a much steeper

profile to the south. The south beach was also affected by the presence of a 300m long rock revetment built along the backshore, although the survey plot does not show this. The effect of the revetment was to limit the landward migration of the waterline, but it did not slow the total loss of material from the beach and nearshore and downdrift erosion occurred beyond the site of the LNG. The rock revetment was removed during the summer of 2004.

Despite the management effort between April and October 2004 (Table 2), the October 2004 survey (Figure 6) clearly showed a continued build up of material to the north of the harbour. There was also a build up of sand around the outer edge of the breakwater indicating that natural bypassing processes were occurring, with likely infilling of the dredged channel. It is also evident that the south beach had a much steeper profile and there were no signs of the bar and channel system that existed pre-harbour construction, as shown in Figure 5. The April 2005 survey showed a similar pattern of sand movement with a continued build up of material to the north of the harbour.

During the period February 2005 to July 2005 the removal of the construction harbour took place. The final survey was undertaken in July 2005 and is presented in Figure 7. This Figure clearly shows that the shoreline had largely returned to its natural position except for the small residual promontory between profiles 10 and 11, and the remaining cut-back south of the ELNG site at profiles 21 – 23. The offshore contours still exhibit the effects of the harbour, with a substantial build up remaining in the area north of the harbour. The nearshore loss to the south, and particularly the loss of the nearshore bar feature, is a cause for concern, as the beach may no longer be able to respond to severe wave conditions in a natural and dynamic way.

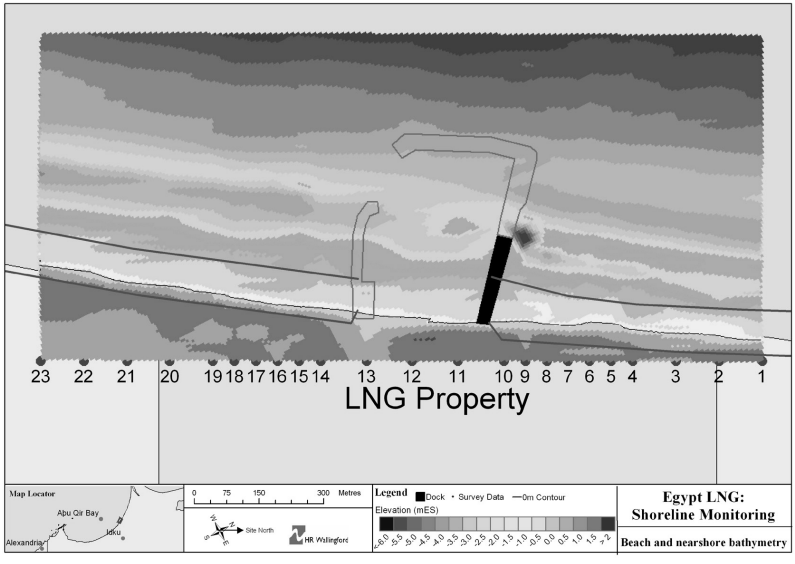

Fig. 5. Beach and bathymetric contours: April 2003

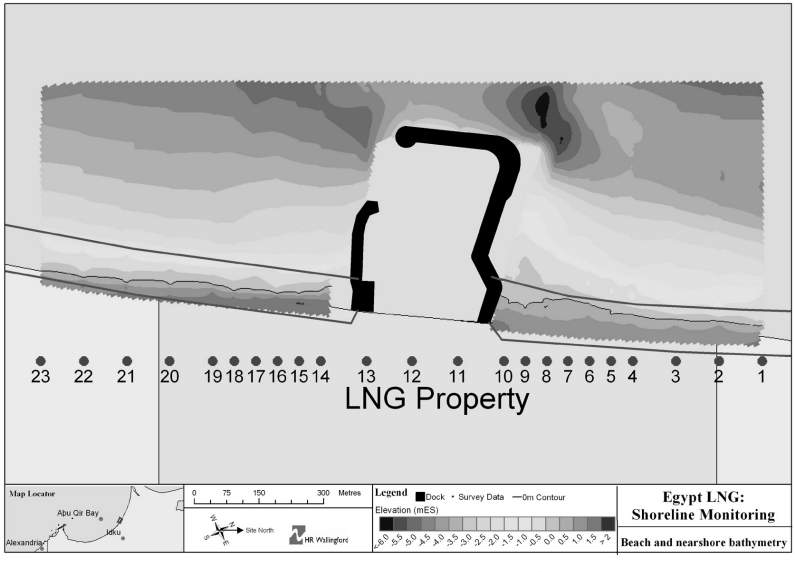

Fig. 6. Beach and bathymetric contours: October 2004 (Note new dock layout)

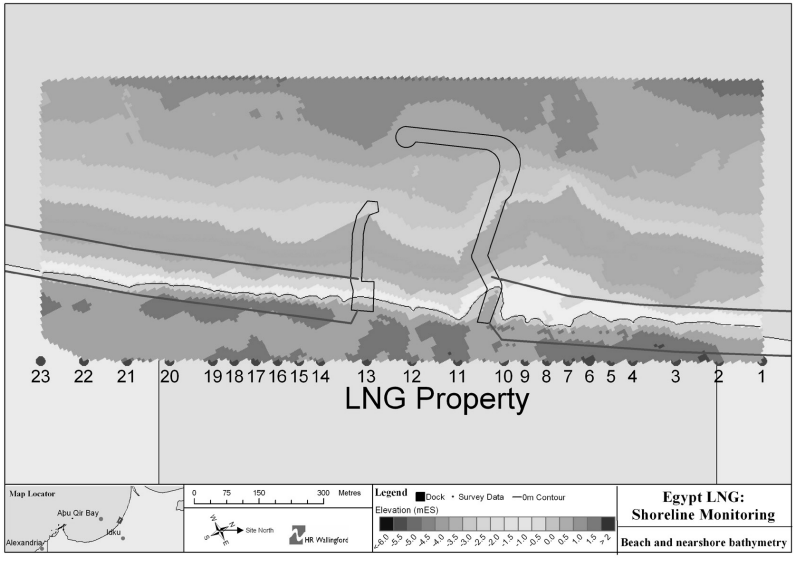

Fig. 7. Beach and bathymetric contours: July 2005 (note dock now removed)

Shoreline Position

The intended fortnightly waterline position surveys were actually completed at intervals from weeks to months. Measurements of the distance from a fixed baseline to the waterline were taken at intervals along the ELNG frontage to assess short term variability. The method used was simple and rapid and therefore allowed the contractor to respond to shoreline changes before the more detailed surveys and therefore keep the shoreline within the agreed limits of variation.

The peak rate of change in shoreline position was calculated and shows that the shoreline was accreting by 2.5m/wk at the north beach and was eroding by 1.3m/wk at the south beach during the first few weeks following construction and highlights the rapid response needed to effectively manage the shoreline.

MODEL PERFORMANCE

Prediction of accurate drift rates by numerical models is notoriously difficult, especially on open coastlines where there is little accurate historical data or even obstructions to the drift to provide evidence of the direction and intensity of the sediment transport rate. The monitoring programme at the ELNG has provided a unique dataset of measured beach evolution over the whole project (including removal of structures), therefore allowing an assessment of the performance of the numerical modelling undertaken as part of the initial shoreline impact predictions.

The use of GIS to store and plot both the modelled shoreline positions and the subsequent measured shoreline positions has allowed a direct comparison to be made between the two data sets, as shown in Figure 8. This figure clearly demonstrates that the modelled shoreline

position after 6 and 12 months closely match the corresponding measured shoreline position (August 2003 and February 2004) to the north of the harbour. The maximum amount of accretion against the north harbour arm after 6 months was predicted by the modelling to be 78m and when this is compared with the 83m accretion measured by the August 2003 survey, it is clear the model was accurately predicting the shoreline evolution. The predicted figure also compares well against the shoreline position measurements over the same time period. Looking further ahead in time, 24 and 36 months, the predicted shorelines do not match the measured. This is understandable as the shoreline was required to be maintained within agreed limits of movement and beach bypassing was undertaken in a responsive manner beginning in November 2003. Volume calculations of the survey data, although of a crude nature also tie in to the average longshore drift along the modelled stretch of coastline.

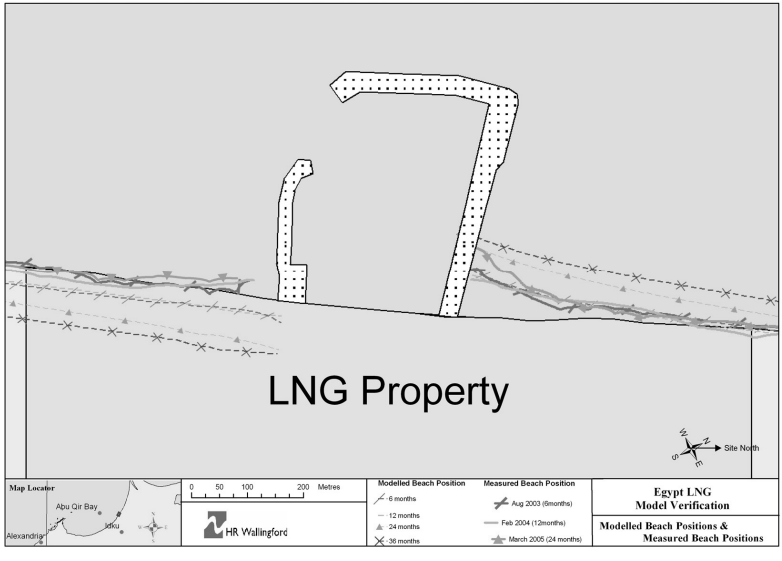

Fig. 8. Comparison of predicted beach positions and monitored beach positions

On the beach south of the harbour the surveyed positions do not match the shoreline position predicted by the modelling. However, the weekly shoreline position measurements tie in with the rate of erosion predicted at this location and as a result of the rapid erosion beach management (Table 2) was required before the August 2003 survey. Furthermore a rock revetment was placed along the shoreline to restrict any further landward movement of the shoreline south of the harbour. Therefore the surveyed shoreline position will not match the predicted shoreline position.

The beach plan shape model predicted that the beach would return to its pre-harbour position within three years after removal. Following removal of the harbour the waterline was artificially restored to its pre-existing state and it has subsequently not been possible to verify the recovery element of the modelling.

CONCLUSIONS

A comprehensive desk study of coastal processes was undertaken to assess the impact of the temporary construction harbour for the ELNG facility, before the BEACHPLAN model was used to predict future beach evolution. This model is applied as a first-stage tool in understanding coastline behaviour and the impact of engineering works upon it.

Drift rates are notoriously difficult to accurately predict and are sensitive to small changes in beach orientation (or wave direction). Caution must therefore be exercised when calculating them and sensitivity test should be carried out. In this study a shift in beach orientation of only 1° led to a 50% change in drift rates. This is clearly important when modelling along a curved shoreline such as the one in this study and led us to make a conservative estimate of the drift rates for the purpose of providing guidance to the required beach management.

Following the analysis of the survey data a comparison between measured and predicted beach position revealed that the modelling turned out to be reasonably accurate, despite the lack of any suitable calibration data. In situations where there is a lack of good data for calibration a comprehensive desk study and the undertaking of sensitivity tests gain increasing importance and any modelling should be done with a suitable amount of caution and conservatism.

As a result of the identification of the scour hole its subsequent impact on the trestle, it was recognised that that it is important to carry out a separate study to assess these impacts using a 2-D wave/current sediment transport model.

THE DESIGN OF STABLE AND AESTHETIC BEACH FILLS: LEARNING FROM NATURE

Paul D. Komar

College of Oceanic & Atmospheric Sciences
Oregon State University, Corvallis, OR 97331
pkomar@coas.oregonstate.edu

ABSTRACT: Beach fills come in two forms, the most common being the nourishment of a beach with sand to improve its recreational use and to enhance its capacity to buffer backshore properties from wave attack. The other form is a cobble berm (dynamic revetment), similarly used to protect shorefront properties, involving the construction of a cobble beach ridge. Both tend to be acceptable as shore-protection strategies due to their having natural forms found on coasts, acceptable where seawalls and conventional stone revetments are unacceptable. The design of beach fills should include considerations of the characteristics of their natural counterparts, so they have the visual aesthetics of natural beaches and respond to ocean processes during storms in much the same manner, increasing the probability that the fill will be stable in forming a permanent beach and in providing the desired level of protection for backshore properties.

INTRODUCTION

The term "beach fill" is broadly used to include the practice of restoring an eroded beach by the importation of sediment, or the development of a recreational beach where one had not previously existed. This of course is the common practice of beach nourishment, with sand generally being the material employed. Another form for a beach fill, one less common, is the use of gravel and cobbles to construct a beach ridge that provides protection to backshore properties. It has been observed by coastal geologists and engineers that natural cobble beaches can impart significant degrees of shore protection, and there has been a few examples where their artificial counterparts were constructed as beach fills to protect coastal developments; those fills are alternately termed "cobble berms' or "dynamic revetments". Beach fills

therefore come in a variety of forms, but the underlying objective in their construction is to restore a beach or to provide a natural form of shore protection. Having this natural form, their installation tends to be more readily acceptable within the framework of coastal management, including within jurisdictions where the use of hard structures is outright forbidden, or locally within parks or similar environments where soft solutions are preferred over the use of conventional seawalls and revetments.

It is apparent that the design of beach fills should include considerations of the characteristics of their natural counterparts, so these artificial fills have the visual aesthetics of natural beaches rather than it being apparent that they had been designed by an engineer. Conformity with the natural forms found in Nature will likely also increase the probability that the fill will be stable in forming a more permanent beach and in providing the desired level of protection for backshore properties. This assumes a level of "intelligence" on the part of Nature, with her having formed beaches composed of sand, gravel and cobbles that represent levels of stability necessary for them to remain along the shore. Viewed another way, the beaches we find along the coast represent examples of "survival of the fittest", implying that they have naturally evolved in their morphologies to maximize their stabilities.

The implication is that we can learn from Nature in our design of beach fills, in effect to "Design with Nature". This was the title of a book published in 1969, written by the Scotsman Ian McHarg, a town planner and landscape architect. With advances in the science of ecology during the latter half of the 20th century, efforts were made to determine what constitutes a balanced and sustainable environment, making possible man's prosperity while minimizing our adverse impacts on the environment — McHarg's book is a reflection of that idealism. It is telling that the first environment he considered is the coastal zone, with his primary focus having been on barrier islands and their fragility. As outlined above, I tend to put a somewhat different spin on the concept of designing with Nature, that we can learn from it in our search for improved ways to develop the coast and to protect those developments from the forces of Nature that seem bent on our destruction. The objective of this paper is to explore that concept in the application and design of beach fills, for both beach nourishment projects and cobble berms, drawing on the designs of Nature to serve as a guide. But it will be seen that on occasion Nature make mistakes, resulting in unstable beaches, but her mistakes can also serve as guides in our development of more stable beach fills.

BEACH MORPHODYNAMICS — THE KEY FOR STABLE BEACH FILLS

Whenever coastal scientists and engineers undertake investigations of beaches, they make observations and collect data that potentially are of value in the design of artificial beach fills. Specifically, in those designs we need to adopt a profile for the fill that takes into account the morphologies of natural beach profiles and how they are effective in dissipating the energy of storm waves, thereby surviving the storm. Specifically, we need to know how the slope of the beach depends on the grain sizes of its sediments and the wave conditions, and perhaps even how the wave swash sorts

the ranges of particle sizes and shapes into regular patterns across the profile, this being a particularly distinctive feature of gravel and cobble beaches. High on the scale of relevance to beach-fill design is an understanding of how natural beaches respond to the forces of extreme waves and elevated tides during major storms, their response in general being to move some of their sediment offshore to yield a profile that is more effective in dissipating the energy of the storm waves. From our research on beaches over the decades, we have acquired a reasonable understanding of how Nature acts to maximize the stabilities of its beaches, to be drawn upon in the design of beach fills.

This stability is an inherent component in the classifications of beaches, particularly the morphodynamics classification of Wright and Short (1983), and that of Jennings and Shulmeister (2002) that considers the full range of beach types depending on their proportions of sand versus a coarse-grained component, gravel and cobbles. The well-known classification of Wright and Short includes beach categories that range from Dissipative to Intermediate to Reflective, defined on the basis of their contrasting profiles and accompanying differences in wave breaking and surf-zone processes. A Dissipative Beach is one having a low average slope and a wide surf zone, whereas a Reflective Beach at the other extreme has a steep beach face and a relatively narrow swash zone that experiences the direct forces of the runup and backwash of the breaking waves. The distinction between these extremes in the classification is fundamental in that on the low slope of a Dissipative Beach, the waves break well offshore and progressively loose their energy while they travel as bores across the wide surf zone. Whenever the heights of the waves increase during a storm, they simply break further offshore, with a minimal increase in the incident-wave energy at the shore (although there is an increase in the long-period infragravity motions). The morphology of a Dissipative Beach therefore effectively acts to dissipate the energy of the waves, a successful design by Nature. In contrast, on the steep Reflective Beach the incident waves break close to shore with little prior loss of energy. However, some of that energy is reflected from the steep beach face, generating waves that return seaward; hence the term "reflective". The Intermediate Beach categories incorporate a series of morphological types that are more three dimensional, and cannot satisfactorily be represented as simple two-dimensional profiles. The morphology may include the presence of complex patterns of nearshore currents, including rip currents that locally erode embayments into the beach, each becoming the site of localized “hot-spot” erosion that represents a hazard to shorefront properties.

The ramification of the morphodynamics classification of Wright and Short (1983) to the design of beach fills, where stability is of prime importance, is that it is preferable to have a Dissipative Beach. Reflective beaches can also be reasonably stable in that a significant portion of the incident wave energy is reflected, and in the case of steep beaches composed of gravel and cobbles, much of the remaining incident wave energy is expended as it washes up the beach face, with some of its water percolating into the permeable gravel. Therefore, within the scope of the morphodynamics classification the Intermediate categories tend to be the least stable and experience the

greatest morphological change, with the highest prospects of there being property erosion. The ramification for beach-fill design is clear — Intermediate beaches are to be avoided.

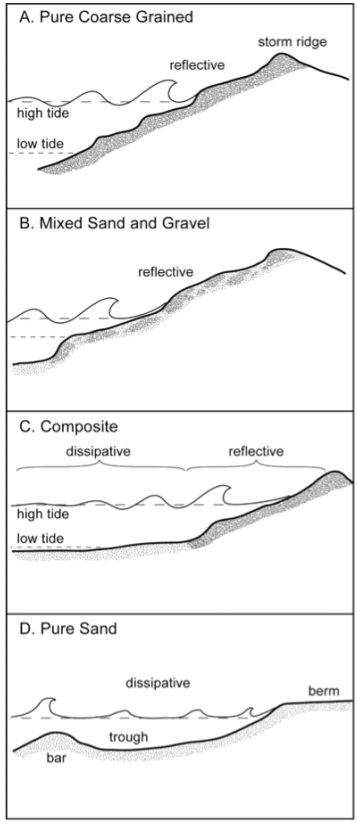

Fig. 1. The classification of beaches depending on the proportions of sand versus gravel and cobbles. [*after* Jennings and Shulmeister (2002)]

Also relevant to the design of beach fills, specifically of beach berms or dynamic revetments consisting of gravel and cobbles, is the classification of Jennings and Shulmeister (2002), Figure 1, that places beaches into four categories depending on their relative proportions of sand versus the coarse-grained component, and how Nature has sorted those fractions across the profile. The vast majority of coastal research has focused on the two extremes, coarse-grained beaches containing minimal quantities of sand, and sand beaches where the quantity of gravel is sufficiently small it does not affect the morphology and dynamics of the beach. Of interest are the mixed sand-and-gravel beaches and composite beaches, Figure 1, differing in how

Nature has dealt with the range of sediments available to form the beach; in the former there is an intimate mixing of the two size fractions in the beach face (Kirk 1980), whereas in composite beaches the sand and coarse-grained fractions are largely separated across the profile, the upper foreshore or backshore ridge being composed of gravel and cobbles while the lower foreshore is sand, there generally being a distinct boundary between them. Again, this classification has ramifications to the design of stable beach fills to be used for shore protection. The presence of the sand within the mixed sand-and-gravel beach acts to reduce the deposit's permeability and capacity to dissipate the energy of the wave swash, while the composite beach is ideal in having combined a Dissipative sandy foreshore and Reflective cobble backshore, the two most stable forms in the morphodynamics classification. We therefore recognize in these classifications where Nature has been most successful in the development of stable ocean beaches, and it behooves us to follow her directions in the design of artificial beach fills.

COARSE-GRAINED BEACH FILLS FOR SHORE PROTECTION

Coastal geologists and engineers involved in the study of natural gravel or cobble beaches have come to recognize that given sufficient volumes of coarse sediment to construct a beach ridge, Nature can provide her own solution for the protection of backshore properties. I came to my "eureka moment" on the Oregon coast after having seen several examples, Figure 2, only to later read the publications of others to find that my observations had not been unique.

Fig. 2. A cobble beach on the Oregon coast, providing natural protection to a sea cliff. [*photo courtesy of* Jonathan Allan]

It is unclear when or where such observations were followed by the construction for the first time of an artificial coarse-grained beach specifically for shore protection. There are early papers on the nourishment of gravel beaches, adding similar material to an already existing gravel beach (e.g., Muir Wood 1970). However, that practice differs from what has come to be known in the engineering literature as the construction of a "dynamic revetment", or is alternatively referred to as a “cobble berm”, a preferable name in coastal management in having diluted the implication of it being a type of revetment. On the other hand, the term dynamic revetment provides a contrast with a conventional “stable” revetment that consists of large quarry stones, where stone movement can lead to the failure of the structure. A further extension of the concept is that of rubble-mound breakwaters, and artificial islands that have been constructed to serve as oil-drilling platforms. The earliest published paper I have found that might be considered to involve the design and construction of an artificial gravel beach in the form of a cobble berm is that of van Hijm (1974), the application having been along the bank of the entrance to Rotterdam Harbor in the Netherlands, but needed to dissipate wave energy rather than to serve as shore protection. Whatever the origin of the concept, the basic strategy has evolved into one of building a gravel or cobble beach that can adjust and deform in response to storm wave action, being dynamic in expecting stone movement rather than static as in revetments of large quarry stones. By being dynamic, the cobble berm is effective because the mound of gravel and cobbles is able to disrupt and dissipate the wave energy, partly through its absorption of the runup by the permeability of the deposit, and it can alter its overall morphology just as a natural cobble beach does at the time of a storm.

The initial research into dynamic structures was undertaken at the Delft Hydraulics Laboratory, having been directed toward the design of the wave-dissipating structure to be built in Rotterdam Harbor, but relevant also for the design of rubble breakwaters for harbors, or artificial islands. Accordingly, those experiments were undertaken in a laboratory wave channel with deep water in front of the structure. Ahrens (1990) extended the research through additional laboratory investigations, but with shallow water fronting the rubble mound. Even then the laboratory studies differed from the typical situation where one wants to construct a cobble berm/dynamic revetment for the protection of shorefront properties, with it commonly being placed at the back of an active, sand beach.

A preferred approach upon which to base the design of cobble berms for use in shore protection is to investigate their natural occurrences, morphologies, and responses to extreme storms. There is a wealth of relevant information in the published literature to be drawn upon. To cite a few examples: the origin and distinctive characteristics of gravel and cobble beaches (e.g., Carter and Orford 1984); the movement of the particles depending on their shapes and sizes (e.g., Carr 1974; Nicholls and Wright 1991); the resulting patterns of particle shapes across the beach profile (e.g., Bluck 1967; Orford 1975; Williams and Caldwell 1988); the rates of gravel abrasion (e.g., Matthews 1983; Dornbusch et al. 2002); and the unique morphodynamics of mixed sand-and-gravel beaches (Kirk 1980).

Particularly informative are the field studies of cobble beaches that specifically had the objective of collecting data to be used in the design of cobble berms. Everts et al. (2002) investigated natural cobble beaches on the coast of southern California, with the objective to design a cobble berm for shore protection in Ventura. We have undertaken similar investigations of cobble beaches on the Oregon coast, to compare their dynamics with a cobble berm that was constructed in Cape Lookout State Park in response to major problems with erosion and flooding (Allan and Komar 2002, 2004). Its design was based primarily on surveys of nearby cobble beaches to determine their natural slopes, and the elevations reached by the combined tides and wave-swash runup that had occurred during an extreme storm in March 1999, the storm that in particular had impacted the park. The design of the cobble berm therefore focused on potential extreme water levels in order to prevent its overtopping during major storms, and the volumes of coarse sediments needed to provide those elevations; in this respect, the design represents something of a hybrid between that of a riprap revetment where elevations are important, and a conventional beach nourishment project where sediment volumes are most important. This cobble berm has been monitored since its completion in 2000 by a program of seasonal surveys, tracing the mobility and net transport of the cobbles with PIT-tags, and a documentation of the changing grain sizes and sorting patterns (Allan and Komar 2004; Allan et al. 2006); similar investigations are underway on natural cobble beaches along the Oregon coast, in order to provide comparisons with the process-responses and evolution of the constructed cobble berm. To date, the cobble berm, backed by a re-constructed sand dune, have been successful in providing protection for the park, and have remained fairly intact under the forces of major storms, including extreme events when both the cobble berm and artificial dune were overtopped.

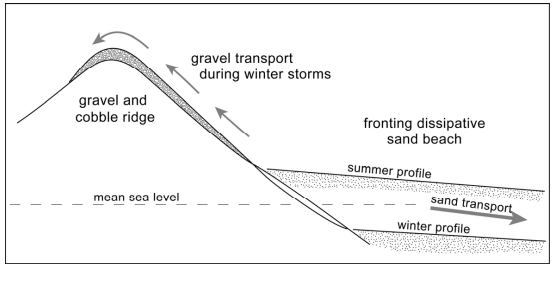

Fig. 3. The contrasting patterns of sediment movement on the cobble ridge and fronting sand beach of a composite beach during storms.

The investigations by Everts et al. (2002) of cobble beaches on the coast of southern California, and ours on the Oregon coast (Allan and Komar 2002, 2004), compliment one another in their observations and conclusions. Both involved composite beaches in the classification of Jennings and Schulmeister (2002), consisting of Dissipative sand beaches fronting Reflective cobble beaches; on the California coast the cobbles

have tended to accumulate in ridge deposits, whereas on the Oregon coast they primarily form sloping beaches in front of sea cliffs or high sand dunes. Of particular interest, documented in both studies, are the contrasting responses of the sand and coarse-grained deposits during storms, depicted in Figure 3, or as part of the overall seasonal shifts in profiles from summer to winter. As expected, during a storm the sand beaches erode due to the offshore transport of the sand from what had been the dry summer berm, into offshore bars, this being the typical seasonal cycle for sand beaches along the West Coast. With the lowered elevations of the fronting sand beaches in the fall to early winter, the waves are only then able to reach and impact the cobble deposits. During a storm the increased intensities and elevations of the runup move cobbles landward, while the backwash weakened by percolation produces less offshore movement. The general result is accretion and a steepened profile of the cobble beach, Figure 3, and an increase in its maximum elevations, particularly if the storm waves result in overwash of the cobble ridge. Everts et al. (2002) found that the most substantial episodes of cobble-ridge accretion occurred during the 1982-83 El Niño and during the most extreme storm of the study period in January 1988, events when the sand beaches experienced their greatest degrees of erosion. A similar response has been found for the cobble berm constructed at Cape Lookout State Park, with storms steepening the slope of the berm due to the accumulation of cobbles at the base of the dunes, enhancing their protection from the forces of the storm waves, even during overwash events.

During the summer months with the return of sand to the fronting beach, the cobble deposits are partly to entirely covered. While this sand cover improves the recreational use of the beach during the summer, it potentially has a detrimental effect on the stability of the cobble beach with the return of the fall storms, since the sand fills the voids within the deposit and thereby increases the intensities of both the swash runup and backwash. Usually that sand is removed by the first storms of the fall, but Everts et al. (2002) reported on a site where in 1995 more than a million cubic meters of sand was placed atop and in front of the cobble beach; this led to its erosion during the next winter, even though the storm waves were relatively modest. Also of importance to the stability of the cobble deposits are their patterns of net longshore transport in the winter, during the few months when the waves are able to impact them. Everts et al. (2002) found on the California coast that while the net longshore transport of the sand on the fronting beach is to the south, there is not a net longshore transport of the cobbles, this enhancing their stability and effectiveness in protecting backshore properties. In contrast, on the Oregon coast there is not a net longshore transport of the sand (being confined within "pocket-beach" littoral cells with bounding headlands), but the cobble-tagging experiments of Allan et al. (2006) have documented a significant northward transport due to the dominant approach of the winter storm waves from the southwest. In such a case where the longshore transport results in a net loss of material from a constructed cobble berm, it requires periodic maintenance of the structure by the addition of gravel and cobbles.

Our experience with the construction of this cobble berm on the Oregon coast has illustrated the advantages of this shore-protection strategy (Allan and Komar 2004),

discussed more generally by Ahrens (1990). In keeping with its dynamic nature, the stone sizes are significantly smaller than required for armor in a traditional static revetment. Accordingly, its construction can use the small-size debris from a quarry that is often considered to be waste, although at times the demand is for pre-rounded cobbles, for aesthetic reasons, requiring that the source be a gravel-bed stream or another beach where there is an excess of material so some extraction is possible (this having been the source for the Oregon cobble berm). In reality the requirement that the introduced cobbles be rounded may be unnecessary, as investigations of the rates of gravel abrasion have shown that it can occur quite rapidly, rounding the sharp edges of the particles within a couple of years (Matthews 1983; Dornbusch, et al. 2002). In addition, the placement of the gravel and cobbles in the berm during its construction is straight forward, only requiring its grading into what is assessed to be the approximate equilibrium slope of a natural cobble beach having those particle sizes; in contrast, the construction of a conventional riprap revetment ideally involves the individual placement of the stones to insure their stability. The consequence is that the construction of a cobble berm will be much less expensive than a conventional structure, a riprap revetment or a seawall; in the case of the cobble berm and artificial dune at Cape Lookout State Park, the total cost was about $125,000, whereas the estimated cost for a riprap revetment for that site was $500,000. In addition to these practical advantages derived from constructing a cobble berm for shore protection, its natural and aesthetic form makes it ideal for a park setting, our impression being that few if any people visiting Cape Lookout State Park recognize the cobble berm and artificial dune for what they are, shore-protection structures.

The initial incentive for including the artificial dune backing the cobble berm, to protect the park, was to downsize the berm so that smaller volumes of cobbles were required. As a result, the cobble berm alone would have been insufficient in providing protection to the park, the monitoring program having shown that during even modest storms and high tides, the cobble berm is overtopped (Allan and Komar 2004). The dune was therefore needed to provide back-up protection, to reduce overwash occurrences and flooding of the park's campground. In order to enhance its stability, the dune was constructed with a core of geotextile bags, each filled with sand, covered with loose sand planted with native dune grass. Although the dune does contain this artificial structural component, this combination of a sand dune backing a cobble berm still conforms with the "Design with Nature" philosophy, since one can see this combination at many locations along the West Coast, including within Cape Lookout State Park. As found naturally, this combination has been particularly effective in protecting the park, with the cobble berm primarily having the role of reducing the wave-swash impacts on the dune, while the presence of the dune has reduced the occurrences of overwash and flooding into the park grounds, and has largely prevented the waves from hurling cobbles ballistic-fashion into the campground. A similar hybrid solution could be employed in the protection of sea cliffs that are experiencing erosion, in that case constructing a dynamic cobble berm that fronts a structure of large stones meant to be fixed in position at the base of the cliff; with a sufficient level of wave dissipation by the cobble berm, this backup structure could in effect be a downsized riprap revetment, but constructed to have the

appearance of its being a continuation of the cobble beach, again just as one finds naturally along the coast.

BEACH NOURISHMENT — THE STABILITY OF BEACH FILLS OF SAND

The practice of beach nourishment involves the importation of large quantities of sediment, generally sand, to widen a beach that has experienced erosion, the objective being to restore its recreational uses and to improve the capacity of the beach to buffer shorefront properties from wave attack. In more extreme examples (e.g., the Mediterranean coast of Spain), the undertaking might involve the placement of sand to form a recreational beach where one had not previously existed. Both represent examples of beach fills, akin to the construction of cobble berms but differing in the approaches of their designs as well as sediment sizes. Beach nourishment in particular focuses on the selection of the sand so it provides a reasonable match with the sand already present on the beach, in terms of both its composition and grain sizes, this being a clear instance of "Design with Nature". Another important aspect in the nourishment design is a decision as to how the imported sand will be placed on the beach: should it be spread evenly across the profile, including the surf zone and offshore bars?; should the sand be added only to the visible beach?; should some of the sand be used in the construction of a dune at the back of the beach? Guidance can be derived from Nature as to what to do, or what not to do.

Nature is far less fussy than we are, it working with the sediments available and then molding those sediments into beach forms that are compatible with the forces of the ocean's waves and currents. Here our guidance mainly comes from how Nature designs its beaches in terms of the sediment particle sizes it selects to form the beach, how it sorts those particles according to their sizes and densities, and the morphologic forms acquired by the beach as a whole that yields a degree of stability. For example, on the Oregon coast Nature has a wide spectrum of sediment sizes to work with, from silt and sand contributed by its rivers, to gravel and cobbles eroded from basaltic headlands. Massive landslides are a frequent contributor, containing the full range of particle sizes. It is amazing how rapidly the waves and currents can deal with even the largest inputs of sediment, removing the unwanted silt and fine sand to the offshore, and concentrating the coarser sand into a beach that is effective in dissipating the energy of the waves. If present in the original range of particle sizes supplied to the shore, the gravel and cobbles are selectively transported onshore by the waves to form a cobble ridge at the back of the sandy beach, forming a composite beach (Fig. 1) that maximizes the stability of the shore by having incorporated both Dissipative and Reflective elements in the profile.

One lesson to learn from Nature is that she can take care of herself. If the sand imported for a beach nourishment project contains silt, so be it — so does the sediment supplied by rivers. We tend to underestimate the resilience of Nature, her ability to separate out the grain sizes that best suit her purposes for that coastal site, "flushing" the unwanted silt to deep water with minimal lasting consequences. The same can be said for the placement of the imported sediment on the beach in the nourishment project. No matter where the sand is placed, Nature will go to work on

its rearrangement, just as she does when the delivery is from a river or landslide. It can be argued that the placement should approach as closely as possible the expected natural equilibrium profile — with less sediment redistribution being required, the argument is that less sand will be lost from the nourishment site due to its offshore and longshore transport. This practice, however, would require that the imported sediment be spread evenly across the profile, including through the surf zone and offshore bars, not easily accomplished and increasing the cost of the project. It can equally be argued that the imported sand be placed on the visible portion of the beach, its berm and possibly with some used to construct a foredune. Analyses have shown that this placement temporarily maximizes the protection of backshore properties from the forces of storms, the storm surge and waves, at least until those processes succeed in redistributing the sand into an equilibrium profile by moving a portion of it into the surf zone (Hansen and Byrnes 1991).

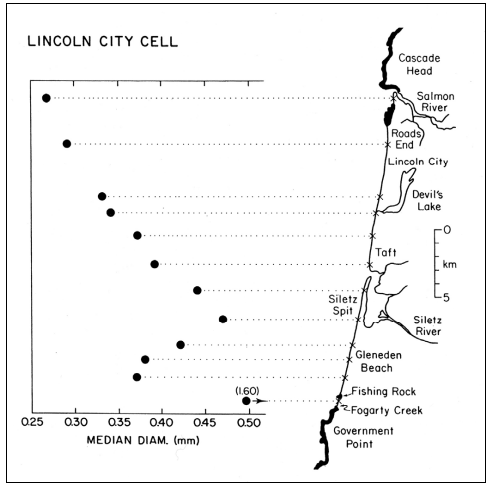

Fig. 4. The longshore variation in beach sediment median grain sizes within an Oregon littoral cell, due to the introduction of coarse sediment by sea-cliff erosion south of Siletz Spit. [*after* Shih and Komar (1994)]

We should not mistakenly accept that Nature always gets it right. Her experiments with forming beaches have not always been successful in terms of maximizing their stability, but we can learn from her mistakes. Again, an example is found on the Oregon coast (Shih and Komar 1994), where Nature is in the process of undertaking her own beach nourishment project, but one that has turned out badly by having rendered the beach more unstable. The shore of interest is the central stretch of beach within the Lincoln City Littoral Cell, Figure 4, a "pocket beach" cell trapped between rocky headlands, where there is a seasonally reversing longshore sediment transport but with the net transport in the long term being effectively zero. Initially this beach would have been composed of a medium-grained sand (0.25 mm), typical of the

Oregon coast; with that grain size it would have been a Dissipative beach in the morphodynamics classification of Wright and Short (1983), and therefore would have been relatively stable. The beach nourishment experiment undertaken by Nature is interpreted to have begun about 300 hundred years ago, precisely on 26 January 1700 when a magnitude-9 subduction earthquake caused this stretch of coast to abruptly drop down by 1 to 2 meters, resulting in the inception of the sea-cliff erosion that continues today. The cliff immediately south of Siletz Spit and along the shore of Gleneden Beach is composed of Pleistocene coarse sand and granules, with some small-diameter gravel. Nature's beach nourishment project was therefore forced to use this coarser sediment, and its introduction at that site has resulted in the longshore variation in beach sediment median grain sizes graphed in Figure 4, produced by the spreading (diffusion) of the introduced sand. The beach at the nourishment site now has a median diameter of 0.47 mm, whereas at the far north end of the Cell's shoreline (Roads End) the median diameter is still 0.25 mm. Nature's experiment with beach nourishment here on the Oregon coast would appear to conform with our general practice of selecting a somewhat coarser sediment for the material to be added to the beach, the expectation being that it would reduce offshore losses and enhance the stability of the beach. Nature's experiment on the Oregon coast has had just the opposite response; the addition of the coarser sediment increased the beach slopes in the Gleneden Beach and Siletz Spit areas, so they were converted from stable Dissipative beaches into highly dynamic Intermediate beaches. As a result, this stretch of shore now has one of the highest rates of erosion along the Oregon coast; in contrast, the beach at the far north end of the Cell, where the sand still has a 0.25mm diameter, has remained Dissipative and relatively stable under identical wave conditions. With the local enhanced sea-cliff erosion at Gleneden Beach, still more coarse-grained sediment is being added to the beach, continuing Nature's experiment, and unfortunately in doing so is further exacerbating the erosion problems.

In terms of the coasts of the United States, the above example has the primary relevance to the West Coast where the combination of relatively fine-grained beaches and swell waves of low steepness result in the beaches being Dissipative. If one is to undertake a beach nourishment project, caution is required not to add sediment that is of sufficient coarseness it converts the beach into an Intermediate category in the classification of Wright and Short (1983), as this will likely insure that there are increased problems with erosion. On the other hand, on the East Coast the beaches are generally already Intermediate, with that at the Field Research Facility of the U.S. Army Corps of Engineers, in Duck, North Carolina being a well-studied example [see Lippmann and Holman (1990) in the context of placing its morphodynamics into the classification of Wright and Short (1983)]. In this case, in principle it would be good from a stability standpoint to add sufficient quantities of coarse-grained sediment to push the beach into the Reflective category, but this would likely be objected to on the basis of its recreational uses. However, my impression is that the beach at the Field Research Facility provides a natural example where the stability might be improved by the addition of relatively small quantities of gravel. At that site the natural presence of the gravel has resulted in its concentration at the base of the beach face, forming something of a step along the seaward edge of the swash zone. As a

result, although the offshore bars have experienced the dramatic cycles one expects of Intermediate beaches under the changing wave conditions, the beach face and width of the sand berm have been more stable than found on other East Coast Intermediate beaches where a gravel component is not found. Nature may be telling us something in this example, holding a key to the improved stability of those beaches.

SUMMARY AND DISCUSSION

The theme of this paper has been that we can learn from Nature in the development of new strategies directed toward increasing the stability of our coasts, approaches that are aesthetic in having adopted natural forms while providing sufficient protection to shorefront properties. We have examined a range of beach fills, from cobble berms (dynamic revetments) that involve the construction of an artificial beach composed of imported gravel and cobbles, to the common practice of beach nourishment with sand. Research completed over the years on their natural counterparts found along coasts can serve as the basis for the designs of these beach fills, with recent investigations having focused specifically on gathering data from the natural beaches on coasts where cobble berms are to be constructed.

It is apparent that these natural strategies will seldom provide the same degree of shore protection as a massive riprap revetment or seawall that has been properly designed by an engineer. Therefore, their use will likely be primarily in natural settings such as parks where those conventional structures are undesirable, or in jurisdictions where they are outright forbidden. In order to enhance their abilities to provide sufficient protection, it may be necessary to employ combinations of forms, hybrids, just as commonly found in Nature. For example, we have seen that composite beaches (Fig. 1) can yield the greatest degree of stability, where a sand beach fronts a cobble berm, each contributing to the dissipation of the storm-wave energy. Similarly, the constructed cobble berm might be backed by a down-scaled static revetment of large stones, blended to give more of a continuum as found naturally along rocky coasts. Otherwise, as constructed at Cape Lookout State Park on the Oregon coast, the cobble berm could be backed by an artificial sand dune reinforced with a core of sand-filled geotextile bags to enhance its stability. We need to be more imaginative in our approaches directed toward shore protection, as in those combinations, so the resulting structure maintains a natural appearance while at the same time offers a significant measure of stability.

With this approach to restoration and protection being rather unconventional, its undertaking might best be accomplished as a team effort, including a coastal engineer and a geologist who is familiar with the details of the natural beach forms; and where the placement of the beach fill is within a park, a landscape architect could also make a contribution.

VARIATION IN THE ORGANISATION OF GRAVEL-DOMINATED COASTAL SYSTEMS: EVIDENCE FROM NOVA SCOTIA AND SOUTHERN ENGLAND

Abstract: Over the last two decades, a model of coastal gravel barrier evolution dependent on paraglacial reworking of limited, point-sourced glacigenic deposition has been proposed based on the Holocene evolution of the Nova Scotia Atlantic shoreline. Essential controls in this sequence were dependent on relative sea-level rise rate, sediment supply, basement structure and wave climate. Key in this sequence was the move from drift-aligned to swash-aligned barriers as a one-way process, with an emphasis that such swash alignment induced relative stability of barrier in the face of wave climate variability. Contemporary evidence from Nova Scotia following an extreme event and inferred environmental reconstruction of the gravel dominated barriers of southern England, suggest that swash-alignment is not as stable as hitherto identified, and that reversals from swash to drift-alignment and quick breakdown by extreme storm need to be considered as part of the potential sequence of gravel barrier evolution.

INTRODUCTION

The mesoscale dynamics and organization of gravel dominated coasts including source, transport and sink elements has been developed in a series of papers (Orford et al. 1991; 1996; 2002) dealing with the Eastern Shore of Nova Scotia (NS) (Fig.1A). These developments have been noted particularly in the context of; fast relative sea-level rise (RSLR: c.4mm a^{-1}); finite paraglacial sediment source supply in the form of drumlins; and discordant lithified basement plan-geometries (estuaries and headlands); all contributing to coastal barrier evolution over time scales of c 2-3ka. A key element in

this barrier evolution sequence was the move from sediment-rich, drift-aligned (DA) barriers to sediment-deficit swash-alignment (SA) barriers, with an emphasis that once SA was achieved there was a domain shift in spatial barrier activity as longshore transport transformed into cross-barrier transport through barrier rollover processes. Orford et al. (1991) identified the basic sequence of such barrier morphological change based on the limited glacigenic sediment sources characteristic of the NS coastline. The swash domain was thought to occupy a longer time phase compared with the drift domain, eventually transforming into a breakdown phase. The conditional basis for this transformation has remained uncertain, given that the SA barrier was thought to be well tuned to storm events: even to catastrophic events (Orford et al. 2003). Hurricane activity on the Eastern Shore (Sept 2003) provided the forcing to address the extreme event issue and possible barrier breakdown. This NS barrier sequence has yet to be tested elsewhere, so this paper also addresses how in comparison the gravel-dominated shoreline of southern England (Fig.1B) evolved in the mid- to late-Holocene. The use of similar concepts of sediment cell development and associated morpho-sedimentary assemblages are considered in the light of both limited RSL change and sediment supply, but where spatial freedom of barrier morphology is radically restricted by lithified basement morphology that is strongly cliff-controlled, unlike the low-lying NS coastline.

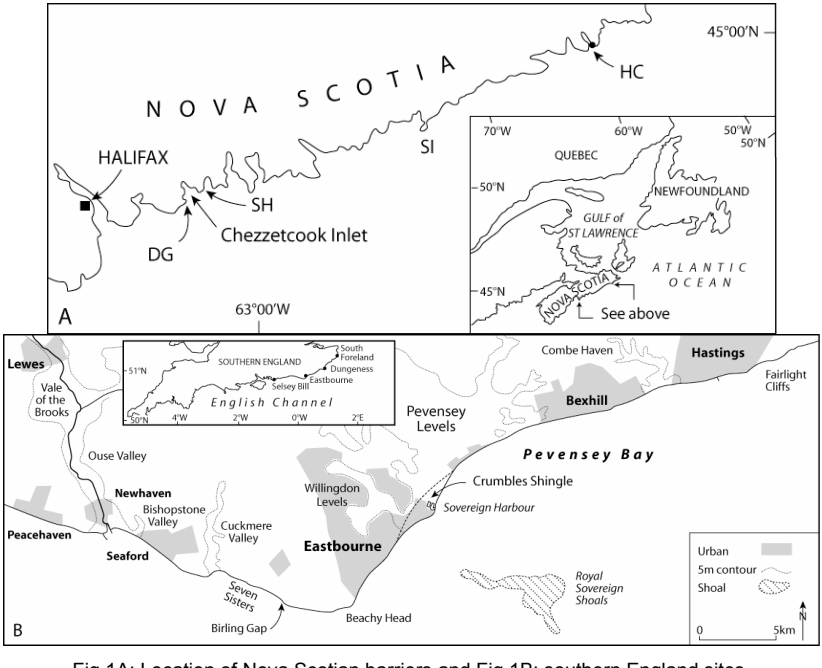

Fig.1A: Location of Nova Scotian barriers and Fig.1B: southern England sites.

METHODS

The analysis of Nova Scotian barriers (pre-2000AD) was based on comparison of serial air photography (over 50 years), and field survey of barriers and nearshore morphology. Recent extreme event forcing of morphology post-2000AD, along the NS coast has been examined from two sources: aerial photography taken pre- and post Hurricane Juan (28.9.03) (courtesy of N.S. Dept Natural Resources) and satellite images post-2003 (via Google Earth™). The H. Juan imagery is only available for the hurricane track path that crossed the NS coast east of Halifax, and offers GIS vector overlays of shoreline change post hurricane passage (DNR 2003). This allows direct shoreline examination of two key SA barrier sites from previous analyses: Story Head and Grand Desert (both at the mouth of Chezzetcook Inlet). These hurricane change outlines have been superimposed on existing barrier retreat data over the period of c 1933 to 1987 (Orford et al. 1996 2002) and allow examination of both barrier morphology and barrier retreat. This source of post-hurricane analysis is not available for positions at the eastern end of NS, however examination of two further key SA sites in this eastern zone (Sober Island and Haulover Cove) using Google Earth imagery (albeit at small scale) allows definition of major domain changes in both barriers since 2000AD.

The reconstructions of southern English barriers are based on an analytical deduction process by which published lower-estuary stratigraphies (Table 1) are translated into phases of environmental control on estuary deposition through the presence or absence of cross-estuary mouth barriers sufficient to allow organic deposition, or marine sands/silts respectively, to dominate the estuary fill.

RECENT BARRIER ACTIVITY IN NOVA SCOTIA

Nova Scotian Model

In Nova Scotia the speed and totality of the exhumation of point sediment sources (drumlins) under fast RSLR (c.4mm a-1) has generally led to single mesoscale cycles of variable longshore sediment transport dominated by early rising limbs of sediment surplus, and later falling limbs of sediment deficit, both of which define the cycle. These two domains of sediment supply have led to temporal overlapping of dual semi-synchronous phases of sediment aggradation through DA and then subsequent sediment cannibalisation leading to SA. The clarity of these morpho-sedimentary phases and the cessation of longshore sediment supply from the source area means that the

cannibalisation phases appear to be dominant in contemporary shorelines, such that resultant morphologies are dominated by a single crested SA ridge that is being forced towards breakdown phases under fast RSLR.

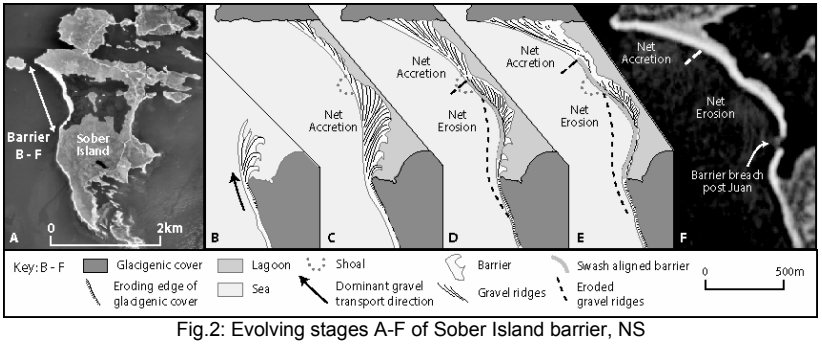

Fig.2: Evolving stages A-F of Sober Island barrier, NS

Figure 2 shows the likely spatial sequence of barrier development at Sober Island (75km east of Halifax) as an example of this barrier evolution. Figure 2A shows SI in the late 1980s with longshore sequences of SA and DA beach ridges. A period of a prior DA spit growth (Fig.2B) under high sediment transport rate relative to sink shoreline length, has changed into proto SA as the barrier sink distance expands relative to diminishing sediment volume from the drumlin source (Fig.2C-E). Cannibalisation of the old drift barrier, as witnessed by the expanding SA section, is supplying sufficient sediment to maintain a down-drift DA section, though this process is controlled by the extent to which the SA barrier can remain coherent as it is forced further backwards by rollover, and extends northwards as longshore cannibalization continues. The natural rock basement to the north of the barrier acted as a groyne and prevented loss of gravels further down-drift away from the barrier system. This lack of onward down-drift transport appeared to be the control on rate of longshore swash-alignment encroachment. In 2000AD this barrier appeared to be transport-deflected from complete swash-alignment, as shown by other previously mixed alignment systems (e.g. Haulover Cove: Fig.3A).

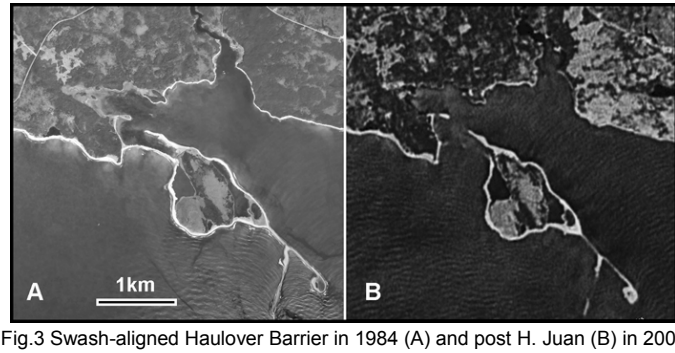

Fig.3 Swash-aligned Haulover Barrier in 1984 (A) and post H. Juan (B) in 2003

Swash-alignment was thought to be the stable long-term barrier configuration, especially when RSL rise was not fast (<2mma^{-1}). Barrier stability has to be considered in terms of the barrier volume being stretched over an increasing barrier extension distance, as it retreats through both RSL rise, and by rollover. However, in areas of fast RSL (and with an eye on future management problems of accelerated RSL) stability of swash-alignment is somewhat of a moot point. If swash alignment leads to stability, then the length of shoreline with swash-alignment features should be high relative to existing barrier length, though this would diminish as RSLR increases. Jennings et al. (1998) suggest that with RSLR of >8mma^{-1}, barrier coherence is radically threatened and breakdown likely. In NS there is a scarcity of SA, (<10% of the Atlantic NS coastline), which while being greater than DA, is significantly less than what would be expected given the potential of basement structure and sediment sources. However given that the rate at which barriers could move into the breakdown phase is unknown, the long-term stability of SA remains unknown.

Extreme events have been identified as a significant forcing in gravel barrier retreat (e.g. Orford et al. 2002), however evidence for catastrophic breakdown has been limited. Post Hurricane Juan (Sept.2003) an assessment of what a severe extreme event can do to swash alignment can be made. Hurricane Juan was, a Category 2 event that made landfall west of Halifax NS (28.09.03), and is regarded by Dept of Natural Resources (NS) as NS's worst 20th century coastal storm (DNR 2003). Juan generated southerly waves with H_s of 9m off Halifax harbour and H_{max} of 19-20m at hurricane landfall, while moving onshore associated with a 1.5m surge at Halifax harbour (Bowyer 2003).

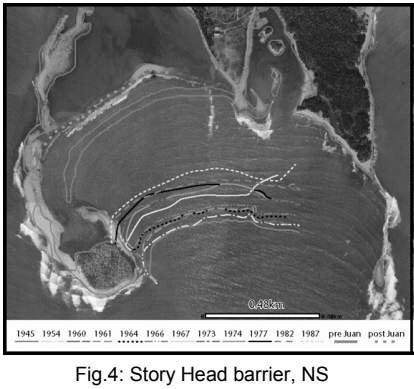

Fig.4: Story Head barrier, NS

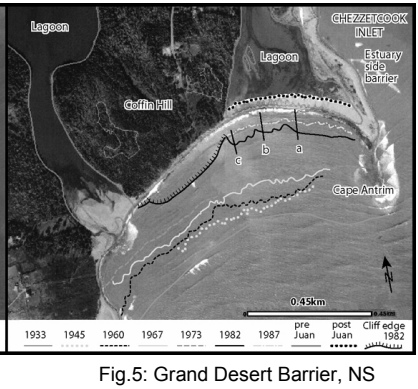

Fig.5: Grand Desert Barrier, NS

Story Head is a SA barrier (25km east of Halifax, Fig.4) facing south at the eastern side of Chezzetcook Inlet entrance. It had a well-documented rapid barrier retreat history between 1930-90 (Orford et al. 1996), but post-Juan is now broken down into wave washed shoals. Story Head was a low barrier (crest height at <4m NAD (1928)) and height appears to be a major factor in breakdown, given that Grand Desert barrier (western side of Chezzetcook, Fig.5) at 8-9m NAD (1928) crest height, also facing directly into the wave path was forced to retreat, but retained its overall SA structure.

The severity of the storm reduced towards the east, but was sufficient, as Fig.2F indicates, for Sober Island's SA section to be breached, with the northerly hard rock groyne now overlapped by reworked barrier sediments under southerly wave activity, identifying a new sediment pathway by which the sediment volume of the barrier can be reduced. Haulover Cove (120km east of Halifax: Fig.3B) exhibits a total reduction of the SA barrier to a sub-tidal elevation. SA barriers in both cases were evidently insufficient (in terms of barrier height and width) to resist the wave climate extremes and in the case of Haulover, to rebuild the barrier in the manner identified by Orford et al. (2003), i.e. the sediment volume was insufficient to recreate a stable profile.

MID- TO LATE-HOLOCENE BARRIER CHANGES IN SOUTHERN ENGLAND

This issue of overall spatial organization of gravel-dominated barriers and the balance of DA to SA has to be reconsidered when the context of sediment supply and RSL change rates are restricted. The south coast of England represents a near-iconic gravel dominated (≈ shingle) coastline with world-known classic depositional structures in Chesil Beach and Dungeness Foreland. In particular the gravel systems of Sussex (central southern England: between Brighton - Beach Head – Hastings – Dungeness: Fig1B)), which may have linked to the major Dungeness Foreland gravel accumulation, have had limited consideration in terms of source and transport corridors. The contemporary coast is one that is gravel starved (and sand starved; Anthony 2002), yet is managed through a process of beach replenishment and profile maintenance into a posture of barrier coherence implying SA around hard points of Tertiary cliffs and 20th century built-infrastructure.

This coastline presents a difficult task in establishing barrier reorganization given the scarcity of sediment record under the managed volumes. To obtain a perspective on how past barriers have evolved, stratigraphical analysis of freshwater and salt water organic phases as well as minerogenic deposition have been considered in six estuaries operating along this coast (Table 1: Fig.1B). Because there is no evidence for any RSL fall along this coast during the last 5ka, it is likely that the consolidation of barrier beaches principally controlled these regressive organic deposition/episodes. Barrier consolidation is likely to reflect periods of greater sediment input and throughput, and therefore, by implication, a period of stronger longshore transport, with cell elongation and greater spacing between cell boundaries. Under these conditions, the inlets to the six estuaries narrowed or closed, depending on the volume of river discharge. Conversely, periods when estuarine or marine silty clays and fine sands were deposited represent transgressive episodes resulting principally from inlet widening as a consequence of reduced longshore sediment transport. Such episodes would have been associated with cell breakdown and reduced cell boundary spacing, the boundaries located principally around the inlets. On this basis four time-slices in the last 5ka have been identified in which varying storminess and access to sediment have been specified to account for barrier structure. The full establishment of the total drift cell was probably only achieved briefly during some of the stormiest conditions of the Little Ice Age (16th - 17th centuries AD), a perturbation which has dominated coastal cell development and management lasting to the present day.

The early Holocene legacy

The reconstruction of cell development, discussed below, begins around 5,000 Cal yrs BP. This is because prior to this period, RSL was below –5 m O.D. and the configuration of the coastline was controlled more than it is today by the shape of the buried channel systems emanating from these former estuaries and coalescing with the palaeovalley system eroded into the bed of the English Channel (Antoine et al. 2003). Potentially, this more indented coastline of the early Holocene would have had a very different sediment transport system to that of the mid- to late-Holocene, with greater control exerted by headlands. Under this scenario, as RSL rose sufficiently to drown these headlands, the potential for the development of more extensive transport corridors increased. However, the abundant sediment available in the early Holocene, inherited from Pleistocene periglacial processes, probably facilitated an active drift system with sediment able to by-pass headlands. Therefore, early-Holocene barrier inception and consolidation was likely, together with the segregation of sand and gravel into discrete depositional zones within the English Channel (Anthony 2002).

The drowning of this landscape had two major consequences on the subsequent macroscale development of cell formation. First, it transferred shoreline processes to areas of flatter relief associated with former interfluves and to shore platforms whose formation may have been initiated under previous high RSL episodes. Second, it trapped and drowned extensive gravel deposits in the palaeovalleys of the English Channel (Bellamy 1995; Antoine et al. 2003), effectively removing a substantial body of sediment from contributing to the later-Holocene sediment transport system. Consequently, the coastline entered a phase of gravel sediment starvation, relying on very limited supplies from near-shore deposits, which were/are in sufficiently shallow water to be activated and moved onshore by (storm) waves, on the re-working of isolated raised beach deposits to the west (e.g. at Selsey Bill and Brighton) and on 'freshly' weathered flint from chalk cliffs, the latter providing only low volumes of material.

Cell development episodes

Four episodes of cell development from 5,000 Cal yrs BP have been identified, based principally upon the nature of estuary infill, as discussed above.

Episode 1: 5,000 Cal yrs BP (Fig. 6). At this time the estuaries to the west of Beachy Head (BH on Figs.6-9) were accumulating organic, regressive sediments, associated with freshwater fen (Thorley 1981; Jones 1971). However, estuaries generally to the east of Beachy Head were open to the sea (Jennings & Smyth 1987 & 1990). The Royal Sovereign Shoals, immediately to the east of Beachy Head would have been above MHW, effectively forming an extension to Beachy Head. The shoals today are exposed at LWST, and it is likely that they formed a significant landmass during the early- to mid-Holocene. Therefore, sediment was being transported in sufficient quantities to restrict tidal access in the western estuaries, and it is likely that a transport corridor existed east to the Royal Sovereign Shoals. Because eastern estuaries were open to the sea, this transport corridor must have had a boundary on the Royal Sovereign Shoals

(Fig. 4), with sand and gravel accumulating in the down-drift segment of the cell.

The form of the coastline to the east of Beachy Head was very different to that of today.

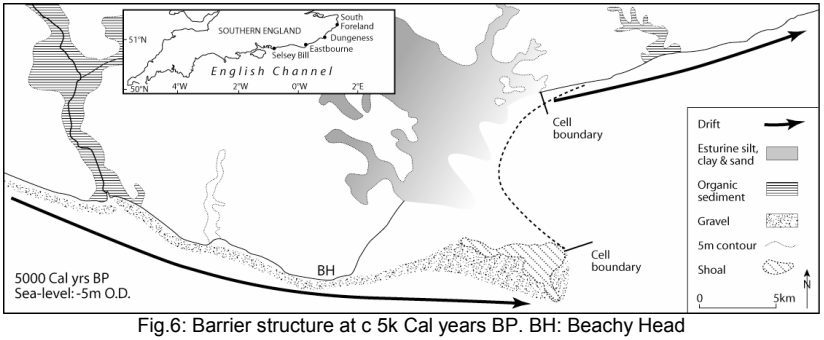

Fig.6: Barrier structure at c 5k Cal years BP. BH: Beachy Head

A broad estuary fronting Willingdon and Pevensey Levels (northeast of Beachy Head) probably extended southeast towards the Royal Sovereign Shoals. Evidence for this, is the existence of mid-Holocene estuarine sediments that reach the present coast at Willingdon Levels, and therefore are likely to have extended beyond this point.

Episode 2: 4,000 cal yrs BP (Fig.7). By 4000 years, western estuaries had opened while eastern ones had closed. The regression establishing largely freshwater conditions in these estuaries identifies a period of approximately 700 years when all the eastern estuaries of East Sussex may have been closed, and a single drift cell established: similar conditions to that from the inception of the current cell (in the 12th century – see Episode 4) to its modern breakdown.

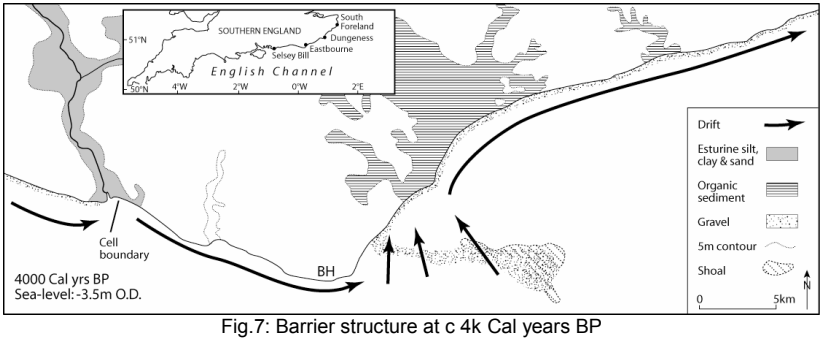

Fig.7: Barrier structure at c 4k Cal years BP

The opening of the western valleys indicates the establishment of a cell boundary at their entrance, and was likely to have triggered the formation of an ebb-tidal delta, imparting a positive feedback to the establishment of a cell boundary. As a consequence, sediment in the down-drift section of the former cell, now cut off from up-drift supplies, would have

been cannibalised and the associated gravel barrier would have broken down. This is depicted on Fig.5 by arrows showing sediment moving from the Royal Sovereign Shoals onto the adjacent section of coast at Willingdon and Pevensey Levels. Such a breakdown of the down-drift section of a former cell would have injected sediment in sufficient quantity to close off the former estuary mouth and create a stronger sediment transport corridor from Willingdon Levels eastwards, ultimately feeding Dungeness, the store at the down-drift end of the cell. Long & Innes (1993) provide evidence for gravel accumulation at Dungeness at around this time. These changes to cell positions and size, and the re-distribution of gravel from stores to adjacent sections of shoreline occurred approximately at the start of a period of increasingly wetter (and stormier?) conditions (Blackford 2000).

Episode 3: 2,500 Cal yrs BP (Fig.8). This period of the mid- to late-Holocene was characterised by a very slow rate of RSL rise, and therefore resulted in very limited sediment input from freshly weathered gravel. Also, most of the offshore, 'inherited' gravel sediment had been transferred onshore, although there may have been a remnant on the Royal Sovereign Shoals. As a consequence of this diminished sediment supply, the two cells present in the previous episode broke down into a number of smaller units, their boundaries located at estuaries. This fragmented and diminished drift system caused all the estuaries to be open. The continuation of this episode of fragmented cell development to the present day was prevented by a major perturbation that re-activated the sediment transport system. This re-activation resulted in major geomorphological changes, in particular the re-establishment of barrier beaches (as drift-dominated) and a switch from open to closed estuaries, resulting from the establishment of a single coastal cell defining an active and extensive transport corridor. This perturbation was driven by a climatic change to the increasingly stormier and colder conditions of the Little Ice Age, which had set in by the mid-13th century and ended by the mid-19th century (Higgitt 2001).

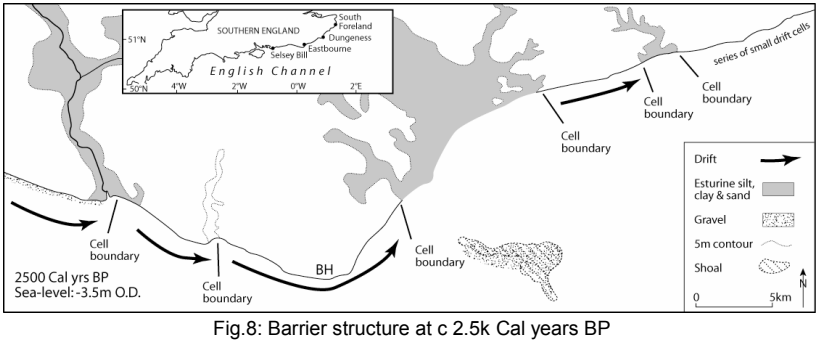

Fig.8: Barrier structure at c 2.5k Cal years BP

Episode 4: 12th to 17th centuries (Fig. 9). Evidence for the inception of the present cell system, dating to around the 12th century, is reclamation on Pevensey Levels (Salzman 1910; Dulley 1966) and on the marshes adjacent to the Rye barriers (Eddison 1998), which appears to correspond to a period of increased sediment supplies, at least locally.

For example, near Pevensey a tide mill was becoming inoperative by the second half of the 12th century, due to reduced tidal flow (Salzman 1910). Salt working on Pevensey Levels ceased in the mid-13th century (Dulley 1966) due to the cessation of regular tidal inundation, and gravel drifting across inlets is in evidence at Hastings by the 14th century (Ward 1920). This build-up and transport of gravel was probably the consequence of the initial stages in the formation of a major gravel assemblage known as the Crumbles Shingle (Fig.9).

The development of the Crumbles Shingle begins with the prior extensive estuarine conditions (Episode 3) at the mouth of the former Willingdon and Pevensey estuaries, inferring a possible ebb delta origin (Jennings & Smyth 1987). This substantial sand body subsequently formed a foundation for gravel accumulation, a pattern that is similar to the development of Dungeness (Basa et al. 1997; Long et al. 2006). The trigger for a change from a sand-dominated to a gravel-dominated system at the Crumbles means a re-activation of gravel supplies feeding onto the dissipative shoals. Jennings & Smyth (1990 &1991) have argued that the source of this gravel was more likely from offshore than longshore, as gravel deposits originating from alongshore were limited in extent, and the size of the former Crumbles was substantially bigger (Waghenaer's chart of 1588 and John Norden's map of 1595 indicate a 2km shoreline seaward of the present day) than local cliff-sourced longshore sediments could supply.

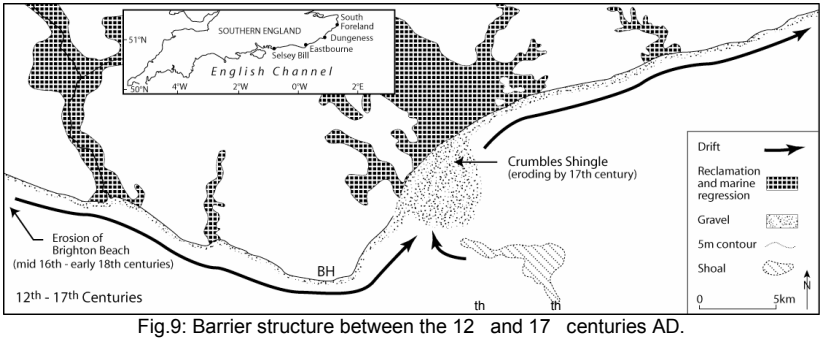

Fig.9: Barrier structure between the 12th and 17th centuries AD.

The proximity of the shoreline of the original Crumbles Shingle to the Royal Sovereign Shoal infers a sediment transfer from those shoals onshore and onto the sand body that lay between the Royal Sovereign Shoals and the entrance to Willingdon and Pevensey inlets. Under the initial prevailing dissipative conditions, gravel would have accumulated on the sand body until it had formed a structure large enough to establish reflective morphodynamic conditions (Jennings & Smyth 1990). Once that had occurred, longshore drift would have been initiated due to changes in the breaker characteristics as reflective conditions replaced dissipative ones.

This reconstruction of the origin of the Crumbles Shingle assumes a residual body of gravel on the Royal Sovereign Shoals following Episode 3, and its re-activation shoreward under the increased storminess of the Little Ice Age. Precisely dating the

origin of the Crumbles Shingle is problematic as it occurred at a time that pre-dates detailed documentary and map evidence, but a date of around the 12th century is commensurate with the documentary evidence summarised above. Intriguingly the re-entry and reworking of Crumble gravels into the eastern drift system did not appear to alleviate the sediment deficit position of the East Sussex barrier (e.g. SA) linking via the Rye barrier to the Dungeness Foreland. The period from the 12th to the 15th centuries witnessed numerous marine floods that regularly threatened reclamation attempts (Dulley 1966; Brandon 1972) and gave rise to substantial coastal re-alignment, especially in Rye Bay (adjacent to eastern limit of Fig. 1B). The possible 'breakdown' of the Rye Bay Barrier corresponds to a sequence of storms between 1250 to1291AD (Eddison 1998) leading to a pattern of continuous or episodic retreat of the barrier, rather than breakdown *per se*, a continuation of a process that started as the barrier rolled-over during Episode 3, as a consequence of diminished sediment supplies. Edison (1998) estimates the rollback as c. 2 km in approximately 300 years. This gives an approximate (minimum) retreat rate of 7 m a^{-1}. This realignment isolated Dungeness from up-drift supplies of gravel.

The early development of the Crumbles could be described as a localised redistribution of near-shore supplies. By the 16th to 17th centuries sufficient volumes of gravel were being transported along the coastline to the east of Beachy Head to prevent regular flooding, for example, at Pevensey (Salzman 1910; Dulley 1966). This period also saw major progradation of gravel ridges to the south of Rye, (Eddison 1998) which failed to connect with Dungeness due to the major indented realignment of the transport corridor by the rapid retreat of the original Rye barrier (cf. Long et al. 2006). This increase in the volume and spatial extent of longshore drift was largely due to erosion of the Crumbles Shingle, with the gravel being transported eastwards into Rye Bay.

Therefore, by the 16th century the re-distribution of gravel from the Crumbles was largely responsible for the establishment of an extensive cell and marked a significant change to the morphodynamics of the East Sussex coast. The consolidation of gravel beaches and barriers signaled the emergence of predominantly reflective conditions, which was a pre-requisite for the formation of an extensive cell. This cell, to the east of Beachy Head, functioned principally to re-distribute gravel from the Crumbles to the Rye Bay barrier. This episode of cell development ended 'naturally' soon after the 17th century. Cell fragmentation, resulting from decreasing volumes of sediment redistributed from the Crumbles would have been inevitable. However, the interplay between coastal management and cell fragmentation has modified cell development over the last two hundred years. The construction of groynes since the mid-19th century, and more recently gravel recharge on the Crumbles Shingle area has slowed erosion there. However, this has caused acceleration in the fragmentation of the down-drift part of the cell, with severe erosion occurring from Pevensey Bay eastwards. This coastline is now only stabilized through constant management by gravel recharging.

DISCUSSION

In Nova Scotia, of the four SA barriers monitored, H. Juan forced a breach in one, broke down two and forced major retreat in the fourth – all occurring in a storm whose wave excitation was of a 110 year return period. In a 2-3ka organizational span of drumlin-sourced barriers in NS, this return periodicity drives a high statistical likelihood that SA barriers will be moved into a breakdown phase and associated shoal features. The low percentage of SA along the NS coastline is interpreted as showing that the breakdown transition may occur more often than hitherto identified. If this is the case, then SA barriers should not be considered as sustainable features, with obvious implications for future management of such barriers. This perspective has to be constrained by three other factors: (1) the RSLR rate which sets the tempo of barrier change, (2) the spatial density of hinge positions on the basement relief upon which SA is fixed relative to sediment availability for barrier linkage; and (3) the consistency of longshore sediment supply. The last point is critical, as it is noticeable in NS that those SA barriers that are less prone to storm damage, are those with a major sand component that appears via a distinct foreshore apron and nearshore dissipative bottom that attenuate severe wave attack. In effect, the greater the domination by the gravel component of barrier volume, the more reflective the beach face is, and the longer and deeper the plan-view arc of the barrier (and concomitant loss of barrier height with increasing barrier length), then the more likely rapid rollover and final breakdown by storms will occur.

Southern England barriers show overall barrier behavior fitting into a punctuated self-organization of gravel barrier coasts (Forbes et al. 1995) that is characteristic of NS. In southern England over a time resolution approximately similar to the NS cycle, there have been periods of quiescence, characterised here by fragmented cells and open estuaries, that were interrupted by shorter episodes of rapid reorganization, marked by gravel barrier genesis and breakdown, and the establishment of active longshore sediment transport corridor and inlet closure. The major contrast has been in the variation of the basement zone in which these periods of reorganization have been able to take place. NS has a wider horizontal freedom whereas southern England has a constrained corridor. The narrowness of the coastal zone has seen barrier reorganization overlying barriers in a similar spatial position (building limited palimpsest) during the last 4-5ka, hence suggesting a different model of spatial organization than that identified for Nova Scotia. It is still one controlled by sediment supply and position of sources, but one where such sources are spatially constrained and barriers constantly cannibalised at smaller length and diminishing time scales as the overall volume of gravel availability declines. The four-time slices identify a changing gravel barrier organization with the development of DA that closes estuaries, and then reopens as the barriers segment into SA units. There is a revitalization of barriers that relates to a redistribution of gravel sinks into new phases of DA, though the overall reduction of such gravel sinks leads to a progressive thinning and segmentation of barriers. The survival of these depleted barriers as SA features has now more to do with post mid-19th century coastal defence policy than anything else. Without this defensive element these barriers would have now moved into a breakdown phase.

CONCLUSION

Swash-aligned barriers are not now thought to be long-term semi-equilibrium features, as they are prone to breakdown with extreme storms likely to be the agent of such breakdown. The breakdown process is controlled by the virtual cessation of longshore sediment transport, sufficient for swash alignment to develop as a precursor to breakdown. Where revitalization of transport rates is available, then SA barriers can be restructured as DA, as seen in southern England. The major difference between Nova Scotia and southern England barrier development is in the effective spatial width of the coastal pathway in which barriers were built. Where RSLR is low and basement morphology exerts spatial constraints on the barrier building, then forcing changes are more likely to allow revitalization of existing barriers, so that sequences of DA to SA to DA barriers can occur. Coastal defences (as in southern England) can deflect barrier breakdown and by masking breakdown trends may account for contributing towards the supposed resilience of swash-aligned barriers.

PROFILE DYNAMICS AND PARTICLE TRACER MOBILITY OF A COBBLE BERM CONSTRUCTED ON THE OREGON COAST

Jonathan C. Allan and Roger Hart

Oregon Department of Geology and Mineral Industries, Coastal Field Office,
P.O. Box 1033, Newport, OR 97365, USA. jonathan.allan@dogami.state.or.us.

Abstract: In response to the erosion of Cape Lookout State Park on the Oregon coast, a cobble berm (dynamic revetment) was constructed for shore protection, designed to be similar to a natural cobble beach. For added protection it is backed by an artificial dune reinforced with a core of sand-filled geotextile bags. We have monitored these structures since 2001, including periodic surveys and measurements of cobble mobility through particle tagging. The surveys have demonstrated profile responses to storms that are the same as found for natural cobble beaches, while the particle tagging has documented a high degree of cobble mobility, including a significant net longshore transport. To date the structures have survived five winters, including several major storms that have resulted in periodic overtopping, providing the desired level of protection to the park. However, due to the loss of cobbles from the cobble berm, its long-term stability is uncertain.

INTRODUCTION

Gravel beaches, consisting of pebbles to large cobbles, have long been recognized as an effective form of natural coastal protection, exhibiting a remarkable degree of stability in the face of sustained wave attack while also minimizing the potential for overtopping and inundation (Nicholls and Webber 1988; Sherman 1991; Bradbury and Powell 1992). This is because gravels exhibit a greater propensity for onshore movement compared with sand-size particles, partially due to their high threshold of motion and because of the asymmetry of shoaling waves and swash velocities on the beach face. As a result, the gravels accumulate landward of the swash zone where they form a high, steep sloping gravel beach that is able to disrupt and dissipate the incident-wave energy, adjusting its morphology to the prevailing waves. Thus,

artificially constructed gravel beaches have been suggested as a viable approach for protection from coastal erosion (van Hijum 1974; Ahrens 1990). However, few studies have demonstrated the effectiveness of such structures on high energy shores.

During the past decade, significant erosion has occurred along the Pacific Northwest coast of Oregon produced by an unprecedented number of severe storms and as a result of the occurrence of major El Niños. This erosion has been especially chronic at Cape Lookout State Park (CLSP), Figure 1, located at the south end of Netarts Spit on the northern Oregon coast (Komar 1998).

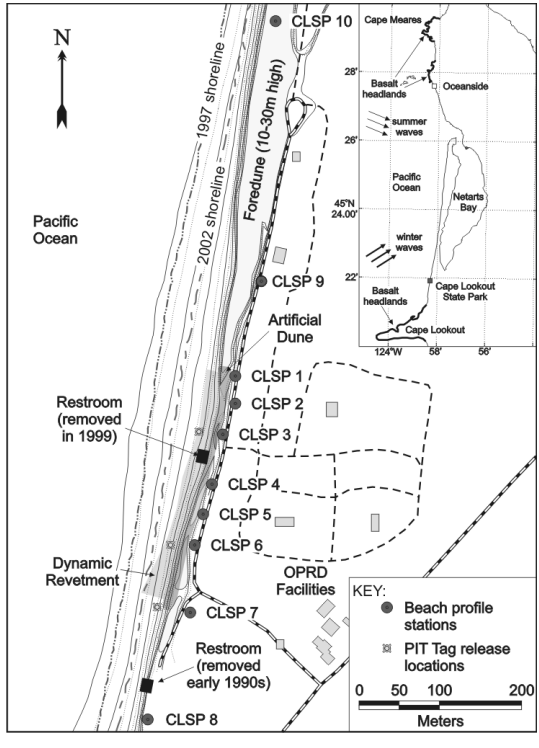

Fig. 1 Location map of Cape Lookout State Park showing the beach monitoring sites and the gravel tracer release points.

Netarts Spit has a history of alternating phases of erosion, followed by subsequent beach and dune rebuilding. For example, Stembridge (1975) observed that the spit was breached at multiple locations as a result of a period of intense storm activity during the winter of 1939. However, the breaches soon filled and the spit remained stable up until the early 1980s. Erosion returned to Netarts Spit as a result of the 1982-83 El Niño (Komar 1986), which produced a combination of high ocean water levels coupled with large waves. The arrival of the storm waves from the southwest resulted in "hotspot" erosion at the south end of the spit, with the sand having been

removed to offshore bars and to the north as the result of longshore transport. The erosion eventually destroyed a wooden bulkhead constructed in the 1960s seaward of the campground by the Oregon State Parks and Recreation Department (OPRD). While the beach did rebuild during the late 1980s, the amount of aggradation was generally small. Erosion returned during the late 1990s, first as "hotspot" erosion associated with the major 1997-98 El Niño (Komar 1998; Revell et al. 2002), followed by the extreme 1998-99 winter characterized by four 100-year storms (having been estimated in 1997 to be a 10-m significant wave height). The largest storm generated 14.1 m significant wave heights that effectively destroyed the remaining foredune fronting the park's campground, flooding the park and damaging its facilities. The cumulative erosion of these two winters resulted in the dune toe receding landward by on average 18 m, while the estimated volume of sand lost from the foredune along Netarts Spit was about 1.2 million m^3.

It was clear that CLSP could expect additional damage during subsequent winters, unless some form of shore protection was installed. However, instead of constructing a conventional riprap revetment commonly used along the Oregon coast, the decision was made by the OPRD to construct a cobble berm (dynamic revetment), in effect a gravel beach backed by an artificial dune reinforced with sand-filled geotextile bags (Figures 2 and 3)(Allan and Komar 2002; Komar et al. 2003; Allan and Komar 2004). The construction of the cobble berm/dynamic revetment at CLSP has presented a unique opportunity to investigate the stability and effectiveness of a prototype structure in a high-energy environment, and to compare the dynamics of such structures with natural cobble beaches. The objective of this paper is to examine two components of gravel beach stability, the profile responses during storms and the use of Passive Integrated Technology (PIT) tag tracers to measure the mobility of the gravels.

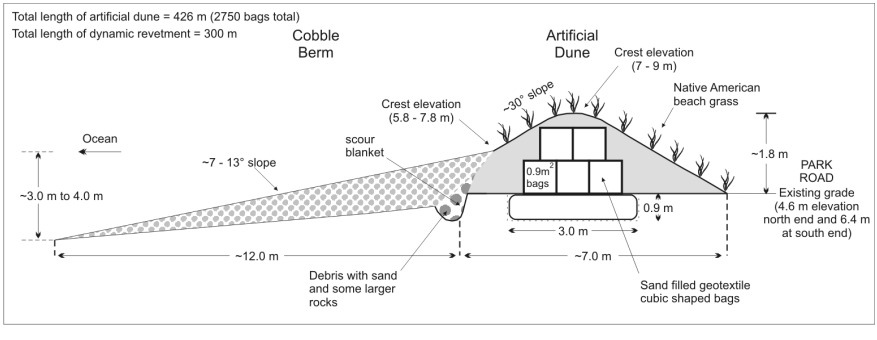

Fig. 2 Conceptual design elements of the gravel beach and artificial dune constructed at Cape Lookout State Park.

STUDY SITE

Cape Lookout State Park is located at the southern end of the Netarts littoral cell, a 15 km sandy shore bounded by two prominent headlands; Cape Meares marks the northern boundary while Cape Lookout is at the south, extending some 3.2 km out

into the Pacific Ocean. The park itself is located approximately 2 km north of Cape Lookout. The beaches within this cell are composed of fine sand and are characterized by low slopes (~2.3º), making them fully dissipative in the morphodynamics classification of Wright and Short (1983). Along the southern 4 km of the spit, a narrow (10 to 15 m wide) gravel beach backs the otherwise sandy beach, with the crest of the gravel beach ranging in elevations from 6 to 7 m relative to the North American Vertical Datum 1988 (NAVD88); NAVD88 is approximately 0.1 m above Mean Lower Low Water (MLLW) at CLSP. Mean grain-sizes along the gravel beach range from –5.5Ø to –7.2Ø (45 to 147 mm), very coarse gravel to large cobbles, the deposit is moderately well sorted and there is little evidence of either cross-shore or longshore sorting of the gravels along the beach. The gravels are entirely basalt in origin and have a mean hardness of 47.3 N/mm^2 (Newtons/mm^2) (standard deviation of 3.7 N/mm^2). With this beach consisting of a steeply-sloping upper foreshore or backshore ridge composed of gravel, fronted by a lower foreshore of sand (Figure 3A), with a distinct boundary between them, it can be classified as a "composite beach" using the classification system of Jennings and Shulmeister (2002).

COBBLE BERM DESIGN AND CONSTRUCTION

The basic concept of a cobble berm (dynamic revetment) is the construction of a gravel beach that can adjust and deform its morphology in response to the prevailing waves (Figure 3), being dynamic in permitting particle movement as opposed to being static as in a conventional revetment where large riprap stones are used. As a result, the construction of such structures is simpler compared with conventional riprap revetments since the particles used (gravel) are smaller, and their placement of the gravel does not require special care (Ahrens 1990). The major design elements can therefore be reduced to a few critical aspects: the size and type of gravel, the slope of the gravel face, the volume of material, and the determination of an appropriate crest elevation. Of these, the identification of a suitable gravel source is probably the most problematic, with distant sources possibly precluding the construction of dynamic revetments due to the high costs involved to transport the material to a site (Allan et al. 2005).

Since there are a number of gravel beaches present along the Oregon coast that offer protection to shorefront properties, the decision was made to base the design elements on the morphology of natural cobble beaches found along Netarts Spit and elsewhere (Komar et al. 1999). Surveys of the natural gravel beaches yielded slopes on the order of 11º to 14º (between 1-in-5 and 1-in-4), and this was recommended for the constructed dynamic revetment. The required elevations were based on an application of the wave runup model developed by Ruggiero et al. (2001), which considers the combined effect of the measured tides plus the calculated swash runup level achieved during storms. Analyses of potential extreme events yielded swash runup levels of 7 to 8 m, which when added to a Spring tide yielded total water elevations ranging from about 9 to 10.5 m NAVD88. Surveys of the gravel beach to the north of CLSP supported these estimates since their crest elevations were found to range from 7 to 8.5 m. Accordingly, it seemed reasonable to construct the dynamic revetment to attain a crest elevation of 8 to 9 m to prevent overtopping during extreme storms. However, because the volume of gravel required to construct the cobble berm to such specifications was found to be substantial, the decision was made by the OPRD to develop an artificial dune landward of a smaller scale cobble berm (Figure 2 and 3). Thus the artificial dune would form the backbone of the overall structure, providing both mass as well as the necessary height needed to minimize wave over-topping. Figure 2 depicts the overall design elements of the artificial dune, which was completed in April 2000. The dune was subsequently covered with a jute/coconut fiber cloth and planted with Native American grasses (Figure 3).

Construction of the cobble berm at CLSP was initiated early in the 2000 winter. Gravel were extracted from the natural cobble beach in the north along Netarts Spit (~3000 m^3) and from the south end (~2300 m^3) of the cell in areas where it was believed that more than sufficient volumes were present to protect the dunes and where no park infrastructure is present. The cobbles were carried to the construction site on a front loader, and placed evenly across the pre-existing profile. The volume added along the length of the constructed dynamic revetment varied depending on the antecedent beach morphology. The top of the added cobble overlaid a scour blanket placed beneath the artificial dune (Figure 2). No attempt was made to provide toe protection for the placed cobbles; the natural deposit of cobbles extends below the sand beach, providing the only toe support. The total cost of the structures was $125,000, and was able to be kept to a minimum since the construction phase was carried out with the aide of work-released labor from the State penitentiary.

METHODS

In order to understand the dynamics and effectiveness of the cobble berm, we initiated a research program to quantify its responses to storms through a monitoring program that has included repeated surveys and analyses of its response to storms, measurements of evolving grain-size statistics, and observations of particle movement by tagging experiments. At the same time, similar data are being collected on nearby gravel beaches for comparisons.

Monitoring of the cobble berm and artificial dune was initiated in July 2001, six months after the structures were completed. Our initial monitoring efforts focused on seven transects (CLSP 1 through 7 in Figure 1), but was eventually expanded to 10; seven of the profiles, spaced approximately 35 m apart, cross the cobble berm, while 3 profiles are located on natural cobble beaches to the north and south of the structures. Surveying was initially undertaken using a conventional Total Station theodolite. Since December 2004, measurements of the beach morphology have been accomplished with a Trimble 5700/5800 Real Time Kinematic-Differential Global Positioning System (RTK-DGPS), using procedures outlined in Ruggiero et al. (2005). The surveying has typically been concentrated in the winter to capture the effects of storms, with fewer surveys occurring in the summer.

Assessment of cobble transport was undertaken using a variety of approaches. Initial experiments focused on using painted particles to document their mobility. However, due to the extreme wave and current regime at CLSP, this approach was soon abandoned as our recovery rates were low, likely due to the particles having been buried. We also experimented with magnetized tracers but discovered that the cobbles at CLSP are strongly magnetic, which meant that this approach also had to be abandoned. Our attention then turned to using Radio Frequency Identification technology (RFID) to detect Passive Integrated Transponder (PIT) tags inserted in the cobbles (Allan et al. 2006). This approach has been used extensively for tagging fish and most recently has been experimented with in a sediment transport study undertaken in a gravel bed river (Lamarre et al. 2005).

The RFID system consists of three main components, the transponder "PIT" tags that are inserted into the cobbles, a palmtop computer and RFID reader unit, and an antenna; we developed RFID systems based around a 0.3 m and a larger 1.0 m diameter antenna. A complete description of our approach is described in Allan et al. (2006). Our experiments used 32 mm long PIT tags that have a detection range of up to 1.0 m. The tags are glass-encapsulated with each tag factory programmed with a unique identification number, and have an estimated potential lifespan of 50 years. A range of cobble sizes were collected from the cobble berm and a tag inserted into each and cemented in place; the particles ranged in size from -6.0Ø (64 mm) to -7.5 Ø (181 mm), with a dominant size mode centered at -6.5Ø (90.5 mm). Each of the cobbles was weighed and analyzed to determine its general characteristics, including orthogonal measurements of the particle's long (*L*), intermediate (*I*) and short (*S*) axes using a digital caliper, and measurements of its mass and hardness. A total of 200 particles were initially released at four locations on 15 March 2004; two injection points were established respectively at CLSP 6 and 3 (Figure 1). An additional 200 particles were released on 31 January 2005 at CLSP 7 bringing the total number of tracers presently being tracked to 400.

Relocating the tracer particles is technically simple, albeit time consuming. An operator simply drags the antenna and RFID reader unit across the gravel and sand beach, walking track lines. The discovery of a PIT tag tracer is identified by an audible noise from a siren attached to the RFID unit, followed by the particle's

identification number appearing on the palmtop screen. Having identified the location of the tracer, its' position is then observed using the Trimble 5700/5800 RTK-DGPS system. Relocation of the tracers has been accomplished on several occasions over the past two and half years, with the most recent complete survey having been carried out in May 2006. Over time, a number of the tracers have been removed from the beach in order to assess whether the cobbles have undergone measurable abrasion according to their weight reduction. On 14 December 2006, forty-five of these cobble tracers were re-released onto the cobble berm near the sand/cobble junction at CLSP 6 just prior to a major storm in order to assess their response to a significant wave event. At the same time 150 gravel particles were released (the particles ranged in size from -4.3Ø (20 mm) to -6.5Ø (91 mm), with a mean size of -5.9Ø (59.9 mm)), tagged by having painted them, in order to document the mobility of these smaller particles compared with the cobbles.

RESULTS

The CLSP cobble berm has a mean elevation of 6.4 m, and is steepest in the south (~8º) compared with the north (5º). The elevations of both the berm and the artificial dune vary along the shore, Figure 4, with the highest elevations (8.9 m) located near CLSP 5 at the south end, decreasing to the north and south; with the exception of a beach access path (Figure 4), the dune crest reaches its lowest point (6.7 m) adjacent to CLSP 2. Figure 4 also documents that the cobble berm aggraded in the north during the years 2002 to 2005, having raised the berm crest by on average 0.5 m. This response was accompanied by an overall steepening of the berm's slope. In contrast, the elevation of the cobble berm decreased by almost 1.0 m south of the CLSP 6 profile site. As will be shown below, this change is due to the movement of gravels from the south, and their redistribution to the north. Between profiles CLSP 6 and CLSP 4, the cobble berm has remained essentially unchanged.

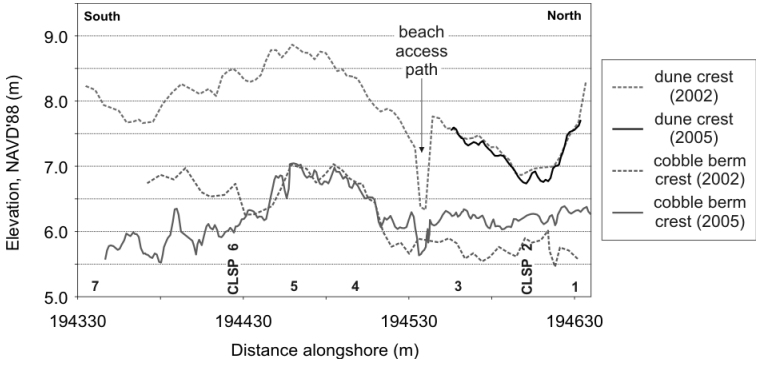

Fig. 4 Changes in the alongshore variability in the elevations of the cobble beach and artificial dune at CLSP

Figure 5 presents a summary of the measured profile changes at CLSP 2 located at the north end of the structures (Figure 1). The figure identifies the profile elevation on the right axis, while the left axis depicts the difference between the minimum and

maximum envelope of change. The latter provides a measure of the range of variability across the sand beach and cobble berm (graphed as the red dashed line in Figure 5) and is derived from almost 30 surveys of the beach. An average profile is also shown (black line), while results from the most recent survey (24 December 2006) of the beach are plotted in blue.

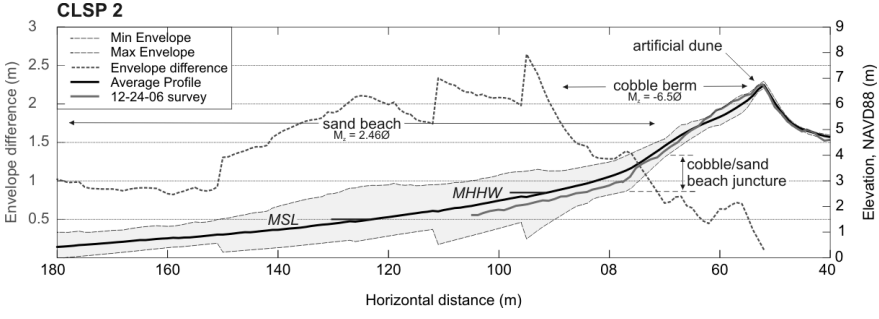

Fig. 5 Beach profile responses at profile CLSP 2, including the average beach profile and envelope of variability. Note: MSL denotes Mean Sea Level and MHHW indicates Mean Higher High Water.

The most noticeable feature of Figure 5 is the greater variability shown for the elevation of the sandy portion of the beach, and the degree to which it covers the cobble berm. Typically, the sand beach aggrades against the cobble berm over the summer months, which causes the junction between the sand beach and gravel foreshore to be positioned further landward and at higher elevations, compared with the winter when the sandy beach is eroded and its profile morphology is lowered. As a result, the lower cobble face typically experiences negligible gravel transport for several months, until the sand beach has lowered sufficiently in the following winter, allowing waves to once again mobilize the cobbles. The largest vertical excursion seen in Figure 5 occurred in January 2004, when a rip embayment formed in front of the cobble berm and lowered the sand beach elevation by 2.5 m. These changes clearly contrast with the magnitude of change observed across the cobble berm, having experienced a maximum vertical excursion of no more than 0.5 m, while the standard deviation of vertical change is ±0.1 m. This small level of response highlights the resilience of the cobble berm to storms.

Figure 6A documents the major cross-shore profile changes found in the surveys of the cobble berm at CLSP 2, while Figure 6B depicts the response of the berm at five select contour elevations (6.5, 6, 5.5, 5, and 4.5 m) during the five years of surveys, contrasting the trends in the upper portion of the berm's profile compared with its lower half. The results indicate that the central to lower part of the cobble berm initially eroded, with some of the gravel having been transported up the berm to produce the progradation of the 5.5 m contour during the 2001/03 winter. However, the response shown between July 2001 and 17 November 2002 for changes at the 4.5 and 5.0 m elevations, Figure 6A, probably incorporates some component of the sand beach also having been eroded; the sand beach at the time was in its most aggraded

state while subsequent summer surveys have been characterized by smaller sand volumes. By 27 January 2003, the cobble berm had prograded approximately 6 m seaward in response to the arrival of a slug of gravel at the site, transported en mass in the longshore direction along the cobble beach. Some gravel was also transported up the cobble berm face, raising the berm crest elevation slightly (Figure 6).

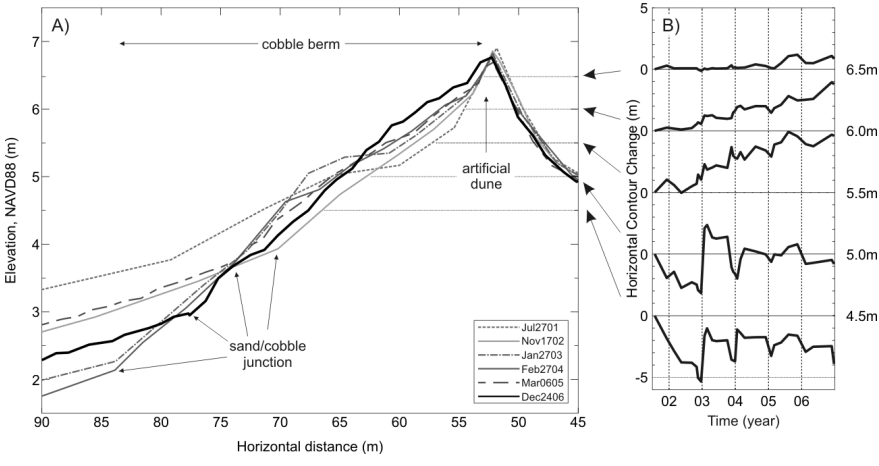

Fig. 6 A) Major morphological changes derived from the beach surveying. B) Long-term response of the cobble berm as defined by the response of the berm face at five select contour elevations.

Aside from an early phase of erosion during the 2003/04 winter, the cobble berm continued to gain material, resulting in further aggradation at its crest. The most recent survey (24 December 2006) reveals that this process has continued, with the berm having raised its crest elevation to such an extent that cobbles are now periodically carried over the artificial dune during major storms (Figure 7). This last aggradation phase occurred primarily as a result of a major storm on 21 December 2006, which generated an 8.2 m significant wave height (H_s) and a peak spectral wave period (T_p) of 16 seconds. The calculated total water level (wave runup plus tide) for this event using the Ruggiero et al. (2001) wave runup model was 6.9 m NAVD88, which produced minor overtopping of the artificial dune in the north (Figure 7). The patterns shown in Figure 6B reveal that the most significant morphological changes on the cobble berm occur during the winter, while the summer months are characterized by little to no change, this of course being expected since the waves are only able to impact the berm during the winter months. While the upper portion of the cobble berm has clearly gained material over time, the lower section of the berm continues to experience alternating phases of erosion and accretion, as particles are transported to the site and then subsequently removed. These patterns are consistent with observations by Everts et al. (2002) of natural cobble beaches on the southern California coast, whereby aggradataion and profile steepening occur during winter storms, as the cobbles and gravel are carried up the beach face.

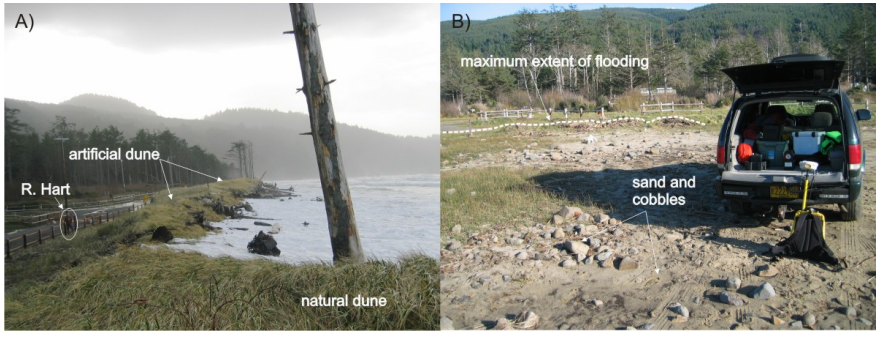

Fig. 7 A) wave overtopping on 21 December 2006. B) A major storm on 3-4 February 2006 overtopped the entire structure. This event transported a significant amount of gravel over the artificial dune and into the park.

To understand the patterns of cobble transport responsible for the profile changes, we have undertaken a series of experiments to track the movement of individual cobbles by inserting PIT tags into 400 cobbles as described in the METHODS section (Allan et al. 2006). Recovery rates have been very good, 90% one month after their release, while our most recent survey in May 2006, 27 months after the particles were released, yielded a recovery rate of ~33%. This most recent survey includes the results of particles injected at the CLSP 7 profile site on 31 January 2005 (Figure 8A). Much of the decrease in particle recovery over time can be attributed to the offshore transport of the cobbles down the berm's face, to its lower reaches that are exposed during the winter. With the return of summer, the sand beach aggrades across the lower cobble berm, burying those tracer cobbles to depths where they cannot be detected (recall that the PIT tags used have a maximum detection depth of about 1.0 m, while the sand beach envelope of change may reach as much as 2.5 m). Our survey undertaken in May 2006, following the re-exposure of the lower cobble berm during the 2005/06 winter, confirmed the presence of those cobble tracers, and also discovered a number of cobble tracers that had not been seen since they were first injected onto the cobble berm two years earlier. Nevertheless, Figure 8A reveals that several tracers have been transported significant distances (up to 334 m) along the cobble berm during a relatively short period of time (essentially 16 months). As a result, it is also possible that we may not be covering a sufficiently large area when scanning for the tracers, with part of the reduction in recovery rates being accounted for by extreme longshore transport distances.

As shown in Figure 8A, the cobble tracers on average document a net northwards transport along the shore, consistent with the morphological response of the cobble berm, with the surveys having indicated that its south end has experienced a net loss of gravel. The updated results presented here confirm our earlier observations of northward cobble transport, discussed in greater detail by Allan et al. (2006). Unexpected, the cobble tracers released at CLSP 7 appear to be moving at a faster rate along the beach, indicated both by their greater dispersion and distance of transport compared with the tracers released earlier in March 2004. This is despite

the fact that these latter cobbles are comparable in size to those earlier tracers. Allan et al. (2006) observed that the predominant northward transport of the gravels was due to the prevalence of waves from the west to southwesterly directions, which results in their breaking obliquely to the shore forming strong northward-directed longshore currents. In contrast, summer wave conditions are characterized by lower wave energy levels (from west to northwest directions), and with the eventual return of a fronting sand beach, the cobbles are not transported back to the south. These findings contrast with observations by Everts et al. (2002), who found no evidence for a net longshore transport of the cobbles on the coast of southern California.

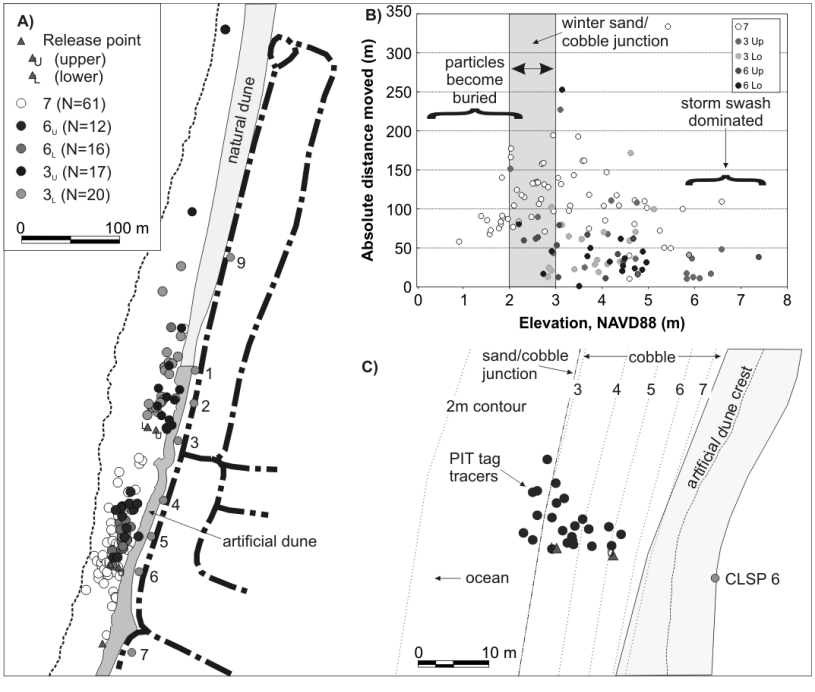

Fig. 8 A) Particle tracking results as of May 2006. B) Relationship between gravel tracer movement (absolute values) versus the elevations of the tracers on the cobble berm. C) Particle dispersion in response to a single storm on 21 December 2006.

Of interest, the bulk of the cobble tracers (61% of those recovered) tended to be located close to the sand/gravel beach junction, approximately between the 2 to 4 m contour elevations (Figure 8B). The cobble tracers also locally exhibit a strong cross-shore transport, characterized by both upslope and downslope movements, with a few being carried out onto the sand beach. As a result, those particles that are transported down the cobble berm face, below the 2.5 m contour elevation, may experienced negligible transport for extended periods of time, as the sand aggrades against the cobble berm during the summer. Future movement of these tracers will therefore be dependent on sufficient lowering of the sand beach elevation. Similarly, those particles that are transported up the cobble berm (e.g. above the 6 m contour) may

also exhibit slow to negligible transport rates, since at those high elevations their movement depends on occurrences of rare major storms that occur at high tides (Figure 8B). Within the mid-range of elevations are those particles that are moving quickly along the shore, since this is the region dominated by a higher incidence of swash runup excursions.

Comparisons between the particle size, as determined by the intermediate (*I*) and short (*S*) axis of the cobbles, revealed some evidence of preferential sorting with distance along the shore. Initial observations by Allan et al. (2006) indicated that the larger particles were tending to outrun the smaller particles. However, our updated results suggest that this process is beginning to reverse, with the smaller particles (~60-80 mm size range) tending to outrun the larger cobbles (i.e. *I*-axis greater than 80 mm). Nevertheless, the plots were characterized by considerable scatter, indicating that all grain-sizes were capable of moving both short and long distances. Our monitoring of the gravel tracers has also revealed evidence of particle abrasion over time that is correlated with the net distance moved by tracers (Allan et al. 2006).

Finally, Figure 8C shows the response of the cobble tracers during a storm on 21 December 2006. A total of 45 cobble tracers were released prior to the event at the sand/gravel junction on profile CLSP 6. In addition, these cobble tracers were supplemented with 150 painted gravel-size particles, 75 released at each of two positions across the profile on 12 December 2006; the injection points were the same as those used during our initial release in March 2004 (Figure 8A). These gravel particles had a mean grain-size of -5.9Ø (59.9 mm), significantly smaller than the cobble tracers, the objective of this experiment having been to document their different mobility during the storm. Figure 8B shows the dispersion of the tracers based on their relocation immediately following the storm. The results indicate that the cobble tracers were dispersed in the cross-shore direction, with several of the particles having been transported up the cobble berm, while the majority of the cobbles were transported in a northward direction. This response is consistent with our observation of the other PIT tag tracers as depicted in Figure 8A and 8B. The painted gravels were exposed to two separate events, with the first event occurring on 15 December 2006. Those gravels injected near the sand/cobble junction disappeared entirely, while the gravels released higher up on the berm were dispersed mainly in the cross-shore direction, but remained congregated around their injection point. Following the second storm on 21 December, we were unable to relocate any of the painted gravels, highlighting the limitation of tagging particles by painting them. However, the experiment did provide evidence for the extreme mobility of the gravel under the vigorous swash of those storm waves, a significantly greater mobility and transport than experienced by the cobbles. Efforts to understand these patterns and the response of the gravels to swash activity during individual storms is ongoing.

CONCLUSION AND DISCUSSION

Since its construction in 2000, the cobble berm and artificial dune constructed at CLSP have performed well, having survived several major storms, when both structures were overtopped. To date, damage to the structures has been generally

minor, suggesting that they can be a viable alternative to conventional engineered solutions.

Our beach monitoring efforts have revealed that the cobble berm has over time tended to aggrade along its northern end, while its southern half has remained essentially unchanged; in contrast the berm south of the CLSP 6 profile site has progressively eroded over time. Results from the beach surveying also demonstrate the resilience of the cobble berm, which has been characterized by a maximum vertical excursion of no more than 0.5 m, while the standard deviation of vertical change has been only ±0.1 m. This reinforces the perception that gravel beaches are an effective buffer in the face of sustained wave attack. Assessments of particle transport using RFID technology and PIT tags inserted in 400 cobbles has revealed a predominant net northward transport of the cobbles over time, with the particles tending to congregate near the sand/cobble beach junction due to its greater susceptibility to wave swash activity. The tracer experiments also revealed significant cross-shore movement, with the particles tending to move in both upslope and downslope directions during major storms. Of concern, the existence of a predominant net northward migration of the cobbles documented by the tracer experiments will in time degrade the reliability of the structure due to the net loss of gravel and cobbles, leading to the need for periodic 'top-ups' to maintain the structure's integrity.

ACKNOWLEDGEMENTS

This work was conducted under the National Shoreline Erosion Control Development and Demonstration Program (Section 227) authorized by the Water Resources and Development Act of 1996 (Public Law 104-303, 110 Stat. 3658), under contract number W912HA-04-C-0028. We are grateful for the assistance provided by Dr. Don Ward and Mr. Bill Curtis from the Engineer Research Development Center (ERDC) of the U.S. Army Corps of Engineers. We are especially grateful to Dr. Paul Komar who provided comments on the manuscript, and Dr. Alan and Wendy Niem for their assistance with sample preparation.

Abstract: Mixed sediment beaches are morphologically distinct from and more complex than either sand or gravel only beaches. Three digital imaging techniques are employed to quantify surficial grain size and bedload sediment transport rates along the mixed sediment beaches of Kachemak Bay, Alaska. Applying digital imaging procedures originally developed for quickly and efficiently quantifying grain sizes of sand to coarse sediment classes gives promising results. Hundreds of grain size estimates lead to a quantitative characterization of the region's sediment at a significant reduction in cost and time as compared to traditional techniques. Both the sand and coarse fractions on this megatidal beach mobilize into self-organized bedforms that migrate alongshore with a seasonality reflecting the temporal pattern of the alongshore component of wave power. In contrast, the gravel bedforms also migrate in the cross-shore without significant seasonality suggesting that swash asymmetry is sufficient to mobilize the gravel even during low energy summer conditions.

INTRODUCTION

The majority of our knowledge of nearshore sediment transport and associated beach morphodynamics is derived from studies of beaches dominated by a single sediment type. Typically that sediment type is sand, and numerous studies have documented the rates of sediment transport along well-sorted, sand-rich beaches resulting in correlations (and models) relating sediment transport to forcing by waves and currents. To a lesser extent, gravel (shingle) beaches have also been the focus of numerous coastal studies but predictions of coarse-grained transport are often unreliable (Osborne, 2005). The

dynamics of mixed-grain size beaches, however, have received relatively little attention in the scientific literature (Mason and Coates, 2001) in spite of the fact that heterogeneous sedimentary environments comprise approximately 80% of the worlds' non-rocky coastal regions (Holland et al., 2004). Mixed sediment beaches occur on shores where glaciation has provided significant sources of sands and gravels and are recognized as being morphologically distinct from and more complex than either sand only or gravel only beaches (Kirk, 1980). Two recent studies of mixed-sediment beaches, Osborne (2005) and Allan et al. (2006), reveal interesting relationships between transport rates and coarse-grained material size and shape. Unfortunately, a detailed understanding of the processes governing mixed-sediment transport remains elusive.

Fig. 1. Study location. Kachemak Bay is located on the Eastern shore of Cook Inlet in south central Alaska. The star marks the location of the Argus cameras used in this study.

The tectonically active, megatidal (spring tide range greater than 8m), and sea dominated beaches of Kachemak Bay, AK (Figure 1) exhibit a wide range of interesting characteristics and provide an ideal natural laboratory for investigating mixed sediment beach processes. The surficial sediments range from fine sand to large boulders and this broad range of sediment size is reflected in intriguing morphodynamics in which self-organized bedforms composed of fine-to-medium sand migrate as coherent packages over a coarse substrate which is also dynamic (Figure 2). Understanding sediment transport patterns and rates along the north shore of Kachemak Bay is particularly

important as net southeasterly transport is primarily responsible for maintaining the Homer Spit (Figure 1), the economic engine of the region, at engineering/planning time scales.

Our goals in this paper are to first characterize the mixed sediment environment of the north shore of Kachemak Bay, AK, then quantify the rates and modes of sediment transport. We achieve these goals through the application of three novel digital imaging techniques. Due to the general lack of detailed understanding of mixed-sediment systems as discussed above, our approach here is to build, and report on, a high quality data set which will be used to develop sediment transport and morphological evolution models for these systems in future efforts.

Fig. 2. Proto-typical mixed sediment beach along the north shore of Kachemak Bay, AK. Note the discrete sand bedform in the far field migrating over the coarse substrate and the mobile gravel berm (near field).

METHODOLOGY

Understanding the range of natural variability of mixed sediment beaches is essential to the management of these complex systems. Historically, quantitative characterization of surficial grain size variability has been difficult because standard techniques are inadequate due to the sampling and processing efforts required and because of the volumes of material that must be handled to capture the full range of variability. Quantifying sediment transport patterns at event-seasonal-interannual scales on these beaches also poses complex sampling problems. Here we apply three digital imaging techniques (beachball camera, cobble-cam, and an Argus Beach Monitoring System) to overcome these sampling issues in investigating the mixed sediment dynamics along the north shore of Kachemak Bay, AK.

Beachball Camera

Recently, Rubin et al., (2006) developed digital imaging methodologies for quickly sampling surficial bed sediments in a variety of field environments. Images of surficial sediment, either sub-aqueous (flying eyeball) or sub-aerial (beachball), sand are taken by simply pressing a watertight camera system into the bed. Grain-size analysis from the digital images requires a calibration process in which sediments from the field area are sieved at quarter-phi size intervals and digitally photographed. An autocorrelation algorithm (Rubin, 2004) between pixels in the digital images has been developed to compute the average grain size of sediment on the bed and the grain size distribution of bed sediment. This emerging technique is extremely rapid and has the potential to revolutionize our ability to quantify grain size information in heretofore inaccessible regions.

The 'beachball' camera is simply a grain-imaging digital still camera fitted with macro lenses and housed in a watertight plastic case. In summer 2004 we collected approximately 150 images using this system on the north shore of Kachemak Bay, AK. Images were collected at low tide and only on the self-organized sand bedforms that exist in the region. Figure 3a shows the spatial distribution of many of the beachball images (red asterisks) overlaid on a gridded topographic surface derived from GPS measurements of the beachface during the same sampling period that the images were taken.

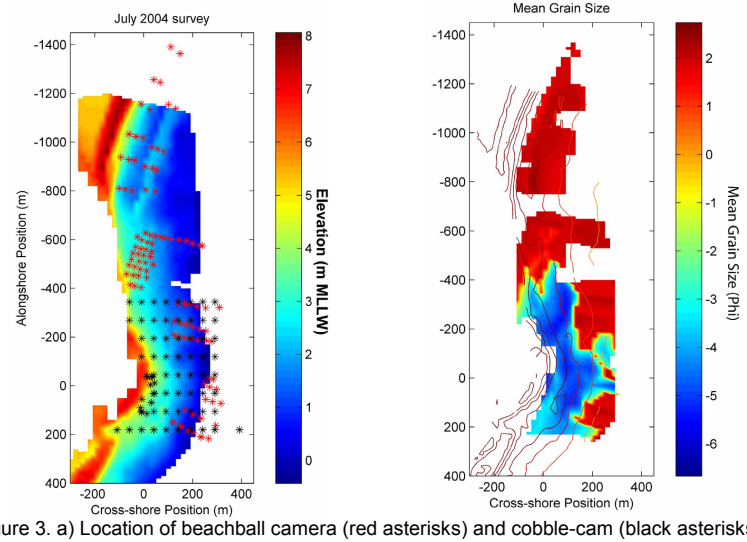

Figure 3. a) Location of beachball camera (red asterisks) and cobble-cam (black asterisks) images overlaid on 2004 gridded topographic surface. b) Gridded surface of surficial sediment grain size.

Cobble-Cam

We are extending the methodology developed by Rubin et al. (2006) to also estimate the size distribution of the coarse component of the region's sediments (Harney et al., in press, Warrick et al., in prep.). The 'Cobble-Cam' consists of a digital still camera mounted on a downward looking, vertically-telescoping tripod designed for capturing a population of coarse grained material. A bubble level on the tripod enables horizontal positioning while an adjustable, rotating extension arm allows for the camera to be mounted looking downward at the sediment surface without capturing the legs of the tripod in the field of view. Typically, the camera is mounted approximately 1.5 m above the bed and images are triggered using a remote control to minimize camera movement. Two images at each location are taken and a scale bar in one of the image's field of view enables the development of a conversion factor defined as the number of pixels in the image equal to 1 mm ground distance. In a summer 2004 pilot effort we collected cobble-cam images at a handful of locations while in summer 2005 we collected approximately 70 images approximating a 50x50 m rectilinear grid as shown in Figure 3a (black asterisks).

For each digital photograph, a regular spaced (200-pixel) grid was overlain producing a 9-by-12 matrix for the photograph using the commercially-available Abode Photoshop computer application. The longest exposed length of each rock underlying each grid intersection was then measured in pixels using a line-drawing tool. If there was no distinguishable rock under the grid point, the rock directly up and to the left was measured. Notes were made if the rock was partly buried (<50% of rock perimeter buried), mostly buried (>50% of perimeter buried), and/or off of the photograph. A second length measurement was then made for each rock along the "short" axis, which was defined to be the longest visible distance perpendicular to the "long" axis measurement. Rocks that were too small to be measured with the resolution of the photograph (typically 3-4 pixel length, ~1.2-mm long) were defined to be "sand" and given an arbitrary grain-size equal to the mean of the beachball samples. These length measurements in pixels were then converted to actual distances using the conversion factor for each photograph.

Argus

In February 2003 we installed an Argus Beach Monitoring System (Lippmann and Holman, 1989; Holman et al., 1991; Holman et al., 1993) along the north shore of Kachemak Bay, AK to observe and quantitatively document the mixed sediment dynamics of the region (Adams et al., in press). The system consists of 8 digital cameras spanning a field of view of approximately 220º. Within this field of view, a geometry solution is computed allowing for the conversion from oblique merged panoramic views (Figure 4) to merged planform views, thereby defining true geographic coordinates to each pixel in the merged planform image. Typically snapshots and time averaged exposures (approximately 3 minutes) for each camera are taken each hour. However, since summer 2005 we sample each camera every 15 minutes during spring tides. Utilizing low tide images in which bedforms are exposed and a tidal contouring algorithm (Plant and Holman, 1997, Aarninkhof et al., 2003) we quantify the rates and

directions of sediment transport exhibited by the sand and cobble fractions of the bi-modal sediment distribution, respectively.

RESULTS

Intertidal beach sediments along the north shore of Kachemak Bay are composed of a poorly sorted coarse component (glacial till), consisting of fist-sized cobbles (5-10 cm) to Volkswagen-sized boulders (1-3 m), and a fine component, fine-to-medium, well-sorted sand. The average mean grain size of the sand bedforms estimated from the approximately 150 digital sand samples collected is 0.29 mm (medium sand), ranging from 0.15 mm (fine sand) to 0.83 mm (coarse sand). In general, the sand fraction is well sorted; however, there is a trend of coarsening toward the trailing edge of individual sand bedforms with finer sands at the leading edge (Figure 3b).

Fig. 4. Merged panoramic images from the Homer, AK ABMS site; top panel: June 2004; bottom panel: June 2005.

For two of the 70 cobble-cam samples approximately 15-20 rocks were labeled in the field and then removed following photographing to allow for physical measurements of the rock dimensions. For both samples, the size estimate of the major (long) axis derived from the photo method (pixel counting) compared extremely well with the physical measurements of the major axis of the rock. The correlation coefficient between the two techniques exceeded 0.97 (Figure 5a) indicating the point counting method is sufficiently accurate to quantify the mean grain size of each cobble-cam image. The mean grain size derived from all of the cobble-cam images was 44 mm (coarse gravel) while the estimated means ranged from 10 mm to 105 mm.

Calibration curves, similar to those developed for Rubin's (2004) autocorrelation algorithm for sand grains, were constructed by Warrick et al., (in prep.) from coarse

samples extracted from a similar mixed sediment beach at the mouth of the Elwha River in Port Angeles, WA. Surprisingly, the Kachemak Bay images, when processed with the autocorrelation algorithm using the Elwha calibration curves, showed remarkable agreement between point count size estimates and computer derived size estimates (Figure 5b). This result suggests that estimates of coarse grain sizes may be computed with significant reduction of cost and time as compared to traditional techniques.

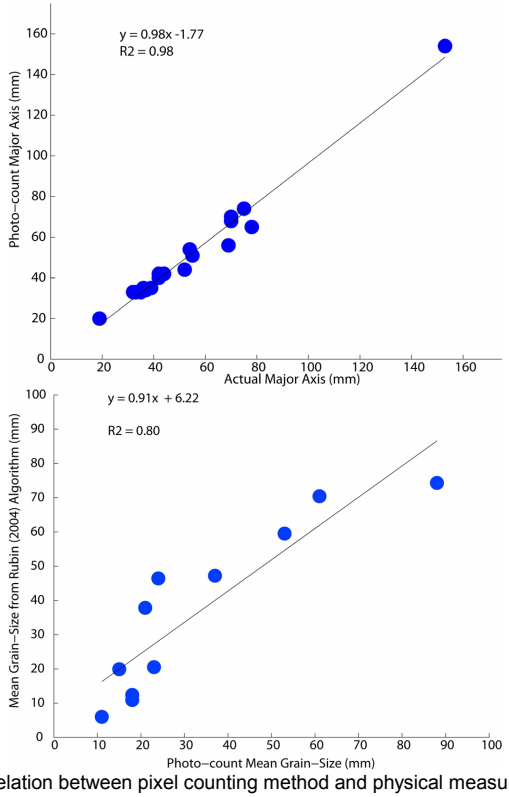

Fig. 5. top) Correlation between pixel counting method and physical measurements of grain size for a single cobble-cam image. bottom) Relationship between mean grain sizes estimated from the Rubin (2004) algorithm and pixel counting size estimates.

The beachball and cobble-cam results give us reasonably accurate estimates of mean grain size at over 220 locations within the field of view of the Homer Argus cameras. From these data we develop a gridded surface of the surficial grain size in the study area (Figure 3b). While in this example we combine data collected over a two year period to construct a composite surficial sediment surface, our goal here is to demonstrate that these relatively simple techniques can be applied to accurately and efficiently characterize the range of variability in heterogeneous environments.

Alongshore migration rates of intertidal sand bedforms, 1-2 m amplitude and ~200m wave length (Figure 2), over the coarse gravel substrate have been documented to be approximately 250 m/yr (Adams et al., in press). Strong seasonality in alongshore migration rates is evident with the majority of sand body movement, up to weekly-averaged rates of movement exceeding 6 m/day, occurring during large wave events. The seasonal signal of the alongshore bedform migration rate (proxy for bedload transport) is well correlated with seasonal variability in the alongshore component of wave power suggesting that the sand component of this mixed sediment system behaves much as most sand beaches with strong net longshore sediment transport rates.

The cobble substrate, over which the organized sand fraction is transported, is dynamic as well. Field observations (Figure 2), Argus video measurements (Figure 4), and ground surveys (Figure 6) have documented the growth and migration of a large gravel bedform over a life cycle of more than two years.

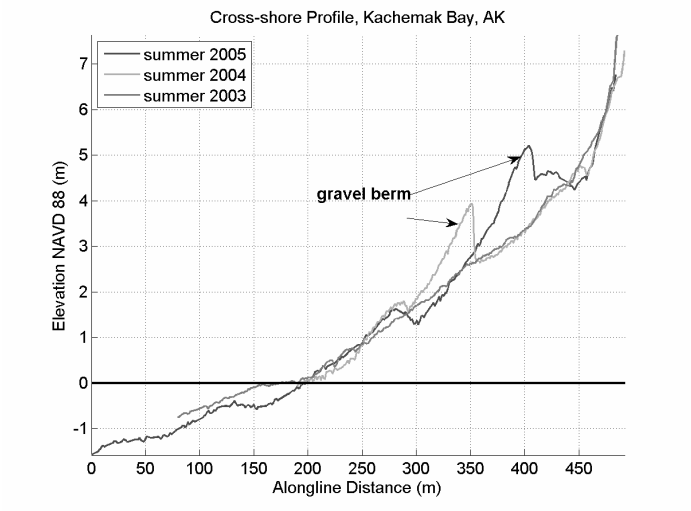

Fig. 6. Profile view of development and onshore migration of gravel berm. Data collected by walking cross-shore transects with RTK-GPS.

The cobble bedform was initially formed during late fall early winter 2003/2004 (note that the feature does not exist in summer 2003 in the cross-shore profile shown in Figure 6) by a now abandoned tidal slough outlet (flows typically exceed 1 m/s) immediately to the west of the Argus cameras. Human intervention may have played a role in the formation of the gravel feature in that the outlet of the slough was forced to the west in late 2003 as it had been steadily migrating toward the east and was beginning to threaten private property with erosion. The coarse material associated with the remnant stream

bed was then impacted by only marine processes rather than the balance between marine and fluvial processes that previously existed. While it is difficult to resolve the detailed processes associated with the formation of the feature with the Argus cameras (poor weather caused unusable images), the feature soon became large enough to accurately track using the cameras. By spring 2004 (Figure 4) the bedform had organized into a mobile gravel berm with a landward slipface approximately 1.5 m high and a cross-shore length of about 50 m. During the following year this feature increased in volume and migrated approximately 50 m in the cross-shore and over 100m in the alongshore direction while the berm crest gained over 1.0 m in vertical elevation (Figure 6).

By mapping the location of the gravel bedform in subsequent merged rectified Argus images we quantify the pattern and rate of migration of this feature much in the same manner as Adams et al., (in press) quantified the sand body migration rates at the same site. Figure 7 illustrates the gravel bedform's footprint at three distinct times in its life cycle. From the initial development of the feature until late spring 2005 the primary direction of transport was in the alongshore (with some cross-shore movement). From summer 2005 until the feature's eventual collapse, the bedform primarily moved onshore. The gravel feature also elongated during its life cycle from extending approximately 100 m in early 2004 to over 300 m in late 2005.

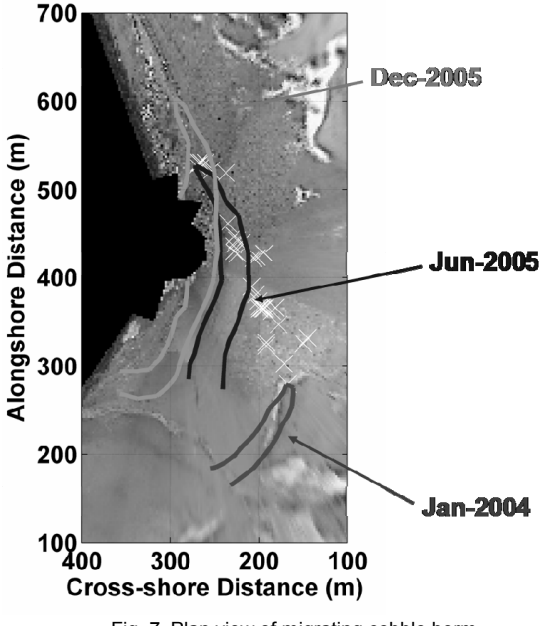

Fig. 7. Plan view of migrating cobble berm.

The white asterisks in Figure 7 represent the position of the easternmost tip (toward the top of the page) of the gravel bedform at approximately bi-weekly intervals, every spring tide from early 2004 until late 2006. This data is used to estimate the migration rate of the gravel berm as illustrated in Figure 8. Similar to the transport pattern of the sand bodies (Adams et al., in press), the cobble berm migration rate experiences a significant seasonality to its movement. In early 2004, when storm waves were still frequent, the gravel berm migrated at a rate of approximately 0.7 m/day (primarily in the alongshore direction). During the relatively calm spring and summer months of 2004 the gravel berm halted only to resume its movement when waves increased in late fall/winter. During the first year of its existence the gravel berm migrated approximately 150 m resulting in an annual average migration rate of 0.4 m/day.

The megatidal nature of Kachemak Bay is ideally suited for quantifying beach changes using tidal contouring methods (Plant et al., 1997, Aarninkhof et al., 2003). Knowing the time of each merged rectified time averaged exposure and the corresponding tidal elevation (taken from the NOAA tide gage located at Seldovia, AK on the south shore of Kachemak Bay approximately 25km south-southwest of Homer) we construct monthly cross-shore beach profiles at three alongshore locations (Figure 9). Unfortunately, because ponding occurs on the landward side of the gravel berm as the tide recedes, we are not able to resolve the slip face of the gravel berm and the beach face immediately landward of the bedform (Figure 9b).

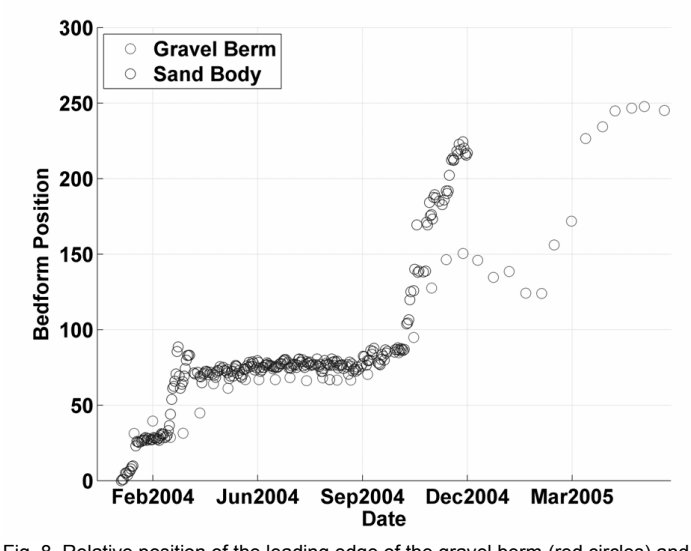

Fig. 8. Relative position of the leading edge of the gravel berm (red circles) and the approximate center of mass of a single sand body (blue circles).

In order to accurately resolve the cross-shore migration of the gravel berm we extract the cross-shore position of the 4.5 m (MLLW) contour at monthly intervals (Figure 10). At all times when the gravel feature is present at a particular alongshore location, the 4.5 m contour is on the seaward sloping face of the bedform. Therefore, tracking this contour serves as a reasonable proxy for the cross-shore migration of the gravel berm. Figure 10 illustrates that the migrating gravel berm reaches the transect located at alongshore position 400 m (Figure 9) in November 2004, as evidence by over 75 m of offshore migration of the contour. From February 2005 until December 2005 the 4.5 m contour migrates steadily onshore with an average rate of 0.1 m/day.

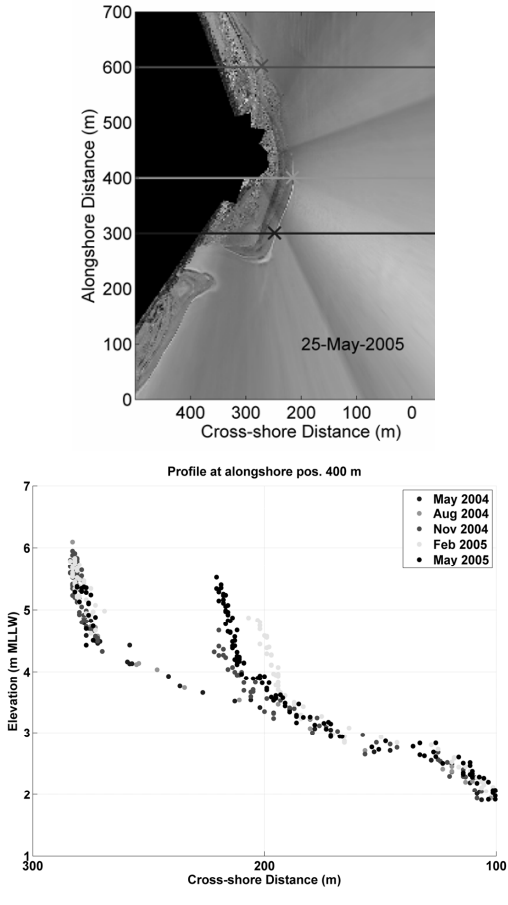

Fig. 9. top) Plan view demonstrating tidal contouring methodology. bottom) Quarterly cross-shore profiles extracted from tidal contouring method at alongshore position of 400 m.

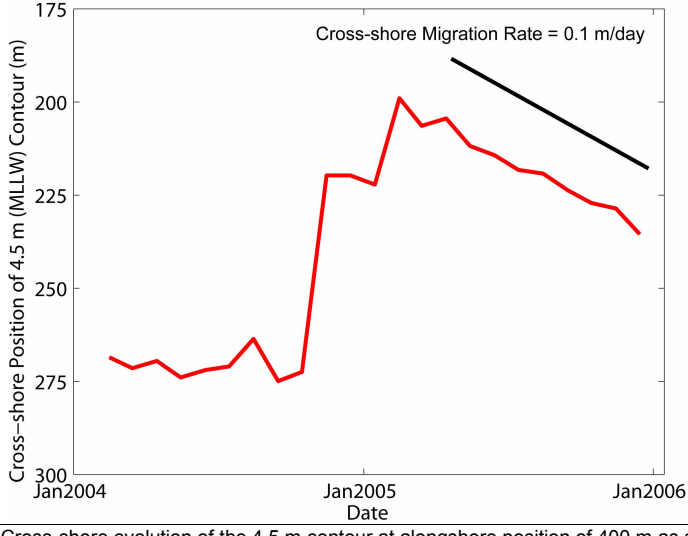

Fig. 10. Cross-shore evolution of the 4.5 m contour at alongshore position of 400 m as shown in Figure 9 (top).

CONCLUSIONS

New digital imaging techniques now available for quantifying grain size allow for quick, inexpensive, and relatively accurate characterization of mixed sedimentary environments. We have initiated the extension of a technique initially developed for sand (Rubin et al., 2006) to produce sufficiently accurate estimates of coarse sediment (gravel and cobble) sizes in order to resolve the cross-shore and alongshore gradients of surficial sediments in a highly heterogeneous sedimentary environment.

Along the sea-dominated, megatidal, mixed sediment environment of Kachemak Bay, AK, both the sand and gravel fractions are highly mobile with the dominant mode of sediment transport being the migration of self-organized bedforms. Employing merged rectified Argus images we estimate the annual migration rate of the sand bedforms to be approximately 0.75 m/day (Figure 8, blue circles) while the gravel bedform migrates at 0.4 m/day. Surprisingly however, the bedforms of different size components migrate in the alongshore with a similar seasonality which is well correlated with the seasonality in the alongshore component of wave power. This result suggests that simple models, similar to the "CERC formula" (Komar and Inman, 1970; U.S. Army Corps of Engineers, 2002), for alongshore bedload transport of the coarse fraction may be developed, at least for this system.

Intriguingly, the cross-shore migration rate of the gravel berm is relatively constant during most of 2005 (February to December) without exhibiting seasonality. This perhaps suggests that the asymmetric swash motions on the seaward flank of the gravel

bedform are always sufficient to mobilize the coarse sediment, even during the relatively calm summer conditions. Presumably the permeability of the gravel bedform produces a net onshore shear stress over the swash backwash cycle leading to net onshore transport. Future experiments performed using Argus images and Argus time stacks will specifically test this hypothesis by determining whether or not swash velocities are sufficient to mobilize the gravel bedform throughout the year.

ACKNOWLEDGEMENTS

The U.S. Geological Survey supported this work through the 'Geological Characterization and Sedimentary Processes of Nearshore Habitats in Kachemak Bay, Alaska' project. Logistical support was provided by the Kachemak Bay Research Reserve. We thank Guy Gelfenbaum, Jodi Harney, and Jodi Eshleman for stimulating scientific discussions and excellent field support. Special thanks go to Dr. Paul Eneboe who continues to allow us to maintain our Argus cameras on his lovely property. Finally, we would like to thank Carl Schoch for his continued vision and strong support of sediment dynamics studies in Kachemak Bay.

Abstract: A mixed sand and gravel beach 1,100 feet (335 m) in length was designed and constructed during 2005-2006 in Puget Sound as beach restoration, and is being monitored for changes in sediment distribution and profile shape. The beach is to function as improved habitat specifically for salmon, provide public access to the shoreline, and to control erosion of backshore fill. The beach was designed to mimic to the extent feasible the beach face slopes, elevations, and materials of a natural Puget Sound shoreline. Design beach dimensions and morphology were patterned after those of beaches documented at other Puget Sound locations. Forebeach material size gradation was designed from published relationships and judgment based on measured gradations at beaches having similar wave exposure and habitat as targeted for the project site. Construction monitoring assured the intent of the design was implemented. Post-construction monitoring has shown that the constructed beach is performing as designed.

INTRODUCTION

A beach in central Puget Sound, Washington, USA was rehabilitated for a distance of 1,100 feet (335 m) as part of a pier construction project owned by the Port of Everett. Figure 1 is a location map of the project area. The reach of shoreline containing the project had been degraded by industrial activities of several different owners for over a century. Figure 2 shows the pre-project beach and rock bulkhead. Objectives of the restoration are to (1) create a beach that will function as improved habitat specifically

for salmon, (2) provide public access to the shoreline, and (3) control erosion of backshore fill by maintaining morphology and material types of natural, functioning Puget Sound beaches. Beach construction and monitoring are elements of a Conservation Measures and Monitoring Plan (CMMP) developed during environmental permitting of the overall pier project. The beach restoration is not required mitigation, but a rather proactive measure undertaken by the Port of Everett to enhance the environmental and physical functions of the beach.

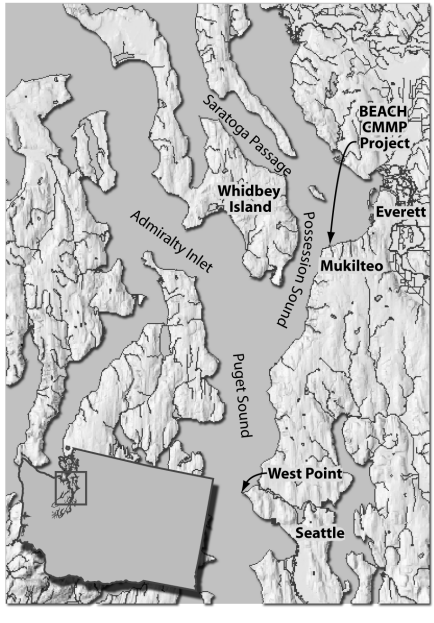

Fig. 1. Location map of constructed beach

Fig. 2. Pre-project shoreline at pier project site

Typical Puget Sound shorelines are backed by bluffs composed of glacial outwash deposits. Bluff erosion is a mechanism for delivering sediments to the shore. The site is exposed to moderate or low wave energy and an 11-ft diurnal tide range. When the sediment budget is balanced the resulting beach surface has a slope and distribution of sediments that form habitat for food sources of endangered fish species. Topography channels winds in central Puget Sound in predominantly northerly, and secondarily in southerly directions. The project area has a generally north-facing shoreline, and is exposed to a fetch having an effective length of 7.5 nautical mi (13.9 km). Deepwater significant wave heights reach 3 to 4 ft in strong winter storms. Predominant longshore transport direction is from west to east as interpreted from shore forms and erosion patterns.

BEACH DESIGN

Beach design accounted for the physical processes that would modify the constructed beach during placement and during the project life. Prototype beaches and their physical environment provided the basis of design that would maintain morphology and beach composition that create desired habitat. Typical self-formed morphology of northern Puget Sound beaches consists of a low-gradient low tide terrace composed of silt and sand, and a steeper high tide beach composed of coarse sand and gravel, and in some cases cobbles (Keuler 1988).

Criteria

Habitat performance criteria were established in consultation with the project biologist and regulatory agencies at the start of the design process and were balanced with engineering criteria of physical functionality, ability to provide shore protection, longevity, constructability, and economics. Sediment predominantly in the size range of medium sand to pea gravel is required in the beach surface material to serve as habitat in the upper elevation zone for forage fish spawning (WDFW Undated a, b). Evidence of Pacific sand lance usage, although sparse, was found in the pre-existing beach, despite the beach's degraded state. For the rehabilitation to be judged successful, the completed beach will be required to develop improved biological functions, compared to the area covered.

Project design must therefore mimic the morphodynamics of a self-formed beach composed of a mixture of sediment sizes. The beach form must be stable in a design storm even though the beach contains fine sediments. The concept developed for the beach cross section is a core and berm composed of coarse material in the size range that is found at the berm crest on natural beaches. The forebeach is constructed with a sand and gravel mixture known as "habitat mix," because the distribution of material sizes has a significant component in the range of coarse sand to fine gravel. The back beach is composed of sand with a zone of soil to support riparian vegetation.

Design Process

Mixed sand and gravel beaches differ from shingle beaches in that the high percentage of sand in mixed beaches reduce swash infiltration in the beach face. The resulting uprush and downrush velocities are more symmetrical in the zone of higher sand content, creating a flatter slope than is found where only gravel is present. Quick and Dyksterhuis (1994) noted in their study of a limited range of wave heights and mixed beach compositions that a mixture having a sand percentage greater than a certain amount behaved nearly as sand. That sand percentage varied with the energy of the incident waves. A design objective was to specify a beach face slope and sediment gradation that function as habitat and remain in dynamic equilibrium with the wave environment after natural sorting of sediment. The design process consisted of the following tasks.

- Document existing site conditions
- Analyze wave and water level statistics
- Test applicability of design formulas
- Specify target grain size for forebeach
- Apply formulas to calculate combinations of median grain size, size gradation, and beach face slope for selected wave conditions
- Determine berm crest elevation and berm width
- Complete final engineering design, plans, specifications, and cost estimates

Pre-project beach surface sediment sizes were documented with an initial field reconnaissance. Tide level statistics are listed in feet above mean lower low water (MLLW) in Table 1 below. Mean higher high water (MHHW) is 11.02 ft above MLLW at the site. Wave statistics applicable to the site were developed with wave hindcasts using wind data from the northern quadrants recorded at the West Point lighthouse (see Figure 1).

Table 1. Extreme Value Statistics for Tides, Winds, and Waves for Beach CMMP Project Site

Return Period, year	Tide Level, feet	Wind Speed, mi/hr	Hmo Wave Height, feet	Spectral Peak Period, sec
5	13.50	36.3	3.61	3.87
10	13.71	38.4	3.86	3.99
20	13.90	40.4	4.11	4.10
50	14.11	42.7	4.40	4.22

Note: Tide elevations of Glendale, Whidbey Island, in feet above MLLW. Wind speeds developed from west and north winds measured (2-min average) at West Point, WA 1984-2002.
Hmo is zero-moment wave height.

A relationship developed by Powell (1993) among median particle size (d_{50}), beach grading (ratio of d_{84} and d_{16} sizes), incident wave height and period, and beach face slope was applied in the design of the forebeach because it incorporates a measure of the size distribution of sediments as well as the median grain size. The maximum grading of beach sediments which Powell included in his laboratory studies was 8.3, with median size of 6.7 mm, which does not describe the "habitat mix" size distribution, however. Figure 3 shows gradations of habitat material from a natural Puget Sound beach, a commercially produced habitat mix, and calculated median diameter and d_{84} and d_{16} sizes corresponding to a 7:1 slope using the Powell formula. Prediction of equilibrium states between sediment size distribution and foreshore slope is less certain for habitat mix because the sand content is typically higher than in beaches that Powell studied. Formulas for equilibrium beach slopes of Powell (1993), van der Meer and Pilarczyk (1986), and for on- or off-shore transport of Ahrens and Hands (2000), and those listed in Larson and Kraus (1989) were applied to the 5-year wave height and period and observed beach face slope. Formulas based on a single grain size generally indicated that most of the material termed the natural Puget Sound beach in Figure 3 would remain in place or be moved onshore by the design waves. The formula incorporating gradation indicated the equilibrium slope was flatter than that measured at Puget Sound beaches.

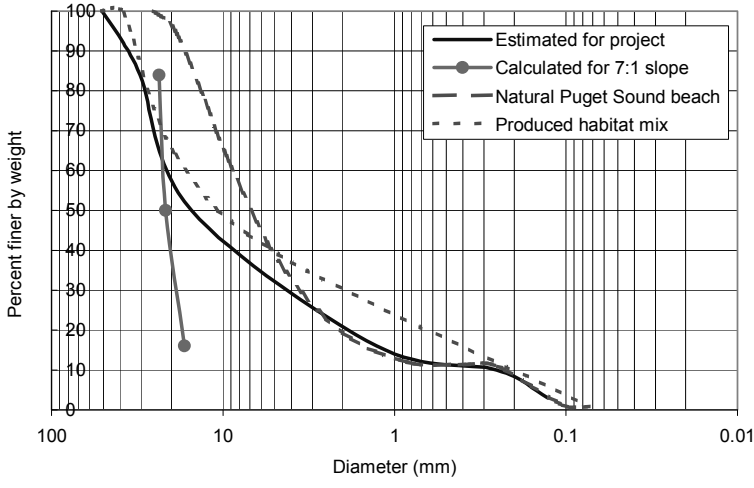

Fig. 3. Shore structures and beach in project reach

Wave heights and periods corresponding to the 5-year exceedance probability were input with a 7H:1V slope to formulas referenced above to predict combinations of median particle size and grading for designing the foreshore material. Gradations were developed through the formulas as a starting point, then modified in consideration of gradations measured at natural beaches, and to account for gradations of commercially available material that could be used to construct the project. The design gradation of the project habitat mix is shown in Figure 4. Size characteristics of the gravel core of the designed beach cross section were determined using a 4H:1V slope and wave of the 20-year exceedance frequency (Figure 4). The design gradation for the project habitat mix is also shown in Figure 3 to compare with gradations of other habitat material. The design slope of the foreshore is 7H:1V, but the slope calculated as being in equilibrium with the design habitat mix is 12H:1V according to the Powell formula. Designing the habitat mix gradation relied more on observed gradations than on formulas in their current state. This difference is cause for concern because the project would not be considered successful if the foreshore flattened to the predicted 12H:1V slope. Post-construction monitoring will focus on the performance of this material and the foreshore slope.

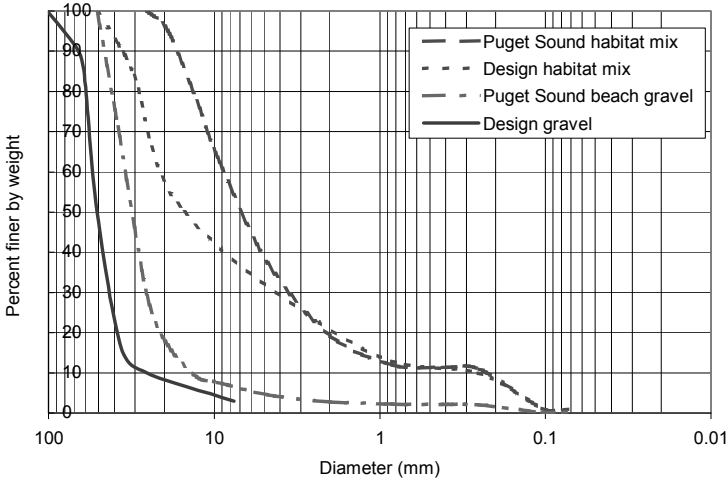

Fig. 4. Observed and calculated gravel and habitat mix gradations

The model RBREAK2 (Kobayashi and Poff 1994) simulated wave runup and overtopping of the berm designed to various heights. Model output assisted in determining the berm elevation and dimensions that would minimize wave overwash on the back beach and maximize stranding of large woody debris on the berm crest. The optimum berm elevation was 13 ft MLLW and back beach width was 30 ft.

Transitions of the designed berm to unimproved shorelines at both the east and west ends of the project were based on the interpreted net eastward longshore sediment transport pattern. The eastern transition to the unimproved beach included a beach sill composed of cobbles. The sill is a permanent feature to retain beach material that would otherwise be transported alongshore to the east. The estimated average replenishment rate of habitat mix is based on a projected loss rate of initially placed material. The loss rate was calculated with the shoreline diffusivity parameter, as defined in Coastal Engineering Manual (2002) Part III Chapter 2, using pre- and post-project beach face slopes, which influence the location and height of waves at breaking. The ratio of diffusivity parameters is the basis of the estimated 10 percent loss rate after construction. The renourishment cycle was assumed to be once per 5 years.

Design Plan, Section, and Specifications

Figure 5 shows the design plan of the beach rehabilitation. The plan accommodated construction of a beach face on which habitat would develop and meet other project objectives and criteria, with the minimum quantity of imported material. The greatest increase in beach elevation from pre-project to design surface is 6 ft, at the location of the berm crest at the eastern end of the project. The widest footprint of the designed beach is 115 ft. Four beach sections include designs for conveying storm water

through the constructed beach from existing culverts located at the back beach, two by culvert extensions and two by means of a porous cobble portion designed into the section. Access paths descended from the upland to merge with the berm crest at two locations. The path was supported with structural fill, which was protected at its base above the beach with rock revetment, vegetation, and anchored logs.

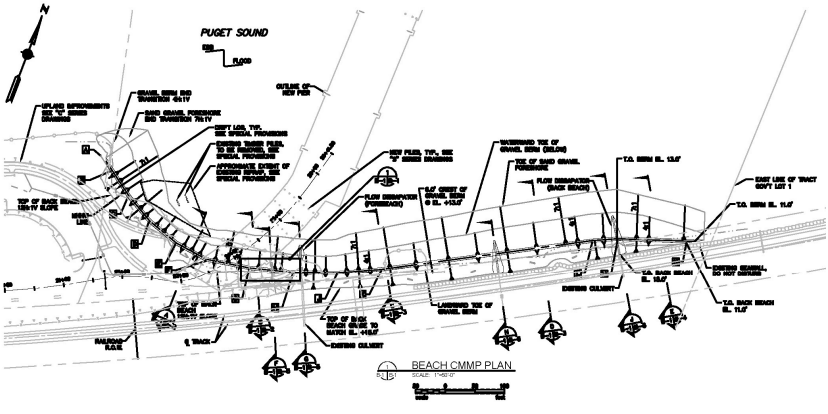

Fig. 5. Plan of beach rehabilitation

Size gradations specified for habitat mix are shown in Figure 6. Beach material quantities were specified by tons and costs were estimated on an in-place basis. Quantities were determined by computing with CADD the volumes of the separate materials between the surface constructed with the pre-project beach surface and the design beach surface. Volume was converted to weight with the factor 1.7 tons per cubic yard. The specified tolerance of the completed beach surface was plus or minus 4 inches of the design surface. Beach construction was to proceed in reaches 300 ft in length, which were to be accepted by the Engineer before the Contractor could finish the next reach in sequence. After the Engineer accepted a reach the Contractor was to minimize construction impact to that section, but was also no longer responsible for repairing damage of the section caused by natural processes.

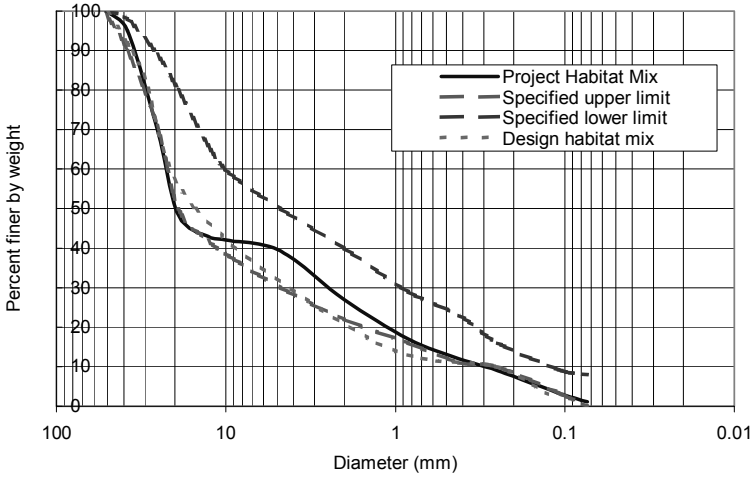

Fig. 6. Gradations of specified and supplied habitat mix for constructed foreshore

CONSTRUCTION

All beach materials were transported over surface streets to the site with dump trucks and stockpiled. Gradation curves of materials proposed for constructing the beach were evaluated for conformance to the construction documents and were visually assessed before the material was placed in the project. Beach rehabilitation construction began in September 2005. A single 22-cu-yd capacity off-road truck transported beach material from the stockpile to where it was placed. A small dozer bladed and compacted the material to lines and grades. The rate of material placement by this operation was 220 tons per hour on the eastern extent of the project, farthest from the stockpiles.

Locations requiring cobbles were constructed first. Gravelly core material was then placed and used as a haul road to advance the placement toward the eastern end of the project. With this sequence, operation was unimpeded by high tide levels. After the core section at the eastern terminus was constructed, back beach sand placement alternated with habitat mix placement, as tide height permitted. The Engineer verified that the finish surfaces of the beach components were within specified tolerance, using the construction surveys. The Contractor constructed 750 feet of beach by November 3, 2005, and delayed further beach construction until tide levels during daylight were more favorable, starting in January 23, 2006. Beach construction was completed with transition to the pre-existing armored fill at the western end of the project by the end of January 2006.

The placed quantities of materials were within 8 percent of the design volumes, except for the habitat mix, which had a significant over-run. The overrun could have been caused by loss of some of the fines in the habitat mix into the porous structure of

the gravelly core as well as washed into Puget Sound during initial tidal inundation. The 2005 cost of the constructed beach was $585 per lineal foot, not counting landscaping and irrigation for new vegetation on the back beach.

PERFORMANCE ASSESSMENT

Monitoring program

A monitoring program to evaluate beach performance against success criteria was developed during the permitting process and was finalized with an agreement among the Port of Everett and resource agencies before environmental permits were granted. Monitoring results will be reviewed to determine the need for beach renourishment, document the constructed beach response to waves and tides, and assess the accuracy of predictive relationships that were the basis of design.

The monitoring program specified establishment of a minimum of six transects in the project area for surveying beach cross sections after construction is complete and in the late summer after 1, 2, 3, and 5 years following construction, and within one month following a significant storm from the north. Monitoring will be extended to years 7, 10, and 20 unless it has been shown that a significant storm from the north produces no long-term changes in the beach profile or substrate. With every monitoring, sediment is sampled at four locations on each transect and analyzed for size distribution. Photo points are to be established and reoccupied for photographing and comparing beach appearance through time. Figure 7 shows locations of monitoring transects A through F.

Beach rehabilitation success is measured with biological and physical factors. The physical measures of successful rehabilitation listed in the CMMP (Pentec 2004) are the following:

- Beach profiles will not change by more than +/- 1.5 foot by Year 5
- Substrate composition along the upper beach will be suitable for forage fish spawning over a minimum of 50 percent of the beach length enhanced
- No adverse impacts to eelgrass in the adjacent lower beach areas will result from material lost from the rehabilitated beach

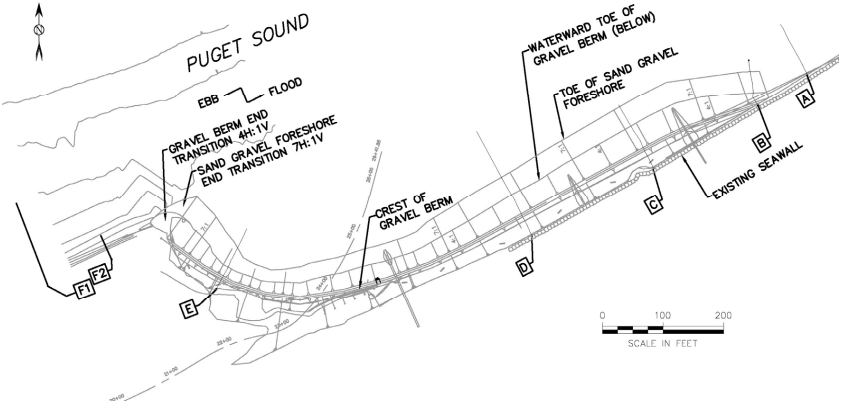

Fig. 7. Location of monitoring transects

Beach Cross Section

By November 2006, the constructed beach had not been impacted by design waves. Wind speeds from the north that produced a hindcast significant wave height of 2.6 ft incident on the rehabilitated beach occurred only in February and April 2006. Figure 8 shows monitoring transect D (see Figure 7) surveyed on May 26, 2006 and November 16, 2006 as an example of beach response to the wave climate since the time of construction. The beach face above mean tide level had remained at a slope of 7H:1V in both May and November. The slope below mean tide level to the intersection with the pre-project profile was 7.5H:1V in May. The berm crest elevation increased to 14 ft above MLLW from the constructed elevation of 13 ft. Some material has been lost from the western end of the project, where the shoreline angle with respect to incident waves is most oblique. Thus far the design intent of providing the specified beach face slope has been met. The transition section at the eastern end of the project (Transect B) has undergone the greatest change, exhibiting retreat and lowering as the plan form attained a smoother transition to the unimproved beach. Sediment volume adjustment of the constructed beach is being monitored as surveys are repeated at the monitoring transects.

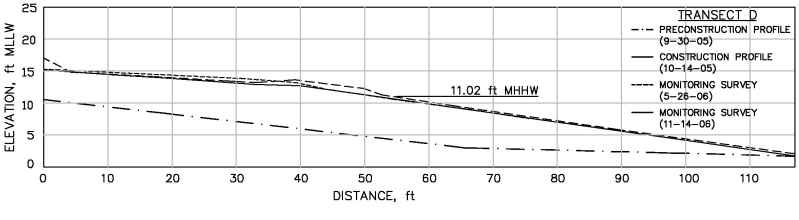

Fig. 8. Profiles of monitoring transect D, May and November 2006

Sediment Analysis

Sediment samples were taken from the beach surface and below the surface along the monitoring transects on May 26 and November 16, 2006 at the times the cross sections were surveyed. Samples are identified by survey shot numbers in Figures 9 and 10. Sediment size distributions of surface samples taken on the beach face at about elevation 9 ft on Transects C and D on the two monitoring dates are plotted in Figure 9. The gradation of the placed material is shown in the figure for comparison. Modification of the gradation by natural sorting is evident for some samples, but other sample pairs show remarkable similarity from May to November. At some locations the surface material became coarser from May to November and at other locations the sediment became finer (Figure 9). Figure 10 compares the gradation of the beach surface material and the material below the surface layer at the same location and time. The surface layer thickness was one to two diameters of the larger particles in the layer. Size statistics of the surface samples and the subsurface samples are plotted separately in Figure 11 as median size versus ratio of d_{84} and d_{16} sizes. For comparison, statistics of the beach sediments used to develop the empirical equation of Powell (1993) are also shown along with gradations of other Puget Sound beach samples are also plotted for comparison. The figures show that the habitat mix placed in the project and sorted by the wave climate, as well as other natural Puget Sound beaches, have larger ratios of d_{84} and d_{16} sizes than do sediments used in developing the formula.

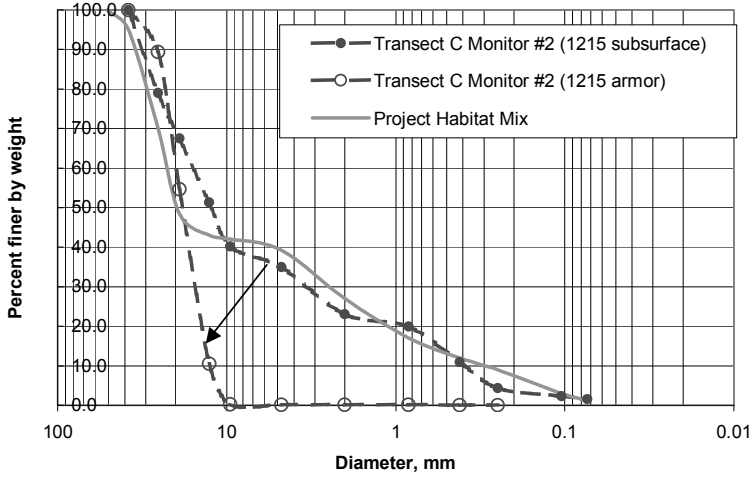

Fig. 10. Sediment gradations of forebeach surface and subsurface, November 2006

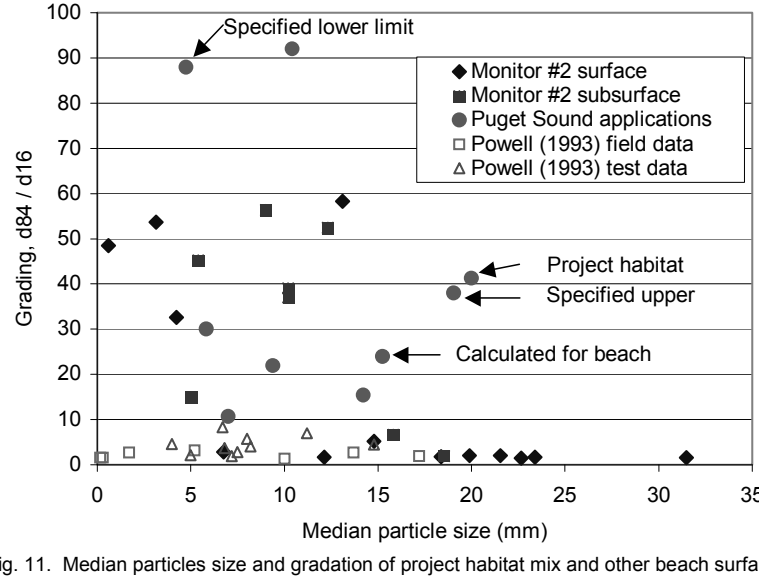

Fig. 11. Median particles size and gradation of project habitat mix and other beach surfaces

Beach Appearance

Photographs of the beach taken in 2004 before construction and November 2006 (after construction) show that the beach features desired to be created have been maintained over the first year since placement. Comparison of Figures 12a and 12b illustrate the distinct beach berm and woody debris that accumulated on the beach crest after construction.

Fig. 12. Beach appearance before and after beach construction, view toward east

SUMMARY DISCUSSION

A beach composed of sand and gravel was constructed at a Port of Everett property with three objectives: habitat restoration, shore protection, and public access. Size gradations of material comprising the forebeach and the gravelly core and berm were designed using knowledge of sediment gradation of naturally formed Puget Sound beaches, and with the aid of empirical formulas that accounted for both sediment median size and ratio of d_{84} and d_{16} sizes. Empirical formulas appear to have limitations in design of Puget Sound habitat beaches because these beaches have a greater sand percentage than those from which the formulas were developed. The beach has been in place for parts of two winter seasons. Habitat features of beach slope, surface material size distribution and beach dimensions that were the design goal have been maintained. The project shows the viability of constructing mixed sand and gravel beaches in particular Puget Sound locations when design procedures are followed.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support of the Port of Everett in constructing and monitoring the beach at its Rail/Barge Transfer Facility, and the permission by the Port of Everett to publish this information.

Abstract: The morphodynamic response of a mixed gravel and sand barrier is considered, by reference to storm conditions of varying magnitude, and under differing management regimes. Observations focus on evolution of the barrier at the temporal scale of the storm event, but the response during these episodic events is placed in context with potential impacts on longer term decadal scale geomorphological evolution. Decadal scale evolutionary trends indicate that the total volume of the barrier is declining and that the frequency of overwashing events and rate of rollback of the barrier is likely to increase. Changing profile and sediment sorting responses are evident during the interim phase, immediately following changes in management practice. Modifications to management practice present new issues that may include the possibility of fragmentation on the barrier.

INTRODUCTION

The mixed gravel and sand barrier between Blakeney and Salthouse, lies on the North Norfolk coast of the UK (Figure 1); it is an integral part of a complex coastal geomorphic system that also provides the first line of defence against tidal flooding to the villages of Cley and Salthouse, during extreme surges.

The 11km long barrier forms part of a macro tidal environment, with a mean spring tidal range of 4.4m. The distal terminus is very active, extending through a sandy ebb delta

system. Historical records indicate that that the barrier has migrated at a rate of circa $1ma^{-1}$ since the 16th century. Episodic storm surge events have historically resulted in extensive overwashing and flooding (Orford et al, 2003).

The back barrier area has historically been subject to considerable intervention. Some natural development of intertidal saltmarsh system occurs towards the distal end of the barrier, but extensive reclamation of the proximal end of the back barrier during the 20th century, to form coastal grazing marsh with an extensive drainage system, has substantially reduced the intertidal area (Orford et al 2003). This reclamation has reduced the potential for flood inundation via the estuary, but has also modified the geometry of the back barrier area over which the barrier rolls back. This compounds the complexity of future possible evolution of the barrier, by modifying the accommodation space and by increasing the surface emergent cross-section area; this effectively reduces the potential rate of roll back. . The grazing marshes and freshwater habitats defined and protected by Blakeney barrier are of the highest habitat value particularly for ornithology and are protected by a range of national and international designations.

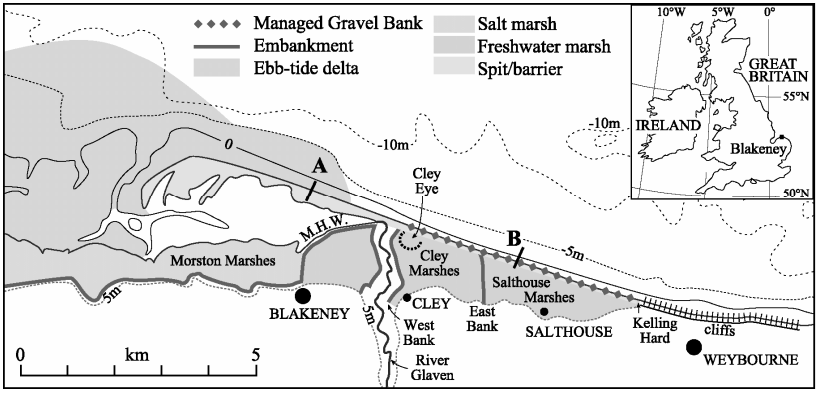

Figure 1. Location and Structure of Blakeney-Salthouse Gravel Barrier (source Orford et al 2003).

The western section of the barrier has remained unmanaged for the last 50 years and has been allowed to evolve naturally. By contrast, the proximal eastern section of the barrier was managed at least since the 1950s until 2005, with mechanical plant used to profile the beach following storm events. This management practice has been considered to be unsustainable, both financially and also environmentally, especially with regard to the EU Habitats Directives. The UK government requirement on returning 95% of designated sites to a satisfactory level by 2010AD means that the barrier management regime has recently been altered to one of virtual non-activity in physically managing the barrier, so as to enable "natural' evolution of the barrier and allow back-barrier area to revert back to a more natural form. Following some fifty years of management this approach presents some complex issues and there is some uncertainty regarding the

likely future patterns of evolution, whilst the barrier adjusts to the new regime.

This investigation seeks to examine the early stages of transition from a managed barrier, to a more naturally evolving system. The implications of earlier management practice on long term evolution are examined. Morphodynamic responses and evolutionary patterns are examined, with respect to defined hydrodynamic conditions, prior to and following changes in management practice. Hypotheses are examined to examine predictions for future changes. For the purposes of comparison the beach is divided into two segments reflecting the unmanaged and managed beach sections (Figure 1).

FIELD OBSERVATIONS

Field observations span the period 1992-2006 and include some 30 independent surveys of beach profiles spaced at approximately 1km intervals (Figure 1). These are supplemented with more detailed recent surveys derived from LIDAR (0.25m resolution), covering the whole of the barrier and back barrier area. Post storm beach profile survey data also provides evidence of beach evolution, during events that have followed the changes in management policy. A series of orthorectified aerial surveys, spanning epochs from 1946-2004, provide the basis for determination of plan shape changes. Hydrodynamic data are provided by tide gauge (Cromer 1km west of the site) and wave measurements, and hindcast offshore wave data, transformed to nearshore locations.

MANAGEMENT PRACTICE

Prior to 2005 two distinct management practices were evident on the barrier (Figure 1). The beach exhibits differing performance and evolutionary characteristics on each section. Active management of the barrier ceased during 2004, since when the barrier has been allowed to modify naturally.

Unmanaged beach

The morphodynamic evolution of the unmanaged beach section is consistent with the classical processes normally associated with gravel barriers (Orford et al, 1995). The classical dynamic equilibrium shingle beach profile (Powell, 1990) develops whilst conditions are sufficiently benign that wave run-up cannot exceed the crest; this provides a distinct berm, breaker-step and toe at the seaward limit. The dynamic equilibrium profile can be predicted reliably for given combinations of wave, water level and sediment size under such conditions. Clearly defined ephemeral berms form beneath the crest, in response to the dynamics of the wave and water level conditions. As the combination of wave period and water level conditions become more severe however, wave-run up may exceed the crest and at this point the predictive profile model fails to function, as it is not designed to deal with a cross-section of finite area (Bradbury, 2000).

Overtopping may occur as conditions become more severe. The swash limit is initially small as a result of the high beach permeability and most water percolates harmlessly through the permeable structure. Modification of the crest may occur with build up of

sediment arising under such conditions (Orford et al. 1991). Evolution of the crest is confined to those conditions where sufficient wave energy reaches the crest to cause sediment movement. Saturation of the beach occurs under the most severe conditions and this may result in larger scale movements of sediment resulting in overwashing, which can reduce crest height (Carter and Orford, 1993, Carter et al 1993).

Beach sorting processes result in general coarsening of grain-size, and increasing permeability of the beach sediment towards the crest. The crest is generally characterized by coarse open-work shingle, whilst the sandy component washes through towards the base and toe of the beach. Layering and intermixing of sand layers with coarser gravels is sometimes evident, but these layers are usually ephemeral, arising from rapid changes in deposition in overwashing events, within the more severe storm events. Long term processes gently wash the finer fraction from the surface layers maintaining a permeable structure over much of the beach.

Maintained beach

Regular maintenance of the shingle ridge has been carried out for at least 50 years, to the east of Cley Eye (Figure 1). The beach cross-section has been maintained with an artificially high crest elevation and over-steep upper beach crest ridge. The crest elevation has typically been maintained at between 8-9mODN, some 2-3m higher than the typical crest of the natural beach. This has been achieved by bulldozing beach material landwards with mechanical plant, to reform the crest ridge following storm activity. This practice of cross-shore recycling has several impacts. Cross-shore movement of beach material results in a modified profile shape, which is much steeper than would form naturally. Additionally, the mechanical profiling process results in movement of the finer fraction of material from the lower beach to the beach crest, mixing of coarse and fine sediments, and compaction by the mechanical plant to form a cohesive matrix; this is able to stand close to a vertical angle, until undermined and reworked by wave activity. Permeability of the beach and any infiltration by water is reduced, thereby generating greater overland flow on the beach face under backwash. No additional beach recharge material has been added to the system – though some longshore sediment transfers are likely.

Following mechanical profiling of the beach, changes to the modified profile are rapid under wave action, as the beach seeks to reproduce a more natural dynamic equilibrium profile. The cohesive matrix of the upper beach is maintained until the whole of the upper beach has been reworked. As maintenance of the crest ridge has continued for more than 50 years, the reworking process has not been permitted to complete this cycle. A reflective upper beach face is formed therefore, which accelerates the return of beach material to the lower foreshore and modification of the profile towards a dynamic equilibrium shape. Although the lower beach is reworked, this does not generally occur above an elevation of about 4mODN. A hard impermeable core has resulted within the unworked section of the barrier crest. On rare occasions wave activity is able to reach the crest in severe events, but the beach crest performs with similar characteristics to an impermeable vertical seawall under these conditions, resulting in overtopping of the

crest and waves plunging vertically onto the lee face of the beach and forming deep runnels. The sediment characteristics of the beach are defined by a heavily mixed foreshore and an oversteep crest ridge of matrix dominated fine materials, with occasional clasts.

Geometric characteristics of managed and unmanaged sections

The geometric characteristics of the managed and unmanaged sections of the beach provide some marked contrasts. Whilst the natural crest elevation of the unmanaged beach lies at between 5-6.5mODN (MHWS=2.45mODN), the managed beach sections are typically within the elevation range 8-9mODN. The beach cross-sectional area above MHWS is however typically approximately 60% larger on the unmanaged beach section than the managed section. This is significant in context with the predictive approach to the threshold of barrier overwashing (Bradbury et al, 2005), which suggests that the surface emergent cross-section area at the storm peak provides the most significant geometric control. Threshold conditions leading to overwashing might reasonably be expected to be somewhat less severe on the managed section therefore. Although the beach cross-section area varies between the managed and unmanaged sections, the wave climate conditions are very similar along much of the barrier length. Differing beach responses are likely to be a function of beach geometry and sediment structure therefore.

DECADAL SCALE EVOLUTION

The unmanaged western 5km of the barrier exhibits classical gravel barrier evolution characteristics (Orford et al 1991), with high permeability, regular overtopping, overwashing and landward transgression during extreme events. Decadal scale evolution of the back barrier fringe, determined from aerial surveys, suggests an annual average rate rate of 0.9m a^{-1} for the period 1946-2004 (Box, 2005). Profile analysis demonstrates the episodic nature of crest and back barrier evolution. For instance, a single event (19 February 1996) is responsible for transgression of the back barrier fringe by approximately 25m, and reduction of the crest elevation by 1m. Regular crest evolution and overwashing is clearly evident within a 15 year evolutionary sequence of profile data (Figure 2). Washover fans that do not reach the back barrier margin can extend as far as 40m from the beach crest. Changes in crest elevation are typically small (<1m) even under the most extreme events. Numerous events have resulted in deposition of veneer deposits 0.1-0.2m thick under overtopping conditions. The crest has been within a building phase for most of the period.

By contrast, the pattern of evolution on the managed beach is somewhat unclear. A lower rate of barrier migration (0.6m a^{-1}) is suggested by aerial survey data; this rate has been controlled however, largely by the mechanical reprofiling process that has resulted in artificial holding of the crest line and limited evolution of the back barrier margin. As the barrier inertia is somewhat lower on the managed section of beach a more rapid rate of transgression might reasonably be expected under naturally evolving conditions.

Profile analysis indicates net losses in the upper beach volume (above MHWS) over the period 1992 to 2004 of approximately 300,000m^3 spread equally between the managed and unmanaged sections of the barrier (Halcrow, 2006). This represents a total proportional loss of 13%, from the original total volume of 2.3million m^3 above this elevation. The downward trend appears to be reasonably linear. The implications of these losses and the ongoing trend of a gradually reducing effective cross-section area, combine with factors such as relative sea level rise, and increasing intensity of wave climate; these variables increase the vulnerability of the barrier to overwashing processes and future rates of change of evolution. As losses continue, the frequency of overwashing events is expected to increase. Whilst the freeboard of the managed section of the beach is consistently higher than the unmanaged beach, the cross-section area is generally significantly smaller. Cross section areas above MHWS on the managed barrier vary from about 160-250m^2, whilst those on the managed barrier vary between 100-220m^2. The cross-section area of the unmanaged beach is on average 60% higher than the managed beach, which suggests that a more volatile response might be expected on the managed beach section. It is clear that without supply of additional beach material from new sources the beach volume will continue to decline and the frequency of overwashing will increase.

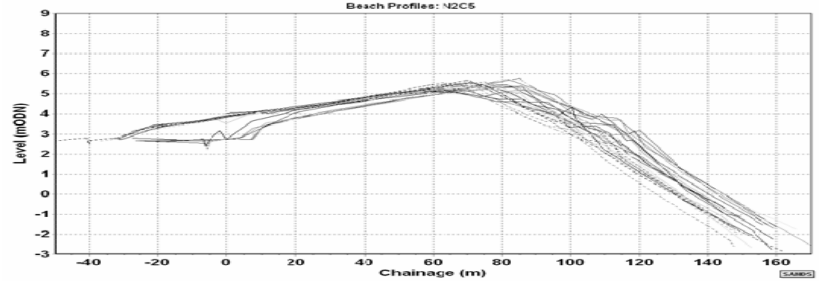

Figure 2 Evolution of the unmanaged barrier from 1992-2005

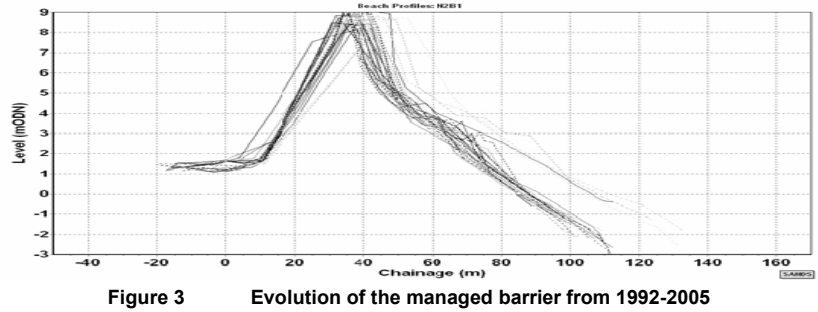

Figure 3 Evolution of the managed barrier from 1992-2005

A variable longshore wave energy gradient is evident but this is inconsistent along the length of the barrier. Although sediment transport calculations (Halcrow, 2006) suggest differential rates that might possibly induce the formation of tears and fragmentation in the barrier, the transport rates are consistently low, with the exception of the distal end of the spit. Given the potential limitations of the modeling exercise the differentials identified could be within the expected scatter of results. There is no evidence of tears forming within the beach at this stage, although two sections do show signs of preferential thinning.

WAVE CLIMATE

The Met-Office UK waters regional wave model provides the source time series data (1986-2006) for generation of an offshore wave climate. The lengthy time series is extrapolated using a Weibull probability distribution to provide an estimate of extreme conditions (Table 1). The regional wave climate is dominated by the most severe wave conditions occurring from the north-northeast sector (300-60^{O}). Historically, all recorded events that have resulted in overwashing of the barrier have arisen from waves generated from this direction sector.

Numerical modeling of shallow water wave transformations provide nearshore conditions at a series of points, above the 10mCD depth contour (see Figure 1); this provides wave conditions in an effective water depth of 10-15m, across the tidal range, in conditions close to the seaward limited of wave driven sediment movement or depth of closure. Provision of the nearshore wave climate across this range of water depths provides the most appropriate conditions for input to investigations of models of barrier profile development, including estimation of the overwashing threshold conditions (Bradbury, 2000).

Table 1. Offshore and Nearshore 3-hourly Extreme Wave Conditions for All Directions.

Return period (years)	Extreme offshore wave height H_s (m)	Extreme nearshore wave heights H_s (m)
0.1	4.51	2.71
0.2	4.83	2.91
0.5	5.23	3.17
1	5.52	3.36
2	5.79	3.54
5	6.14	3.77
10	6.40	3.95
20	6.65	4.11
50	6.97	4.33
100	7.20	4.49
200	7.43	4.64

Key storm events have been hindcast and transformed to the nearshore locations (Table 2). The three events described have all resulted in overwashing at some location on the barrier. Individual storm events are placed in a probabilistic return period context relative to the regional wave climate. Extreme water levels are shown in similar context, based upon earlier investigations (Halcrow, 2006). Sensitivity testing of the longshore

gradient and variability of the wave climate for these extreme conditions indicates very small changes in conditions along the length of the barrier, with the exception of the distal recurves where the wave intensity is reduced and the angle of wave attack much more oblique. Significantly, the nearshore conditions result in virtually normally incident wave conditions at the barrier site for each event.

Table 2. Nearshore Storm Characteristics of Events Resulting in Barrier Overwashing

Event peak	Hs (m)	Tz (s)	Tp (s)	Dirn O	Wave Return period (yrs)	Water level (mODN)	Surge Residual (m)

Storm profiles

The storm profiles of major events provide a valuable insight into the hydrodynamic conditions impacting on the barrier. Both major events shown (Figures 4 and 5) have resulted in major overwashing and flooding.

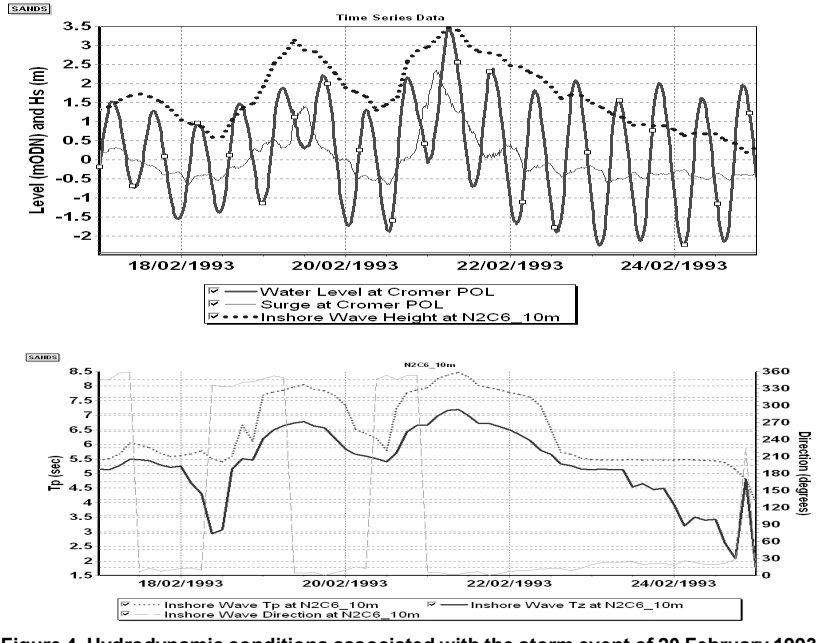

Figure 4. Hydrodynamic conditions associated with the storm event of 20 February 1993

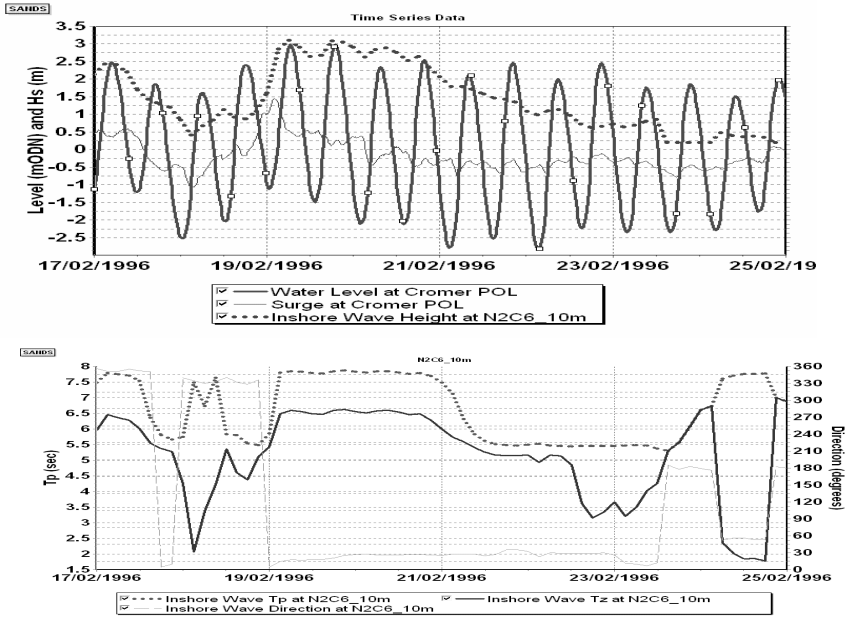

Figure 5. Hydrodynamic conditions associated with the storm event of 19 February 1996

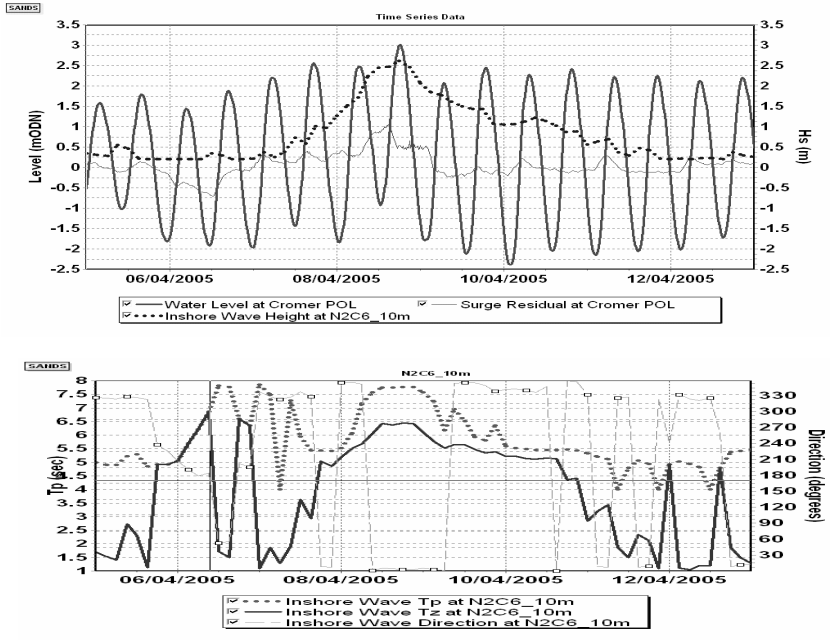
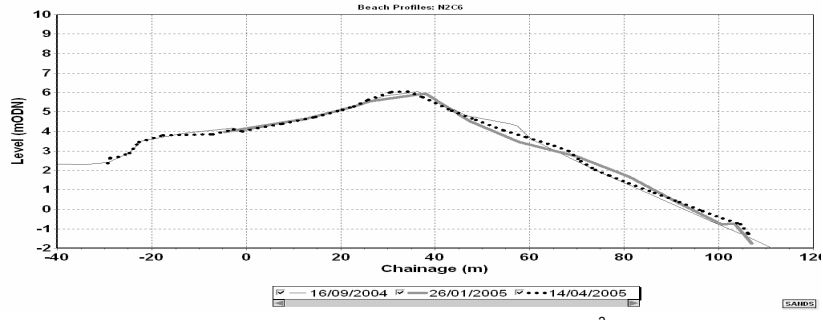
The characteristic conditions for both events show some similarities, with major storm surges (>1m) being associated with both events. Although the storm event of 20 February 1993 provides the most severe combination of significant wave height and extreme water level conditions, profile analysis demonstrates that more extensive evolution of the barrier is evident during the event of 19 February 1996. This may reflect maintenance of the storm intensity over a period of several tidal cycles around the 19 February 1996 event (Figure 5), during which period the resistance of the barrier would have been significantly reduced following initial overwashing. Storm duration is considered to be a significant factor in the rate of evolution, if the overwashing threshold has been exceeded and insufficient material is available to enable a dynamic equilibrium profile to form within the beach cross-section.

POST MANAGEMENT REGIME EVOLUTION

Since the change of management policy in 2004, wave conditions have generally been relatively benign, by comparison with the major flooding events (Figures 4 and 5). A storm event of moderate intensity on 8 April 2005 (Figure 6) provides an opportunity to examine the early stage impacts of modification of the management policy on the beach response. The storm peak is coincident with the high spring tide, which is also supplemented by a small storm surge.





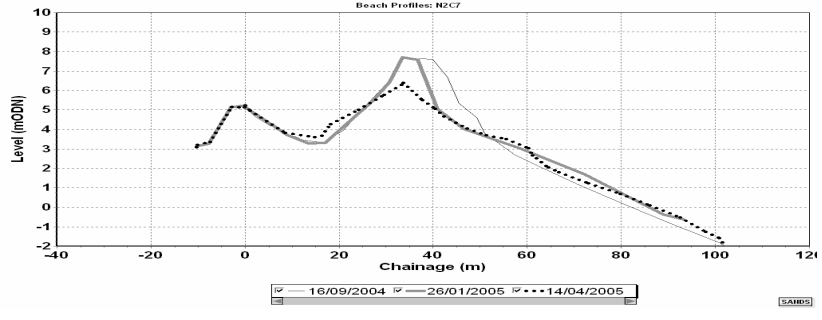


Figure 6. Hydrodynamic conditions associated with the storm event of 8 April 2005

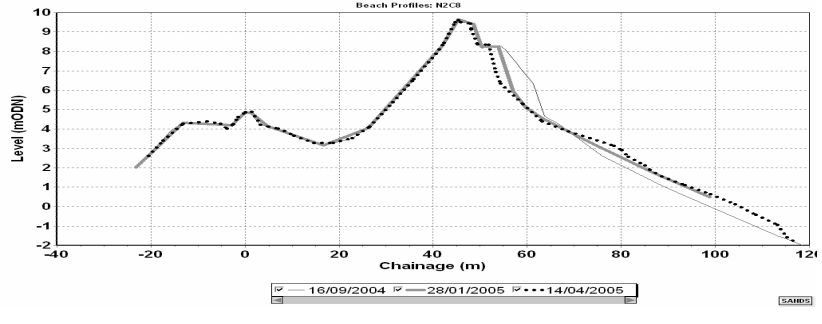
Sample profiles are presented, representing the beach response at various locations (Figure 7). Contrasting responses are evident according to pre-storm cross-section area and previous management practice. The beach performance on the unmanaged beach section is very similar to responses observed previously (Figure 7a). Conditions are very close to the overwashing threshold, with evidence of a thin veneer of washover deposits extending beyond the crest ridge, but with maintenance of the crest elevation.



The storm has resulted in reworking of the over-steep crest ridge over most of the length of the previously managed barrier. Observations made during and following the storm demonstrate clearly that the overwashing threshold was exceeded (Figure 8) at several isolated locations; this was confined to those areas of the beach where the pre-storm beach cross-section area above MHWS was below 110m^2. The extent of washover fans is limited to approximately 10-12m length to landwards (Figure 7b). The relatively small changes in the profile response, and maintenance of a sharp crest ridge suggest that conditions were close to the overwashing threshold. Profile analysis demonstrates that gradual thinning of the oversteep beach crest has occurred since maintenance has ceased. This is particularly pertinent on sections of the beach with low cross-section area.

7a. Unmanaged beach section (CSA = 155m^2)

7b. Previously managed beach section with small cross-section area (CSA=110m^2).

7c. Previously managed beach section with high freeboard (CSA= 220m^2).

Cross-sectional areas are all above MHWS (2.45mODN

Figure 7 Post storm profile response to storm event of 8 April 2005

Elsewhere on the beach there is evidence of erosion of the crest ridge and typically reduction of the crest width, but the upper crest ridge has maintained its steep upper profile (Figure 7c). Initial erosion of the crest ridge has resulted from waves that have been unable to reach the beach crest. Undermining of the steep beach face has resulted in cut back of the crest ridge and drawdown by reflected waves. The remaining upper beach crest remains matrix dominated and highly impermeable. The beach zone below an elevation of about 4mODN is showing signs of better sorting however. A steep leeward slope has been maintained, although there is evidence of plunging overtopping waves causing runnels in this area.

DISCUSSION

There is evidence that some parts of the barrier are already adapting and following a more natural evolutionary form, following changes to the management regime; this is more clearly evident where the crest elevation is low or the barrier cross-section is relatively small. There is clear evidence that the profile form is changing as better beach sorting, arising from re-working, results in increased localized permeability. The barrier crest remains matrix dominated at those locations where reworking has not yet occurred. A broader more well sorted foreshore is evident in the zone from mean tide level to about 2m above MHW, which is showing clear signs of increased permeability and sorting with clast domination.

Several stages are evident in the transition process. Firstly, the whole of the previously engineered cohesive barrier crest must be subject to wave activity and all sediment reworked before the barrier can evolve in a natural manner. On the basis of changes observed in profile trends since 2004, it seems likely that a further period of 3-5 years will elapse before this transitional process is complete. In the event of a major storm event, such as the February 1993 or 1996 events, this period could be substantially shortened.

Overwashing may occur at many locations prior to the completion of the re-working process. The elevation of the beach is so high at some locations that wave run-up is unable to reach the beach crest. Overwashing will arise as a result of undermining and

thinning of the crest at such locations. The cross-section area above MHWS exhibits high spatial variability, which lies in the range 100-250m^2. Regular (annual) overwashing can be expected where the cross-section is less than about 160m^2, based on historical trends on the unmanaged section. More frequent overwashing might reasonably be expected where the cross-section is smaller. Once the crest ridge has been reworked and overwashing processes become more regular, the rate of rollback is likely to increase. The long term loss of sediment from the system is likely to accelerate the overwash process, provided that this trend is maintained. Without further supply of material to the system, the barrier is expected to decline in volume further. Losses might reasonably be expected to occur at the historical rate observed between 1992-2004 (23,000m^3 a^{-1}), at least until such time as the barrier becomes more precisely swash aligned, when more volume might be maintained.

The impacts of back barrier controls will become much more significant on long term evolution. Features such as the glacial eye deposits could have a major impact on interruption of the rollback process. These will provide local restrictions on the rate of roll back at some locations, acting as headland structures. Fragmentation of the barrier is possible at these hard points, as tears may develop arising from differential resistance of the barrier. The potential breakdown of the barrier into smaller barriers
is linked also with uncertain issues related to sediment supply, and differential sediment transport rates along the length of the barrier. The major question arising is - will the barrier continue to form as a coherent single entity? Breakdown will depend upon many factors including tear propagation. The position of the 'eyes' is likely to hold up the ridge and push tear development as perturbations in a consistent spatial rate of barrier retreat - hence the possibility of smaller barrier segments

The elevation of the reclaimed land behind the previously managed beach will slow the rate of recession, providing greater effective cross section. Reworking of fine reclaimed material is likely to become a significant process that will modify the geometry and response of the lower beach zone. Similarly, migration over a back barrier of varying topography will present compaction issues, given the organic basis of the back barrier facies.

.

The historical management practice has enabled more mature development of features such as saline lagoons which are naturally ephemeral features and has also preserved shingle vegetation which might normally be destroyed. It is expected that
with greater overwash the saline lagoons (as a priority designation in the EU) may be better maintained. However the increased flood routing that has occurred in the back barrier (new sluice gates for storm discharge) might mitigate against that.

CONCLUSION

The mixed gravel and sand barrier between Cley and Salthouse is in a transition phase as it reverts from a heavily managed barrier to more natural structure. Changes in beach response have become evident within one year of the change in management practice. Transition phases will be followed by periods during which rate of overwashing and

rollback is expected to increase. Subsequently, the back barrier geometry will become a more dominant control on evolution. Ongoing monitoring of the transition from a managed barrier to more natural evolution will provide further evidence of changes in morphology and response.

Abstract: This paper reports on laboratory experiments carried out on fine and coarse sand beaches under raised and lowered back beach groundwater levels. Onshore sediment transport was enhanced when the groundwater level was lowered under both accretionary and erosive conditions, whereas higher groundwater level promoted offshore sediment transport. Under swell conditions, the coarse beach showed accretion at all groundwater levels. In contrast, on the fine sand beach, lowering the groundwater level was able to induce accretion on a previously erosive profile. The groundwater level had less effect on beach profile evolution under storm conditions, suggesting that artificially lowering groundwater levels would not help much in the control of storm erosion, but could promote post-storm accretion on permeable beaches. Agreement between measured and modelled head levels was better on the coarse beach than on the fine beach, and better in the swash zone and within the beach than in the surf zone.

INTRODUCTION

The relative importance of infiltration and exfiltration for sediment transport and beach profile evolution in the swash zone has not yet been resolved. Many researchers have suggested that infiltration losses in the swash provide a mechanism by which beach accretion occurs above the still water level (e.g. Bagnold 1940; Duncan 1964; Nelson and Miller 1974; Packwood 1983; Turner and Nielsen 1997; Masselink and Li 2001). Because the uprush and backwash are relatively shallow, a small change in water volume

due to infiltration losses could influence uprush/backwash flow asymmetry and therefore the energy available for sediment transport (Nelson and Miller 1974). The potential for infiltration or exfiltration has been linked to beach watertable elevation, with a low watertable favouring infiltration and onshore sediment transport and a high watertable favouring exfiltration and offshore sediment transport (Grant 1946, 1948). A practical application of this concept is the use of beach dewatering systems, where the watertable is artificially lowered within the beach by a system of drains and pumps. However, attempts to modify beach morphology by controlling groundwater levels or through beach drainage have had mixed success and the effectiveness of the dewatering concept in maintaining beach stability and controlling coastal retreat is yet to be convincingly demonstrated at the prototype scale (Turner and Leatherman 1997). In addition, the conditions under which infiltration is a significant process have not yet been definitively determined. Numerical studies have suggested that the effects of infiltration/exfiltration on sediment transport are greater in the uprush than in the backwash (Packwood 1983; Turner and Masselink 1998; Masselink and Li 2001). However, the inferences drawn from this modelling about infiltration effects in the swash has not yet been verified. A number of studies also indicate that infiltration in the swash zone may only be important for profile evolution on coarse-grained beaches (Bagnold 1940; Quick 1991; Packwood 1983). The beachface gradient has been shown to increase with the amount of swash infiltration (Quick 1991; Masselink and Li 2001), and infiltration loss in the swash is often given as the reason why gravel beaches are steeper than sand beaches. This has led to the suggestion that hydraulic conductivity is an important factor in the different response of fine and coarse-grained beaches, and therefore that beach groundwater dynamics play an important role in beach profile evolution.

EXPERIMENTAL SETUP

The experiments reported here were carried out in a section of the Coastal Wave Basin in the Department of Civil Engineering, University of Queensland, Australia. The section used in the experiments was 27.3 m long, 1.4 m wide and 0.8 m deep, with a working depth of 0.5 m (Figure 1). The experimental setup was designed to simulate a coastal barrier dividing the ocean from a relatively constant back beach water level, conditions approximating a closed off lagoon system or beach aquifer. Under this scenario, the backshore water level was fixed at an elevation that was either higher than, lower than, or the same as the still water level (SWL), comparable to varying the groundwater level according to the tidal stage. Thus at high tide the groundwater level at the beach boundary may be raised above that inland, whereas at low tide it may be lower, with wave runup subsequently further influencing the groundwater levels in the beach. Varying the back beach groundwater level influenced a much larger region of the upper beach than if a point or line drain were used. The water level in the basin was kept constant using a small inflow near the wave generator and a weir behind the beach. The back of the beach was supported by a wire mesh located 0.2 m from the back wall of the flume, which prevented the loss of sediment while allowing water flow in and out of the permeable beach. The water level behind the beach was controlled by an adjustable pipe which was connected through the back wall.

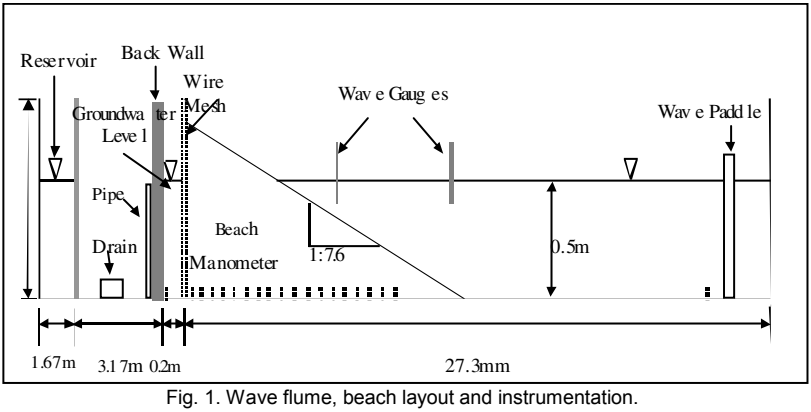

Fig. 1. Wave flume, beach layout and instrumentation.

At the start of each experimental run, the watertable behind the beach was set at a chosen level (nominally 0 to ± 0.075m) relative to the offshore level and the piezometric head levels recorded. A series of regular waves were then generated by the wavemaker and wave parameters were measured with two surface-piercing wave gauges. A set of 20 damped manometer tappings on the bed of the flume provided time-averaged mean piezometric head levels in the cross-shore direction from offshore of the breakpoint to the back of the beach. According to Dupuit-Forchheimer theory, the piezometric heads can be assumed to give the watertable elevation as long there is no significant vertical flow (Kirkham 1967). The water level in the manometer tubes responded quickly to uprush and backwash, and eventually reached steady state conditions.

Table 1. Experimental runs for each grain size

Run	H (m)	f (Hz)	Ω (H_b/w_sT)	Profile Type
1-3	0.05	0.4	0.15	swell
4-6	0.1	0.4	0.31	swell
7-9	0.15	0.4	0.46	swell
10-12	0.05	0.6	0.23	swell
13-15	0.1	0.6	0.46	swell
16-18	0.12	0.6	0.7	swell/storm
19-21	0.15	0.6	0.56	storm
22-24	0.05	1	0.39	storm
25-27	0.1	1	0.77	storm
28-30	0.15	1	1.16	storm

Two sets of experiments were carried out, one with coarse sand (d_{50}=0.84 mm) and one with fine sand (d_{50}=0.197 mm). In all experiments, the initial beach profile was planar, with a slope of approximately 1:7.6, with the beach gradient starting from the weir mesh and extending 5.4 m from the back wall. The beach was regraded between runs so that each run started with the same initial profile. The relative back beach water levels and wave heights were set to simulate the typical tidal range and wave heights on a micro-mesotidal beach. For each sediment size, experiments were run with regular waves at three wave frequencies (0.4, 0.6 and 1 Hz), three wave heights (0.05 m, 0.1 m and 0.15 m), and three groundwater levels in the beach (0.05 m above SWL, 0.05 m below SWL and equal to SWL), in order to simulate high tide, low tide and mid-tide conditions (Table 1). Note that three runs were carried out at each wave setting in order to vary the groundwater levels for these waves. All tests were run for an hour. Manometer readings were taken at the start of the experiment and at 10, 20, 35 and 55 minutes into each run. The beach profile was measured along the centre line of the beach at the start of the experiment and at 15, 30 and 60 minutes into each run.

BEACH PROFILE EVOLUTION

Figure 2 shows the initial planar beach profile and the measured beach profiles for the fine and coarse sand beaches after 60 minutes for swell conditions for the case where the back beach groundwater elevation was the same as the SWL (run 7 on Table 1). Under these conditions, onshore transport and accretion above the SWL were observed on the coarse sand beach, with a berm developing on the upper beachface. In contrast, the fine sand beach showed offshore transport, with the upper beachface eroding and a bar developing in the same offshore position where the coarse sand beach showed erosion (approximately 2-3 metres from the back wall).

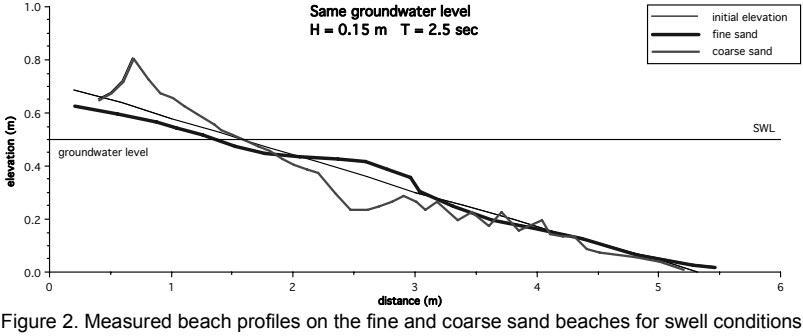

Figure 2. Measured beach profiles on the fine and coarse sand beaches for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level the same as the SWL

Figure 3 shows the initial profile and the profiles after 60 minutes for the fine and coarse sand beaches for swell conditions when the back beach groundwater elevation was lower than the SWL (run 8). In contrast to the situation when the groundwater level in the beach was the same as the SWL (run 7, shown in Figure 2), both beaches showed onshore transport and accretion above the SWL with a lowered back beach groundwater

level. However, only a small amount of accretion was observed on the fine sand beach, whereas a large berm developed on the coarse sand beach. One bar developed below the SWL on the fine sand beach. As in the previous case, the coarse sand beach showed erosion below the SWL, with a series of small bars developing further offshore.

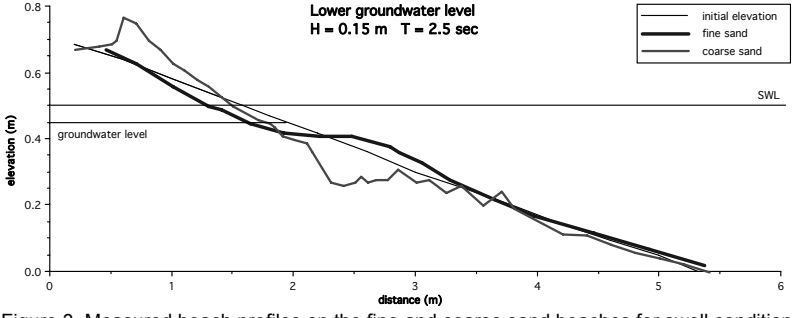

Figure 3. Measured beach profiles on the fine and coarse sand beaches for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level lower than the SWL

Figure 4 shows the initial profile and the profiles after 60 minutes for the fine and coarse sand beaches for swell conditions when the back beach groundwater elevation was higher than the SWL (run 9). The results show the same pattern as run 7, with onshore transport on the coarse beach and offshore transport on the fine beach. However, with raised inland groundwater levels, much less accretion occurred on the coarse beach, whereas the amount of erosion on the fine beach was similar to that in run 7. This suggests that the reduced infiltration due to the raised groundwater level affected sediment transport on the coarse beach, but had little effect on transport on the fine beach, where the profile was virtually identical to that in run 7.

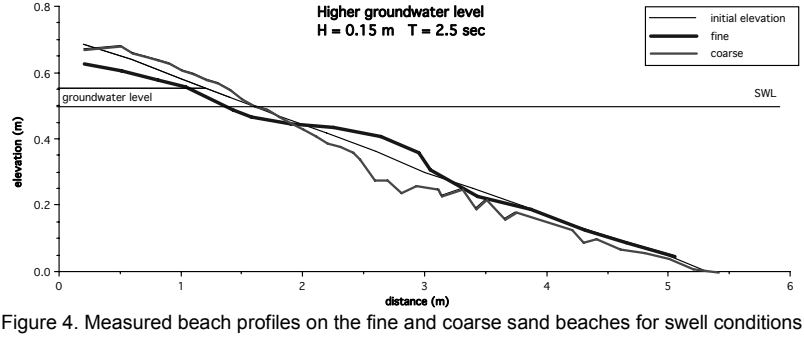

Figure 4. Measured beach profiles on the fine and coarse sand beaches for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level higher than the SWL

Figure 5 shows the initial profile and the profiles after 60 minutes for the fine and coarse sand beaches for storm conditions when the back beach groundwater elevation was the

same as the SWL (run 25). Under storm conditions, as expected, offshore transport occurred on both the fine sand and the coarse sand beach. However, the coarse sand beach appeared to show more erosion above the SWL and bar development below the SWL than the fine sand beach. In contrast, the fine sand beach showed relatively little change from the initial profile. Field experiments have also shown that the amount of profile change on coarse beaches is often greater than on fine beaches (e.g. Van Wellen et al. 2000; Kulkarni et al. 2004; Horn and Li 2006).

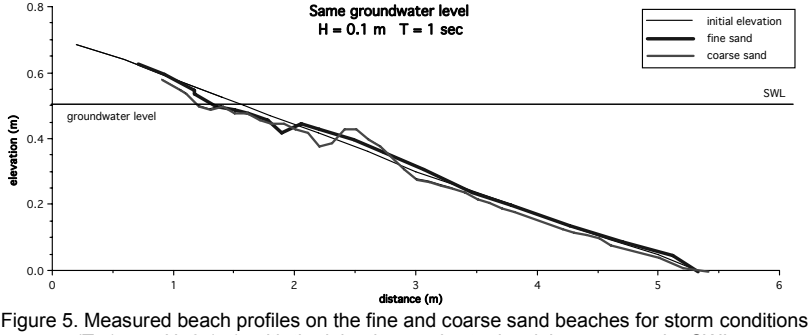

Figure 5. Measured beach profiles on the fine and coarse sand beaches for storm conditions (T=1 sec, H=0.1m), with the inland groundwater level the same as the SWL

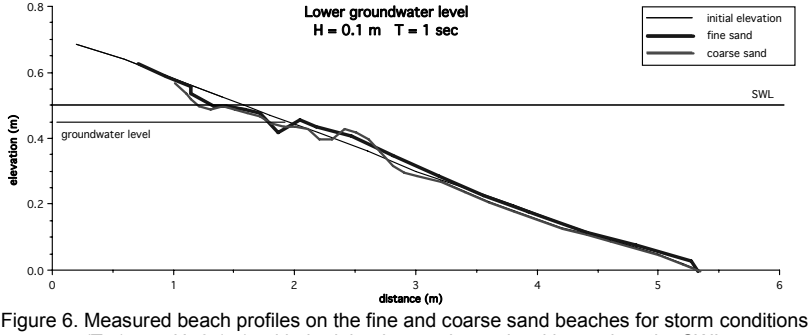

Figure 6. Measured beach profiles on the fine and coarse sand beaches for storm conditions (T=1 sec, H=0.1m), with the inland groundwater level lower than the SWL

Figure 6 shows the initial profile and the profiles after 60 minutes for the fine and coarse sand beaches for storm conditions when the back beach groundwater elevation was lower than the SWL (run 26). Again, more erosion was observed above the SWL on the coarse beach than on the fine beach. The upper beachface on the coarse beach under the lowered groundwater level was considerably steeper than in run 25, whereas the profile on the fine beach was very similar to the profile in run 25.

Figure 7 shows the initial profile and the profiles after 60 minutes for the fine and coarse sand beaches for storm conditions when the back beach groundwater elevation was

higher than the SWL (run 27). Again, the profile on the fine beach was very similar to that in runs 25 and 26, although there was slightly more erosion above the SWL and the bar developed a bit further offshore. The erosion on the coarse beach occurred at a lower elevation above SWL, but the pattern was otherwise comparable to runs 25 and 26.

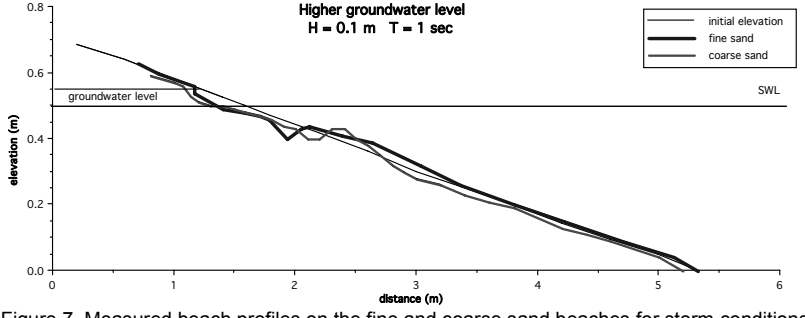

Figure 7. Measured beach profiles on the fine and coarse sand beaches for storm conditions (T=1 sec, H=0.1m), with the inland groundwater level higher than the SWL

In terms of flow through the beach, the coarse sand beach is comparable to a gravel beach at full scale. The laboratory experiments indicated that infiltration played a significant role in beach profile development on the coarse beach, with onshore transport and berm development under all inland groundwater levels, particularly when the inland groundwater level was lowered. In contrast, accretion above the SWL on the fine sand beach only occurred when the inland groundwater level was lowered, suggesting that only under these conditions was infiltration significant. Although saturation levels in the beach were not measured during these experiments, the implication is that the sand above the watertable on the coarse sand beach was always unsaturated, whereas on the fine sand beach the sand was only unsaturated when the groundwater level in the beach was lowered. Lowering the groundwater level on the coarse beach under swell conditions increased the amount of accretion and raising the groundwater level decreased the amount of accretion, but accretion occurred at all groundwater levels on the coarse beach.

Only a few of the results appear to support the conceptual model of Grant (1946, 1948), who suggested that a dry beach (which he interpreted as one with a low watertable) is associated with net onshore transport and beach accretion and a wet beach (which he interpreted as one with a high watertable) is associated with net offshore transport and beach erosion. In the case shown here (runs 7 to 9), and in a few other cases, a lowered groundwater level on the fine sand beach resulted in a small amount of accretion on the upper beach, with erosion occurring everywhere on the beachface under the same wave conditions for the other two groundwater levels. The results of these experiments therefore do not confirm previous suggestions that infiltration only plays a significant role in profile evolution on coarse-grained beaches and does not affect fine-grained beaches. In fact, these experiments suggest that altering the groundwater level is only

able to induce accretion on an eroding profile on a fine sand beach.

Although beach groundwater did influence profile evolution in almost all of the runs, the changes in groundwater elevation in these experiments were usually not sufficient to change an erosive profile to an accretive profile or *vice-versa*. In general, however, onshore sediment transport was enhanced when the groundwater level was lowered under both accretionary and erosive conditions, whereas the back beach groundwater level had less effect on beach profile evolution under storm conditions. This suggests that artificially lowering groundwater levels would not help much in the control of storm erosion, but could promote post-storm accretion on permeable beaches.

MODELLING

The laboratory measurements were compared to simulations using the BeachWin model (Li et al. 2002), a numerical model that simulates interacting wave motion, beach groundwater flow and sediment transport in the swash zone and part of the surf zone. The BeachWin model has been used to investigate the effect of infiltration on swash zone hydrodynamics and sediment transport on sand and gravel beaches. Simulations carried out by Masselink and Li (2001) showed that on a relatively impermeable beach (fine sand, hydraulic conductivity 0.01 cms^{-1}), beach profile development was characterised by offshore sediment transport resulting in steepening of the beachface and the formation of a bar/step feature below the still water level. On a permeable beach (gravel, hydraulic conductivity 1.6 cms^{-1}), the beach profile showed onshore transport and development of a bar/step feature at the beginning of the simulation, followed by onshore transport and berm development. Li et al. (2002) showed the results of simulations with both high and low watertables. With a low watertable, significant infiltration occurred in the swash zone, with a smaller amount of exfiltration on the lower profile; whereas with a high watertable, no infiltration occurred during runup. Their profile simulations showed that with a lower watertable, swash infiltration enhanced onshore sediment transport, leading to the formation of a steeper beach and a large berm. However, none of these simulations were validated against field or laboratory data. While analytical and numerical models for beach groundwater have been verified against data at tidal frequencies, the only known validation at wave frequencies are those of Horn et al. (2003), Ang et al. (2004) and Horn and Li (2006).

In the present study, BeachWin was set up identically to the experimental arrangement and using the measured hydraulic conductivity of the beach sediment (0.001 ms^{-1} for the coarse sand and 0.0001 ms^{-1} for the fine sand). Two sets of model runs were carried out for each experimental run, one in fixed beach mode, i.e. without profile evolution over time, and one where the profile was allowed to change during the model run. Only the comparisons of the measured and predicted piezometric heads from the model runs in fixed beach mode are shown here. The mobile bed modelling, including comparisons of measured and simulated beach profile evolution, will be shown in a later paper (Baldock et al. forthcoming). Model-data comparisons are shown only for the first 10 minutes of each run, as despite the often significant profile changes described above, the groundwater levels generally exhibited steady state conditions after that. At this time the

groundwater level had reached equilibrium with the waves and beach morphology, but the changes in morphology from the initial plane state were small. Subsequent tests suggested that later changes in morphology lead to only minor changes in overall piezometric head levels. Differences between model predictions for small changes in morphology are also minor. Hence, taking the beach boundary as the initial plane state has little effect on the model predictions and model-data comparisons (Ang et al. 2004).

Figure 8 shows the measured and modelled groundwater levels on the coarse sand beach after 10 minutes for swell conditions when the back beach groundwater elevation was the same as the SWL (run 7). The initial beach profile and the profile after 60 minutes are also shown on Figure 8. The model overpredicts the head levels in the surf zone and underpredicts landward of the SWL. Agreement between measured and simulated head levels is reasonably good in the swash zone and within the beach, suggesting that the model's representation of the internal flow within the beach is correct. A similar pattern can be observed for the lowered back beach groundwater level (Figure 9, run 8); however, the agreement between the measured and simulated head levels is not as good when the inland groundwater level is lowered (Figure 9) or raised (Figure 10, run 9).

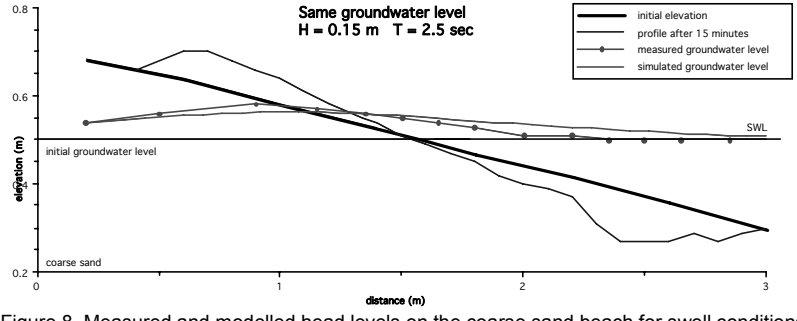

Figure 8. Measured and modelled head levels on the coarse sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level the same as the SWL

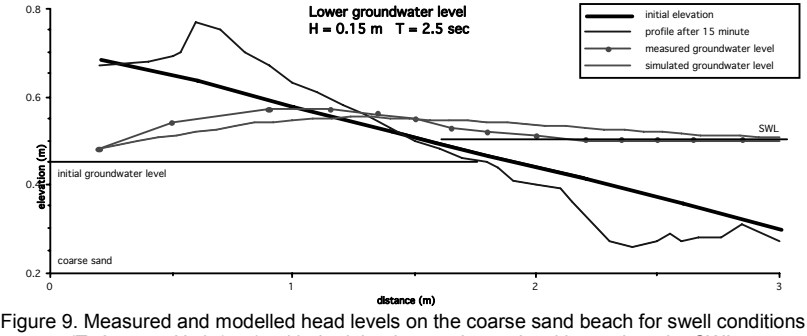

Figure 9. Measured and modelled head levels on the coarse sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level lower than the SWL

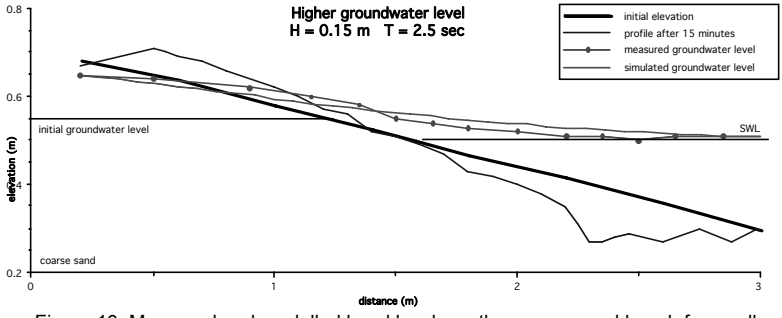

Figure 10. Measured and modelled head levels on the coarse sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level higher than the SWL

Figure 11 shows the measured and modelled groundwater levels on the fine sand beach after 10 minutes for swell conditions when the back beach groundwater elevation was the same as the SWL (run 7). In this case, the model overpredicts the head levels both offshore and onshore of the shoreline, and agreement between measured and modelled head levels is less good than in the coarse sand beach. This pattern is also observed when the inland groundwater level is lowered (Figure 12, run 8) and raised (Figure 13, run 9).

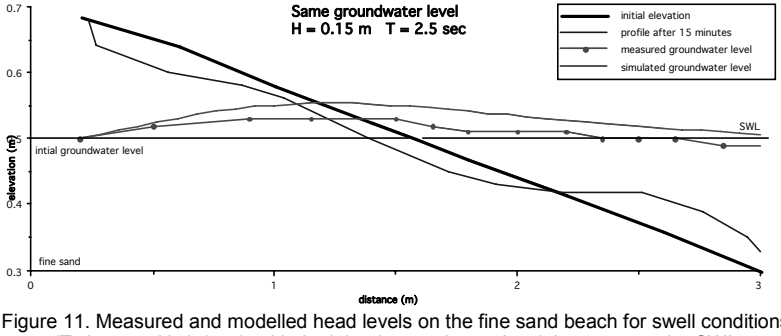

Figure 11. Measured and modelled head levels on the fine sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level the same as the SWL

Similar results were observed under erosive conditions. Figure 14 shows the measured and modelled groundwater levels on the coarse sand beach after 10 minutes for storm conditions when the back beach groundwater elevation was the same as the SWL (run 25). Figure 15 shows the measured and modelled groundwater levels on the comparable run on the fine sand beach after 10 minutes for storm conditions when the back beach groundwater elevation was the same as the SWL (run 25). On the coarse beach, simulated head levels were overestimated offshore and underestimated landward of the SWL. On the fine sand beach, simulated head levels were always higher than measured.

These patterns were similar for the other runs (26 and 27), which are not shown here, and also very similar to the predictions under swell conditions.

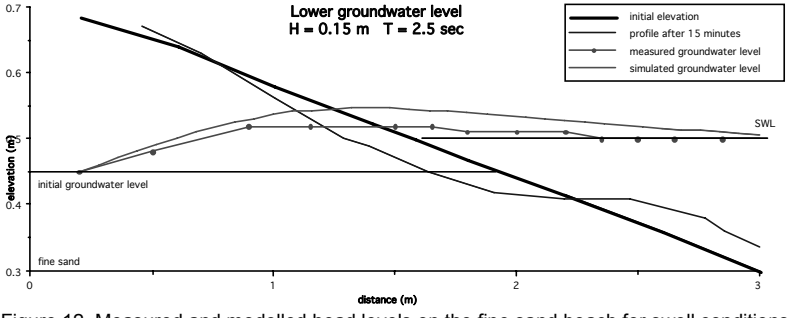

Figure 12. Measured and modelled head levels on the fine sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level lower than the SWL

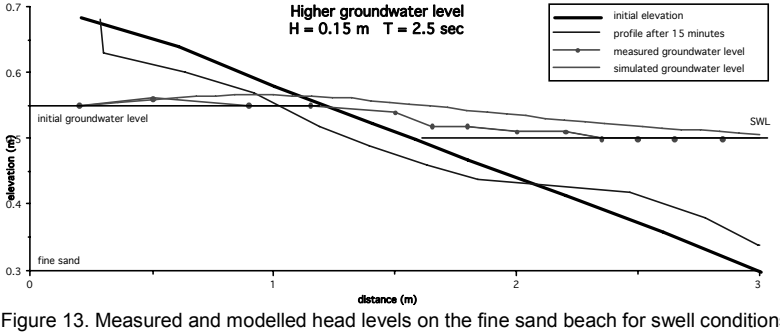

Figure 13. Measured and modelled head levels on the fine sand beach for swell conditions (T=2.5 sec, H=0.15m), with the inland groundwater level higher than the SWL

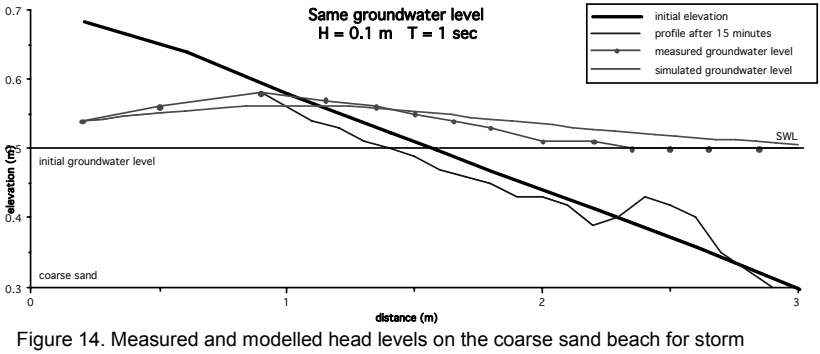

Figure 14. Measured and modelled head levels on the coarse sand beach for storm conditions (T=1 sec, H=0.1m), with the inland groundwater level the same as the SWL

The two main boundary conditions influencing the beach groundwater head levels are the back beach water level and the surf zone setup due to waves, which interact through the flow within the beach. For longer wave periods the back beach water level appears to have little effect on the head offshore of the initial shoreline, indicated by near constant setup in the surf zone, irrespective of the back beach water level (Ang et al. 2004). For a shorter wave period and smaller wave height (f=1Hz, H=0.1m) the measured data show that the back beach ground water level can influence the setup in the inner surf and swash zones, with smaller setup observed for a lower overall beach groundwater (Ang et al. 2004). These observations are consistent with the influence of swash-swash interactions on nearshore setup, which becomes proportionally larger for shorter period waves (Baldock and Holmes 1999).

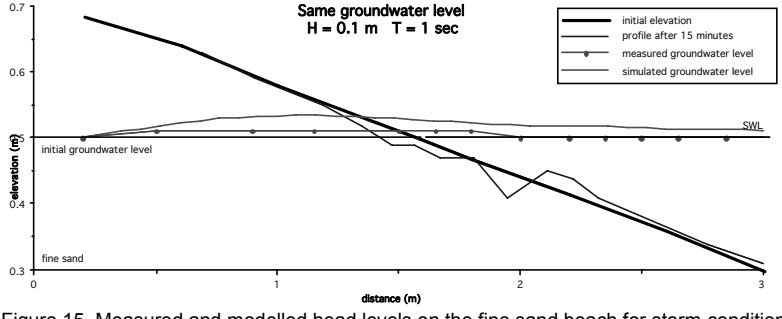

Figure 15. Measured and modelled head levels on the fine sand beach for storm conditions (T=1 sec, H=0.1m), with the inland groundwater level the same as the SWL

Profile evolution had little effect on measured or modelled head levels, which were primarily governed by the back beach head level and the wave runup limit (Ang et al. 2004). Overall, model predictions are better for the coarse beach than for the fine beach, because measured head levels were higher on the coarse beach due to greater infiltration. The model tends to underestimate groundwater levels for longer period waves and overestimate groundwater levels for shorter period waves. Model predictions are better in the swash and within the beach than offshore. The reason for this appears to be a significant overestimation of the wave setup in the inner surf zone, which may be related to the energy dissipation routine within the model (Ang et al. 2004). Thus the main discrepancies between measured and simulated head levels appear to be a result of inaccurate prediction of the nearshore hydrodynamics rather than poor representation of the internal flow in the beach. Since the main aim of these experiments was to improve understanding of the effect of beach groundwater on beach profile evolution, the poor prediction of surf zone head levels is not a significant problem; however, it does suggest that in future the wave component of the model will require modification.

CONCLUSIONS

1. Accretion above the SWL occurred at all groundwater levels on the coarse beach suggesting that infiltration played a significant role in beach profile development.

Onshore transport and berm development occurred under all inland groundwater levels, and particularly when the inland groundwater level was lowered.

2. Accretion above the SWL on the fine sand beach only occurred when the inland groundwater level was lowered. This suggests that altering the groundwater level is only able to induce accretion on an eroding profile on a fine sand beach, in contrast to previous suggestions that infiltration only plays a significant role in profile evolution on coarse-grained beaches and does not affect fine-grained beaches.

3. Although beach groundwater did influence profile evolution in almost all of the runs, the changes in groundwater elevation in these experiments were usually not sufficient to change an erosive profile to an accretive profile or *vice-versa*.

4. Onshore sediment transport was enhanced when the groundwater level was lowered under both accretionary and erosive conditions, whereas the back beach groundwater level had less effect on beach profile evolution under storm conditions. This suggests that artificially lowering groundwater levels would not help much in the control of storm erosion, but could promote post-storm accretion on permeable beaches.

5. The data provide the first controlled experimental verification of a numerical model which simulates wave and beach groundwater interaction in the coastal zone with forcing at wave frequencies. Profile evolution had little effect on measured or modelled head levels, which were primarily governed by the back beach head level and the wave runup limit. Agreement between measured and simulated head levels is better for the coarse beach due to greater infiltration. The main discrepancies between measured and simulated head levels appear to be a result of inaccurate prediction of the nearshore hydrodynamics rather than poor representation of the internal flow in the beach.

Abstract: This paper examines the performance of a mixed sand-gravel beach in comparison with that of a pure gravel beach through a series of controlled laboratory experiments. The gravel beach was modelled using anthracite of a uniform (single) grain size while the mixed sand-gravel beach modelled by means of graded anthracite of the same median sediment size (D_{50}). The two model beaches were tested under identical wave conditions and beach profile changes were recorded. Significant differences were observed in the performance of the two beaches. The reduced permeability of the mixed sand-gravel beach seems to have the effect of reducing the onshore transport but increasing the offshore transport.

INTRODUCTION

Mixed sand and gravel beaches are particularly common in the UK, where over one third of the beaches in England and Wales, and almost all of the beaches on the heavily populated south coast, are composed of combinations of sand and gravel (Fuller and Randall 1988). Beaches with an important component of gravel are estimated to occur along approximately 19,000 km of the British coast, with pure gravel beaches estimated to occur along almost 3500 km (Randall et al. 2001). Mixed beaches in the UK range from predominantly sand, with small proportions of visible gravel along the upper beach, through sand platforms with a distinct sandy gravel

upper beach ridge, to predominantly gravel (or cobble) barrier beaches extending to low water mark or beyond. However, even the best known gravel ridge beaches often have a mixed zone at their toe, which may be more apparent on a seasonal basis, or are known to have high proportions of sand below their surface layer. A recent report on mixed beaches in the UK concluded that it is perhaps more sensible to consider all 'shingle' ridge and mixed beaches as elements of a continuous spectrum in which the sediment type should not be defined by a single size parameter (Defra 2003). Many of these mixed beaches constitute an important defence against erosion and flooding, forming barrier beaches in front of low-lying marshes, toe protection along eroding cliffs, and wide prograding areas where local conditions promote deposition, which help to protect substantial urban areas and high value agricultural, recreational and environmental assets (MAFF 1999, Defra 2003). Many of these coarse-grained beaches are subject to long term erosion with a concurrent risk of flooding of adjacent low-lying land (Coates et al. 2001).

Although interest in mixed sand and gravel beaches has increased in recent years, processes on mixed beaches are less well understood than on sand beaches or gravel beaches. While a mixed but dominantly gravel beach may be expected to behave to a large degree like a pure gravel beach, it is now also recognised that, due to the presence of sand, a mixed sand-gravel beach tends to have a significantly reduced permeability compared to a pure gravel beach (Mason 1997), which may greatly alter the performance of the beach. The objective of this study is to look at how the reduced permeability of a mixed sand-gravel beach affects its behaviour compared to a pure gravel beach, when subjected to the same wave conditions.

EXPERIMENTAL SETUP

The experiments were carried out in a wave flume of 10m in length, 0.45m in width and 0.5m in depth. The model material was graded anthracites with a density of 1400 kg/m^3. Both model beaches had the same dimensions and these are shown in Figure 1.

The sediment characteristics of the two beaches are shown in Figure 2. Assuming a model scale of 1:30, the corresponding prototype sediment sizes can be estimated in terms of the threshold of motion criterion or onshore-offshore criterion. The median size of the prototype beaches is of an order of 15mm, thus the model beach of a uniform (single) grain represents a pure gravel beach free from the influence of sand. The mixed beach model represents a prototype sand-gravel beach containing approximately 10% sand. The prototype water depth at the toe is 4.8 m.

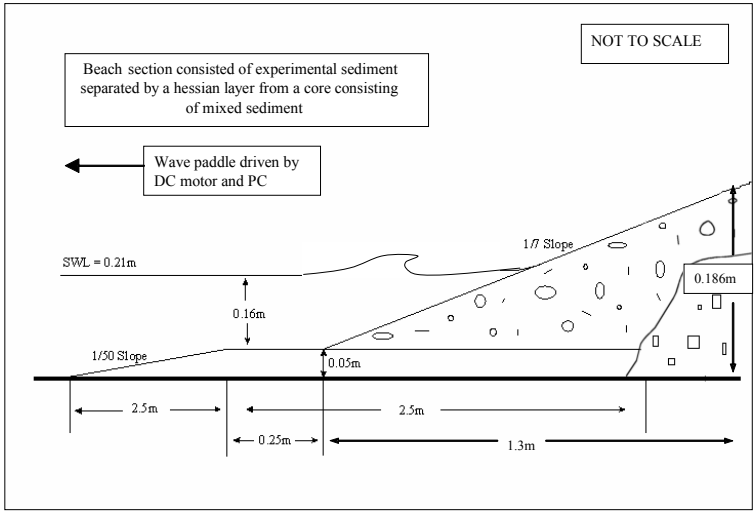

Fig. 1. Schematic of beach model set-up.

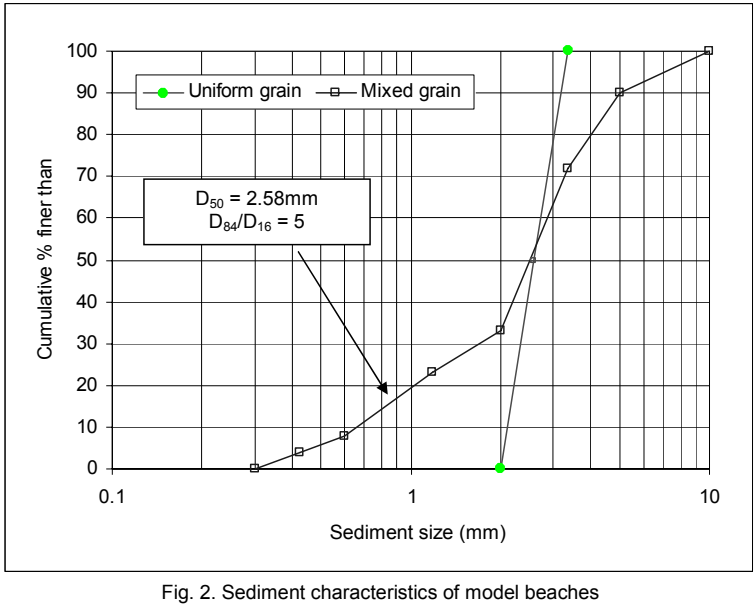

Fig. 2. Sediment characteristics of model beaches

TEST CONDITIONS

Waves were produced by a PC operated DC piston-type wave generator supplied by HR Wallingford. The test conditions included both monochromatic and random waves of a range of wave height and period, as given in Table 1. The random waves were generated based on the Jonswap Spectrum. Both model beaches were subjected to the each wave condition for a duration of 30 minutes, which is approximately 3 hours under prototype conditions.

Table 1. Experimental wave conditions

EXPERIMENTAL CONDITIONS			
Model Frequency	Model Wave Height	1 in 30 Scale	
		Prototype Frequency	Prototype Wave Height
Monochromatic Wave Conditions			
0.53Hz	0.02m (A), 0.04m (B)	0.10Hz	0.6m, 1.2m
1.05Hz	0.02m (C), 0.04m (D), 0.06m (E)	0.19Hz	0.6m, 1.2m, 1.8m
1.58Hz	0.02m (F), 0.04m (G), 0.06m (H)	0.29Hz	0.6m, 1.2m, 1.8m
Random Wave Conditions			
0.53Hz	0.052m (I), 0.084m (J)	0.10Hz	1.6m, 2.5m
1.05Hz	0.033m (K), 0.053m (L), 0.069m (M)	0.19Hz	1.0m, 1.6m, 2.1m
1.58Hz	0.025m (N), 0.04m (O), 0.052m (P)	0.29Hz	0.8m, 1.2m, 1.6m

With an initial slope of 1:7, the beach profiles were manually measured at 10 minute intervals. This was done by marking the profiles with coloured markers onto the glass sidewalls of the tank during the test. At the end of each test, the marked profiles were measured and recorded. Each profile consisted of an elevation measurement for each 50mm chainage to an accuracy of 1mm. Differences were present between the profile readings on the two sidewalls. Complete symmetry in the evolution of a 2D beach model can never be attained, partly due to the imperfections in the initial beach slope and partly due to the variations of sediment sizes across the beach. At a result, the average readings of the two walls are used for the final analysis.

RESULTS

In general, the beach underwent rapid changes within the first few minutes and a pseudo-steady state was attained after 10 minutes, as demonstrated in Figures 3 and 4. Both summer and storm profiles were observed under both monochromatic and random wave conditions. The general trend of profile evolution was similar for both model beaches but there were significant differences in the quantity of sediment movement. The first difference is that, where the onshore transport took place, the mixed beach experienced less movement of material. This can be clearly seen from Figures 5, 6 and 7 under monochromatic wave conditions, and Figures 8, 9 and 10 under random wave conditions. In the case of offshore transport, the profiles of the mixed beach showed greater losses of material from the beach head. This may be seen from Figures 11, 12 and 13 under monochromatic wave conditions, and Figures 14, 15 and 16 under random wave conditions.

DISCUSSIONS

The differences observed between the two beaches may be explained with reference to the permeability of the beaches. Note that the uniform grain beach model represents a pure gravel beach while the mixed beach model represents a mixed sand-gravel beach. The two beaches have the same D_{50}. A critical difference between the two beaches is in their permeability. The study of Mason (1997) showed that the sediment mix as a result of adding a small percentage of sand into gravel tends to have significantly reduced permeability compared to that of gravel without any sand. She et al (2006) further demonstrated that the percentage reduction in the sediment permeability is inversely proportional to the sand percentage. Assuming 10% of sand in the mixed beach model, its permeability is estimated to be 30% smaller than that of the uniform grain beach model, which will have a fundamental impact on the behavior of the beach.

Due to their difference in the permeability, the percolation flow in the uniform grain (gravel) beach is much greater than that in the mixed beach. In the cases where the wave energy and period are such that the onshore transport takes place, the wave breaking brings the sediment particles into temporary suspension and at the same time creates an uprush that takes the sediment up the beach surface. The subsequent backwash brings some of the sediment back down. The net sediment deposition is the difference between the sediment taken up during the uprush and that taken down by the back wash. The gravel beach allows much greater percolation flow into the beach, thus reducing the uprush but more significantly the backwash. As a result, greater onshore transport takes place on a gravel beach than on a mixed beach even though the wave conditions are identical.

In storm conditions, the backwash carries sufficient energy to moves more sediment than that by the uprush, due in part to the slope advantage of the backwash and in part to a more saturated upper beach above the mean water level. In comparison, a mixed beach is more saturated due to smaller percolation flow within the beach, which may be identified in terms of an increased ground water level in the upper beach. This means an increased backwash on the mixed beach compared to a gravel beach. The result is that, under the same wave conditions, a mixed beach loses more material than a gravel beach.

CONCLUSIONS

The performance of a mixed beach was investigated by testing two laboratory models under controlled wave conditions. The presence of sand in a mixed beach was shown to lead to reduced permeability, which in turn affects the sediment transport processes on the beach. The results from the study indicated that a mixed sand-gravel beach will tend to lose more beach material than a pure gravel beach when subjected to storm wave attacks while less material may be recovered under swell wave conditions

The second implication is that the hydraulic conductivity of the sediment bed is of great significance in influencing the sediment transport processes on the beach. Reducing the sand fraction seems to hold the key to improved hydraulic conductivity and thus the beach performance but the question is how to improve the beach recharge techniques to achieve this.

Abstract

Data on the transport of material on mixed sand and shingle beaches using newly designed synthetic pebbles has been collected on a macrotidal beach at Cayeux-sur-Mer in northern France. Deployment occurred on three separate days at three locations: on the upper, the middle and the lower part of the beach, down to depths of ~ 30 cm. The recovery rates varied from 26% after one tide to 95% at the end of the experiments. The pattern of pebble behaviour after one tide on the lower, middle and upper parts of the beach seemed to be consistent. Pebbles injected on the lower and middle beach showed a clear longshore displacement whereas pebbles injected at the top of the beach were mostly displaced cross-shore (seaward). The distance pebbles travelled varied with the location in which they were placed, with pebbles from the upper beach tending to travel further than pebbles placed in the middle and lower parts of the beach. Wave conditions and water level also influenced pebble movement.

Introduction

Shingle and mixed sand-shingle beaches are present in many parts of the world, especially in mid to high latitudes, and act as a valuable natural coastal defence. They have attracted growing scientific interest over the past 30 years, and many studies have been made of their morphology and erosional dynamics. Particular attention has been paid to investigating longshore and cross-shore sediment transport.

In order to study pebble behaviour *in situ* and to quantify longshore transport on shingle and mixed beaches, many tracer techniques can be used: fluorescent paint (e.g. Jolliffe 1961), aluminium pebbles (e.g. Van Wellen *et al.* 1998), electronic pebbles (Workman *et al.* 1994), non-indigenous pebbles (e.g. Hattori and Suzuki 1978), radioactivity (e.g. Kidson 1959). Tracers are non-invasive and can be used successfully in high-energy conditions, even if the input parameters for the calculation of transport rates remain uncertain and require further evaluation (Van Wellen *et al.* 2000). Many previous research studies have used tracers trying to appreciate of how pebbles behave.

Despite all these efforts to monitor shingle movement, tracer studies are still not completely reliable. Bodge and Kraus (1991; in Van Wellen 1999) concluded that estimates of total longshore transport volumes derived from tracers can be in error by a factor of 4 due to limitations in sampling methodology (or the recovery rate, when dealing with individually identifiable tracers).

Cross-shore and longshore sediment transport changes the morphology of beaches and the positions of shorelines (e.g. Pedrozo Acun□a 2005). Due to the coarse grain size, steep seaward slopes are usually sustained on shingle (e.g., Longuet-Higgins and Parkin 1962), inducing a high reflective potential and also a high degree of stability under wave attack. Mixed sand and shingle beaches are generally characterised by lower slopes and a larger foreshore, allowing the incident waves to progress further inshore. Breaking is rapid and a parallel breaker line often forms directly in contact with the beach without the creation of a surf zone. All the wave energy is therefore transferred to an incident swash motion. This leads to the conclusion that most of the transport occurring on gravel and mixed sand-shingle beaches is linked to swash processes (e.g. Austin and Masselink 2006). The precise mode of transport on gravel and/or mixed beaches remains contentious. Austin's (2006) observations led him to claim that transport occurs as bed load (in accordance with Horn and Mason 1994) and as sheet flow through the swash motion, with some quasi-suspended load at the point of bore collapse, as confirmed by Pedrozo's (2005) research. However, in laboratory experiments on a scale model beach Coastes (1994) observed more suspended load than anticipated, which shows how little is actually known about the processes responsible for sediment transport. Van Hijum & Pilarczyk (1982) used hydraulic laboratory experiments to try to identify the effects of various factors on pebble behaviour, and concluded that the transport of material takes place essentially as a single moving layer, and not as the independent responses of individual sediment fractions, because the larger pebbles impede the movement of the smaller ones (e.g. Carter 1988). They also concluded that flatter pebbles are carried further than round ones. These results contradict those of Allan *et al.* (2006) who found no relationship between particle shape and distance moved in the field.

A further complication is that pebble transport rates are dependent on their location on the beach, which influences the time that they spend under the influence of the swash. Van Hijum & Pilarczyk (1982) showed that differences in the distances covered in a

given time are a reason for the sorting often observed across beaches and for possible differences in the amounts of longshore transport. They also proved through their laboratory experiments that when the angle between the wave crest line and the beach increases, the transverse component of the motion becomes smaller and the longitudinal component larger. All this has important implications for the study of how pebbles behave on actual beaches.

This paper presents tracer pebble measurements obtained on a mixed sand and shingle beach in the north of France at Cayeux-sur-Mer. The measurements were made under varying wave conditions over a complete neap-spring tide cycle from October 28 to November 11, 2005. The tracers were of a new type made of epoxy resin with copper cores to allow recovery by both visual searches and metal detection. A differential GPS was used to determine locations. Deployments were normally made at three locations: on the upper, middle and lower part of the beach, at the surface and down to depths of up to 20 cm or occasionally 40 cm. It was hoped to obtain a picture of the overall movement of the pebbles on the beach, and to provide data for the long-term management of beaches of similar type, as well as to create an opportunity to calibrate and create predictive longshore transport formulae.

Field site and method

The beach at Cayeux-sur-Mer experiences strong longshore transport in an overall northerly direction. It is part of a 40-50 million m^3 mixed sand and shingle spit that extends from chalk cliffs at its southern end 16 km northwards to the mouth of the River Somme. This spit has developed during the last 2500 years. Between 1500 and 1900 it grew 6 km northwards without any major human intervention. However, cliff retreat to the south is no longer supplying shingle in sufficient volume to sustain the growth of the spit. To combat shingle loss and possible flooding of the land behind, groynes have been built northwards from Ault to just south of Cayeux-sur-Mer where at present the beach is still wide enough to prevent any flooding. Each year, 70 000 to 80 000 m^3 of sand and shingle are removed from the northern end of the spit and dumped on the beach at Cayeux (just downdrift of the northernmost groyne) in the form of a ridge 450 m long. This recycling is intended to balance the natural drift.

At Cayeux-sur-Mer (figure 1) the beach is aligned N20-30º and the tidal range is 6.6 to 11.2 m. The beach material has bi-modal distribution with a peak in the gravel size range (10 to 20 mm) that is sometimes mixed with sand, and a peak in the cobble size range (40 to 50 mm; Dolique 1998). The beach volume is composed about 20% of sand. This study site was north of the most northerly groyne and was selected because of its simple morphology and bathymetry, absence of groynes, and abundance of flint shingle, thus conforming to the recommendations of Van Wellen (1997).

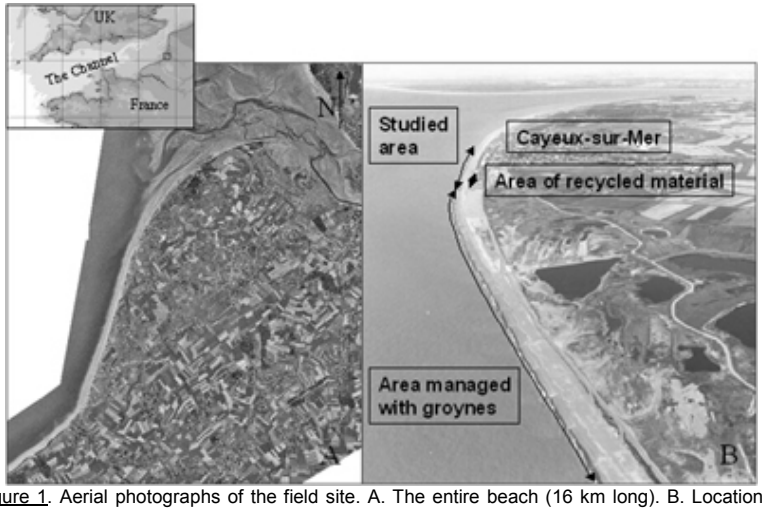

Figure 1. Aerial photographs of the field site. A. The entire beach (16 km long). B. Location of the field site.

The resin tracer pebbles were 6-7 cm long (a-axis) and 4-5 cm wide (b and c-axis), and individually numbered. Their copper cores allowed them to be re-found using a metal detector even when buried to depths of up to 30 cm. Having the same density as natural flint pebbles of the same size, they could be expected to provide realistic data.
The tracer pebbles were deployed on a cross-shore transect at elevations of +0.34 m, +2.10m and +3.86m above mean low water level. On the first day of the experiment the upper deployment was located 8 m along the transect from the most recent berm and 16 m from the artificial seawall. The lowest deployment was made 8 m landward from the base of the shingle. The middle deployment was midway (15 m) between the top and lowest deployments. Deployments took place on the 31st October, the 7th and 8th of November. The study period ended on the 11th of November.

The experiment was designed to investigate variations in transport rates in relation to the cross-shore profile. The top of the beach mainly experiences a dynamic of swash/backwash, and is only reached at high tide. By contrast, the bottom of the beach over a tidal cycle is subjected to a strong but short swash/backwash phase when the tide rises; then a long period under breaking waves; and finally another short period of swash/backwash when the tide falls. Tracer recovery took place during every other low tide following deployment at the preceding low tide. Each pebble was searched for by the metal detector. Buried tracers had to be excavated to identify them. Metal detection took place by walking along tracks at least 70m long downdrift from the injection area.

Location and depth were recorded with a Topcon RTK-DGPS. A total of 510 pebbles were deployed on the beach over the study period. The hydrodynamic conditions were recorded with an S4 directional wave recorder located directly on the sandy lower foreshore.

Results

The inshore tidal signal, is a typical intertidal, semi-diurnal and macrotidal signal. During the study period the water level changed from neap to spring and back to neap tide (Figure 2). The wave climate was representative of the year wave height climate with significant wave heights (Hs) ranging from 0.4 m to 2.7 m, punctuated by two storm events on the 1st and 4th of November 2005. The incident waves were from the west, with an angle of incidence to the beach of between 7 and 60° and an average of between 15 and 40°. Almost half (49.7%) of the significant wave heights (Hs) were less than 1 m, 96.4% less than 2 m, and only 3.6% exceeded 2 m. The wave period varied between 4 and 9 s and two distinct wave periods were clearly be identified. Firstly, a group of waves that were the most representative with a period of between 4 and 6 s and secondly, a group with a period of between 6 and 9 s. During the tidal cycle, current velocities were the strongest at mid-tide and weakest at high tide. Current direction was mainly northward in accordance with the waves and the expected longshore drift direction.

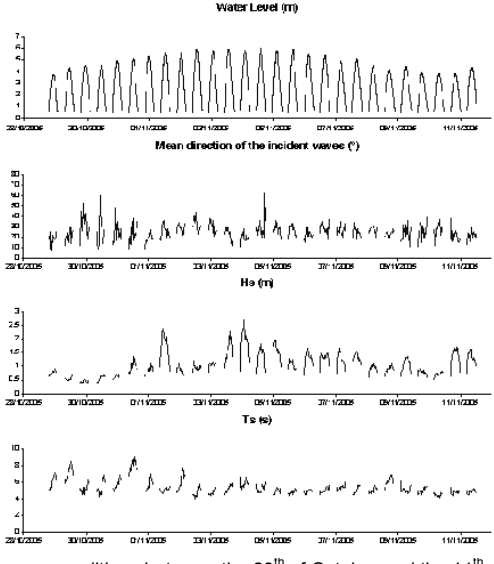

Figure 2. Inshore wave conditions between the 28th of October and the 11th of November 2005.

Date of deployment	Location of the injection	Recovery rates (Total of pebble recovered)		
		After 1 tide	After 3 tides	At the end of the experiments
31/10/05	Upper beach	47% (37)	59% (47)	86% (68)
	Middle beach	39% (31)	65% (52)	95% (76)
	Lower beach	26% (13)	58% (29)	88% (44)
07/11/05	Upper beach	44% (22)	56% (28)	60% (30)
	Middle beach	64% (32)	84% (42)	92% (46)
	Lower beach	42% (21)	76% (38)	88% (44)
08/11/05	Upper beach	78% (39)	84% (42)	88% (44)
	Middle beach	70% (35)	78% (39)	82% (41)
	Lower beach	48% (24)	62% (31)	68% (34)

Table 1: Recovery rates for tracer deployments on the 31st of October, the 7th of November and the 8th of November 2005. The figures in brackets are the cumulative number of tracer pebbles recovered at the time indicated.

Recovery rates for three deployment days, at the three locations (upper, middle and lower beach) and over different time periods (after one tide, three tides and finally at the end of the observation period) are shown in Table 1. Recovery rates varied from 26% to almost 95%, depending on the location and date of deployment. Recovery rates increased with time. Despite the lower recovery rates recorded after one tide, after 3 tides they reached, or were very close to expected recovery rates for a "passive" tracers i.e. ≥ 60% (Allan *et al.* 2006). By the end of the experiment, the recovery rates were mostly above 80%, which is higher than that described from other studies.

After one tide, the lowest recovery rates were recorded on the lower beach and the highest recovery rates on the upper beach, except on the 7th of November. At the end of the experiments, recovery rates from the tracers injected at the middle of the beach were the highest (almost > 90% recovery). Such high recovery rates confirm firstly that the technique used in this experiment allows successful relocation of tracer pebbles even during stormy or relatively agitated conditions, and secondly that the results are reliable enough to track pebble movement patterns and beach topographic changes under different wave and tide conditions.

The locations of tracer pebbles recovered after one tide and at the end of the experiment have been mapped for each of the deployment dates (31th October, 7th and 8th of November; Figures 3, 4 and 5). On each survey, the tracers were scattered to the north of their injection point in accordance with the expected drift direction under south westerly waves. During the period of the experiment no tracers were found to have moved in an updrift direction. The movement pattern shown by tracers between the 31st of October 2005 and the 11 of November 2005 is representative of the entire experiment (Figure 3). After one tide the longest-travelled tracer pebble was recovered 30.9 m from its injection point. At the end of the experiment, 21 tides after deployment, the longest-travelled tracer pebble was 311.4 m from its injection point. After one tide the shortest-travelled

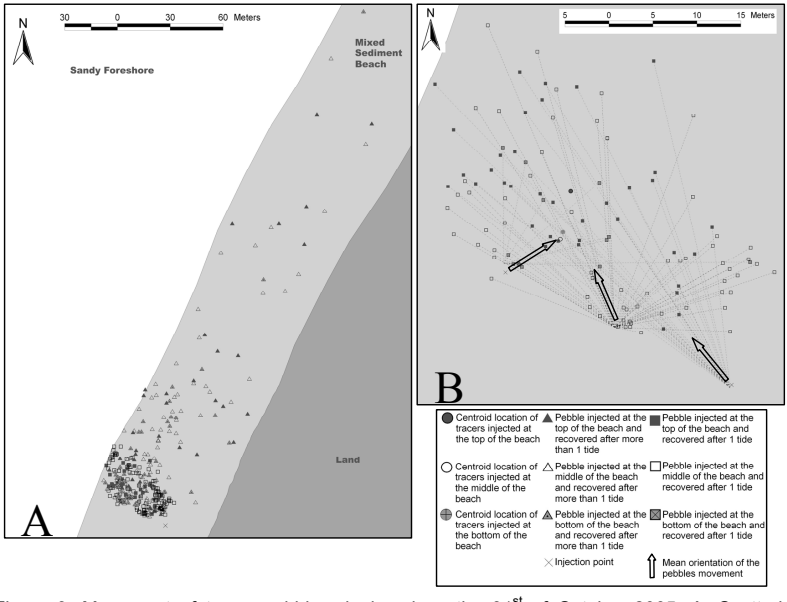

Figure 3. Movement of tracer pebbles deployed on the 31st of October 2005. A. Scattering observed over the whole survey period. B. Scattering observed after one tide.

tracer pebbles was only 0.3 m from its injection point whilst after 21 tides the shortest-travelled pebble was only 2.8 m from its injection point. Over this single tide, the wave approach angle ranged from 8 to 38° and averaged 22.7°; the significant wave height ranged from 0.77 to 1.36 m, averaging 1.1 m; the mean wave period ranged from 6.8 to 9.1 s and averaged 7.9 s (Figure 2). The centroid location obtained from the cloud of pebbles recovered for each deployment location, showed that the mean distance travelled after one tide by the tracers deployed at the top of the beach was 28.77 m. Tracers deployed in the middle and lower beach travelled only 11.55 m and 7.66 m respectively. This initial observation indicates that pebbles located at higher elevations on the beach have the potential to travel further than those at lower elevations. However, this observation does not take into account the bearing of the centroid trajectory from its deployment point. The angle of the trajectory has been calculated for each deployment using the beach angle ($N23^{o}$) as the direction of longshore movement from the original injection points. All tracer movements up the beach, in a landward direction, recorded a positive value whilst those that moved down the beach, in a seaward direction, recorded a negative value. The results indicated that tracers injected in the upper beach had a trajectory angle of -84.2°. Those injected into the middle beach recorded a trajectory

angle of -53°. Tracer pebbles that were injected into the lower beach unexpectedly recorded a trajectory angle of +38°.

In summary, pebbles injected at the top of the beach tended to travel across the beach in a seaward direction and also longer distances than the other tracers. Those injected in the middle of the beach also recorded a cross-shore scattering in a seaward direction but it was less than those injected into the upper beach. Pebbles injected into the middle of the beach typically travelled less than half the distances recorded by those deployed on the upper beach. Finally, the pebbles deployed on the lower beach travelled the shortest distances but showed a tendency to scatter up the beach in a landward direction.

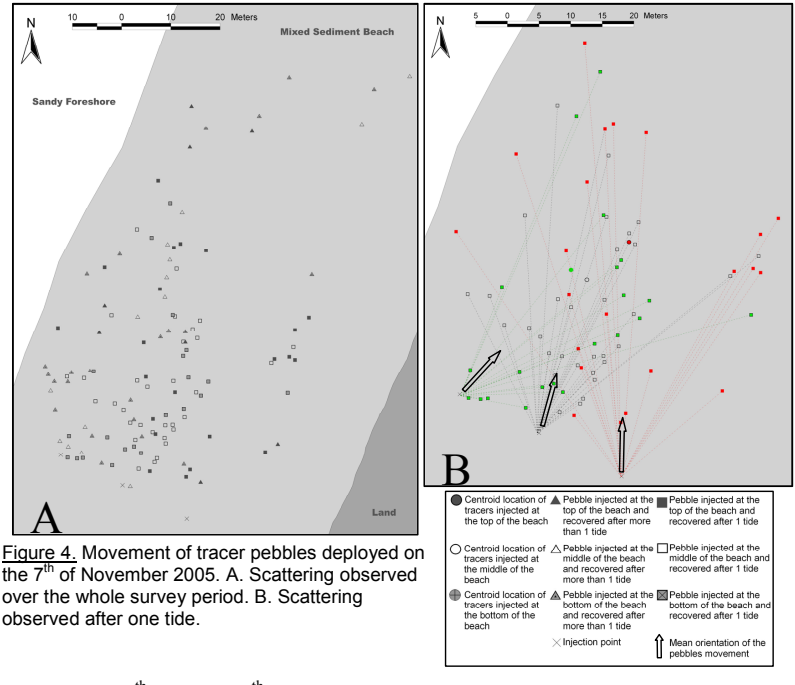

Figure 4. Movement of tracer pebbles deployed on the 7th of November 2005. A. Scattering observed over the whole survey period. B. Scattering observed after one tide.

Between the 7th and the 11th of November 2005 (Figure 4) the furthest-travelled pebble recovered was 101.6 m away from its injection point on the 11th of November 2005 (7 tides after deployment). After one tide, tracers were scattered distances of between 1.34 and 68.88 m from their injection points. The location and orientation of centroids after one tide on the upper, middle and lower beach were, respectively: 33.42 m with an angle

of –21.3°, 21.5 m with an angle of –1.6° and 21.6 m with an angle of +31.3°. Here again, the pattern observed previously is displayed.
In addition, the mean angle of scatter of tracers deployed on the upper beach on the 31st of October was significantly greater than that recorded on the 7th of November. On that particular tide, the angle of wave approach was between 20.1 and 30.4° (average 27.6°); the wave height ranged from 0.74 to 1.14 m (average 0.95 m) and the mean wave period varied between 4.6 and 5.9 s (average 5.1 s; see Figure 2).

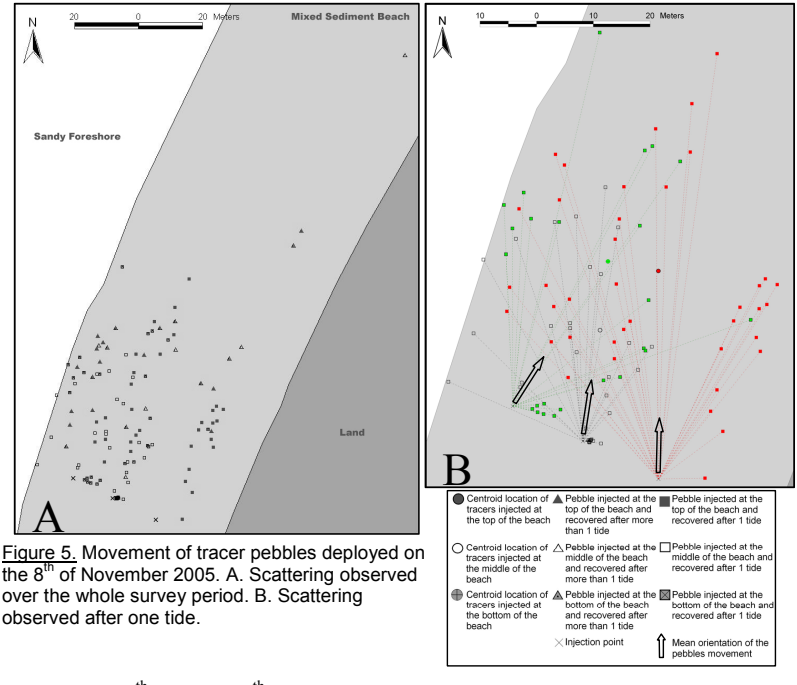

Figure 5. Movement of tracer pebbles deployed on the 8th of November 2005. A. Scattering observed over the whole survey period. B. Scattering observed after one tide.

Between the 8th and the 11th of November 2005 (9 tides in total), the furthest-travelled tracer pebble after one tide was 75.5 m from its injection point and after seven tides 101.6 m (Figure 5). The centroid locations, from the upper to lower beach, of each tracer scattering after one tide show respectively: a mean distance travelled of 34.7 m with a mean angle of –25.5°, a mean distance travelled of 14 m with a mean angle of –27.2° and a mean distance travelled of 24.11 m with an angle of +9.6°. The results displayed the same tendencies as the two previous cases in both the distance travelled and the orientation of the tracer movements. However, the tracers injected into the middle of the beach travelled a significantly shorter distance than was expected from the first two

examples. On that date, the wave approach was between 14.4 and 30.4° (average 22.4°), the wave height ranged between 0.62 to 1.36 m (average 1.09 m) and the mean wave period between 4.8 and 5.7 s (average 5.01 s; see Figure 2).

The results of the experiment have revealed patterns of tracer pebble movement that are dependent on location of the injection point. Tracers deployed on the upper beach travelled the furthest distances. These pebbles were also subject to the most significant cross-shore movement in a seaward direction in comparison to those deployed in the middle and lower beach. Tracers deployed in the middle and lower beach travelled similar distances but moved in different directions. Pebbles deployed in the middle of the beach showed a tendency to migrate seaward, but the main component of their movement was alongshore rather than across-shore. In contrast, pebbles deployed on the lower beach displayed a tendency to migrate landwards, although the main component of movement was again in the longshore direction.
In addition, tracers deployed at different times during the experiment travelled different distances. Those deployed on the 31st of October travelled, on average, a shorter distance than those injected on the 7th and the 8th of November 2005. They also recorded a stronger cross-shore movement component than those deployed on the two later dates.

Discussion

One possible explanation for the low recovery rate of pebbles injected into the lower part of the beach was movement of pebbles from the beach onto the adjacent sandy foreshore. However, no pebbles were ever detected during regular surveys of a two metre wide track along the sandy platform directly in front of the beach toe. This suggests that pebble exchanges between the foreshore and mixed sand and pebble beach are rare even during relatively agitated periods and cannot be the cause of the low recovery rates.

Nevertheless, the shingle beach toe is an area of important topographic change induced by the change of slope and the combined effect of wave breakage and swash during each tidal cycle. As a result, the most likely explanation for the low recovery rates of pebbles placed on the lower beach is their burial within the indigenous beach material to depths below the detection limits of the metal detector.

Burial of the tracers to depths below the detection limit is probably the explanation also for the “abnormally” low recovery rate for those injected into the top of the beach on the 7th of November. On this occasion burial most probably resulted the change in water level between the spring and neap tides of the tidal cycle. At the time the tracers were injected, wave and tide conditions were transporting the coarser beach material up-beach to create a berm which probably trapped and buried many of the tracers below detection depths.

Despite the low recovery rates after just one tide, the recovery rates achieved by the end of the experiment are sufficient to give a high level of confidence regarding the pattern of transport they display (Table 1). It is apparent that those injected in the upper beach demonstrate a clear tendency to move seawards across-shore and move further than those injected in the mid and lower beach (Figures 3, 4 and 5). It is well known that on a steep coarse grained beach, the width of the swash zone may be significantly greater than that of the surf zone. It has been shown in models and experiments (e.g. Van Wellen 1999; Pedrozo Acun□a 2005), that most of the morphological changes on a steep beach profile occur in the swash zone. The difference in distance travelled is a function of the greater time swash is active and is the reason why pebbles from the upper beach move furthest. Regarding the strong seaward cross-shore tendency, Van Hijum and Pilarczyk (1982) showed the distance covered is a function of time spent in the swash. However, this does not explain why the tracers injected at the lower beach migrate landward while pebbles from the top of the beach migrate seaward.

Nielsen (1997) identified ground water dynamics in the swash zone as one of the processes that might be important for predicting net sediment transport in this area. Ground water flows are a determining factor of variations in the morphology of beaches with a high permeability (Elfrink and Baldock 2002). These flows are even more significant when the tidal range is larger, which creates high hydraulic gradients between the water table and the water level (Turner 1995). The three sites where tracers were injected were in completely different ground water environments. The injection site on the upper beach was above the water table throughout the tidal cycle. The site where the tracers were injected in the middle of the beach was also above the water table at low tide but when the tide rises is quickly saturated by water. At the bottom of the beach considerable quantities of water drained out of the sediment even at low tide.

Observation of the tracers as the tide rose over the lower site, showed that they were immediately mobilised and quickly disappear, apparently due to seaward migration. This may result from swash flows interacting with the groundwater flow. The consequence of downward directed pressure gradients increases the effective weight of the sediment, stabilises the bed and decreases the potential of sediment to be transported during the uprush. In contrast, during backwash the upward directed pressure gradient increases sediment transport reducing the effect of the weight of sediment. The net effect of this process is movement towards the offshore direction (Hughes *et al.* 1997; Nielsen 1997). However, the majority of the tracers from the lower beach eventually move up the beach. This may be explained by the fact that after a short period of time, with the rising tide, the water level and the water table are at an equal height and this impedes the ground water flow, resulting in the uprush becoming dominant and beach material being moved up the beach. This uprush only affects a thin surface layer of sediment. As the water level continues to rise, the steepness of the beach face causes the waves to break directly onto the beach. As a result a lot of energy is delivered to the beach face in a very short period of time which results in entrainment, mixing and movement of a greater

depth of material. During this period the tracers at the surface of the sediment are likely to become well mixed with the beach sediment and buried at depth, where the backwash during the falling tide cannot remobilise them. The net result is for the pebbles to migrate landward. This is in addition to the main tendency for them to move down-drift, alongshore.

The middle of the beach is above the water table level and as a result all the wave energy released in the uprush will transport the surface sediment landward. At the same time infiltration into the beach face will strongly reduce the energy of the backwash. This tendency changes when the water table and the water level reach the same elevation. At that point, the sediment will be saturated by water, and seaward currents will be strong enough to remobilise the beach material during the high tide (at least that of a comparable size to the tracers used). In addition, the backwash during the falling tide drags surface material down across the beach. During the three days of deployment of the tracers, wave breakage at high tide occurred between the shingle beach toe and just below the point where the middle tracers were injected. Under the breaking waves, some tracers were buried deep enough not to be removed by the decreasing tide and the associated swash.

It has been identified that on the 7th and the 8th of November the centroid of tracer movement was at a smaller angle than that of the 31st of October, whilst the mean distance travelled was greater than on the 31st (Figures 3,4 and 5). On the 7th and the 8th of November berm accretion occurred, and this coincided with the changeover of tidal level from a spring tide to a neap tide. As a consequence, coarse material on the upper beach was pushed landward to build up the berm. In contrast, on the 31st of October, this berm suffered erosion as a consequence of the tidal range going toward a spring tide and the coarse upper beach material was spread out across the beach as described previously. It is mainly pebbles from the upper beach area that contribute to the berm construction. The distance travelled by the tracers is mainly due to the energy delivered by the wave onto the shore face. Looking at the wave conditions and the water level (Figure 2), there was little difference in Hs, water level and wave direction during the periods displayed. However, there was a significant difference in the significant wave period (Ts). It is well known that the longer the wave period, the greater the longshore wave energy. This probably explains why the distances travelled are greater on the 7th and the 8th of November than on the 31st of October.

Conclusion

Observations of hydrodynamic conditions inshore, morphological changes and sediment motion from one low tide to the following have been made on a mixed sand and shingle beach at Cayeux-sur-Mer, France. The results highlight constant patterns of movement for a specific grain size over time and for specific wave conditions. Good recovery rates allow a high level of confidence in the results. The new findings provide a better insight to particle behaviour on mixed sand and shingle beaches, drawing on existing

knowledge of hydrodynamic conditions, swash flows, groundwater flow, beach slope and grain size.

Material from the upper part of the beach tends to migrates seaward and further down-drift than the other parts of the beach. It is suggested that this is linked to a continuous swash action from the high tide to the low tide. Pebbles from the lower beach tend to migrate up the beach, although alongshore transportation is dominant. It is suggested that these movements are explained by the combined effect of the groundwater flow, the swash flows and the action of breaking waves. Pebbles from the middle of the beach display a preference to move down the beach which may also be explained by the interaction between the groundwater flow, swash flows and the action of the breaking waves. Alongshore drift is again significantly greater than cross-shore movement.

The experiments show that pebble material on a mixed sediment beach is extremely sensitive to position on the beach profile and to changes in the water level and wave conditions associated with tidal conditions. Formulae and models for longshore drift fail to take this differential transport on such beaches into account and this could be one of the main reasons for their inaccuracy. Future work will seek to first validate the hypothesis of pebble movement suggested in this paper by more field measurements and then include it into an improved model or a formula for better predicting longshore drift on mixed sand and pebble beaches.

WHY ARE SHINGLE BEACHES REPLACING SANDY BEACHES?
(coastal zone of NW Portugal)

Abstract: The progressive thinning of sandy beaches in NW Portugal has exposed: large areas of rocky outcrops in the low tide and sub-tidal zones; older marine deposits in the sub-tidal zone; and older beach deposits in the foreshore. All these environments were previously covered by sands.

As a result, sandy beaches have progressively been replaced by shingle beaches. This phenomenon migrates from north to south along the coast. Morphological change generally pass through a state where sand and gravel coexists in a beach cusp morphology (the beach horns being made of pebbles) until the sand disappears and only pebbles, cobbles and boulders remain.

The main purpose of this study is to understand shingle behaviour under different wave climate conditions and the mechanisms that led the shingle beaches to be more stable than the sandy beaches they replaced.

INTRODUCTION

Gravel beaches did not dominate the coastal landscape of Northwest Portugal some years ago (Fig. 1). On the contrary this coastal zone was dominated by extensive sandy beaches with dune systems, from the Little Ice Age (LIA), at the backshore (Fig. 2a).

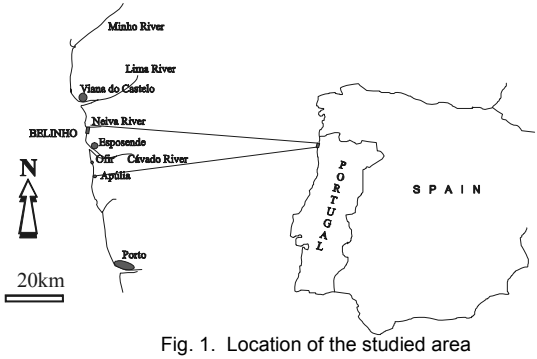

Fig. 1. Location of the studied area

However, on the most northern sector of the coast (between the Minho and Lima rivers; Batista, 1992), small pocket gravel beaches, between rocky headlands, have dominated the coastal landscape for more than a century. These small and narrow beaches did not show large yearly or seasonal morphological changes (except during overwashing; Alves, 1996), though, in time, they have been slowly migrating inland (e.g. Gelfa Beach). The gravels of these beaches cover medieval salt pans, like in Areosa (Almeida, 1979). They are swash-aligned barriers.

But since 2000, gravel beaches (Fig. 2c) that have become a progressive and dominant feature of the coastal landscape in the coastal zone between the Lima and Cávado rivers, are a new phenomena, involving mechanisms acting very fast in time. Unfortunately, the understanding worldwide of the behaviour of gravel beaches is still very rudimentary compared to that of sandy beaches as worldwide (Sherman, 1991).

Fig. 2. Belinho Beach (Esposende). a. sandy beach (June1994); b. sandy and gravel beach (June1998); c. gravel beach (June 2003)

One particular character of these new gravel beaches is that they are progressively, and irreversibly, replacing the former sandy beaches, though maintaining the dune systems on their backshore (Fig. 2). The new coastal landscape is composed by exposed rocky abrasion platforms, steep gravel beaches (with cobbles and pebbles, and, sometimes, small sand aprons), and dunes (composed of fine sand), inherited from the previous sandy beach morphology.

This paper, through the description of the development and facies change of a wave dominated, high energy beach (Belinho Beach), tries to give an explanation about probable mechanisms that changed it from a dissipative state (sands) to a reflective state (pebbles, cobbles and boulders), which has become the new permanent equilibrium.

GEOMORPHOLOGICAL BACKGROUND OF THE STUDY SITE

The sector of the NW coastal zone of Portugal where gravel beaches have been replacing sandy beaches is characterized by a narrow coastal zone, extending from the sea till a dead cliff, and composed of two rocky platforms (Fig. 3), the lower one extending underwater, which have been exposed over the last years.

The dead cliff and the associated higher platform are carved from Hercynian granite, with several fault systems. This granitic intrusion has metamorphosed the Palaeozoic rocks (Teixeira *et al*., 1969) that compose the lower platform, which is part of a NW-SE oriented complex syncline. The Ordovician quartzitic beds are present in both flanks, interbedded with Ordovician schists and a conglomerate with elongated quartz pebbles (due to post-Devonian tectonic deformation) on the western flank. At Belinho Beach, the rocky platform is made of the schists.

The surface of the lower platform is slightly irregular, with some depressed areas due to some probable faults. In these depressions, a thin Holocene formation is present (Granja, 1999; Ribeiro, 2003). The base of these depressions consists of a layer of marine pebbles, probably reworked from fluvial deposits and marine gravel ridges of Pleistocene age, which are present on the higher areas of the same platform (Soares de Carvalho *et al*., 2006).

Due to the strong erosion of this coastal zone over the last years (since 1995-1996), different sedimentary deposits are now exposed. Holocene deposits, including lagoon, beach deposits, and gravel ridges, have been exposed in some sectors of the beaches, due to accelerated dune cliff retreat. At the same time, sand has been lost from the beaches, and large areas of the low abrasion platform on the intertidal zone have been exposed.

On the inner shelf, till –20m depth, some preliminary data from SCUBA campaigns have already shown (Granja and Ferreira, 2006): a marine sea level stand at –15m depth, revealed by the presence of a N30ºW notch; channels with the same orientation, between rocky outcrops with 18m height walls; many pebbles and

boulders; and clasts exclusively composed of organic detritus (shell hash). Sand is very fine and silty, and only confined to a narrow band along the coast.

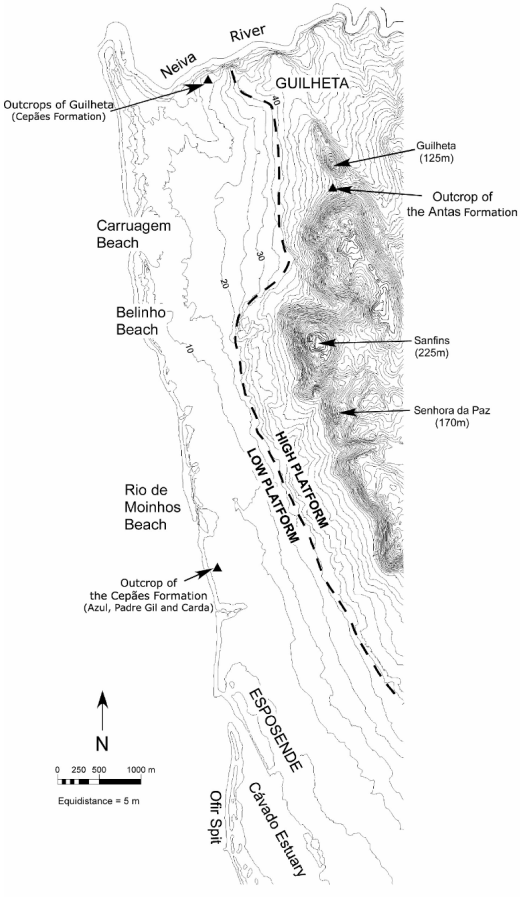

Fig. 3. Main landscape features of the coastal zone between the Neiva and Cávado rivers. Crowded contour lines indicate the position of fault scarps (dead cliff) (after Soares de Carvalho *et al*, 2006)

THE EVOLUTION FROM A SANDY TO A GRAVEL BEACH STATE

Belinho Beach is one of the beaches where the replacement of sand by gravel was the most spectacular. For this reason it was chosen as case-study.

For more than two decades, erosion has been a constant along the NW coastal zone of Portugal (Teixeira, 1980; Granja, 1990; Veloso Gomes, 1993; Oliveira, 1997;

Oliveira *et al*., 1982, Carvalho *et al*., 1986, Dias, 1990, Mota-Oliveira, 1990, Ângelo, 1991. Ferreira and Dias, 1991; Bettencourt and Ângelo, 1992, Carvalho and Granja, 1992, in Magalhães, 1999; Veloso Gomes *et al*., 2002). Inland beach migration, thinning of beaches and cliff retreat are the geoindicators of that phenomenon (Carvalho *et al*., 2002).

However, only from 1996 onwards, beaches began definitively to loose sand, which has been replaced by much coarser sediments – like pebbles, cobbles and boulders. This process was initiated in Castelo do Neiva (north of the Neiva River) by the end of the 1980's, when sandy beaches began to show beach cusps with horns composed of pebbles (intermediate state, with sand and gravel). These beaches evolved progressively towards a gravel state, extending southwards along the coast. Today, gravel beaches extend till Redonda Beach, at the town of Esposende (Fig. 1).

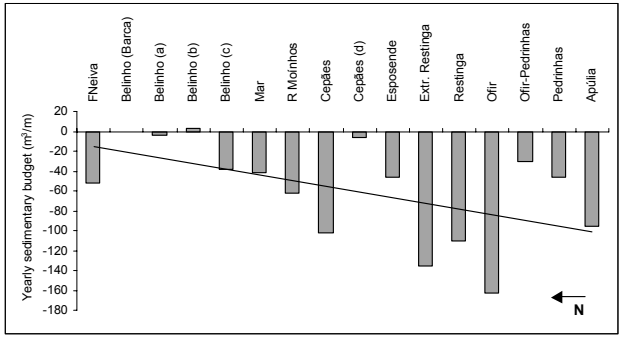

Fig. 4. Sedimentary budget along the beaches, between the Neiva River and Apúlia (2001-2004)

The coast of NW Portugal is of mixed energy, wave and tide-dominated, according to the classification of Davis and Hayes (1984). Tides are mesotidal, semi-diurnal, with maximum amplitude of 3.9m and a minimum of 0.2m. The wave climate is characterized by a mean H_s and T_s of 2m and 9s, respectively; the main direction is from NW (79% of frequencies). The net sedimentary drift is from North to South, though at some points this is inverted due to the presence of outcrops or shoaling bars (as around the ebb tidal delta of the Cávado mouth) that refract and diffract the dominant NW incoming waves. The presence of some engineering structures (groynes and revetments) also contributes to some interference patterns on the general circulation, promoting up-drift wedge beaches against groynes, thinning of beaches in front and excavation on both sides of the revetments.

According to Short (1999) spatial changes in beach type are driven by changes in both wave climate and sediment characteristics. However, the available wave data is scarce and not continuous. The number of recorded data of the Hydrographic Institute (IH) at the Leixões wave-buoy, although significant, shows a series of breaks in the sequences. The common situation of sample collection produces 240

monthly data (8 per day). But, between 1981 and 1985, the data from storms are very rare, probably due to technical problems (Coelho, 2005).

With these limitations, and due to the impossibility to use data from pressure transducers (PTs), it is extremely difficult to find any explanation based on wave climate changes. However, even taking into consideration the scarcity of data, there are some slight changes concerning the breaker heights and the steepness of incoming waves, that can help to explain some changes in beach behaviour (Fig. 5).

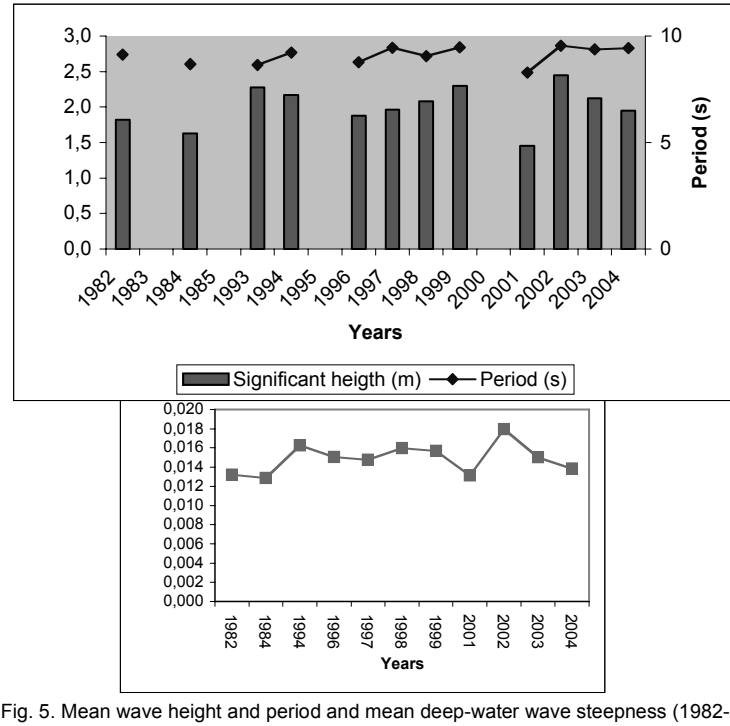

Fig. 5. Mean wave height and period and mean deep-water wave steepness (1982-2004)

Beach facies

The coastal segment between Belinho and Mar is 3000m long. Till 1995, Belinho was a sandy, 100m wide dissipative beach, with a slope of 0.07, well-developed 30-40m wide berm dipping landward, and a smooth beach face (Fig. 2a and Fig.6).

After1995, the beach evolved progressively into an intermediate state one, as did also facies and grain size of sediments (Fig. 2b and Fig.6). The emergence of rocky outcrops of the platform contributed to a change of wave refraction and the formation of large-scale rip circulation. This mechanism, associated to the ridge-and-runnel systems, produced variations in the wave breaker heights parallel to the shore and on the direction of approach. The morphology stimulated deposition at the lee side of the bars, the growth of megacusp horns, and the scouring in the bays due to higher diverging waves. As the morphology helps to reinforce and attenuate the dynamics, the morphodynamic coupling is maintained with continued low waves (Short, 1999). Bars will move shoreward while the megacusps horns will grow seaward, producing scarping in the rip embayment. Progressive shoreward moving will create a low tide terrace.

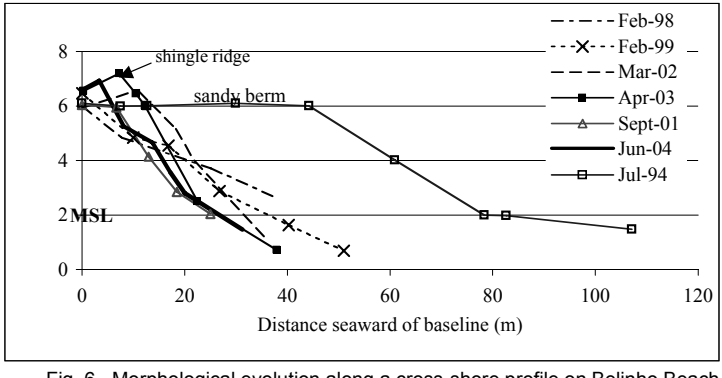

Fig. 6. Morphological evolution along a cross-shore profile on Belinho Beach

Today, and since 2000, the gravel beach is fully reflective (Fig. 3c and Fig.9). It shows a 10-20m wide berm, oriented N10ºE-N40ºW, and backed by a dune cliff, where four active overwashing areas cut through it. The steep beach face shows several series of beach cusps with different wavelength (Fig. 7a). In the intertidal zone there are extensive rocky outcrops of the lower platform.

Fig.7. a. Series of beach cusps in Belinho Beach (June 2006, fair weather conditions); b. smooth profile after storm (November 2006)

The sedimentary cover of the beach is composed of gravel, pebbles, cobbles and boulders of different lithology (quartzite, the most abundant, schist, conglomerate, quartz and granite) and shape (discs, rods, spheres, and blades). The dominant size lies within the 45-64mm range (Loureiro and Granja, 2001). Sometimes, some sandy aprons are present on the lower beach face during fair weather conditions.

Shingle shape zonation on the beach is a function of wave energy conditions. The wave climate and the existence of rocky outcrops in the intertidal and subtidal zones have an important role in the distribution and selection of pebbles on the beach, contributing to the existence of different morphosedimentary behaviours.

Over the year, the shingle beach of Belinho may exhibit a range of facies responses to the wide spectrum of wave energy it receives. Different shape particles react differently to wave conditions, permitting the subdivision of the beach into different morphodynamic zones (Loureiro and Granja, 2001).

Beach Dynamics

On reflective beaches, seaward of the breaker point, shoaling waves induce onshore sediment transport as well as a preferential shoreward movement of coarse sediments, that will accumulate in the swash zone. The waves breaking at the base of the beach face expend all the remaining energy in the swash zone. Much of the energy goes into the wave uprush which builds a steep beach face aided by coarser sediments (Short, 1999).

Cusps are a product of sub-harmonic edge-waves, meaning that the waves have a period twice that of the incoming wave (Wright *et al*., 1979, in Short, 1999). The edge wave period and the beach slope determine the edge wave-length, which in turn determines the cusp spacing, which on swell coasts can range from 20 to 40m (Short, 1999), like here, in Belinho (Fig. 10).

The distribution of particle size across a beach profile shows a decrease from the ridge crest to the bay of the beach cusps. The accumulation of large discs and spheres in the berm of the beach occurs during storm periods. Small spheres are also projected by the waves and lodged among the bigger particles.

During storms, the beach profile is smoothed with the destruction of the cusp morphology and pebble imbrication, while the build-up of the berm crest turns the profile steeper (Fig. 7b).

METHODS

Foreshore morphology

The topographic surveys consisted of cross-shore profiles along the beaches using a Leica theodolite (all surveys are referred to ZH level, the national hydrographic level, 2m below mean sea-level and to Hayford/Gauss Datum). Each profile was surveyed between the low tide line and the top of the dunes on which crests fixed reference points were established. Sediment budgets and beach slopes were thus calculated. The

sedimentary volumes were calculated along 17 profiles covering about 1000m of beach extension in 1994, 1998, 1999, 2002, 2003, and 2004.

The shoreline retreat was based on the sample mean standard deviation and the maximum shoreline landward movement (Byrnes and Hiland, 1994; Anders *et al.* 1990 *in* Gorman *et al*., 1998). The volume calculation was obtained with the program Surfer, version 8.0, using the Trapezoidal, the Simpson and the 3/8 of the Simpson methods, with a relative error lower than 0.05%.

The morphological vulnerability index (Larson and Kraus, 1995), a resilience measure of the beach face to adverse marine agitation conditions, was determined.

Wave measurements

In the absence of pressure transducers, IH data were used to calculate wave parameters. Wave characteristics were obtained by statistical averaging of significant wave heights and periods. These analyses were based on wave data from 1982 till 2004. Breaker height was estimated in the surf zone according to Komar and Gaughan (1972) and the deep-water wave steepness (H_s/L_0) was calculated.

The surf scaling parameter $\varepsilon=(2\pi^2 H_b)/(gT^2 \tan^2\beta)$, the surf similarity parameter $\Sigma=\tan\beta/(H_b/L_0)^{0..5}$ and the Dean's number $\Omega= H_b/(WsT)$ were calculated. The beach was classified according to its morphodynamic state and the type of wave breaker (Short, 1999).

Sediment sampling

The morphometric indexes (R.I and F.I) and the shape of the pebbles were determined along the beach transects during a field campaign in 1998, when the beach was already in a reflective state, but with only a series of beach cusps (Fig. 2 b). 1405 quartzitic pebbles and cobbles were sampled on the ridge crest and on horns and bays of beach cusps, using a square metre sampling net (Loureiro and Granja, 2001).

RESULTS

Sediment characteristics

Considering the total of the beach, discs were the most abundant shapes (43%), followed by spheres (29%), rods (19%) and blades (11%). The percentage of discs shows an increasing trend with size, while rods and blades show a decreasing trend. Spheres are abundant in all size classes. There is an increase of the roundness index with the decrease of particle size, while the flatness index shows a slight increase with increasing sizes.

A seawards decrease of size particles was observed across shore. This particle size differentiation can be due to an asymmetric swash flow, the size gradient depending on the pulsation of a distinct groundwater surface flow operating in conjunction with backwash (Orford *et al*., 2002). The larger sizes at the berm crest are due to storm conditions, when onshore transport is dominant at the top of the beach.

Discs represent the most frequent shape on the ridge, horns and bays of cusps (80%, 81% and 77%, respectively), being predominant in the highest size ranges (40-50 to 60-70mm). Rods (76% in the ridge; 59% in the cusp horns; 42% in the cusp bays) are represented most in the lower size ranges, decreasing in the higher ranges. Spheres and blades are regularly distributed over all size ranges. In the cusp bays there are all the shapes in the lowest ranges (<20mm) and their absence in the range size 60-70mm, while in the ridge and cusp horns only the shapes <20mm are absent (Fig. 8).

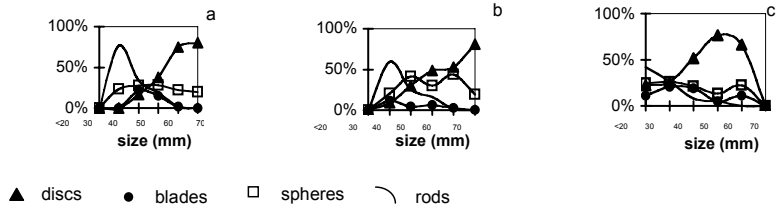

Fig. 8. Pebble shape percentages: a. ridge crest; b. horn of beach cusps; c. bay of beach cusps (after Loureiro and Granja, 2001)

It is interesting to note that on Belinho Beach, size ranges for cusp horns and bays are higher than those of other beaches cited by authors like Sherman *et al.* (1993). For example, in bays, discs are mostly in the 40-60mm size range, a higher range than the ones presented by those authors.

In the beach cusps, the mean value of the R.I. (585±100) in the bay is higher than that of the horns (519±190). In the ridge crest the R.I. is 514±104. Along the beach, R.I decreases from north to south. The presence of larger outcrop areas on the southern sector of the beach would reduce the pebble mobility, explaining perhaps the decrease of R.I.

Wave climate

Between 1982 and 2004 the mean wave characteristics concerning height and period were calculated (Table 1) from the IH records as was the deep water wave steepness (Fig. 5).

The yearly mean of the wave height was 2.0m and 9.1s for the period, though with important seasonal variations. During winter (2.6m) and fall (2.5m) the mean height values exceeded by about 1m those of summer and spring. The differences between the maximum and the minimum of the means was about 1.6m. The maximum height was observed in October 2003 (9.2m) and in February 2002 (7.4m).

Observing the mean wave heights for each year of this period of time (Fig. 5), there is a slight decrease between 1993 and 1994 and a more accentuated one between 1999 and 2001. From 2002 till 2004 there is also a decrease. The highest values of

the period were observed during fall (10.1s) and winter (11.0s), while the lowest was registered in summer (7.9s).

Between 1981 and 2004, the strongest situations of marine agitation occurred during the year 2002, with waves H_s>3m during 106 days and T_s>12s during 88 days of the year.

Deep water wave steepness shows an irregular behaviour (Fig. 8). The highest values prevailed during part of 1993 (0.018), 1999 and 2002 (0.016), while the lowest values (0.013) were related to small waves during the years 1982, 1984 and 2001. Although irregular, a small decreasing trend was observed between 1994 and 1996, 1999 and 2001, 2002 and 2004. In 1994, the beach was still dissipative, the change to an intermediate state having occurred by 1996 with a great loss of sand. Looking at Fig. 6, those periods correspond to steeper beach face profiles. The steeper beach face and higher ridge crests correspond to April 2003, when the wave steepness and wave height diminished.

Table 1. Wave Climate Statistics, 1981-2004, Esposende

Time Period	Mean Height, m	Mean Yearly Max Height, m	Maximum Height, m	Mean Period, s
Winter (Jan-Mar)	2.6	4.2	7.4	11.0
Spring (Apr-Jun)	1.7	3.7	6.3	8.6
Summer (Jul-Sep)	1.3	2.6	3.7	7.9
Fall (Oct-Dec)	2.5	4.1	9.2	10.1
Yearly Mean	2.0	3.7	2.5	9.1

Beach morphology

Today, Belinho Beach is characterised by Ω values between 0.15 and 0.10, which means that this coastal segment is reflective with plunging breakers, the beach face presenting a high steep slope during all the year.

The dominant morphology of the beach, today, is a 7 to 12m wide shingle ridge (boulders, cobbles, and pebbles) parallel to the foredune, a steep beach face where the pebbles show imbrication, series of pebble beach cusps with different wavelength (7 to 18 m), and small areas of coarse sand between the lower beach face and the rocky outcrops (sand aprons). During storm conditions, pebbles and cobbles overwash the foredune.

With breaking wave heights Hb<0.5m, in some sectors of the beach, pebbles accumulate between the lower beach face and the rocky outcrops, where they are covered by sand transported from seawards during summer.

The retreat of the sandy cliffs between 1994 and 1997 was between 20 and 40m, but from 1998 till 2004, the mean retreat has decreased to 5m due to the presence of the

shingle ridge in front of it. Only in the overwashing areas the retreat had a maximum of 30m.

Between 1998 and 2004, the base of the beach face was subjected to a yearly mean lowering of about 0.7m, and the width of the berm decreased by about 2m. The mean retreat of the sandy cliffs in this sector was about 4±2.5m, with a maximum retreat of 8m in the overwashing areas (Fig. 6).

Table 2. Morphodynamic Parameters (mean values concerning 2001-2004)

Belinho Beach	Slope (tanβ)	Foreshore width (m)	Grain size (mm)	Ω	Σ	ξ
Yearly	0.15	25	≥50			
winter				0.15	0.91	1.8
summer				0.10	0.93	1.7

Concerning the vulnerability index, before 2001 the behaviour of the beach was weak (0.36 to 0.62), but after then, when shingle definitively replaced sand, the beach changed to a robust behaviour (0.02 to 0.26).

DISCUSSION

This is a good example of a beach segment with a fast and extreme evolution trend. The change from a sandy state to a gravel state was reached in just a few years. This is not situation of stripping of beach sands during winter storms and the exposure of a cobble/boulder lag deposit, a temporary change of sediment and beach type, as documented by Shepard (1963) or Short (1984). Here it is a permanent state. The fundamental question here is why a sandy, dissipative beach turned into a very coarse, reflective gravel beach. The evolution from a dissipative state to a reflective state is exactly the opposite of all those beaches that evolve into a dissipative state at some stage, although most never reach the fully dissipative state according to Short (1999).

On Belinho Beach, the present reflective state should be analogous to the one responsible for the emplacement of the fossil gravel beach ridges situated under the LIA dunes. Orford *et al.* (2003) have presented a similar case in NE Ireland and discussed the mechanisms responsible for the decoupling of gravel and sand into different modal-sized components in Holocene coastal sedimentary environments, or how two distinctive coastal domains with radically different morphodynamic beach contexts could alternate to generate superimposed units of widely contrasting particle size.

One of the explanations for that superimposition suggested by Orford *et al.* (2003) points to different energetic conditions, the gravel source being preferentially deposited under high-energy conditions, followed by the fine sediment when the gravel supply is exhausted. But if so, why are there no observable significant wave climate changes, over the last 20 years, when the replacement from sand to gravel state took place?

Another mechanism discussed by the same authors is that gravel ridges were emplaced under a reflective morphodynamic regime that would deplete the sediment source. The superimposition of the dune cover would follow it, with sand moving into the beach to replace or possibly bury (the case of Belinho) the gravel component residing on the beach face (the ante-LIA ridge). According to them, such a switch in sediment source may also have resulted from a joint occurrence of energy and sediment source changes. In the case of Belinho Beach, it would mean that, during LIA, the sand availability was large and the winds strong enough to mobilize it (which is confirmed by historical texts, see Felgueiras, 1998), under a regime of high-energy wind-blown sand.

The dunes superimposed on gravel beach ridges is thought to be the result of an alternating sediment decoupling (modulated by falling sea level) rather than a sequential sediment sourcing, according to Orford *et al.* (2003).

The presence of outcrops in the lower foreshore contributes to sediment accretion on the beach, making the seaward cross-shore and alongshore sediment transport more difficult (pebbles have smaller R.I.), which leads to an increase of the berm height and of the beach face slope. The ridge protects the foredune cliffs against a direct attack of the waves, and also stimulates the infiltration of water from the swash, decreasing the backwash over the beach face. This contributes to a strong reduction of sediment movement offshore.

Like in other cases (e.g. Portmore Beach, Sherman *et al*, 1993), Belinho Beach is a beach subject to a wide range of energy conditions and constantly reworked, though maintaining a sedimentary equilibrium (Fig. 4).

Although the beach slope is 0.13 (>0.10), the deep-water wave steepness is in the range of 0.016-0.013, higher than what was proposed (<0.01) by Bauer and Greenwood (1988) (cited by Sherman *et al*., 1993) for the occurrence of reflective conditions under all wave regimes. Plunging breakers are the dominant wave breaker type, and during high tide, in the zones where the beach is steep enough ($\tan\beta$=0.15 to 2.0), the waves are of the collapsing breaker type.

The volumetric changes (Fig. 4) since the beach became fully reflective are small and the erosive processes affect the beaches only during storms, when partial foredune overwashing occurs. The small difference between the maximal and minimal sediment volumes in this sector indicates that the beaches keep some morphodynamic stability. Consequently, the beach shows a robust behaviour, resulting in some stability following a new morphodynamic equilibrium.

CONCLUSIONS

Between 1981and 2004, the beach characteristics of Belinho Beach (Esposende coast) show a trend to: 1) increase in grain size; 2) change in sediment composition (quartz sands to quartzite pebbles and cobbles); 3) increase in rocky-outcrop areas in

the intertidal zone; 4) increase in negative sedimentary budget and cliff retreat; 5) gradual shift from dissipative to reflective morphotypes.

Between 2001 and 2004, the cliff retreat and the sediment budget were different along the coastal zone of Esposende, although mainly erosive (Fig. 6). The negative sediment budget recorded today on the beaches can possibly be the result of a lack of significant sediment sources available, sand starvation on the shoreface which is now beginning to be confirmed by diving campaigns, and sea-level rise (Granja, 1999). Sand starvation and increasing water-depths resulting from sea-level rise, leads to a decreasing sediment transport shoreward. Also, the predominance of the plunging breaker type promotes a strong backwash, which contributes to an important cross-shore transport seawards, increasing the erosion of the beach.

However, today on Belinho Beach and on the other gravel beaches, the erosional processes are less accentuated than on the still sandy beaches of the Esposende coastal zone.

Sediment transport is conditioned by local factors such as: 1) the strong wave refraction over a bigger or smaller intertidal area of rocky outcrops, reducing the alongshore component of the energy flux; 2) a different orientation of the beaches in relation to the approaching waves; 3) local bathymetric characteristics; 4) the existence of different circulation cells; 5) the availability and grain size of the sediments; 6) the Cávado river mouth; 7) the presence of groynes and breakwaters.

However, what has led and still leads to a general loss of sand on these beaches and to the change from a dissipative to a reflective state? Wave climate change? From the 20 years wave data available from IH there is no evidence of significant changes. Sand starvation? Undoubtedly yes, especially if the inner shelf cover is also considered. But, if so, where is the sand going? The sand trapped against the groynes and breakwaters southwards and into the estuary of the Cávado River is not enough to justify the losses from adjoining beaches.

At times of maximal sand deficit, the morphodynamic regime of the beach face switches to one of inner-beach reflectivity, which is a response to gravel ridge development at high-water positions, which in turn will be fixed during dissipative conditions, after a new influx of fine-grained sediment. These cycles of sediment renewal would be related to variations in the rate of sea level drop and reworking of near-shore sediment (Orford *et al.*, 2003). On Belinho Beach, if one of the gravel sources could be in the beach ridges under the LIA dunes, another is certainly on the inner shelf itself, which is being reworked under present sea level rising and higher frequencies of storms.

In the case of coastal risks today, the northern segment (Belinho) of the Esposende coast is less vulnerable to storm surge flooding and infrastructural damage due to an undeveloped shore, predominance of large outcrop areas in the intertidal zone, a shingle ridge parallel to the foredune, and a well-developed dune system. The

southern sector, with intermediate and dissipative beaches (Esposende and Ofir spit), is prone to higher risks due to a flat beach face and intensively developed backshores without protective dunes.

ACKNOWLEDGEMENTS

We greatly appreciate the cooperation of Dr. Carlos Coelho from the University of Aveiro, concerning wave data information and we are very grateful to Dr. Th. de Groot for the revision of the English text. We acknowledge the Área de Paisagem Protegida do Litoral de Esposende and the Câmara Municipal de Esposende, that have sponsored this work. All wave data used is from the Hydrographic Institute (IH).

Abstract: This study investigated the effects of bulkheads and other armoring on beach conditions in Thurston County, Washington. Beach characteristics were measured at paired beach sites – neighboring and otherwise similar sites with and without bulkheads or other armoring. The study focused on beach characteristics relevant to spawning habitat for pacific sand lance and surf smelt, known as forage fish because of their importance to salmon. Armored locations, particularly in reaches of the shoreline where armoring was common, were found to have narrower beaches, with the greatest loss of beach typically at the higher elevations. Beach slope and sediment size were not significantly affected by the armoring. In a separate GIS-based investigation, it was determined that smaller, typically unnamed creeks contribute insignificant amounts of sediment in this area compared to the potential sediment supply from larger rivers or (most likely the largest contribution) from landslides and other mass wasting.

INTRODUCTION

Thurston County is located at the southern tip of Puget Sound, WA (see Figure 1). The county has 120 miles of marine shoreline along four north-trending inlets: Totten, Eld, Budd, and Henderson. The shoreline is macrotidal, with generally coarse and narrow beaches backed by coastal bluffs, predominantly composed of quaternary glacial

outwash. Approximately 36% of the shoreline is armored, largely with vertical bulkheads.

The study described here was performed to evaluate the effect of shoreline armoring, particularly bulkheads, on spawning habitat for forage fish (pacific sand lance and surf smelt) – specifically, the availability of sand and gravel beach at elevations between Mean Tide Level (MTL) and Mean Higher High Water (MHHW). Secondary aims of the study were to understand sediment sources in the area, and general geographical trends within the inlet. A more detailed description of the study background, aims, activities, and results is given in Herrera Environmental Consultants (2005).

METHODS

An intensive field program during the summer of 2003 measured beach characteristics at paired beach sites – neighboring and otherwise similar sites with and without bulkheads. The purpose of the field survey was to document and categorize the various geomorphic beach characteristics present, to identify the effect of bulkheads on sediment and beach characteristics, and to aid in identification of sediment sources and sinks. The field survey was supplemented by a GIS study of existing aerial photographs and digital elevation data that identified mass wasting sites (landslides) feeding the littoral system.

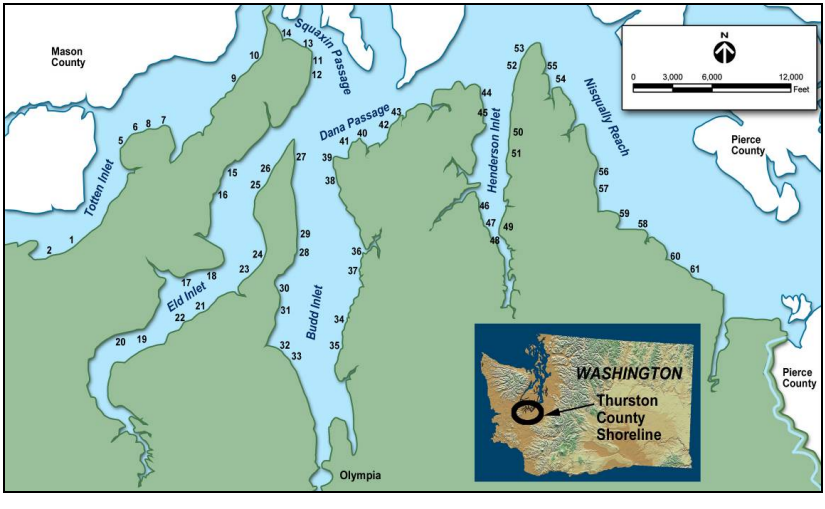

Fig. 1. Vicinity map including the location of beach sites

The majority of the field work was performed between August 25 and August 28, 2003. The marine shoreline of Thurston County was analyzed using 29 pairs of beach sites; the individual sites are shown in Figure 1. Each pair of beach sites consisted of one armored and one unarmored location. Three additional sites, not shown in Figure 1, were used to investigate the characteristics of small creeks. As is typical of the marine shoreline of

Thurston County, the beach at each site was backed by armoring or a bluff face. The majority of the armoring consisted of concrete bulkheads, although a few sites with riprap revetment and/or anchored logs were selected.

The following criteria were used in selecting each pair of sites, in order that they be as well matched as possible:

- Located in the same drift cell, as mapped by Schwartz and Hatfield (1982);
- Similar aspect;
- Similar geology;
- Similar slope and bluff relief upland of the sites;
- No recent landslide activity nearby;
- At least 250 feet and preferably about 500 feet between the two sites;
- No significant features protruding into the water between the two sites.

In some locations, bulkheads were originally constructed encroaching on the beach. These were typically indicated by return walls, of the same construction as the main bulkhead, used to retain upland fill. Such locations were not selected as beach sites.

The full beach profile was measured at each of the 58 sites. The beach profiles were measured at relatively low tide (no higher than MTL and much lower when possible). The beach profiles were measured from the lowest elevation available by wading to the armoring or bluff face. The most common and secondary sediment types (boulder, cobble, gravel, sand, fines, or other – generally shell hash) were determined visually and recorded at each point along the profile. The presence or absence of the following characteristics was noted:

- Hardpan, either exposed or a few inches below the beach surface;
- Coarser sediments on the beach surface (surface armoring, indicating erosion);
- Barnacles (indicating relatively low wave energy);
- Woody debris, either driftwood or locally sourced through mass wasting.

As a separate effort, six mass-wasting sites were surveyed in September 2003 to field-verify the landslide identification from the GIS analysis, described below.

All sampling locations were georeferenced using a Trimble® GeoExplorer3 handheld global positioning system (GPS) unit (resolution 6 to 16 feet).

FIELD PROGRAM RESULTS: BEACH CHARACTERISTICS

Figure 2 illustrates a typical beach in Thurston County, while Figures 3 and 4 are typical of the beach profiles measured. The photographs were taken, and both profiles were measured, in Henderson Inlet. Figure 3 is typical of those cases where the unarmored and armored beach profiles were very similar, while Figure 4 is typical of those cases where the armored beach is narrower than the unarmored beach.

Fig. 2. Typical Thurston County Beach (photographs in Henderson Inlet, unarmored site 49)

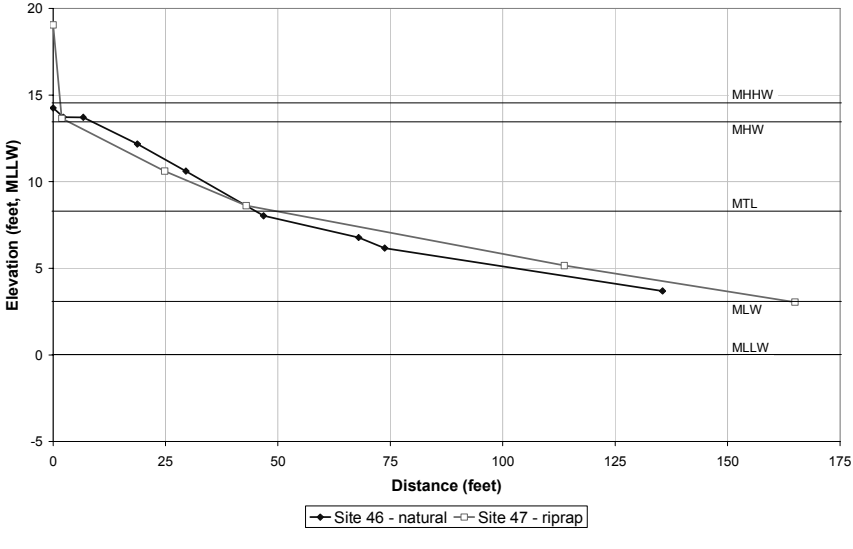

Fig. 3. Paired beach profiles where the armored and armored beach are similar (Henderson Inlet, sites 46 and 47)

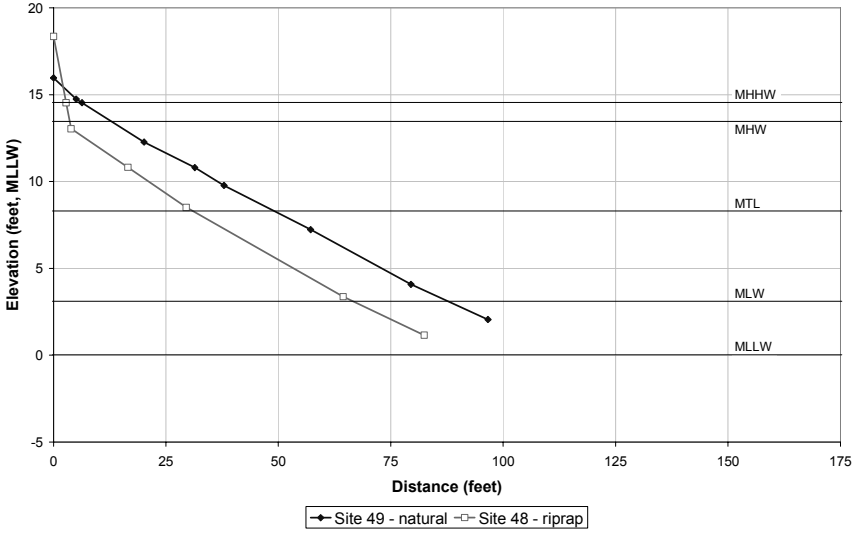

Fig. 4. Paired beach profiles where the armored beach is lower than the unarmored beach (Henderson Inlet, sites 48 and 49)

The average beach slope (between MHHW and the lowest limit measured), the width of the upper beach (from MHHW to MTL), and the width of the upper beach suitable for forage fish spawning (that part of the upper beach where the substrate was sand or gravel) were calculated for each profile, and the results compared for armored and unarmored sites.

Table 1 shows the results of this analysis. It indicates that armored shorelines differ significantly from unarmored shorelines in that the bulkheads effectively encroach on the upper beach – leading to a lower beach crest elevation and a generally narrower beach. (The beach crest is defined here as the point where the beach meets the bulkhead, other armoring, or bluff face). However, the beach slope, sediment characteristics, and the apparent wave energy on the beach (indicated by the presence of barnacles as well as by sediment characteristics) are not affected by local armoring. Woody debris is more likely to be present in unarmored areas, although this is likely to result from beach grooming by landowners rather than being a direct effect of the armoring. A slight but not statistically significant difference between the beach sediment grain size for armored and unarmored beaches was observed (Figure 5).

Table 1. Beach Characteristics Compared for Armored and Unarmored Beaches

Attribute	Median Difference *	Probability difference occurred by chance	Statistically Significant?
Upper Beach Width, feet (m)	-8.5 (-2.6)	p < 2.5%	Yes
Beach Width Suitable for Spawning, feet (m)	-9.4 (-2.9)	p < 2.5%	Yes
Slope, %	0.2%	p > 25%	No
Elevation of Beach Crest, feet (m)	-1.8 (-0.5)	p < 2.5%	Yes
Hardpan Exposure, yes/no	N/A	p > 25%	No
Beach Surface Coarsening, yes/no	N/A	5% < p < 10%	No
Presence of Barnacles, yes/no	N/A	p > 25%	No
Presence of Woody Debris, yes/no	N/A	p < 2.5%	Yes

* Median values of (armored-unarmored) measurements, for numerical measures

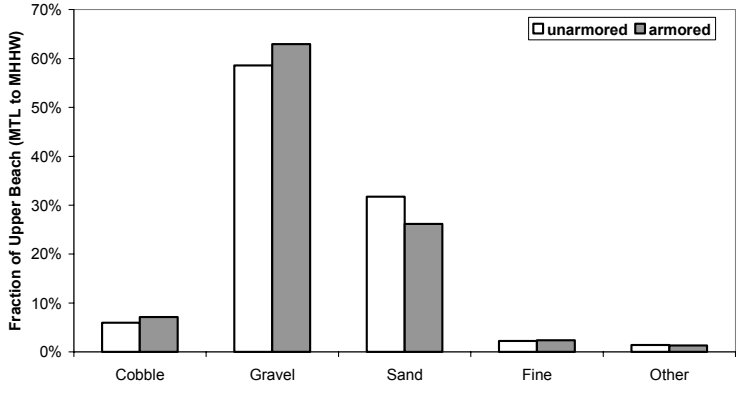

Fig. 5. Sediment size characteristics

At ten out of 23 armored sites where the armoring consisted of bulkheads, the bulkhead footing was exposed (e.g., Figure 6). This suggests that the decrease in beach width has resulted from erosion (with the upper beach fixed by the bulkhead rather than retreating along with the beach), and not simply to encroachment at bulkhead construction.

The relative decrease in crest elevation when comparing armored to unarmored beaches was found to be greater in those parts of the shoreline where armoring is common – defined here as those locations where more than 50% of the shoreline within 600 feet is armored. Beaches adjacent to isolated bulkheads are little affected by the armoring. The fact that the beach crest elevation is affected more by armoring in areas where armoring is common could be a cumulative effect due to long-term impoundment of bluff

sediments behind bulkheads. Alternatively, it could simply be the case that property owners are more likely to construct armoring along erosional stretches of beaches.

Fig. 6. Exposed bulkhead footing, Totten Inlet. August 25, 2003.

As a separate observation, the beach sediments generally coarsened from south to north, reflecting an increase in wave energy to the north.

Observed differences between armored and unarmored sites within each individual inlet, while not statistically significant (due to the smaller sample size), were consistent with the results described above.

GIS RESULTS: SEDIMENT SOURCES

A major aim of the GIS study was to identify the most significant sediment sources for the marine coastline of Thurston County. The three general sediment sources considered were: mass wasting (including landslides and bluff erosion); larger rivers; and smaller (typically unnamed) creeks.

The marine shoreline of Thurston County is typical of Puget Sound, with beaches set against steep, forested hillslopes composed of relatively unstable glacial sediments. Feeder bluffs are hillslopes that contribute sediment to the shoreline either through chronic surficial erosion or through periodic landsliding. The GIS study estimated only the sediment quantity delivered to the littoral zone through landsliding. As such, the results given here do not include sediment supply from chronic surficial erosion and represent a lower limit on the sediment supply from mass wasting.

Vegetation and topographic relief were used in the GIS analysis to identify and measure the area of each landslide. The approximate age of each landslide was estimated based on vegetation characteristics at the site; see, for example, Figure 7. A subset of the landslides was spot checked in the field. The landslides were further compared to those shown on available Washington Department of Natural Resources (WDNR) geologic maps as landslide deposits (WDNR 2003a-e, 2004a). WDNR only recorded landslides in

areas where the landslide obscures the underlying geology and consequently did not map many smaller landslides that were mapped in this study.

Fig. 7. Example of landslide in Eld Inlet. Riparian vegetation indicates slide is approximately 10 years old.

The annual volume of sediment supplied from mass wasting was estimated using this GIS analysis of landslide areas and ages together with field observations of recent landslides that suggested that the landslide depth was typically 3-5 feet (1-1.5 m). It was assumed that 30 percent of the sediment supplied to the beach by landslides was sand or gravel, and was therefore able to contribute significantly to the littoral sediment supply. The potential coarse sediment supply delivered by landslides – a lower limit of the total supply from mass wasting – is summarized in Table 2 for each inlet and reach.

Table 2. Estimated lower limit on the potential sediment supply due to mass wasting

	Totten Inlet *	Squaxin Passage	Eld Inlet	Budd Inlet	Dana Passage	Henderson Inlet
Potential supply, cubic yards (cy)/year (m^3/year)	1,300 (1,000)	50 (40)	3,200 (2,500)	1,700 (1,300)	400 (300)	2,500 (2,000)

* Thurston County shoreline only.

The potential sediment supply from larger rivers was evaluated based on dredging records from Capitol Lake, reported by Thurston Regional Planning Council (2002). Capitol Lake, which is located in Olympia at the southern tip of Budd Inlet, is formed by impoundment of the Deschutes River, so that the sedimentation rate in the lake is equal to the volume rate of sediment transport by the river. At present, this sediment is not available to the littoral system. For the other rivers, an estimate of sediment transport was

based on the relative watershed areas of the different rivers. The fraction of coarse sediment (sand sized or larger) was also based on dredging records from Capitol Lake.

Table 3 gives the estimated potential sediment supply from large rivers for the different inlets and reaches. It is possible that a large fraction of the coarse sediment is immediately transported offshore and is not delivered to the littoral system – meaning that the volumes given here provide an upper limit on the sediment supply from larger rivers to the littoral system. The quantities shown in Table 3 are of a similar magnitude to the quantities in Table 2, indicating that the sediment supply from large rivers is similar to or less than the sediment supply due to mass wasting.

Table 3. Estimated potential sediment supply from large rivers for each inlet and reach in Thurston County

Inlet / Reach	Potential Supply	Notes
Totten Inlet, cy/year (m^3/yr)	1,900 (1,500)	Half the total input to Totten Inlet; the western shore is in Mason County.
Squaxin Passage, cy/year (m^3/year)	0 (0)	No significant rivers.
Eld Inlet, cy/year (m^3/yr)	2,300 (1,800)	
Budd Inlet, cy/year (m^3/yr)	2,600 (2,100)	In addition to this quantity, the potential supply from the Deschutes River (currently impounded) is 9,500 cy/year.
Dana Passage, cy/year (m^3/yr)	0 (0)	No significant rivers.
Henderson Inlet, cy/year (m^3/yr)	2,900 (2,300)	

Small, typically unnamed creeks individually transport small quantities of sediment. However, there are many such creeks. Additionally, a small creek that flows over the top of a beach, rather than cutting through it, could deposit all of its sediment on the beach. This is in contrast to some larger rivers which can deposit much of their sediment so far offshore to that the material is unable to return to the littoral system. For these reasons, it is important to assess whether the small creeks, in aggregate, provide a significant sediment supply to the littoral system.

An analysis of the watershed areas of larger rivers (included in Table 3) and other areas, assumed to be drained by smaller and unnamed creeks, showed that minor creeks have a much smaller watershed area, even in aggregate, than the larger rivers. Furthermore, recent work by Haugerud (2003) indicates that forest vegetation effectively "froze" the topographic expression of the Puget Sound Lowlands shortly after the continental ice sheet receded 10,000 years ago. This suggests that historically, all but the larger rivers were relatively minor sediment sources.

This watershed analysis suggests that the sediment input from small creeks is insignificant compared to the input from larger rivers. The sediment input from small creeks is also insignificant compared to that from mass wasting. Individual small creeks could be important for small drift cells but, in the aggregate, their effect on the littoral sediment budget appears minor. Consequently, a program of culvert removal for smaller creeks would not be effective in increasing the sediment supply to the littoral zone. There may, of course, be other good reasons (such as fish passage) for culvert removal in smaller creeks.

CONCLUSION

The study found the following statistically significant differences between unarmored and armored shorelines within Thurston County:

- Armored shorelines have a reduced beach area, with a beach crest elevation that is lower compared to unarmored shorelines;
- As a consequence, the armored shorelines have less spawning area suitable for forage fish;
- Less woody debris is found on the armored shorelines.

The loss of upper beach area is more pronounced as the percentage of shoreline protection increases. This may be a cumulative effect (e.g., due to impoundment of feeder bluff sediment behind armoring), or it may simply result from a greater tendency for landowners to armor their property in highly erosional areas.

The study found no statistically significant differences in the following areas:

- Beach slope;
- Beach substrate (i.e., grain size);
- General indicators of wave energy including hardpan exposure, beach surface coarsening, and the presence or absence of barnacles.

These results are entirely consistent with the concept of passive erosion: the armoring fixes the upper limit of the beach in generally erosional areas, causing the beach to narrow relative to unarmored areas. The results do not specifically support the concept that the effective wave energy is increased by reflection from bulkheads.

The analysis of sediment sources shows that both mass wasting and the larger rivers have the potential to supply significant quantities of sediment to the littoral zone. The sediment from larger rivers may be delivered directly offshore, bypassing the narrow littoral zone, indicating that the landslides are likely more significant than larger rivers as an effective sediment source. Small, typically unnamed creeks do not and have not historically provided a significant source of sediment.

Abstract: Extreme storms in reef environments have long been recognized as a mechanism for depositing ridges of reef-derived coarse clastic sediment. This study revisits the storm ridges formed by Tropical Cyclone Bebe (1972) on Funafuti, Tuvalu and Tropical Cyclone Ofa (1990) on Upolu, Western Samoa in the South Pacific, and Hurricane Lenny (1999) on Bonaire, Netherlands Antilles in the Caribbean. Ridge characteristics produced by these storms include: heights of 1-4 m, widths of 8-50 m, and lengths up to 18 km. The ridges tend to be higher and steeper on their landward margins than on their seaward margins and are composed mostly of re-worked coral rubble derived from reef front settings with smaller amounts of fresh broken coral (5-30%). Characteristics of these modern gravel storm ridges can be used to help identify ancient storm deposits and to differentiate between other coarse-grained deposits such as those created by tsunamis.

INTRODUCTION

Extreme storms in coral reef environments are capable of constructing large ridges of reef-derived coarse sediment that can ultimately lead to island growth (Maragos et al., 1973). As early as 1904, David and Sweet (1904) recognized the importance of storms as an island-building mechanism and described older "hurricane banks" as an important component of atoll islet development from Funafuti, Tuvalu (Figure 1). McKee (1959) and Blumenstock (1961) were some of the first to examine storm impacts and sedimentation resulting from an extreme storm in a reef setting (Jaluit Atoll, Marshall Islands). Their observations included geomorphology and sedimentology descriptions of storm deposits such as reef flat gravel ridges

(ramparts), shore ridges, and gravel sheets.

This paper examines the characteristics of storm ridges created by Tropical Cyclone Bebe (1972) on Funafuti, Tuvalu, South Pacific, Tropical Cyclone Ofa (1990) on Upolu, Western Samoa, South Pacific, and Hurricane Lenny (1999) on Bonaire, Netherlands Antilles, Caribbean Sea. This study is not intended to be a synthesis of all storm-ridge deposits, but rather a description of particular sites where significant coral-gravel ridges were created by known events, and where the sizes, morphologies, textures, and positions with respect to sea level and the shoreline could be established.

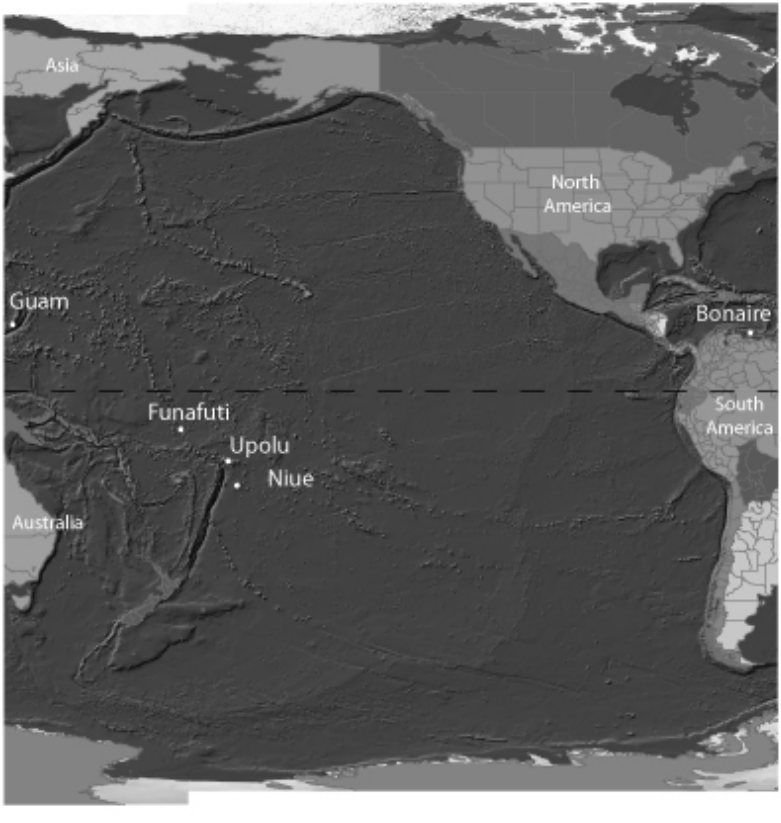

Figure 1. Locations of coral-rubble storm ridges studied.

CORAL-GRAVEL STORM RIDGE FORMATION

Brief Descriptions of the Studied Islands and Storms

The island of Funafuti is an atoll with near continuous islet development along its eastern (windward) margin and scattered islets along the western (leeward) and northern margins. A narrow reef rim surrounding a central lagoon is dissected by several deep passages that allow water exchange between the lagoon and open ocean. Tropical Cyclone Bebe was a category 3 storm (Saffir-Simpson scale) and one of only three severe storms to strike Funafuti in the last 140 years (Maragos et al. 1973). The slow-moving storm approached from the east with the eye passing directly over the atoll (note: cyclonic storms in the southern hemisphere rotate in a clockwise direction with most of the damage occurring in the left front quadrant). Much of the eastern side of the island was inundated by a wave (storm surge?) that exceeded 3 m (Baines et al. 1974).

Upolu is a high volcanic island bordered by both fringing and barrier reefs. The north shore of Upolu is characterized by a narrow coastal plain fronted by fringing reef that is reduced in width or absent opposite the major stream valleys (Richmond 1992a). Tropical Cyclone Ofa occurred in early February 1990 and was the strongest storm to strike Western Samoa in over 160 years (Elmqvist et al. 1994). The category 4 storm had winds in excess of 210 km/hr and passed within 160 km west of Upolu. Deepwater wave heights exceeded 7 m and were superimposed on a storm surge of 1.6 m (Rearic 1990). The strong winds and high waves caused extensive damage to buildings, roads, and natural habitats along the north coast of Upolu.

Bonaire is an uplifted and tilted high limestone island with a volcanic core and is surrounded by a narrow fringing reef system. Fringing reef and reef flats are best developed along the western shores. Much of the windward (east) coast is characterized by low coastal cliffs fronted by a steep nearshore zone. The cliffs are underlain by last interglacial reef deposits and vary in elevation from near present sea-level in the south, 5-8 m along the east and northeast coast, 3-9 m along the west and northwest coast, and 15 m along the north coast (Scheffers 2005). Hurricane Lenny was a category 3-4 storm that moved in an unusual easterly direction passing about 200 km north of Bonaire in November, 1999 (National Oceanic and Atmospheric Administration 1999). Lenny was the strongest storm to impact Bonaire in nearly 100 years and produced waves 6-8 m high along the Bonaire coast causing significant impacts along the western shores.

Although the islands studied represent three distinct types (atoll, high volcanic, and uplifted limestone), they have many similar characteristics including: impacts by infrequent major storms, prolific coral reef growth, well-developed reef flats, and nearshore reef areas capable of storing reef debris for subsequent mobilization and re-deposition by major storms.

Storm Ridge Characteristics

Studies by Maragos et al. (1973) and Baines et al. (1974) documented the impacts of Tropical Cyclone Bebe on the atoll of Funafuti. Bebe created a coral-gravel ridge in

excess of 18 km long and up to 4 m high along the southeast reef platform. The Bebe ridge averaged about 37 m in width and 30 m from the seaward edge of the reef. The base of the ridge on the reef flat was intertidal and the crest was above normal tide levels. The initial seaward face was concave in profile while the landward face formed a steep escarpment or avalanche face and the entire ridge was separated from the islet shorelines by a moat (Figure 2). The deposit was composed of cobble to boulder size coral rubble consisting of approximately 5% "fresh" coral and the remaining 95% previously rounded and re-worked coral clasts that had been stored in reef front environments. Internally the deposit was poorly sorted with some evidence of crude stratification. In addition to the storm ridge, "rubble tracts" or sheets of coral rubble, were deposited in some areas of the reef flats and islets. Landward of the Bebe ridge there is one or more older and higher storm ridges that form the backbone of windward Funafuti (David and Sweet 1904; Dickinson 1999; Richmond 1992b).

Figure 2. From right to left, the steep landward margin of the Bebe ridge, moat, and eroded beach from Funafuti. Photograph by Jim Maragos, December 1972.

Rearic (1990) examined the "cyclone banks" created by Tropical Cyclone Ofa along the north coast of Upolu a few months after their formation. In general, the ridge formed discontinuous segments (longest about 2 km long) presumably related to source material availability and offshore bathymetric conditions. The ridges were deposited on the intertidal reef flat approximately 10-20 m from the seaward reef edge and contain occasional low sections that are flooded during high tide resulting in the appearance of separate ridge segments. The ridge averaged 2-3 m in height with a maximum width of about 50 m. The landward avalanche face was steeper (~ 40 ^{o}) than the seaward face (~ 20^{o}) (Figure 3). The internal ridge structure was generally

disorganized, clast supported, and with little or no sand present in the upper meter. There are no older ridge deposits landward of the Ofa ridges; however, rubble sheets on the reef flats may represent older re-worked cyclone deposits.

Figure 3. The seaward face of the Ofa ridge about two years after original deposition. Landward migration and reworking of the ridge has resulted in a sheet of coarse rubble on the seaward (to the right) reef flat (backpack for scale).

Scheffers (2005) described the characteristics of Hurricane Lenny deposits on the island of Bonaire. Lenny formed discontinuous coral gravel ridges along more than 18 km of west-facing Bonaire shoreline. The Lenny ridges were typically 1 m high, with a maximum of ~ 4 m, and they were relatively narrow at 8-10 m wide. There was no broad intertidal reef flat on Bonaire, therefore ridge deposition occurred just seaward of the existing shoreline. A coral-rubble spit was deposited partially across an embayment in northwest Bonaire where the maximum Lenny ridge elevation of 4 m was recorded (Figure 4). The Lenny deposits were composed of coral rubble with about 20-30% of the clasts being "fresh" coral fragments. The deposits were clast supported with minor initial sand component. As with the Bebe and Ofa ridges, the landward slope of the ridge was stepper than the seaward face. In many places the Lenny deposits lie seaward of older and higher gravel ridges.

Figure 4. Coral-rubble ridge constructed by Hurricane Lenny on the northwestern coast of Bonaire. This spit-like feature was reworked by Hurricane Ivan in 2004.

DISCUSSION

Storm Ridge Characteristics

There are several features common to the Bebe, Ofa, and Lenny storm ridges (Table 1), these include: a) A relatively even, gently curved seaward edge that is roughly reef/shore parallel; b) A sinuous landward edge with debris tongues and embayments; c) Ridge heights ranged from 1-4 m above the reef flat surface and varied from ~8-50 m wide; d) In cross section the ridges have steep faces on both their seaward and landward margins with the highest part of the ridge usually near the seaward edge and the steepest face occurring along the landward edge; e) The ridges are formed mostly of gravel-sized coral rubble derived from the adjacent reef. Most of the rubble is composed of previously eroded and rounded coral fragments that were stored in reef depositional sites and subsequently reworked and deposited by the storms. A smaller percentage of material (5-30 %) was derived from living coral that was broken during the storms; f) The gravel clasts of the seaward margin tend to be imbricated seaward, whereas the internal structure of the ridges are more disorganized but may contain some crude sub-horizontal bedding; g) Megaclasts of meter-sized reef material were moved by the storms but form a relatively minor component of the overall deposits; h) The ridges are subject to subsequent reworking by waves and tides and landward migration has resulted in a reduction of ridge size, and in the case of Bebe (Baines and McLean, 1976) and Lenny (Scheffers and Scheffers, 2006) deposits they have

merged with the pre-storm shorelines.

Table 1. Summary of Storm Ridge Characteristics

Ridge Characteristics	T.C. Bebe Funafuti, Tuvalu	T.C. Ofa Upolu, Western Samoa	H. Lenny Bonaire, N.A.
Height (m)	3.5 (ave) 4 (max)	2-3	1 (4 max)
Width (m)	37 (ave) 21-50 (range)	50+ (max)	10 (max)
Length (km)	19 (continuous)	2+	Discontinuous (4 km max)
Composition	Coral Rubble (~5% "fresh") (cobble-boulder size) (minor sand)	Coral Rubble (minor sand)	Coral Rubble (20-30% "fresh") (cobble-boulder size) (minor sand)
Maximum clast size	7x3x3 m	Boulder ?	12 t (Curaçao)
Distance from reef edge (m)	30 (ave)	10-20	Beach Ridges
Slopes(degrees) **L = landward** **S = seaward**	"steep escarpment" L 20-30 S (concave)	40 L 20 S	Steep L Gentler S
Older Ridge(s) Present	1+	None	1+
Internal Structure	Poorly-sorted	Clast supported. Disorganized	Clast supported.

The formation of coral-gravel storm ridges has been noted from a number of tropical settings but they are not produced on a regular basis during extreme storm events and the reasons for this paradox remain unclear. Funafuti, Upolu, and Bonaire are subject to seasonal high waves and storms but are outside of the main cyclonic storm pathways; hence, extreme storms are a relatively rare event for these islands. Islands that are impacted by storms annually, but only infrequently subjected to extreme storms, may produce and rework reef debris, storing it on the reef where it is available for storm ridge building during extreme events (Scoffin, 1993). It is possible that islands regularly impacted by hurricane force storms are less likely to accumulate reef debris in shallow submarine environments for later storm redeposition as ridges. For example, the island of Guam in the western Pacific is regularly struck by typhoons. Studies in the aftermath of Typhoon Russ (1990) on a coral rubble islet on the barrier reef rim of southern Guam, documented coral-gravel sheet deposition over island surfaces rather than ridge deposition on the reef flat (Jaffe and Richmond, 1992). Most of the island washover sediment was derived from the pre-storm beach with very little sediment originating from the living reef and shallow marine environment.

Older Storm Ridges

Although the processes of gravel ridge formation are poorly understood, there are several conditions that are necessary to develop a ridge structure and morphology. These include: elevated water levels associated with the storm passage, extreme waves, an abundant supply of coarse sediment, a suitable depositional substrate, and ample time (hours) for clast excavation, transport, and construction by the high frequency waves. Flooding before and concurrent with deposition of the ridge is necessary for construction of the steep avalanche face that characterizes the landward margin of a ridge. Rearic (1990) thought that the ridge structure may be analogous to a bedform (break-point bar?) formed predominantly by bedload transport under elevated water levels and extreme waves. On both Funafuti and Bonaire there are older, higher, and more massive ridge deposits than those formed either by Bebe or Lenny. For example, Figure 5 is a photograph of an older coral-gravel ridge from the southwest coast of Bonaire showing a wide range of sediment sizes (sand through gravel), crude bedding and distinct sand layers, and seaward imbrication of some of the larger clasts. The ridge stands nearly 5 m above the adjacent toe of the beach, is steep on both landward and seaward margins, and has ridge and swale topography landward of the crest (Figure 6). Although Bebe and Lenny are major storms of the last century there are geologic records of deposition by greater storm on both Bonaire and Funafuti.

Figure 5. Photograph of an older coral-gravel ridge on the southwest coast of Bonaire. The ocean is to the right. The red ticks on the scale are 10 cm apart.

Figure 6. Small-scale (meters) ridge and swale topography on landward side of coral-rubble ridge shown in Figure 5.

Along the east coast of Bonaire, there are spectacular coral-gravel ridges that dwarf the storm deposits described here (Morton et al. 2006; Scheffers, 2005). Compared to the deposits described in this paper, the windward ridges of Bonaire are larger, contain bigger clasts, and occur both near sea level and on elevated Pleistocene-reef wave-cut platforms 5 or more meters above present sea level. These ridge deposits contain many of the storm ridge characteristics described here, but on a larger scale. Their origin however has been ascribed to the work of a few extreme tsunami waves rather than multiple extreme storm wave events (Scheffers, 2004, 2005). Some of the criteria used by Scheffers (2004, 2005) to identify the windward ridges as tsunami depositional features include the presence of megaclasts (> 2 t), bimodal sediment distribution (i.e. sand and gravel mixture), deposition up to 400 m inland from the shore, and deposition on elevated reef platforms.

The characteristics of the coral-gravel storm ridges described in this paper and studies in the aftermath of the 2004 Indian Ocean Tsunami provide important criteria for distinguishing extreme storm-wave deposits from those produced by a tsunami. For example, the Indian Ocean tsunami of 2004 impacted thousands of kilometers of coastline bordered by coral reefs, yet no comparable ridge-like deposits have been described. Rather, tsunami generated deposits of coarse debris include coral boulder

fields of individual clasts and relatively thin sheets (< 1 m) of beach and reef sediment (Richmond et al. 2006). There is also some question regarding the relative ability of storms versus tsunami to transport megaclasts above sea level (Morton et al. 2006). Recent studies by Hall et al. (2006) have demonstrated that storms can quarry and transport megaclasts up to 50 m above sea level and form coarse-clast ridges. Another modern example is for Cyclone Heta, which in 2004 deposited 4-ton reef blocks 20 m above sea level on the cliff coast of the high limestone island of Niue (Russell Howorth, SOPAC, Suva, Fiji, pers. comm.).

Not all extreme storms in reef environments create ridge deposits and it is not clear why some storms create ridges and others do not. It does not appear to be storm power related, but rather a complex relationship involving sediment availability, storm characteristics including duration, and physical setting. What are the mechanisms that lead to ridge versus sheet deposition? What is the role coastal orientation relative to the storm track and how important is cross-shore versus longshore sediment transport processes in ridge formation? Does storm frequency and magnitude dictate whether or not a ridge forms? These are questions that remain unanswered.

CONCLUSIONS

Coral-gravel storm ridges are important depositional features in low-latitude coastal environments subject to intense cyclonic storms. The three depositional ridges studied here occur on diverse island types, but with similar physical settings including:

- Areas of relatively high reef productivity (i.e. abundant sediment source).
- Nearshore areas suitable for the storage of reef debris.
- Infrequent large storms that allow the accumulation of reef debris between events.
- Suitable coastal environments for storm deposits to accumulate (reef flats).

General characteristics of the three storm ridges include: ridge heights ranging from 1-4 m above the reef flat surface and varying from ~8 to 50 m wide; in cross section the ridges have steep faces on both their seaward and landward margins with the highest part of the ridge usually near the seaward edge and the steepest face occurring along the landward edge; the ridges are formed mostly of cobble-boulder sized coral rubble derived from the adjacent reef and most of the rubble is composed of previously eroded and rounded coral fragments; the gravel clasts of the seaward margin tend to be imbricated seaward, whereas the internal structure of the ridges are more disorganized but may contain some crude seaward-dipping beds; and, megaclasts of meter-sized reef material were moved by the storms but form a relatively minor component of the overall deposits.

ACKNOWLEDGEMENTS

We are grateful to Anja and Sander Scheffers and Dieter Kelletat for sharing their knowledge of the Bonaire deposits and for many interesting and provocative discussions regarding extreme waves and their deposits. Bruce Jaffe and Guy

Gelfenbaum provided hours of discussion both in and outside of the field and we thank them for many fruitful discussions. We greatly appreciate Jim Maragos for providing photographs of the initial Bebe deposits. Theresa Fregoso assisted with the figure preparation. This is dedicated to the memory of Doug Rearic.

Abstract: A data set consisting of detailed measurements of the hydrodynamics, morphological and sedimentological change, and sediment transport, has been collected from the region of the beach step on a macrotidal gravel beach. The step is an accretionary feature which evolves with a different relaxation time to that of the berm. Initiation of the step requires relative tidal stationarity and is thought to be triggered by increasingly reflective conditions. Despite its location, the step has remarkably stable sedimentology, differentiated from the swash zone using sedimentary moments. Co-spectral analysis indicates that sediment transport in the region of the step is related to sub-incident wave frequencies. A reconstructed ensemble sediment transport event confirmed that sediment transport at the base of the step occurs as a negatively skewed wave, perhaps sensitive to wave groups. The transition matrix of the nearshore gravel bed motion data closely resembled that of a 'memoryless' queuing process.

INTRODUCTION

The step is a common feature on reflective coarse-grained sand and gravel beaches (Bauer and Allen, 1995). The presence of the step imposes a steep hydrodynamic gradient across the nearshore which controls wave breaking. In fact, the beach step has been considered analogous to a breakpoint bar common to sand beaches (Buscombe and

Masselink, 2006), which would imply it was a region of on/offshore sediment convergence. As well as controlling wave breaking, the importance of the step lies in the fact that it is a beach protective feature, providing a locally steepening the active beachface, thus maintaining reflectivity during storms (Hughes and Cowell, 1987). It is able to do this because it is remarkably responsive to the semi-diurnal tidal cycle (Strahler, 1966; Miller and Ziegler, 1958), even on macrotidal beaches. The lack of previous studies into beach step dynamics belittles its importance, and belies the fact that it is an interesting case study for coarse-grain beach morpho-sedimentary-dynamics. We sought to redress this fact by carrying out a series of detailed field experiments, taking a holistic approach to the step with context to its evolving hinterland, and measuring hydrodynamic forcing, morphological and sedimentological change, and sediment transport.

FIELD EXPERIMENT AND METHODS

A field experiment was carried out on 27th September 2005 at Slapton, a 4 km-long macrotidal gravel barrier beach in Devon, UK. According to the Jennings and Shulmeister (2002) classification scheme, Slapton is a 'pure' gravel beach morphotype. During the measurement period the intertidal gradient was tan β=0.23 (Fig. 1), with a median sediment size of ~6mm. For a more detailed description of the field site refer to Austin and Masselink (2006a). The aim was to collect high-resolution concurrent and co-located morphological, sedimentological and hydrodynamic data from the step region as it evolved over a 6 hour period around high tide (+/- 3 hrs). The experiment was one of a three similar experiments within a wider morpho-sedimentary monitoring campaign of Slapton, 16-30th September 2005 on a spring-spring tidal cycle. The 27th September data set was the most comprehensive, and coincided with a period of major berm building just after neap tide (Fig. 1). Until this time the beach had been morphologically relatively inactive (Fig. 1). This is the first time measurements of each hydro-, morpho-, and morpho-sedimentary-dynamics have been made in the field across the step on a gravel beach.

Two instrument rigs were deployed aligned cross-shore. The first maintained a pressure transducer (PT) and a bi-directional electromagnetic current meter (ECM) measuring water depth and cross-shore and alongshore velocity respectively, logging at 16Hz 3cm above the bed around mid-step position. The second was located at the base of the step and measured velocity at 0.1, 0.25 and 0.4 m above the bed with a vertical array of Acoustic Döppler Velocimeters (ADVs), logging at 32Hz, and an ECM logging at 16Hz. An underwater colour digital video camera was also located here to observe the bed, logging at 25Hz. Swash excursion was measured using an electrical resistance wire maintained at 2cm above the bed, logging at 16Hz. Morphological measurements were made every 5 minutes across the foreshore and nearshore beyond the base of the step using Sallenger and Richmond's (1984) rapid profile technique. In addition, manual sediment samples taken at regular 5 minute intervals on the foreshore, to be dried and sieved at 1/4Φ. An additional video camera recorded the entire experiment from an oblique position just beyond the berm crest.

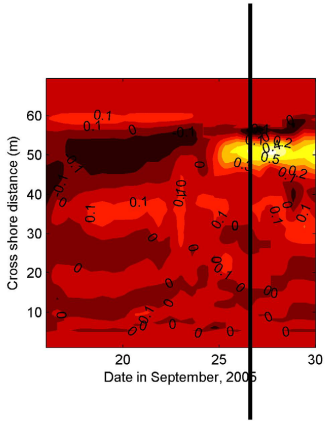

Fig (1) The antecedent morphological conditions prior to the experiment on the 27th (solid line) showing profile change (cm) relative to initial.

The size of gravel clasts and nature of gravel sediment transport precludes the use of optical and acoustic backscatter sensors to quantify sediment flux in the nearshore, which occurs almost exclusively as bedload and sheetflow. Instead, the underwater video was used as a measurement tool to quantify the magnitude of sediment transport (e.g. Williams, 1990; Stive et al. 2005). The video was decompiled into individual frames, converted to greyscale, and filtered for various sources to noise using powerful relaxed median (e.g. Hamza et al., 1999) and complex-valued log Gabor wavelet (Kovesi, 1999) filters. A two-dimensional correlation was applied between each consecutive frame, the reciprocal of which proved useful as a dimensionless 'bed motion coefficient', Ω sensitive to changes in bed 'texture' or gross (non-directional) bed mobility.

$$1/\Omega = \frac{\sum_m \sum_n \alpha\beta}{\sqrt{\left[\sum_m \sum_n (\alpha)^2\right] - \left[\sum_m \sum_n (\beta)^2\right]}} \quad (1)$$

where m and n denote dimensions of image ι, $\alpha = {}_{mn}(t) - \acute{\iota}_{mn}(t)$ and $\beta = {}_{mn}(t+1) - \acute{\iota}_{mn}(t+1)$ where the over-dash denotes mean and t denotes time. High values of Ω indicate poorer correlation, therefore most change, and most sediment transport.

RESULTS

Hydrodynamics

Figure 2 summarises the hydrodynamic forcing derived from the pressure record. Water depth varied by c. 0.75m on a slightly asymmetrical neap tide, wave height was maintained between 0.5 and 0.6m, and spectral wave period increased from c. 5 to 10s. The trend in wave skewness (Elgar and Guza, 1985) was one of increasingly negative skew, and the spectral wave field displayed two prominent peaks at 5 and 12 seconds, the relative prominence of the latter increasing with time. Directional deviations away from shore-normal were uncommon and unsustained.

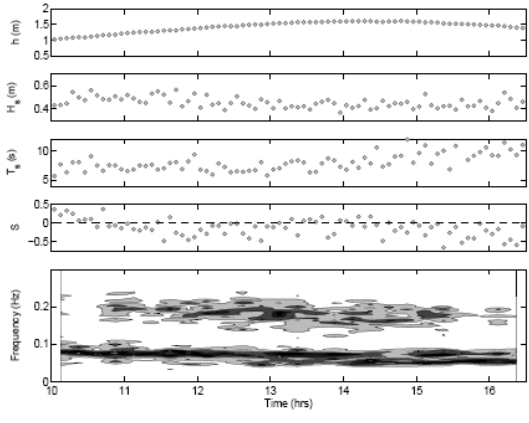

Fig (2). Hydrodynamic summary. Left panel (from top to bottom): water depth (m), significant wave height (m), significant wave period (s), wave skewness, and normalised spectral density (Hz m^2).

Morphodynamics

The pressure record was used to derived the surf scaling ε (Guza and Inman, 1975) and surf similarity ξ (Battjes, 1974) morphodynamic parameters for each 5 minute interval, using the 'active' intertidal slope, defined as the region of beachface between the 2% and 80% runup exceedance limits, measured with the resistance wire. The tidal translation rate (TTR) was calculated as the change in the 2% runup exceedance over consecutive 5 minute periods. The variation in these measures over the survey period may be seen in Fig. 3, where the period 10.45 – 11.30 has been highlighted since it was at this time that wave breaking regime moved from one of plunging/surging to fully surging. In the absence of significant change in wave steepness at this time, this change would have come about because the rising tide was advecting up an increasingly steep concave beach profile, making conditions more reflective. The surf scaling and similarity parameters are generally agreed to be taxonomic for sand beach morphodynamic state, but in the relative scarcity of a gravel beach studies it was thought prudent to substantiate and

validate the use surf similarity parameter to predict wave breaking on gravel beaches through independent means. Breakers were thus classified 'wave-by-wave' visually using the subaerial video record, and it was found that the agreement between visual observations and ξ was excellent. The wave breaker regime derived using visual observations from the video record is shown in the right panel of Fig. 3 (left), which shows the change in wave breaker type over the period 10.10 – 11.40, showing a marked transition between plunging and surging breaker types just before 11.00.

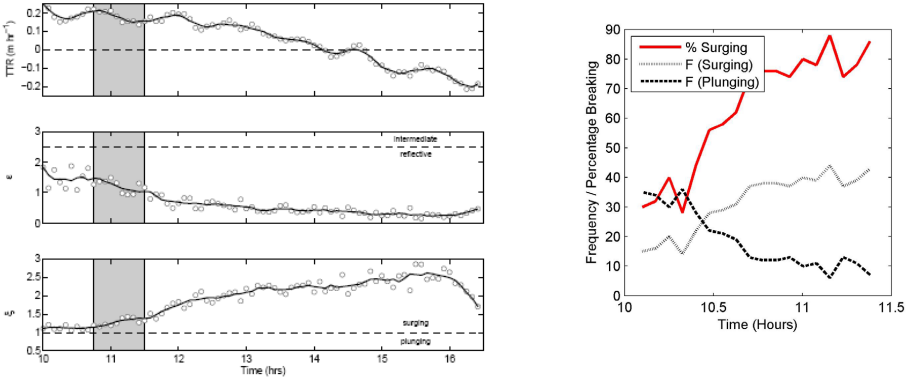

Fig (3). Left, from top to bottom: tidal translation rate (m hr^{-1}), surf scaling, and surf similarity. Grey patches on the right panels indicate the period 10.45 - 11.30 a.m. The solid black lines are a 5 point (25 minute) moving average. Right: changing wave breaker conditions based on video observations when step-berm morphologies begin to take hold.

A morphodynamic 'trigger' mechanism seems to control step initiation. Here, any causative relationships dictate that timing is crucial, i.e. whether the step begins to build before or after the change in wave breaking. If the step forms before the change in breaker type from plunging to surging, then that would be the necessary increase in slope to affect ξ, yet if the wave breaker transition precedes step formation then it is more likely that tidal excursion over a concave slope is key. The development of the step does not begin until after 11 a.m, by which time the change in hydrodynamic forcing has occurred.

Morphological change relative to initial was computed for every 5 minute survey of the beachface and nearshore, and the results are shown in the left panel of Fig. 4 (figures are in centimetres, therefore lighter shading represents relative accretion). The berm (at c. 53-50m) and step (at c. 58-56m) are clearly accretionary features, distinct from 'erosive' regions in the mid-swash (c. 56-53m) and nearshore (> 58m). Over the measurement period there is a net increase of 1.4 m^2 over each unit metre of beachface (contributed to predominantly by the berm). Incidentally, berm formation coincides almost exactly with the changing breaker regime, and we have no reason to suppose that berm formation did

not occur according to onshore swash asymmetry overtopping mechanisms of Hine (1979); Austin and Masselink (2006); and Weir et al. (2006), since gross morphological change is consistent with these earlier findings. The step and berm are effectively independent features forced by discordant timescales: the relaxation time of the berm is linked with spring-neap tidal cycle (Fig 1), whereas the relaxation time of step is linked with semi-diurnal tidal cycle, and relative tidal stationarity (Fig. 4), and with the mid-foreshore remaining a morphological 'pivot point'. With this latter point in mind, there is little evidence to support the notion that the step forms due to an onshore/offshore convergence of sedimentation (e.g. Miller and Ziegler, 1958).

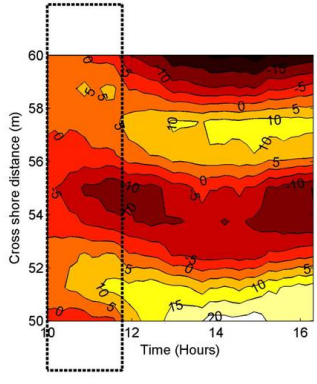

Fig (4) Morphological change, in cm, relative to initial (left panel) across the nearshore (seawards up the page) – light areas indicate accretion, dark depletion

Sediment Dynamics

The reported persistence of predominantly coarse sediments at the beach step (Miller and Ziegler, 1958; Bauer and Allen, 1995) dictates that the spatial and temporal characteristics of sediment size may have an important morphodynamic role, especially on gravel beaches (Sherman et al., 1993; Buscombe and Masselink, 2006) where the range of sediment size is so large. Spatial patterns of morpho-sedimentary variation are mixed over the entire foreshore (Fig. 5, both panels). Coarsening is associated with the development of step and berm features, but also with the depletion of material in the nearshore. Fining is associated with the upper foreshore, co-incident with removal of material, and step crest which is coincident with the deposition of material (Fig. 5, both panels). In a gross sense, each hydro-kinematic region thus has a distinct 'morpho-sedimentary domain', so it is possible to trace the gross trend of berm and step building-coarsening through time, and it may be seen that the mid-foreshore is a sedimentological as well as morphological pivot point. By contrast, the time-averaged grain size distribution remains relatively unchanged (i.e. no temporal trend).

Figure 6 reveals that step sediments are characteristically coarser skewed, more poorly sorted, and more platykurtic, than the sediments of the foreshore and berm. Despite the

location of the step, it has remarkably stable sedimentology, and it is thus possible to distinguish the step from the foreshore using sedimentary moments.

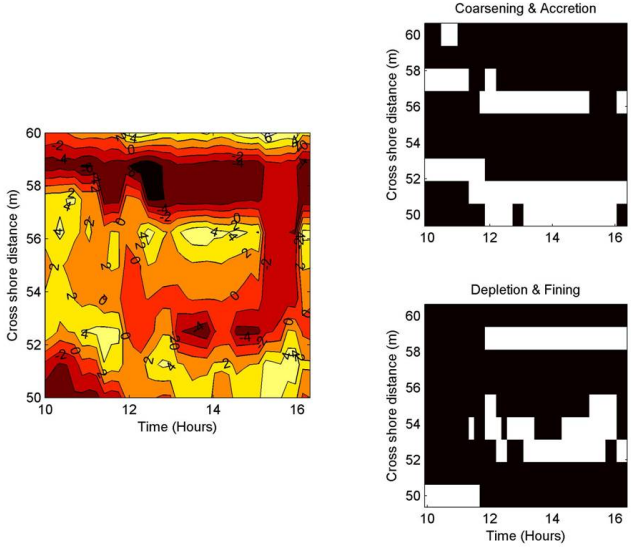

Fig (5) Sedimentological change (left panel), in mm, relative to mean size profile (lighter shading indicates coarsening); regions of morpho-sedimentary co-variation (right panels) – coexistence of relative sediment accretion and coarsening (top), and relative sediment depletion and fining (bottom).

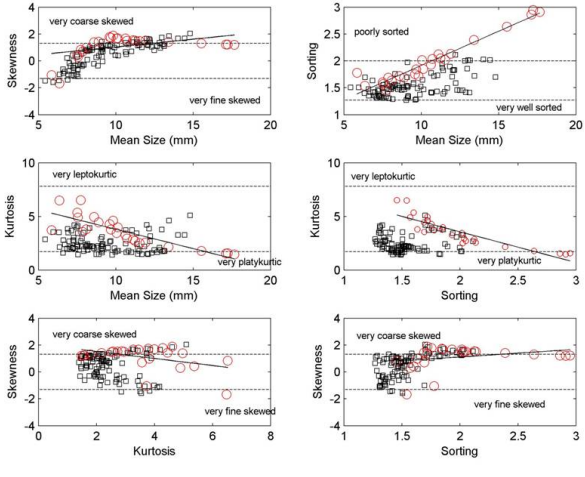

Fig (6) Bivariate scatterplots of geometric moments for swash/berm (black squares) and step (red circles) sediments. Solid lines show linear least squares fits through the step data;

dashed lines show dependent variable classification boundaries (Folk and Ward, 1957).

Sediment Transport

The limited amount of work which has quantified transport of gravel-sized sediment in coastal environments has been shown transport to be a highly irregular function of instantaneous fluid forcing and mechanistic properties of the bed. Heathershaw and Thorne (1985) demonstrated that the majority of gravel sediment transport under tidal currents occurs as short duration, turbulent and particular events, un-related to time-averaged flow parameters. Further work by Thorne (1986b), Williams (1990), Hardisty (1991) and others (generally in deeper water) demonstrated the role particle inertia and the various mechanical properties of the bed may have to play on the (therefore highly nonlinear) response of natural gravel sediments to nearshore flow velocity. What is clear from this work is that gravel sediment transport is dependent on both deterministic (e.g. oscillatory and mean flow velocities), and probabilistic phenomena (e.g. bed configurations, sediment properties, turbulence), but little work has been carried out to quantify sediment transport in the nearshore because of the measurement difficulties associated with such work. Recent researchers have emphasised the role of fluid accelerations (and associated horizontal pressure gradients) on coarse particle transport (e.g., Drake and Calantoni, 2001; Hoefel and Elgar, 2003; Stive et al., 2005).

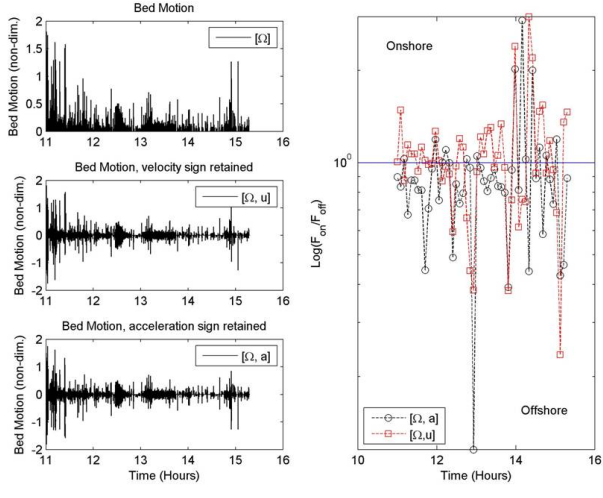

Fig (7). Magnitude-response diagram for Ω. The original time series of Ω is depicted in the upper left panel; the middle left panel shows Ω magnitude with the instantaneous directional component of velocity retained; and the lower left panel shows Ω magnitude with the instantaneous directional component of velocity acceleration retained. The right panel shows normalised bed motion magnitude (see text) for acceleration (black circles) and velocity (red squares).

The bed motion data was re-sampled to 4Hz to correspond with the velocity sample frequency. Upon visual inspection there was systematic bed motion response to neither velocity direction nor magnitude; acceleration direction nor magnitude. Indeed, bed motion induced by similar velocity or acceleration events was often very different in duration and magnitude. Assuming instantaneous sediment transport response to nearshore fluid motions, the sign of Ω was scaled according to the instantaneous directional component of velocity and acceleration (i.e. positive onshore, negative offshore), to yield +/-Ω_u and +/-Ω_a respectively, and the following calculations were performed for each 5 minute segment of data:

$$\delta_a = \log\left(\frac{\sum|\Omega_a|}{\sum|-\Omega_a|}\right); \quad \delta_u = \log\left(\frac{\sum|\Omega_u|}{\sum|-\Omega_u|}\right) \tag{2}$$

providing a ratio of time-averaged onshore:offshore dimensionless sediment flux, assuming instantaneous response to fluid forcing. Fig. 7 (right) shows these ratios over time, showing that in general values lie close to unity, however in general in can be seen that sediment flux which occurs when flows are accelerating offshore is greater than sediment flux which occurs when flows are accelerating onshore. Conversely, sediment flux is greater when velocity is directed onshore.

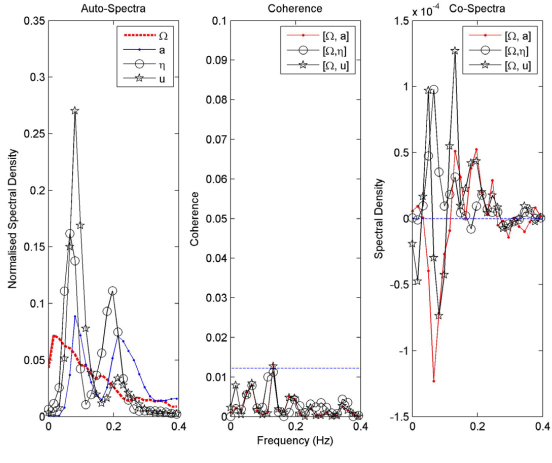

Fig (8) Spectral analysis of *u*, *a*, η and Ω. Left panel: autospectra of Ω (non-dim. Hz^{-1}) shown as red dashed line; η (m^2 Hz^{-1}) as open circles; *u* (ms^{-1} Hz^{-1}) as open stars; and *a* (ms^2 Hz^{-1}) as blue dots (note that the auto-spectra have been normalised by their total variance, e.g. m^2 $Hz^{-1}/\Sigma m^2$ Hz^{-1} for η). Middle panel: cross-spectral coherence (the dashed line is the 95% confidence interval) for [Ω, *a*], [Ω,*u*], and [Ω, η] denoted as red dots, open circles and stars respectively. Right panel: co-spectra for [Ω, *a*], [Ω,*u*], and [Ω, η] denoted as red dots, open circles and stars respectively

Figure 8 shows the spectral characteristics of the bed motion (Ω, Eq. 1) surface elevation (η), cross-shore current velocity (u) and cross-shore current acceleration (a). Auto-spectra for Ω showed peaks at low frequencies (0.03-0.05Hz), compared to the corresponding spectra of u and a which showed peaks at 0.08 and 0.2 Hz. These spectral peaks indicate a wave field composed of 12 and 5 second period waves, travelling in groups with a period of approximately 33 seconds. Cross correlation between the velocity envelope and a lowpass-filtered Ω (not shown – refer to Austin and Buscombe, *submitted*) shown a highly significant positive correlation at ~5 second lag. This could suggest that sediments respond strongest to sub-incident wave frequencies, which could mean that individual waves stir/destabilise sediments, and the largest wave(s) in a group carry out most of the transportation. Equally, it could indicate that the importance of the magnitude of the velocity event which transports most sediment is diminished, if the *sequence* of individual waves which are large enough to stir the bed is long enough. In which case, stress 'histories' are more important in the movement of clasts than instantaneous bed stresses (Paphitis and Collins, 2005).

Co-spectral analysis between Ω and u (e.g., Huntley and Hanes, 1987) showed very poor coherence and significance over the frequencies of interest (Fig. 8). Low coherence between velocity and transport suggests transport is highly intermittent, highly variable at swell frequencies, and clearly a highly non-linear function of flow velocity.

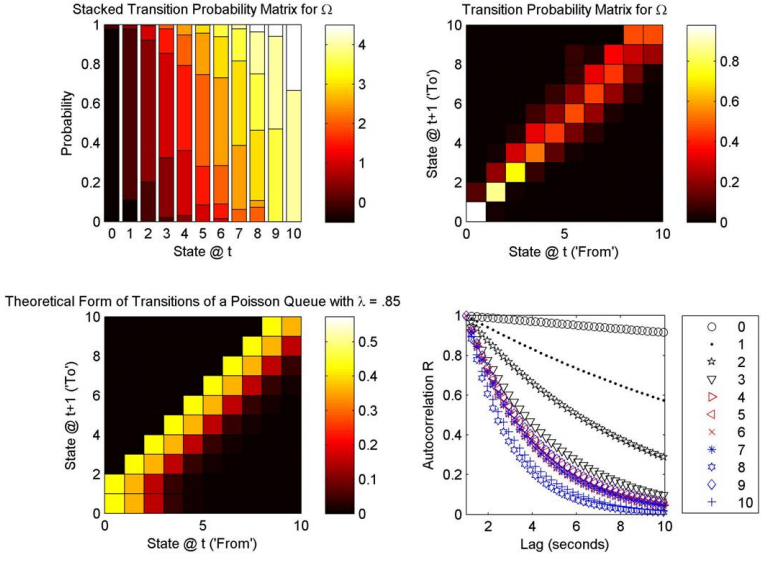

Fig (10) Sediment transport as a Markov chain: transition probability matrix for Ω_{rr} (top

panels); autocorrelation functions, R, for Ω_{rr} states (bottom panels)

In order to glean further information about the nature of bed motion, the data was analysed further using a probabilistic model in order to reconstruct an ensemble or 'typical' transport event. Dimensionless raw Ω was linearly rescaled to span the interval 0-10, and rounded to the nearest integer in order to obtain a discrete record Ω_{rr} which maintained similar resolution. A transition probability matrix (TPM) of the Ω_{rr} data was constructed (Fig. 10), and using Markov Chain theory (e.g., Kemeny and Snell, 1976), analysed for its general distributional form and persistence characteristics.

With reference to the TPM for Ω in Fig. 10, the absence of transitional extremes validates the sample frequency at which the data was collected. The transition matrix shows that sediment transport 'events' are in general negatively skewed. For example, the transition probabilities are not symmetrical about the inertial left-right diagonal, and the probability for an event of *increased* magnitude to follow an event of *given* magnitude is larger than the vice-versa (i.e. incline tendencies). Specifically, values of average magnitude have a larger transitional spread; therefore the skew in the wave will not be drawn by the mode (event peak) or tails but by the falling limb. In order to reconstruct the ensemble event the remaining information required is the persistence characteristics of every magnitude. The rank autocorrelation function of a Markov chain is given by (Basawa, 1972):

$$R = \frac{\sum_{i,j} ij\Theta_{ij} - \left(\sum_{i,j} i\Theta_{ij}\right)^2}{\sum i^2\Theta_{ij} - \left(\sum_{i,j} i\Theta_{ij}\right)^2} \tag{3}$$

where $\Xi_{ij} = \pi^T P^T$ such that $\Sigma_{ij}\Xi_{ij} = 1$, and where T, i,j, P, and π denote matrix transpose, row, column, transition matrix, and steady state probability vector, respectively. The steady state vector is found by solving the set of equations:

$$\pi = P\pi \tag{4}$$

subject to $\Sigma\pi = 1$. The autocorrelation functions for each magnitude are shown in Figure 10 (bottom right panel), showing an almost linear decrease in persistence with increasing magnitude. What this means in a physical sense is that a typical sediment transport event resembles a negatively skewed wave which is composed of a series of steps of increasing shorter length. This general form complies with visual inspection of the data, and could be interpreted as the first waves in a group 'clearing' the bed of a certain proportion of movable grains, until a threshold is reached where the conditions have been primed for the greatest amount of transport, after which the bed is relatively immobile. This implies a great deal of initial resistance to movement imposed by the micro-mechanical configurations of the bed (temporal and spatial distributions of grain size, 'hiding' factors, relative flow protrusion, etc).

The transition matrix for Ω (Fig. 10) resembled the theoretical form of a 'memoryless' Poisson queuing process, given by;

$$P_n(t) = e^{-\lambda t}\frac{(\lambda t)^n}{n!} \tag{5}$$

which expresses the probability of an event n in time t given by average number of occurrences per unit time, λ such that there would be λt events on average in t, implying inter-arrival times are exponentially distributed by $e^{-\lambda t}$, and the average number of events is the same for each unit interval of t, which is the 'memoryless' property (e.g. Kleinrock, 1975). For example, the TPM associated with a Poisson queue controlled by arrival rate λ=0.85 is depicted in Fig. 10 (bottom left). This draws strong parallels with similar work carried out on gravel sediment transport in fluvial settings (e.g. Einstein, 1937; Hassan et al., 1991).

CONCLUSION

The gravel beach step is an accretionary feature strongly linked to tidal stage, evolving with a different relaxation time to that of the berm. Initiation of step morphology requires tidal stationarity and is perhaps triggered by a change wave breaker type from plunging to surging. The beachface at short timescales is effectively a closed sedimentary unit although the step and beachface may be differentiated using sedimentary moments. Different morphological features such as the step have typical spatial sedimentary responses. Nearshore sediment transport is related to sub-incident frequencies (wave groups) but is not a linear function of either velocity magnitude or direction. Therefore, a better description of sediment transport requires instantaneous sediment size information, which has to be remotely sensed. It is possible to reconstruct an ensemble sediment transport event using the transitional properties of the data The transition matrix for bed motion resembled the theoretical form of a 'memoryless' Poisson queuing process.

Abstract: Morphological model computations based on uniform (non-graded) sediment revealed an unrealistically strong scour of the sea floor in the immediate vicinity to the west of Maasvlakte 2. By means of a state-of-the-art graded sediment transport model the effect of natural armouring and sorting of bed material on the scour process has been examined. Sensitivity computations confirm that the development of the scour hole is strongly reduced due to the incorporation of armouring processes, suggesting an approximately 30% decrease in terms of erosion area below the -20m depth contour.

INTRODUCTION

Rotterdam is creating a prime new European location for port activities and industries which will be reclaimed from the sea, linking directly to the current port and industrial zone. The total land reclamation known as Maasvlakte 2 will consist of 1,000 hectares of commercial sites for deep sea container handling, chemical industry and distribution (figure 1).

The most obvious spot for the new port is situated in an area known as Natura 2000 site Voordelta, a Special Area of Conservation (SAC) (figure 2). Safeguarding the natural values of the Voordelta was one of the leading principles on which the design of Maasvlakte 2 is based.

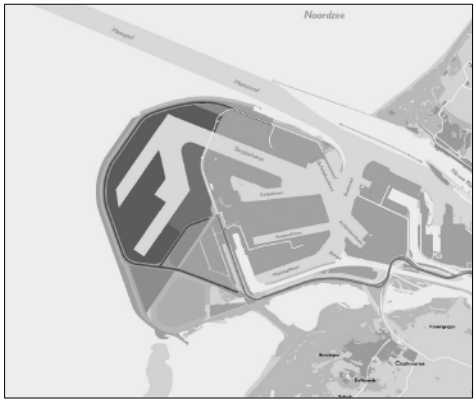

Figure 1. Design of Maasvlakte 2

The effects of the construction, presence and use of Maasvlakte 2 have been determined by means of an Environmental Impact Assessment (EIA) and an Appropriate Assessment (AP) of the effects on SAC. The Maasvlakte 2 project includes compensation projects for the natural values which will or may be lost. Compensation will be found in the realization of a 25.000 ha marine reserve and 35 ha new dunes. In this way the foundation is laid for the construction of a functional and optimal accessible port area, while impact on the natural features and the environment is limited and compensated to the greatest possible extent.

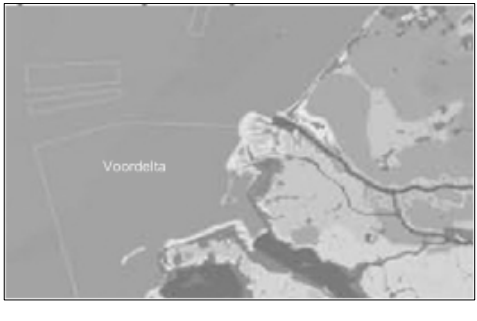

Figure 2. Natura 2000 site Voordelta

Within the framework of the Maasvlakte 2 project extensive studies have been executed to determine the impact of Maasvlakte 2 on the existing current pattern and the transport of sand and silt, and the resulting morphological changes.

In this paper specific attention is given on the issue of large scale scour of the surrounding sea floor, which is important from various perspectives, viz.:

- environmental effects: erosion of the sea floor below NAP -20m needs to be compensated in view of loss of habitat and loss of potential feeding area, for protected birds that tend to feed not deeper than -20m.
- maintenance need of the sandy sea defence of Maasvlakte 2: extent and location of the scour hole may cause additional erosion of the beach and dunes.
- dredging requirements: sand originating from the scour hole may cause additional accretion of the existing access channel to the port of Rotterdam (Maasgeul).

SCOUR DEVELOPMENT PRESENT SITUATION

The present port entrance dates from the period 1968-1976 (figure 3). Regular bathymetrical surveys have been carried out during construction and after completion of the works. Surveys were executed both in the immediate vicinity of the works in progress (Zuiderdam and Noorderdam) and in a larger sea area to the west of the Maasvlakte.

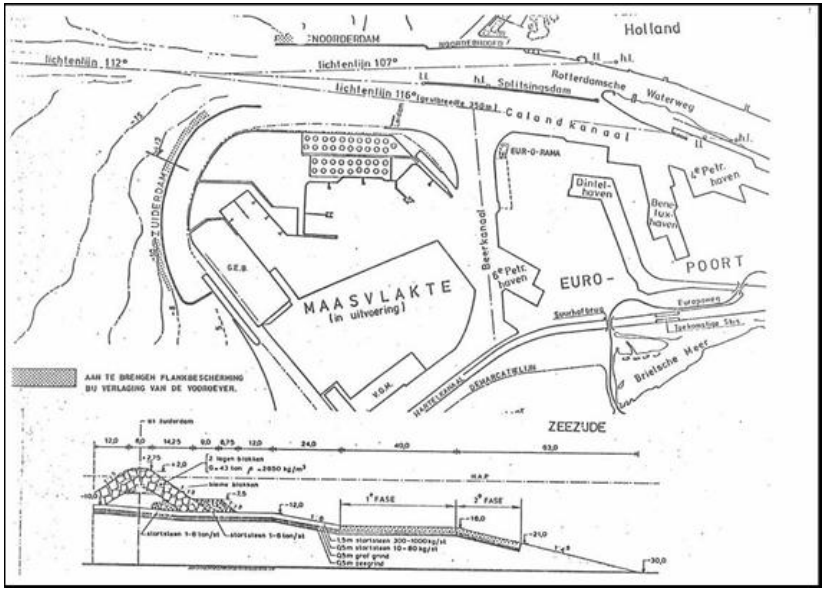

Figure 3. Original situation

During construction local erosion was observed along the Zuiderdam moving along with the temporary head of the structure. At two locations the erosion remained present during a longer period: along the southern bend of the Zuiderdam, at the transition from the rock protection to the sandy beach, and 2 km northward of it, approximately along the middle part of the Zuiderdam (figure 3).

During construction only limited erosion was observed at larger scale: erosion rates between 1970 and 1976 were approximately 0.1 to 0.2m per year in the immediate vicinity to the west of the Maasvlakte. Locally, also areas with some accretion were found: accretion rates were less than 0.1m per year.

After completion of the port entrance erosion in the sea area to the west of the Maasvlakte has continued. However, successive bathymetrical surveys indicate that the erosion process gradually has slowed down over the years. Presently, the scour hole has reached more or less an equilibrium state (figure 4). The scour hole exists nearly along the whole outer contour of the Zuiderdam covering an area of approximately 160 hectares. The maximum bottom depth is approximately NAP -18m. This implies that since 1970 a maximum erosion of approximately 6 m has occurred (based on the initial depth of NAP -12m).

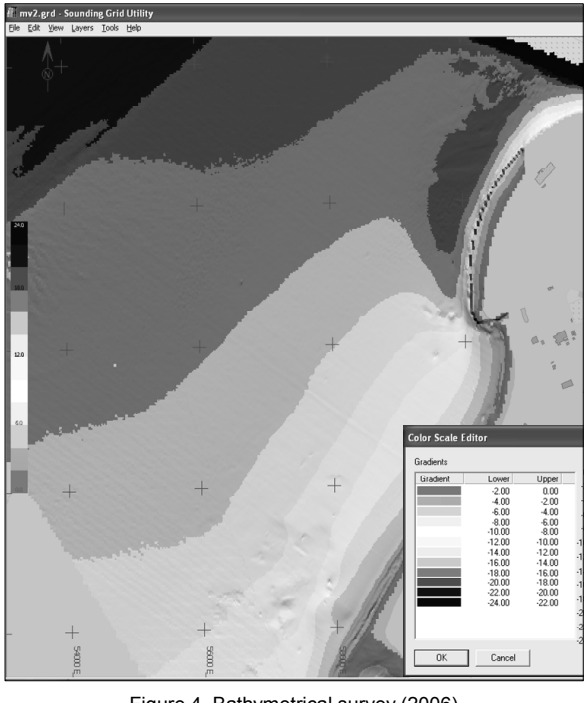

Figure 4. Bathymetrical survey (2006)

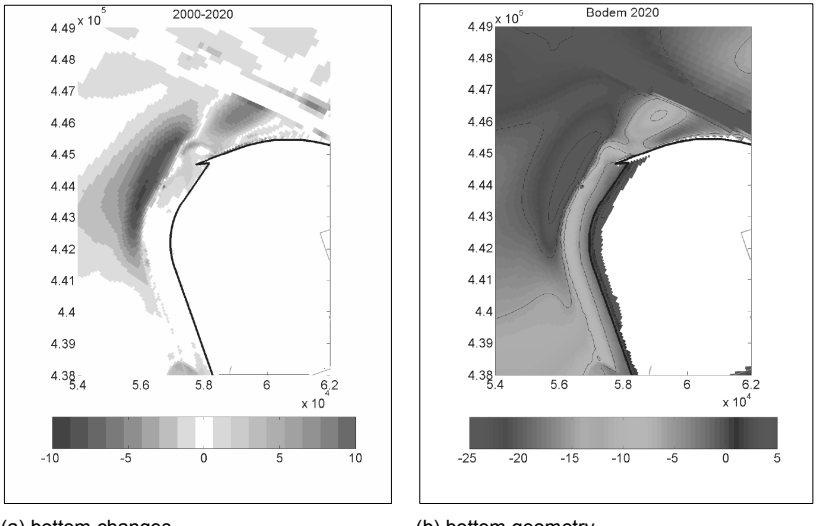
The design of Maasvlakte 2 shows much agreement with the presently existing situation. Computations for the situation of Maasvlakte 2 indicate that the main flow characteristics in the future situation will undergo only little changes as compared to the present situation. Therefore, it is reasonable to expect that the development of scour in the future situation with Maasvlakte 2 will show much resemblance to that of the present situation.

Table 1. Morphodynamic modules DELFT3D system

DELFT2D-MOR: this process based module which is a subset of DELFT3D system is designed to simulate sediment transports and morphological developments in coastal, river and estuarine areas (Roelvink and Van Banning, 1994). The 'standard' morphodynamic method involves a coupled simulation of waves, currents, transport and bottom changes. A morphological process is built up from morphological time steps, which consist of a simulation of wave-current interaction over a tidal cycle, followed by a number of intermediate steps where transport is computed and averaged over a tidal cycle, and the bottom is updated. The transport and bottom computations are repeated a number of times using "continuity correction" (= constant discharge trough cells), until bottom changes are so large that a full hydrodynamics computation is required. The method requires full transport computations through tidal cycle, which can be time-consuming especially when suspended-load transport induced by waves and currents in shallow areas is to be accounted for.
DELFT2D-RAM: this hybrid module which is also a subset of DELFT3D system can be applied for Rapid Assessment of Morphology (Roelvink et al., 2001). The RAM module can be characterized as a 'quick-and-dirty' bottom updating scheme (based on the "continuity correction') in combination with repeated detailed computations of hydrodynamics and sediment transport using DELFT2D-MOR.
DELFT3D-ONLINE: this module which is the latest refinement of Delft3D system can operate in 2DH and in 3D mode. The module is characterized by online coupling between hydrodynamic and transport/bottom modules which enables simultaneous computation of flows and transports and simultaneous feedback to bottom changes. Therefore, hydrodynamic flow calculations are always carried out using the correct bathymetry. Only the wave model is executed separately. Acceleration of the morphological developments is achieved by up-scaling the bottom developments during each time step by means of a so-called morphological scaling factor. In this project the Delft3D-ONLINE module was used in 2DH mode. The Maasvlakte 2 computations have been carried using a recently developed calculation scheme in which the simulation is split into a number of parallel processes, which all represent different conditions; at a given frequency all processes provide bottom changes to the merging process, which returns a weighted average bottom change to all processes which then continue the simulation (Roelvink, 2006).

MORPHODYNAMIC COMPUTATIONS



The morphological impact of Maasvlakte 2, including the issue of large scale scour of the surrounding sea floor, has been determined on the basis of morphodynamic computations. Thereby use has been made of the integrated modelling system Delft3D developed by WL|Delft Hydraulics, including the modules Delft2D-RAM, Delft2D-MOR and Delft3D-ONLINE (Table 1). For the various investigations, which were carried out in the course of time, always modules with latest functionalities and improved usability have been used.

In this paper only results from the most recent studies which were carried out in 2005 and 2006 for the current lay-out of Maasvlakte 2 will be presented (figure 1).

Study 2005 (Roelvink and Aarninkhof, 2005)

The set-up and execution of this study elaborated as much as possible on earlier investigations in order to enable the comparison of the results (e.g. wave- and current conditions, bed material characteristics, roughness size). However, the most important shortcomings of the previously used Delft2D-RAM/MOR module were overcome by:

- the use of the wave propagation model SWAN and the DELFT3D-ONLINE approach which was required for a realistic reproduction of bottom changes in the shallow areas of the Voordelta site.
- the incorporation of wave effects which was considered to be important for the development of the scour hole and the maintenance of the sandy beach and dunes.

(a) bottom changes (b) bottom geometry

Figure 5. Computation DELFT3D-Online (2005)

In figure 5 a typical example of the morphological development is given after 20 years. Both (a) the erosion- sedimentation pattern and (b) the final bottom geometry are shown. It appears that a scour hole will develop almost along the entire north-westerly coastline of Maasvlakte 2. A depth of NAP-25m is exceeded in a rather large area. Sand originating from the scour hole is mainly deposited in the access channel but also in the area to the north of Maasvlakte 2 accretion can be observed.

The location of the scour hole agrees very well with the area with maximum tidal current velocities during flood phase (figure 6).

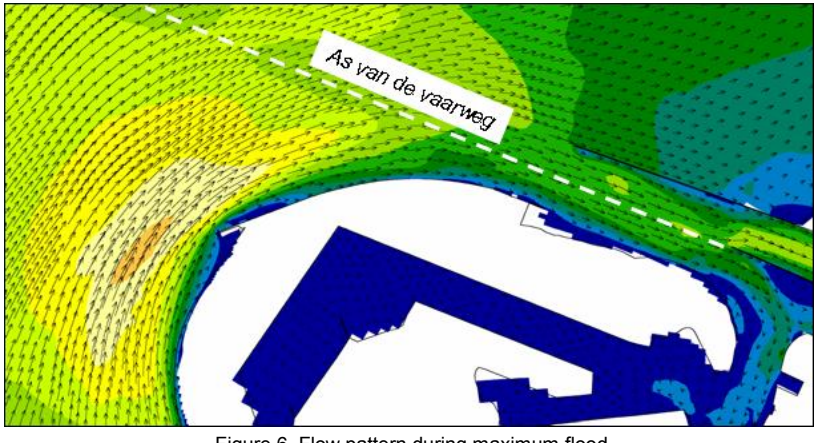


Figure 6. Flow pattern during maximum flood

In Figure 7 the time development of the scouring is shown in terms of (a) the area subjected to erosion with a depth larger than 1 m, (b) the area which is eroded below NAP-20m and (c) the maximum erosion depth. The applied model and the associated input parameters result after 20 years in a scour hole with a size of 1420 hectare. The area below NAP -20m is about 760 ha and the maximum depth is about NAP-27m.

From these figures it can be seen that the process of scour continues after 20 years and that equilibrium is not yet reached. A similar calculation for the existing situation (autonomous situation) also showed a persistent scour for the next 20 years. These unrealistically strong developments do not correspond with the experience from the existing Maasvlakte. The observed scour is much smaller than the calculated scour. The calculated size and depth of the scour hole for the situation of Maasvlakte 2 are therefore considered as rather conservative estimates.

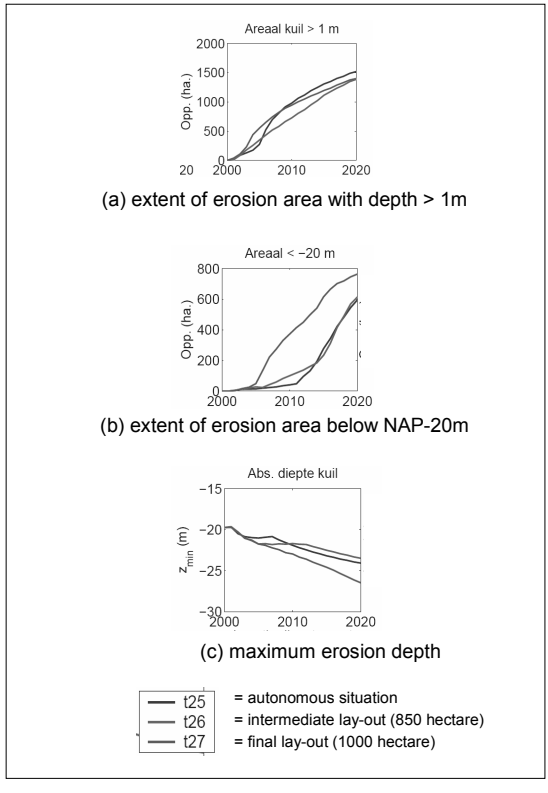

Figure 7. Computation DELFT3D-Online (2005)

Study 2006 (Elias et al., 2006)

Further analysis revealed that the overestimation could be related to the schematization of the sea floor by means of uniform non-graded sediment with a mean particle size of 160 micron.

From literature it is known that sorting of graded bed material and natural armouring of the surface bottom layer may result in a strong reduction of the scouring process. Also a heterogeneous composition of the sub-sea floor may have a strong impact. Until recently experience with the modelling of graded material was mainly restricted to river applications; for coastal areas such applications were still rare. However, with the latest version of DELFT3D this process can be simulated in a schematized way by distinguishing several sediment fractions and bottom layers.

Within the framework of the Maasvlakte 2 project the graded sediment model has been applied to carry out sensitivity computations. The computations are of a comparative nature not aiming at providing an accurate prediction of the location and extent of the scour hole. The latter can only be achieved by extensive calibration and verification of the model and the incorporation of the effect of both wave-induced and current-induced sediment transports.

1. Case IJmuiden

Because only little experience with the model existed, a concise investigation of the scour hole near the harbour moles of IJmuiden has been conducted firstly. The underlying reasoning is that this scour hole is well measured and documented. Also some studies with DELFT3D for this area have been carried out in the past (Roelvink et al., 1994; Lesser et al., 2004).

From these computations the correct functioning of the model was demonstrated. The sorting process of bed material in the scour hole by erosion of finer fractions and lagging behind coarser fractions could be reproduced in a satisfactory manner (figure 8). Also a lot of experience was obtained about the best way of schematisation, viz.: number of layers, layer thickness and fractional partition of bed material.

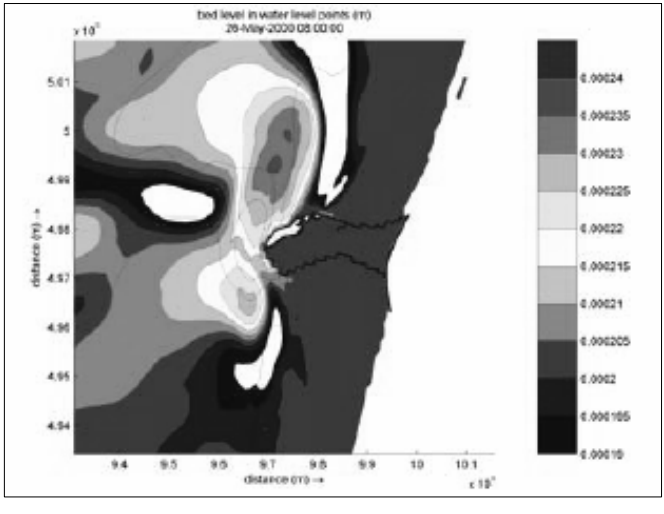

Figure 8. IJmuiden, spatial distribution of mean grain size (after 20 years)

2. Case Maasvlakte 2

Subsequently, computations have been performed for the situation of Maasvlakte 2 using the graded sediment model. The set-up of the model was, wherever possible, chosen in accordance with the previous study of 2005.

Computations were carried out for uniform and graded bed material. For the computations with uniform sediment a number of mean particle sizes have been distinguished, viz: 160 and 200 micron (overall values entire area) and 160/285 micron (with a distinction between the characteristics of seabed and cross-shore profile of Maasvlakte 2). The characteristics of the graded material have been derived from grading curves determined from soil drilling samples collected in the area during a survey in 2005 (figure 9).

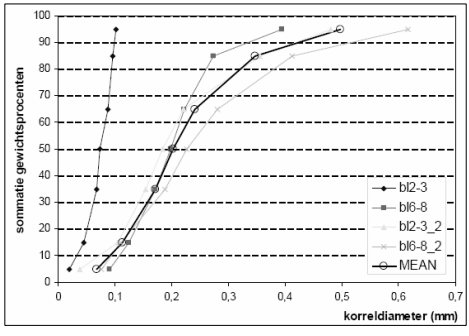

Figure 9. Grading curves from soil drilling samples collected in the area

The bed material is schematized using the average grading curve represented by 5 sediment fractions (Table 2).

Table 2. Sediment fractions

Fraction	D50 (micron)	relative distribution (%)
1	91	20
2	171	30
3	242	30
4	347	10
5	487	10

It appears that the average D50 of the bed material is 200 micron. This is considerably larger than the value of 160 micron which was used in all previous computations of Maasvlakte 2 (as a representative mean value of the whole study area). Further on it is seen that this difference in particle size will already have some impact on the development of the scour hole.

In the original computations several schematizations for the sub-sea floor were tested. The results presented in this paper only refer to the schematization with 15 bottom layers each layer having a thickness of 1 m.

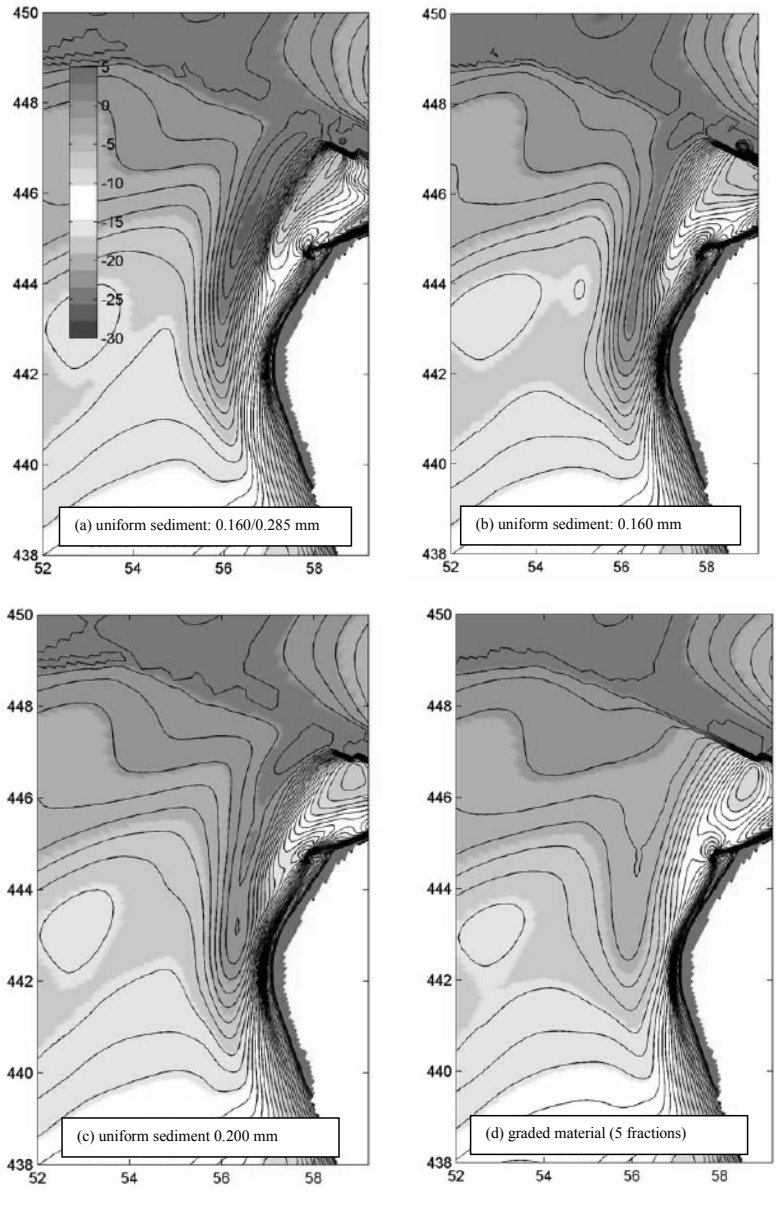

Figure 10. Example DELFT3D-Online (2006)

In figure 10 the calculated bottom geometry after 20 years is shown for the various simulations with uniform and graded bed material. From this figure the difference between graded and uniform material can be seen very clearly. With graded material the maximum erosion depth and the extent of the erosion area are strongly reduced. The results of the cases with uniform material are very similar to the results of previous studies. Some differences in extent and depth of the scouring hole can be observed, depending on the particle size. However, the general shape of the scouring hole remains the same in these cases.

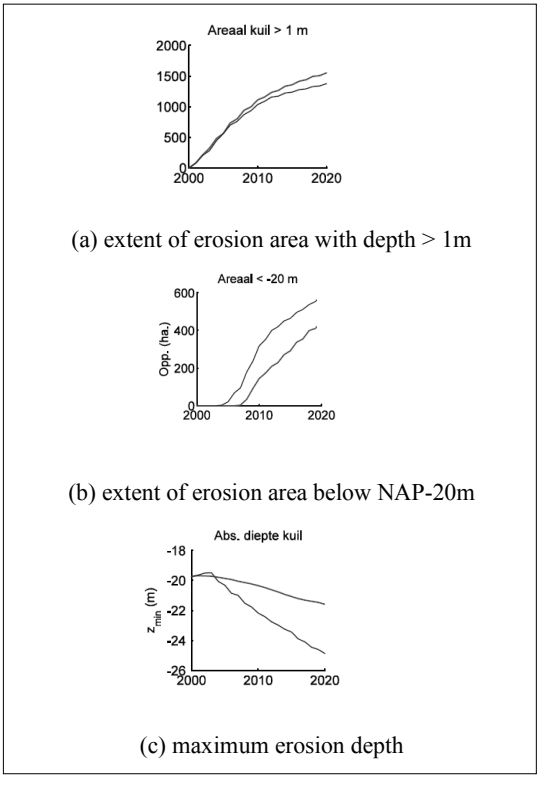

Figure 11. Example DELFT3D-Online (2006)
(bottom material: red - uniform; blue -graded)

In figure 11 a comparison is made between the computational results with graded bed material and uniform bed material (with a D50 of 200 micron). The differences between these two cases are both related to the maximum scour depth and the extent of the erosion area. With uniform bed material a maximum depth of more than 10m below the

original bottom level is reached after 20 years (NAP -26.5m). With graded material this is reduced to 4m (NAP-20.5m). With the effect of graded material incorporated the development of the scour hole is strongly reduced; an approximately 30% reduction in terms of the area below the NAP-20m depth contour is suggested.

CONCLUSION

Morphological predictions on the basis of uniform (non-graded) sediment revealed an unrealistically strong development of a scour hole in the area directly west of Maasvlakte 2. Additional calculations with a state-of-the-art graded sediment transport model have shown that armouring effects and sorting of the bed material do indeed reduce the depth and extent of the scour hole. By means of sensitivity calculations the impact of armouring on the scour development has been examined. The calculations confirm that the incorporation of armouring processes have a strong impact on the development of the scour hole, suggesting an approximately 30% decrease in terms of the area below the NAP-20m depth contour.

In summary, the use of an innovative, graded sediment transport model has shown the potential for improved prediction of the morphological evolution of scour holes. These techniques enable the Port of Rotterdam to anticipate well on the expected scour hole development, the resulting access channel maintenance and additional compensation for the scour below NAP-20m in the planned marine reserve. Additionally the model can contribute importantly to future EIA's for large-scale coastal interventions.

ACKNOWLEDGEMENTS

We thank the Port of Rotterdam Authority giving this opportunity to publish and to present the results of the research in question at the Coastal Sediments '07.

DUNE EROSION PREDICTION METHODS INCORPORATING EFFECTS OF WAVE PERIODS

Marcel R.A. van Gent[1], E. Martijn Coeveld[1], Hans de Vroeg[1], Jan van de Graaff[2]

Abstract: Recently, the influence of wave periods on dune erosion was studied in a series of large-scale physical model tests (Van Gent *et al.,* 2006). In these tests dune erosion was simulated under extreme storm conditions. The aim of the study presented in this paper was to develop dune erosion prediction methods that take effects of wave periods on dune erosion into account. An existing dune erosion prediction method was used as starting point for the development. The obtained prediction method will be used to evaluate the dunes along the Dutch coast, where longer wave periods occur than previously assumed.

INTRODUCTION

Dunes in The Netherlands act as primary sea defense for the lowlands behind them. Since this is a densely populated area, it is important to assess their safety against flooding. Therefore, the strength of the dunes needs to be predicted under the hydraulic loads in a normative storm surge. In The Netherlands the normative conditions refer to rather small chances of failure ($\approx 10^{-4}$ to 10^{-5} per year). The strength of the dunes can be determined by predicting the volume of dune erosion during an extreme storm. Failure of the dunes takes place when the rate of dune erosion is so large that flooding of the lowlands behind the dunes occurs. In The Netherlands dune erosion is predicted by using rather simple empirical relations (Vellinga, 1986). These predictions are mainly based on the cross-shore dune profile before a storm, the expected storm surge level, the wave height at deeper water, and characteristics of the sediment.

Recent insights led to the conclusion that wave periods during an extreme storm event along the Dutch coast could be longer than previously assumed. In order to achieve information on possible effects of longer wave periods, large-scale physical model tests were performed in the Delta flume of Delft Hydraulics (Van Gent *et al.,* 2006). These tests indicated that the eroded dune volume increases for longer wave periods (*e.g.* an increase in the wave period of 50% led to an increase in dune erosion volumes of 15% to 25%). However, the method to predict dune erosion that has been applied in The Netherlands does not account for the influence of the wave period. Therefore, the aim of this study is to extend the existing method taking the effects of the wave period into account using the data obtained from the tests.

APPROACH

The scope of this study allowed only for an extension of a yet existing method for predicting dune erosion instead of developing an entirely new method. Several concepts of incorporating effects of wave periods into the existing formulations were already developed based on existing data and insights before the recent data from large-scale model tests (Van Gent *et al.*, 2006) became available. These large-scale dune erosion tests were used to verify and to optimize the developed concepts. The dune erosion prediction method that was used as a starting point in this study is described hereafter. A summary of the most important results of the recent large-scale dune erosion tests is also presented in this section.

Current dune erosion prediction method

In the safety assessment which is presently applied for the Dutch dunes (based on the method described by Vellinga, 1986), use is made of a 2DV description of the dune erosion profile after a very severe storm event with a characteristic significant wave height and water level. With this description of the shape of the dune erosion profile, the location of the dune erosion profile can be obtained by horizontally moving the shape of the dune erosion profile over the initial profile until the total erosion volume is equal to the total accretion volume, see Figure 1. This provides a prediction of the dune erosion volume above storm surge level (*A* in Figure 1). If this volume exceeds the initial volume above storm surge level, flooding occurs. This prediction method will from hereon be referred to as the 'current method'.

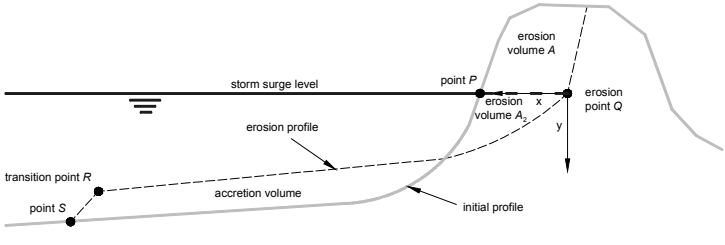

Fig. 1. Definition of characteristic erosion profile, erosion volumes and (erosion) points in a cross-shore profile.

The derived equation for the erosion profile (between point Q and R in Figure 1) is described by Vellinga (1986) and reads:

$$\frac{7.6}{H_{0s}} \cdot y = 0.4714 \left[\left(\frac{7.6}{H_{0s}} \right)^{1.28} \cdot \left(\frac{w}{0.0268} \right)^{0.56} \cdot x + 18 \right]^{0.5} - 2.0 \qquad (1)$$

where H_{0s} = significant wave height at a depth of Datum -20 m (m); w = fall velocity of a grain of sand with diameter $D = D_{50}$ (m/s); y = depth beneath storm surge level (m); and x = horizontal cross-shore distance from point Q (see Figure 1) positive in seaward direction. Point Q is defined at the maximum storm surge level and forms the origin $x = 0, y = 0$ in Equation 1. Equation 1 describes the erosion profile between point Q and transition point R, which is described by:

$$x_R = 250 \cdot \left(\frac{H_{0s}}{7.6} \right)^{1.28} \cdot \left(\frac{0.0268}{w} \right)^{0.56}$$
$$y_R = 5.717 \cdot \left(\frac{H_{0s}}{7.6} \right) \qquad (2)$$

The upward slope on the landward side ($x < 0$ and $y < 0$) is fixed at 1:1. The slope on the seaward edge between the erosion profile and the initial profile (between point R and S in Figure 1) is fixed at 1:12.5.

The equations above were derived on the basis of many experiments including series of large-scale tests for a basic situation with a wave height of $H_{0s} = 7.6$ m (prototype value) and sediment fall velocity of w = 0.0268 m/s. This basic situation can be clearly recognized as reference values in the equations. The equations were derived for waves with a peak wave period T_p = 12 s, corresponding to a wave steepness of $H_{0s} / L_0 = H_{0s} / 1.56 \cdot T_p^2 = 0.034$. Delft Hydraulics (1982a) states that the method is only valid for situations in which (1) the maximum storm surge level minus 1 m is exceeded for 5 to 6 hours, (2) the grain size diameter is 150 μm < D_{50} < 400 μm, and (3) the wave steepness is larger than $H_{0s}/L_0 = 0.02$. It is also noted that a post-storm beach profile as measured shortly after the storm will be a little lower than the predicted profile, because of a redistribution of sand after the peak of the storm.

Results of large-scale dune erosion tests

Large-scale dune erosion tests with different wave periods (Van Gent *et al.,* 2006) were carried out to provide the data necessary to verify the developed concepts. In the tests use was made of the same initial coastal profile (see Figure 2) based on a profile that is considered as characteristic for the Dutch coast. To translate this prototype profile to a model that fits in the flume, use was made of the set of scaling relations derived by Vellinga (1986) that was based on an extensive series of dune erosion tests on different scales and with different sediment diameters (see Section 3.3). In the present tests, geometrically distorted models needed to be applied to properly model the fall velocity

of the sediment with respect to the other relevant parameters. The dune erosion tests were carried out with a depth scale of $n_d = 6$. Sediment with a diameter of $D_{50} = 200$ µm was applied in the tests and a wave height of $H_{m0} = 1.5$ m. The tests used here were performed with a Pierson-Moskowitz spectrum with peak wave periods that varied from $T_p = 4.9$ s to $T_p = 6.12$ s to $T_p = 7.35$ s (model values), denoted with T01, T02 and T03 respectively. This corresponds to peak wave periods of $T_p = 12$ s, $T_p = 15$ s and $T_p = 18$ s in prototype. This means that there is an increase in wave periods (T_p, $T_{m-1,0}$ and T_m) with 50% between conditions T01 and T03. Note that T01 was performed with the same wave period as the condition on which the current method was based.

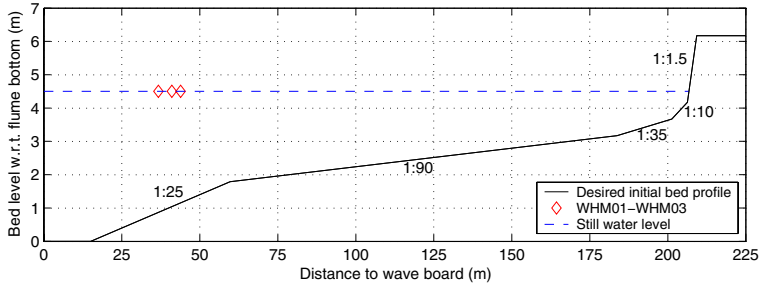

Fig. 2. Initial bed profile (WHM = wave height meter).

During the development of the current dune erosion prediction method (Section 2.1), a characteristic storm duration was defined at maximum storm surge level. This storm duration was 5 hours. At a depth scale of $n_d = 6$, a prototype storm duration of 5 hours corresponds to a test duration of 2.04 hours ($2.04 = 5 / \sqrt{n_d}$). The tests were carried out with a constant water level.

The tests included measurements of the bed profile, wave conditions, flow velocities and sediment concentrations. Furthermore, particle size distributions and fall velocities were determined for several sediment samples.

Figure 3 shows a comparison of the bed profile measurements after 6 hours (model scale) for Tests T01, T02 and T03. This figure shows that the retreat of the dune face (the relative steep part of the bed profile above the still water level) is largest in Test T03 (with the longest wave period) and smallest in Test T01 (with the shortest wave period). The differences in the shape of the bed profile for different wave periods are small, but the changes in dune foot location, slope of the beach profile and the shape of the deposit area for increasing wave periods are consistent. The dune foot is located at the intersection of the relatively steep dune face and the beach just in front of the dune face. It appears that the horizontal position of the dune foot moves more landward for the longest wave period, while the vertical position of the dune foot hardly varies. The slope of the bed profiles around and below the still water level is a bit gentler for the longest

wave period. The seaward edge of the deposit area is located farther seaward in Test T03 than in Test T01. Dune erosion volumes were obtained from the bed profile measurements. The volumes were based on the difference between the initial profile and the profile measured after a certain period of time. Tests T01 and T03 have each been repeated. Repetition of the tests led to differences of less than 2.5% in the total eroded volumes after 1, 2 and 6 hours. The differences after 0.1 and 0.3 hour were slightly larger. This indicates that the reproducibility of the results of the tests is good. Hereafter, for Tests T01 and T03 the average of the two test results with equal wave conditions has been used.

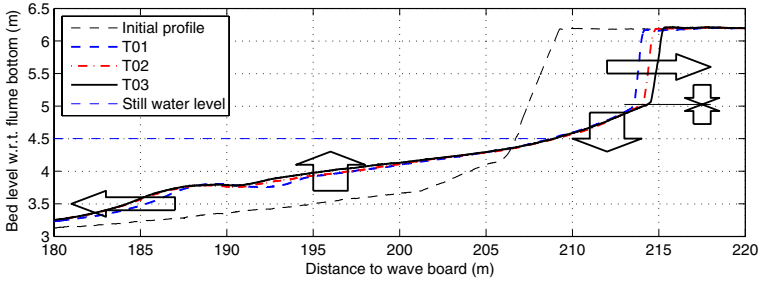

Fig. 3. Comparison of measured bed profiles after 6 hours (model scale) in Tests T01, T02 and T03 and indications of qualitative effects of wave period on erosion profile.

It was found that after 2.04 test duration (*i.e.* 5 hour storm duration in prototype) the dune erosion volume above the still water level increases with 24 % for an increase in wave period with 50% (Figure 4b). It should be noted that an equilibrium situation has not yet been established at that stage, see for example the development of the erosion volume above the still water level with time in Figure 4a.

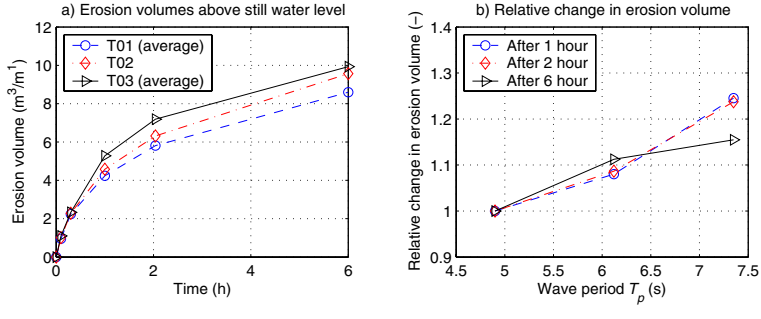

Fig. 4. Development of erosion volume above still water level (a) with time (left) and (b) depending on the wave period (right).

NEW DUNE EROSION PREDICTION METHODS

In this section new deterministic dune erosion prediction methods to take effects of the wave period into account will be discussed. These methods have the current method as a starting point. The methods were initially based on data that were already available prior to the execution of the described large-scale tests (Van Gent *et al.,* 2006). With the results of these large-scale tests, the methods were calibrated and evaluated. The methods are subdivided into two categories (1) period-dependent erosion volumes, and (2) period-dependent erosion profiles. In the first category, the shape of the erosion profile as described in Section 2.1 by Equations 1 and 2 remains unchanged and effects of the wave period on dune erosion are taken into account by means of a horizontal translation of the erosion profile based on an additional volume of dune erosion. This volume can be expressed as a function of the wave period (or wave steepness). Methods in this category are discussed in Section 3.1. In the second category, Equations 1 and 2 are extended in order to include effects of the wave period. Methods in this category are discussed in Section 3.2.

Category 1: Period-dependent erosion volumes

The first method, Method 1, is based on the assessment of a factor P_{extra} for the extra volume of dune erosion ($= P_{extra} \cdot A$) due to effects of an increased wave period compared to the condition for which the current method was derived. This method results in a dune erosion volume of $(1+P_{extra}) \cdot A$, in which A is the erosion volume above the water level calculated with the current prediction method, see Section 2.1.

This method can be considered as an extension of earlier methods described in Delft Hydraulics (2006) that were based on a limited number of small-scale tests reported in Delft Hydraulics (1982b). By also using small-scale tests by Coeveld *et al.* (2005) an improved fit could be made, resulting in the following relation between the wave steepness and the dune erosion volume:

$$\begin{cases} \dfrac{H_{0s}}{L_0} < 0.015 & P_{extra} = 0.31 \\ 0.015 \le \dfrac{H_{0s}}{L_0} \le 0.04 & P_{extra} = -16.5\left(\dfrac{H_{0s}}{L_0} - 0.034\right) \\ \dfrac{H_{0s}}{L_0} > 0.04 & P_{extra} = -0.10 \end{cases} \qquad (3)$$

This method was not adjusted based on the large-scale tests, although the large-scale tests showed less dependency on the wave period than Equation 3 (based on small-scale tests) would suggest. With Equation 3 an erosion volume is obtained, but not yet a dune erosion profile. In order to find also a shape of the dune erosion profile with this method it was chosen to deduce information on the erosion profile by letting the newly obtained dune erosion volume be the target volume in a series of iterative dune erosion

predictions with the current prediction method. In the iterative predictions the diameter of the sand is reduced until the target volume is obtained.

Category 2: Period-dependent erosion profiles

In this category two methods are considered, Method 2a and Method 2b. In Method 2a the dune erosion profile beneath storm surge level and the transition between the dune erosion profile and the initial profile are modified. A new equation was derived for the erosion profile using a methodology similar to the one applied in Delft Hydraulics (1982a). In Delft Hydraulics (1982a) the available profiles were all based on tests with a (prototype) peak wave period of about T_p = 12 s. Here, data from small-scale tests, including tests with other wave periods, were used for the derivation of Method 2a. Method 2a was not adjusted based on the results from the described large-scale tests. Also similar scaling relationships have been assumed here. This yielded a modified erosion profile beneath storm surge level, with gentler profile slopes for larger wave periods. Method 2a is described by Equation 4:

$$\frac{7.6}{H_{0s}} \cdot y = 0.4714 \cdot \left[\left(\frac{7.6}{H_{0s}} \right)^{1.28} \cdot \left(\frac{w}{0.0268} \right)^{0.56} \cdot x + \frac{\left(T_p + 6 \right)^2}{18} \right]^{0.5} - \left(\frac{T_p + 6}{9} \right) \qquad (4)$$

This equation gives the same result as Equation 1 for a peak wave period of T_p = 12 s, and the location of the dune foot does not shift (in other words: if $y = 0$ then $x = 0$). The slope between point R and S (see Figure 1) is equal to the slope in the current method (1:12.5). The transition point R is located at:

$$\begin{aligned} x_R &= 250 \cdot \left(\frac{H_{0s}}{7.6} \right)^{1.28} \cdot \left(\frac{0.0268}{w} \right)^{0.56} \\ y_R &= \left(\frac{H_{0s}}{7.6} \right) \cdot \left[0.4714 \cdot \left(250 + \frac{\left(T_p + 6 \right)^2}{18} \right)^{0.5} - \left(\frac{T_p + 6}{9} \right) \right] \end{aligned} \qquad (5)$$

This implies that the horizontal position of the transition point (x_R) relative to the dune foot is equal to the position in the current method. Since the erosion profile between the dune foot and the transition point changed (Equation 4 instead of Equation 1), the vertical position of the transition (y_R) is different.

Similar as for Method 2a, also for Method 2b the dune erosion profile beneath the storm surge level and the transition between the dune erosion profile and the initial profile are modified. The dune erosion profile is modified in a rather straightforward way, viz. by adding a term $(12 / T_p)^{\alpha}$ as indicated in Equation 6. In this way, the term for the wave period is included in a similar way as the wave height and the fall velocity (effect relative to reference value):

$$\frac{7.6}{H_{0s}} \cdot y = 0.4714 \cdot \left[\left(\frac{7.6}{H_{0s}} \right)^{1.28} \cdot \left(\frac{12}{T_p} \right)^{\alpha} \cdot \left(\frac{w}{0.0268} \right)^{0.56} \cdot x + 18 \right]^{0.5} - 2.0 \qquad (6)$$

The exponent α was initially determined with a fitting procedure on data from small-scale tests at $\alpha = 0.5$. The validation with the large-scale tests led to a small adjustment of this exponent to $\alpha = 0.45$. For wave periods longer than T_p=12 s, a smaller value for α leads to a smaller landward shift of the dune face and shows a steeper bed profile below the still water level. Equation 6 gives the same result as Equation 1 for a peak wave period of $T_p = 12$ s, and the location of the dune foot does not shift (in other words, if $y = 0$ then $x = 0$). The slope between point *R* and *S* (see Figure 1) is equal to the slope in the current method (1:12.5). The transition point *R* (see Figure 1) is located at:

$$\begin{aligned} x_R &= 250 \cdot \left(\frac{H_{0s}}{7.6} \right)^{1.28} \cdot \left(\frac{0.0268}{w} \right)^{0.56} \\ y_R &= \left(\frac{H_{0s}}{7.6} \right) \cdot \left[0.4714 \cdot \left(250 \cdot \left(\frac{12}{T_p} \right)^{\alpha} + 18 \right)^{0.5} - 2 \right] \end{aligned} \qquad (7)$$

Evaluation of prediction methods

The dune erosion prediction methods presented in Sections 3.1 and 3.2 were verified with the measurements of Tests T01, T02 and T03 (see Section 2.2). The validation was carried out by comparing the measured and predicted erosion profiles and erosion volumes above the still water level. For the comparison of the predicted and measured profiles reference is made to Figure 3, which summarizes the qualitative effects of the wave period on the shape of the erosion profile.

SCALE RELATIONS

Because the prediction methods should be applied for prototype conditions, all measured bed profiles are translated to a prototype situation for this purpose. Use is made of the set of scaling relations described by Vellinga (1986):

$$\begin{aligned} n_l &= n_l \cdot \left(\frac{n_d}{n_w^2} \right)^{0.28} \\ n_H &= n_d \\ n_T &= n_t = n_d^{0.5} \end{aligned} \qquad (8)$$

where n_l = scale factor for horizontal geometrical measures ($n_l = x_{proto} / x_{model}$); n_d = scale factor for vertical geometrical measures; n_w = scale factor for the fall velocity of the sediment; n_H = scale factor for the wave height; n_T = scale factor for the wave period;

and n_t = scale factor for the time. Vellinga (1986) concluded that the hydraulic and morphologic processes need to be scaled with the same time scale factor to appropriately simulate dune erosion on a smaller scale.

The fall velocity scale factor n_w in Equation 8 is obtained by dividing the prototype value of the fall velocity by the model value. For the prototype fall velocity a value of $w = 0.0268$ m/s is chosen, which was also used in earlier analyses and corresponds with the fall velocity of a grain diameter of $D_{50} = 225$ µm. To obtain a prototype profile the horizontal dimensions of the model are multiplied with the horizontal length scale factor n_l, and the vertical dimensions (*e.g.*, water depth and wave height) with the depth scale factor n_d. Prototype values for the wave period and the time at which profile measurements were carried out are obtained by multiplying the model values with the square root of the depth scale factor n_d. By multiplying the measured dune erosion volume (per linear meter) with $n_A = n_l \cdot n_d$ the prototype volume is obtained.

COMPARISON OF PREDICTION METHODS

A comparison between prediction methods is discussed here, primarily focused on the prediction of dune erosion volumes, not on the prediction of dune erosion profiles.

The current method, derived for a wave period of T_p=12 s, over-predicts the erosion volume above still water for this basic condition. This current method is used as starting point for the new methods. The new methods that take into account an extra amount of dune erosion for longer wave period will therefore also over-predict the measured dune erosion volumes, see left panel in Figure 5. Therefore, to obtain better insight into the relative performance of the methods, the erosion volumes have been normalized for T_p = 12 s, see right panel in Figure 5.

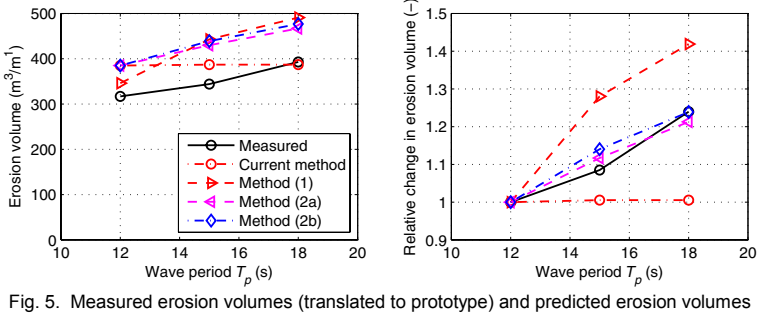

Fig. 5. Measured erosion volumes (translated to prototype) and predicted erosion volumes above still water level and change in erosion volume relative to volume in Test T01 (T_p = 12s)

For all three methods, the predicted erosion volume increases more between T_p = 12 s and T_p = 15 s, than between T_p = 15 s and T_p = 18 s, while for the measurements the opposite applies. Nevertheless, the predicted relative change in erosion volume between

T_p = 12 s and T_p = 18 s corresponds best to the measurements when using Method 2a or Method 2b.

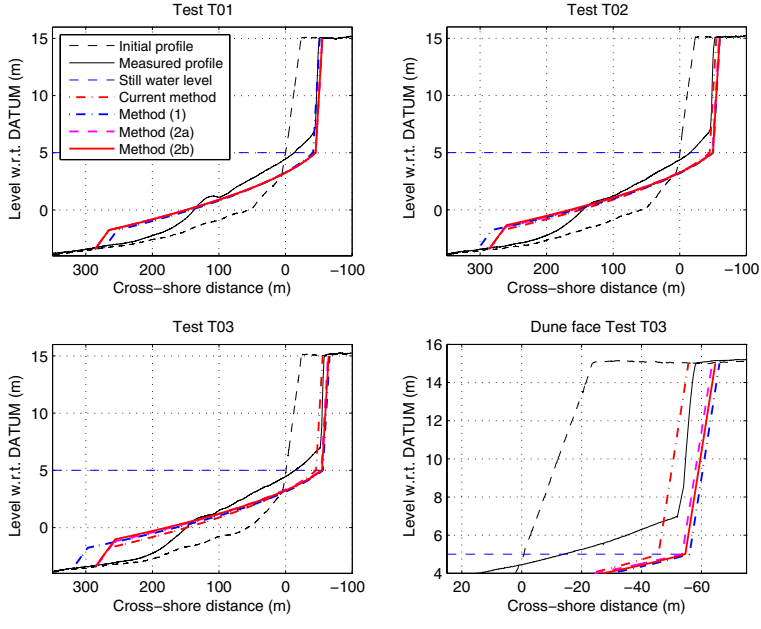

Fig. 6. Measured bed profiles (translated to prototype) and bed profiles predicted with Methods (1), (2a) and (2b) for Tests T01 (T_p = 12 s), T02 (T_p = 15 s) and T03 (T_p = 18 s).

The main goal of the prediction method is to predict the dune erosion volume. Nevertheless, attention is also paid to several aspects of the predicted bed profiles. Figure 6 shows measured and predicted bed profiles for Tests T01, T02 and T03 translated to a prototype situation. The bed profiles predicted with the current method (which is used as a starting point for the other methods) are equal in all tests, because the current method does not take the wave period into account. Furthermore, the following can be observed:

- With the current method the horizontal position of the dune face is predicted more landward than the measured position for Test T01. For Test T03 the opposite applies. By definition, the vertical position of the dune foot predicted with the current method is located at the still water level, while the measured location of the dune foot is well above the still water level. The horizontal position of the dune face

predicted with Methods 2a and 2b corresponds reasonably well with the measurements.

- The slope of the predicted profile directly seaward of the dune face is less steep than the measured profile. The correspondence of the bed profile below the still water level predicted with Methods 2a and 2b and the measurements is poor, which is also the case for the current method.
- The predicted deposit area extends significantly more seaward than the measured deposit area. Method 1 shows a larger influence of the wave period on the length of the deposit area, than the predictions of Methods 2a and 2b.

In general, the bed profile predictions do not correspond very well with the measurements irrespective of which prediction method is used. Because this is also the case for the current method, while the current method is used as a starting point for the new methods, no significant improvements can be expected with the new methods with respect to predicted bed profiles. The same is valid for the vertical position of the dune foot.

INFLUENCE OF WAVE SPECTRA ON DUNE EROSION

Based on dune erosion tests with double-peaked wave energy spectra Van Gent *et al.* (2006) concluded that the influence of wave spectra on dune erosion is more appropriately taken into account using the wave period $T_{m-1,0}$ than using the peak wave period T_p. The wave period $T_{m-1,0}$ can be incorporated in Equations 6 and 7 in the following way:

$$\frac{7.6}{H_{0s}} \cdot y = 0.4714 \cdot \left[\left(\frac{7.6}{H_{0s}} \right)^{1.28} \cdot \left(\frac{10.9}{T_{m-1,0}} \right)^{0.45} \cdot \left(\frac{w}{0.0268} \right)^{0.56} \cdot x + 18 \right]^{0.5} - 2.0 \qquad (9)$$

and

$$\begin{aligned} x_R &= 250 \cdot \left(\frac{H_{0s}}{7.6} \right)^{1.28} \cdot \left(\frac{0.0268}{w} \right)^{0.56} \\ y_R &= \left(\frac{H_{0s}}{7.6} \right) \cdot \left[0.4714 \cdot \left(250 \cdot \left(\frac{10.9}{T_{m-1,0}} \right)^{0.45} + 18 \right)^{0.5} - 2 \right] \end{aligned} \qquad (10)$$

The value 10.9 is based on the fact that the ratio $T_p/T_{m-1,0}$ comes close to a value of $T_p/T_{m-1,0} = 1.1$ for a standard single-peaked spectrum such as the Pierson-Moskowitz spectrum applied in the tests on which Equations 1-7 are based. Figure 7 shows the measured erosion volumes and the volumes predicted with Method 2b based on Equations 9 and 10.

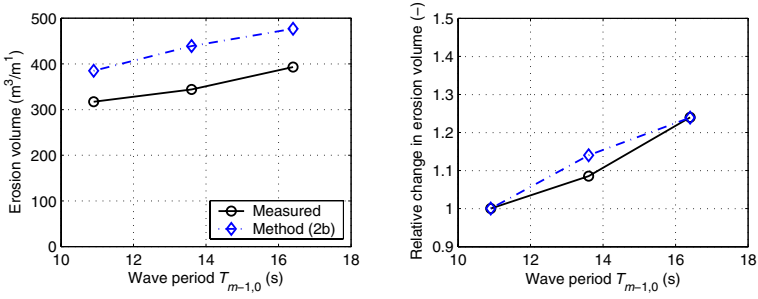

Fig. 7. Measured erosion volumes (prototype) and volumes predicted with Method 2b (Equations 9 and 10) and change in erosion volume relative to Test T01 ($T_{m-1,0}$ = 10.9 s).

DISCUSSION

Application of selected dune erosion method

Method 2b is selected to replace the current dune erosion prediction method in the safety assessment procedure for the Dutch dunes in the coming years, because of its simplicity.

Figure 8 shows the sensitivity of Method 2b to the input parameters H_s and $T_{m-1,0}$. A higher wave height leads to a longer deposition area, a more landward located dune face and a larger dune erosion volume. A longer wave period leads to gentler slopes of the bed profile below the still water level, a more landward located dune face and a larger dune erosion volume.

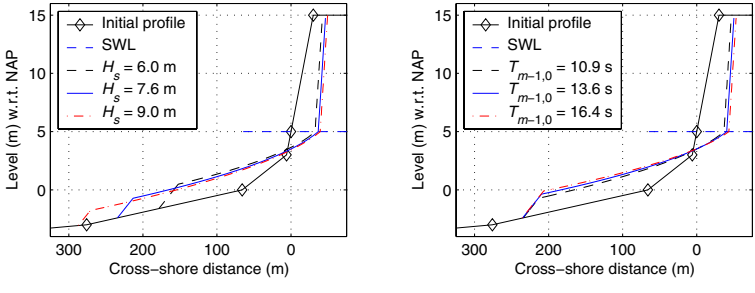

Fig. 8. Sensitivity of Method 2b to input parameters.

An example application of Method 2b is presented in Figure 9. The figure compares the current and the new dune erosion prediction method for a cross-section of an arbitrary Dutch dune for an extreme event. It shows that Method 2b predicts more dune erosion than the current method for the hydraulic conditions indicated in the figure. Obviously, the current method would have predicted the same bed profile for other wave periods.

The increase in erosion volume above the still water level between T_p = 12 s and T_p = 18 s is about 23 %, which agrees well with the observed increase in erosion volume in the physical model tests. It should be noted that the effects of the wave period on dune erosion depend on the initial bed profiles or hydraulic condition if they deviate significantly from the situation in the tests. Different initial profiles may lead to a significantly larger or a significantly smaller dependency on the wave period.

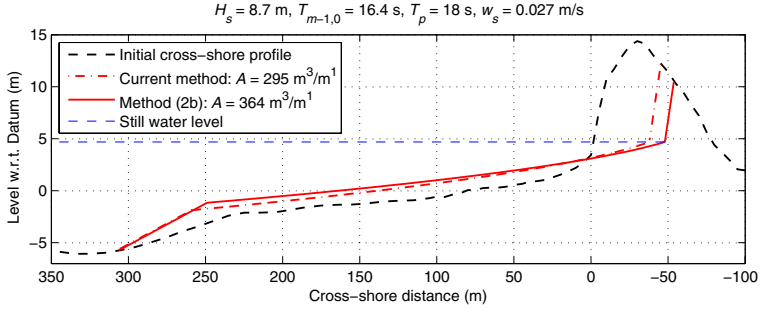

Fig. 9. Example application of current and new dune erosion prediction method for a cross-section of a dune (dashed line = initial bed profile, solid line = predicted erosion profile).

Method 2b has the same range of validity as the current method (see Section 2.1), except that for the wave steepness this method is considered valid for a wider range. Because of the limited amount of data for smaller wave periods, it is recommended to use Method 2b only for conditions with a deep water wave steepness of $0.02 < s_{m-1,0} < 0.063$ (or for standard single-peaked wave energy spectra of $0.017 < s_p < 0.04$).

Future developments

The method described above provides an indication of dune erosion volumes under extreme storm conditions. Because it is an empirical method, its validity is quite limited. For instance, the development and duration of a storm are strongly schematized, and the influence of the initial cross-shore profile cannot always be correctly reproduced. It is desirable to have methods available that do also account for these effects. Therefore, it is useful to develop a dune erosion prediction method that simulates dune erosion processes rather than an empirical representation of these processes. The large-scale tests will be analyzed to gain more insight into the physical processes underlying dune erosion.

CONCLUSIONS

The aim of the study was to develop a dune erosion prediction method that takes effects of the wave period on dune erosion into account. The dune erosion prediction method by Vellinga (1986) was used as a starting point for the new prediction method. Several prediction methods were developed on the basis of existing data and verified with the bed profiles and erosion volumes measured in recent large-scale dune erosion tests.

Based on the comparisons of predictions and measurements of dune erosion, it can be concluded that the relative increase in dune erosion volume for increasing wave periods observed in the tests corresponds well with the predictions of the newly developed methods. The new method can be used to predict dune erosion volumes, including effects of wave period. However, the shape of the bed profile below the still water level is not very well predicted. This is also the case for the current prediction method by Vellinga (1986). The new and current methods are therewith not very suitable to predict the bed profile below the still water level.

ACKNOWLEDGEMENTS

This research was carried out in an assignment of the National Institute for Coastal and Marine Management of the Dutch Ministry of Transport and Public Works. Dr. M. Boers of this institute is acknowledged for his contribution to this research.

Abstract: A modification of the equilibrium beach profile scale parameter is proposed to account for wave effects. The modification is expressed in terms of a multiplication factor applied to the profile scale parameter and considered to be a function of the fall velocity parameter. The recommended modification is based on large-scale wave flume tests. The differences between summer and winter profiles in nature can be explained qualitatively by the proposed model and the application of the model to predict seasonal shoreline changes is promising.

INTRODUCTION

The concept of an equilibrium beach profile (EBP) is one of the coastal engineer's most valuable tools in providing a framework to consider disequilibrium and thus cross-shore sediment transport (Kriebel and Dean 1985; Larson and Kraus 1989; Zheng and Dean 1997). Also many useful and powerful conceptual and design relationships are based on profiles of equilibrium (Dean 1991).

The commonly accepted EBP shape from Bruun (1954) and Dean (1977) is

$$h = Ay^{2/3} \tag{1}$$

in which h is the water depth at a seaward distance, y, and A is the profile scale parameter with dimensions of length$^{1/3}$. Dean (1977) found that this relationship is consistent with uniform wave energy dissipation per unit volume, D_*, within the breaking

zone. From linear shallow water wave theory, it can be shown that D_* and A are related by

$$A = \left[\frac{24 D_*}{5 \rho g^{3/2} \kappa^2} \right]^{2/3} \tag{2}$$

where ρ is the water mass density, g is gravity, and κ is a constant relating wave height to water depth within the surf zone.

Moore (1982) collected and analyzed a number of published beach profiles and developed a relationship between A and D_{50} (the grain size median diameter). Later, Dean (1987) transformed the A vs. D_{50} relationship to the A vs. w (the fall velocity) relationship. Table 1 presents the recommended A values (in $m^{1/3}$) vs. the median sand size in 0.01-mm increments over the range of sand sizes from 0.1 mm to 1.09 mm (Dean et al. 2001). A limitation in the relationships between A and D_{50} (or w) is that wave conditions are not included. Thus, as questioned by Pilkey et al. (1993), this representation cannot explain one phenomenon that occurs in natural beaches: the profiles are of milder slope in the winter under high wave energy, compared to the summer conditions associated with milder and less steep waves. In the present study, a modification function is developed to account for wave effects on EBP shapes.

MODIFICATION OF EBP PROFILE SCALE PARAMETER

The fall velocity parameter (Dean 1973) includes information of both sediment size and wave conditions and has been used in many coastal problems. The hypothesis tested here is that a relationship exists between the profile scale parameter A and the fall velocity parameter H_b/wT as

$$A = f(D_{50}) \cdot F(\frac{H_b}{wT}) \tag{3}$$

in which the first term is determined from Table 1, and the second term is a modification term which is a function of the fall velocity parameter. To investigate this modification function, the large-scale wave flume experimental data from LWT (Kraus and Larson 1988) are analyzed. LWT used monochromatic waves and all commenced with an initial profile slope of 1:15. Most of the final profiles in this experiment had almost achieved equilibrium.

The analysis procedure is as follows: first using the wave transformation model of Dally et al. (1985) or from measurements, determine the breakpoints and the corresponding breaking wave heights in the final measured profiles; then, applying the least-squares method from the shoreline positions out to the breakpoint positions, determine the best-fit A values by assuming that the final profiles are in equilibrium. Figure 1 shows one example from Case 300 in the LWT experiments. For final profiles having multiple bars and a wide trough landward of the primary bar, such as LWT Cases 500 (Figure 2), they are fit to the breakpoint near the inner bars.

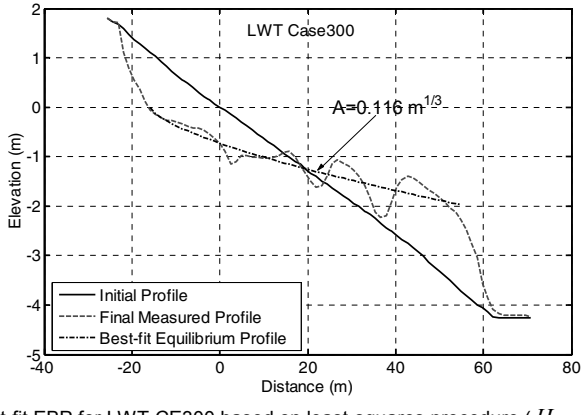

Fig.1. Best-fit EBP for LWT CE300 based on least-squares procedure (H_b = 1.88 m, T = 11.33 s, D_{50} = 0.22 mm). The A value based on Table 1 is 0.106m$^{1/3}$.

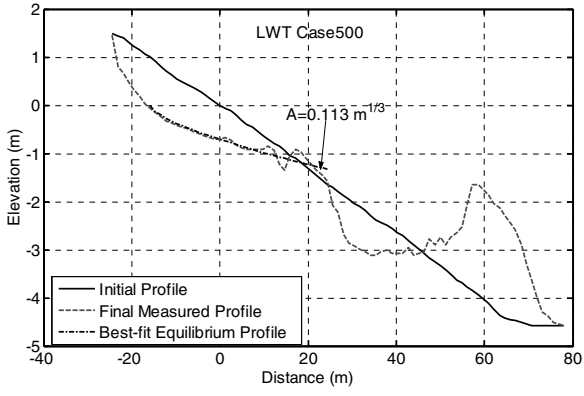

Fig.2. Best-fit EBP for LWT CE500 based on least-squares procedure (H_b = 1.88 m, T = 11.33 s, D_{50} = 0.22 mm). The A value based on Table 1 is 0.106m$^{1/3}$.

A plot of the ratio of the best-fit A values (A_{fit}) to the recommended values from Table 1 (A_{rec}) vs. the fall velocity parameter is presented in Figure 3. A reasonable fit to the data is

$$F(\frac{H_b}{wT}) = 0.868 + 1.406\left(\frac{H_b}{wT}\right)^{-1} \tag{4}$$

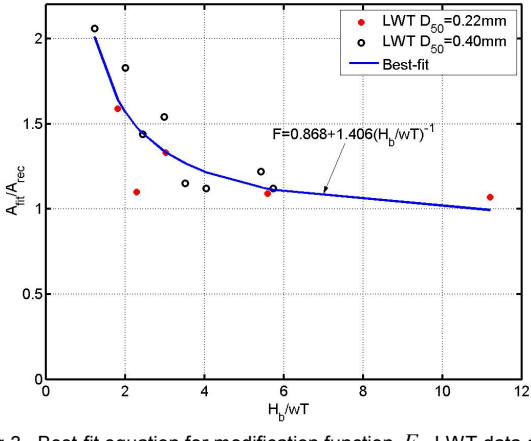

Fig.3. Best-fit equation for modification function F , LWT data only.

APPLICATION TO SEASONAL SHORELINE CHANGES

Of special interest, seasonal profile changes can be explained qualitatively on the basis of Eq.4: from winter to summer, the A value becomes larger with the fall velocity parameter decreasing, thus the profile becomes steeper in summer and the shoreline advances seaward relative to winter conditions.

Figure 4 shows an idealized scheme for the calculation of seasonal shoreline changes from summer to winter based on equilibrium beach profile concepts. This process is assumed to be reversible, which may not be exact when considering profile changes from winter to summer following the depth of closure concept. Considering volume conservation in Figure 4, the shoreline change, Δy , can be determined approximately as

$$\frac{\Delta y}{W_*} = -\frac{\frac{3}{5}\left(\frac{A_s}{A_w} - 1\right)}{\left(\frac{B}{h_*} + \frac{A_s}{A_w}\right)} \tag{5}$$

where A_s and A_w are the respective EBP profile scale parameters for summer and winter profiles determined from Eq.3, h_* is the depth of closure, B is the berm height, and $W_* = (h_* / A_w)^{3/2}$ is the active beach width.

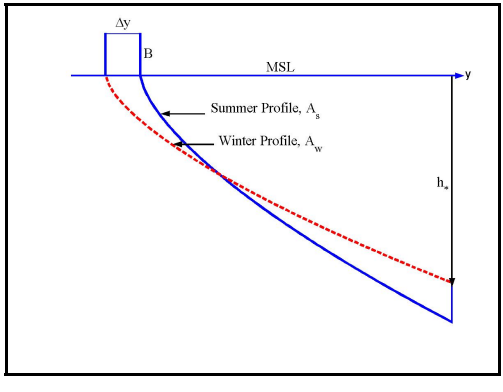

Fig.4. Scheme for calculating seasonal shoreline changes

For example: for Florida beaches, with a representative sediment size of 0.2 mm (Charles et al. 1994) which corresponds to a fall velocity of 0.03 m/s, the observed averaged seasonal shoreline change is in the range of 10 to 20 m (Dewall 1977). From Table 1, the recommended A value is 0.1 $m^{1/3}$. Taking the averaged wave conditions from the Wave Information Studies hindcast data (http://frf.usace.army.mil/wis/) on Florida beaches as: H_b = 0.6 m, T = 8 s in summer, and H_b = 1.0 m, T = 6 s during winter, the

modified A values are 0.143 $m^{1/3}$ and 0.112 $m^{1/3}$ for summer and winter profiles, respectively. Thus, the calculated potential seasonal shoreline change from Eq.5 is about 20 m ($h_* = 4$ m, and $h_* / B = 2.0$ based on the authors' experience), which is close to the observed value.

SUMMARY

The modification function proposed provides a basis to account for the effects of wave and sediment characteristics on equilibrium beach profiles through the fall velocity parameter. Based on investigation of the measured profiles from the large-scale wave flume experiments, an inverse relationship between the profile scale parameter and the fall velocity parameter was obtained. An example for seasonal shoreline changes on Florida beaches has demonstrated that the modified profile scale parameter model can be applied to predict reasonable seasonal shoreline changes; however, additional testing with more field data is needed to further verify and refine the model.

Abstract: This paper evaluates shoreface change in response to a decrease in sediment supply over three timescales – Holocene (millennia), historical (century), and contemporary (interannual). The reduction of sediment supply is due to northern migration of the Columbia River ebb-tidal delta over the past few thousand years and construction of jetties during 1885–1917. Data analyzed include shoreface vibracores, historical regional bathymetry since 1868, and upper shoreface and beach profiles since 1997. At late Holocene to historical time scales the lower shoreface eroded while the upper shoreface and barrier accreted. At recent interannal time scale, the primary dune prograded. This behaviour resulted in a net rotation (i.e., steepening) of the shoreface and implies onshore sediment supply from the lower shoreface to the barrier. The study area is along northern Clatsop Plains, Oregon, USA.

INTRODUCTION

Shoreface rotation (i.e., progradation of the upper shoreface and deepening of the lower shoreface) has been observed on the Pacific Northwest coast, USA, both as a natural mean trend at millennial scale and as a response to engineering intervention at historical scale. This behaviour suggests that the inherited lower shoreface previously had a higher sediment supply and evolved toward a deeper equilibrium under both

natural and modified conditions. The lower shoreface erosion provided a sand supply for strandplain progradation under both sets of conditions, but at different rates.

The data are from the northern ~10 km reach of Clatsop Plains, Oregon, USA (Figure 1), where dramatic erosion of the lower shoreface ensued after construction of the south jetty (1885–1917) at the Mouth of the Columbia River (MCR). Jetty construction effectively eliminated sediment supply to the Clatsop shoreface (from shore to ~60 m water depth). Analysis of regional historical bathymetry since 1868 reveals an alongshore gradient of lower shoreface deepening, with the greatest magnitude of change close to the jetty. The erosion has substantially contributed to jetty deterioration, the need for several jetty rehabilitations, and more recently an evaluation of dredged-material management strategies for nourishing the shoreface.

This paper extends previous work (e.g., Kaminsky *et al.* 2001; Gelfenbaum *et al.* 2001; Moritz *et al.* 2003) that focused on the post-jetty multi-decadal evolution of the ebb-tidal shoals and adjacent coasts of the Columbia River mouth. The present work provides a detailed quantitative analysis of both pre-historic and historical evolution of the northern Clatsop sub-cell in order to better estimate future conditions and to inform management strategies for addressing the impacts of the sediment deficit. The study site and the available data are unique because they provide the opportunity to evaluate shoreface response to reduced sediment supply over millennial to inter-annual timescales. At millennial scale, the Columbia River entrance migrated northward across the present northern Clatsop shoreface. The river mouth also narrowed in width, implying that the ebb-tidal delta of a few thousand years ago also extended farther to the south than in historical time. Although the river mouth narrowed as the Clatsop Plains and sub-aerial Clatsop Spit prograded northward and seaward, the offshore area of the northern Clatsop Plains remained a broad ebb-tidal delta complex of shallow shoals and migrating channels affected by fluctuations in river discharge. Prior to jetty installation, the river mouth was approximately 9.6 km in width. Upon construction of both jetties, the width of the river mouth was reduced by two-thirds to approximately 3.2 km.

METHODS

This study presents results from 10 vibracores recently collected on the Clatsop shoreface (Kaminsky and Ferland 2003, 2005), which are interpreted in combination with previously-interpreted seismic reflection data (Twichell and Cross 2001). Radiocarbon (^{14}C) Accelerator Mass Spectrometry (AMS) dating and sediment grain size analysis of vibracore samples are also performed. In addition, this study analyzes historical shoreface change from four eras of extensive regional bathymetric data (1868, 1926, 1958 and 2000). Interpretations are informed by decadal-interval MCR condition surveys including exploration surveys beginning in 1841, several decades prior to jetty construction. Finally, a time series of upper-shoreface bathymetric surveys (< -12 m MLLW) from 1999 to 2006 and beach profiles from 1997 to 2005 are analyzed to compare contemporary shoreface and beach changes to recent decadal-scale trends.

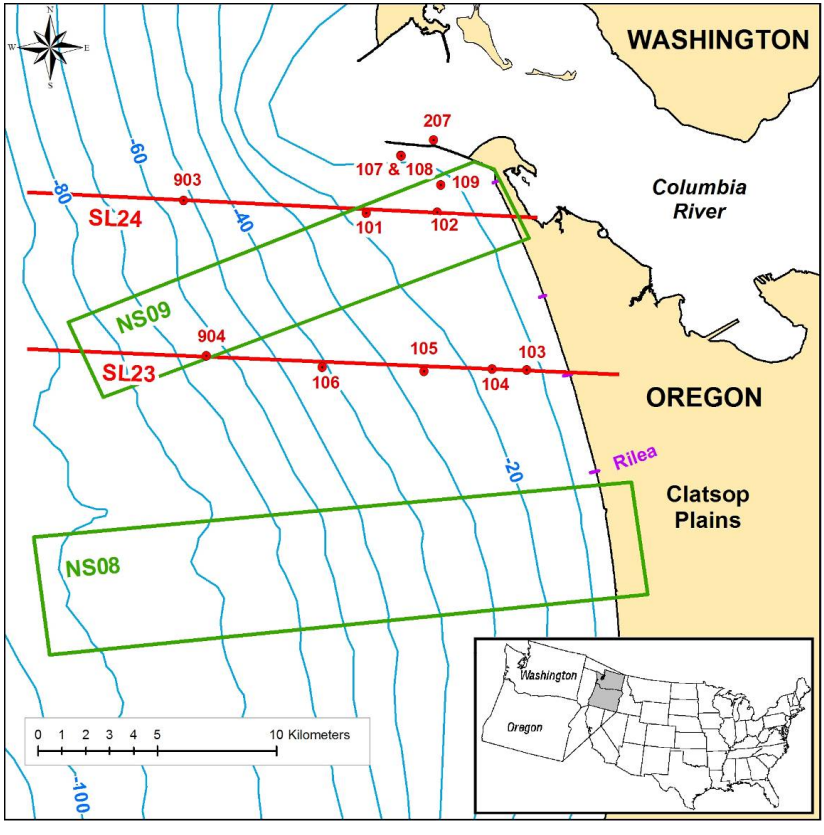

Fig.1. Clatsop Plains shoreface on the northern Oregon coast, including vibracore sites, shoreface profiles, and alongshore-averaged areas referenced in the text. Depth contours are in m relative to the North American Vertical Datum of 1988 (NAVD 88)[1].

ANALYSIS

Holocene Time Scale

In prehistoric time, the Columbia River valley was located south of the present location of the mouth. Figure 2 shows the lowstand surface (>14,000 years ago) interpreted from seismic reflection data (Twichell and Cross 2001) and reveals the shape and position of the ancient Columbia River valley that runs between the north and south transects of the Clatsop shelf cores.

[1] NAVD 88 m at the MCR = 0.16 m above Mean Lower Low Water (MLLW)

As sea level rose by some 110 m over 14,000 years, the Columbia River valley filled with sediment as the environment transitioned from fluvial to estuarine. Twichell and Cross (2001) indicate that as recently as 3,000 years ago, Clatsop Plains was narrow and did not extend as far north as it does now. Rather, the river mouth was even wider than it has been in recent historical time prior to jetty construction. This implies that the ebb-tidal delta of a few thousand years ago also extended farther to the south than in historical time. Evidence in the vibracores indicates long-term erosion of the inner shelf, which is consistent with a narrowing and substantial reduction in the size of the ebb delta from its previous, more southerly extent. As the environment transitioned from ebb delta to shoreface, the sediment of the delta was redistributed, resulting in a lowering of the seabed, as the historical and vibracore data indicate.

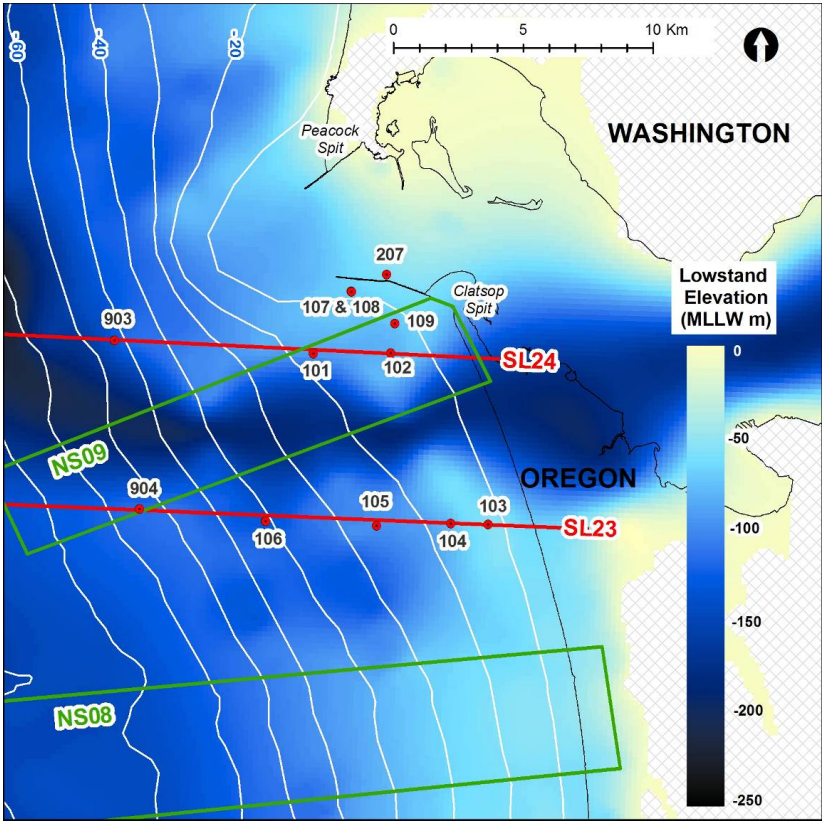

Fig. 2. Lowstand surface (>14,000 years ago) interpreted from seismic reflection data (Twichell and Cross 2001). For reference purposes, the figure includes the 1999 shoreline, the jetties, and the modern bathymetric depth contours in 10-m intervals.

Most of the vibracores collected on the Clatsop shoreface in 2002 and 2003 have laminated mud and sand units (cores 101, 102, 105, 106, 108, 109). In order for these units to be preserved in shallow water on this high-energy shoreface, they would have to be buried soon after deposition. The lack of bioturbation in these units supports this hypothesis of rapid burial. It is possible that the laminated mud and sand units were deposited at the margin of the once-wide and dynamic entrance with at least two major channels (north and south) separated by a large sand bank/shoal, and large, shore-connected shoals extending from the south and north (Clatsop Spit and Peacock Spit, respectively). Rapid burial would be possible, indeed likely, as ebb-delta shoals shifted and deposited sand. Erosional events were likely, and may be evidenced in the cores as sharp, angular contacts within the laminated unit that cut bedding at a low angle.

Samples from laminated units on the Clatsop shoreface have been analyzed by AMS, and the results indicate that these units are 'relict' (i.e., were not deposited in the last 1000 years). The calibrated ages of the organics within the laminated mud are youngest closest to the inlet (2000–2500 Before Present (BP)[2]; cores 108, 109) and are progressively older with distance from the inlet (> 4000 BP; cores 105, 106). In fact, within the present inlet, laminated mud and sand units in core 207 are younger than 339 BP, providing a modern analog to the relict deposits found on the shoreface. In contrast, the old dates near the surface of the shoreface cores indicate that relatively little sediment has accumulated on the Clatsop shoreface since the dated material was deposited, and/or that sediment has been eroded.

Additional evidence for long-term erosion on the Clatsop shoreface is provided by radiocarbon dates of carbonate material from two cores. In each core, the dates are not in stratigraphic order, because an older date occurs above a younger date. In core 104 (-17.3 m) a bivalve fragment collected at 112–116 cm depth interval returned a calibrated age of 2391 BP, whereas another bivalve fragment at 184–189 cm had a >Modern age. This result suggests that the seabed has been actively reworked to nearly 2 m along this shallow shoreface. Relatively old dates out of stratigraphic order were also found at lower depths in this core. A bivalve fragment at 322 cm returned a calibrated age of 4744 BP, while a shell fragment at 464–472 cm had a calibrated age of 3836 BP. Together, the dates in this core suggest recent sedimentation at the toe of the progradational (upper shoreface) sediment wedge over relatively older reworked sediment. In core 106 (-40.5 m) a bivalve fragment collected at 76–77 cm returned a calibrated age of 5649 BP, whereas another bivalve fragment at 184–185 cm returned a younger calibrated age of 4962 BP. This result is more likely when there is a slow rate of sediment accumulation, and sediment is eroded and redeposited locally. In addition, both of these relatively near-surface samples are old (another indicator of an erosional setting).

[2]0 calibrated ^{14}C years BP = Anno Domini (AD) 1950 (Gregorian calendar years)

The only exception to the trend of long-term erosion on the Clatsop shelf occurs in the shallow nearshore zone, adjacent to the central Clatsop Plains. In core 103, located in 10.8 m water depth, a sand dollar fragment at 133 cm returned a calibrated age of 558 BP, another sand dollar fragment at 237 cm had a calibrated age of 588 BP, and another sand dollar fragment at 549 cm returned a calibrated age of 1800 BP. These dates indicate sediment accumulation on the upper shoreface at rates on the order of 30 cm/100 years. This nearshore accumulation is not surprising given the history of long-term progradation of Clatsop Plains (Kaminsky *et al.* 1999; Peterson *et al.* 1999).

The radiocarbon ages and inferred accumulation rates derived from the vibracores are consistent with the historical bathymetric changes observed on the Clatsop shoreface. Relatively old radiocarbon dates occur at shallow depths within cores 101, 102, 105 and 106, and indicate very low sediment accumulation rates in the same areas where high rates of historical seabed erosion have been measured. Similarly, within core 103 young dates moderately deep within the core and indicate relatively high accumulation rates on the upper shoreface where historical seabed accumulation has been measured. In core 104, recent accumulation over old and out-of-sequence dates is consistent with the trends shown over historical time scales (next section). The old (and shallow) radiocarbon ages found on the Clatsop lower shoreface stand in sharp contrast to the much younger (and deeper) radiocarbon ages found on the Long Beach lower shoreface north of the MCR (Kaminsky and Ferland, 2005). The pattern of older radiocarbon ages and relict mud deposits in the southern-most and offshore Clatsop shoreface cores, and progressively younger dates associated with these deposits in the onshore and northerly direction, is consistent with the northward migration of Clatsop Spit over the past few thousand years and the subsequent movement of the ebb delta (Twichell and Cross 2001).

Historical Time Scale

Regional bathymetric changes for three historical periods are shown in Figures 3–5. These figures were developed from merged regional bathymetric surfaces developed by Buijsman *et al.* (2003) and include the locations of the vibracores. These figures illustrate the regional decadal- to century-scale morphological changes primarily attributed to the construction of the Columbia River jetties.

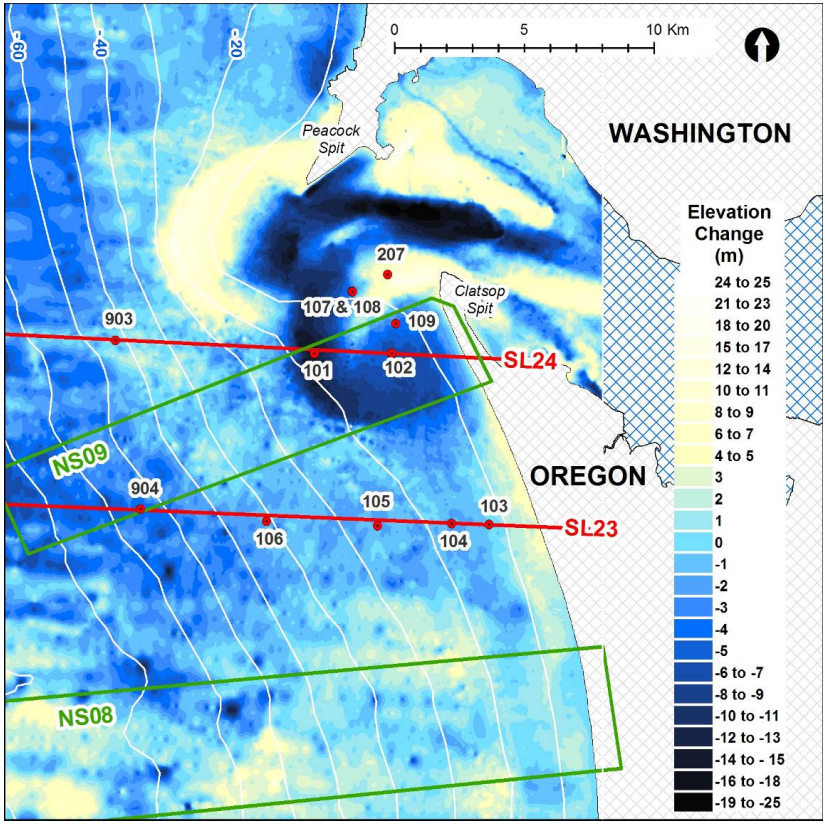

Fig. 3. 1868–1935 bathymetric change from Buijsman *et al.* (2003) shown with the vibracore sites. Data compiled from 1877 to 1926 for shelf; 1868 to 1926 for delta; and 1868 to 1935 for entrance and estuary. Bathymetric contours derived from data from 1998–2003 in meters relative to NAVD 88.

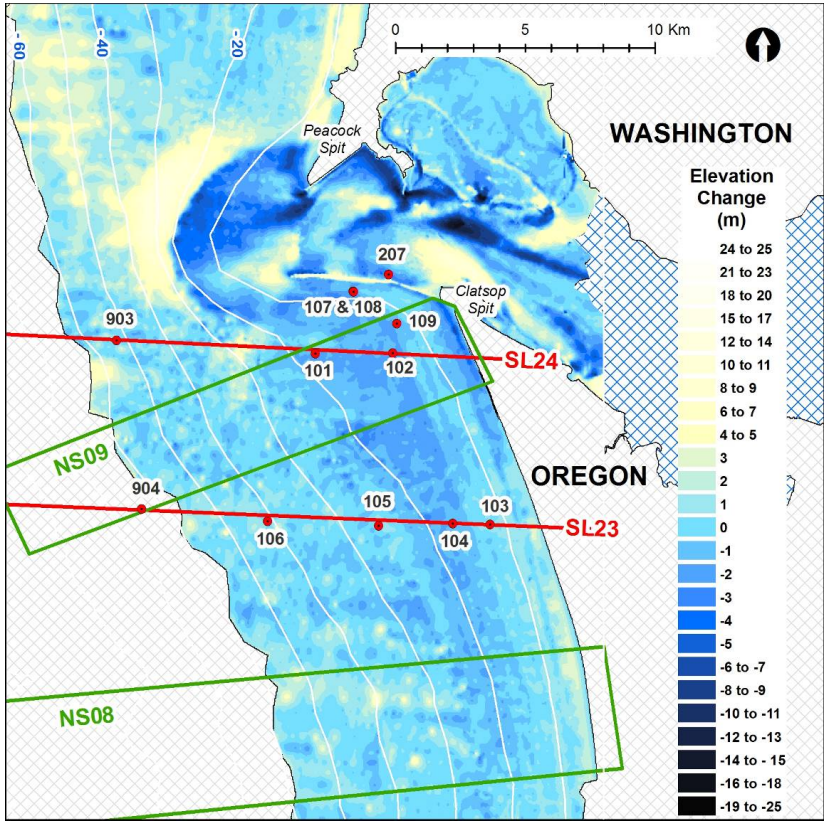

Fig. 4. 1926–1958 bathymetric change from Buijsman *et al.* (2003) shown with the vibracore sites. Data compiled from 1926 to 1958 for shelf, delta, and estuary; 1935 to 1958 for entrance. Bathymetric contours derived from data from 1998–2003 in meters relative to NAVD 88.

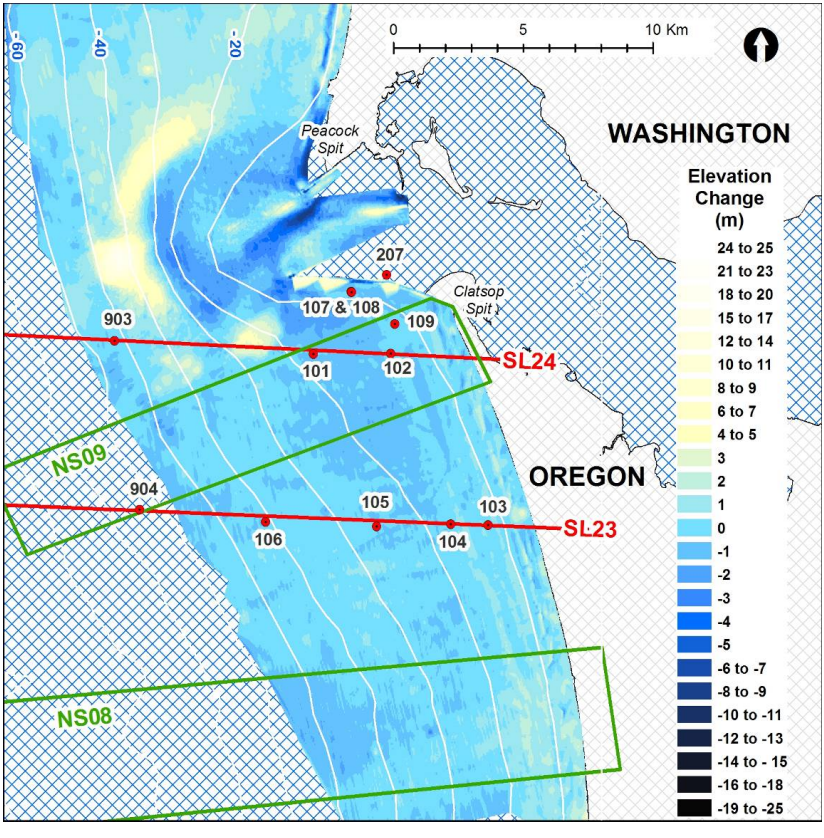

Fig. 5. 1958–2000 bathymetric change from Buijsman *et al.* (2003) shown with the vibracore sites. Bathymetric contours derived from data from 1998–2003 in meters relative to NAVD 88.

The historical erosion of the Clatsop shoreface has been most severe in the vicinity of core 101, often near the crest of the ebb-delta in the pre-jetty surveys. From 1868 to 1883 there was 3.7 m of vertical erosion at this site, and from 1883 to 2000 there was an additional 11.7 m of erosion at this site. Shoreface lowering at the site of core 102 from 1883–2000 was similar, at 9.7 m (Figure 6). Both cores 101 and 102 contain laminated mud units in the shallow subsurface. In core 101, the relict mud unit is less than 10 cm below the seabed, and only 85 cm below the seabed in core 102. Figure 6 shows the shoreface profile change from 1868 to 2000 at these core sites. The profile change shows the rapid initial adjustment from an ebb-shoal environment to a shoreface environment. The apparent shoal feature near km 3 in Figure 6 in the more recent profiles is Ocean Dredge Material Disposal Site A, where more than 18.25 million m^3 of dredged material was placed during 1956–1994.

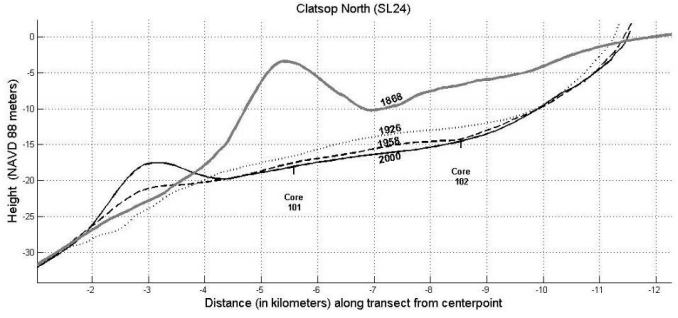

Fig. 6. Historical shoreface profiles and vibracore sites at the SL24 transect.

Figure 7 shows the historical shoreface profile change at the Clatsop south seismic line (SL23), where the progradation of the upper shoreface and the extensive lowering of the mid- to lower shoreface has occurred. Core 103 is located near the toe of the upper shoreface progradation. Profile analyses of the SL23 transect reveals that the toe of the upper shoreface progradation migrates from -10.5 m in 1868 to -17.5 m in 2000.

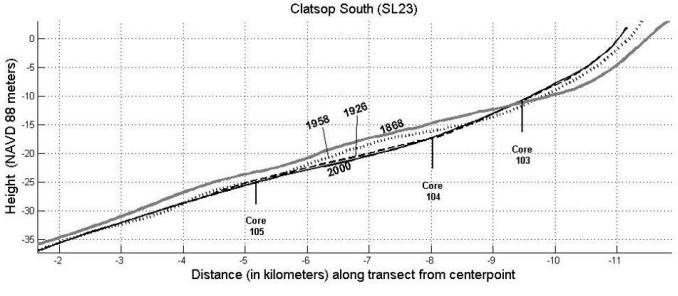

Fig. 7. Historical shoreface profiles and vibracore locations at the SL23 transect.

The major observation of change in the NS09 (along-shore averaged) profile is that of significant lowering of the profile to about 25 m water depth, as shown in Figure 8. During 1868–1926, the NS09 profile rapidly lowered, much more so than during any other period. Between water depths of -1.2 m and -24.9 m, the average rate of shoreface lowering was -9.6 cm/yr. The erosion peak occurred at an interval-average depth of -12.6 m at a rate of -17.8 cm/yr. During 1926–1958, the shoreface lowered between -0.8 m and -26.0 m at an average rate of -3.3 cm/yr, a substantial slowing from the previous period. The erosion peak during this period occurred at an interval-average depth of -14.0 m at a rate of -5.3 cm/yr. During 1958–2000, the shoreface continued to lower, but at a lower rate and with a greater extent offshore. The shoreface between -8.7 m and -26.2 m lowered by an average rate of -1.5 cm/yr, less

than half the rate of the previous period. The erosion peak occurred at an interval average depth of -16.3 m and had a rate of -2.3 cm/yr. Between -26.2 m and the end of the profile at -55.7 m, the profile lowered at an average rate of -0.7 cm/yr. Over the three intervals spanning 1868–2000, the average rates of lowering were -9.6 cm/yr, -3.3 cm/yr, and -1.5 cm/yr, while the peak rates of lowering were -17.8 cm/yr, -5.3 cm/yr, and -2.3 cm/yr.

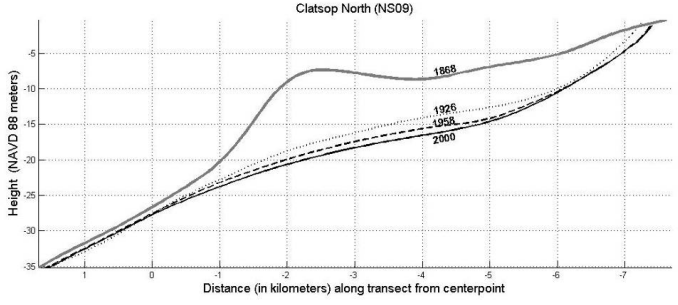

Fig.8. Historical shoreface profile change at the NS09 alongshore-averaged transect from 1868 to 2000.

Farther south, at the NS08 alongshore-averaged transect, the historical profiles suggest slight profile translation over the entire period from 1868 to 2000 (Figure 9). However, during the interval from 1958–2000, the lower shoreface slightly eroded with a minor increase in magnitude with distance offshore from the toe of the progradational sand wedge. This trend is consistent with a time lag in reduction of sediment supply since jetty construction, and follows the shoreline change trend presented in Kaminsky *et al.* 1999. We surmise that the rapid deflation of the profile in the northern sector provided a pulse of onshore and southerly migrating supply of sand to induce historical shoreface translation on the central Clatsop shoreface.

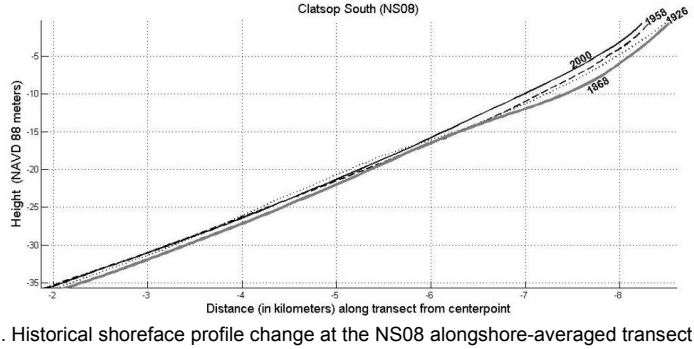

Fig. 9. Historical shoreface profile change at the NS08 alongshore-averaged transect from 1868 to 2000.

Interannual Time Scale

Since 1997 upper shoreface profile data have been collected from (typically) ~12-m water depth to landward of the primary dune (Ruggiero *et al.* 2005). Individual nearshore bathymetric profiles (Figure 10) along Clatsop Plains reveal that interannual morphodynamic variability within the upper shoreface is large, masking trends at these time scales. As demonstrated by Ruggiero *et al.* (2003), the variability is large in the nearshore zone and lower beachface but decreases landward and upward on the beach profile. In this case, we observe evidence of a net residual trend of onshore sediment supply from the lower shoreface that is resolvable at interannual time scales on the dune face (Figure 11). The time series of topographic beach profiles at Rilea (profile location indicated in Figure 1) reveals a consistent trend of dune face progradation at an average rate of ~2.5 m/yr during 1997–2006.

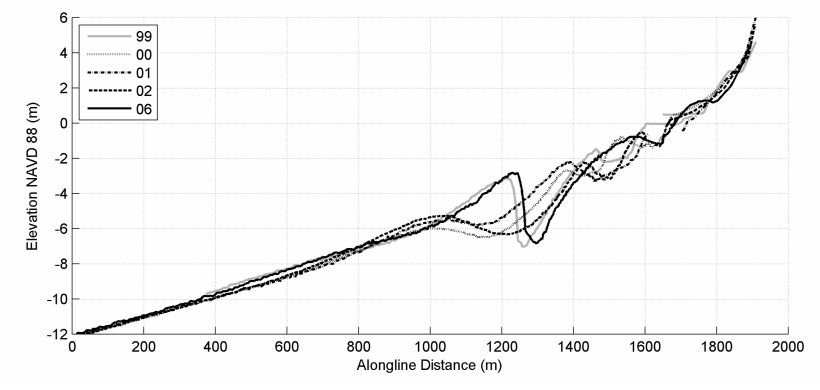

Fig. 10. Upper shoreface profile change at Rilea from 1999 to 2006.

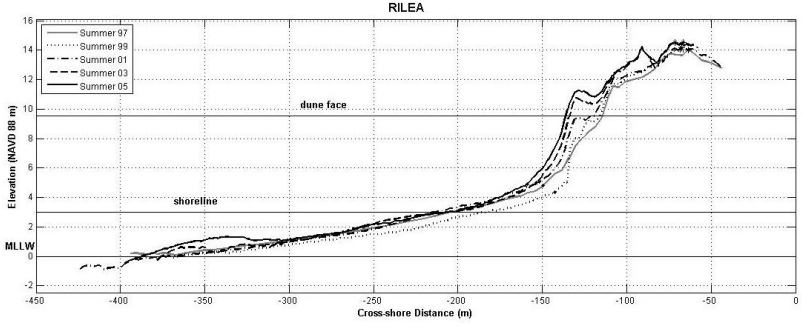

Fig.11. Beach profile change at Rilea showing the prograding dune face from 1997 to 2005.

CONCLUSION

Evidence of long-term erosion of the Clatsop lower shoreface comes from several sources. First, the vibracores contain relict laminated mud and sand units that occur near the top of many cores, 'old' radiocarbon ages, winnowed or lag deposits, and inferred rip-up clasts and mud clasts. Radiocarbon dates on carbonate that are out of stratigraphic order are indicative of re-working in a low sedimentation or erosional setting. Near-surface sediment samples across this shoreface are found to be significantly coarser than samples from the adjacent Long Beach shoreface north of the MCR. Next, the time series of historical bathymetric data from 1883 to 2000 shows a consistent erosion pattern that reveals as much as 10 m of shoreface deepening within a few km of the south jetty. Recent upper shoreface surveys suggest a gradient in morphology change, with highest erosion rates observed closest to the jetty (across the entire profile) and accretion only on the upper shoreface shallower than approximately -8 m MLLW several kilometers to the south, which is consistent with the longer term, regional data. Together, there is abundant evidence that the lower Clatsop shoreface has significantly eroded over contemporary, historical and late Holocene timescales. These results provide a sound basis for predicting future shoreface changes and informing management strategies to reduce the impacts of shoreface erosion due to a sediment deficit.

ACKNOWLEDGEMENTS

The authors are grateful for the funding provided by the University of Sydney Institute of Marine Science, the U.S. Geological Survey – Coastal and Marine Geology Program, the U.S. Army Corps of Engineers – Portland District, the Washington Department of Ecology, and the Northwest Association of Networked Ocean Observing Systems (NANOOS). We thank Bobbi Conard for supporting the processing of the vibracores at the Oregon State University Core Facility. Many individuals contributed to the collection of vibracores, beach topography and nearshore bathymetry. Dinah McCandless provided a wealth of GIS support and assistance with figures. We thank Candice Holcombe for help with formatting and preparation of this manuscript.

Abstract: Louisiana's barrier islands provide not only habitat but protection for interior marshes. The loss of these islands would expose interior marshes to increased wave heights, flooding, and loss of wetland habitat. The restoration of Louisiana barrier islands poses a combination of challenges, starting with quantifying project goals, developing a project design based on meeting those goals, through to construction of the project. This paper outlines design and construction details unique to Louisiana barrier islands using East Grand Terre and the Chaland Headland Restoration CWPPRA projects as case studies.

INTRODUCTION

East Grand Terre and the Chaland Headland are part of a chain of barrier islands that separate the Gulf of Mexico from Barataria Bay. The islands are located approximately 80 km due south of New Orleans and provide a first line of defense against waves and storm surge during storm events. Figure 1 provides a location map of the two project areas.

The island restoration projects are being constructed under the Coastal Wetlands Planning, Protection and Restoration Act (CWPPRA) with the Louisiana Department of Natural Resources as the local sponsor and the National Oceanographic and Atmospheric Administration's (NOAA) National Marine Fisheries Service as the federal sponsor.

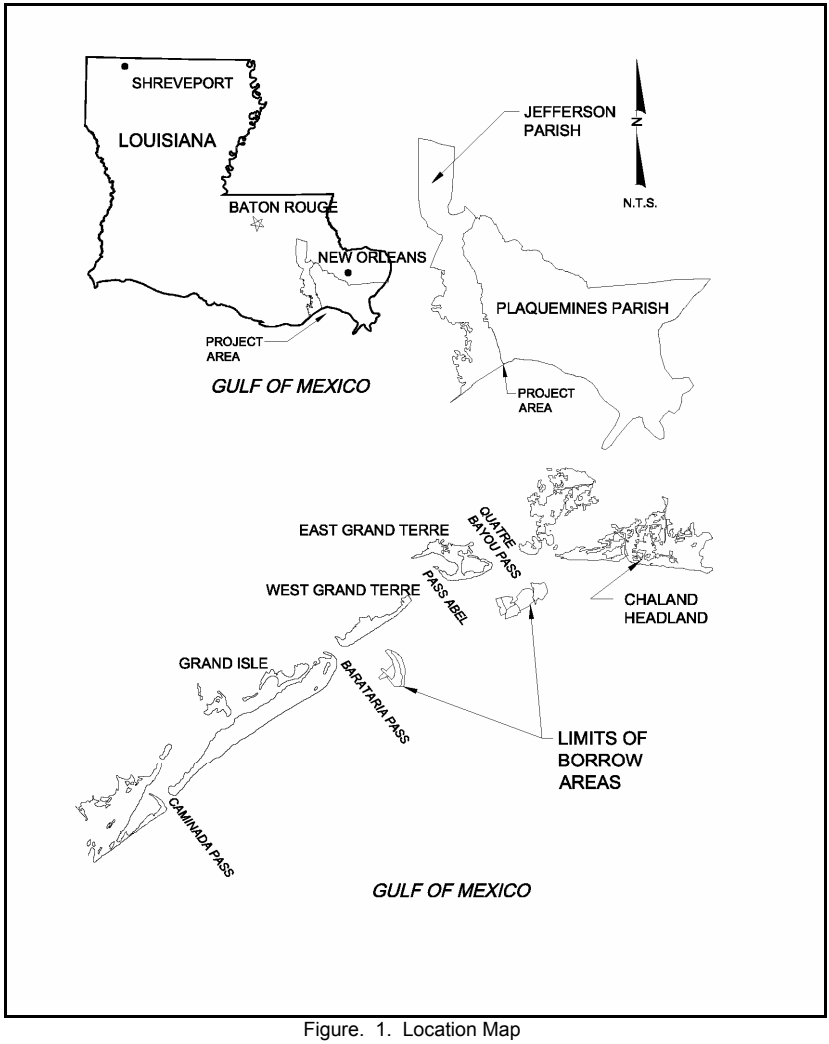

Figure. 1. Location Map

Some of the design challenges encountered with restoring Louisiana's barrier islands include: 1) Estimating the performance of a beach nourishment project that is composed primarily of sand, when the historic shoreline recession rates reflect the recession of islands that can contain upwards of 60% clay/silt material; 2) A relative sea-level rise rate (RSLR) that is amongst the highest in the world; 3) CWPPRA projects require a one-time construction event and a 20-year project life.

DYNAMIC MORPHOSEDIMENTARY PRINCIPLE

Mann and Thomson (2003) showed that at Holly Beach, Louisiana, the cross-shore profile changed from a sandy bottom to a silty bottom at approximately -1.7 m, MHW (-4 feet, NAVD). This change in the characteristic bottom sediment coincided with a break in the slope of the cross-shore profile. Above this elevation, the profile was a concave upward curve of the approximate form $y=ax^{2/3}$. Below this elevation, the profile was relatively flat with a slope of 1 Vertical (V):400 Horizontal (H). They suggested that this break in slope be used as the bottom of the active profile height for sand.

Campbell *et al*. (2006, in press) developed this concept further with a dynamic morphosedimentary model (DMSM) that explains the high shoreline recession rates observed along Louisiana barrier islands. The DMSM proposes that the beach is composed of a thin veneer of sand that overwashes the island during large storms. This exposes the marsh sediment that comprises the bulk of the barrier island. As the island erodes, silts and sand are released. The silts are transported offshore while the sand is concentrated along the beach face due to natural sorting by wave action. This reforms the sand veneer but in a more landward location. However, the high percentage of silt in the body of the island results in large shoreline recession until the sand veneer reforms. Overwash of the barrier islands also deposits sediment in the back marshes, which helps to counteract elevation loss due to relative sea level rise.

The construction of a wide sandy beach along the front of barrier islands should result in lower shoreline recession rates because the erosive marsh will not be exposed following storm events. However, overwash of the island is still important to maintain the back marsh elevation. While the constructed elevation of the beach can be minimized to allow overtopping during low frequency storm events, the additional width of the beach can reduce this effect. Therefore, nourishment of the back marshes is an integral component of the project.

PROJECT GOALS

Louisiana barrier islands constructed under coastal restoration authorities are evaluated differently from beach nourishment projects constructed elsewhere in the nation. The majority of current shoreline restoration projects in Louisiana are not evaluated using a typical cost-benefit analysis (USACE, 1999) that assesses infrastructure protection and recreational use. The CWPPRA program recognizes that these islands provide important habitat for flora and fauna, and protection against storm surge and wave action. Project performance of the restoration of barrier islands under CWPPRA is typically evaluated using a Wetland Value Assessment (WVA) (Environmental Work Group, 2002). The Barrier Island Community Model is used to determine the WVA and assess the performance of barrier island projects in providing fish and wildlife benefits.

The Barrier Island Community Model includes variables such as the percent of subaerial area that is classified as subtidal, intertidal, supratidal, or dune habitat, the percent of each subaerial area that is vegetated, percent vegetative cover by woody species, marsh

edge interspersion, and beach/surf zone features (Environmental Working Group, 2002). The definitions of these various habitat classes are shown in Table 1.

Table 1. Habitat Description (after Williams and Sweeney, 2005)

Habitat	Description
Dune	≥ +1.02m MHW (+5 feet, NAVD[1]) The portions of the dune platform anticipated to be above the specified elevation.
Supratidal	≥ +0.21m, MHW (+2 feet, NAVD) to < 1.02m, MHW (+5 feet, NAVD) Beach berms and portions of the fore and back slope of the dune within the elevation range. Also includes primary retention/ containment dikes for the period anticipated to remain in the elevation range. Generally includes major portion of the marsh platform until the time dewatering and consolidation reduce the elevation to intertidal.
Gulf Intertidal	≥ -0.5m, MHW (0 feet, NAVD) to < +0.1m, MHW (+2.0 feet, NAVD) Gulf side beach slope / shallow open water.
Bay Intertidal	≥ -0.50m, MHW (0 feet, NAVD) to < +0.1m, MHW (+2.0 feet, NAVD) Bayside elevations including vegetated wetlands, flats, and bayside open water areas.
Subtidal	≥ -0.96m, MHW (-1.5 feet, NAVD) to < -0.5m, MHW (0 feet, NAVD) or 300m (1,000 feet) bayward of the 0.0m contour Shallow Open water bayside area only.

1. NAVD – North American Vertical Datum

The application of the Barrier Island Community Model poses a challenge from an engineering design perspective, as the design must optimize different habitat area classifications along with the cost. The variables within the model are estimated for each year over the project life to develop expected benefits, which allows various alternatives to be compared.

Interestingly, the Wetland Value Assessment method does not address island integrity, which was omitted from the model to ensure that project evaluation is consistent with the CWPPRA authority (Environmental Work Group, 2002). It was considered that island integrity was an important factor in project design but that erosion of the barrier island would be reflected in a loss of habitat acreage and thus not needed to characterize habitat quality. However, an additional project goal for the East Grand Terre and Chaland Headland Projects is that the island would not be breached within the 20-year project life and that the minimum dune elevation would not be less than 0.7m, MHW following any storm event.

BEACH FILL DESIGN

The project design steps for East Grand Terre (Coastal Planning & Engineering, Inc, 2005) are outlined here. East Grand Terre was chosen because it involves a more

complex shoreline development than the Chaland Headland and provides some additional insight into the geomorphic changes that occur along Louisiana barrier islands.

East and West Grand Terre used to be one continuous island until a significant breach occurred in the center of the island in 1926, creating Pass Abel (Figure 2). The creation of Pass Abel has influenced shoreline retreat of the adjacent shorelines. After the creation of Pass Abel, the west end of East Grand Terre eroded until Bay Melville was open to the Gulf of Mexico. Since 1988, a spit has been extending in a west-northwesterly direction, enclosing Bay Melville once again. Shoreline recession calculations of the eastern side of the island were therefore used to analyze volume losses. The growth of the western spit enabled the development of a move complete sediment budget.

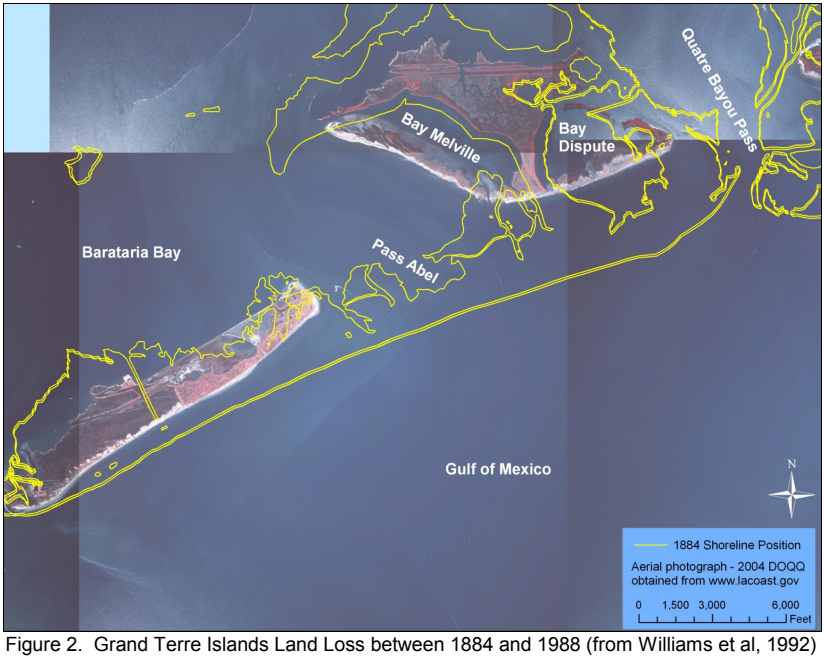

Figure 2. Grand Terre Islands Land Loss between 1884 and 1988 (from Williams et al, 1992)

The shoreline along the eastern side of East Grand Terre retreated at a rate of 8.0 m/year (26 feet/year) between 1884 and 1988 (CPE, 2005). The shoreline recession rate has increased in the last few years and has averaged 11.4 m/year (38 feet/year) since 1996. The island has narrowed significantly and small breaches have occurred in several areas along the island.

Typically shoreline recession rates can be correlated to volumetric erosion. However, while shoreline location data is available back to 1884, profile data along East Grand

Terre was only available from surveys conducted in November 2000 and August 2002. A comparison of volumetric changes and shoreline changes did not provide a strong correlation, possibly due to the short record. Therefore, volumetric change was developed along the island by multiplying the shoreline change by the active profile height and distance between profiles (CPE, 2005).

The top of the active profile was determined for each profile line from the August 2002 survey. Thus, there was a varying active profile height along the length of the island. The bottom of the active profile height was taken as the change in slope of the profile. The change in slope was observed to be approximately -1.5 m MHW (-5 feet, NAVD) at East Grand Terre.

Once the volumetric changes along the island had been established, a sediment budget was developed to distinguish between alongshore and cross-shore losses of silt and sand, as well as shoreline recession due to relative sea-level rise and overwash. By accounting for the various components, a longshore sand transport curve could be developed to assist in the prediction of sediment transport following construction.

The first element in developing the sediment budget was to estimate the sand percentage along East Grand Terre. The reformation of the western end as a spit like feature suggested that this end of the island should have a higher sand content than the western end. Vibracores collected along the dune crest and within the back bay showed that the west end of the island was composed primarily of sand (90%) while the east end of the island contained only 40% sand. It was assumed that the silt fraction would be transported offshore while the sand was transported in a longshore direction or overwashed into the back bay.

The second element was to determine the volumetric "loss" due to RSLR. Shoreline recession due to RSLR does not result in a net volume change in the cross-shore profile but simply a redistribution of the sediment across the profile. However, the volume change calculated from shoreline recession must be reduced to account for relative sea level rise prior to calculating the volume change used to develop the sand littoral transport rate. It was estimated using the Bruun rule (1962) that relative sea level rise results in a shoreline recession of 1.4 m/year (4.6 feet/year). The break in slope was used as the bottom of the active profile for application of the Bruun Rule.

The third element within the sediment budget was overtopping. The average crest elevation along East Grand Terre is low, approximately 0.6 m, MHW (3.4 feet, NAVD). As a result, sediment is transported over the top of the island by waves during storm events. This is the primary mechanism of island rollover. The landward movement of sediment conserves some sediment within the system despite the landward shift of the shoreline. The volume change, calculated from shoreline change, must be reduced to account for the conservation of sediment within the system. An estimate of overwash along the islands was estimated using the November 2000 and August 2002 profile data.

An overwash estimate of 4.8 m^3/m/year was developed by comparing the November 2000 and August 2002 surveys.

The sand conservation equation allows the littoral transport for adjacent reaches to be estimated using Equation 1.

$$LT_{out} = \Delta V_{measured} * \% \, sand + LT_{in} - V_{overwash} - V_{RSLR} \quad (1)$$

where LT_{out} = Littoral transport out of the reach; LT_{in} = Littoral transport into the reach (LT_{out} from updrift cell); $\Delta V_{measured}$ = Volume change calculated based on shoreline change; % sand = Factor applied to volume change to account for silt in island composition; $V_{overwash}$ = Volume of overwash = 4.8 m^3/m/year x reach length; V_{RSLR} = Volume associated with shoreline retreat due to relative sea level rise;

Typically a nodal point (a point of zero net sediment transport) is chosen as the starting point for the solution of Equation 1. It is easier to locate an area with zero net sediment transport than the transport rate elsewhere along the island (such as at the end) because the nodal point can usually be identified by the location with the highest shoreline recession rate. This was close to the eastern end. Aerial photograph interpretation, wave modeling, and analysis of the coastal processes along the island also suggested that there was sediment transport towards both ends of the island and that the nodal point was located close to the eastern end of the island. Solution of equation 1 along the length of the East Grand Terre provided the longshore sand transport rate shown in Figure 3.

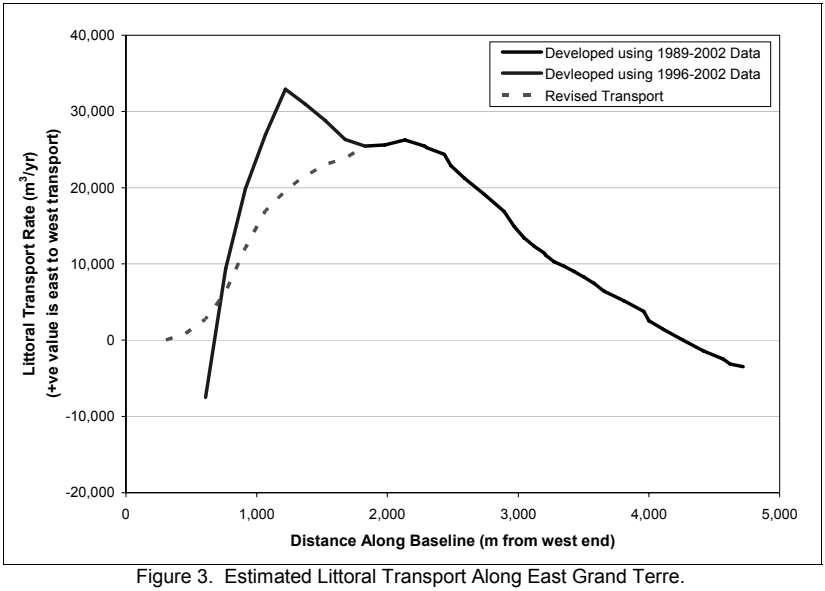

Figure 3. Estimated Littoral Transport Along East Grand Terre.

Figure 3 shows that two data sets had to be used to develop the longshore sand transport rate. This was due to limited available data along the west end. The general trend of sediment transport increasing from the east end towards the center of the island and then decreasing along the western spit agrees with features observed on the island. First, the spit feature at the eastern tip of the island is very small, which suggests that sediment transport is relatively low at this point. Second, the island has a distinct change in orientation where the western spit formation started and the sediment transport rate starts to decrease just around this bend. Third, the growth of the western spit would indicate a decreasing longshore transport rate. Lastly, the sediment transport at the western tip of the island must be small because a small tidal channel connecting Bay Melville to Pass Abel remains open. The tidal currents in this channel are weak because the tidal range in the project area is only 0.3m and Bay Melville is only 1.5 km^2. Therefore, a large sediment transport rate would be expected to overwhelm the tidal currents and close the pass.

A beach nourishment cross-section has two components: the design section, which is the fill volume required at TY20 to meet the project goals, and advanced nourishment, which is the sacrificial portion of the fill that will erode over the 20-year project life. This two-section design is in accordance with the National Research Council (1995) recommendations. The advanced nourishment volume can be estimated using the sediment budget. The design section was determined by cross-shore modeling using SBEACH (Larson *et al*. 1990).

Cross-shore modeling was used to determine the minimum design dune width necessary to meet the project goals. The cross-section has a 1V:30H landward slope, which is similar to the landward sides of the existing dunes. A 1V:45H seaward construction slope was adopted based on the post-construction profile slope attained during the Holly Beach Sand Management Project, Louisiana (CPE, 2003) using similar fill material. The constructed dune elevation was set to +1.3 m, MHW (+6 feet, NAVD), based on cross-shore modeling. The +1.3 m, MHW dune elevation is above the 20-year return period surge elevation (+1.2 m, MHW) estimated for target year 20 (includes relative sea level rise over the life of the project).

The USACE (2001) estimated that island breaching occurs when the overtopping rate exceeds 0.05 m^3/s (1.7 cfs), and this standard was used to evaluate the likelihood of breaching. The modeling suggested that the maximum overtopping rate will be 0.02 m^3/s (0.6 cfs) so breaching is not anticipated during a 20-year storm event.

The cross-shore modeling showed that the design cross-section to achieve the project goals is a 27.4m (90-foot) dune crest. The design cross-section is shown in Figure 4. This corresponds to an average fill density of 160 m^3/m (64 cy/ft) or a total of 708,750 m^3 (927,000 cubic yards) of beach fill over the 4.42 km (14,500 feet) project length.

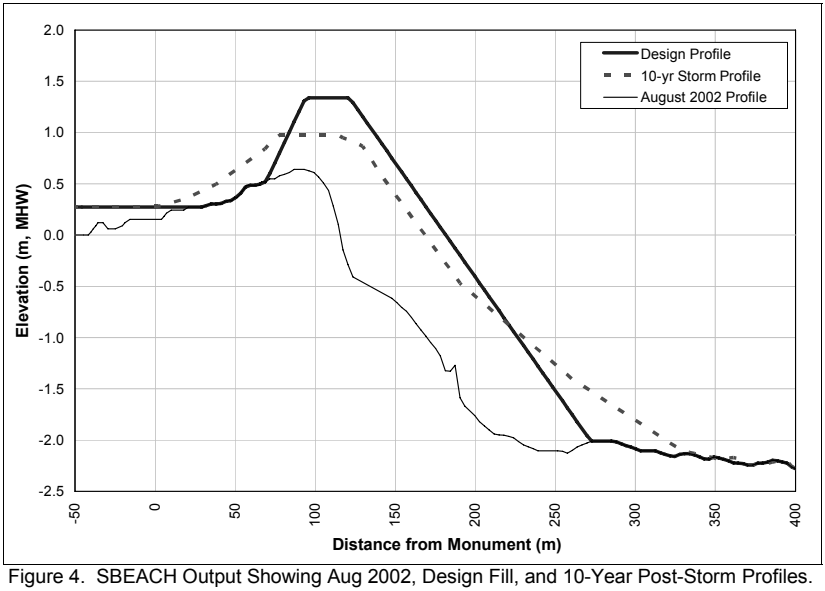

Figure 4. SBEACH Output Showing Aug 2002, Design Fill, and 10-Year Post-Storm Profiles.

The Generalized Model for Simulating Shoreline Change (GENESIS) (Hanson and Kraus, 1989) was used to optimize the fill placement. Since GENESIS assumes a fixed active profile height and does not account for mixed sediment, GENESIS was calibrated using the sediment transport rate developed through the littoral budget. The total volume of beach fill proposed at East Grand Terre is 1,163,000 m^3 (1,521,000 cubic yards).

While the design fill is placed uniformly along the project length to ensure that the design section is in place throughout the length of the project life, the advance nourishment is placed non-uniformly to account for the varying longshore transport. Since the eastern end of the island has a higher longshore transport rate, while the western side has been accretional, more than 80% of the advanced fill was placed on the eastern side of the island.

MARSH FILL DESIGN

The average elevation of the existing marsh platform was determined to be -0.2 m, MHW (+1.1 feet, NAVD) based on measurements taken along three survey lines. Ideally, to maximize intertidal functions, the marsh platform should have an elevation between mean high water and mean low water over the majority of the project life. Eustatic sea level rise will result in the mean high and mean low water levels rising an estimated 0.061 m (0.200 feet) over the 20-year project life (NRC, 1987). The marsh platform will drop in elevation as a function of three processes: geologic subsidence of the region; consolidation of the marsh fill material; and consolidation of the underlying soils due to the weight of the marsh fill.

The geologic subsidence is independent of the project and will occur under the without project condition as well as the with project condition. It is considered to be constant at 0.009 m/year (0.0292 feet/year) (NRC, 1987) over the 20-year project life. The extent of marsh fill consolidation will be a function of the classification properties of the borrow material (sand, silt, clay & organic content), the thickness of the lift and the placement techniques (i.e., dredge pipe discharge velocity and flow, containment and cell capacity). The soil underlying the marsh fill will consolidate due to the addition of an overburden (the constructed marsh). Settlement of the underlying soils is a function of the consolidation properties of the underlying soils, the area of the applied load and the amount of fill above the water table (surcharge load). Marsh settlement curves (Figure 5) were developed to help determine a target elevation for marsh construction that would maximize the time that the marsh elevation was intertidal during the 20-year project life.

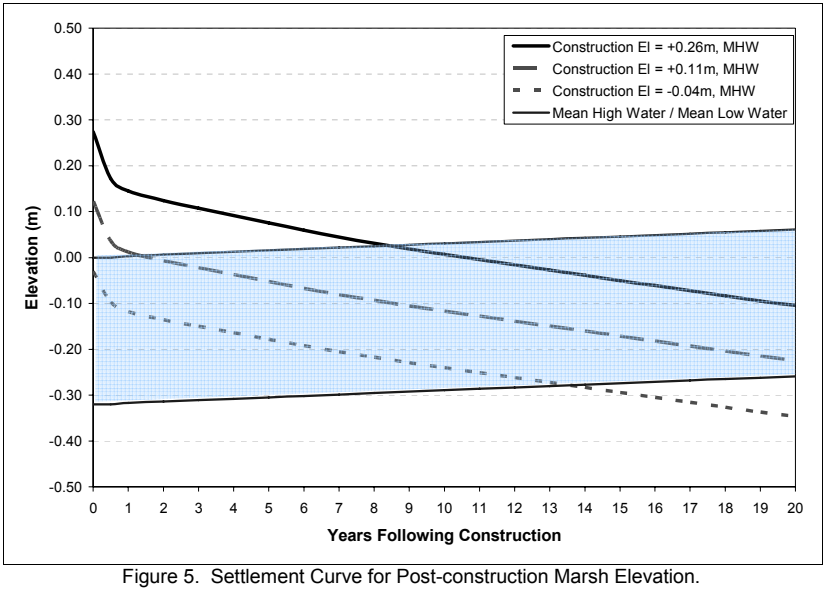

Figure 5. Settlement Curve for Post-construction Marsh Elevation.

The total volume of marsh fill proposed for the East Grand Terre Project is 1,390,000m^3 (1,817,000 cubic yards).

Chaland Headland Construction

The Chaland Headland Project bid package included the placement of 1,370,000m^3 (1,792,200 cubic yards) of beach fill, 726,500 m^3 (950,200 cubic yards) of marsh fill, along with other ancillary items. Bids were opened for the Chaland Headland Restoration (BA-38-2) CWPPRA Project on 19 July, 2005, just 41 days prior to landfall of Hurricane Katrina. It was envisioned that there would be changes to the project area between the development of the bid documents and the start of construction of the

project. Therefore, the project specifications allowed for changes to the project layout following the pre-construction survey. This proved useful as the eye of Katrina passed only 15km (9 miles) to the east of Chaland Headland forming a second breach and causing additional beach fill loss.

Shoaling of the contractor's access route (Robinson Canal) during the passage of Hurricane Katrina was not anticipated, necessitating additional permitting, oil infrastructure investigations, and oyster lease coordination. Hurricane Katrina also destroyed the closest monument requiring that this be reset prior to the start of the pre-construction survey.

Chaland Headland is similar to many Louisiana barrier islands in that there is significant oil infrastructure in and around the island. Photo 1 shows a pre-construction aerial of the project site. The dashed red line highlights the location of the "W" Canal, which was dredged to allow access to oil infrastructure. As can be observed in Photo 1, the "W" Canal has resulted in several breaches forming in the island, as the shoreline receded. The breaches then exacerbated the shoreline retreat.

Photo 1. Pre-Construction Aerial of the Chaland Headland with A Trace of the "W" Canal.

A field study was performed to determine the tidal currents flowing through the western breach and whether the pumping rate of a 30" cutterhead dredge would be sufficient to close this breach without having to resort to a structural solution. Several oil pipelines traverse the project area and it was preferred to avoid a structural closure solution. The analysis suggested that pumping rate of sand would be sufficient to close the breach. This was confirmed during construction as the contractor (Weeks Marine, Inc.) closed the breach with no difficulty.

Locating/ identifying sand resources in Louisiana has, and will continue to pose a challenge, to barrier island restoration. A borrow area (Quatre Bayou) was identified by Coastal Planning & Engineering, Inc approximately 5 km (3 miles) southwest of the project site. The Quatre Bayou borrow area was located in water depths of -4.0 m to -5.8 m, MHW (-12 to -18 feet, NAVD). The sand portion of the borrow area varied in thickness from 1 to 2.5m (3 to 8 feet) thick but was covered by a silt overburden that was between 0.5m and 3m (1 to 9 feet) thick. A portion of the overburden was used to construct the marsh, while the sand layer was used as beach fill material. The beach fill material was fine sand (0.11 mm) and had a silt content that ranged from 4% up to 40% percent. Similarly, the silt layer contained varying percentages of sand (5% to 50%).

The varying content of the different types of fill provides both a unique opportunity and challenge at the same time. It is useful to have a sandy marsh from both an ecological and engineering perspective. A sandy marsh will limit the amount of settlement that the marsh will experience and provide additional resistance to wave attack if it were to become exposed. A varying sand content in the borrow area also results in varying fill type through the marsh, which can add to habitat diversity. However, a varying sand content in the marsh fill material makes it challenging to achieve a specific elevation range. During the bidding process, dredge contractors indicated their concern for the tolerance of ±0.1 m (±0.3 feet) required in the specifications. This tolerance was required because the project performance relies on achieving the target marsh elevation. The contractor was capable of meeting the target elevations along the project though some sections of the marsh were sand and higher while other sections contained less sand and were slightly lower in elevation. Post-construction marsh surveys were conducted 30 days following the placement of fill in a given section to allow time for dewatering and initial settlement.

The Chaland Headland specifications required that the beach fill contain less than 15% silt and that the beach be constructed without confinement. The majority of the beach fill along the project length fulfilled the silt requirement. However, the beach fill at the far eastern end contained a higher volume of silt even though the vibracores and seismic records suggested that the section of the borrow area being dredged to supply the sand was the cleanest in the entire borrow area. The volume of overburden exceeded the volume required for marsh creation so the overburden was sidecast back in to the borrow area. It is hypothesized that the previously sidecast marsh fill material was flowing into the area being dredged, increasing the silt content. The depth of cut in this area was also the deepest in the entire borrow area creating a steep slope for the silty material to flow down.

The contractor experienced higher levels of sediment loss out of the template than originally anticipated (Johnson, 2006). It appears that there is a threshold silt level at which the silt acts to suspend the sand fraction and results in the sand being deposited further away from the discharge pipe. At Holly Beach, the silt content was less than 15%, the mean grain size was 0.13 mm, and the fill flowed approximately 100 m to 200 m (300 to 600 feet) from the discharge. At the Chaland Headland the average silt content was 15% to 30% with a grain size of 0.11 mm but the contractor used dikes up to 400 m (1,200 feet) long. The specifications allowed the contractor to request a change in the construction slope during the project. The construction slope was changed to 1V:30H above -0.2 m, MHW (1.0 feet, NAVD) and 1V:90H below -0.2 m, MHW. The Contractor reduced their losses when using this slope.

Overall, the Chaland Headland project was very successful with over 1,906,000m^3 (2,493,000 cubic yards) of beach fill placed. Approximately 706,000m^3 (924,000 cubic yards) of marsh fill placed. Photo 2 shows a photograph of the project area.

Photo 2. Aerial Photograph Mid-way during Construction.

Considerations for Future Louisiana Barrier Island Restoration Projects

Future projects may experience difficulty in finding sand deposits with low silt contents. Therefore, future projects may have to use borrow areas that have a high silt content. The dynamic morphosedimentary model (Campbell *et al*. 2006) will allow for prediction of barrier island performance with higher silt contents. Another option that is currently being investigated is the use of sand from the Mississippi River (Finkl *et al*. 2006).

The size of the marsh should be developed following delineation of the borrow area. Many of the borrow areas in Louisiana have an overburden that needs to be removed to access the sand deposit. Cost optimizations can be achieved by basing the size of the marsh on the volume of overburden to be removed. The marginal cost of pumping the overburden to a containment cell may be worth the additional benefits accrued under the project performance assessment method rather than sidecasting the material.

Monitoring of these projects and applying lessons from the projects, such as the Chaland Headland Project, are an important element of the design and construction process.

CONCLUSION

The Louisiana barrier islands provide an important first line of defense from waves and storm surges. Several challenges arise when designing and implementing restoration projects for these islands. The challenge of predicting shoreline performance can be overcome with the use of sediment budgets, which can differentiate between sand and silt movement and assess losses due to relative sea level rise. Marsh elevations can be designed and constructed to maximize project benefits. Construction specifications can be flexible to accommodate changes immediately prior to or during construction. Lastly, project monitoring and adaptive management must be implemented to meet the challenges of the design and construction of Louisiana's barrier islands.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support of the Louisiana Department of Natural Resources and NOAA National Marine Fisheries Service for their support of these projects.

Abstract: Two instrumented platforms were deployed for over two months on the shallow (<8 m depth) Atchafalaya shelf in Spring 2006. The instruments monitored wave, sediment and current evolution throughout the entire water column. High-resolution measurements of near-bottom velocity and suspended sediment concentration show clearly the formation and erosion of fluid mud layers in response to wave and current forcing.

INTRODUCTION

The processes governing the interaction between surface waves and sediment bed on muddy coasts are poorly understood. Two classes of possible dissipation mechanisms have been proposed: friction-type direct bottom interaction, characterized by a direct transfer of energy from the wave-field to the soft muddy bottom, and indirect processes, where the energy transfer is mediated by additional mechanisms, typically related to the formation of near-bed high density suspensions. The former has been modeled using various approximations of mud rheology (percolation, Carter et al., 1973; poro-elastic beds, Yamamoto et al., 1978; Yamamoto and Takahashi, 1985; visco-elastic beds, Jiang and Mehta, 1995; Jiang and Mehta, 1996; visco-plastic beds, Mei and Liu, 1987; viscous Newtonian fluid mud, Dalrymple and Liu, 1978; and others). The latter, much less studied, might involve surface-lutocline wave interactions (Jamali et al. 2003a; Jamali et al. 2003b), and development of instabilities of the Kelvin-Helmholtz/Holmboe type (Mehta and Srinivas, 1993; Traykovski et al., 2000).

Laboratory and field experiments (Chou et al., 1993; Foda et al., 1993; Sterling and Strohbeck, 1975) suggest that realistic models of wave propagation over muddy sea beds have to address the issue of mud-state variability. The character of the muddy sea bed (and its wave-dissipation efficiency) changes in response to the sea state. Smooth and hard consolidated muds are no more dissipative than sandy bottoms (e.g. Lee, 1995). However, wave action can liquefy bottom sediment (Chou et al., 1993; Foda et al., 1993) producing fluid or soft, unconsolidated muds with non-Newtonian behavior and significantly higher wave dissipation efficiency (e.g. Gade, 1957). Catastrophic mud liquefaction events have also been recorded, leading to massive submarine landslides (Sterling and Strohbeck, 1975).

Modeling and laboratory research efforts suggest a number of possible mechanisms for wave-mud interaction. The range of applicability of each of these mechanisms is largely unknown, mainly due to the scarcity of coherent field observations of wave, currents and cohesive sediment dynamics. Here, we present a field experiment effort to assess the importance of wave-sediment coupling through high-resolution measurements of wave-current-sediment motion in the first 1 mab (meter above the bottom).

INSTRUMENTATION AND FIELD SITES

The instruments were deployed on the Atchafalaya shelf in spring 2006. Figure 1 shows a map of the Atchafalaya shelf with the approximate sediment distribution and the location of the instruments. The large amount of sediment discharged in the area by the Atchafalaya River is typically carried to the West by the nearshore currents associated with the prevailing winds and the Gulf of Mexico loop current. The instruments were deployed for approximately 2-week periods, interrupted by a short break for maintenance and data downloading. Two deployment configurations are shown in Figure 1. The experiment was timed to coincide with the part of the year characterized by the energetic waves and high river discharge.

An example of instrument cluster mounted on a deployment tripod is shown in Figure 2. The instruments include a high-resolution, downward-looking Sontek PC-ADP (pulse-coherent acoustic Doppler profiler) and an upward-looking RDI ADCP (acoustic Doppler current profiler). The PC-ADP provided high-resolution information of water and sediment motions in the first 50 cmab by sampling pressure and three-dimensional current velocity at 2 Hz, in 17 bins 3-cm high, continuously for the entire duration of a deployment (approximately 14 days). The ADCP measured current and directional wave motions in the upper water column in 30-cm bins. In addition to the directional wave information provided by the ADCP, waves were measured continuously a 2 Hz using a redundant array of pressure sensors (one independently logged and one on each of the profilers).

Near-bed sediment dynamics was monitored using OBS (optical backscatterance sensors). A pencil-beam 600-kHz ABS (acoustic backscatter sensor) was used to

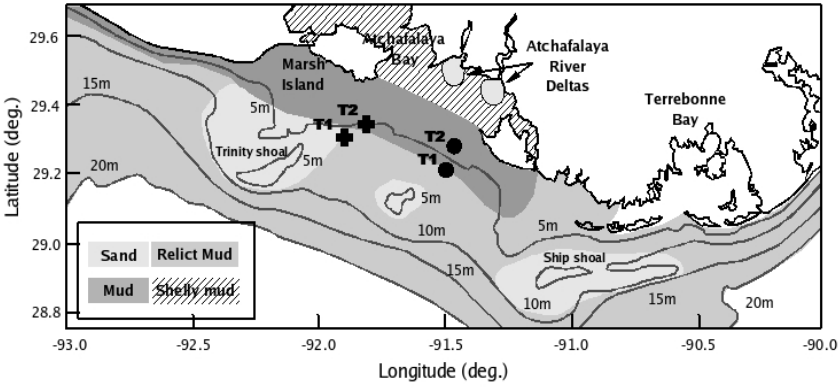

Fig. 1. Facies map of the surficial sediments of the Atchafalaya inner shelf, Louisiana, USA (Neill and Allison, 2005). Relict sediment units sometimes are mantled by thin (less than 20-cm thick), ephemeral modern mud. The locations of the two tripods (T1 and T2) are marked with circles / crosses.

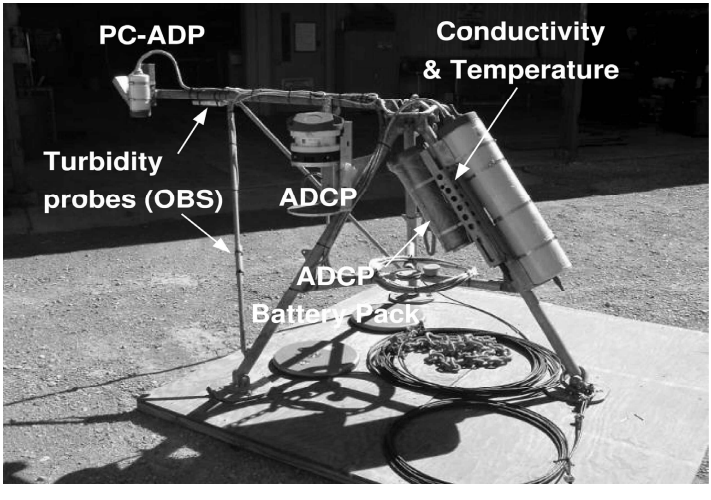

Fig. 2. An image of one of the instrument clusters (tripod T1, see Figure 1 for deployment configuration) before deployment, showing the type and mounting of the instruments. The height of tripod is approximately 1.2 m.

monitor the position of the bottom and strata formation. At this frequency the ABS signal can penetrate the lutocline and provide clear image of the evolution of fluid-mud layers. Later in the experiment, a Sequoia Scientific LISST (system for in-situ measurement of particle size and distribution) was also deployed. Additional details about the experiment can be found in Jaramillo et al. (2007).

OBSERVATIONS

The instruments were deployed in several configurations along the 5-m isobath on the shelf fronting Atchafalaya Bay (Figure 1). During the approximately 2 months of deployment, February through March 2006, a number of cold fronts swept through the area, accompanied by increased wave and current activity. Here we compare sediments response to two energetic storms that occurred March 8-13 and March 19-21 2006.

Figure 3 shows a summary of PC-ADP observations (T1 cluster, circles in Figure 2) of wave-current-sediment evolution during the storm of March 8-13 2006. At that time the tripods were distributed in the cross-shore configuration (circles in Figure 1). The storm was fairly energetic, with waves reaching over 2m significant height at the peak of intensity. The behavior of the spectral band with frequencies larger than 0.2 Hz (short waves, sea) and the band with frequencies below 0.2 Hz (long waves, swell) is typical of a frontal passage on the Atchafalaya shelf. Figure 3a shows the evolution of swell and sea wave height. Short waves are generated locally and show a fast response to intensifying surface winds. They spin up quickly to about 0.75-m height and stay at that level for the entire duration of the storm. The swell band develops more slowly and becomes significant only within a narrow 2-day time window (March 09-11). At the peak of activity the total wave height exceeded 2 m. The nearshore velocity profile is well correlated to the wave activity, reaching a peak of about 40 cm/s at about 50 cmab (Figure 3b) at the peak of activity.

Current profile observations (Figure 3b-c) also reveal indirectly details of sediment behavior. The two lines in Figure 3c mark the position of two surfaces: the continuous one represents the surface which reflects strongest the PC-ADP acoustic signal, which also coincides in some cases to an elevation characterized by very strong shear (e.g. March 11, in Figure 3c). The dashed line marks the position where the horizontal velocity becomes zero. The latter represents the hydrodynamic bottom, the deepest level where current and wave motion can penetrate. For the sake of argument we will define this level as the “solid bottom”. The solid bottom position coincides with the strongest reflector during the calm periods. There are though two events during which these two lines separate. These are fluid-mud events of about 15 cm thickness, lasting for about half a day to a day. Significant values of horizontal velocities recorded with the layer (that is below the strongly reflecting surface) suggest that both events are mobile fluid-mud layers, in one instance (March 11) moving against the average direction of the upper column layers.

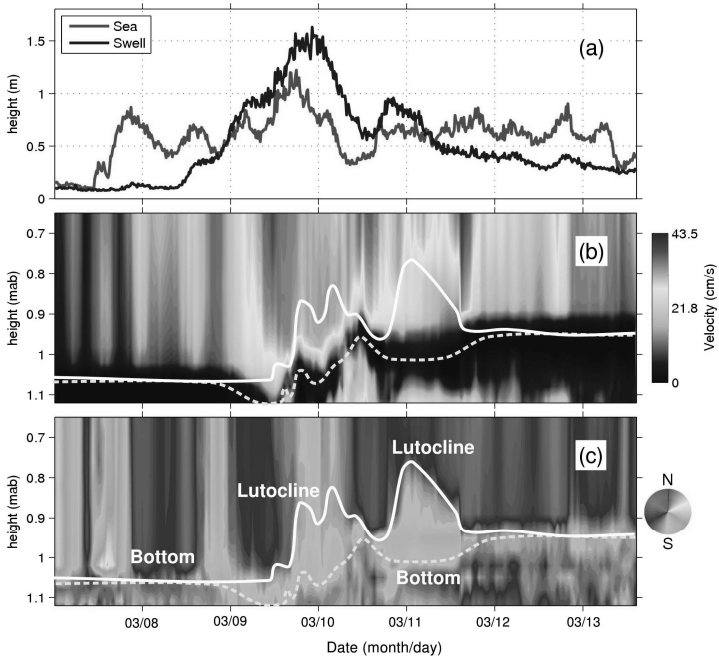

Fig. 3. PC-ADP observations of fluid mud formation during the storm of March 8-13 2006. Deployment configuration is shown in Figure 1 (circles). a) Wave heights (blue/dark line -- swell, frequency < 0.2 Hz; red/light line -- seas, frequency > 0.2 Hz). b) Velocity profile, magnitude. c) Velocity profile, direction. The continuous line marks the position of strongest-reflection surface (bottom and lutocline). Dashed line marks the position of zero horizontal velocity (hydrodynamic bottom).

The sequence and timing of the fluid-mud events with respect to wave and current activity suggests that the first event was due mainly to bed-liquefaction (note the dip in the position of the hydrodynamic bottom at the beginning of the storm) whereas the second event was probably a combination of resuspension-advection event. It is interesting to note here that T2 observations (not shown) do not indicate significant fluid-mud layer formation.

Figure 4 shows a summary of PC-ADP observations (T2 cluster, crosses in Figure 1) during the second storm March 19-21 2006. The ocean was calm throughout the first three days shown, but in the 4th day stronger winds associated with a fast approaching front produced relatively large high-frequency seas (Figure 4a) and strong northward currents (Figure 4b, direction not shown). Swell energy began to increase March 20, indicating that the peak of the storm occurred sometime on March 20-21. At the peak

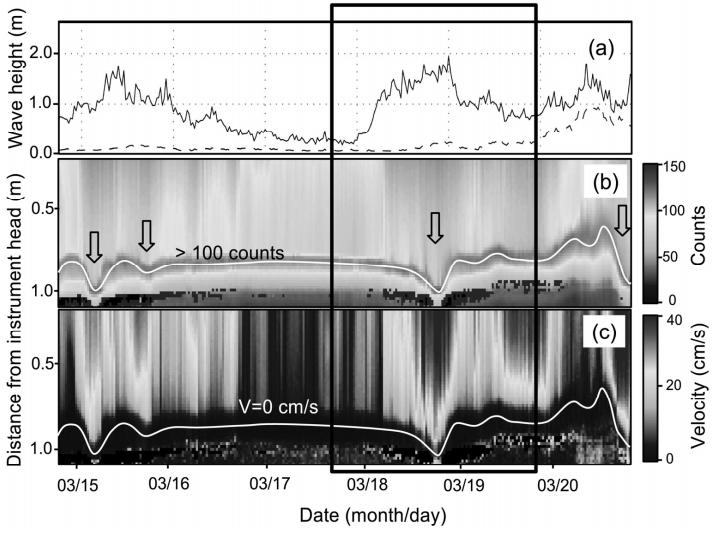

Fig. 4. PC-ADP observations of fluid mud formation and erosion (arrows) in response to currents. Deployment configuration is shown in Figure 1 (crosses). a) Wave heights (continuous line – swell, frequency < 0.2 Hz; dashed line -- seas, frequency > 0.2 Hz) b) Intensity of instrument return signal; white line contours the highest-return surface. c) Horizontal current velocity; the position of zero velocity (hydrodynamic bottom) is indicated by a white line. Details of the lutocline evolution within the time interval marked by the black rectangle are shown in Figure 5.

of wave activity the total significant height was just under 2 m, with mean near-bottom currents of approximately 40 cm/s. Sediment response as recorded (indirectly, as before) by the downward looking PC-ADP is shown in Figure 4c.

Figure 4b shows the strength of the PC-ADP acoustic signal return. Higher intensities (large "count" number) indicate strong reflection. The position of the maximum return strength is marked by a white line. In contrast to the March 8-13 observations, fluid-mud layers cannot be identified here based on periods of disagreement between the position of the hydrodynamic bottom (white line in Figure 4b) and the strongest reflecting surface (white line in Figure 4c), as they are virtually identical. It the reflecting surface is a lutocline, this observation suggests that these fluid mud layers are high density and stationary (in contrast to the first example). That this is indeed the case as supported by coherent, lower-frequency ABS measurements which can penetrate deeper into the layers. A 2-day detail of ABS observations (corresponding to the enclosed rectangle in Figure 4) is shown in Figure 5. The location of the "solid" bottom is relatively constant at approximately 1.1 m from the instrument head. The high-density suspensions during this event have typical suspended sediment

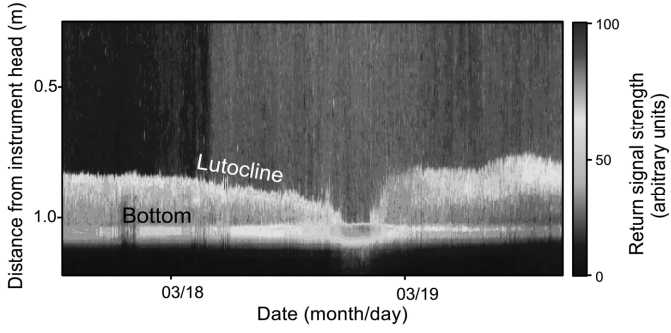

Fig. 5. Detail of ABS observations of near-bottom sediment showing the evolution of the lutocline during a current pulse (see Figure 4, time interval enclosed by rectangle). The PC-ADP signal is absorbed within the thick fluid mud layer and only the lutocline remains visible (Figure 4b). The 600-kHz ABS signal penetrates the lutocline and reveals the bottom location. The thickness of the fluid-mud layer is clearly visible.

concentrations in the range of 5-10 kg/m^3 and thickness of 15-20 cm. In this example, the maximum thickness is approximately 30 cm.

The pronounced difference between the dynamics of fluid muds in the two cases discussed is remarkable, given that the forcing conditions (waves and currents) are quite similar in magnitude. The fluid-mud layer events also differ significantly in duration.

Due to a dominant westward circulation on the shelf, the observation site (crosses in Figure 1) receives a large percentage of the sediment discharged inside the bay by the Atchafalaya River. During periods of calm (weak currents and waves) sediment settling contributes to the formation of fluid-mud (Allison et al. 2000; Sheremet and Stone 2003; Sheremet et al. 2005). While these processes likely play an important role in the formation and time span of the fluid mud events seen in Figure 4, their origin is not entirely apparent since they were present when the tripods were deployed at this site. However, Figure 4-5 illustrates their typical behavior in response to the near-bottom circulation. Increased turbulence at the lutocline level associated with high near-bed mean current velocities (arrows in Figure 2a) result in increased sediment resuspension and an erosion of the lutocline. Observed maximum velocities coincide with a minimum of fluid-mud thickness. In fact, the exception of the second event (evening of March 15th) all high velocity events shown in Figure 2 completely erode the fluid-mud layer. When the current weakens, the layer reforms likely through sediment settling. These processes can be recognized to affect also fluid muds at the first site (Figure 3, corresponding to circles in Figure 1). The last fluid mud event in Figure 3 (March 11) ends abruptly, being swept away by a strong current pulse which occurred about noon on March 11 (Figure 3b).

CONCLUSION

The experiment produced a significant amount of information. At the time of the writing of this account, the datasets resulting from this experiment are still being processed. Large segments of data have yet to undergo quality control procedures, while others have yet to be explored. We have not yet attempted any modeling of the processes observed. From the data analyzed so far, however, an interesting picture emerges of the interaction between hydrodynamic and cohesive sediments sediment processes.

Field and laboratory observations of wave-current-sediment interaction in muddy environments suggest that sediments respond to changes in the sea state on temporal and spatial scales similar to those characteristic of wave-current evolution. This hypothesis, however, have not been thoroughly verified in the field.

In an effort to fill in this gap, we deployed clusters of instruments to monitor water and sediment motions in the entire water column, with increased resolution in the first meter above the bottom, on Atchafalaya Shelf, an area dominated by cohesive sediments. The small subset of the data collected shown here illustrates the rapid response of fluid muds to variations in near-bed mean currents (shown here for the first time in field observations and a high resolution).

We identified at least two different types of fluid-mud dynamics, one associated with mobile, the other with stationary layers. These regimes seem to be associated with similar hydrodynamic forcing, but they appear to have different origins and generating mechanisms. In both cases, near-bottom currents appear to be the triggering factor in erosion processes.

Phenomena discussed here are only a small subset of the many processes that characterize the strong coupling between sediment and water-column hydrodynamics. Other aspects, which will be discussed elsewhere, include changes of consolidated mud state due to energetic wave-fields, triggers for gravity flow of the fluid muds, and the feedback these changes have on wave propagation processes.

ACKNOWLEDGEMENTS

The work presented here was supported by the Office of Naval Research and the Naval Research Laboratory at Stennis Space Center. We are indebted to Dr. T.K. Holland for valuable discussions, encouragement and instrumentation. Field data was collected with expert support by the Field Support Group in the Coastal Studies Institute, Louisiana State University, lead by Captain Steve Dartez.

Abstract: Although basic causes of barrier island retreat and area loss of Louisiana Barrier Islands are known, there has been limited success in unraveling and quantifying how these processes interact to generate observed barrier island behavior. Processes that make up a conceptual-analytical dynamic morphosedimentary model (DMSM) are evaluated here using a process-based numerical model. The model is specifically used to investigate the morphodynamic behavior of non-cohesive (sand) and cohesive (fines) sediments under different hydrodynamic conditions (mild waves, cold fronts and tropical storms). The primary modeling focus is on the seaward limits of sand deposition during high wave energy conditions and the selective deposition of different grain sizes (sand, clay and silt, and mixed sediments) during low wave energy conditions.

INTRODUCTION

Louisiana barrier islands are naturally dynamic features that change in shape (length, width, height, and planform), geographic position, and orientation in response to waves,

relative sea-level rise (RSLR), sediment supply, winds and currents. Although basic causes of barrier island retreat and area loss are known, there has been limited success in unraveling and quantifying how these processes interact to generate the observed barrier island behavior.

Processes that make up a conceptual-analytical dynamic morphosedimentary model (DMSM), developed originally by Campbell (2005), are evaluated here using a process-based numerical model. The DMSM simplifies barrier island retreat, volumetric losses and recovery from the barrier islands into four basic stages. These four-stages include: Stage 1, the initial (relatively stable) state of barrier beaches, which is generically described in terms of a thin sand cap that sits on top of mixed (sand, silt and clay) deltaic sediments that also underlie relatively wide backbarrier marshes. Stage 2, when the sand cap is eroded (removal of protective beach), cohesive deltaic sediments are uncovered on the upper shoreface and marshes are exposed to the direct attack of Gulf waves. These sediments are easily eroded and transported offshore causing large shoreline retreat. Stage 3, loss of the protective beach and sandy cover on the upper shoreface which promotes erosion of deltaic sediments and marsh sediments. Sandy sediments are also released to the system, as the shoreline retreats. Stage 4, sandy sediments reworked in Stage 3 eventually deposit as a sand cap on top of the deltaic sediments and form a protective beach in front of residual marsh that is now much reduced in area, setting the stage for another morphosedimentary cycle of erosion (Figure 1).

The DMSM is based on some assumptions that include a limiting depth of sand transport that is shallower than for most open coast sandy environments and is linked to a 'break of slope' in the nearshore profile. This 'break of slope' is a noticeable transition between steeper, sandy profiles and flatter, muddy profiles and is commonly observed offshore Louisiana's barrier islands. The DMSM also assumes that the largest part of barrier island retreat is caused by erosion of fine sediments in post-storm periods, after the sandy beach is eroded away (by overwash and longshore transport processes) and the mixed sediment core of the island (silts and clays) are exposed to Gulf waves. It assumes that, while the sandy sediments remain above the break of slope, the fine grained sediments are deposited offshore of the break of slope. Many of the assumptions of the DMSM are supported by the existing literature as shown in table 1, while other assumptions have not been properly investigated in the field. The DMSM is commonly used to calculate volumetric requirements for barrier island restoration projects in Louisiana, as described by Campbell *et al.* (2006).

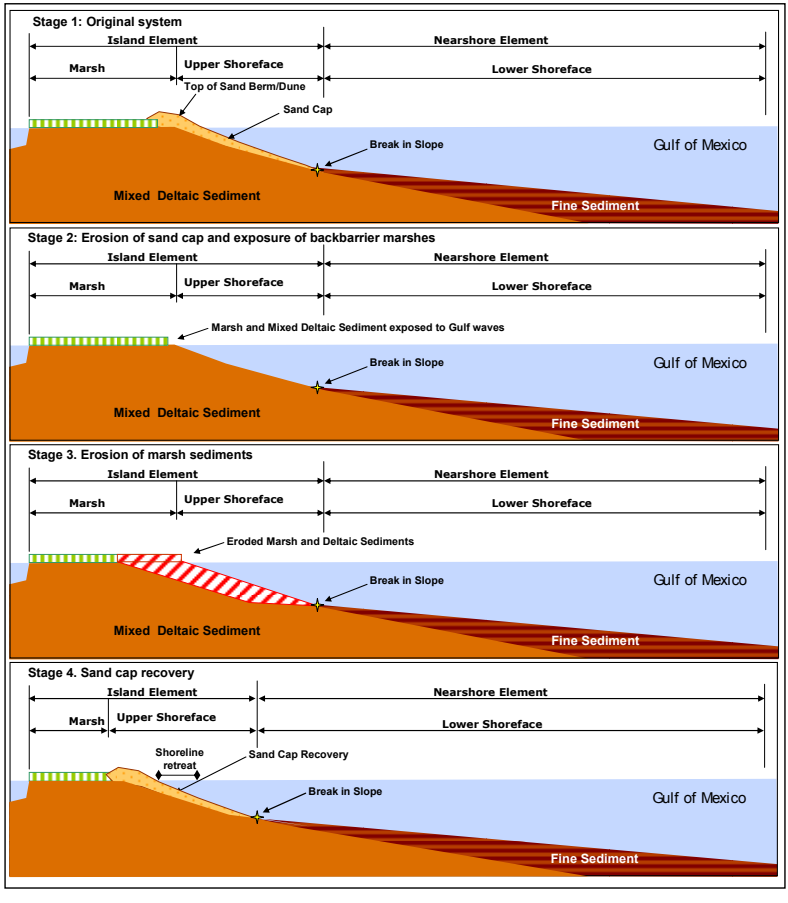

Figure 01: Four stage conceptual model that diagrammatically shows erosion, shoreline retreat, and recovery processes for Louisiana's barrier islands (after Campbell, 2005).

In this investigation a process-based numerical model (Delft3D), is used to investigate the morphodynamic behavior of non-cohesive (sand) and cohesive (fines) sediments under different hydrodynamic conditions (mild waves, cold fronts and tropical storms). The primary focus is on the seaward limits of sand deposition during high wave energy conditions and the selective deposition of different grain sizes (sand, clay and silt, and mixed sediments) during low wave energy conditions. The model setup is described in the following paragraphs.

Table 01: DMSM processes that are reported in literature and field research

NUMERICAL MODEL SETUP

To investigate the physical processes causing barrier island retreat, a simplified representative bathymetry is used. For this, the bathymetry of Shell Island is deduced from the Atlas of Sea-Floor Changes (SFC) (List *et al.*, 1994), slightly simplified, and implemented on a computational grid. For the model boundary conditions, two representative high wave energy conditions are distinguished to determine the limits of sand transport and a low wave energy condition to describe selective deposition of different grain sizes.

The model cases have constant water levels that depend on representative storm surge levels. Tides and winds are disregarded because focus is given to wave-driven processes. The cases were run in a cross-shore (two-dimensional-vertical – 2DV) model to investigate cross-shore morphodynamic processes contributing to barrier shoreline retreat. The same wave cases were also run in an area (two-dimensional-horizontal – 2DH) model to investigate alongshore processes contributing to barrier shoreline retreat, however due to space limitations we concentrate in the 2DV results.

2DV Model

The 2DV model has a cross-shore length of 10 km. For the barrier island bathymetry, representative cross-shore dimensions of Shell Island are selected. Because this former barrier island had a typical Louisiana barrier island profile with a break in slope around -2 m and an island height of 1.5 m. The depth profile (Figure 2) is obtained from of the Atlas of Sea-floor Changes (List *et al.*, 1994). From the break in slope (-1.7 m) to the top of the island (+1,5m) (*b*) a Dean Equilibrium profile for sandy beaches is applied with the concave shape of $h(y) = Ax^{2/3}$ (Dean, 1991). Backbarrier dimensions obtained from Campbell (2005) include elevation of +1,0 m with a width of approximately 250 m.

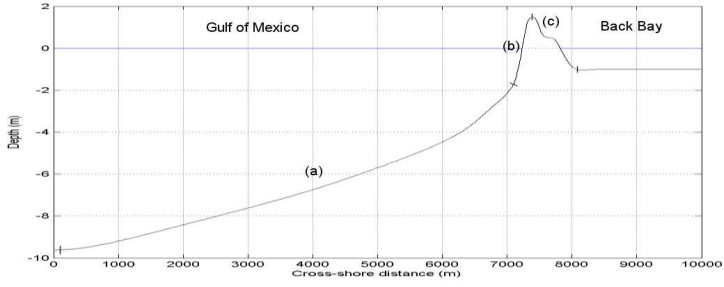

Figure 2. Cross shore profile use din the 2DV model.

Boundary Conditions

The wave climate and associated barrier island erosion in Louisiana is largely dependant on the occurrence of two typical events: 1) cold fronts and 2) tropical storms. The remaining days of the year are characterized by a relatively mild wave climate. Therefore, the modeling is divided into three cases: (1) cold front conditions, (2) tropical storm conditions and (3) average wave condition. Simulated waves approach the coast at normal angles.

To obtain representative wave heights, periods and duration, an analysis of existing wave data (USACE WIS station 132) was performed. For representative cold-front conditions, an active cold front year is chosen (1993). In this year, 24 cold fronts occurred (if a cold front is defined as an occasion where the wave height > 1m). Five major cold fronts (producing waves from 90-315°) were selected to determine the average wave height, period and duration of a typical cold front event. The resulting wave condition is shown in the Table 2. For representative tropical storm conditions, waves during Hurricane Lili (2002) were used. Wave information was provided by CPE (2003). Average wave height, angle and period calculated for the the Barataria shoreline, based on wave statistics from 1976 to 1995 calculated by CPE (2003) were used for the average wave case (Table 2).

Tides and relative sea-level rise were not considered in our short-term simulations. Therefore, filling of tidal basins is not considered and a constant water level boundary is prescribed at the seaward and back bay boundary. The height of the water level boundary depends on the storm surge during the three events (see Table 2).

For the first case (cold front conditions), a level of 0.4 m is selected (barrier island non-submerged), because water levels during cold fronts are relatively low (Pepper and Stone, 2002). During Hurricane Lili (2002), a storm surge of 2.0 m was observed (Alfegame and Cañizares, 2005). A storm surge level of 2 m used in the second case implies that the island is submerged during this event.

Table 2: Wave cases simulated.

	H_0	T_m	*Storm Surge*	*Duration*
Representative cold front conditions	2.0 m	6.1 s	0.4 m	60 hrs
Representative tropical storm conditions	3.0 m	10.0 s	2.0 m	24 hrs
Average wave conditions	0.8 m	5.0 s	0.0 m	1 week

Main Model Parameters

The overall regional Mississippi Delta sediment stratigraphy is fine-grained. Grain sizes range from fine sand to clays or silts. Although the distribution of the sediments is quite complex, numerous studies by the state and federal survey are available which link sediment characteristics to the depositional environments. Sand-rich environments include distributary channels, inner-shelf shoals, recurved spits and tidal inlets (Kulp *et al.*, 2005). Clay and silt-rich environments are predominantly found offshore and in the shallow backbarrier environments. According to measurements by CPE (2003) for the Barataria shoreline, a representative grain size is approximately 150. This value will be used in the model simulations for the sand fraction.

In the Delft3D-version used in this study, no distinction is made between clay and silts. All grain sizes smaller than 63 are assumed to be 'mud' and to behave as cohesive sediments. The morphodynamic behavior of these cohesive sediments is determined by the mud transport parameters, following the approach of Parteniades (1965). In this computation, erosion of mud (E) occurs once the critical bed shear stress for mud erosion (= 0.7 N/m2 in this study) is exceeded by the acting maximum bed shear stress ( ). A user specified erosion parameter (M = 2 Kg/m2/s) determines the speed of erosion. The amount of deposition (D) is controlled by the concentration in the near bottom computational layer and the fall velocity (= 0.0005 m/s) of the mud particles. All mud transport occurs by means of suspended load, as cohesive sediment transport usually does not occur in the form of bed load.

The value for of $\tau_{cr,d}$ is calculated with a relationship between critical shear stress and bulk density (ρ_b), that was derived during laboratory experiments performed on artificial mixed sediment beds (*e.g.* Mitchener and Torfs, 1996). The other mud transport parameters are left on their default value (cited above), because no calibration data specific to mud erosion is available. A sensitivity analysis was conducted to evaluate the effect of these parameters on model results. Sand transport calibration factors SusW and BedW are initially set at a commonly used value of 0.2 based on previous modeling experience (*e.g.* Walstra *et al.*, 2005).

A simulation timestep of 12s was used, for the 2DV model this resulted in a maximum courant number $\sigma = 9.8$, stable in Delft3D implicit scheme. Other model parameter settings include the horizontal and vertical eddy viscosity and diffusivity. Delft3D-FLOW with the roller extension computes the viscosity each time step and is therefore

self-regulating. The horizontal eddy viscosity and diffusivity are set at an initial value of 0.1 m²/s. For the 2DV cases, the vertical exchange of momentum and mass in is computed using the vertical eddy viscosity and diffusivity calculated with the k-ε turbulence model (WL Delft hydraulics, 2003).

Other model parameters not mentioned here are left on their default value. For the model spin up time, 240 min. is chosen, based on the fact that virtually all water level and velocity profile oscillations dampen after four hrs. The hydrodynamic simulation time is 20 hrs. For the morphodynamic development a morphological scale factor was defined for each wave case separately.

RESULTS AND DISCUSSION

Sand transport and profile change during storms

During cold front conditions, the magnitude of the velocity varies considerably in the nearshore zone (Figure 3). The highest flow velocities are observed from x = 7100 m to the shoreline, in the shoreward part of the breaker zone. The magnitude of the flow velocity has a maximum value of 0.18 m/s near the bed. In the top layers of the nearshore breaker zone (x = 7000 m to x = 7200 m), another slight increase in flow magnitude is observed. The flow circulates in the nearshore breaker zone, caused by wave-induced mass flux driving an onshore current in the top water layers, with a returning offshore current in the bottom layers. The return current is stronger than the shoreward current causing net erosion of the upper part of the profile (Figure 4).

During tropical storm conditions, higher wave-induced flow velocities are observed from x = 7200 m to x = 7400 m, above the island because the island is overtopped by a storm surge of 2 m prescribed in the model (Figure 3). The magnitude of the currents is larger in the top layers (1.8 m/s), decreasing slightly towards the bed. Lower flow velocities at the bed can be attributed to bed friction. Once the flow passes the island, it reduces gradually to a value of around 0.25 m/s. All flow is directed onshore in this case. There are no offshore directed or circulating currents. This is consistent with literature (*e.g.* Pirello, 1992) that also suggests a lack of return current when the storm surge level exceeds the island level during storm conditions. The localized water level set-down due to the increase in flow velocity above the island (Bernoulli's law) is clearly visible in Figure 3. Behind the island the flow slows down and the water level rises again.

During tropical storm conditions, both bed load and suspended load transport are directed onshore. This occurs because transport follows the water flowing over the island (See Figure 3). Secondly the suspended load reaches a high peak of $7.5 \cdot 10^{-3}\,m^3/ms$ on top of the barrier island, about 175 times the value of the offshore suspended sediment transport in the first few cases. This is caused by the high flow velocities and concentrations on top of the island. It also shows that, in this case, bed load is almost negligible compared to the suspended load transport. The suspended load transport starts far offshore near x = 4000 m with a relatively low value of $2 \cdot 10^{-3}\,m^3/ms$ and rapidly increases at approximately x = 7200 m, where the steeper slope area begins.

During the cold front the bed load is generally positive, indicating that it is onshore directed, following the wave direction. This transport is mainly caused by wave asymmetry and wave streaming, which in this case is larger than the offshore transports current related transports (explanation: prevails over the bed load transport, asymmetry and streaming acts on both suspended and bed-load! as it just a hydrodynimcal forcing). Highest values of bed load transport (up to $1.2 \cdot 10^{-5}$ m^3/ms) are observed in the breaker zone. The suspended load, on the other hand, is offshore directed following the net direction of the flow. The magnitude and volume of the suspended load is significantly larger than the magnitude of bed load. The highest peak value reaches ($4.2 \cdot 10^{-5}$ m^3/ms) occurs in the nearshore area where maximum sediment concentrations and flow velocities are observed.

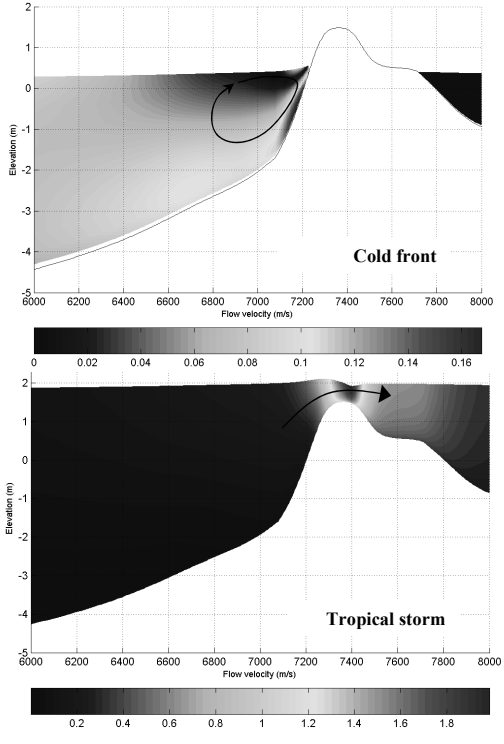

Figure 3: Predicted 2DV wave-induced flow velocities for the cold front (top plot) and the tropical storm case (bottom plot). For wave case parameters see table 1.

The offshore directed suspended load transport causes erosion in the upper part of the profile and deposition in the lower part of the profile. The morphological development

shows resemblance to a 'classic storm erosion profile', as described in Stive and Battjes (1984).

Two observations mark the area where sand deposition takes place. The main deposition takes place between x = 6900 and x = 7130 m near the break in slope (Figure 4). A very thin sand sheet is also deposited on the inner shelf from a distance of x = 5500 m (Figure 4). About 50% of the offshore sand transport is deposited between of 1 m and 2 m water depth, the remaining 50% are deposited between -2 m and -4.9 m water depth. The outer limit of sand transport is located at about 1500 m offshore from the shoreline. The main reason why sand transport takes place at a large offshore distance is the low shelf gradient that causes waves to break and dissipate energy far offshore thus causing seabed remobilization.

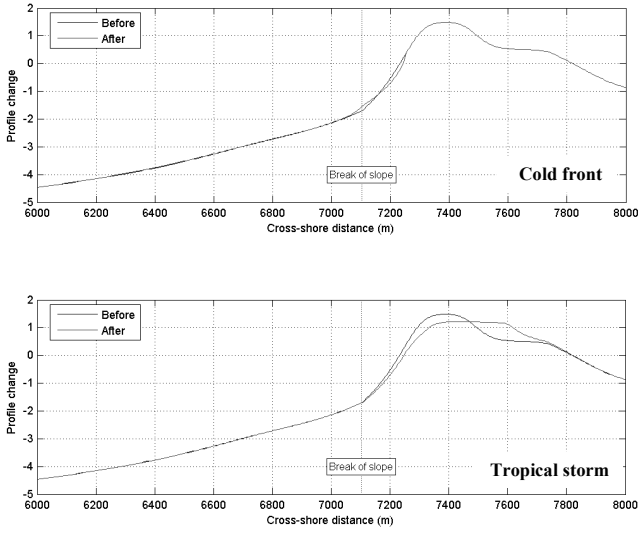

Figure 4: Profile change for a sandy barrier island during cold fronts (top plot) and tropical storm (bottom plot) conditions.

Within the context of the DMSM that considers the break in slope at around – 2 m as the seaward limit of sand transport, it is concluded that, according to profile modeling results, most of the sand is deposited at or near the break of slope, although sand can be transported beyond this limit during cold fronts. It remains unclear how much of this sand is transported onshore during the post-storm period since this is a difficult

phenomenon to evaluate by modeling. Experience with Louisiana beach profiling and sediment sampling, however, tends to indicate that most of the sandy sediments are confined to relatively shallow areas of the profile suggesting significant post-storm recovery. Phenomena of wave dissipation by fluid muds (*i.e.* Sheremet and Stone, 2003) were also not included in the model. For example, if wave energy were reduced by 50%, current velocities would be greatly reduced and the limit of offshore sand transport would be shifted landward to shallower water.

Movement of sand and mud during average wave conditions

During average wave conditions higher flow velocities are observed in the shoreward part of the breaker zone. The flow velocity is 0.14 m/s near the bed, decreasing in offshore and upward directions. In the top layers of the breaker zone a slight increase in flow magnitude is observed. The largest difference with the cold front case is the width of the surfzone and resulting offshore extent of higher bottom flow velocities. The surfzone in this average wave case is narrower resulting in currents confined to a zone much closer than in the cold front case. The circulating flow pattern of shore-directed current in the model upper layers and offshore-directed currents in the bottom layers is, however, similar to that of the cold front (Figure 3).

Suspended transport magnitudes and directions are shown in Figure 5, top plot. Negative values indicated offshore directed transport and positive values indicate onshore transport. Highest values of bed load transport (up to $0.8 \cdot 10^{-5}$ m^3/ms) are observed in the breaker zone. All bed load transport is directed onshore in the direction of the wave propagation. Sand suspended load is negative (offshore), because the net offshore directed currents at the surf zone transport the suspended sand particles offshore. The magnitude of the suspended load is significantly larger than the magnitude of bed load, reaching a peak of $3 \cdot 10^{-5}$ m^3/ms in the breaker zone. All suspended sand load deposits at the seaward boundary of the breaker zone (Figure 5). Mud transport is directed to the offshore at the breaker zone (x = 6700 m to x = 7100 m in Figure 5) with peak values reaching $2.7 \cdot 10^{-6}$ m^3/ms. Offshore of the breaker zone, onshore mud transport is observed, reaching to an offshore distance of x = 4000 m with a maximum magnitude of $6 \cdot 10^{-6}$ m^3/ms (Figure 5). Onshore transport seems illogical, with a mean offshore directed flow at the surf zone. However, the mud transport outside of the surf zone is dependent on other processes, like wave streaming, a process that occurs near the bed in the direction of wave propagation causing locally observed onshore transport.

Erosion and sedimentation of sand and mud fractions can also be visualized in Figure 5. Mud erosion takes place on a larger cross-shore length than in the sand erosion. On the other hand, erosion and sedimentation of the sand portion is confined to the surf zone and reaches higher magnitudes. The main observation concerning the mud deposition is that it occurs on a significantly longer length scale. It starts slightly (20 m) more offshore and is stretched out in offshore direction almost twice as far as the sand deposition to an offshore distance of about 6600 m. The deposition of mud occurs mostly offshore of the break in slope and the deposition of sand occurs landward of the break in slope in water depths shallower than –2 m (Figure 5) under average wave conditions.

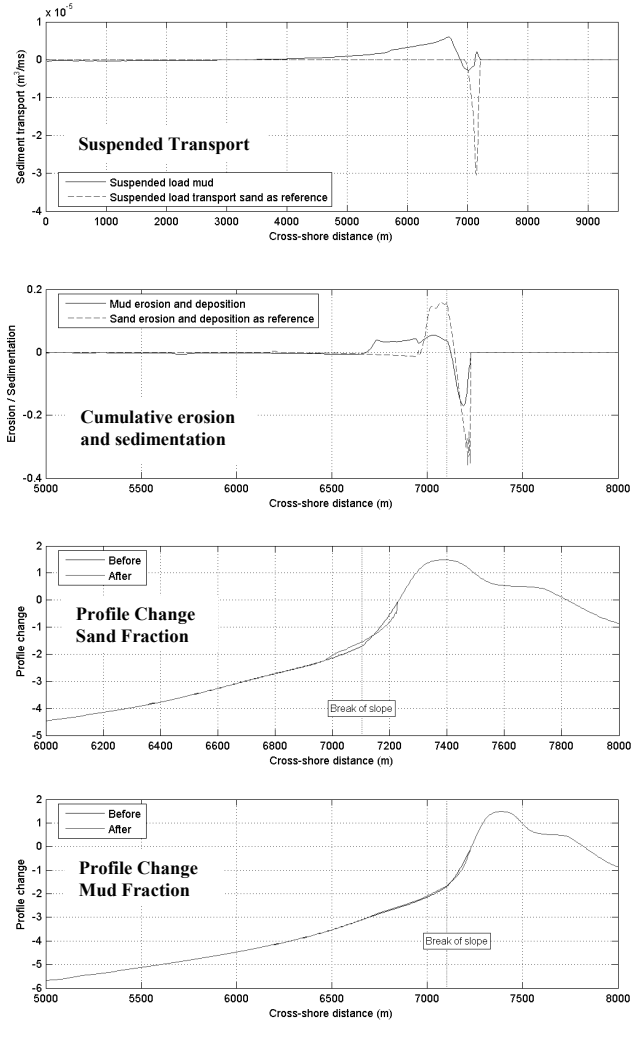

Figure 5: Suspended sediment transport, cumulative erosion and sedimentation and profile change during average wave conditions.

Simulations with sand and mud mixtures

The previous discussion compared the behavior of a sandy versus a muddy barrier island under average wave conditions. Delft3D-FLOW also allows for a computation with

multiple sediment fractions in the same model. Current model limitation is, however, that no interaction between the sand and mud particles is considered. The sediment types are assumed to erode and deposit independently. A new feature in Delft3D-FLOW is using a 'transport layer'. When this feature is enabled, Delft3D computes the volumetric changes of specified sediment types (*e.g.* 'sand' and 'mud') in a user specified top layer ('transport layer'). The relative volumetric percentage change ('fraction change') is computed for each time step. This enables observations of selective erosion and deposition of different sediment types.

Model simulations are performed with mixed sediment of the types 'sand' and 'mud'. Initial volume fractions are equally distributed (50%-50%). Because the sand and mud are assumed to behave morphologically independently and their behavior was discussed previously, we will only describe the sediment fraction change with time in this section. The volume fraction change of mud in the top sediment layer for 7 days of morphological development under average wave conditions is shown in Figure 6. Initially the volume fraction of mud is 50% (light green). The mud fraction changes significantly between x = 6700 m and x = 7200 m where the erosion and deposition was observed. In the rest of the model area the mud fraction remains 50%.

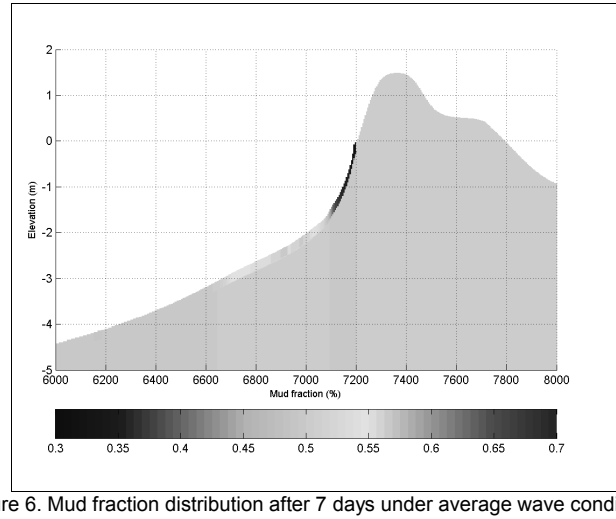

Figure 6. Mud fraction distribution after 7 days under average wave conditions.

The model results of this case show that, under average wave conditions the selective deposition of mud is located further offshore than that of sand. This selective deposition pattern can cause spatial variations of sediment grain sizes, creating zones in which certain sediment types dominate. Domination of certain sediment grain sizes could subsequently control profile characteristics (*e.g.* gradients), providing an explanation for the presence of a break in slope in Louisiana. An interesting detail is that, in these model

results, the fraction transition zone (the zone where the mud dominated volume fraction turns into sand dominated) lies close to the often observed break in slope in Louisiana (± 2 m), where sediments transition from sand to mud according to previous sediment sampling (*i.e.* CPE 2003).

CONCLUSIONS

The numerical modeling conducted here provides valuable insights into the processes behind the conceptual-analytical Dynamic Morphosedimentary Model (Campbell 2005). This study provides, for the first time, a possible process-based explanation for the prominent break in slope commonly observed in beach profiles obtained along the Louisiana Coast.

Sand transport is mainly directed offshore in cases where the island is not overtopped. When the island is submerged (strong tropical storms and hurricanes) there is no significant offshore sand transport and sand is transported onshore by overwash processes. Under low wave energy conditions, mud is transported offshore and deposition occurs offshore of the break of slope, while sand deposition is mostly confined to the surf-zone. Simulations of the behavior of mixtures of sandy and muddy sediments in the model predicted a transition between the sand-mud depositional zones around the break of slope, similar to what is observed in the field.

The selective transport and deposition of mud and sandy sediments can be explained by considering the mechanisms behind the sediment transport of the two sediment types. Outside of the surf zone, offshore directed suspended mud particles deposit. Simultaneously, onshore bed load transport of sand causes erosion in this zone. These processes combined increase the mud content in this area. In the inner surf-zone to the beach the onshore bed load of sand dominates, this process combined with mud erosion in suspended mode, causes the mud content to decrease significantly in the surf zone. Model results are, however, sensitive to variation of the mud transport parameters. Varying these parameters mainly affects how far offshore the muddy sediments move but do not result in mud deposition above the break of slope, in turbulent surf-zone waters.

Abstract: In an effort to more accurately evaluate sand volumes that are potentially available for coastal restoration, high-resolution geophysical data were collected followed by detailed geotechnical investigations in two study areas in Ship Shoal Complex. Interpretation of vibracores helped to identify about 13.2 x 10^6 m^3 of clean sand (<5 % silt: D_{50} ~0.20 mm) in portions of Ship Shoal Blocks 88 & 89. Geotechnical exploration of South Pelto Blocks 12 & 13 also identified mostly clean sand (D_{50} grain size 0.15 to 0.2 mm) with less than 5% silt in upper stratigraphic units 4 to 6 m thick. Combined volumes of three closely spaced potential borrows amounted to approximately 21.6 x 10^6 m^3. Comparison of sediments on emergent barrier islands with those on the drowned barrier known as Ship Shoal indicates a high level of compatibility for restorative work on Isle Dernieres and Lafourche delta coastal segments.

INTRODUCTION

The degradation of mainland Gulf shorelines and deltafront barrier islands jeopardizes the vitality of strategic economic and biological resources (including aquatic habitat) as well as the protection of coastal residents from surge flooding. Unless significant efforts are made to restore barrier islands and coastal wetlands, Louisiana will lose productive and protective islands (beaches, dunes) and marshes (Penland *et al.* 2005; Campbell *et al.* 2005, Hester *et al.* 2005, Laska *et al.* 2005). The primary objective of mitigation is to attempt to stabilize the landward retreat and the disintegration of the barrier islands by adding sediment to the system and translating the barriers into various types of modified morpho-sedimentary environments (Khalil *et al* 2006). To promote large-scale restoration (*e.g*. beach nourishment, dune development, marsh creation) of the Louisiana coast, appropriate sand resources must be identified and quantified as these restoration efforts primarily depend on the emplacement of sand and suitable sediment to build up barrier and deltaic systems (Khalil *et al* 2006). Large accumulations of offshore sand provide a valuable resource for the supply of volume-needs required for building the first line of defense in shore protection. These integrated beach-dune-marsh environments, which themselves comprise a fragile coastal system, can protect the immediate Louisiana hinterland by absorbing wave impacts and diminishing the effects of surge flooding.

Restoration of Louisiana's barrier islands requires large volumes of sand (for beaches and dunes) and mixed sediments (for marshes). Such large volumes can only be obtained from offshore sources and consequently, marine sand searches originally focused on reconnaissance surveys in efforts to ascertain general trends in sediment distribution on the seabed. Preliminary or reconnaissance efforts (Suter *et al.* 1991; Kindinger *et al.* 2001) discovered potential sand sources in a range of depositional systems that include spit platforms, delta sheet sands, ebb-tidal deltas, distributary mouth bars, and distributary-channel fills, and inner shelf shoals. Although these types of deposits occur on the continental shelf, a single large deposit is attractive for island restoration because it is cohesive, not dispersed, and not covered by muddy overburden. According to the MMS (2004), estimates of total sand volumes comprising Ship Shoal are on the order of 1.2×10^9 m^3. The drowned barrier sediments range from very fine- to medium-grained sand that in volume are comprised of 112×10^6 m^3 in the shoal crest, 430×10^6 m^3 in the shoal front, and 640×10^6 m^3 within the shoal base. Kulp *et al.* (2001) estimate that there is an additional 123×10^6 m^3 of sand in distributary channel fill deposits under the shoal. As promising as these volumes estimates are, based on reconnaissance data, more detailed studies of the Ship Shoal sands indicate a scope that is limited by subsea infrastructures placed by the oil and gas industries, environmental concerns over dredging, and variability of deposits in the shoal. Nevertheless, these sediments are required for restorative purposes, as indicated below, however constrained by competing needs and restrictive human activities.

Detailed high resolution geophysical surveys were undertaken in 2003 by the Environmental Protection Agency and Louisiana Department of Natural Resources to address archaeological and hazard concerns in South Pelto Blocks 12 &13(CEI, 2003a)and Ship Shoal Blocks 88 & 89 (CEI, 2003b). Such surveys are also pre-requisite

for MMS to grant leases for future dredging in these areas. In both these study areas about 26 square kilometers of the area was covered by high resolution geophysical surveys (bathymetric, seismic, sonar, and magnetic) along approximately 660 line kilometers of track lines almost all trending east-west with a spacing of 50 m and a few north-south with 900 m spacing (CEI, 2003 a & b). Odom Echo Trac DF 3200 bathymetric system, EdgeTech 500 kHz side scan sonar, Edgetech Geostar SB 512i subbottom profiler, and Geometrics 880 cesium magnetometer were used for the geophysical surveys with C-Nav globally corrected GPS for positioning in both these areas (CEI, 2003a & b). CEI (2003a) identified twelve sonar targets and eleven magnetic clusters in the South Pelto Blocks 12 &13. This paper reports offshore geotechnical investigations in the South Pelto Blocks 12 &13. The results of this geotechnical investigation summarize the deposit in terms of its submarine geomorphology, sedimentology, and stratigraphy. Sediments in the study area appear to be suitable for barrier island restoration. Although good quality sediments occur in the Ship Shoal environment, the occurrence of cultural resources and petroleum industry infrastructure impede development of sand resources. The problem of locating sand resources for barrier island restoration is thus not simply a matter of marine exploration but also being cognizant of hazards to dredging and awareness of potential hazards posed by borrows to existing structures. Complex patterns of pipeline corridors and other infrastructures restrict exploration for sand resources and reduce potential volumes that can be dredged. Eight pipelines transit the study area and seven occur adjacent to it (CEI 2003a). Six production platforms and two wells (CEI 2003a) also exist just outside the bounds of the study area. These pipelines and structures are protected by 150 m buffer zones within which no dredging can occur.

STUDY AREA LOCATION AND GEOLOGICAL FRAMEWORK

Most of the seafloor beneath the study area consists of a large, submarine sand body that is locally known as Ship Shoal, the largest shoal off Louisiana. The potential of Ship Shoal as a source of sand for restoring parts of Louisiana's rapidly eroding coastline has been summarized by various researchers including Krawiec (1966); Suter *et al*. (1985); Penland *et al*. (1985, 1986); Williams *et al*. (1989); Kulp *et al*. (2001); Stone (2001); Finkl *et al.* (2005). A 40- to 45-m thick wedge of deltaic sediments, deposited by the Mississippi River during the Holocene, underlies the Ship Shoal region. Although processes of Mississippi River Delta formation have been intensively studied (*e.g*. Coleman and Gagliano 1996; Frazier 1967; Saucier 1994), they are briefly summarized here as they relate to the formation of the Ship Shoal environs. The shoal crest, with surface sand thickness >1 m occupying an area of about 560 km^2, forms an ancient barrier shoreline that has been modified by processes related to transgression and submergence of the Maringouin delta complex (Krawiec, 1966; Frazier, 1967; MMS, 2004).

A result of deltaic abandonment and marine transgression, Ship Shoal (Figure 1) is the largest and easternmost of a series of sand shoals on the inner continental shelf of Louisiana (Kulp *et al*. 2001). The elongated shoal, lying parallel to the coast approximately 12 to 19 km off Terrebonne Parish, measures approximately 50 km long in an east-west direction. The central portion of the shoal ranges 5 to 12 km in width, but its distal margins narrow to points.

South Pelto is located on the eastern segment of Ship Shoal, about 14 to 20 km offshore

the eastern part of the Isle Dernieres barrier chain (Figure 1). The area encompasses portions of five MMS lease blocks (12, 13, 14, 18, and 19) (MMS, 2004). In order to better appreciate the deposit geometry of South Pelto, sedimentary geology, and geomorphology, it is necessary to understand the stratigraphic implications of river diversion (avulsion and branching) and delta switching in major deltaic depositional environments. These processes contribute to the formation of transgressive sand bodies, such as Ship Shoal, and evolution of modern barrier islands such as those lying landward of the Shoal (*e.g.* Isles Dernieres and Timbalier).

Ship Shoal was formed about 7,000 years ago (early Holocene) in association with the abandonment and reworking of distal sediments from the Maringouin Delta Complex. The Isles Dernieres, located landward of Ship Shoal, are associated with the winnowing and reworking of sediments from the abandonment and submergence of the Caillou Bay headland (abandoned about 600 to 800 years ago) of the Lafourche delta complex (Penland *et al.,* 1988).

Deltas are dynamic depositional systems that exhibit a wide range of depositional features. The Mississippi deltaic plain is characterized by major river diversions that promote large-scale delta lobes. These delta complexes occur on millennial scales. Bay fills are built and abandoned in centennial time frames, whereas the smallest sub-deltas exist only for two centuries, on average (Coleman and Gagliano, 1964).

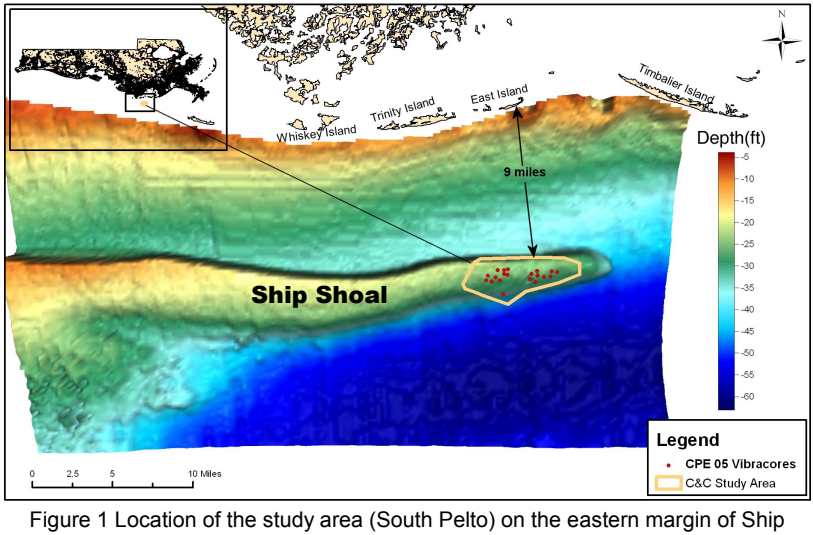

Figure 1 Location of the study area (South Pelto) on the eastern margin of Ship Shoal, in relation to the Isles Dernieres (Whiskey, Trinity, and East Islands) and regional bathymetry of Ship Shoal

Scruton (1960) employed the term *delta cycle* in reference to alternating phases in deltaic sedimentation. Each delta cycle is initiated by (1) sedimentation and rapid growth (a

constructional-progradational phase) that is followed by (2) systematic loss of flow efficiency, (3) sediment dispersal and abandonment of the delta by the sediment delivery system (delta switching), and concludes with (4) a destructional phase in the form of delta deterioration. The coastal plain of Louisiana exhibits all stages of the delta cycle, from the newly constructed Atchafalaya-Wax Lake bayhead deltas to abandoned destructive deltas (*e.g*, Lafourche) (Roberts, 1997). At the present time (Holocene epoch), eighteen delta lobes coalesce within six major delta complexes to make up the Holocene deltaic plain of Louisiana (Coleman *et al*., 1998; Kulp *et al*., 2005). The entire deltaic plain is transgressive, with the exception of the Birdfoot (Balize complex) and the Atchafalaya River delta complex. The most recent abandoned lobes are the Laforche and Plaquemines lobes of the modern Balize-Birdfoot delta.

Older lobes of the Mississippi delta began to accumulate sediment about 7,000 YBP (years before present), when the rate of sea-level rise decelerated and MSL (mean sea level) approached present levels (Fisk *et al*., 1954; Roberts, 1997). River avulsion (rapid channel switching) and diversion, which often result in delta switching, are responsible for the present complex and diverse geomorphology and stratigraphy of the Mississippi deltaic plain. Study of the sedimentary record suggests that delta building occurred at different locations about every 1000 to 2000 years (Roberts, 1997; Coleman *et al*., 1998. The Mississippi River has thus built a broad and complex coastal plain by these basic processes. Throughout the current deltaic plain, late Pleistocene mud-rich and stiff clay deposits underlie Quaternary depositional deltaic sequences. Typically, the Pleistocene facies is denser than overlying Quaternary sediments (compaction occurs mostly in Quaternary sediments). During late (destructive) stages of a delta cycle, abandoned delta complexes subside due to compaction (dewatering of clastic sediments and oxidation of organic-rich materials). As coastal processes rework the seaward margin, the delta lobe enters a transgressive-destructive phase where erosional headlands, flanking barriers, barrier island arcs and erosional headlands develop, as described by Penland *et al.* (1988). A mechanism for the genesis and evolution of transgressive depositional systems in the Louisiana deltaic plain is suggested by Penland *et al.* (1988) in a three-stage geomorphic model. This evolution begins when marine processes transform the abandoned delta complex into a Stage 1 erosional headland with flanking barriers. At this stage, sediment is supplied to flanking barrier development by shoreface erosion. Relative sea-level rise, land loss, and shoreface erosion leads to submergence of back barrier lands and the separation of the Stage 1 barrier from the mainland shoreline, forming the Stage 2 barrier island arc. When relative sea-level rise and overwash processes overcome the ability of the barrier island arc to maintain its subaerial integrity, submergence initiates the formation of inner shelf shoals under Stage 3. Following submergence, the drowned barrier islands continue to be re-worked by marine/coastal processes to form a marine sand body in the inner shelf. This is the last stage in the evolution of transgressive depositional systems. These evolutionary processes were collectively subsumed under the heading of "transgressive submergence" by Penland *et al*. (1988). According to Penland *et al.* (1988), Ship Shoal is an inner shelf shoal that represents Stage 3 of the model.

The controlling variables that differentiate transgressive submergence (Penland *et al.,* 1988) from other models of shoreline sand formation such as shoreface retreat (Fisher, 1961; Swift, 1975) and in-place drowning (Sanders and Kumar, 1975) are: (1) high rates of relative sea-level rise, (2) low gradients of continental shelves with limited local sand sources, and (3) a storm-dominated environment. Formation of barrier islands and shoals by mainland detachment processes and regression generally results in a coarsening upwards stratigraphic sequence (sediment grain size increases upwards from the bottom of the deposit toward the top) that is commonly found in barrier islands arc sequences and inner shelf shoals. Reworked inner shelf shoals exhibit a stratigraphic sequence that grades rapidly from silt and sand in the base, to shoal front sand capped by shoal crest sand and shell on the surface (Penland *et al.*, 1988). The sedimentology and stratigraphy of Ship Shoal is further discussed as follows.

SHIP SHOAL SEDIMENTOLOGY AND STRATIGRAPHY

The Ship Shoal system was characterized by Penland *et al*. (1988) and Suter *et al*. (1991) as a sandy submerged barrier island that is about 50 km long by 8 km wide in the central area to about 5 and 10 km on eastern and western margins, respectively. Local relief varies from about 7 m on the western margin to about 5 m elsewhere. Water depths range from 3 m on the west to 5 m on the eastern margin (Kulp *et al*., 2005). According to Penland *et al*. (1988), Ship Shoal has migrated to its present position under conditions of sea-level rise, shoreface erosion, and submergence. Landward asymmetry and stratigraphic position of the shoal indicates that it is a transgressive sand body that is migrating landward.

Penland *et al*. (1988) described seven (7) lithofacies on Ship Shoal that were based on texture, sedimentary structures, faunal assemblages, and stratigraphic position. However the upper three facies that are most relevant to sand resources and include the (1) shoal crest, (2) lower shoal or shoal front, and (3) shoal base. The shoal crest, the facies to explore over the short term, is located in the upper 5 m of the deposit and is comprised by very well sorted quartz sand (99% sand) that ranges from 0.13 mm to 0.16 mm in size. Sediments are very well sorted and coarser on the crest, associated with a general coarsening upward trend in a high-energy active zone where sediments are winnowed and sorted by waves and currents. The shoal front, subsequently overridden by the migrating crest, is slightly thinner (1.2 to 3.4 m thick) and contains finer-grained sand (0.12 to 0.15 mm) compared to the crest. The base of the shoal, underlying the shoal front, contains poorly sorted finer-grained sand that are interbedded with layers of silt and clay. Penland *et al.* (1988) estimates that the shoal crest unit alone contains more than 7.6×10^6 m^3 of sandy sediment. Although there may be large sediment volumes in Ship Shoal, the presence of oil infrastructure and obstructions (pipelines, flow lines, rigs, abandoned pipes, wrecks) may preclude exploration of in many areas.

The available evidence indicates that the majority of the 45 m of Holocene sediments underlying the study area is associated with the Maringouin Delta Complex and has been deposited over the last 7,500. These thick Holocene deposits rest on weathered, Pleistocene Prairie terrace deposits that represent floodplain, deltaic and open shelf sediments deposited between about 120,000 and

20,000 years BP (Frazier, 1974; Saucier, 1994). During low sea-level stands, large expanses of these Pleistocene surfaces were subaerially exposed and streams extended an extensive network of channels across them. Several relict channels trending northwest to southeast are incised into this deeply buried Pleistocene surface near the study area. These relict channels terminate at the head of Mississippi Canyon and represent channels of an ancestral Mississippi River course (Moore *et al*., 1978). About 18,000 to 20,000 years BP (Last Glacial Maximum in Wisconsinan time), shorelines stood approximately 90 m lower than present and approximated the edge of the outer continental shelf. Since that time, sea level has gradually risen and Pleistocene surfaces were drowned and buried by Holocene marine and deltaic sediments.

Analyses of sediments from Ship Shoal and the Isles Deniers indicates compatibility of grain sizes and sorting viz. 2.64-3.72 phi (0.165-0.076 mm) and 2.73-3.94 phi (0.149-0.063 mm) for Isle Dernieres sediment and Ship Shoal, respectively (based on Krawiec, 1966, and reported in MMS, 2004). Both areas contain fine to very fine sand that is very well to well sorted, making the deposits compatible and the Ship Shoal sand ideal for beach nourishment.

GEOPHYSICAL AND GEOTECHNICAL FIELD AND LAB METHODS

Cost effective exploration for offshore sand in deltaic environment needs a systematic approach (Khalil 2004, Finkl and Khalil 2005a). Most of the tasks associated with the phase-wise approach for sand search (Khalil 2004) was undertaken during 2003 when a detailed geophysical survey was conducted is Ship Shoal Blocks 88 & 89 (CEI 2003b) and South Pelto Blocks 12 &13 (CEI 2003a) as stated earlier. Based on the interpretation of bathymetric, seismic, sonar, and magnetic data, geotechnical investigation was undertaken by collecting vibracores (Finkl and Khalil 2005b).

Geophysical/geotechnical equipment and techniques used during this investigation included (Finkl *et.al* 2005):

- Differential Global Positioning System (DGPS) – Trimble GPS and Coast Guard Navigation Beacon (Provides accurate positioning of the survey vessel).
- Navigation/Survey Integration System – Hypack Inc.'s "HYPACK® MAX" (Integrates DGPS data with data collected during the survey).
- Vibracore Acquisition
- Sediment-Size Analysis

The technical methods, analytical tools, and equipment used in this geotechnical investigation for evaluation of sand deposits in the study area are described below.

Navigation System

The navigation and positioning system used during the survey was a Trimble DGPS Global Positioning System (GPS) that was interfaced to Hypack Inc.'s HYPACK® MAX. A Pro Beacon receiver provided differential GPS correction from the U.S. Coast Guard Navigational Beacon located at English Turn, Louisiana. The DGPS initially receives the civilian signal from the global positioning system (GPS) NAVSTAR satellites. The locator automatically acquires and simultaneously tracks the NAVSTAR satellites, while

receiving precisely measured code phase and Doppler phase shifts, which enables the receiver to compute the position and velocity of the vessel. The receiver then determines the time, latitude, longitude, height, and velocity ten times per second. The GPS accuracy, with differential correction used in this study, provides for a position accuracy of one (1) to four (4) feet, which is within the accuracy needed for geotechnical investigations for sediment sources. The U.S. Army Corps of Engineers (USACE) test of the U.S. Coast Guard beacons found an accuracy of at least five (5) feet approximately 94% of the time.

Survey Integration via Hypack Inc.'s HYPACK® MAX

The navigation system was interfaced with an onboard computer, and the data integrated in real time using Hypack Inc.'s HYPACK® MAX. HYPACK® MAX is a state-of-the-art navigation and hydrographic surveying system. Online screen graphic displays include the pre-plotted survey lines, the updated boat track across the survey area, adjustable left/right indicator, as well as other positioning information such as boat speed, quality of fix, and line bearing. All data are recorded on the computer's hard disk and transferred to a USB memory stick each day during the survey to back-up raw survey data. After post-processing, the navigation data (locational) stored in the HYPACK® MAX system was then exported to a *.dxf* file and imported into ArcGIS 8 in order to create a GIS shapefile for analysis and report preparation.

Vibracore Acquisition

A 271B Alpine Pneumatic Vibracore, configured to collect undisturbed sediment cores 20 feet in length, was used for this project. This self-contained, freestanding pneumatic vibracore unit contains the following components: an air-driven vibratory hammer assembly, an aluminum H-beam which acts as the vertical beam upright on the seafloor, a steel coring pipe (with a plastic core liner), and a drilling bit with a cutting edge. An air hose array provided compressed air from the compressor on deck to drive the vibracore. If penetration refusal occurred at less than 80% of expected penetration, the sampled portion was removed from the pipe, a new liner inserted, and a jet pump hose was attached just below the vibracore head. After lowering the rig to the bottom and jetting to one (1) to two (2) feet above the refusal depth, the jet was turned off and the vibrator turned on in order to collect the remaining core. The vibracore unit was deployed by a crane from the "liftboat" M/V *Stingray*.

Sediment-Size (Mechanical) Analysis

Sieve analyses were conducted for samples obtained by vibracoring in accordance with American Society for Testing and Materials Standard Materials Designation D422-63 for particle size analysis of soils (ASTM, 1987). This method covered the quantitative determination of the distribution of sand size particles. Results of the particle-size analyses were entered into gINT® software, which computes the mean and median grain size, sorting, and silt/clay percentages for each sample using the moment method described by Folk (1974).

RESULTS

Twenty (20) vibracores were obtained in the South Pelto study area. The core locations were selected on the basis of results from preliminary geophysical investigations conducted by CEI (2003a). Vibracore locations were overlaid on a three-dimensional (3D) bathymetric image (using NOAA-NOS historic bathymetric data mostly from 1979) to show the relationship between vibracore locations and morphology whereas the latest bathymetric data (CEI 2003a) collected was used to plan the vibracore acquisition. In the study area occurring on the eastern tip of Ship Shoal (Figure 1), water depths decrease from east (mostly between 6 to 9 m isobaths) to west (9 m isobath on the crest) as this inner-shelf ridge increases in width. Shoreward-facing (north) slopes are steeper than the seaward (south) side slopes. Vibracores were located on the eastern shoal crest and concentrated in two main areas (Figure 1). Vibracore #20 obtained off the south margin of the main shoal contained mostly clay and probably represented lagoonal sediments from the Marogouin delta that underlies the shoal base. Other vibracores on the shoal crest recovered mostly sand in surface layers and mixed fine sediments (sand, silt, and clay) in basal layers.

Potential borrow sites, targeted by results of prior work, were reported to be free from dredging obstructions. Figure 2 shows the location of the design borrow sites, buffers (no-dredge zones as defined by cultural resource surveys), vibracore locations (Finkl *et al*. 2005), location of fence diagrams, and MMS lease block boundaries. Potential borrow areas are labeled A, B and C (Figure 2).

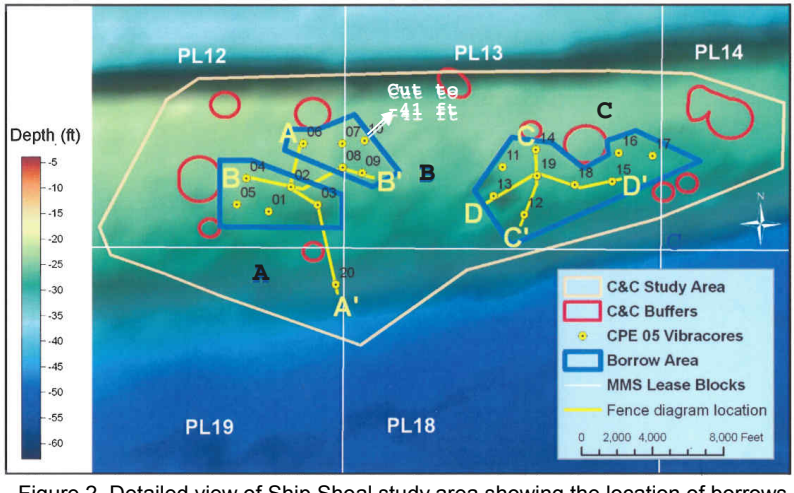

Figure 2. Detailed view of Ship Shoal study area showing the location of borrows.

Potential borrow area A contains five vibracores (Cores # 01, 02, 03, 04 and 05). Sand thickness varies from 3.6 to 4.8 m with greater thickness occurring in the vibracore closest to the center (#04). Figure 3 a fence diagram drawn perpendicular to the shoal

crest shows how the sand deposit thickens to the offshore as the shoal relief decreases and the underlying mud layer outcrops in the shoal seaward (south) side. Upper portions of vibracores generally contained clean sand (mean grain size ranges from 0.15 to 0.22 mm) whereas bottom layers contained clay and silty sand (mean grain size ranges from 0.12 to 0.15 mm). Figure 4, a schematic fence diagram drawn parallel to the shoal's crest illustrates how the sand thickness is constant along the shoal crest (W-E) in contrast to a rapid thinning offshore (N-S).

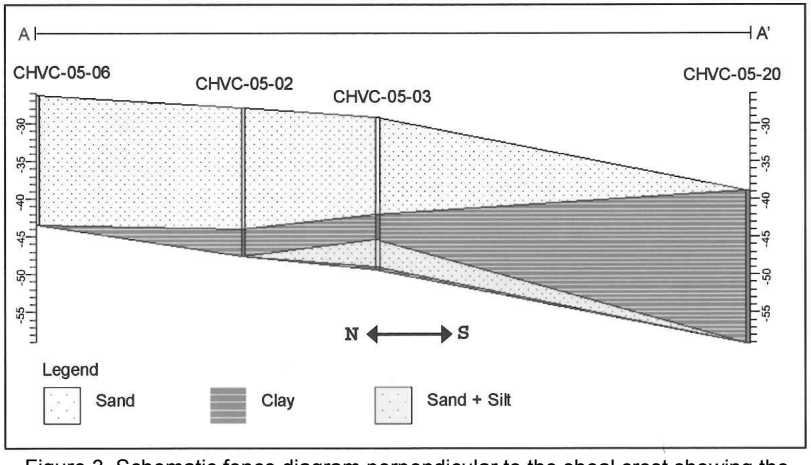

Figure 3. Schematic fence diagram perpendicular to the shoal crest showing the decrease of sand thickness towards the offshore (vibracore 20).

Five (5) vibracores were obtained in potential Borrow Area B (cores # 06, 07, 08, 09 and 10). Sand thickness ranged from 4.6 to 6 m with the greatest thickness occurring in vibracore 07. The fence diagram in Figure 3 illustrates that vibracore 06 contained clean sand from the core top down to the core base, the same pattern is observed in cores 08 and 09 illustrated in Figure 4. Thus, all vibracores along this area contained sand from the shoal crest and displayed a slight coarsening upward trend. Grain sizes range from finer grain sizes (0.15 to 0.18 mm) in the base of the core to slightly coarser sand sizes (0.19 to 0.51 mm, but mostly around 0.2 mm) near the top. Shell fragments and whole shells in the top 0.6 m of vibracore #10 accounted for coarser grains (0.51 mm).

Nine (9) vibracores were obtained within potential Borrow Area C. Sand thickness ranged from 3.9 to 5.7 m but mostly occurred in the 5 m range (see Figures 5 and 6). Silt decreased and mean grain size increased from the core base to the top. Sediments in the upper 3 m were generally cleaner and contained coarser-grained sand than basal layers. Vibracore #12, the seaward most core, contained the thinnest sand layer that at 4 m transitioned to clay (Figure 5). Clayey sediments occurred in basal layers of seven (7) out of the nine (9) vibracores from this area. Most clay layers occurred 5 m below the shoal surface.

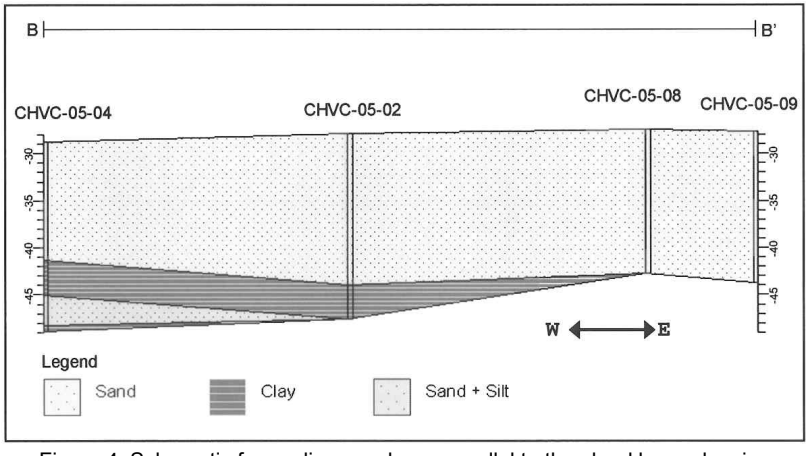

Figure 4. Schematic fence diagram drawn parallel to the shoal base showing relatively homogeneous sand thickness throughout the shoal base unit.

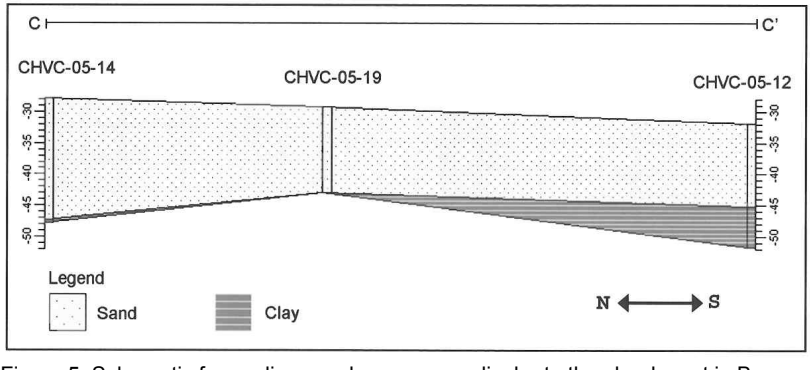

Figure 5. Schematic fence diagram drawn perpendicular to the shoal crest in Borrow Area C. The cleaner upper sand layers thin seaward (to the south).

Based on the interpretation of seismic data compared with historical cores, CEI (2003a) prepared a sand isopach map for the project area. The isopach indicated that sand thickness in the study area varies from 5.7 m on the shoal's crest to 0.3 m on the seaward (south) side of the shoal. Sand thickness decreases abruptly towards the south compared to a more gradual decrease observed to the north. Sand thickness in the Borrow Area C is slightly thinner than borrow areas A and B and ranges from 3.5 to 5.4 m.

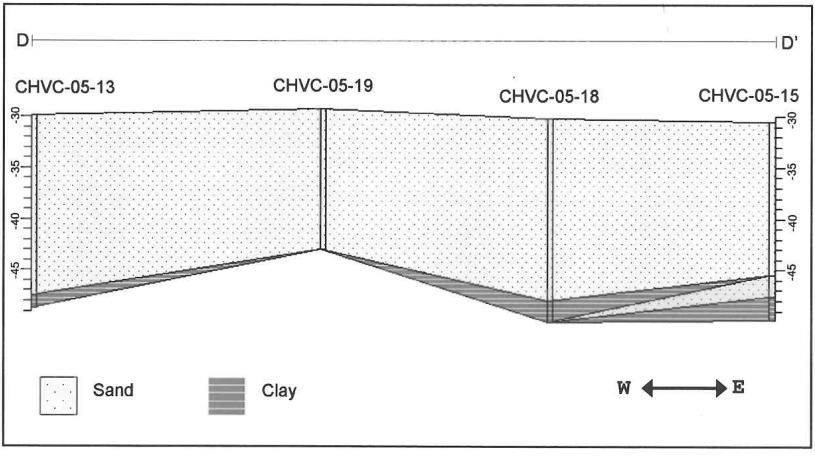

Figure 6. Schematic fence diagram drawn parallel to the shoal crest in Borrow Area C. Clean sandy sediments are associated with upper units (shoal crest and front).

Borrow area cuts were calculated using the isopach data provided by CEI (2003a) compared with vibracore results (thickness of clean sand and textural properties). Sand volume estimated in Borrow Area A is about 6.95 x 10^6 m^3, in Borrow Area B about 4.9 10^6 m^3, and in Borrow Area C about 9.75 10^6 m^3 with a total of about 21.6 x 10^6 m^3 of sand available from all these three borrow sites.

CONCLUSIONS

Sand resources along the southern Louisiana coast are relatively scarce given the large volumes of sand required for restoration of the rapidly degrading barrier systems. During this investigation, twenty vibracores were obtained from Ship Shoal, a well-known sand source offshore of the Isles Dernieres.

The study area along the eastern end of Ship Shoal, commonly known as South Pelto mainly contained very clean sand (less than 5% silt in the upper shoal units) that ranged in thickness from 4 to 6 m and generally ranged in grain size from 0.15 to 0.2 mm. About 21.6 x 10^6 m^3 of clean sand is estimated to occur in three borrow areas. Buffers around oil and gas infrastructures and other magnetic anomalies occurring in and around the study area were avoided during borrow area design to ensure quality of borrow sediments and safety of dredging operations. The sand deposits identified along South Pelto in this study have great potential to support large-scale coastal restoration of Lafourche Coastal segments. Sand from this borrow area is proposed to be used for restoration of Caminada Headland restoration project which is about 48 km. Transporting sand to this distance will be expensive. However in absence of any suitable deposit with adequate quantity of sand in the vicinity of the project area, this might be the only option left.

ABSTRACT Coastal land loss in the Mississippi River delta region contributes to loss of valuable habitat and coastal flooding hazards. Restoration of these ecosystems is a primary activity that requires large volumes of sand to rebuild beach-dune systems and restore wetland habitats. Sand sources have traditionally been sought offshore in the marine environment but there are problems associated with setbacks from oil and gas infrastructure, presence of muddy overburden, and limited reserves of beach-quality sediments. The potential of sand sources in channel and point bar deposits becomes an attractive alternative for barrier island restoration, especially because fluvial sediments are renewable. Results of preliminary geophysical and geotechnical investigations in the lower Mississippi River (south of New Orleans) along a 32-km stretch of the river indicate the presence of at least 23 million m^3 of usable sand.

INTRODUCTION

Land loss in Louisiana leads the nation in degradation of coastal wetlands and destruction of terrestrial, aquatic, and benthic habitats in and around the barrier island systems that are associated with the Mississippi Delta Plain viz. the Isle Denieres Barrier shoreline, Bayou Lafourche Barrier shoreline, Plaquemines shoreline, and Chandeleur Island shoreline. Numerous natural processes are responsible for coastal erosion and land loss in the deltaic environment of Mississippi River, one of the world's largest fluvial systems. Various experts estimate that about 30 percent of the land loss in coastal Louisiana is due to natural causes, the remaining 70 percent being attributable to both direct and indirect negative anthropogenic

effects on the environment (*e.g*. Boesch *et al*., 1994; Williams, Stone and Burruss, 1997). Some of the main causes include land subsidence, sea-level rise, decrease in sediment supply to coastal marshlands due to the levee system, fluid withdrawal from underlying strata by the petroleum (oil and gas) industry, dredging of access channels through wetlands, *etc*.(*e.g.* Penland and Ramsey, 1990; Roberts and Coleman, 1996).

Disappearing at a rate on the order of 65 to 90 km^2 per year, Louisiana looses nearly 9060 hectares coastal wetlands per year. Over the last century, as a result of human activities and natural coastal processes, the State of Louisiana lost valuable coastal wetlands on the order of 2430 to 3650 km^2. If nothing is done to mitigate coastal land loss in Louisiana, another 1760 km^2 could be lost over the next 50 years (LDNR, 2005). Although currently 30% of the total coastal marsh in the conterminous United States occurs in Louisiana, this state accounts for 90% of the coastal marsh loss.

In order to promote large-scale restoration of the Louisiana coast, appropriate sand resources must be identified and quantified (*e.g*. Suter, Penland and Ramsey, 1991; Kindinger *et al*., 2001; Finkl and Khalil, 2005a). Sand resources will supply materials needed for building the first line-of defense of this fragile coastal system, its beaches and dunes. This geotechnical and geophysical study of riverine deposits along the Lower Mississippi River (LMR) was conducted to ascertain the potential of using fluvial sediments for barrier island restoration along the Louisiana coast, northern Gulf of Mexico. Deposit sedimentology, stratigraphy, and relationship to previous work and geomorphic framework are presented here in reflection of prior work by Finkl *et al*. (2005, 2006).

Study Area in the Lower Mississippi River

Sand resources are investigated along the Lower Mississippi River (LMR) reach from Mile Marker [MM] 35 to MM 15 (Figure 1). This area was selected because of its proximity to Gulf of Mexico barrier islands via Adams Bay, Bastian Bay, and associated marshlands. Along the channelized section of the LMR, straight reaches of the river are about 800 m wide but may exceed 2400 m on bends with large point bars. Although river depths average about 20-25 m, they often approach 30 m in the thalweg. Geotechnical and geophysical investigations along the river target active and relict point-bar deposits as well as migrating sand waves on the riverbed. The sedimentary geology and geomorphology of the area is related to river diversions (avulsion) and delta switching, as occur in major deltaic depositional events throughout the region's geologic history.

Geological Framework

The LMR traverses the delta plain and cuts into deltaic deposits that are older than the present river position. Deltas are dynamic depositional systems that exhibit a wide range of sedimentary features. The Mississippi deltaic plain is characterized by major river diversions that promote the development of large-scale delta lobes (*e.g.* Kolb and Lopik, 1966; Roberts, 1997). These delta complexes occur on a millennial time scale. Bay fills are built and abandoned on a centennial time scale, whereas smaller sub-deltas exist for two centuries on average (Coleman and Gagliano, 1964).

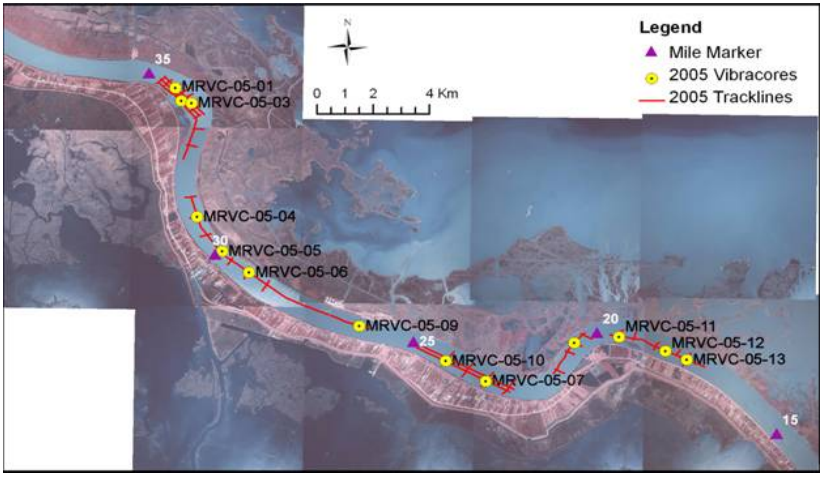

Fig. 1. Photomosaic showing the location of vibracores and geophysical tracklines in the Lower Mississippi River between Nairn (top left) and Ft. Jackson (bottom right).

Of particular interest to this study is the geological setting where the LMR cuts into the delta (alluvial) plain. The river valley is entrenched in the alluvial plain but itself contains bedload (traction materials) sands that continue to accumulate on relict point bars (since channelization and training of the river were initiated in the 1930s) and as channel margin, sheet (with rippled bedforms), and shoal deposits. Mixed sediments similar to those on the inner continental shelf and deltaic plain (Stanley *et al*., 1996) underlie the modern (Holocene) river channel. Because the channel is entrenched, classic morphological patterns associated with graded streams (*e.g*. oxbows, meanders, meander scars, Yazoo meaner loops) are not present in the LMR. Critical to rationalization of sediment patterns and strategies for sand searches in this fluvial-deltaic environment depends on comprehension of different stages of fluvial geomorphological development.

SAND RESOURCES IN THE LOWER MISSISSIPPI RIVER

One of the most studied, engineered and heavily trained rivers in the world (*e.g*. Kessel, 2003), the Mississippi River features flood control structures, levees, floodways, floodwater retention structures, and reservoirs. Today the LMR is the product of natural influences modified by engineered channel improvements constructed under the aegis of Mississippi River tributaries projects (Biedenharn *et al.,* 2000).

Studies relevant to riverine (fluvial) sand searches in the LMR include several noteworthy reports viz. Biedenharn *et al*. (2000), Dunbar *et al.* (1994), Fisk (1944, 1947, 1952 and 1961), Keown *et al.* (1977, 1981, 1986), Kessel (2003), Kolb and Van Lopik (1966), Kolb (1962), Mossa (1996), Nordin and Queen (1992), Saucier (1996), Smith (1996), among others. Based on nearly one hundred borings, Stanley *et al.* (1996) prepared a generalized stratigraphic description of the LMR deltaic plan. Results of their investigations showed a top-to-bottom sequence for the alluvial plain that comprehends Holocene progradational facies of deltaic sediments that overlie Pleistocene sandy sediments.

Holocene deltaic sediments (Deltaic Progradational Facies) range in thickness down river from 18 m in the vicinity of New Orleans to about 75 m at Head of Passes. Thickness of the deltaic sediments from MM 35 to MM 22 is about 30 m to 45 m (Stanley *et al.*, 1996). The texture (percent sand, silt, and clay) of the deltaic sediments varies from muddy (silty-clays) to sandy deposits that occur in paleo-meander point bars, crevasses, and low-relief natural levees. Deltaic sediments in the LMR (*i.e*. MM 34 to MM 22) are likely to contain sedimentary deposits similar in composition to those found on the inner shelf offshore Plaquemines Parish but accentuated by greater variation due to paleo-riverine deposits that are mixed within the Holocene deltaic sedimentary package. The Pleistocene sandy sediments in the Mississippi delta plain, defined by Stanley *et al.* (1996) as a late-Pleistocene to early Holocene Transgressive Facies (LPEHT), underlie the Holocene deltaic sediments. The Pleistocene sandy layer, about 4.5 to 7 m thick in the New Orleans area, decreases southward to about 2.4 to 5 m at Head of Passes and occurs beneath the Holocene sedimentary package.

Formation of new point bars is prohibited, because river-stabilizing structures prohibit lateral migration of meander belts in the modern Mississippi River (Smith, 1996). This observation is important because point bars are good sources of sand deposits in fluvial systems. Noting that the Mississippi River is a highly trained channel, Smith and Winkley (1996) report that the river now responds to channel-forming flows by building 'mid-channel bars,' also referred to as 'sand waves' (Allison, 2004; LeClair, 2004), instead of migrating and producing natural meander cutoffs. LeClair (2004) reports that macro sand waves are scaled by channel width and planform. Symmetric dunes at Red Eye Crossing in the LMR (MM 223 to MM 225, near Baton Rouge), for example, have lengths of about 120 m and heights of 3 m with superimposed asymmetric dunes about 11-m long and 1-m high. The mean flow depth was 27 m and velocity was about 1.8 m s^{-1} (LeClair, 2004). Similar small dunes migrate on the point bar but the main channel features larger dunes 69-m long by 2.6-m high with celerity up to 2 m h^{-1}. Study of probability-distribution curves for bedload in the main channel suggests steady sediment supply and transport rate (LeClair and Blom, 2005), parameters that are particularly important to evaluation of fluvial sand resources. Significantly, navigation maintenance of the LMR involves dredging of "problem reaches" where there is bed elevation (sedimentary aggradation) and chronic formation of mid-channel bars (sand waves, ripples).

From the point of view of sand searches, location of these problem reaches may fortuitously point to a renewable sand resource. Examination of sediment deposition rates and grain sizes in the LMR further indicates that bedload varies from fine sand to gravel depending on local geometry and hydraulic conditions (Smith and Winkley, 1996).

The LMR exhibits greater variability of thalweg elevation (due to the presence of mid-channel bars and sand waves) than many up- and downstream segments. Kessel (2003) suggests that variation of thalweg is a hydrodynamic response to decreased sediment input from upriver sources. Thalweg data presented by Kessel (2003) indicates that bed aggradation in this reach of the LMR may have resulted from larger bed loads in recent times. He thus concludes that because the river is no longer allowed to meander, sediment storage capacity of the channel is greatly reduced. Fisk (1944) long ago described downstream grain-size variation in terms of riverbanks that become progressively composed of finer deposits, a channel cross-sectional area that becomes narrower and straighter, and sandbars that become more infrequent.

Grain-size of bedload decreases downstream from sand-dominated deposits near the Atchafalaya diversion (Old Control Structure) to silt-dominated at Head of Passes (Mossa, 1996). Grain size decreases from 0.21 to 0.10 mm from MM 200 to MM 100 and from 0.17 to 0.05 mm between MM 100 and MM 0 (Keown *et al.*, 1981, 1986) and fluctuates from 0.19 to 0.28 mm between MM 28 and MM 30 (Allison and Nittrouer, 2004).

Temporal trends in composition of bed materials, initially reported by Robins (1977) and updated by Nordin and Queen (1992), were evaluated and again updated by Biedenharn *et al.* (2000) who report a general decrease in the D_{50} size since 1932. The Nordin and Queen (1992) study reported, however, that there has not been significant change in the character of the bedload since the pre-cutoff period (late 1920's to the present).

Allison and Nittrouer's (2004) seismic surveys of the LMR (from MM 86 at English Turn downstream to MM 0 at Head of Passes) mapped the active sand sheet that is formed by bedload sediment transport. The active sand layer (traction bedload deposits) is present throughout most of the study area in deeper parts of the river and ranges in thickness from 2 to 3 m. Point bars are now relatively inactive but may represent a significant source of sandy sediments (*e.g*. Smith, 1996; Kessel, 2003) due to the presence of river control structures (*e.g*. levees) in the LMR.

Nordin and Queen (1992), studying particle size distribution of bed sediments along the thalweg of the Mississippi River from Cairo (Illinois) to Head of Passes (Louisiana), acquired data from field sampling in 1989 using a WES drag sampler (a 10-cm inside diameter steel pipe 1.2-m long closed at one end and flared to about 20 cm diameter at the other end). The thalweg sediment samples obtained by Nordin and Queen (1992) in the project area (MM 35 to MM 15) range from 0.13 to 0.35 mm; sediment sorting is similar to inner shelf and beach environments (between 1 and 2 phi, or moderately sorted) except for a sample at MM 30.4 that contained very poorly sorted sediments (high variability attributed to a higher than normal percentage of fines). The thalweg data from Nordin and Queen (1992) also indicated that the relative percent of coarse sand (2 to 4.7 mm) and gravel sediments is reduced when compared to a sampling survey conducted in 1932. From MM 100 to MM 0, thalweg sediment composition is dominated by fine sand (0.15 to 0.25 mm) - percent silt is generally less than 10%, percent clay is generally less than 5% and percent gravel and coarse sand is generally less than 2%. The Nordin and Queen (1992) data indicate that favorable grain sizes (*i.e*. suitable for beach restoration) occur in reaches of the LMR. This information is, however, only a proxy of channel sand in the LMR because bank sediments differ from thalweg sediments.

McClelland (1988) indicates that previous USACE boring data for the Nairn Point Bar describe sand thicknesses of 21 m. The point bar deposit has two major sedimentary units: (1) a featureless (flat) mud bottom from the riverbank to about 8 m water depth and (2) a sand bottom with surface sand waves from 8 m to their survey depth limit (Figure 2). Sand composition is homogenous with a slight coarsening downward (fining upward) trend. The Nairn Point Bar, shown as a seismic image in Figure 2, is described as "a massive point bar at least 70 feet [21 m] thick" (McClelland, 1988). These reports indicate, based on 36 samples obtained from 16 vibracores in the Nairn Point Bar, an average (composite) grain size of 0.17 mm with 0.92 phi sorting.

Results of a recent study of river geomorphology (potamological interpretation of fluvial forms, bathymetry, sedimentary deposits, and hydrology) indicate that large volumes of sand may be available in the lower section of the river. Three primary potential sand targets were

identified between MM 35 and MM 22 (CPE, 2004). One target was located 3 to 6 km upriver from Empire between MM 32 and MM 34, near the City of Nairn and another near Empire between MM 31 and MM 25. The third target was located near Fort Jackson between MM 24 and MM 22. A smaller secondary potential target was identified between MM 20 and MM 18 at the Fort Jackson river bend.

Of these three deposits, greater sediment thickness was anticipated in a river meander where the presence of relict (vertically stacked) sand bars occurred. Surface samples obtained along a gentle river bend on the eastern side of the river had a mean grain size of 0.19 mm to 0.28 mm. Sand waves were about 2 m thick, but underlying sands may increase the total thickness of sand deposits. An additional target was identified along a riverbank about 10 km downriver from Empire and 3 km upriver from the Fort Jackson river meander. The 3-km long target is limited upriver and downriver by riverbank revetments. The secondary sand targets, *e.g.* those mapped along the Fort Jackson meander, may be morphologically and compositionally similar to the primary targets because they are located in a similar hydro-geomorphological setting (river meander-point bar).

GEOPHYSICAL, GEOTECHNICAL AND LAB PROCEDURES

The geophysical survey of the study area between MM 35 to MM 15 involved geographical positioning, bathymetric survey, magnetic survey, seismic sub-bottom profiling, and side-scan sonar survey of the riverbed. These geophysical methods were deployed to accurately determine water depth (bathymetry), types of fluvial bedforms (presence of planar beds, sand waves, megaripples), and the nature and thickness of sedimentary deposits between banks of the river (slipoff slopes, point bars, and thalweg). The purpose of the magnetometer survey was to ascertain the presence of shipwrecks and other artifacts of archaeological significance in addition to debris that could be harmful to dredging machinery. The geotechnical surveys involved vibracoring and grain-size determinations from subsamples of sedimentary layers in the cores.

Presurvey Planning

The first phase of a sand search involves literature searches and design of the exploration program. Experience (*e.g.* Finkl, Khalil and Andrews, 2002; Finkl *et al.*, 2005a,b) has shown that this phase is crucial to evaluation and re-interpretation of prior knowledge, to the development of conceptual models of sedimentary environments, and to guide the planning of future survey options. Thus, the purpose of literature (data) review is to familiarize survey planners with local environmental conditions and to flag any special conditions that require avoidance or focused attention. Unfamiliarity with peculiarities of local environments or geomorphological features holds potential for obtaining less than desirable results. Tasks proposed for this riverine sand search were adjusted to local conditions according to procedural strategies suggested by sand search guidelines (*e.g.* Finkl; Andrews and Benedet, 2002; Finkl and Khalil, 2003; Khalil, 2003; Finkl, Khalil and Andrews, 2005).

Navigation and Survey

A Trimble DGPS Global Positioning System (GPS), interfaced to HYPACK® MAX (A Pro Beacon receiver) was used for navigation and positioning. Differential GPS correction was provided by the U.S. Coast Guard Navigational Beacon located at English Turn, Louisiana. Navigational, magnetometer, and depth sounder systems were integrated in real time using HYPACK® MAX, a state-of-the-art navigation and hydrographic surveying system. After post-processing, the navigation data (locational) stored in the HYPACK® MAX system

was then exported to a *.dxf* file and imported into ArcGIS 8 in order to create a GIS shapefile for analysis and report preparation.

Bathymetric Survey

A single frequency portable hydrographic echo sounder (Hydrotrac, Odom Hydrographic Systems) was used for the bathymetric survey. The Hydrotrac operates at frequencies of 24, 33, 40, 200, 210, or 340 kHz and is a digital, survey-grade sounder. Prior to use, the sounder was calibrated and checked periodically throughout the survey. Speed of sound through water and other selected parameters were adjusted to accurately reflect physical water conditions in the survey area.

Magnetometer Survey

A Geometrics G-882 Digital Cesium Marine Magnetometer was used in a cursory investigation of magnetic anomalies within the potential borrow areas. The purpose of the magnetometer surveys was to establish the presence, and subsequent exclusion zones around, any petroleum pipelines within the potential borrow areas. The HYPACK® MAX software recorded magnetic anomalies directly from the Geometrics magnetometer.

Sidescan Sonar Survey

A sidescan sonar system (EdgeTech 4200 FS) was used to interpret morphological features on the unconsolidated sediment. The full-spectrum chirp technology delivered wide-band, high-energy pulses coupled with high resolution and superb signal to noise ratio echo data. The sidescan was towed at an optimum position and depth to ensure isolation from sources of interference and for optimum record quality. The resulting digital data was merged with positioning data (DGPS via HYPACK® MAX), video displayed, and recorded to disk for post processing and/or replay. The position of the sensor relative to the DGPS antenna was documented to ensure proper positioning of the data. Range scales were set at 150 m, providing over 100% coverage for the South Pass study area. Dual frequency provided a differential aid to interpretation.

Data was processed by Isis Sonar software in a geographical framework for target interpretation and delineation. The geo-encoded sonar imagery data were stored as *.xtf* files and then converted to *DDS_VIF* raster imagery files. Raster images were then imported into Triton Elics DelphMap software to be further processed, merged, and exported in the form of geo-referenced sidescan mosaics (*geo-tiff* files).

X-STAR Chirp 512i Sub-bottom Profile Survey

The EdgeTech SB512i system was used because it shows a distinct reflector at boundaries between sand deposits and finer-grained accumulations (*i.e.* submerged channel plugs, back levee fills, delta plain deposits). This wideband FM sub-bottom profiler collected digital normal incidence reflection data over many frequency ranges and generated cross-sectional images of the sea(river)bed to a depth of 15 m in this survey. Transmission of an FM pulse that is linearly swept over a full spectrum frequency range (called a “chirp pulse”) produces a tapered waveform spectrum that results in images that have virtually constant resolution with depth. Post-processing of the seismic data was accomplished with SonarWebPro®, a software program that can produce georeferenced HTMLs that can be incorporated into a GIS database.

Geological Investigation

Field investigations are required to ascertain correspondence between actual conditions in the study area compared to those described in the literature. In addition, specialized information is required to prove out potential borrow areas that were selected on the basis of literature reviews and inspection of proprietary reports. Because vibracores provide the kind of detailed information that is required (collection of undisturbed sediment samples), vibracore surveys are often conducted in tandem with geophysical investigations. Geophysical surveys and geotechnical work is thus able to definitively establish deposit geometry, and the quality and quantity of sand. Vibracores were thus deployed in this sand search investigation to determine the nature of sedimentary deposits in the river and to help calibrate the seismic reflection profiles obtained by the CHIRP 512i sub-bottom profiler, as described procedurally by LDNR (2003) and Finkl and Khalil (2005) for conditions in Louisiana.

Vibracore Survey Sediment cores 6 m in length were collected by a 271B Alpine Pneumatic Vibracore. This self-contained, freestanding pneumatic vibracore unit contains an air-driven vibratory hammer assembly, an aluminum H-beam which acts as the vertical beam upright on the riverbed, a steel coring pipe (with a plastic core liner), and a drilling bit with a cutting edge. An air hose array provided compressed air from the compressor on deck to drive the vibracore. Complete description of vibracore survey procedures may be accessed in Finkl and Khalil (2005b).

Sediment-Size (Mechanical Sieving) Analysis Sieve analyses were conducted for samples obtained by vibracoring in accordance with American Society for Testing and Materials Standard Materials Designation D422-63 for particle size analysis of soils (ASTM, 1987). This method covered the quantitative determination of the distribution of sand size particles. Mechanical sieving was accomplished using calibrated sieves, with a gradation of half phi intervals with the addition of sieves that represent key ASTM sediment classification boundaries. Grain-size frequency distribution curves were prepared for each vibracore and a composite compiled for each vibracore.

The basic procedures for sediment analysis via mechanical sieving involve weighing approximately 75-100g of representative material to the dish. Large clasts or other materials that are not characteristic of the sub-sampled horizon, or layer as a whole, were removed and noted in the comments field (composition and size) of the lab report sheet. The wet Munsell color should be obtained from the vibracore log. The sample was dried fro 12 hr at 110˚ C.

The dried sample was then weighed on a tarred electric scale and the weight recorded. The sample was totally immersed in deflocculent (approximately 80 g of sodium hexametaphosphate [Calgon] in 1 liter of water) and soaked for 3 hr. The sample was then placed on a #230 sieve and gently washed until the water draining from the bottom of the sieve ran clear. The washed sample was then returned to the dish and dried. When dry, the sample was reweighed. Bulk shell content and bulk carbonate content are estimated at this point (if appropriate).

The standard sieve stack was set up and the sample poured onto the top of the sieve nest. The sieve stack was hand shaken for 30-60 sec. After the weight of the sample dish was recorded, contents of the top (3/4) sieve were returned to the dish. Percent shell (if any) was recorded, as was the weight of the dish and the sample. The weight retained on each sieve was recorded in this manner through the #14 sieve. The remaining sieves were placed in a mechanical sieve shaker for 20-30 min. The weight retained and percent shell for the remaining sieves and pan were recorded. Weight retained was entered into a sieve analysis program (gINT® software),

which computes the mean and median grain size, sorting, and silt/clay percentages for each sample using the moment method (Folk, 1974).

RESULTS OF FLUVIAL SAND SEARCH INVESTIGATIONS

Geophysical and geotechnical investigation of selected reaches in the LMR permitted the identification of significant sand resources in point bar deposits on river bends and in bed load materials in the active channel. The active sediment transport layers and underlying relict deposits in the LMR collectively constitute good quality sand deposits that are suitable for restoration of barrier islands.

Sand Resources in the LMR (MM 35 – MM 15)

Thirteen vibracores and 23 line-miles of geophysical survey were obtained from the LMR between MM 35 and MM 15. Most of the cores contained relatively clean sand from top to bottom with exception of the cores obtained near riverbanks. Three cores were obtained in the Nairn Point Bar, downriver from MM 35. Vibracores MRVC-05-01 and MRVC-05-03 were obtained in 13 m and 18 m water depth and contained mostly siliciclastic sand with few fines (less than 3% fines) and a slight coarsening upward trend with sand grain size increasing from 0.14 mm at the base of the core to 0.22 mm in the top of the core (MRVC-05-01) and from 0.22 mm in the base to 0.24 mm in the top (MRVC-05-03). Recovered sand thickness was 5.2 m in MRVC-05-01 and 5.3 m in MRVC-05-03. Vibracore MRVC-05-02, obtained in shallower water (6.6 m deep), contained sand intercalated with clay and silt layers in the upper 4.2 m (mixed sediment layer) below which there is clean sand about 1.5 m thick.

Vibracores MRVC-05-07 and MRVC-05-10 were obtained on a wide bank downriver from MM 25 in -13 m and -17 m of water, respectively. Both vibracores recovered about 4.5 m of clean siliciclastic sand (less than 5% silt) with grain size slightly coarsening upward (from 0.13 mm to 0.20 mm in the base of the cores to 0.24 mm to 0.26 mm at the top).

Vibracores MRVC-05-11, MRVC-05-12 and MRVC-05-13 were obtained on the western side of the river downriver from MM 20, in an area commonly known as the Fort Jackson Point Bar. Vibracore MRVC-05-11, obtained in the narrower northern segment of the deposit in -16 m of water, contained 6 m of intercalated layers of sand and clay (mixed sediments). These mixed sediments are characterized by darker reflectors in the seismic imagery compared to lighter reflectors that characterize sand. Vibracore MRVC-05-12, located in the mid-section of the deposit in -12 m of water, contained clean sand in the upper 2.4 m and sand with two clay layers (2.5 to 3.4 m and 3.8 to 4.3 m). Vibracore MRVC-05-13, located in the wider southern segment of the deposit in -12 m of water contained mostly clean sand with basal clay lamina. Sand in this core showed a slight coarsening upward trend (0.13 mm at the base to 0.15 mm at the top) with less than 5% silt content overall. The lack of well-defined reflectors and uniform light tones in the seismic trace suggests the presence of sand below the depth of vibracore MRVC-05-13. Sand thickness in Fort Jackson Point Bar ranges to at least 15 m thick. Relative relief of these sand waves seldom exceeds 1 m and is thus subdued compared to surface bedforms previously described.

Sediments grade downriver from mixtures of silt and clay mixed with sand (vibracore MRVC-05-11) to predominantly sandy sediments (cores MRVC-05-12 and MRVC-05-13). Deposit width (distance between 10 m and the 21 m contours) increases downriver and the sub-bottom profile of the southern segment of the deposit shows light tones in the seismic trace and relatively homogenous seismic reflectors that are characteristic of riverine sand.

Sidescan sonar investigations were conducted in an effort to map the occurrence of potential dredging obstructions and bottom topography. Georeferenced sidescan mosaics, overlain on top of aerial photographs show surface sand waves that are generally orientated transverse to riverbanks. Well-developed sand waves, parallel to the direction of flow and transverse to riverbanks, occur near vibracores MRVC-05-01, 02 and 03 and near vibracores MRVC-05-04, -05, -06 and -09. As a general spatial trend, the sonar imagery tends to become darker (more reflectivity) near riverbanks and lighter (less reflectivity) towards the thalweg. This pattern is most prominent along the Nairn Point Bar and in the river bend between cores MRVC-05-04 and MRVC-05-05. Lighter toned sonar imagery is not infallibly associated with sandy sediments. The area where vibracore MRVC-05-10 was acquired, for example, is darker toned but composed of clean sandy sediments. Reflection patterns from sidescan imagery should not be used to assess surface (river bottom) sediment texture without further image processing, filtering and calibration (which is beyond the present scope of work).

Potential sand volumes were calculated from data contained in vibracores and seismic reflection profiles. Sand thickness was extrapolated beyond vibracore recovery length when seismic records indicated continuity (and extension) of the sand deposits. The total volume estimated from seven potential borrow sites is 23 x 10^6 m^3 of clean sand. These volumes were based on sediment thickness, as determined from vibracore and seismic data. Deposit volumes are summarized in Table 1. Deposits are named from north to south as MR (Mississippi River) potential borrows A, B, C, D, E, F and G in relation to mile markers.

Table 1. Estimated sand volumes in potential borrows in the Lower Mississippi River.

Borrow Area	Approximate Location	Volume (m^3)[1]
MR A	Nairn Point Bar, 0.8 km downriver from MM 35	2,164,000
MR B	Across river from Empire intersection, 2.4 km upriver to 3.2 km downriver from MM 30	11,422,000
MR C	1.6 km upriver from MM 25	1,010,000
MR D	About 150 m upriver from MM 25	187,000
MR E	Upriver Ft. Jackson Point Bar about 1.6 km downriver from MM 25	4,877,000
MR F	Ft. Jackson Point Bar 0.8 km upriver from MM 20	722, 000
MR G	Ft. Jackson Point Bar 2.4 km south of MM 20	2,737,000
Total		**23,119,000**

1. Based on Finkl *et al*. (2006).

CONCLUSIONS

Sand resources along the southern Louisiana coast, particularly along the Plaquemines coast, are relatively scarce. Alternative sand sources for the restoration of the Plaquemines coast were investigated in this study along the Lower Mississippi River (LMR).

Thirteen vibracores and 37 line-km of geophysical data (seismic reflection profiles, bathymetry, vibracore, and magnetometer surveys) were obtained along the LMR between MM 35 and MM 15. Thick sand deposits (15-20 m thick) comprised by clean (generally less than 5% silt) fine to medium sands (0.12 to 0.4 mm, but mostly around 0.2 mm) were found in most of the investigated sites. These deposits are composed of modern sands associated

with fluvial bedload transport in the upper 1 to 2 m (as sand waves) and relict riverine sands below these surface bedforms. The sand deposits identified in this study of the LMR have great potential to support large-scale coastal restoration of the Plaquemines coast. Total volumes estimated in seven deposits are on the order of 23 x 10^6 m^3. Bedload deposits in the Mississippi River may provide an important renewable resource for restoration of Louisiana's barrier islands. Feasibility studies are being conducted to determine the best mode of delivery of sand from the Mississippi River to the barrier islands, whether pumping through long pipelines, by barge, or combinations involving booster pumps or sediment staging areas.

RE-ENGINEERING THE MISSISSIPPI RIVER AS A SEDIMENT DELIVERY SYSTEM

Harley S. Winer[1]

1. U.S. Army Corps of Engineers, New Orleans District, P. O. Box 60267, New Orleans, LA 70160-0267, USA. Harley.S.Winer@mvn02.usace.army.mil.

Abstract: Engineering works on the Mississippi River constrain the River in its present course and prevent flood waters from overflowing the river banks. Thus, very little of the river's sediment load goes into the wetlands, with the major fraction transported off the edge of the continental shelf into deep water. A realistic approach is presented that reconfigures the arrangement of structures at the Old River Complex so that a predominance of the sediment load would go down the Atchafalaya River where it would be deposited in the shallow waters of Atchafalaya Bay, thus creating a large expanse of marsh lands that would help to compensate for the loss of wetlands in the rest of southern Louisiana. The purpose of this paper is to advocate for a comprehensive analysis, in the form of a feasibility study, of the benefits and drawbacks of redirecting the sediment load at Old River.

INTRODUCTION

The average annual sediment load of the lower Mississippi River (below Old River Control Complex) is estimated to be 131 million tons. Because the natural delta building processes have been drastically altered, a very large portion of this sediment goes off the edge of the continental shelf and is deposited in the deep waters of the Gulf of Mexico. The deltaic processes that built the landmass of southern Louisiana have been altered by the river engineering that has provided flood protection to the local residents and navigation benefits to the region and the nation. At present only a small portion of the sediment load is directed into marsh building through the beneficial use of dredged materials program and engineered sediment diversions. To counter the steady loss of the Louisiana coastal wetlands, it is imperative that a method be found to fully utilize the Mississippi River sediment load by directing its totality into wetland creation. It is

unrealistic to think in terms of removing existing levees so as to allow the river to naturally flood its banks and deposit sediment in the adjacent wetlands. Annual flooding is not an option for the citizens of the developed areas along the Mississippi River corridor. A more realistic approach is presented that reconfigures the plumbing at the Old River Control complex so that the predominance of the sediment load would go down the Atchafalaya River where it would end up being deposited in the shallow waters of Atchafalaya Bay, thus creating a large expanse of marsh lands that would help to compensate for the loss of wetlands in the rest of southern Louisiana.

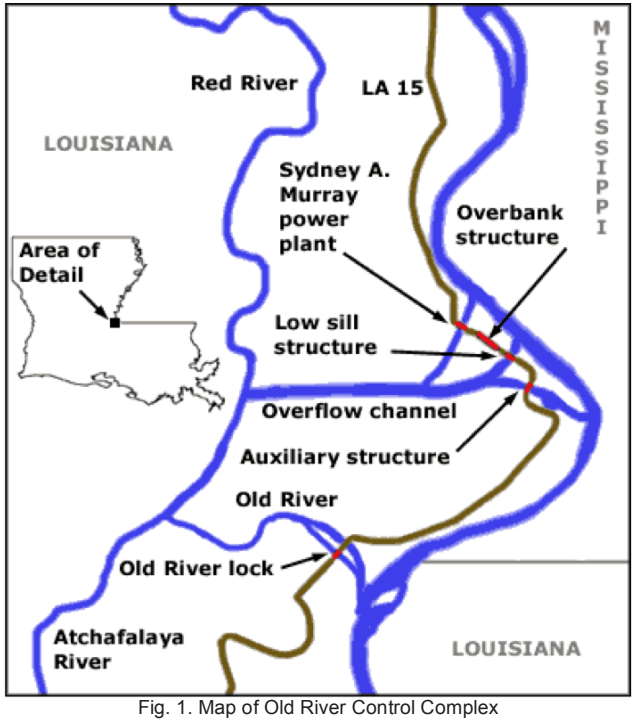

Fig. 1. Map of Old River Control Complex

The distribution of flow at the Old River Control Complex has been fixed by legislation. Seventy percent of the latitude flow (Latitude flow refers to the combined flow from the Mississippi and Red Rivers crossing the latitude of the Old River Control Complex) is to go down the Mississippi River and thirty per cent of the latitude flow is to go down the Atchafalaya. This was the distribution of flow at the time of the enabling legislation more than half a century ago. Although the enabling legislation provided for the same distribution of sediment, more than the allotted seventy per cent goes down the Mississippi River. The Old River Auxiliary Structure, which was built after the 1973 flood weakened the Old River Control Structure, was specifically designed so that the inflow channel would capture a sediment rich flow, and thus help to correct the sediment

distribution problem. However, shortly after the Auxiliary Structure was put in service, a hydroelectric power plant, with a sediment lean inflow channel was installed to take advantage of the head differential between the Mississippi and the Old River Outflow Channel. (See Figure 1 for a map of the existing structures at Old River.) Because of the operation of the hydroelectric plant, the legislated sediment distribution has not been met in recent years. Despite the fact that the Atchafalaya sediment load has been less than legislated, there is sufficient sediment so that there is delta formation at the mouth of the Atchafalaya and the Wax Lake Outlet. This is one of the few places in Louisiana where land is actually accreting. Figure 2 shows recent delta growth at the mouth of Wax Lake Outlet. If the sediment load in the Atchafalaya River were to be significantly increased, the rate of delta growth at Wax Lake Outlet and the mouth of the Atchafalaya River would be significantly increased.

Fig. 2. Delta Growth at Wax Lake Outlet and Atchafalaya river mouth.

Since the flow and sediment distribution at Old River is mandated by existing legislation, any change in the operation of Old River would require new legislation. The purpose of this paper is to advocate for a comprehensive analysis, in the form of a feasibility study, of the benefits and drawbacks of redirecting the sediment load at Old River. The arguments in favor of such a study are many fold. First and primary is the impact of coastal land loss in southern Louisiana and the potential impact upon the entire Gulf of Mexico ecosystem. Most of the commercial Gulf fisheries are dependant in one way or another upon fringing coastal wetlands. The Louisiana coastal wetlands are the largest

extent of these coastal wetlands fringing the Gulf of Mexico. It is imperative that new coastal wetlands be created to replace the on going loss in the rest of Louisiana. It is not feasible, either monetarily or technically, to pump all of the sediment out of the lower Mississippi. Only by directing the flow into shallow water and allowing for natural deposition, is it feasible to utilize the sediment load for land building. The advantage of using the Atchafalaya as opposed to a major river division into the Barataria or Breton estuaries is that deep draft navigation would not be impacted. Redirecting the sediment load to the Atchafalaya River would have another benefit of reducing the maintenance dredging in the lower Mississippi River. This would be a quantitative monetary benefit.

The technical problems of maintaining navigation, flood control and freshwater supplies to the lower Mississippi River corridor are easily solved, as are also the issues of how to reconfigure the control structures at Old River to accomplish the proposed flow regimes. These are presented in the paper. The major problems are not technical but political. This paper also discusses the political and social implications of changing the flow and sediment distribution at Old River.

HISTORY

The Mississippi River is a heavily engineered river. The proposed scheme in this paper merely suggests re-engineering the system to resolve problems created by the engineering.

In 1831, under the direction of Henry Shreve, a cut was made across a narrow neck of the River that eliminated Turnbull's bend. This cut reduced the river mileage by seven miles. It also removed the mouth of the Red River from the river, eliminating the problem of shoaling at the mouth of the Red. The part of the river formerly known as Turnbull's Bend that was eliminated from the main stem of the Mississippi River came to be known as the old river channel, hence the name Old River. The north portion of the old river eventually silted in. However, it can still be identified in aerial photos of the area. The south portion of the old river carried flows into or out of the Mississippi depending upon the relative magnitudes of flows in the Red and the Mississippi. The Old River channel would sometimes flow east to west into the Atchafalaya and at other times flow west to east into the Mississippi.

In 1839 the state removed a massive 30 mile long log jam in the Atchafalaya. The removal of this impediment to flow allowed greater flow to go down the Atchafalaya. This greater flow eroded a larger channel which in turn allowed ever increasing flow down the Atchafalaya. This was a gradual process. Eventually the flow in the Old River channel was almost entirely from east to west.

By the 1930s this increasing proportion of flow going down the Atchafalaya began to worry scientists and engineers involved with the management of the river. In 1941 the Mississippi River Commission engaged Harold N. Fisk, a geologist at Louisiana State University, and a team of geographers and geologists to investigate delta-lobe switching by the Mississippi. The report of this team (Fisk, 1944) contributed greatly to the

understanding of the physical mechanisms involved in river channel switching. The Fisk report stated that the Atchafalaya was in the process of capturing the flow of the Mississippi. Furthermore the report made the prediction that by 1972 if nothing was done to alter the situation, the channel switching would be irreversible since the predominance of the flow would be down the Atchafalaya.

Since this channel switching was seen as a potential disaster for flood control and navigation, the response was to prevent the river from switching course. Within a very short period of time a Chief of Engineers report with a recommendation was submitted to Congress, funds were appropriated, and the Old River Control Structure was designed and built. This structure, comprised of eleven gates each 44 feet wide, enabled the regulation of the flow distribution as mandated. It became operational in 1955. In 1973 there was a record flood on the Mississippi River. Scour caused the collapse of a wing wall and emergency measures were necessary to save the structure. Inspections after the flood receded revealed scour holes and support piles dangling in the water underneath the structure. Repairs were made to strengthen the structure but the need for structural redundancy was clearly evident to the river managers. The Old River Auxiliary Control Structure was thus authorized, designed and built. It became operational in 1987. In addition to structural redundancy, the auxiliary structure offered the important feature of the ability to pass more sediment to the Atchafalaya. This is because the intake channel of the original structure was located on the outside of a river bend in a sediment lean location, whereas the new structure had its intake channel located on the inside of a river bend, i.e. in a sediment rich location. Generally, the suspended sediment concentration is greater on the inside of a bend then on the outside of a bend. (If it were otherwise river meanders would be self correcting). This ability to pass more sediment was of importance because the congressional authorization mandated not only the distribution of flow but the distribution of sediment.

In 1985, construction began on the Sidney A. Murray, Jr. Hydroelectric Plant. It is situated just north of the Low Sill Structure (another name of the first structure) and has its intake from the Mississippi at a sediment lean location on the outside of a bend. This facility, sponsored and owned by the town of Vidalia, Louisiana produces power from the head difference between the Mississippi River and the outfall channel flowing to the Atchafalaya. The plant began full-scale operation in 1990. Since the power plant takes a large portion of the flow going from the Mississippi to the Atchafalaya and because it is a sediment lean flow, the sediment going to the Atchafalaya is often less than the 30 percent mandated. None-the-less, even with reduced sediment going down the Atchafalaya, there is delta growth at the two outlets of the Atchafalaya as shown in Figure 2.

The present policy of preventing the Mississippi River from changing course has maintained flood control, navigation and freshwater supply to the lower Mississippi but has had disastrous unintended consequences not anticipated by the designers of the Old River Control complex. Because the mouth of the Mississippi River in Southwest Pass has been extended to the edge of the continental shelf, the sediment load of the

Mississippi River is deposited in deep water off the edge of the continental shelf. By contrast the continental shelf at the mouth of the Atchafalaya River is quite wide as is shown in Figure 3. Because the continental shelf is wide at the mouth of the Atchafalaya, sediment carried by the Atchafalaya is deposited in shallow water and builds land as is seen in Figure 2.

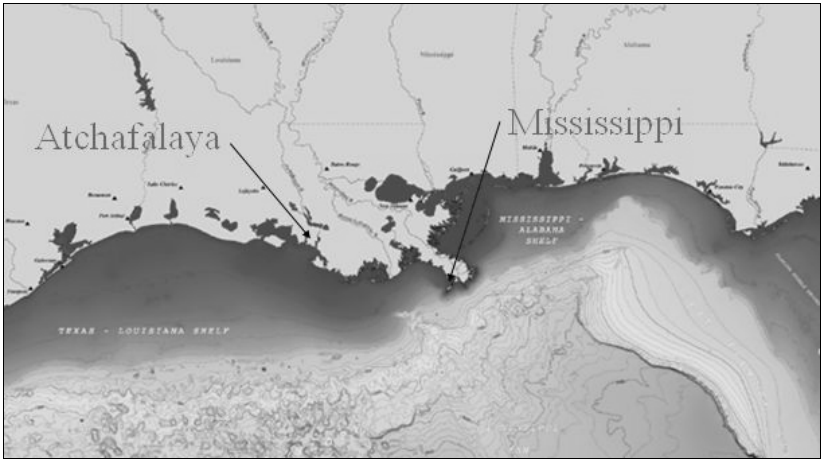

Fig. 3. Bathymetry of the Northern Gulf of Mexico. Dark (red in color version) shading is shallow water.

FLOW DISTRIBUTION

In a previous paper (Winer 2006) the author argued for a new paradigm in managing the flows of the lower Mississippi River. The proposed paradigm was "How do we provide for navigation, flood control and water supply along the lower Mississippi River corridor while allowing the River to change its course?" The suggested flow distribution was that for normal flows (i.e. neither flood flows or low flows) only the minimum flow necessary to keep the saltwater wedge out would go down the lower Mississippi and all of the rest of the flow along with the predominance of the sediment would go down the Atchafalaya. The minimum flow necessary to arrest the saltwater wedge was determined following the work of Soileau et. al. (1989). During flood flows the lower Mississippi would be utilized the same as it presently is along with flood control structures such as the Bonnet Carre Spillway. During low flows the scarcity of flow would be distributed the same as it is presently, as 70 percent of the latitude flow to the Mississippi and 30 percent to the Atchafalaya.

CONSTRUCTION SEQUENCING

The River could be allowed to change its course in a controlled manner through the construction of additional structures and the re-alignment of outfall canals from the existing structures. The sequencing proposed herein is meant as an initial stab at a feasible method of accomplishing the objective of allowing the River to change course to

the Atchafalaya channel. Only a detailed feasibility study can address all aspects of the river channel change and come up with the right and proper method.

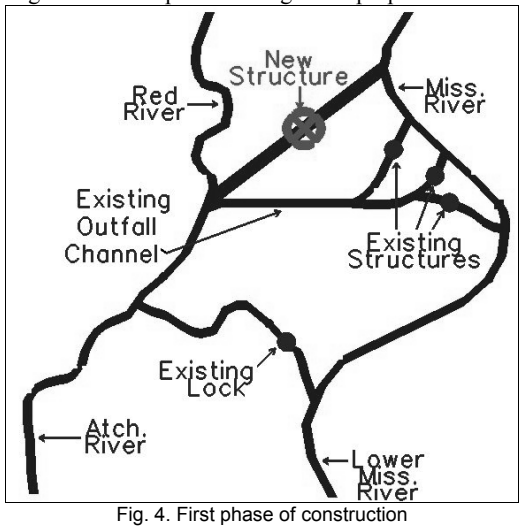

Fig. 4. First phase of construction

First, a new structure could be constructed in the dry and then have connecting channels dug to it. The new structure should be sufficiently large so as to be capable of passing the maximum flow determined. This structure could be located north of the existing complex of structures where the construction would not interfere with operation of the existing structures. This structure would also have a very low still for passing sediment. Upon completion of the new structure and the connecting channels as shown in Figure 4, this structure would be used for passing water to the Atchafalaya while the remaining phases of construction are taking place. There could be a time lag between the first phase and subsequent phases of construction, using this first structure to progressively increase flows in the Atchafalaya channel. Only a detailed study could estimate this time to allow the Atchafalaya channel to grow to accommodate increased flows.

The second phase of construction would be to realign the outfall channel so that the existing structures could be used to divert water into the lower Mississippi River. This would involve dredging a new channel and blocking the present outfall channel. By directing the outfall from the three existing structures to the lower Mississippi River and building a lock and dam across the lower Mississippi River just above the discharge of the outfall canal (see figure 5) the existing structures could then be used to divert flow into the lower Mississippi River. The lock and dam would need to be constructed at the same time as the realignment of the outfall canal (but not completed prior to the completion of the realignment of the outfall channel.) This would best be done swiftly so as to minimize the time that the hydro-electric plant is inoperable due to the channel realignment and/or insufficient heads. The lock and dam would need to be designed so

as to pass the projected flood flow in concert with the existing structures that would now be diverting water to the lower Mississippi River.

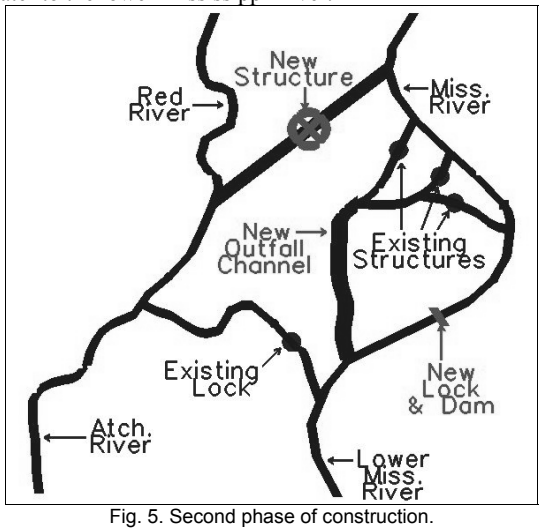

Fig. 5. Second phase of construction.

CHALLENGES AND OPPORTUNITIES

Reconfiguring the Old River Control Complex and increasing the flow distribution to the Atchafalaya will require extensive study and planning. The list presented here is only the beginning. A detailed study would inevitably add numerous issues to the list. First, the design and configuration of the structures at Old River needs to be optimized. A possible re-configuration has been presented but it requires considerable refinement. Second, a plan of gradually increased flows in the Atchafalaya would be necessary to increase the flow capacity of the Atchafalaya by allowing the river to carve a bigger channel. This would eventually necessitate the relocation of pipelines and bridges (both rail and highway) that cross the Atchafalaya. Levees and flood protection may also need to be relocated and raised.

Additional conveyance through the Teche ridge would also be necessary. The existing channels through the Teche Ridge (Wax Lake Outlet and the lower Atchafalaya River) would have to be enlarged or possibly an additional outlet would need to be created. At present the existing two outlets require a very high head to pass design flood flows.

Another issue is the possible change in stages along the Red River due to back water effects from increased stages in the Atchafalaya. This could impact agriculture along the river banks inside the levee system.

OPPOSITION

Opposition could come from those who would prefer to see marsh created near the metropolitan area of New Orleans in the hopes that it would provide protection from

hurricane storm surge. First, it is not certain that marsh creation is a viable hurricane protection method. Hurricane surge can travel great distances inland over low coastal lands. Second, even if it were a viable hurricane protection, there is no viable method to capture the entire sediment load of the lower Mississippi River and create marsh. Directing the flow along with the sediment load into shallow water is the only viable method of creating marsh lands with the river's sediment load. A major diversion of the River in the lower reach where there is deep draft navigation would require deep draft locks which would be a detriment to the shipping industry.

Opposition could also come from the citizenry and industries of the Morgan City area. Sending increased flows down the Atchafalaya and building a larger delta would radically affect Morgan City and the surrounding area. First, either an enlargement of the existing flow paths through the Teche ridge or an additional flow path would be required. This would involve the acquisition of real estate with all of the complication involved in dealing with private property ownership issues. Second, as the deltas grow, the length of the channel would also grow so that any particular location would be progressively further from the sea. This would result in a long term gradual increase in stages along the lower Atchafalaya channel. The businesses that use the riverfront of Morgan City would be impacted and in time the flood protection for Morgan City may need to be raised as the delta grows.

CONCLUSION

This proposal represents radical change. Change generally brings opposition. Radical change could well result in intense opposition. Political opposition, however, should not impede the discussion of this proposed alternative or the process to initiate a detailed feasibility study. There are indeed numerous impacts associated with this proposal. However, there are impacts to the present system of preventing the river from shifting course. The process of a feasibility study is to identify and address impacts either by removing, minimizing, or mitigating.

Holding the River in its present position means that a resource of millions of tons per year of sediment is lost off the edge of the continental shelf. Capturing all of that sediment through dredging is not feasible. Only large river diversions can capture and deliver all of the sediment. River diversions below Baton Rouge would require deep draft locks that would have huge costs both for construction and in terms of transit times.

The importance of the coastal wetlands to the entire eco-system of the Gulf of Mexico is well established. The proposed change of course of the river and its sediment load at Old River would insure that there will be emergent marsh in the future to replace the presently eroding marsh.

DISCLAIMER

Abstract: Land-building sediment diversions, such as the Mississippi River Diversion at West Bay, are being used as important building blocks in the conservation and restoration of Mississippi Delta wetlands. We have studied sediment deposition and retention in the West Bay diversion outfall area through analyses of sediment cores, bathymetry, and hydrodynamics. Cores and x-ray samples were collected at twenty stations in March 2004, August 2004, November 2005, and April 2006. Cores were sub-sampled in 2 cm increments and analyzed for grain size distributions and ^{7}Be activities which can be linked to recent sediment deposition. Bathymetric surveys were conducted in November 2005 and April 2006 and will be used to compare significant elevation changes to bay bottom contours. Data analysis for the study focuses on the ^{7}Be results in comparison with hydrodynamic forcing functions such as river and diversion flows and major storm activity.

INTRODUCTION

In the modern Mississippi Delta, subdeltas represent important and dynamic components of the landscape and sediment delivery system. In a general sense, we understand the processes that influence the growth and decay of subdeltas. However, our knowledge is insufficient to allow prediction of sediment deposition and

retention within subdeltas, and so we cannot reliably model the processes and resultant dynamic geomorphology. This inadequacy is problematic, because subdeltas, like the one being built at West Bay, are being used as important building blocks in the conservation and restoration of Mississippi Delta lands and wetlands. The overall goal of this study is to elucidate our understanding of sediment dispersal and retention within subdeltas, thus enhancing assessment, planning, and predictive capabilities for the West Bay Diversion and for future land-building projects of comparable design.

Background

The West Bay Subdelta Complex is located in the Mississippi River Delta in Plaquemines Parish, Louisiana. It is one of the six subdelta complexes defined by Coleman and Gagliano (1964) comprising the most recent framework of the modern Birdfoot Delta as shown in Figure 1.

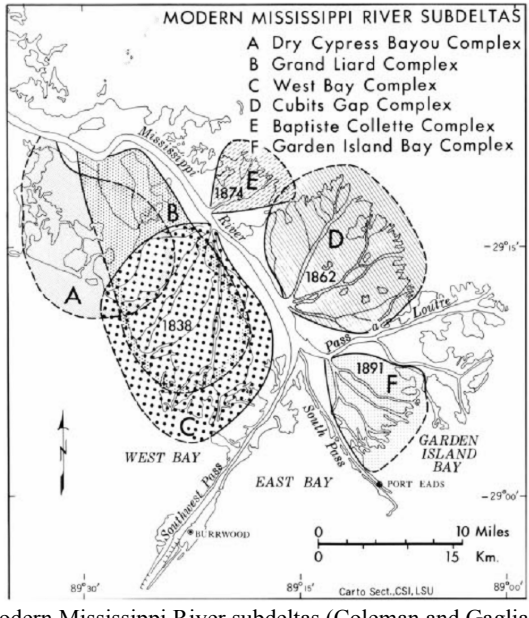

Fig. 1. Modern Mississippi River subdeltas (Coleman and Gagliano, 1964)

Historical dating through map studies has shown that the West Bay subdelta originated around 1838 as a break in the natural Mississippi River levee during flood stage creating an intricate land-building crevasse splay. The location of this break, which is still hydraulically open, is just below the present day town of Venice, LA and is know as "The Jump". Figure 2 shows a progression of subdelta growth and initial stage of deterioration over a timescale from 1845 to 1958.

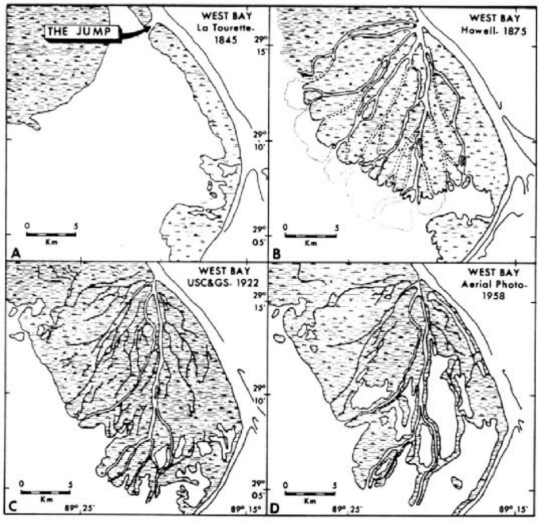

Fig. 2. West Bay subdelta evolution (Coleman, 2006)

This original subdelta growth work performed by Louisiana State University's Coastal Studies Institute (LSU CSI) (Fig. 2) can be extended further into time by comparing these past map studies with recent imagery. Figure 3 illustrates false-color IR imagery from 1998 of the West Bay/Head of Passes region, compared to a 1953 topographic map of the same area, at the same scale. Extensive regions mapped as marsh in 1953 are now open water. Our study area is outlined in black, west of the river.

1998 1953

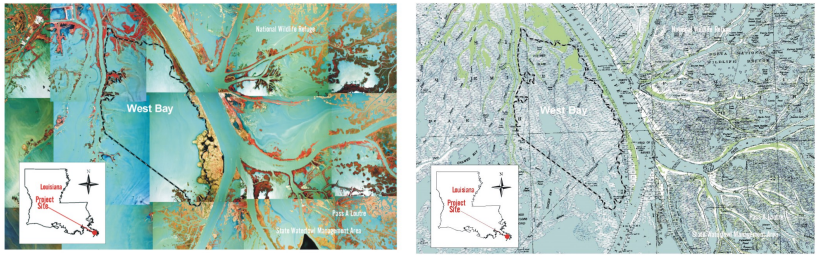

Fig. 3. Project area marsh loss comparison

The extensive mapping study by LSU CSI is summarized in the subdelta life cycle curve shown in Figure 4. The curve is a typical for a subdelta life cycle, which generally lasts from 100 to 150 years from inception to abandonment. In the mid 1900's, the West Bay subdelta entered the natural deterioration phase of its life cycle which was possibly accelerated by river channelization, canal dredging, and decreased sediment loads in the Mississippi River. As hydraulic efficiency of the subdelta decreased, the valuable inputs of fresh water, nutrients, and sediment declined and the marsh succumbed to erosion and subsidence.

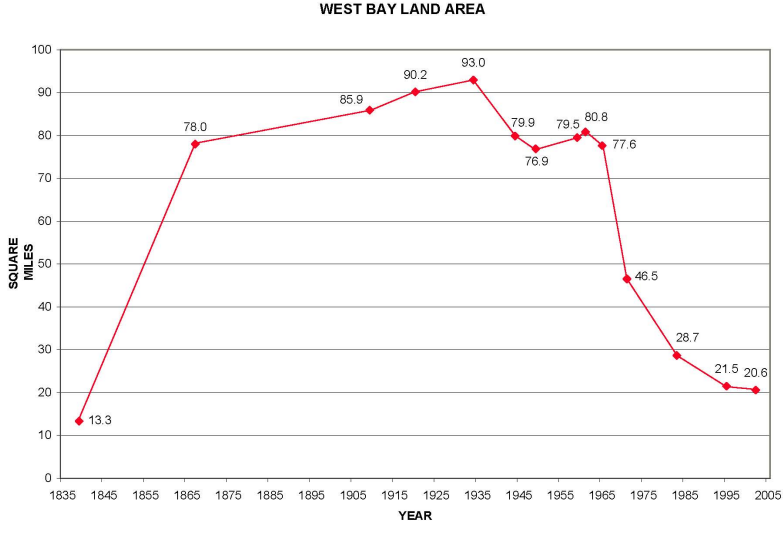

Fig. 4. West Bay Subdelta Complex life cycle curve (Coleman, 2006)

Restoration Efforts

The West Bay Sediment Diversion was one of the first projects approved by the Coastal Wetlands Planning Protection and Restoration Act (CWPPRA) on its first priority list in 1990 and was sponsored by the Louisiana Department of Natural Resources (LDNR) and the U.S. Army Corps of Engineers (USACE). The main goal set forth in the CWPPRA project monitoring plan was to create, nourish, and maintain 9,831 acres of emergent marsh within the project area over the 20 year project life by enhancing the natural process of delta growth and through the beneficial placement of material dredged during construction and maintenance. The project consists of a conveyance channel from the river into West Bay located at river mile 4.7 above Head of Passes along the right descending bank (LDNR, 2003). The initial and present capacity of the diversion is 20,000 ft^3/s (~570 m^3/s) with plans to increase its capacity to 50,000 ft^3/s (~1400 m^3/s) after sufficient monitoring.

Planning and engineering for the project began in 1990. Because of navigation concerns and land rights negotiations, the project was not constructed until late 2003. In November of 2003 dredging of the diversion channel was completed and sediment laden Mississippi River water once again flowed into West Bay.

Study Objectives

In bays, such as West Bay, that are actively receiving river sediment, the exact balance between sediment retention in the bays (i.e., sediment that builds land and wetlands) and sediment bypassing to the shelf is not known. However, the West Bay Sediment Diversion represents an excellent opportunity to study this phenomenon, and a complete quantitative understanding of such processes is essential to predicting the success of such enterprises (and to predicting impacts on downdrift coastal environments). Although the work presented herein represents only a small step toward an ability to understand and predict subdelta evolution, we suggest that these steps provide important insights applicable to future efforts to manage river sediment and build wetlands, particularly in settings where project design needs to be optimized for maximum sediment retention.

This study is intended to increase our understanding of sediment delivery by the diversion, sediment retention within the bay and, ultimately, the success of the diversion toward building deltaic wetlands. Our specific objectives are to: (1) describe sediment deposition patterns within the study area using proven sediment-radiochemical techniques dating techniques and (2) link these patterns to hydrodynamic forcing functions such as river and diversion flows and major storm events.

METHODS

^{7}Be Dating

Radioisotopes, such as Berillyum-7 (^{7}Be, ½-life 53.3 days) can be used to reconstruct the recent sedimentation history of the coastal seabed, particularly in river-influenced settings. In this study, ^{7}Be is used to track sediment flux from the diversion and determine short-term sediment accumulation rates. ^{7}Be is a naturally occurring radioisotope with a half-life of 53.3 days that is formed in the atmosphere by reactions between cosmic rays and nitrogen and oxygen. In fluvial-marine depositional systems, ^{7}Be geochronology is a powerful tool to document and estimate sediment flux and deposition over seasonal timescales (Sommerfield et al., 1999; Allison et al., 2000; Rotondo and Bentley, 2003). In fluvial marine systems where the catchment basin is larger than the region receiving sediment, (such as the Mississippi Delta), the cosmogenic, particle-reactive radioisotope ^{7}Be can be used as a tracer of sediments recently derived from the fluvial source. Sediments that contain significant ^{7}Be must have been deposited within several half-lives of ^{7}Be, or <200 days, based on its 53-day half life.

Sediment Sampling

Most of West Bay seabed is subtidal and > 1 m deep, so cores were collected from shallow-draft vessels using pushcores. Coring was coordinated with the hydrographic

surveys along established CWPPRA bathymetric survey lines at seventeen stations as shown in Figure 5. Sample locations were evenly distributed throughout the study area including areas near the diversion, open water deeper areas in the middle of the bay, shallower areas around the periphery of the bay, and semi-enclosed areas with less efficient hydraulic connections to the bay and diversion flows.

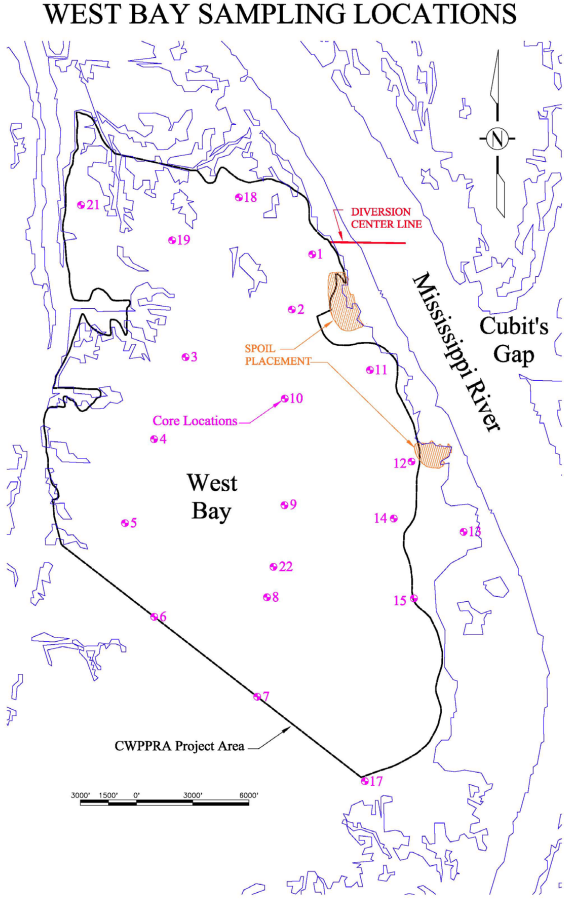

Fig. 5. West Bay Sampling Plan

Samples were collected in four separate events from 2004 to 2006, intended to capture conditions just before and after annual high water. The first sampling event was conducted on March 18-19 (2004) and the second sampling event was conducted on August 23-24 (2004). LDNR provided an airboat and two field personnel at no

cost for these efforts. Subsequently, funding was allocated through a grant from the Coastal Restoration and Enhancement through Science and Technology program (CREST) allowing for more robust data collection efforts. Funding for the CREST program is administered by the Louisiana Universities Marine Consortium (LUMCON) using funds provided by the National Ocean Service of the National Oceanic and Atmospheric Administration (NOAA). In the process of securing this funding, no sampling was conducted in the spring of 2005. The next two field collection events were undertaken by LSU CSI researchers and field support staff. Sampling was conducted from a shallow-draft bay boat that could access most sampling locations, with the exception of a semi-enclosed area which could only be reached by airboat. The third sampling event was conducted on November 3 (2005). It is important to note that this was approximately two months after Hurricane Katrina, which devastated lower Plaquemines Parish making lodging and other logistics very limited. The fourth sampling event was conducted on April 12-14 (2006).

Cores were collected using 10-cm-diameter PVC core barrels. Because this study focuses primarily on short-term accumulation rates produced by recent fluvial processes, core barrels were cut in short lengths of approximately 1 m long. The CSI field staff constructed an efficient self-sealing coring device designed to allow core extraction with minimal effort. The suction head was constructed out of an aluminum billet with a shoulder cut as a bearing surface for core insertion. The barrel was sealed to the suction head with hose clamps and tape. Venting of captured air and water was accomplished with eight (8), 1.75 cm vents that seal with a spring loaded, rubber-faced aluminum plate. Spring tension was adjustable to account for different viscosities of material being vented. When core extraction was initiated, a suction was created to the interior of the core barrel, facilitating removal of the core with minimal material loss. Capping is done once the core was recovered.

X-ray samples were acquired using three-sided Plexiglas trays employing a sliding panel as the fourth side. The tray was initially pushed into the bay floor then the fourth panel was slid into place guided by grooves in the side panels, thereby shearing the sample from the adjacent sediments and enclosing within the tray. The sample was then pulled from the bay floor and capped and sealed for storage and travel. In locations deeper than 1 m this was accomplished using SCUBA gear.

Sediment Analyses

X-radiographic subsamples were imaged soon after collection using a Thales Flashscan digital panel X-ray detector with 14 bit, 127 μm pixel resolution. Images were then stored as 16-bit TIFF files for subsequent study. Activities of ^{7}Be were determined by gamma spectroscopy of dried sediment (477.7 KeV peak for ^{7}Be). The sediment was weighed before and after drying for water content to be used in porosity calculations. A known mass of ground sediment was then placed in a 6 cm petri dish and sealed. The sealed samples were analyzed on a Canberra gamma detector.

RESULTS

The maximum depth of ^{7}Be occurrence is a useful indicator of short-term (months) sediment deposition and mixing because of its relatively short half life (53.3 days). Profiles of ^{7}Be activity in the seabed were determined for each core sampling station in west bay for the four sampling events. Beryllium activity at the time of field sampling (A) measured in decays per minute per gram of sediment (dpm/g) was calculated using the equation:

$$A = A_o e^{-\lambda t} \quad (1)$$

where A_o is the activity at the time of detection, $\lambda = 0.013\ d^{-1}$ is the decay constant for ^{7}Be, and t is the time elapsed between sample collection and detection. Figure 6 shows ^{7}Be activity profiles for station WB01, which is closest to the diversion outfall, and WB05, approximately 3.5 miles southwest of the diversion outfall.

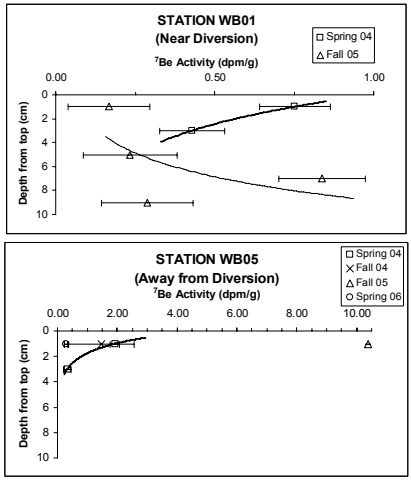

Fig. 6. Graphs of ^{7}Be Activity (dpm/g)

The WB01 results for the Spring 2004 sampling event show a typical logarithmic decrease from 0 to 4 cm depth in the core. The Fall 2005 WB01 results show an increase in activity with depth, suggesting strong physical reworking. Fall 2004 and Spring 2006 sampling events resulted in no detected ^{7}Be, possibly due to sediment erosion, considering the close proximity to turbulent diversion flows. ^{7}Be was detected near the surface of the cores at station WB05 for all sampling events with an exceptionally high amount of activity for the Fall 2005 sample. It is suspected that this is due to a large sedimentary event layer produced by Hurricane Katrina.

The X-radiographic images shown in Figure 7 taken at station WB05 also show evidence of this significant event layer. The Spring and Fall 2004 images show thin layers of fine sediment deposition. The top 4 cm of the these images are also more transparent indicating more recently deposited, less compacted sediments. This compares well with the ^{7}Be activity profiles from Figure 6 which indicate a ^{7}Be penetration of about 4 cm in this core (i.e., the top 4 cm of sediment are recently deposited). The Fall 2005 image shows a much thicker layer of relatively dense sediment above thin layers of lower density sediment identified in previous sampling events. The thickness and higher density of this layer may indicate coarser-grained sediment deposited by Hurricane Katrina. This layer also contains the highest ^{7}Be activity found during any sampling event. Thin layers of finer sediment become more evident above this layer in the Spring 2006 image and the ^{7}Be activity drops back down to below 0.5 dpm/g.

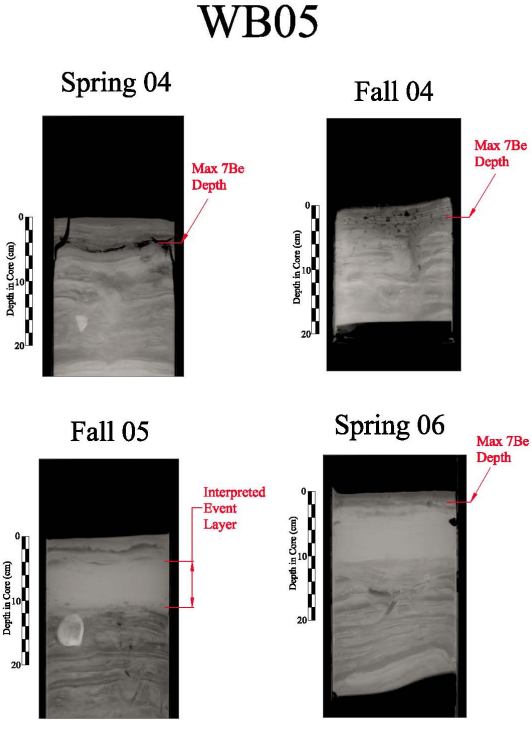

Fig. 7. X-ray images of sedimentary layers for station WB05. Bright zones indicate relatively high density (coarser grain size or lower water content), whereas darker shades indicate lower density, due to finer grain size and/or higher water content.

^{7}Be activity can also be reported on a volumetric basis, calculated as the product of the ^{7}Be activity the solids volume fraction (1-porosity), and the average density of the sediment (2.65 g/cm^{3}). Figure 8 shows ^{7}Be activity profiles for stations WB01 and WB05 after this conversion.

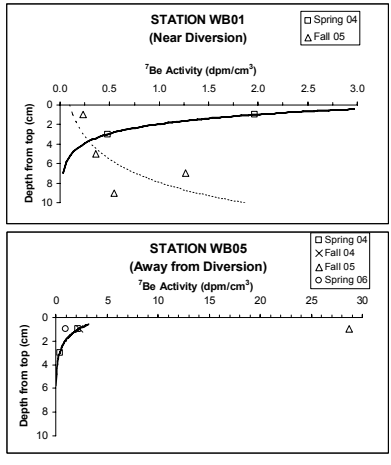

Fig. 8. Graph of ^{7}Be Activity (dpm/cm^{3})

Total inventories were then calculated by integrating volumetric ^{7}Be activity with respect to total core depth for each sampling event. A summary of ^{7}Be inventories for stations WB01 and WB05 are shown in Figure 9.

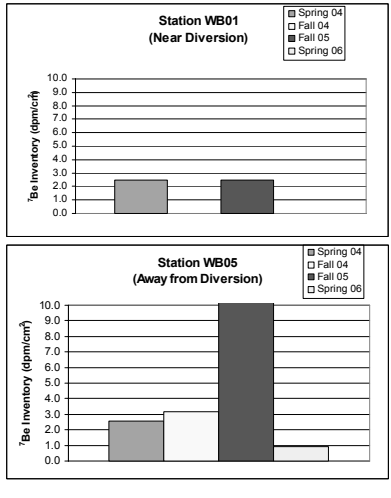

Fig. 9. Summary of ^{7}Be Inventory (dpm/cm^{2})

Figure 10 shows maps of ^{7}Be inventories for each station from all four sampling events. The highest inventories are interpreted to represent the most rapid sediment deposition. The magnitudes and distribution patterns appear to be related to the river hydrograph and corresponding diversion flows summarized in Figure 10 as well as hurricane related deposition and mixing. The Spring 2004 samples were taken after a river hydrograph peak of approximately 550,000 cubic feet per second (cfs). Results for this sampling event suggest fresh sediment deposition along the western margin of the bay, and show the highest ^{7}Be inventories of our study, with the exception of the Fall 2005 samples which were taken approximately two months after Hurricane Katrina. The Fall 2004 and Spring 2006 samples were collected after river hydrograph lows of less than 200,000 cfs. These observations suggest that deposition at relatively low river levels can occur in the middle of the bay, where water depths are on the order of 1-2 m.

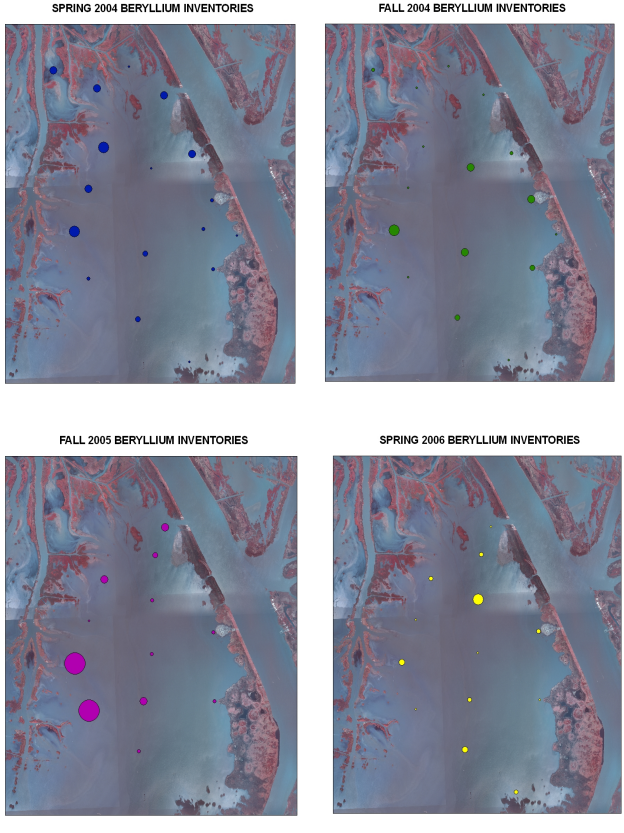

Fig. 10. Spatial distribution of ^{7}Be Inventories.

Figure 11 illustrates the river and diversion flow hydrographs (in cfs) along with total ^{7}Be inventories in dpm/cm^{2} for each sampling event. Total inventories were calculated by summing inventories from core sampling stations which were replicated for each sampling event. No flow data were collected from August to December of 2005 due to Hurricane Katrina. However, the highest total ^{7}Be inventory was calculated during this time period, indicating a large amount of sediment re-suspension, deposition, and physical mixing. The total inventories from the Spring 2004, Fall 2004, and Spring 2006 appear to track river flows and to a lesser extent, diversion flows. For example, the Spring 2004 samples resulted in more than twice the ^{7}Be inventory than that of the Spring 2006 samples which were taken during higher diversion flows but a lower river stage. This suggests that river flows, and therefore suspended sediment, are entering the study area through other avenues than only the diversion. River flows were measured at Venice near "the Jump" where a portion of the flow is diverted to Grand Pass which borders the study area on the western margin.

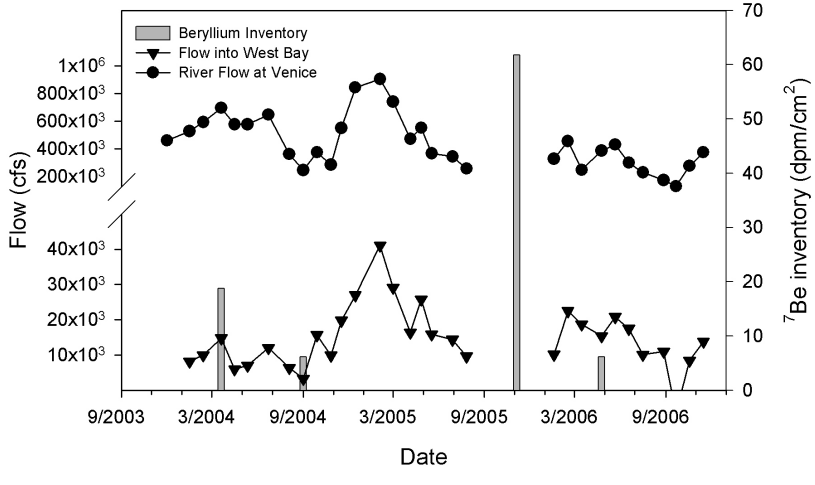

Fig. 11. West Bay Flow and Total ^{7}Be Inventory Analysis (USACE, 2006)

DISCUSSION

The strategy of the initial study plan was to track two (2) normal cycles of the Mississippi River hydrograph by timing sampling events with rising and falling limbs of river flow. The 2004 river hydrograph (Fig. 10) displayed a predictable pattern, however during 2005 irregular flow patterns were encountered. The Spring 2005 flow peak was significantly higher than those of the 2004 and 2006 spring

seasons. No sampling was conducted in Spring 2005, due to cost considerations. Following this peak, Hurricanes Katrina and Rita struck the Louisiana coast in late summer, devastating lower Plaquemines Parish. Flow records were not recorded for the following six months however the study team did manage to conduct a coring trip in November 2005. The results from these samples produced ^{7}Be inventories of much greater proportions than those of the other three coring trips (Fig. 10). From this data and evidence of substantial deposition layer seen in a number of the x-ray images taken during in the Fall 2005 and Spring 2006 (Fig. 7), it is evident the extreme energy of the hurricanes transported copious amounts of sediment with coarser grain size than the sediment being delivered by the diversion or other sources.

The 2006 river hydrograph returned to a more typical pattern resembling that of 2004, however with lower flow magnitudes. This is reflected in the Spring 2006 ^{7}Be inventory which is approximately one third of that found in Spring 2004 despite a higher diversion flow in 2006. This difference certainly warrants additional investigation into other factors which could be affecting the results. These factors could include river sediment loads, sediment loads being captured by the diversion, affects of wind and waves, and associated sediment re-suspension and transport within the bay.

As part of the study, additional data were collected but have not yet been analyzed. These data include continuous records of velocities and turbidity at the diversion cut and at two sites within the bay, as well as continuous wave measurements at the bay sites, bathymetric elevation surveys of both the diversion cut and bay bottom, and grain size analysis of the sediment cores.

Long term records of river flow and sediment loads are also available for additional analysis and insight. They will be used along with the diversion flow records to estimate net sediment influx into the bay and compared against sediment accumulation rates calculated at sampling locations from ^{7}Be activities and penetration depths. Through this analysis sediment retention rates within the project area will be estimated. Comparing ^{7}Be activities at West Bay to activities found at other sites in coastal Louisiana that have no riverine influence may also help decipher river and diversion induced sediment deposition from other background sources.

CONCLUSIONS

Analysis of ^{7}Be activities and inventories, x-ray images of sediment profiles, and diversion hydrographs all show strong indication that the West Bay Sediment Diversion is delivering sediment from the Mississippi River into West Bay. Data collected during the study period also shows strong evidence that sediment deposition in West Bay can also be attributed to major storm events and river flows entering the study area from locations other than the diversion. Upcoming analysis of sediment grain size, flow, suspended sediment concentrations, wind and wave

influences, bathymetry evolution, and previous studies will allow for further understanding of diversion function and performance.

ACKNOWLEDGEMENTS

We appreciate all of the cooperation and support provided by the CWPPRA partnering project sponsors LDNR and USACE. We also appreciate all funding and support from NOAA's CREST grant program and LSU CSI and look forward to continued collaboration with these personnel for a successful study.

Abstract: This paper presents the results of a numerical model study on initial delta formation in basins of different water depths. A process-based model (Delft3D-Online) is used to calculate fluid flow and sediment transport patterns at a newly formed river effluent. In absence of wave and tidal forcing, the river effluent is fully river dominated. The model results are interpreted in terms of morphology and stratigraphy. For the shallow basin case, the delta develops as a complex pattern of channels and shoals analogous to Wax delta. The simulated delta development in the deep basin is markedly different and resembles a classic prograding bird foot delta morphology. Typical clay-rich prodelta deposits underlie sandy bar and channel deposits. The top of the sedimentary sequence consists of a clay-rich delta plain deposit. The potential of the process-based model to simulate typical delta morphologies and a realistic stratigraphy provides many new opportunities to bridge typical engineering and geological research approaches.

INTRODUCTION

Numerical modeling in sedimentary geology has significantly attributed to the understanding of depositional systems and their preserved deposits since the 1970's. The

first models were based on simplified behavior of geometric rules and reproduced large scales (10-100 km) stratigraphic sequences that formed over long periods (10^4 to 10^6 years). To better understand the small-scale variability in sedimentary deposits, models generally became more refined and elaborate. As the level of understanding of depositional systems increased so did the degree of detail in the models. Behavior rules were partially replaced by process-rules leading to models that were constantly at the limit of the computational possibilities of the time. At present, improved processor speed and intelligent up scaling algorithms of sediment transport have led to a new cross-over situation where process-driven morphodynamic models developed by hydraulic engineers can be usefully applied to scales relevant to sedimentary geologists who study detailed sedimentology and stratigraphy. In this paper we apply the process-based model Delft3D-Online to simulate the initial stages of delta formation and view the results with 'geologic eyes'. As such, morphodynamic modeling of initial delta formation opens the opportunity to interpret modeling results in terms of combined morphologic and stratigraphic development. Hence, it provides a bridge to merge knowledge of long term (geological/ sedimentological) and short-term (hydraulic engineering) process understanding. Both fields of expertise have historically focused on deltas as an important research area, but due to the difference in approach relatively little new understanding has been gained by combining expertise. Studies such as these can therefore test the assumptions made in the engineering world for their validity in earth sciences.

This paper shows results of such an approach to a 'newly-formed' river effluent. To reduce the complexity in flow patterns at the effluent we will focus on a river-dominated effluent by assuming no waves and tides to be present. Furthermore, at this stage of our research we try to avoid too much complexity at the same time. Hence, complex flow patterns by salinity mixing effects and the associated flocculation of clay particles have been disregarded by restricting our simulations to homopycnal conditions, c.f. low sediment concentrations at the river effluent and a fresh water basin.

Validating a process-model is extremely difficult due to the vast amounts of processes that can be adjusted in the model. In addition, data time series relevant to delta development at a timescale between years and centuries are absent. Time series measurements are generally too short to determine the overall net sediment transport directions and rates at longer time scales. The sedimentary record provides only data of the preserved sediments and therefore is not a complete data record. Yet this scale is crucial to the understanding of initial delta formation, as well as to the further development of deltas. It is for this reason that numerical modeling can provide and test new hypotheses that relate stratigraphy to their formative processes and boundary conditions (Figure 1).

Numerical modeling of deltaic sedimentary systems can be used to test sedimentological concepts and dogmas thirty years after L.D. Wright's (1977) benchmark paper on deltaic depositional patterns at river effluents. We now can actually simulate river mouth processes and sedimentation during the initial stage of delta formation. According to

Wright (1977), the complexity of river mouth processes, in the absence of disturbance by tide and wave action, can be categorized into three effluent types that are dominated by either outflow inertia, turbulent bed friction and outflow buoyancy. Numerical morphodynamic modeling may enable us to test (1) the applicability of Wright's original ideas on *dominant effluent forcings*, (2) study the relation between variable effluent forcings *and intrinsic delta behavior*, c.f. mouth bar formation, channel bifurcation, channel abandonment, and (3) relate the *continuous range* in effluent forcings to morphological development of initial deltas.

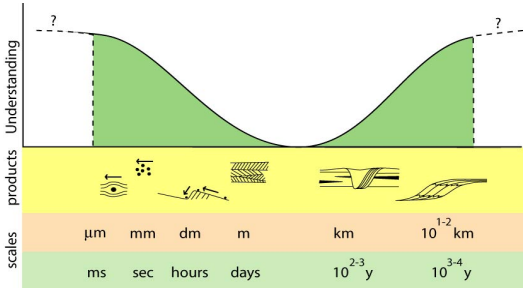

Fig.1. Schematic diagram showing our lack of understanding at the boundary between in situ measurements and stratigraphic data.

MORPHODYNAMIC MODEL

Delft3D-flow solves the unsteady shallow-water equations, that consist of the continuity equation, the horizontal momentum equations, the transport equation under the shallow water and Boussinesq assumptions (Elias 2006). Vertical accelerations are assumed minor compared to gravitational acceleration (shallow water assumption) reducing the vertical momentum equation to the hydrostatic pressure relation. By specifying boundary conditions for bed (quadratic friction law using a Chézy coefficient of 50 m½/s), free surface (no wind stress) and lateral boundaries (fixed water levels on the open-sea boundaries and total discharge at the river inflow with free-slip wall roughness conditions) the equations can be solved on a staggered grid using an Alternating Direction Implicit method (Stelling 1984; Leendertse 1987). Wave effects can be incorporated in the flow simulation by running the 3rd generation SWAN wave processor, but since we are primarily interested in the effluent forcings we have eliminated the effects of waves and tides.

The Delft3D Online Morphology add-on supplements the Delft3D-flow model results with sediment transport computations (Lesser et al. 2004). In this study the default Van Rijn (1993) transport formulation is used for non-cohesive sediment. The suspended load transport is calculated by solving the three-dimensional diffusion-advection equation. There, the sediment eddy diffusivities are a function of the fluid eddy diffusivities as

calculated by Delft3D-flow using horizontal large eddy simulation and grain settling velocity. The total sediment transport is obtained from the sum of the bed load and suspended load transports. Bed load transports represent the particle movements in the wave boundary layer due to currents and waves. Suspended load transports are the transports above the bed layer. Before bed-level updating, sediment transport rates are corrected for bed-slope effects. Overview of the implementation of the Van Rijn transport formulations (Van Rijn 1993) in Delft3D Online Morphology are presented by Walstra and Van Rijn (2003) nad Lesser et al. (2004).

Several methods exist to manage the communication between flow pattern and bathymetric change. Here, a method named 'Online' is used which updates flow, sediment transport and bathymetry all at the same small time steps (Roelvink 2006). The updating of the bottom takes very little computation time, however, this method does not take into consideration the difference in time scales between the flow and morphology. Therefore a simple device can be used, called the 'morphological factor' (Lesser et al. 2004). This factor increases the depth change rates by a constant factor n, so that after a simulation of one day we have in fact modeled the morphological changes over n days assuming that the hydrodynamic changes are small compared to the bed changes within that period. In a typical Delft3D-flow simulation we would apply a time step of 1 minute; with a high morphological factor of $n = 60$ this implies that we update the bathymetry every (morphological) hour. An advantage of this 'Online' method is, that short-term processes are coupled at flow time-step level, which makes it easy to include various interactions between flow, sediment and morphology, and which also removes the need to store large amounts of data between processes (Roelvink 2006).

Delft3D-flow can simulate water flow in three dimensions using a specified number of layers in the water column. However, these computations are extremely demanding. In this paper we exclude the effects of currents induced by tide, waves and density differences between the both fresh water masses (homopycnal). Experiments indicated that the results for 2DH simulations were comparable to the 3D simulations with 5 layers. Therefore all simulations shown in this paper are based on a 2DH approach.

SIMULATION EXPERIMENTS

Two simulations are shown in this paper which have a similar setup except for the receiving basin depth; one basin is shallow while the other basin is deep. Both basin and river effluent are generically modeled, i.e. they are not based on specific real-world river effluents, but both effluents are river dominated in the absence of waves and tides.

The imposed liquid discharge is 1000 m^3/s. The distributary channel and effluent initially are 2.5 m deep and about 200 m wide. The cross-sectional area of the initial channel design is intentionally undersized relative to the imposed liquid discharge. Therefore the initial flow velocity was reasonably high (1.4 m/s) but it is quickly reduced to about 1.1 m/s by the increase of the cross-sectional channel area due to erosion of the substrate (consisting of 50% sand and 50% clay). Sediment is introduced at the inflow point as a boundary condition. Total sediment load at the inflow point is 0.14 kg/m^3, of which half

is non-cohesive sand (125 μm) and the other half is cohesive clay. Local sediment load may be higher due to bed erosion. The maximum erosion depth in the initial channel is limited to 5m, which results in a maximum channel depth of 7.5 m. Total liquid discharge does not change in time. The morphological factor *n* is set to 50. Grid cells size is 50 x 50 m and the total model domain is 10 x 10 km. The time step is set to 60 seconds.

SIMULATED MORPHOLOGY

Figure 2 shows the morphological development of the incipient delta formation in a shallow basin (SIM A) and a deep basin (SIM B). The morphological development for both deltas is notably different. For SIM A, the initial sandy lunate bar is rapidly build up to a water depth of less than ½ m. The decreasing water depth at the lunate bar crest results in a dynamic equilibrium between the sand deposition and flow velocity. In other words, sand is bypassed over the lunate bar, which causes the lunate bar to grow basin ward rather than vertically. In addition to the lunate bar, a small middle ground bar (also named mouth bar) develops in front of the river effluent, which gradually separates the flow along the axis of the river. This preferential flow pattern leads to an inhomogeneous flow pattern across the lunate bar and gradually channels as well as shoals start to develop. In time, the initial channel and shoal pattern matures forming many small channels and a large number of elongated shoals. All shoals, including the middle ground bar, grow both basin wards and towards the river effluent. The area of the emerged delta plain continues to increase with time.

SIM B shows a different morphological development. Here the lunate bar is less extensive while the middle ground bar grows rapidly leading inevitably to flow separation. Instead of forming many shallow channels, two distinct channels form, which resembles a classic bifurcation pattern. It does however take quite a while before the middle ground bar actually emerges. Following the bifurcation, the right channel becomes dominant and discharges the most water. As a result it also becomes the deepest channel with the highest flow velocity. This high flow velocity causes a breach of the subaqeous levee, which leads to the formation of a new channel. Rapidly the old branch is abandoned and filled in. Meanwhile, the middle ground bar has emerged and the original left branch of the first bifurcation is slowly abandoned as well. The only remaining main channel now transports all the discharge and sediment and progrades rapidly in a basin ward direction thereby forming a new lunate bar and middle ground bar. This middle ground bar is at an angle relative to the bathymetric contour lines of the substrate and therefore develops asymmetrically. This leads to a clear preference of the left channel over the right channel, which therefore becomes the main channel. A new breach occurs at the right hand side levee about 1 km landwards from the most recent bifurcation. This breach develops into a crevasse splay and possibly develop into the new shortcut for the main channel, which thereby decreases its overall distance to the basin.

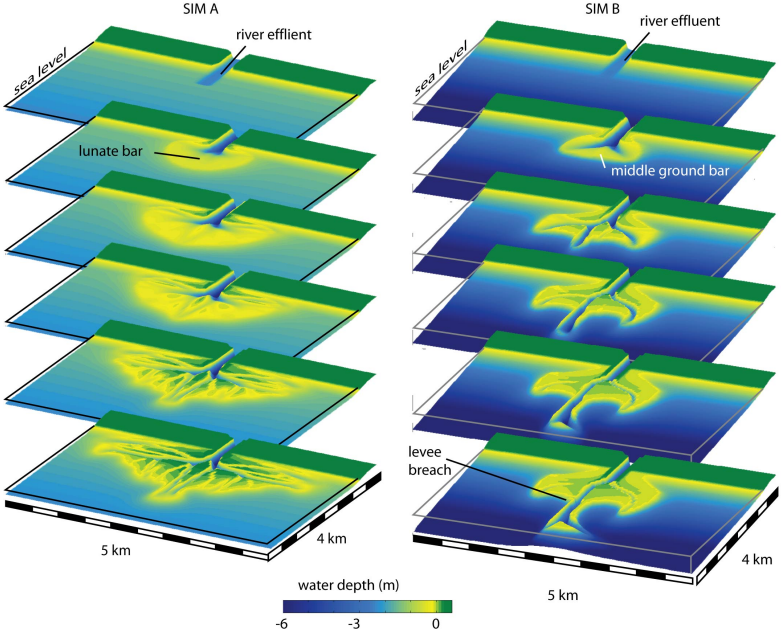

Fig. 2. Simulated delta evolution for SIM A (left) and SIM B (right). The only difference between the two simulations is the depth of the receiving basin.

STRATIGRAPHY

The simulated bimodal sediments distribution can be traced both in top view (Figure 3) as well as in cross section. Figure 4 shows cross sections of the initial lunate and ground middle bar formation just prior to emergence above sea level. The sand body consisting of both the lunate and middle ground bar for SIM A is longer than for SIM B. Yet, it also much thinner (< 1 m) due to the low basin depth (low accommodation space). The contact between clay and sand in both cases is sharp but non-erosive. The clay, which are prodelta deposits according to the classification of standard sedimentological textbooks, have a non-horizontal contact to the overlying sand deposits. This non-horizontal facies contact is not associated to any change in allochtonous forcings (c.f. sea level) but is caused by both the decreasing sand supply per unit area as the lunate bar becomes larger as well as by the high clay deposition rate at the basin ward edge of the lunate bar due to the rapidly decreasing flow velocity by flow expansion. Both sand bodies of SIM A and B show a fining upwards sequence in sediment grain size as would be expected and which is also commonly observed in the field.

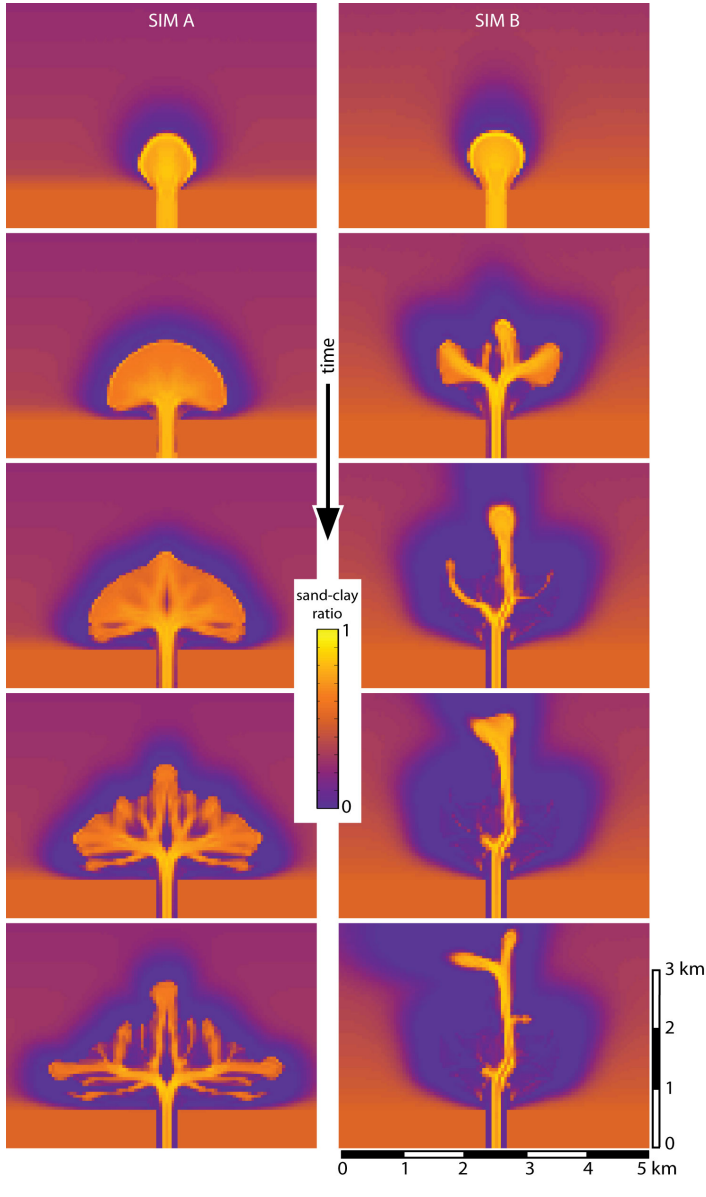

Fig. 3. Time sequence of the top view of the simulated sand-clay ratio in the upper 10 cm of the sediment bed (active layer) for SIM A (left) and SIM B (right).

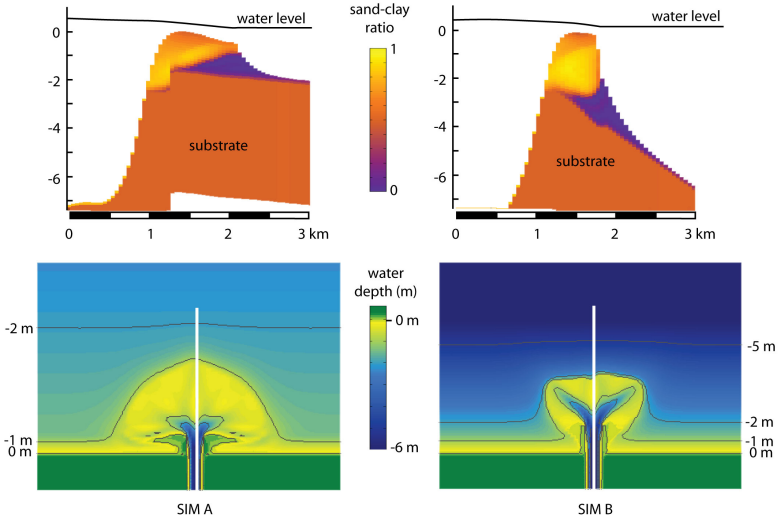

Fig. 4. Cross section (top) and top view (bottom) of the simulated initial bar development at the river effluent. SIM A (left) shows a lunate bar with a weakly developed middle ground bar. SIM B shows a weakly developed lunate bar with a distinct middle ground bar.

As the delta simulation progresses, the simulated stratigraphic record becomes increasingly complex due to the local and temporal formation of the channels and shoals. For SIM A, these channels are generally shallow and unable to erode deep into the initial stage deposits (Figure 5). Deposition through the dense channel network results in a sheet-like sand body that does allow for identification of individual channel sands. Closer to the main channels, large sections of the initial deposits have been eroded and reworked. Due to the fewer numbers of channels, SIM B shows a less complex stratigraphic record than SIM A (Figure 6). As the channels are located further apart, the interdistributary bays allow for clay deposition. Therefore, the sand bodies associated with individual channels can be recognized as the bounded by clay deposits that originate from the interdistributary areas.

In addition to the consistent sharp lower contact between the clay and sand, there is a generally more gradual upper contact between the sandy channel and bar deposits and the overlying clayey delta plain deposits (e.g. Olariu and Bhattacharya, 2006). Sand is generally best 'sorted' (c.f. the highest sand-clay ratio) in the lower portions of the sand deposits and become more mixed in the upper parts of the sand deposits. The timelines in Figure 4 and 5 show that although the sediments are generally near-horizontal deposits, the formation actually takes place as basin ward dipping clinoforms. Especially the clay deposits show the clinoforms in the timelines, which are capped by the sand deposits. This agrees well with field observations and geophysical field data of many other deltas.

The main channels that formed in SIM A have a negative channel bottom gradient. The large number of channels leads to a stepwise decrease in discharge per channel in basin ward direction. This low discharge affects the channel cross sectional area. As a result, inertia actually forces the water to flow uphill. Eventually, the large number of channels and the high flow resistance resulting from the large number of inefficient small channels, combined with the inverse gradient will lead to the dominance of one or a few main channels in time while the small channels will become abandoned. SIM B shows fewer channels than SIM A. Therefore, the decrease in discharge for the channels relative to the inflow is less obvious, making the decrease in channel size relatively small in basin ward direction.

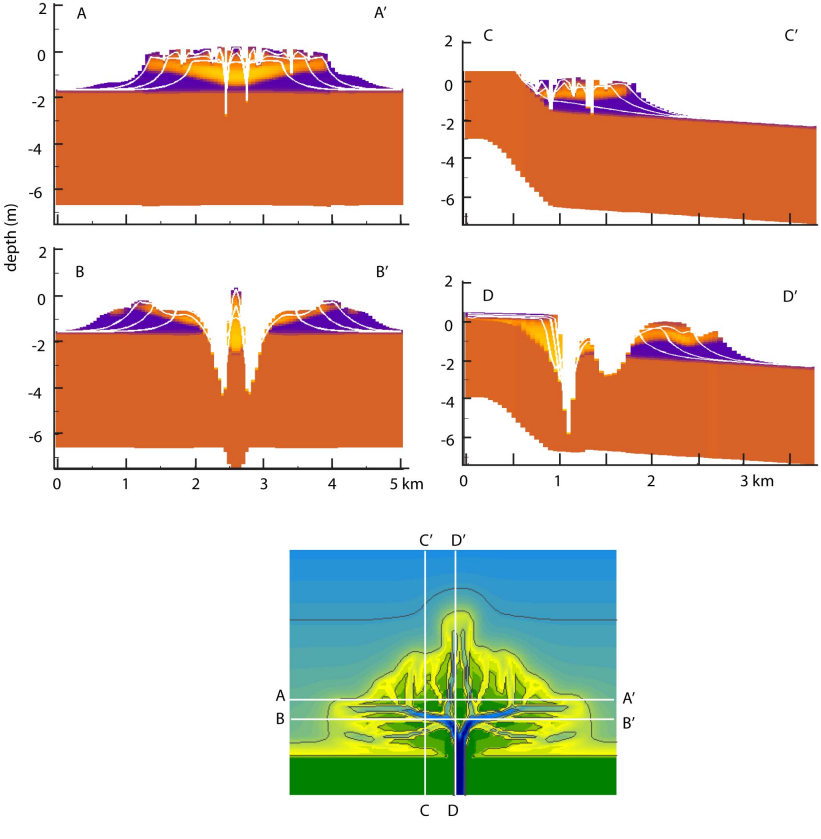

Fig. 5. Lithologic cross sections of the simulated delta deposits in the shallow basin (SIM A). The white lines are time-equivalent lines. The locations of the cross sections are indicated in the lower figure. The color bar for A, B, C and D is shown in Figure 3. The color bar of the lower figure is shown in Figure 2.

The locations of the cross sections are indicated in the lower figure. The color bar for A, B, C and D is shown in Figure 3. The color bar of the lower figure is shown in Figure 2.

DISCUSSION

A quick reality check of the simulated morphology and stratigraphy suggests that the simulations bear an interesting resemblance with both shallow basin and deep basin deltas from the real world. Although the simulations cannot be compared with any real world delta directly, the simulated morphology, stratigraphy and evolution have

similarities with bayhead deltas such as those in Atchafalaya bay. Wax delta has to some extent a comparable configuration of longitudinal shoals and channels as SIM A. However the angle at the initial bifurcation point in the model (nearly 90°) is much higher than for Wax delta. Those angles become more realistic for the downstream channel bifurcations. The lithologic cross section based on core data through Atchafalaya delta (Van Heerden and Roberts, 1988) and Wax delta (Majersky et al., 1997) shows similar lithologic boundaries as the simulated cross sections from SIM A.

One of the main difference between Wax delta and Atchafalaya delta is the width of the river effluent. To understand the effects of the width of the effluent on delta development in a shallow basin, additional simulations were ran that were comparable in setup to SIM A, but with different effluent widths. The results shows a change in morphology of the delta compared to SIM A. For SIM C and SIM D, a large number of small channels and shoals evolve, but for SIM C the flow of the main channel remains along the axis of the river effluent (Figure 7). Here, the width of the main channel prevents the development of the middle ground bar. As a result, no bifurcation occurs in the main channel downstream of the effluent. Shoals emerge predominantly along the main channel. This leads to an elongated delta morphology with shoals aligned along the channel levees. SIM D (Figure 7) has an intermediate channel width when compared to SIM A and SIM D. In contrast to SIM C, a middle ground bar develops that causes the main channel to bifurcate, similar to SIM A. However, the bifurcation angle of SIM C is much smaller than for SIM A compares well to that of Wax delta. The overall delta channel and shoal pattern has a radial pattern rather than an elongated pattern (c.f. SIM C).

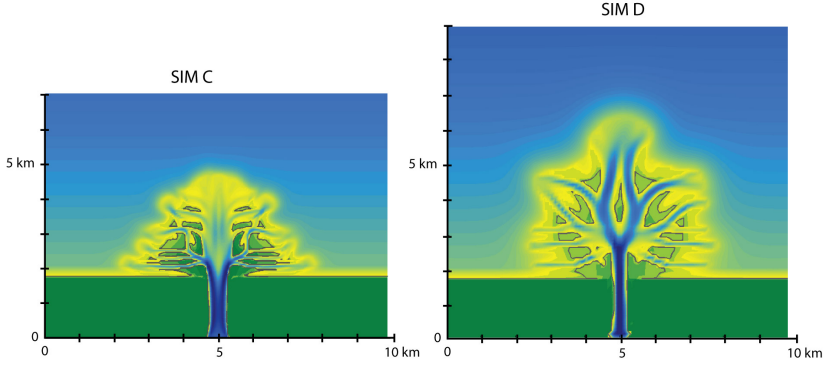

Fig. 7. Simulations of initial delta formation in a shallow basin with a wide (SIM C) initial channel and an intermediate initial channel width (SIM D). The thin black line indicates the coastline. The color bar is shown in Figure 2.

In the simulations, no floods are needed to for land to emerge, for a levee to be breached or for a middle ground bar to develop. This model behavior differs from the observations of Van Heerden and Roberts (1988) who concluded that floods are the dominating control on the initial stage of growth of the Atchafalaya delta. Also Wax delta emerged only after the big river flood of 1973 (Majersky et al., 1997). In our model case, the increase in hydraulic head over time raises the water level up to 0.5 m, which is sufficient to form land above sea level. However, a variable discharge regime with floods most likely will increase the rate at which these processes occur.

The deep-water delta (SIM B) has fewer channels and shoals and is much more elongated. It has more characteristics in common with the present-day Mississippi delta bird foot. There is one main channel that forms subaqeous levees, which are superimposed on prodelta clays in relatively deep water. These subaqeous levees prevent the channel mouth from forming a lunate bar as the flow velocity in the constrained channel remains high. Nevertheless, an elongated middle ground bar emerges which causes an inevitable bifurcation (Figure 4 and 6). As the channel progrades basin wards, the hydraulic head increases due to increase of friction leading to a local breach of a levee. This breach then opens the opportunity for the river to shorten its route thereby increasing its hydraulic gradient and a delta lobe switch has occurred.

Although the simulation results have a morphology and a stratigraphy that show a number of agreements with real-world deltas, care must be taken in its interpretation and application. Process models have many variables that must be set prior to modeling. Little experience exists in using process-based models for generic model applications such as this one and therefore the values of the model variables are not always evident. Yet they do affect the morphodynamic evolution of the delta. A rigorous sensitivity analysis should therefore be undertaken to understand the model behavior as well as the simulated delta behavior. The effect of the grid cell size, time step and morphological factor also need to be addressed for optimized time efficiency. Although the simulations shown in this paper only use two grain-size fractions, in theory it is desirable to use several, but these simulations are computationally very demanding. Also, the interplay between the grain-size classes (hiding effects and armouring for example) are not included in the model.

CONCLUSIONS

The simulations presented in this paper suggest that the smallest physically realizable scale of fluid flow and sediment transport computations can be used explain meso- and macro-scale behavior of fluvial dominated river deltas. The main mechanisms that play a role in delta evolution have been observed in the simulations (lunate and middle ground bar development, channel bifurcations, channel abandonment, channel infill, shoal formation, grain size separation). The model has no special modules for e.g. channel abandonment, it only follows rules of fluid dynamics and sediment transport. The constantly updated bathymetry leads to feedback mechanisms that results is recognizable

morphodynamic responses. As such, the numerical model approach can be very powerful in identifying which morphodynamic behavior will occur under which set of conditions.

Abstract: Over the past several thousand years the Mississippi River has formed one of the world's largest deltas. However, over the last 100 years or so this system has been deprived of most of the sediments vital for its regeneration and maintenance due to organized human interventions (e.g., levees). As a result, the natural channel shifting necessary for replenishment of the delta with fresh sediment is severely impeded. River and sediment diversions are being proposed as way to re-create the historical delivery of river water and sediments into the delta region. Two complementary tools useful for studying diversions are physical models and numerical modeling. First, we present some details and result from a distorted scale, movable bed physical model designed to provide insight into potential river and sediment diversions. We then present some approaches being taken to develop numerical models aimed at providing insight that cannot be obtained using the physical model.

INTRODUCTION

The current Mississippi River delta has been formed over the past 7,000 years (Coleman, 1988). Over the past 200 years, the delta has been deprived of most of the sediments vital for its regeneration, due to organized human interventions such as construction of the levee system for flood protection and navigation improvements. These levees impede the natural channel shift and bank overflow necessary for replenishment of sediment into the delta area. Also, the construction of many storage dams and reservoirs on rivers in the watersheds of the upper tributaries has greatly reduced the sediment load of the Mississippi River. The lost sediment totals between 150-200 million tons annually, which is almost half of the estimated load from the period of 1850 to 1963 (CREST,

2006). The reduction in sediment load in combination with the inability of the sediment to reach the deteriorating coastal wetlands is a major factor in the land loss. Over the past 50 years, coastal Louisiana has lost approximately 34 square miles of coastal wetlands on average per year (Mossa, 1995).

Coastal wetlands are very important to Louisiana's culture and economy (particularly, the petrochemical and fisheries industries) causing state authorities to recognize the necessity to reverse or, at very least, slow down the land loss processes. While impossible to save and/or restore all of the lost wetlands, reversing some of the more dramatic land loss may be possible by attempting to reinstate some of the natural flow patterns that allow the river to interact with the swamps (CREST, 2006).

One proposed method of reestablishing these flow and sediment patterns is use of river diversions (Mossa, 1995). While river diversions specifically designed to transport sediment into coastal wetlands systems are only beginning to be designed and tested, the combination of freshwater siphons and crevasses for delta splay creation have already been used successfully, suggesting that river diversions have the potential to restore wetlands (Miller 2004). A properly designed river and sediment diversion would provide a conduit into the coastal wetlands instead of into the Gulf of Mexico and off of the continental shelf. There is currently one river flow and sediment diversion operating in the lower Mississippi River delta-the West Bay Diversion. It is a sediment diversion built to directly connect the Mississippi River to the West Bay estuary in an attempt to reform a historic sub-delta and associated vegetated wetlands and aquatic habitats. If the diversion is successful, there is a possibility that it could be enlarged (Miller 2004).

Large river and sediment diversions are very complicated systems involving many design components and large amounts of data uncertainty. This makes the study and conceptual design of diversions very complicated. Options to study the potential success of diversions include field tests, numerical modeling, and physical modeling. Field tests are a very common practice used in science and engineering to develop an understanding of a process. If a similar process can be monitored in one place over a period of time, the data analysis might provide some insight into what might occur at a different, but similar location. Field studies, and the accompanying data collection effort, are also very important in the development and use of numerical and physical models. Another hydraulic system design tool is the numerical model. Advantages of numerical modeling include: typically inexpensive compared to field studies; it is easy to change system parameters; the ability to simulate realistic and/or ideal conditions; and the exploration of unnatural events. Among the drawbacks of computational modeling are discretization error (intrinsic to all), input data error, initial and boundary condition error, and modeling error. Physical modeling is often also used for the design of hydraulic systems. One of the major advantages of physical modeling is the ability to replicate complex flow situations which cannot be modeled numerically. One of the signficant limitations of physical modeling is due to scale effects. Scale effects are the "incomplete satisfaction of a full set of similitude criteria associated with a particular situation" and typically "increase in severity as the ratio of prototype to model size increases or the number of

physical properties to be replicated simultaneously increases" (Ettema et al. 2000).Oftentimes, physical and numerical models are used in a combination that accesses the strengths of each type of model.

The objective of this paper is to present complementary approaches for investigating the potential for using large-scale river flow and sediment diversions in the lower Mississippi River delta. First, an overview is presented of a distorted scale movable bed physical model which is capable of providing qualitative and semi-quantitative data on potential diversion scenarios. Next, our initial work directed at the development of numerical modeling of these diversions into coastal wetland systems is described. Finally, we provide some representative results from the SSPM experiments and demonstrate the complementary nature of the numerical modeling work.

SMALL-SCALE PHYSICAL MODEL

In 2002, the Louisiana Department of Natural Resources (LADNR), Office of the Coastal Restoration and Management, initiated and funded a project to use a small scale physical hydraulic model (SSPM) to explore the potential for using large-scale river diversions (150,000 – 500,000 cfs each) in their lower Mississippi River coastal restoration effort (DNR 2003**;** BCG et al., 2004). These large diversions are necessary to capture the spring flows; i.e, the flows which carry a large fraction of the total annual sediment load. The SSPM is currently housed in the Vincent A. Forte Coastal and River Hydraulics Laboratory (VAFCRHL) on the LSU campus.

The SSPM of the lower Mississippi river delta (Figure 1) is a distorted scale movable bed physical model with 1:12,000 horizontal and 1:500 vertical scales. Special care must be taken with distorted models to ensure that the important physics impacting the processes in the prototype are being properly replicated in the model. The important processes are determined from analysis of the problem being studied and the project objectives and then similitude theory is used to derive the appropriate non-dimensional parameters.

The SSPM originally covered 77 river miles (River Mile (RM) 59 to RM -18 (end of Southwest Pass)) and an area of about 3,526 square miles. The bathymetry and topography of the SSPM study region was collected by C&C Technologies of Lafayette, LA from various government and public sources. Each river cross-section is 600 m to the mean axis of the Mississippi River. Additional cross sections at 1200 m apart were used for Southwest Pass. In 2005, the SSPM was extended to replicate the river cross-sections up to RM 77.5 plus an additional seven miles upriver using the RM 77.5 cross-section. This extension was built to create a greater distance from the headbox to the Myrtle Grove region ensuring fully developed flow and sediment transport in the model. As constructed, the model has the capability to model three large (600K cfs) diversions, 12 small (100K -200K cfs) diversions, a slack-water navigation channel w/ two lock gates, the West Bay Sediment Diversion (50K cfs), and the Bohemia Spillway / Pointe a la Hache Relief Outlet (up to 250K cfs natural overflow to the east).

The model was designed and built according to the Froude similarity law. For free surface flow, gravitational effects dominate and hydraulic similitude can be established by equating the ratio of gravitational forces to that of inertial forces (i.e., Froude similarity). While the hydraulics are scaled based upon Froude number similarity, sufficient turbulent flow in the model produces the minimum Reynolds number required for transporting sediment particles in suspension. The size and density of the sediment material is scaled such that the material will move in the same manner for both the prototype and the model; i.e., the incipient motion and resuspension of the sediment occur in the same manner for both. Shields law was satisfied in order to properly scale incipient sediment particle entrainment. The SSPM model sediment has a density of 1050 kg/m^3 which represents coarse and fine sands. For large scale water diversion from the Mississippi River, sand transport and its deposition patterns are modeled directly by model sediment material simulating sands of particle size between 62 and 300 μm which comprise about 20% to 25% of the total sediment load transported by the Mississippi River. The deposition area of the remaining 75% to 80% of the sediment load, consisting of silts (particle size between 62 and 4μ) and clays (particles less than 4μ), are estimated using time-lapse photographs of dye patterns taken at regular intervals.

The hydraulic timescale, determined through the Froude similarity criteria is 1:537 or one year of prototype time equals a little over 16 hours of model time. The sediment time scale is based on the ratio of the times in the prototype and model to build the same feature out of sediment or to fill a certain volume with sediment. The SSPM sediment time scale was based on a similar physical modeling study performed by Sogreah for the Seine River Estuary (Sogreah, 2003). The resultant sediment time scale is 1:17,857 or one year of prototype time equals roughly 30 minutes of model time.

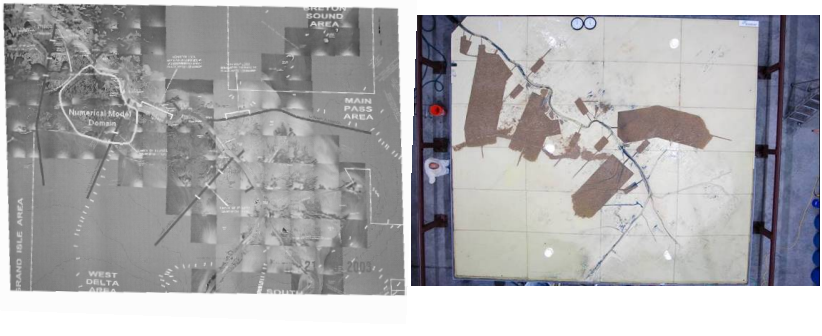

Figure 1: (left) map of the lower Mississippi River Delta; (right) overhead photo of the SSPM. Note that SSPM covers the same area as the map

A detailed discussion of the historical discharge and sediment loading conditions in the lower Mississippi River included in the model can be found in Sogreah (2003) and BCG (2004). In short, historical flowrates measured at Tarbert Landing gage from 1972-1997 were used to create an annual hydrograph. Sediment concentrations measured on a monthly basis at Belle Chase were used as the starting point for the sediment input into the model. The HEC-6 sediment transport model was used to calculate the sediment input at the upstream end of the model. Mississippi River stage data was collected from eight stations between Pointe a la Hache and Port Eads to use in the model calibration and verification.

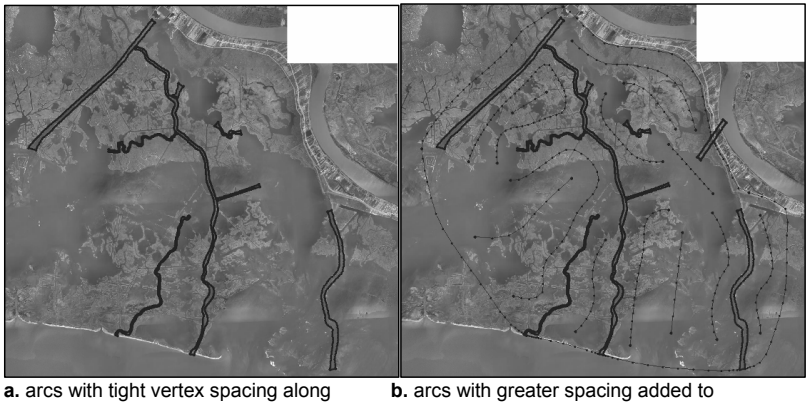
Typical scenarios tested using the SSPM are for 50- or 100-years (i.e., 25 to 50 hours of model time). Two-year flow and sediment hydrographs are used in the experimental program. Projected subsidence and sea level rise of approximately one foot every 25 years is simulated in the model by raising sea level. The amount of sediment that flows out of Head of Passes and off the model is collected, weighed, and recorded as sediment lost to the Gulf of Mexico (GoM). If necessary, the model river is dredged in between cycles in order to maintain 48 ft navigation depth. The amount of sediment dredged is weighed and recorded. Gage readings at the 14 stationary gages within the model are recorded periodically and stage hydrographs at selected gages are measured every ten years. High-resolution overhead photos are taken every 4-6 years to document the temporal sediment deposition patterns. At various points in the experiments, fluorescent dye is injected into the model and time-lapsed photgography used to examine the flow patterns. After each scenario was finished, spatial characteristics of the deposited sediment are determined by collecting, weighing, and sieving the material based upon its spatial location.

To date, over six scenarios have been run along with a couple of replicates. The scenarios differ in the combination of "large" and "small" diversions that were used. Here, results from four tests will be presented: (1) the "Base Case" scenario where the model was run for 100 years without any diversions; (2) the "Large Diversion" scenario where one large (500,000 cfs) and two smaller (~250,000 cfs each) were open for 100 years; (3) the "Multiple Diversion" scenario where seven smaller (~200,000) channels were opened over a 28 year period with a total simulation time of 100 years; and (4) the "Eastern Slack-water Navigation" scenario where a new navigation route, controlled by a sail-through lock chamber, was opened on the east bank and two small diversion were opened on the west bank to reduce the head on the lock and divert some sediment into the wetlands.

NUMERICAL MODELING

Numerical hydrodynamic models of a hypothetical Mississippi River Diversion near Empire, LA were constructed to support the SSPM modeling effort by providing greater detail of the circulation patterns that might arise within the marsh due to the inflow from a diversion. The SSPM can provide a semi-quantitative estimate of how much sediment a particular diversion might capture over relatively long time scales while numerical

models with their greater spatial resolution can aid in understanding where the diverted water and sediment will eventually end up within the marsh. The location just above Empire, shown in Figure 1, was chosen because SSPM observations showed a relatively large amount of sediment captured by a diversion here.



Two popular hydrodynamic codes, RMA2 and ADCIRC, were chosen for the numerical models. Both are 2D finite element models that compute time dependent water surface elevation (WSE) and depth averaged current velocities within the model domain, and are supported by interfaces within the Surface Water Modeling System (SMS) software developed at the Environmental Modeling Research Laboratory at Brigham Young University in cooperation with the US Army Corp of Engineers.

RMA2 solves the depth-integrated Reynolds-averaged form of the Navier-Stokes equations for conservation of fluid mass and momentum (Donnell et al., 2005). The equations are solved by the finite element method using the Galerkin method of weighted residuals. Bottom friction can be specified using Manning n or Chezy's C, and may be calculated automatically. Eddy viscosity may be specified directly; or it may be calculated automatically varying with depth using the Peclet number, or varying with depth and velocity gradient using the Smagorinsky method. Elements may be 1D elements with trapezoidal cross-section or 2D triangles or quadrilaterals or various special elements used to represent control structures; elements must be quadratic and may have parabolic shaped sides. Wetting and drying can be simulated by a method of elemental elimination, or RMA2's marsh porosity option which allows for some flow through elements even when the WSE is below the nodal elevations of the element. This option is useful for simulating flow through wetlands where it is nearly impossible to resolve the micro-topography of sub grid scale streams and channels.

ADCIRC can be run in either a 3D or 2D depth-integrated mode. WSE is calculated by solving the continuity equation in its Generalized Wave Continuity Equation (GWCE) form (Luettich and Westerink, 2004). This formulation requires specification of a factor, TAU0, which weights the relative contributions of the primitive continuity equation and wave equation portions of the GWCE. After WSE's are found from the GWCE, velocities are computed by solving the Reynolds-averaged depth-integrated (for 2D mode) momentum equations. Bottom friction is specified with a drag coefficient which may be spatially variable or may be calculated during a simulation based on the computed depth. Eddy viscosity is specified directly and may vary spatially. Elements are linear triangles with only corner nodes. Wetting and drying can be simulated by elemental elimination.

Direct comparison of RMA2 and ADCIRC models would best be accomplished using meshes representing exactly the same geometry. For this reason the linear triangular mesh for ADCIRC was made first with the intention of simply adding mid-side nodes to make the RMA2 mesh. The mesh generation and GIS tools provided by SMS's map module were used for mesh generation for both models. First, a number of Digital Orthophoto Quarter Quadrangles (DOQQ's) covering the study area were downloaded

from www.atlas.lsu.edu in the form of MRsid files. These 2004 vintage aerial photographs were viewed in SMS and then used as a foundation on which to build the meshes. SMS allows the user to draw a feature map over the photos by clicking out a series of arcs with the mouse. The arcs are made up of a series of vertices linked together by straight lines. Arcs can be combined to form polygons which can be individually assigned a number of different properties including the type of mesh generation algorithm to be used inside that polygon. Once a feature map has been drawn, SMS is able to generate a mesh which preserves all feature vertices as nodes while also filling in the polygons with mesh.

a. arcs with tight vertex spacing along channels

b. arcs with greater spacing added to stretch mesh in flatter areas.

Figure 2. Feature map drawn over DOQQs for generation of ADCIRC mesh.

Unstructured meshes have the advantage of providing higher spatial resolution in areas where it is needed and lower resolution in topographically uninteresting areas as element size can change gradually from one element to the next. For this reason arcs were drawn around some of the larger channels evident in the photographs with a minimum vertex spacing of 100 ft (Figure 2a). Once the channels were outlined in this way more arcs were drawn in the flatter areas with a maximum vertex spacing of over 3000 ft (Figure 2b). SMS's paving algorithm was then used to generate a 2D mesh which resolves the channels while increasing element size into the flatter areas with the overall goal of keeping the number of required elements as low as possible. At this point mesh quality was checked to conform with individual model geometric requirements.

Elevation data for the meshes came from two different sources. LIDAR data for land elevations were acquired from www.atlas.lsu.edu in the form of edited XYZ ASCII files. These data came from measurements made in 2002 and are also projected to the UTM zone 15 coordinate system with horizontal units of meters and vertical units of survey feet. Digital sounding data available from the National Ocean Service Hydrographic database at www.ngdc.noaa.gov were used for bathymetry. The bathymetry data were

also obtained as ASCII xyz files, but with geographic coordinates. All data sets refer to the same horizontal North American Datum 1983(NAD 83), while the LIDAR data refer to the North American Vertical Datum 1988(NAVD 88), and the Bathymetry are referenced to Mean Low Water(MLW). In order to combine the elevation data sets it is necessary to relate the geodetic datum NAVD 88 to tidal datum MLW for the area. The difference between these two data depends on the local tidal range and therefore differs at different Bench Mark locations. In this case NAVD 88 is approximately 0.5 feet lower than MLW. All data sets were converted to units of feet, translated to NAVD 88 if necessary, edited for consistency, and combined. Then the elevations of the mesh nodes were linearly interpolated from the elevation data. Once again the mesh quality was checked and the mesh was edited to smooth contours and remove steep gradients. Finally an 8500 ft long diversion channel was added to the mesh extending 1500 ft into the river.

After the mesh was geometrically complete, a discharge boundary was assigned along a string of nodes at the head of the diversion channel and WSE boundaries were assigned along areas of open water using SMS's ADCIRC interface. Figure 3 shows the resulting ADCIRC mesh containing 12,328 nodes and 24,457 elements, with color contours of the mesh elevation.

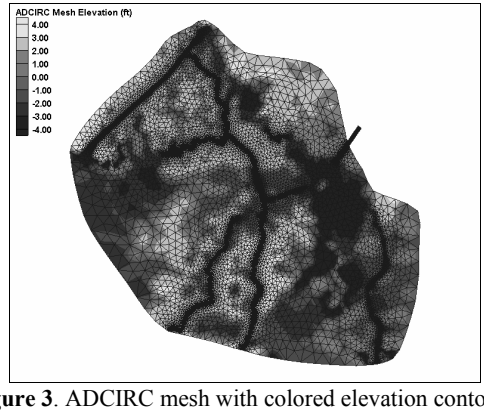


Figure 3. ADCIRC mesh with colored elevation contours.

Initially a RMA2 mesh was created by simply adding mid-side nodes to the finalized ADCIRC mesh. However this resulted in a mesh with 49,131 nodes on which simulations ran slower than real time on a 2.2 GHz Pentium 4 with 1.5 GB of RAM, making it unfeasible to use both ADCIRC and RMA2 meshes with exactly the same geometry. It was therefore necessary to create a RMA2 mesh with fewer elements which could be run with reasonable efficiency. This modification was done by going back to the feature map stage of mesh construction and increasing the vertex spacing on the feature arcs; the map used had a minimum vertex spacing of about 175 ft and maximum of over 4400 ft.

A mesh was generated from this map in the same way the ADCIRC mesh was generated. However quadrilateral elements were generated in addition to triangular elements to further reduce the number of nodes in the resulting mesh. This mesh was edited to maintain the same geometrical requirements as the ADCIRC mesh with the additional requirement that no quadrilateral element had an angle greater than 110 degrees. The nodal elevations for the RMA2 mesh were interpolated from the nodes of the ADCIRC mesh. Also nodal elevations greater than 4 ft were set to a maximum elevation of 4 ft. This was necessary because RMA2 is a "start wet" model requiring that the initial WSE for a model run be greater than the highest elevation in the mesh. In simulations where drying of elements is expected, as in this case, it in necessary to do an initial draw-down simulation to bring the WSE down from the highest nodal elevation to a more realistic elevation. Once the WSE is brought down to a realistic level, further simulations can be hotstarted from the end of the draw-down simulation. The final RMA2 mesh containing 16,070 nodes and 7173 elements (5617 triangles, 1556 quadrilaterals) is shown in Figure 4 with the colored elevation contours

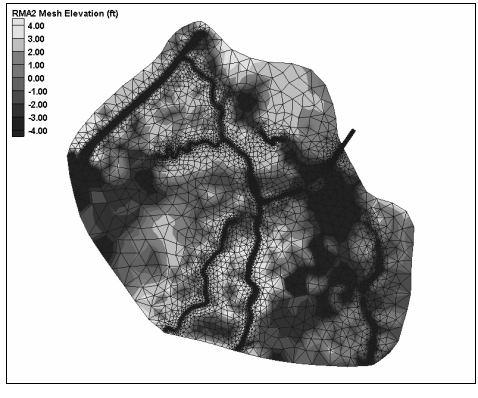

Figure 4. RMA2 mesh with colored elevation contours

Although it was possible to achieve the exact same diversion channel geometry (with rectangular elements), the necessary coarsening of the mesh for creating efficient RMA2 model resulted in the inability to represent all of the channels in the mesh with three elements across as was the case in the ADCIRC mesh.

RESULTS

SSPM Results

The SSPM has been used to simulate a number of potential lower Mississippi River flow and sediment diversion scenarios. One of the major issues in the lower river is the amount of material that must be dredged to maintain navigation. As can be seen from Table 1, the quantity of sediment dredged in the "Large Diversion" scenarios was almost an order-of-magnitude less than the "Base Case" and significantly less than the other

scenarios. The large reduction in the dredging costs could help offset the costs of building and maintaining these diversion structures. While the quantity of sediment dredged in the "Multiple Diversion" scenario seems large, it should be pointed out that a significant amount of the dredging, nearly 33%, occurred in the local vicinity of the diversions. Because the sediment deposition occurs farther upstream than in the "Base Case" scenario and close to the diversions, it could be more feasible to transport this dredged sediment into the wetlands. Additional results including high-resolution photographs depicting sediment distributions, results from dye tests, and other data can be found in BCG (2004).

Table 1: Representative Results from Several SSPM Scenarios. (quantities in parentheses are the percent of injected sediment)

Experiment	Duration [years]	Sediment Injected [Mtons]	Sediment Lost to GoM [Mtons]	Sediment Dredged [Mtons]	Sediment Deposited [Mtons]
Base Case	100	2000	106.9 (5.3%)	1344.1 (67.2%)	549 (27.5%)
Large Diversion	100	2000	400 (20.0%)	192 (9.6%)	1408 (70.4%)
Large Diversion (replicate)	50	1000	93.4 (9.3%)	63.0 (6.3%)	843.6 (84.4%)
Multiple Diversion	100	2000	74.4 (3.7%)	1115.7 (55.8%)	809.9 (40.5%)
Hang A Left	50	1000	64.0 (6.4%)	430.1 (43.0%)	505.9 (50.6%)

Numerical Simulations

A number of simulations were run with varying discharge into the diversion channel to see how the WSE at the head of the diversion channel would be affected at different flows, and conversely how much discharge could be expected for a given river stage and gulf sea level. Simulations for both models were run with steady inflow boundary conditions at the diversion channel and constant 1 ft WSE (very close to MSL in the NAVD88 datum) at the Gulf boundaries. These simulations were run until the velocity field and WSE gradient across the domain remained steady and are made to represent potential steady-state conditions for the hypothetical diversion. For both models the bottom friction parameters were set so that the bottom friction would be calculated as a function of the depth. Although RMA2 and ADCIRC used different formulations for varying bottom friction with depth, the parameters in each model were set so that this behavior would be nearly the same for both models. Similar values of spatially constant eddy viscosity were used for both models, 40 lb-s/ft^2 for RMA2 and 20 ft^2/s for ADCIRC. Wetting and drying in ADCIRC was accomplished using elemental elimination, while the marsh porosity option was used with RMA2.

The results for the stage in the diversion channel produced by 7 different values for inflow discharge between 50,000 cfs and 200,000 cfs is shown in Figure 5.

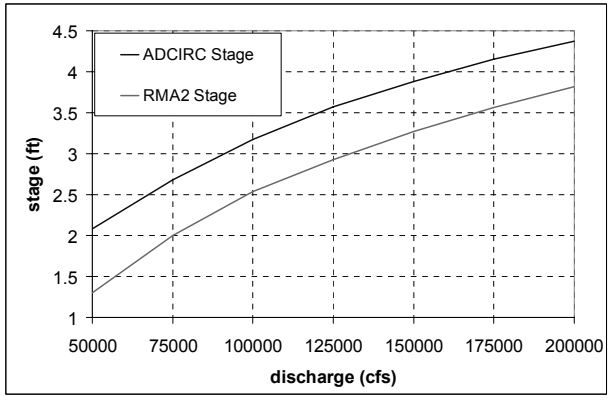

Figure 5. Rating curves for diversion channel for both RMA2 and ADCIRC models.

Overall the ADCIRC model results show a higher WSE in the diversion channel when compared to RMA2. This difference is like due to how wetting and drying is handled within the two models. ADCIRC's elemental elimination limits the flow to only the wet elements thus providing a greater restriction as water flows through the marsh land. RMA2's marsh porosity on the other hand allows for fraction of flow through the dry elements and does not channelize the flow through the marsh as much as ADCIRC.

Two additional simulations were run using a constant discharge of 150,000 cfs over a flat mesh with the elevation set 0.2 ft below the WSE boundary. These simulations were designed to more closely resemble the flat marsh area on the SSPM. After the currents were computed, a particle tracking model was run using the resulting steady-state velocity field to draw streamlines. The particles were initially placed across the diversion channel at points of equal fractional discharge so that the resulting space between any two streamlines represents approximately 0.5% of the total discharge. The particle tracking model was also run for the 150,000 cfs diversion cases where the topography was considered. The comparisons of the streamlines in Figure 6 illustrates the benefit of using numerical models for examining more detailed flow patterns within marsh area that cannot be modeled with the SSPM.

Future simulations which consider time varying river and gulf stage levels could be run using the above curve to assign a time varying inflow discharge based on records of Mississippi River stage for the area.

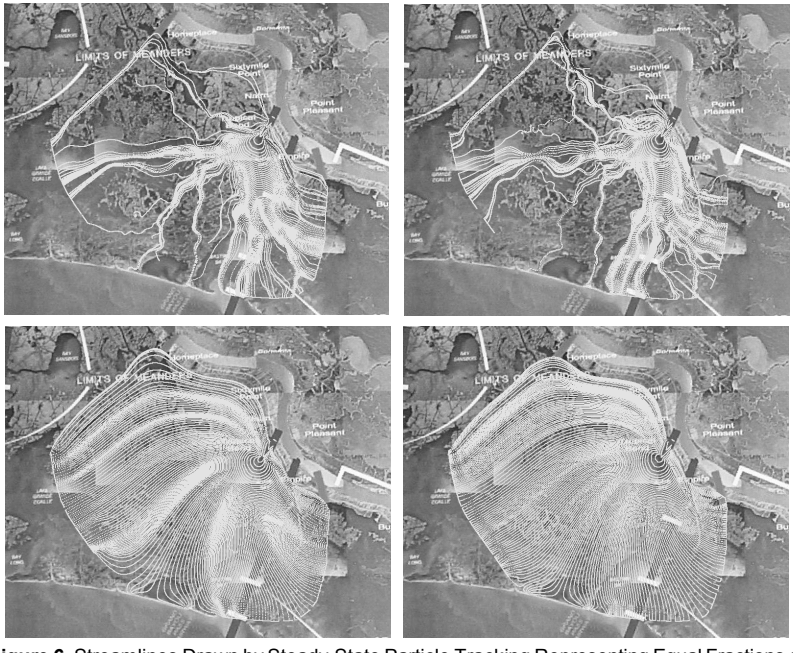

Figure 6. Streamlines Drawn by Steady-State Particle Tracking Representing Equal Fractions of Total Inflow, Steady 150,000 cfs diversion. Upper Left: RMA2 with topography; Upper Right: ADCIRC with topography; Lower Left: RMA2 with flat mesh; Upper Right: ADCIRC with flat mesh.

CONCLUSIONS

There are two main advantages of using the SSPM to study the potential for using large-scale diversions for reintroduction of flow and sediment into coastal wetland systems. The first is that visualization of sedimentation processes along the Mississippi River, through the selected diversion channels and into the wetlands enhances the general understanding of the project impacts on various relevant aspects of concern to the public and State and Federal Agencies. The second advantage is due to the model sedimentation time scale. Since the model is able to reproduce one year's evolution in 30 minutes, it can reproduce relatively long-term sedimentation processes within a few hours of testing time (e.g., 100 years of sedimentation processes in 50 hours of testing). Thus, the model helps to assess and compare the performance of project concepts, possibilities for their improvement, and makes site selection decision-making easier and decisive.

While the SSPM can be used to qualitatively, and semi-quantitatively, examine sediment deposition as a result of large-scale diversions, limitations due to the geometric scaling and distortion limit the insight and conclusions that can be reached. This is why we have begun to use numerical modeling to complement the physical modeling. While the numerical modeling is limited to smaller spatial domains and much shorter study times,

the results provide much needed insight into the role of topography on the flow, and ultimately deposition, patterns of the diverted water and on the potential for depositing finer sediment into the coastal wetlands.

ACKNOWLEDGEMENTS

The SSPM was funded by the Louisiana Department of Natural Resources (LA DNR). The LSU Vincent A. Forte Coastal and River Hydraulics Laboratory (VAFCRHL) was built with funding from the LSU College of Engineering. The physical modeling research is being funded by LA DNR with additional support from the Coastal Restoration and Enhancement through Science and Technology (CREST) program. The numerical modeling work is also supported by LA DNR and the Louisiana Board of Regents NSF EPSCOR Pfund Program.

Abstract: Coastal morphodynamics are evaluated to develop a more-advanced geomorphic model for chenier-plain evolution in southwestern Louisiana. Most ridges on the chenier plain represent open-Gulf paleoshorelines. Past movement trends of individual shorelines allow ridges to be further classified as transgressive, regressive, or laterally accreted. As such, a geomorphic hierarchy of landforms is refined relative to dominant coastal process. To understand long-term evolution of the chenier plain, modern tidal-inlet processes operating at Sabine Pass, Calcasieu Pass, and the Mermentau River mouth are examined relative to the inlet-stability ratio; historical shoreline-change data are used to document trends in shoreline behavior; and air-photo interpretation and topographic profiles are used to address form/process relationships of primary landforms. These datasets and others indicate that the geologic evolution of the chenier plain is more complicated than just channel avulsions of the Mississippi River and downstream delta switching. A six-stage geomorphic process-response model is presented that synthesizes chenier-plain evolution primarily as a function of: 1) the balance between sediment supply and energy dissipation, 2) local sediment reworking and lateral transport, and 3) tidal-entrance dynamics.

INTRODUCTION

The chenier plain of southwestern Louisiana, located west and downdrift of the Mississippi River deltaic plain, extends from Southwest Pass at Vermilion Bay westward almost 200 km to the Sabine River at the Texas/Louisiana border (Fig. 1).

To the west, the chenier plain merges with the barrier-island system of the Texas Gulf Coast. The chenier plain is a late-Holocene, marginal-deltaic environment, up to 30 km wide and is primarily a mud-dominated environment capped by marsh and interspersed with thin sand- and shell-rich ridges known as cheniers.

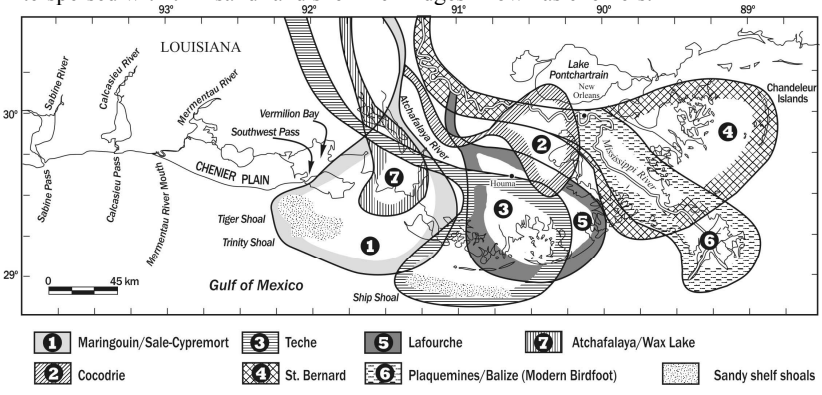

Fig. 1. Study area showing the delta plain of southeastern Louisiana and the chenier plain of southwestern Louisiana. The Mississippi River delta plain is composed of Holocene delta complexes that are illustrated chronologically from oldest (Maringouin/Sale-Cypremort) to youngest (Atchafalaya/Wax Lake) [modified from Frazier (1967), Coleman (1988), and Roberts (1997)].

Although many studies had discussed the geologic and geomorphic development of the chenier plain (Russell and Howe 1935; Howe et al. 1935; Fisk 1948; Gould and McFarlan 1959; Byrne et al. 1959), Hoyt (1969) presented the first detailed depositional model for chenier genesis and mudflat progradation (Fig. 2). According to Hoyt's (1969) model, chenier-plain development reflects changes in Mississippi River flow direction that are caused by channel avulsion, which results in downstream delta switching along the coast (Fig. 1). Channel avulsions of the Mississippi River occur approximately every 1000 to 1500 years (Coleman 1988; Roberts 1997). As the distributary mouth progrades into the Gulf of Mexico, the river course slowly lengthens and progressively becomes hydraulically unstable. To achieve hydraulic efficiency, the Mississippi River seeks a shorter, steeper course to the ocean (i.e., base level) and avulses on a semi-regular interval, resulting in delta switching (Fig. 3).

Hoyt's model is based solely on the delta-switching process. Hoyt correlates mudflat progradation with periods of Mississippi River discharge to the west (Figs. 2 and 3). When the river becomes hydraulically unstable and avulses eastward, fine-grained sediment supply to the chenier plain is reduced significantly, enabling wave reworking and erosion of mudflats, resulting in a transgressive ridge. Mudflat advance recurs when the Mississippi River avulses westward, completing chenier genesis (Fig. 2). Hoyt's hypothesis that the changing position of the Mississippi River is important to overall chenier-plain development is valid, but because it incorporates

only regressive mudflats and transgressive cheniers—omitting ridges created by other means—his model oversimplifies chenier-plain evolution in southwestern Louisiana (McBride et al., in press).

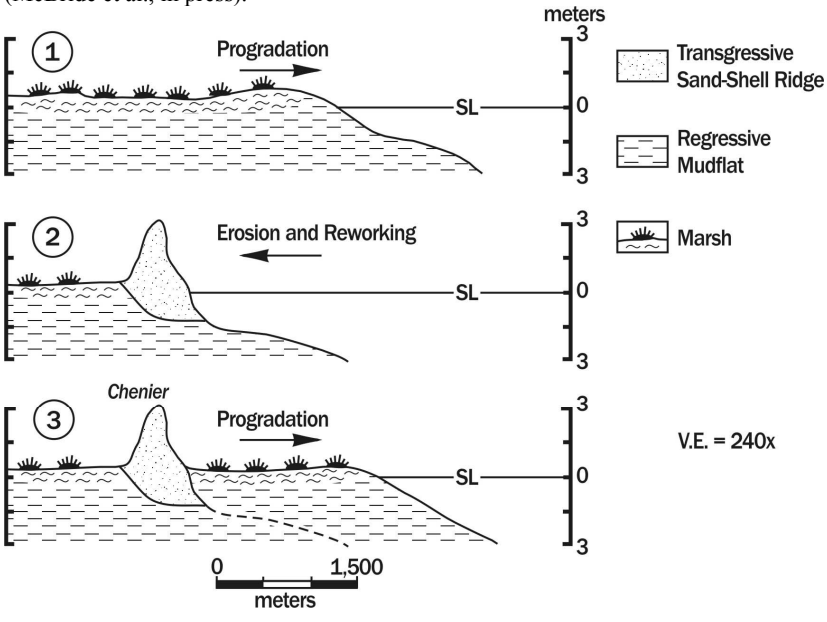

Fig. 2. Depositional model illustrating chenier-plain development through mudflat progradation (1), wave erosion and reworking to create a transgressive ridge (2), followed by mudflat progradation, which completes chenier genesis (3) [modified from Hoyt (1969)]. SL = sea level.

Thus, the purpose of this paper is to provide a more comprehensive understanding and explanation of chenier-plain evolution by examining the geomorphic development of the Louisiana chenier plain relative to regional and local coastal processes.

REGIONAL SETTING

Coastal Louisiana, which consists entirely of Holocene sediments deposited directly or indirectly by the Mississippi River, is divided into two primary geomorphic zones: the deltaic plain of southeastern Louisiana and the chenier plain of southwestern Louisiana (Figure 1) (see Fisk 1944; Gould and McFarlan 1959; Roberts 1997). Distinct ridges, most of which are former open-Gulf shorelines, are interspersed in the mud-dominated chenier plain. Ridges typically are oriented shore-parallel to subparallel, are 10 to 90 km long and < 1 to 5 m thick, and are < 1 km wide. Ridge relief ranges from 0 to 4 m above mean sea level (MSL). The shoreline is classified as a low-energy, microtidal (0.6 to 0.8 m), storm-dominated coast that experiences episodic sediment supply from the Mississippi River (Wells and Roberts 1981;

Byrnes et al. 1995). Net longshore sediment transport is to the west, in response to wind and waves that are predominantly from the southeast (Beall 1968; Becker 1972; USACE 1974; Crout and Hamiter 1981; NOAA 1985b; Hubbertz and Brooks 1989).

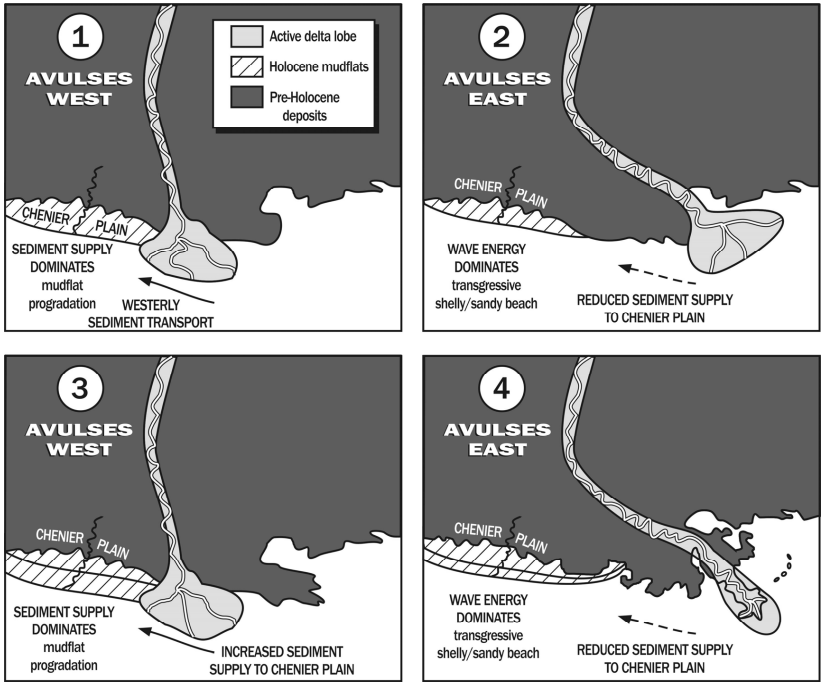

Fig. 3. Geologic model illustrating chenier-plain evolution in response to channel avulsions of the Mississippi River and the resultant downstream delta-switching process along the coast (from McBride et al., in press).

DATASETS AND METHODS

Investigation of the Louisiana chenier plain and construction of the geomorphic process-response model are based on the following data and methods: 28 topographic profiles, 104 sediment samples, and air-photo interpretation and geomorphic base-map construction (Taylor et al. 1995; Taylor 1996; Taylor et al. 1996; McBride et al., in press), historical shoreline-change data from 1883 to 1994 (Byrnes et al. 1995; McBride and Byrnes 1995), ground penetrating radar (GPS) reflection profiles (Zenero et al. 1995), and paleoecological analysis of molluscan assemblages (Anderson et al. 1998).

LANDFORM DEFINITIONS AND GEOMORPHIC HIERARCHY

In this paper we use the term "ridge" simply as a morphologic term for a narrow, linear or curvilinear topographic high (< 4.25 m elevation) that consists of sand and

shelly material accumulated by waves and other physical coastal processes. Under this definition, most ridges in the chenier plain represent relict shorelines. On the basis of past movement trends of individual shorelines, ridges can be further classified as transgressive, regressive, or laterally accreted. As McBride et al. (in press) discussed, transgressive, regressive, and laterally accreted ridges are topographic features that were created through landward, seaward, and lateral movement of the shoreline, respectively. A transgressive ridge that is surrounded by littoral mud deposits also is known as a chenier, a regressive ridge is known as a beach ridge, and a laterally accreted ridge is known as a spit or a recurved spit.

Furthermore, geomorphic zones that contain two or more regressive, transgressive, or laterally accreted ridges are termed *complexes*. A beach-ridge complex contains two or more parallel to subparallel, regressive ridges, and is net progradational, without extensive fine-grained interridge deposits. A chenier complex contains two or more parallel to subparallel, transgressive ridges that are separated by regressive, littoral mudflats (muddy units) and is net progradational. A spit complex contains two or more laterally accreted ridges that primarily have prograded laterally along the downdrift ends of ridges.

On the basis of these definitions, McBride et al. (in press) refined a geomorphic hierarchy of landforms relative to dominant process for the Louisiana chenier plain (Table 1). They defined a chenier plain as a first-order feature (5000 km^2) and as a marginal-deltaic environment because of its genetic link to the Mississippi River. The chenier plain is composed of three smaller, second-order features (30 to 300 km^2): chenier complex, beach-ridge complex, and spit complex. Individual ridges of each complex type are further separated into third-order features: chenier, beach ridge, and spit.

COASTAL MORPHODYNAMICS AND CHENIER-PLAIN EVOLUTION

Understanding the long-term evolution of a coastal depositional system requires recognizing the primary process-response mechanisms and trends along the modern coast. Present-day coastal processes operating along the outer shoreline of the chenier plain are central to providing a new perspective in the development of a more-advanced geomorphic model for chenier-plain evolution, and are synthesized below.

Tidal-Entrance Dynamics and Ridge Occurrence

Tidal prism (Ω) and the quantity of littoral sediment transport (M_{total}) are the primary factors that control inlet stability (Bruun et al. 1978). Greater discharge and/or tidal prism increase the potential for river and estuarine systems to (1) interrupt longshore sediment transport, (2) maintain and naturally stabilize tidal entrances, and (3) promote updrift deposition (Bruun 1967; Todd 1968). In classifying inlet stability, Bruun (1967) calculated an inlet-stability ratio (Ω/M_{total}) number for tidal entrances worldwide.

Table 1. Geomorphic Hierarchy and Landform Classification for the Southwestern Louisiana Chenier Plain [modified from McBride et al. (in press)]

Geomorphic Feature	Formation Process and Shoreline Movement	Order	Dimensions	References
Chenier plain	Net progradational	1	5000 km^2	Russell and Howe 1935; Howe et al. 1935; Fisk 1948; Price 1955; Gould and McFarlan 1959; Hoyt 1969; Otvos and Price 1979; Kaczorowski 1980; Kaczorowski and Gernant, 1980; Penland and Suter 1989; Taylor 1996; Taylor et al. 1996; McBride et al. in press
Chenier complex	Net progradational	2	30 to 300 km^2	Kaczorowski and Gernant, 1980; Taylor et al. 1996
Beach-ridge complex	Net progradational	2	30 to 300 km^2	Stapor 1975; Kaczorowski and Gernant, 1980; Gerdes 1982, 1985; Taylor et al. 1996
Spit complex	Lateral accretion (stationary shoreline) or net progradational	2	30 to 300 km^2	Kidson 1963; Kumar and Sanders 1974; Hine 1979; Kaczorowski and Gernant, 1980; Taylor et al. 1996
Chenier	Transgressive	3	30 to 500 m wide and up to 90 km long	Hoyt 1969; Kaczorowski 1980; Zenero et al. 1995
Beach ridge	Regressive	3	30 to 500 m wide and up to 30 km long	Stapor 1975; Kaczorowski 1980; Gerdes 1982, 1985
Spit	Lateral accretion	3	30 to 500 m wide and up to 10 km long	Evans 1942; Kidson 1963; Kumar and Sanders 1974; Kaczorowski 1980

According to Bruun et al. (1978), Ω/M_{total} is > 150 for stable inlets, between 100 and 150 for moderately stable inlets, and < 100 for unstable inlets. Unstable and moderately stable inlets will migrate laterally and are classified as wave-dominated, whereas stable inlets are much more stationary and are classified as tide-dominated (see Nummedal et al. 1977; Davis and Hayes 1984; and McBride 1999).

Table 2 summarizes river, estuary, and inlet characteristics along the chenier plain and reports the Ω/M_{total} for each tidal entrance. Tidal prism of chenier-plain estuaries increases from 0.94×10^7 to 4.10×10^7 m^3, while longshore sediment transport is about the same along the entire modern chenier-plain shoreline, at 0.62×10^5 to 1.0×10^5 m^3/yr (Bruun 1967; USACE 1971).

Table 2. Quantified Physical Processes along the Southwestern Louisiana Chenier Plain—Maximum River Discharge (Q_{max}), Suspended Sediment Discharge (SSQ), Mean Significant Wave Height (H_s), Wave Approach, Tidal Range, Tidal Prism (Ω), Quantity of Littoral Sediment Transport (M_{total}), and Inlet Stability (Ω/M_{total})[a] (from Taylor 1996)

River, Estuary, or Inlet System	Q_{max}[b] (m^3/s)	SSQ[c] (kg/yr × 10^9)	H_s[d] (m)	Wave Approach (°)	Tidal Range[e] (m)	Ω[e] ($m^3 \times 10^7$)	M_{total}[a,f] ($m^3/yr \times 10^5$)	Ω/M_{total}
Trinity (Texas)	207	0.50	1.1	135.0	0.61	21.00	NA	NA
Sabine (Louisiana)	234	0.29	1.0	157.5	0.76	4.10	0.62 to 1.0	661 to 410
Calcasieu (Louisiana)	73	0.15	1.0	157.5	0.61	3.90	0.62 to 1.0	629 to 390
Mermentau (Louisiana)	32	0.19	1.0	157.5	0.76	0.94	0.62 to 1.0	151 to 94

Mississippi (Louisiana)	14,000	145.00	1.2	112.5	0.37	NA	NA	NA

[a] Bruun et al. (1978), [b] USGS (1995), [c] Mossa et al. (1993), [d] Hubbertz and Brooks (1989), [e] NOAA (1985a), [f] USACE (1971)

As McBride et al. (in press) discussed, Sabine Pass, which has good inlet stability (Ω/M_{total} = 410), has effectively interrupted longshore sediment transport, causing long-term shoreline advance immediately west and east of the inlet (Table 2). Calcasieu Pass has not always been as stable as its present channel. To the west, relict deflected channels of the Calcasieu River, e.g., Hamilton Lake and spits curving into this channel, indicate past periods of inlet instability that allowed longshore sediment transport to dominate fluvial and tidal processes. The presence of a regressive ridge complex adjacent to the present Calcasieu Pass denotes increased stability. Although present discharge of the Calcasieu River is much less than that of the Sabine River (73 vs. 234 m^3/s), tidal prism is of a similar volume and accounts for good inlet stability (Ω/M_{total} = 390) (Table 2).

Historically, the Mermentau River has been characterized as relatively unstable (Ω/M_{total} = 94). Although longshore sediment transport was not sufficient to fill the river mouth naturally, it was adequate to dominate fluvial discharge (32 m^3/s) and tidal exchange (9.4×10^6 m^3), forcing westward migration of the entrance and lateral shoreline accretion (Table 2). Thus, before human modification and stabilization efforts, the Mermentau River entrance would be classified as wave-dominated, Sabine Pass as tide-dominated, and Calcasieu Pass as tide-dominated to occasionally mixed, as discussed by McBride et al. (in press).

Geomorphic Process-Response Model of Chenier-Plain Evolution

Concentration of sand- and shell-rich deposits within the mud-dominated chenier-plain system and the overall response of ridges involve lateral variations in processes and landforms that are not explained fully by simple delta switching as it was

discussed by Russell and Howe (1935), Fisk (1948), Gould and McFarlan (1959), Hoyt (1969), and Penland and Suter (1989). As such, McBride et al. (in press) presented a more-advanced six-stage geomorphic process-response model that explains chenier-plain evolution primarily as a function of (1) the balance between sediment supply (Q_s) and energy dissipation (E), (2) local sediment reworking and lateral transport, and (3) tidal-entrance dynamics (Fig. 4).

The model begins by emphasizing the landward-most ridge trend that represents the Holocene highstand open-Gulf shoreline (Fig. 4, Stage 1). Before chenier-plain development, the open-Gulf shoreline transgressed across an exposed shelf from ~16 to ~4 kyr in response to the last post-glacial rise in eustatic sea level (see Anderson et al. 2004). Some type of transgressive barrier-beach/barrier-island system characterized the open-Gulf shoreline. As this transgressive barrier shoreline (i.e., transgressive ridge) experienced the apex of the Holocene highstand in sea level and/or an increase in sediment supply, and thus ceased its landward migration, the landward-most ridge trend (i.e., Little Chenier/Little Pecan Island paleoshoreline) was created. In Stage 1, vertically-aggraded mud deposits that were deposited landward of the highstand open-Gulf shoreline (landward-most ridge trend) represent estuarine and marsh environments, as Fisk (1948) and Penland and Suter (1989) described, but not progradational littoral mudflats, as Gould and McFarlan (1959) postulated. Past exposure to incident wave processes would cause the contact between the Pleistocene Prairie Complex and Holocene marshes to be curvilinear, not crenulated. Thus, the crenulated contact represents the Holocene bay shoreline (i.e., the leading edge of the Holocene transgression), not a Holocene open-Gulf shoreline. The difference between vertically-aggraded mud deposits laid down behind an open-Gulf shoreline and progradational littoral mudflats deposited in front of an open-Gulf shoreline is subtle, but critical.

Subsequently, the Mississippi River avulsed to a westerly position along the deltaic plain (Fig. 3), and westward-advected, fine-grained sediment was deposited in front of the landward-most ridge trend, resulting in littoral mudflat advance where $Q_s > E$ (i.e., regional processes dominate), as shown in Figure 4, Stage 1. The entire shoreline prograded extensively in response to increased sediment supply and net-westerly littoral drift. When the Mississippi River channel diverted to the east, fine-grained sediment delivery to the chenier plain was reduced, enabling wave energy to dominate ($Q_s < E$) and transgression to occur along major sections of the shoreline, thus concentrating coarser-grained material into ridges (Figs. 3 and 4, Stage 2). Suppose that two inlets also existed, an eastern one that is wave-dominated and unstable ($\Omega/M_{total} < 150$) and a western one that is tide-dominated and stable ($\Omega/M_{total} > 150$). As the shoreline eroded in some localities, creating sand- and/or shell-rich cheniers, most of the eroded sediment was transported downdrift and trapped through lateral accretion (recurved spits) at the wave-dominated inlet and through net shoreline advance (beach ridges) farther west, where inlet processes dominated longshore sediment transport at the tide-dominated inlet. A local reversal in longshore sediment transport occurred west of the tide-dominated inlet, probably in response to wave refraction around an ebb-tidal delta. As such, beach ridges were created on

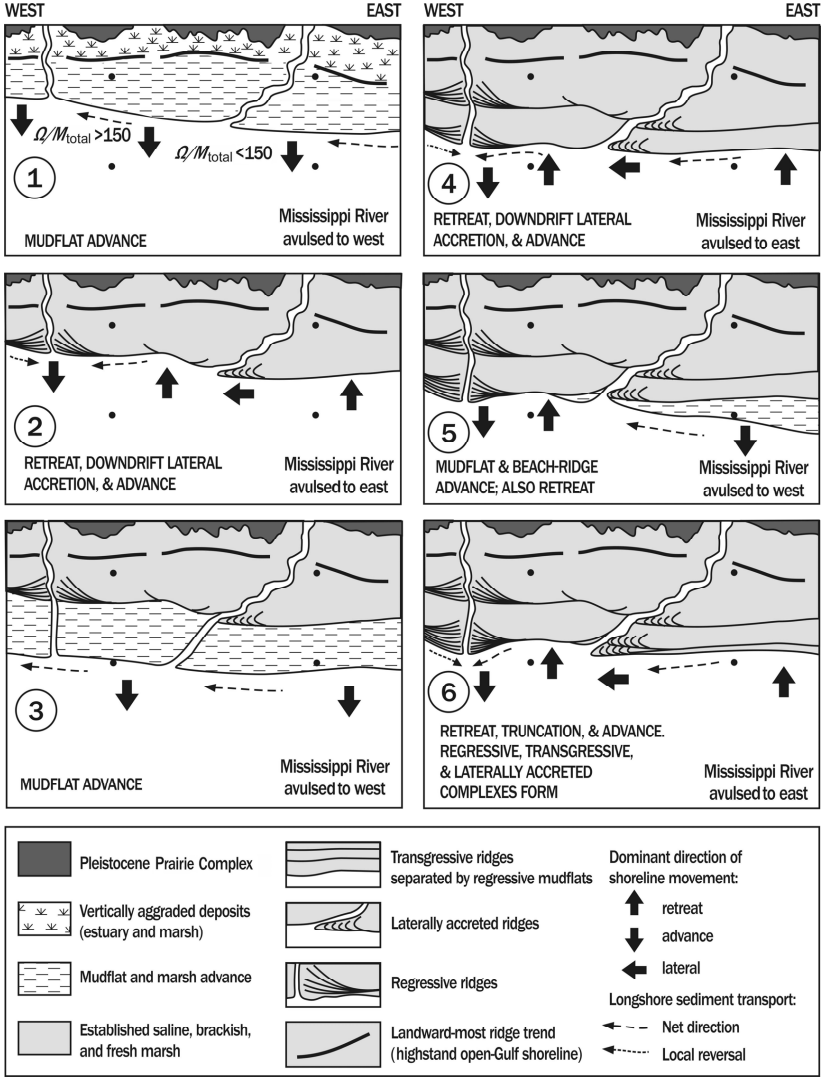

Fig. 4. Six-stage geomorphic process-response model illustrating evolution of the Louisiana chenier plain, where the geneses of three distinct ridge types (transgressive, regressive, and laterally accreted) typically occur contemporaneously along the same shoreline trend at different locations [from McBride et al. (in press)]. The four dots in each stage represent the same position through time.

either side of the tide-dominated inlet. Thus, the geneses of three distinct ridge types occurred contemporaneously along the same shoreline, but at different locations. The different locations represent local variations in shoreline behavior along the coast during periods of decreased sediment supply (i.e., local processes dominate). Moreover, coastwise zones of fresh, brackish, and saline marshes became established across the entire chenier plain in Stage 2, thus masking former environmental demarcations found in Stage 1. During Stage 3, the Mississippi River channel avulsed to the west again ($Q_s > E$), and littoral mudflats advanced seaward of the different ridge types that were formed during Stage 2 (Fig. 4).

When the Mississippi River switched back to the east (Fig. 4, Stage 4), fine-grained sediment supply was diminished, and transgressive, regressive, and laterally accreted ridges again formed contemporaneously while local processes dominated and shaped the coastal landscape, as indicated by historical shoreline-change trends (Byrnes et al. 1995). The unstable, wave-dominated inlet migrated farther west as the ridges accreted laterally with sediment from updrift erosion and ridge truncation (Fig. 4, Stage 4). The area around the stable, tide-dominated inlet advanced farther seaward.

During Stage 5, the Mississippi River occupied a more westerly position, and mudflat growth seaward of the ridges was renewed; however, fine-grained deposition did not extend along the entire chenier-plain shoreline, as it does today; rather, active mudflat advance occurred only along the eastern chenier plain (i.e., the Freshwater Bayou area). This permitted further erosion, reworking, and redistribution of ridge sediment to the west, with continued seaward advance of the shorelines adjacent to the stable inlet, as indicated by historical shoreline-change movements (Byrnes et al. 1995). During Stage 6, fine-grained sediment supply to the chenier plain was reduced again when the Mississippi River switched to the east (Fig. 4, Stage 6). Local transgression was more extensive, which allowed the active shoreline to truncate a greater number of older ridge deposits, thus releasing more trapped sediment into the littoral transport system for lateral accretion to the spit complex updrift of the unstable inlet. The regressive ridge complexes updrift of the stable inlet continued to advance seaward using sediment supplied from updrift erosion.

SUMMARY AND CONCLUSIONS

1. The Louisiana chenier plain contains not only transgressive ridges (traditional cheniers), but also regressive ridges (beach ridges) and laterally accreted ridges (spits or recurved spits). Thus, a geomorphic hierarchy of primary landforms relative to dominant coastal process is presented. "Chenier plain" is defined as a first-order feature and contains three smaller, second-order features: chenier complex, beach-ridge complex, and spit complex. Individual ridges of each complex type are further classified as third-order features: chenier, beach ridge, and spit.

2. Although the Mississippi River plays a primary role in chenier-plain development, chenier-plain evolution and ridge genesis cannot be attributed solely to channel avulsion and attendant delta switching along the southeastern Louisiana coast. Other primary depositional and erosional processes include local erosion, reworking, and

downdrift transport of sediment and the stability and sediment-trapping capability of tidal entrances. The location and level of inlet stability determine the genesis and distribution of beach ridges and recurved spits and their associated complexes. Regressive beach-ridge complexes develop at stable inlets ($\Omega/M_{total} > 150$), whereas laterally accreted spit complexes form at unstable inlets ($\Omega/M_{total} < 150$).

3. The more-advanced, six-stage geomorphic process-response model presented here synthesizes chenier-plain evolution primarily as a function of (a) the balance between sediment supply and energy dissipation in response to channel avulsions of the Mississippi River, (b) local sediment reworking and lateral transport, and (c) tidal-entrance dynamics. The geneses of three distinct ridge types (transgressive, regressive, and laterally accreted) typically occur contemporaneously along the same shoreline at different locations.

ACKNOWLEDGEMENTS

Research was funded by the U.S. Geological Survey Coastal and Marine Geology Program (cooperative agreement 14-08-0001-A0917, Byrnes and McBride co-principal investigators); the Office of Naval Research (Grants N00014-99-1-0817 and N00014-00-1-0247, McBride principal investigator); the Office of the Provost at George Mason University (Faculty Summer Research Grant to McBride); and the Louisiana Department of Natural Resources, Coastal Restoration Division. The R.J. Russell Foundation (Department of Geography and Anthropology, Louisiana State University) also funded a portion of the fieldwork for Taylor's masters thesis. Our thanks to Lisa Duvic, Feng Li, Mary Lee Eggart, Clifford P. Duplechin, and Callan Bentley for technical and cartographic assistance, and to Amanda and Victor Van Beuren of Van Beuren Publication Services and Claudia Holland for their editorial services. Mr. Guthrie Perry and employees at Rockefeller Refuge provided invaluable assistance, helicopter support, and accommodation. We also thank The Nature Conservancy for giving us permission to conduct research on Little Pecan Island. Our gratitude extends particularly to the many residents of the chenier plain for allowing us on their private property and for providing important local insight.

Abstract: Conceptually, the goals and engineering design associated with beach nourishment are very similar to those required for habitat restoration, with the primary component of both being placement of fill material. Similar analyses are required for characterization of historic geologic and environmental conditions, assessment of sediment compatibility, development of design and construction templates, application of coastal structures, and other design elements. With some modification, many of the design methodologies developed for beach nourishment can be adapted to the less-established field of wetlands restoration.

INTRODUCTION

Along the Gulf coast of the United States, estuarine environments such as intertidal wetlands and bird rookery islands have experienced significant losses over the past century. These losses have been caused by a variety of ongoing mechanisms that include accelerated subsidence, wave induced erosion, eustatic sea level rise, reduction of sediment supply, and direct anthropogenic impacts from urbanization and industry. Although traditionally valued primarily for ecological benefits, the storm-protection role of wetlands has gained attention over the past decade, especially following the active 2004 and 2005 hurricane seasons along the U.S. Gulf coast. This increased attention has led to a larger number of projects constructed along the Texas and Louisiana Gulf coasts. Site conditions coupled with rigorous success criteria for these projects pose significant challenges to designers, particularly in the shallow water and soft sediments encountered in bays and estuaries.

A key component of most restoration projects is placement of sediment as fill material. Similar to traditional open-coast beach nourishment projects, placing fill for habitat restoration requires borrow source identification, analysis of sediment compatibility, and prediction of fill performance and longevity. Although extensive guidance is available for locating and assessing sediments for beach nourishment (for example, Dean 2002), relatively little exists for habitat restoration (USACE 2000). Design items not traditionally considered for beach nourishment but typically required for habitat restoration include analysis of sediment nutrient content and sediment consolidation and settlement.

The purpose of this study is to review the components of sediment analysis required for open-coast beach nourishment and explore their application to estuarine habitat creation projects. Similarities and differences are drawn in terms of project goals, analysis and design methodology, and construction considerations. Recommendations are provided regarding design methodology for estuarine habitat creation.

DISCUSSION

Within the context of this study, "estuarine habitat creation" focuses on creation of new and/or replacement of historic wetlands and is simply referred to herein as "wetlands restoration." Unlike beach nourishment, which primarily replaces sand in eroding locations, wetlands restoration often replaces habitat at locations where wetlands may not have existed in the recent past. Typically, the overall goals of wetlands restoration are to (1) replace or create new area, (2) protect new or existing area, and/or (3) provide synergistic benefits to adjacent areas. These goals are also typical of beach nourishment, and the fundamental method of achieving these goals is placement of sediment as fill material[1]. The following discussion provides comparisons between beach nourishment and wetlands restoration in terms of these goals and associated engineering considerations.

Project Goals and Benefits

Table 1 presents a comparison of project goals between beach nourishment and wetlands restoration. Beach nourishment often includes breakwaters or other protective structures for sand retention and provides synergistic benefits through recreation, tourism, and storm-damage reduction to landward infrastructure. Similarly, wetlands restoration often includes breakwaters or other protective structures to minimize fringe recession and provides synergistic benefits through attenuation of storm surge, recreation, and ecotourism.

[1] An exception is the excavation of uplands to create wetlands, not discussed here.

Table 1. Comparison of Project Goals

	Examples	
Goal	**Beach Nourishment**	**Wetlands Restoration**
Replace or Create New Area	Create beach (sand dunes, wide berm, sand bars, feeder berm, etc.)	Create marsh complex (ponds, channels, vegetated area, mud and/or sand flats, etc.)
Protect New or Existing Area	Protect beach with breakwaters, groins, or nearshore berm.	Protect wetlands with breakwaters or reef.
Provide Synergistic Benefits to Adjacent Areas	▪ Storm protection to upland infrastructure ▪ Economic benefits (tourism, property values) ▪ Recreation ▪ Sand source for downdrift beaches	▪ Storm surge attenuation ▪ Economic benefits (ecotourism, fishing) ▪ Recreation (fishing, hunting) ▪ Compliment/expansion to overall ecosystem

Historical Site Conditions

Gathering and reviewing historical aerial photography, bathymetric and topographic data, oceanographic and meteorologic information, and other environmental data is a common step for assessment of physical conditions and geomorphic processes in coastal areas. Specific items of interest for beach nourishment design include analysis of historic shoreline and beach volume change for prediction of project longevity or long-term performance. In addition, analysis of sediment characteristics can provide an indication of historic sources and sinks for development of a sediment budget.

For wetlands restoration design, historic shoreline (or marsh edge) change is also important, although the interaction and relative contribution of wave-induced erosion, subsidence, sea level rise, interior fragmentation, and marsh accretion adds a significant degree of complexity to prediction of future change and project longevity. Analysis of sediment characteristics can provide an indication of the age of a marsh and help explain its origin (such as relic washover deposits, river deltas, tidal shoals, etc.).

A parameter that is unique to wetlands restoration design is the historical percent and geometry of open water (i.e., ponds and channels) within a marsh complex. The total percent open water may increase over time as a marsh progresses through its various stages of growth and development, fragmentation, and decay. Selecting an appropriate historical baseline condition for percent open water can be subjective and largely depends on habitat preference (such as aquatic versus avian). For example, at the Swan Lake restoration marsh in Galveston Bay, Texas approximately 35% open water was targeted to provide both intertidal and aquatic habitat (Figure 1). However, at a restoration marsh under construction by Cheniere Energy in western Louisiana near Sabine Pass, minimal open water was included at the request of the regulatory community.

Fig. 1. Construction of Swan Lake Restoration Marsh (photo courtesy of RLB Contracting, Inc., Port Lavaca, Texas)

Environmental Conditions

Analysis of waves, currents, tides, and storm surge is required for quantification of sediment transport and geomorphology of a beach fill project. These environmental conditions are also important for wetlands design, although primarily for erosion prevention and water circulation instead of geomorphology.

Sediment Compatibility

Borrow material investigations and analysis of sediment compatibility are key components of both beach nourishment and wetlands restoration. While the typical focus for beach nourishment is to locate an ample source of poorly graded (i.e., "clean") sand that resists consolidation and remains loose after placement, sediment for wetlands restoration is usually composed of cohesive material (silt or clay) that contains or attracts organic matter for plant nutrients. Assessing compatibility of beach sediments may include testing for grain size, sorting index, fines content, color, and toxicity. Although the criteria for wetlands sediments are generally less stringent, assessment of compatibility is still critical and may include testing for fines content, toxicity, and organic content. A comparison of required testing for sediment compatibility is summarized in Table 2.

Table 2. Comparison of Testing for Sediment Compatibility

Parameter	Beach Nourishment	Wetlands Restoration
Grain Size	Sieve Analysis ▪ ASTM C 136 ▪ ASTM C 117	Sieve/Hydrometer Analysis ▪ ASTM D 422
Sorting Index	Folk & Ward (1957)	Not Required
Fines Content	Sieve Analysis ▪ ASTM C 117	Sieve Analysis ▪ ASTM C 117
Toxic Content	EPA Methods 9071A, 8440, 3051, 9020B, 8260	EPA Methods 9071A, 8440, 3051, 9020B, 8260
Organic and Chemical Nutrient Content	Not Required	Various Agricultural (Soil Analysis) Testing

As documented by Finkl et al. (2006), detailed methods have been developed for locating and quantifying sand sources that meet project-specific compatibility criteria for beach nourishment. Techniques including review of geologic conditions, subbottom (seismic) profiling, jet probing, and soil borings can also be applied to borrow source investigations for wetlands restoration. Note that jet probing may have limited application where soils contain higher silt and clay content and/or turbid water limits visibility.

Unanticipated shoreline changes from wave refraction, shoaling, and/or reflection at offshore borrow pits have been documented for beach nourishment projects (Finkl 2004) and should be considered for marsh restoration. In addition to adverse shoreline change, borrow pits may cause unacceptable environmental impacts such as alteration or destruction of habitat, or anoxic conditions resulting in fish kills.

Underlying Soil Considerations

Although not typically required for placement of fill material on a sandy beach, underlying soil considerations often dictate the design approach for wetlands restoration projects. The soft soils typical of a marsh can cause fill material to be susceptible to instantaneous settlement (associated with lateral displacement of underlying soils during placement) and subsequent short- and long-term settlement associated with consolidation of underlying soils. In addition, the ability of excavated marsh soils to be mechanically sidecast and "stacked" to construct terraces or small containment levees is often critical. Determination of soil strength parameters and moisture content are therefore key elements of wetlands restoration design.

These design elements should also be considered for beach nourishment at sites where a thin veneer of sand overlies relic marsh sediments such as within the chenier plain extending along western Louisiana and eastern Texas. Without consideration of settlement, a beach fill project at such a location may require a much greater volume of sand than planned or settle to an unacceptable elevation subsequent to construction.

Fill Geometry

Extensive guidance is available for analysis and optimization of length, cross section, transition areas, and other geometry of beach fill projects. For example, equilibrium profile theory (Moore 1982) can be applied for relatively accurate prediction of the average slope of a nourished beach profile. And various numerical models such as GENESIS (Hanson and Kraus 1989) and SBEACH (Larson 1988) are available for prediction of long-term and storm-induced fill performance based on longshore and cross-shore sediment transport. These tools allow development of a design template and its associated construction template. The construction template provides the initial placement geometry and is largely based on constructability considerations. The design template is the desired target geometry of the project after prolonged exposure to waves.

The concept of design and construction templates also applies to wetlands restoration. For development of the design template, an existing reference marsh is typically selected to provide target planting bed elevations, geometry of ponds and channels, and total percent open water. As already mentioned, selection of an appropriate reference marsh for baseline conditions can be fairly subjective and is dependent upon the desired type of habitat. Other design tools include circulation modeling to assess water quality and channel stability and wave analysis to assess potential for marsh fringe erosion. Marsh fringe (or edge) is the area of a marsh immediately adjacent to open water (ponds and tidal channels) and has been recognized as a highly utilized habitat for a variety of significant fishery species (Rozas et al. 2005).

For wetlands restoration, once the design template has been developed, the construction template is determined based on sediment characteristics (of both the fill and insitu soil) and fill placement method. For hydraulic placement associated with pipeline dredging, sandier fill material can be considered for unconfined placement and the adaptation of equilibrium profile theory can be considered, depending on water depth and exposure to waves. However, silt and soft clay will generally require containment with small levees or existing adjacent marsh edge. If placed mechanically, containment is generally not required and much "steeper" side slopes can be achieved as may be desired to reduce fill volume and accommodate small ponds and channels. Mechanical placement allows greater control for constructing complex pond and channel geometry; in contrast, hydraulic placement generally requires more idealized open-water shapes. Figure 2 provides an example of hydraulic placement of dredged material to create "marsh mounds" at Delehide Cove in Galveston Bay, Texas. Note that the "ponds" and "channels" are the areas between the mounds that provide the desired open water.

Fig. 2. Delehide Cove Restoration Marsh (photo courtesy of Texas Parks and Wildlife)

Regardless of the type of fill material and placement method, higher planting bed elevations are usually specified for the construction template than the design template to accommodate settlement. Determining total settlement should consider both sediment characteristics and placement method. Although numerical methods such as the PSDDF model (Stark et al. 2005) can be applied, most were developed for traditional dredged material placement where relatively thick layers of fill are placed in confined disposal cells. Because fill material for wetlands restoration is typically only two to three feet (0.6 to 0.9 meters) thick and is often unconfined, prediction of total settlement often relies as much on experience and judgement as numerical techniques.

Protection with Structures

A common method of improving longevity of beach fill projects is construction of breakwaters, groins, reefs, and combinations thereof as sand retention and wave reduction structures. The extensive knowledge that has accumulated through application of such structures to beach nourishment can be applied for design of similar structures to protect restored (and existing) wetlands. Limiting factors in selection of structural protection in wetlands are soft soils with minimal bearing capacity, shallow water and limited construction access, and the need to maintain tidal exchange. Also, similar to application of structures on beaches, downdrift impacts associated with interruption of longshore sediment transport can be a concern. Additional impacts to adjacent wetlands or private property can occur due to wave reflection.

An example of a lesson learned from beach nourishment projects that is relevant for wetlands restoration is the return flow of water from wave overtopping at low-crested breakwaters. This process was determined to be a significant problem at the Prefabricated Erosion Prevention (P.E.P.) Reef project constructed at the Town of Palm Beach, Florida (Martin and Smith 1997). Consideration of this process may be a

particular concern for breakwaters along marsh edge. Such breakwaters are often low crested to promote water exchange during high tides. Chronic current from return flow along the leeward side of the breakwater may scour the edge of the marsh.

CONCLUSION

As coastal engineers continue to explore and establish successful techniques and develop guidelines for analysis, design, and construction of wetlands restoration, they will rely on experience gained from the more-practiced field of beach nourishment. Key principles of beach nourishment that can be applied to wetlands restoration include the following:

- Similar to helping determine historic flow pathways for a beach, analysis of historic sediment characteristics can provide an indication of the age of a marsh and help explain its origin and evolution (such as relic washover deposits, river deltas, tidal shoals, etc.).

- Assessing compatibility of beach sediments may include testing for grain size, sorting index, fines content, color, and toxicity. Although the criteria for wetlands sediments are generally less stringent, assessment of compatibility is still critical and may include testing for fines content, toxicity, organic content, and consolidation.

- Detailed methods have been developed for locating and quantifying sand sources that meet project-specific compatibility criteria for beach nourishment. Techniques including review of geologic conditions, subbottom (seismic) profiling, jet probing, and soil borings can also be applied to borrow source investigations for wetlands restoration.

- The concept of "design" and "construction" templates employed for beach nourishment design also applied to wetlands restoration and is directly related to sediment characteristics and fill placement method.

- Similar to beach nourishment, structures applied with wetlands restoration can cause downdrift erosion and other adverse impacts to adjacent areas. Limiting factors in selection of structural protection in wetlands are soft soils with minimal bearing capacity, shallow water and limited construction access, and the need to maintain tidal exchange.

ACKNOWLEDGEMENTS

Abstract: Louisiana has embarked on the nation's most ambitious program to restore and protect their ecosystems, wetlands, and wildlife; provide storm protection; and support oil and gas development. Storm erosion has breached the majority of the barrier islands resulting in the development of fragmentary islands and new inlet openings. Environmentally sensitive marsh habitats have declined due to man's impact from oil and gas mining and Mother Nature's effects. One key strategy within the program is marsh restoration to stabilize the integrity of the barrier shorelines. Success criteria mandates that by Year 3 the marsh platform elevations are within the intertidal zone, defined from Mean High Water to Mean Low Water, and remain within this zone through Year 20. Critical steps in the platform design process include subsurface data collection, back-barrier sediment analyses, containment dike design, and prediction of the target platform elevation to achieve the success criteria.

INTRODUCTION

The strategies set forth in Louisiana's Coast 2050 program constitute the nation's most ambitious ecosystem restoration plan to provide storm and flood protection; enhance fisheries production; create, restore and enhance wetlands; protect wildlife resources; and support the activities of oil and gas development, navigation, and ecotourism. Hurricanes, overwash events and increased tidal prism have caused breaches along the majority of the barrier island shorelines resulting in the development of fragmentary islands and new inlet openings. Environmentally sensitive wetland and marsh habitats have declined due to man's impact from oil and gas mining, as well as Mother Nature's effects of sea level rise and storm erosion.

One of the key strategies within the program is restoration of marsh platforms to help stabilize the integrity of the barrier shorelines. The goals of the marsh restoration projects include the following:

- 20-Year project design life
- Create new back-barrier marsh at Year 1 with unrestricted tidal exchange
- Construct marsh platforms such that by Year 3 the platform elevations are within the intertidal zone, defined from Mean High Water (MHW) to Mean Low Water (MLW), and remain within this zone through Year 20
- Close breachments that have occurred due to storm and hurricane damage and prevent breaching during the design life
- Vegetate newly created marsh areas according to these criteria: approximately 25% of the marsh platform shall be 80% or greater vegetated after the first completed growing season after construction, and 100% of the marsh platform shall be vegetated after three complete growing seasons
- Construct tidal creeks and ponds to allow hydraulic exchange and circulation within newly created marshes.

Critical steps in the marsh platform design process include subsurface data collection, back-barrier sediment analyses, containment dike design, and prediction of the target marsh platform elevation to achieve the intertidal zone criteria.

PROCEDURES FOR SUBSURFACE INVESTIGATIONS

Examination of case studies and past projects has led to the establishment of subsurface investigation procedures to guide designers in developing geotechnical data acquisition programs for marsh creation projects. These procedures were developed using the Boussinesq Case for determining vertical soil stresses under embankment loadings and typical containment dike designs. The purpose of the investigations is to determine geotechnical engineering design soil parameters for geotechnical analyses. The locations of the borings shall coincide with the containment dike alignment as well as within the proposed marsh fill area. The boring data acquisition program shall be set according to the following guidelines (Table 1); however, they may vary due to site elevations, cultural constraints, and site specific knowledge of the designer (LDNR, 2005).

Table 1. Guidelines for Soil Boring Collection

Design Component	Location	Depth *	Spacing
Marsh Creation Fill Area	Open Areas per Designer	25' – 40' & (1 – 60')	1 per 50 - 100 acres (3 minimum per site)
Containment Dike	@ C.L.	30' – 60'	1 per 500' to 800'

* Depth is referenced from the mud line
C. L. denotes Centerline

Field data measurements shall include the following information specific to the borings:
- Horizontal position in state plane or latitude/longitude coordinates
- Elevation of existing grade (e.g. bay bottom) referenced to the project datum (e.g. North American Vertical Datum, 1988)
- Depth of penetration (i.e. length of boring)

Field sampling procedures recommended for back-barrier testing in cohesive and semi-cohesive soils follow ASTM D1587 and for non-cohesive soils, ASTM D1586. An appropriate sized drill rig shall be mobilized to the site and using accurate Global Positioning Equipment, the locations and elevations of each sample shall be established. The drill rig shall advance the boring to the desired depth using a three-inch diameter Shelby tube sampler (cohesive) or a split spoon sampler (non-cohesive). The sample and tube shall be extracted from the borehole and detached from the drill rig. Minimum intervals of five feet are recommended. The tubes shall be sealed in the field to protect the samples during transport as well as minimize moisture loss. Further, they are logged on chain of custody forms for transportation to the testing facility.

To ascertain the penetration resistance of the in situ sediments, standard penetration tests may be performed. A split spoon sampler shall be driven into the undisturbed sediment at the bottom of the boring with an appropriately weighted hammer having an appropriately measured stroke. The number of blows required to drive the sampler through two, 6-inch increments is recorded and serves as the measure of penetration resistance (STE, 2004).

BACK-BARRIER SEDIMENT ANALYSES

The following sediment parameters are recommended for testing to provide the necessary geotechnical engineering design criteria. Samples representative of the various sediment strata shall be classified using the Unified Soil Classification System (ASTM 2487). Classification tests shall include Atterberg Limits (ASTM D4318) for cohesive soils and sieve analyses and hydrometer tests (ASTM D422) for non-cohesive soils. Strength tests shall include the miniature vane (ASTM D4648), unconfined compression (ASTM D2166) and triaxial compression (ASTM D2850). Consolidation tests (ASTM 2435) shall be performed. Further, moisture content, organic content, and unit weights shall be determined.

CONTAINMENT DIKE DESIGN

In order to facilitate the placement of hydraulically dredged material, an earthen containment dike system should be designed capable of resisting lateral pressures and environmental effects. Utilizing the results of the back-barrier sediment testing, three geotechnical analyses should be performed to provide design criteria for the containment dike. First, due to the weight of the material, the primary consolidation settlement of the underlying soils is estimated using one-dimensional consolidation theory. Second, the self-weight consolidaton "shrinkage" of the uncompacted dike material is estimated based on soil density, moisture content, and past experience. Third, a global slope stability analysis is performed using the proposed containment dike configuration. This is done by assuming a failure surface and using both the circular arc "normal method of slices" and sliding block methodologies to evaluate the global stability of the dike. The side slopes of the dikes have two types of forces acting on them, driving forces and resisting forces, which depend on the geometry of the site. The driving forces include the soil weight and seepage forces, which can initiate sliding. The resisting forces include the soil shear strength, which opposes soil movement. The ratio of the sum of the resisting and sum of the driving forces is called the global slope stability factor of safety.

Parameters in these analyses include water depth and the initial freeboard of the dike. The freeboard equals the distance from the water surface elevation to the top of the containment dike. The total consolidation increases with increasing freeboard primarily due to the additional weight of dike material.

TARGET MARSH PLATFORM ELEVATIONS

Louisiana's Coastal Wetlands Planning, Protection, and Restoration Act (CWPPRA) designates marsh restoration projects as environmentally benefits based projects, which are funded according to the level of benefits produced versus fiscal constraints. To achieve the highest level of environmental benefits, the marsh platform shall be designed to lie within the intertidal zone, Mean Higher High Water (MHHW) to MLLW, for the significant majority of the design life. A similar analysis employed for the dike design is utilized wherein the total settlement rate, accounting for settlement due to the weight of the marsh fill over the underlying back-barrier sediments and self-weight consolidation within the fill, is predicted.

CASE STUDY

Project Setting

The Bay Joe Wise Headland is located approximately 50 miles southeast of New Orleans, Louisiana, in the Plaquemine's Parish, Coast 2050 Region 2, Barataria Basin (Figure 1). The reach proposed for restoration extends from Pass Chaland in the west to Grand Bayou Pass in the east. The barrier island fronts the Gulf of Mexico and protects the shallow interior bay, Bay Joe Wise, and adjacent wetlands and marsh (Figure 2).

Based upon historical profile characteristics and site observations, the beach and dune along the Headland are low-lying with average berm elevation of +3 to +4 feet NAVD88 and berm slope ranging from approximately 1:20 to 1:30. The dry beach width varies from 0 (non-existent) to approximately 50 feet.

Figure 1: Location Map

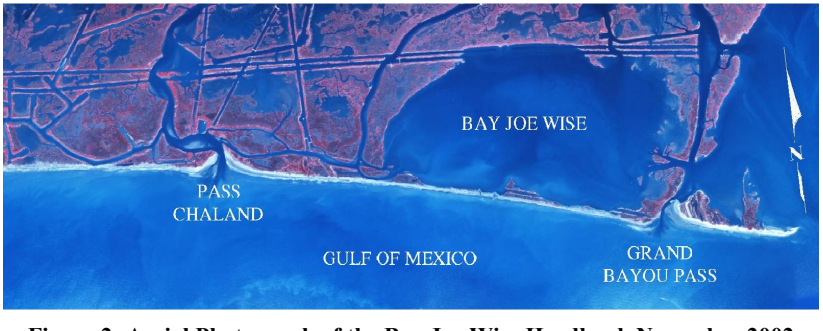

Figure 2: Aerial Photograph of the Bay Joe Wise Headland, November 2002

The offshore slope varies from approximately 1:80 to 1:130. Both Pass Chaland and Grand Bayou Pass are shallow inlets with fairly sizable ebb shoals and relatively small flood shoals. Bay Joe Wise is a shallow interior bay with average water depths of 3 to 4 feet.

The Headland has experienced significant erosion, such that, it has receded to critical width and has breached during recent storm and hurricane activity, e.g. Hurricanes Lili and Isidore in 2002, and Hurricane Katrina in 2005, whose eye passed directly over the Headland. Numerous breaches are open and water exchange is evident from bay to gulf. The marsh, wetlands, beach and dune habitats within the Project reach have undergone significant loss not only due to these extreme events and other natural processes such as sea level rise, and subsidence, but also man-influenced activities including oil and gas exploration and related canal dredging.

The Project area is one of, if not the, most rapidly disappearing areas in Louisiana, experiencing a loss rate of over 73 acres per year since 1988 (Coastal Research Laboratory (CRL), 2000). A photographic analysis was conducted to determine the acreage of land versus water, land acreage change, and breakdown of land mass into distinct habitats. In 2000, the land versus water acreage was estimated to be approximately 1,039 acres and 3,503 acres respectively. The habitat inventory estimated 769 acres of marsh, 41 acres of uplands, 200 acres of shrubs, 7 acres of inter-tidal, and 22 acres of beach. By applying the loss rate of 73 acres per year, the short–term year of disappearance was predicted to be 2014 (CRL, 2000).

Project Proposal

To address the significant land loss and natural resource habitats within this area and restore the structural integrity of the barrier island, the National Marine Fisheries Service (NMFS) and the Coastal Restoration Division of the Louisiana Department of Natural Resources (LDNR) have proposed an ecosystem restoration plan which is being funded and authorized in accordance with the provisions of the Coastal Wetlands Planning, Protection, and Restoration Act (CWPPRA) under 16 U.S.C.A., Sections 3951-3956. The Project is entitled *Pass Chaland to Grand Bayou Pass Barrier Shoreline Restoration Project* (BA-35, CWPPRA Priority Project List 11).

The Project construction proposes to construct a marsh platform approximately 1,000 feet wide contiguous with the northern side of the Gulf shoreline of Bay Joe Wise. It is estimated that approximately 2.67 million cubic yards of dredged material consisting of clays, silts and sands will be required to construct the marsh platform. Further, the construction template includes a beach and dune component to address the severity of erosion along the gulf-front shoreline and multiple breachments that have occurred due to recent storm and hurricane damage. It is estimated that approximately 1.55 million cubic yards of dredged material consisting primarily of sand will be required to construct the beach and dune component. A plan view of the proposed fill template and typical cross section are presented in Figures 3 and 4, respectively.

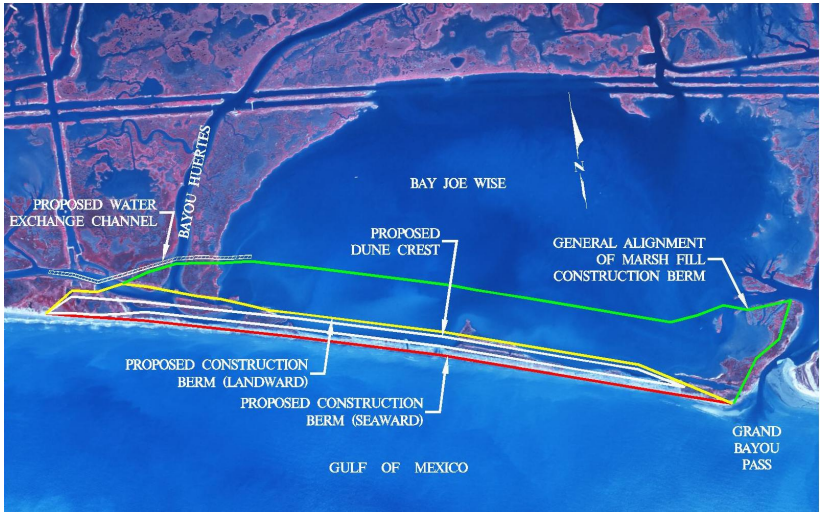

Figure 3: Plan View of Proposed Construction

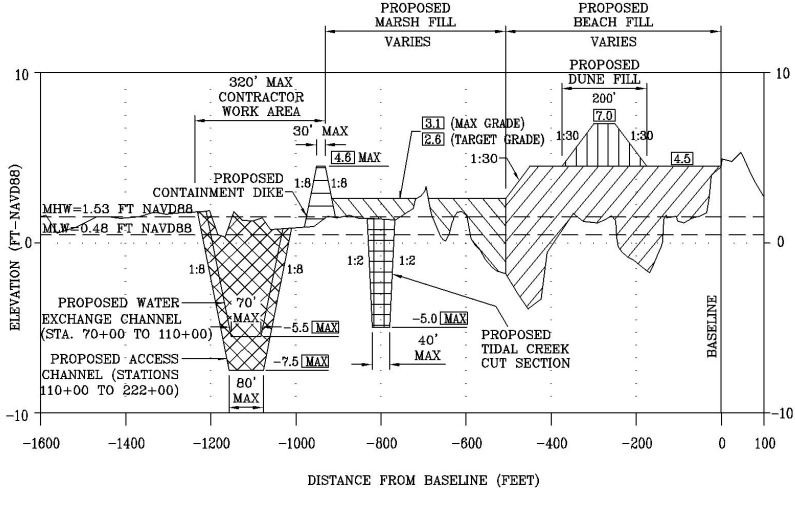

Figure 4: Cross Section View of Proposed Construction

Dike Design Parameters

Tidal Parameters

The mean lower low water (MLLW) elevation and the mean higher high water (MHHW) elevation in the Project area are 0.4 feet NAVD and 1.6 feet NAVD respectively. In order to ensure adequate stability of the dike, MHHW was used as the reference datum to determine the water depth in the fill templates, and MLLW elevation was used as the reference datum to calculate the height of the dike above the water surface, that is, the freeboard of the dike relative to the water surface.

Safety Factors

Soil Testing Engineers, Inc. (STE) (2004) determined that for the Project's geologic setting, sediment parameters and design objectives, a dike side slope of 1(V):8(H) would be needed to maintain a stable dike. Table 2 provides an excerpt from a table of the safety factors presented in STE (2004). Values of 1.3 or higher are considered safe (USACE, 1987). Figure 5 displays a graph of the stability factor data along with regression lines, regression line equations, and R^2 values of the regression. These regression results were used to interpolate the safety factor for varying freeboard heights at water depths of 4 feet and 6 feet, which are typical depths anticipated to be encountered for dike construction, assuming a crest width of 20 feet.

Table 2. Slope Stability Analysis

Initial Freeboard (ft)	Water Depth (ft)	Safety Factor for a Side Slope of 1(V):8(H)
1	4	2.6
2		2
3		1.6
4		1.4
1	6	2.3
2		1.9
3		1.6
4		1.4

Total Effective Settlement

Decreases in the fill and dike elevations are due to the total effective settlement. The total effective settlement accounts for settlement due to the weight of the fill or dike, self-weight consolidation within the fill or dike, geologic subsidence, and sea level rise. The settlement due to the weight of the fill or dike and self-weight consolidation within the fill or dike were calculated by STE (2004) based on the sediment conditions sampled and analyzed in Bay Joe Wise. Both the geologic subsidence and sea level rise occur at an approximate rate of 0.025 feet per year (SJB Group and CEC, 2005).

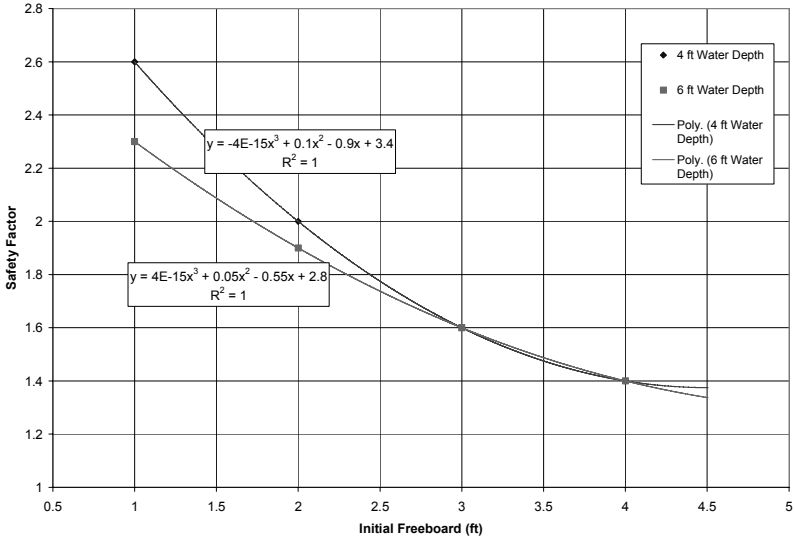

Figure 5. Slope Stability Analysis

Figure 6 depicts the relationships between initial freeboard and the estimated total effective settlement extrapolated from calculations by STE (2004) for varying time periods at the typical bay depth of 4 feet. These relationships were used to calculate the total effective settlement for varying freeboard heights and water depths and served as design criteria for determining the optimal primary dike and marsh fill elevations.

Fairly rapid settlement caused by the weight of the dike or fill and self-weight consolidation occurs over the first two years following construction. Following the initial two years, a steadier settling takes place which is dominated by the fairly constant geologic subsidence and sea level rise. Thus, the dike design life was set at two years.

Bay Joe Wise Wave Analysis

Due to the expanse of the bay, and additional analysis was conducted considering that the primary dike to contain the marsh fill will be exposed to waves from Bay Joe Wise. During the anticipated six month period that the fill is dewatering, the containment dikes must reasonably protect the fill from potentially damaging waves. An analysis of the potential wave propagation across the bay under various scenarios was performed using CEDAS-ACES Version 2.01G (Leenknecht et al., 1992). This analysis was conducted at two points on the proposed dike corresponding to the extreme eastern and western ends of the dike that will potentially be exposed to waves from the bay at points maximizing the potential fetch length.

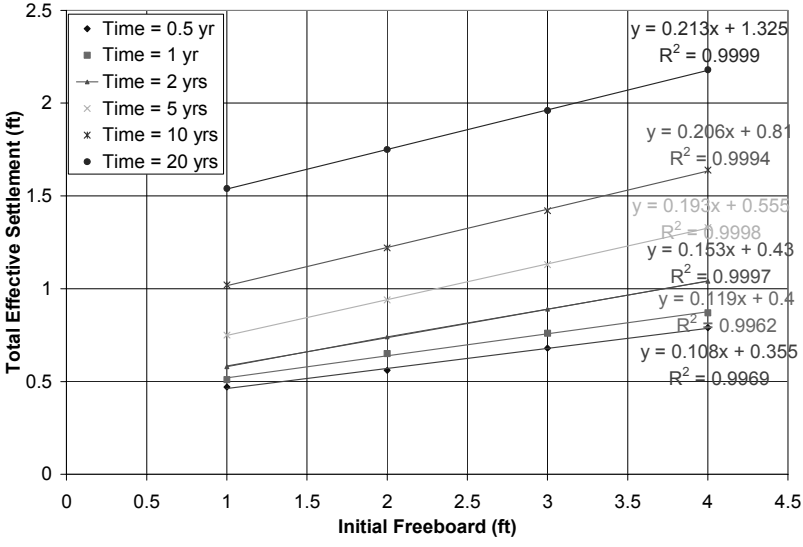

Figure 6. Total Effective Settlement vs. Initial Freeboard in 4 Feet of Water

Design wind and stage data available for the Project area (SJB Group and CEC, 2005) were used as input to the CEDAS-ACES model. Table 3 displays results of the predictive scenarios ran with CEDAS-ACES for the annual, 2-year, 3-year, 4-year, and 5-year storm scenarios.

To further evaluate the overtopping potential, an additional analysis of the wave run-up was performed in CEDAS-ACES. Given the information generated by CEDAS-ACES and the side slopes of the proposed dikes of 1(V):8(H), the maximum wave run-up was calculated to be 1.6 feet for the 2 year storm. The 2 year storm stage of 1.6 feet NAVD plus the wave run-up of 1.6 feet gives a total elevation of 3.2 feet NAVD for the design criteria.

Table 3. Predicted Wave Heights

Storm	Wave Height East (ft)	Wave Height West (ft)	Stage & Wave East (ft NAVD)	Stage & Wave West (ft NAVD)
Annual	1.1	1.1	2.7	2.7
2-Year	1.1	1.1	2.7	2.7
3-Year	1.5	0.7	4.2	3.4
4-Year	1.8	0.3	5.2	3.7
5-Year	1.9	0.1	5.9	4.1

Primary Dike

The primary dike for the marsh platform will be sited along the northern boundary of the marsh fill template. The general native soil elevation along this boundary is -3 feet NAVD or shallower. In order to maintain a conservative estimate of material that may be needed to construct this dike, the design toe elevation of -3 feet NAVD shall be used.

Using the total effective settlement relationships with freeboard and water depth, a trial and error analysis was performed to determine the design dike elevation, 4.5 feet NAVD, which meets and exceeds the 2-year design criteria. Figure 7 depicts the results of the analysis. The initial freeboard of the dike equals 4.1 feet, which has a safety factor of approximately 1.4. The figure shows the total effective settlement for six different water depths. These six scenarios range from the dike constructed on dry ground, that is, 0 feet of water, to the dike constructed in 10 feet of water. The total effective settlement increases for increasing water depth primarily due to the weight of the extra material required to reach the water surface. MHHW and MLLW are denoted on the figure for evaluation of the scenarios. In sections where the dike elevation is above MHHW, the surface of the dike will rarely become inundated with water.

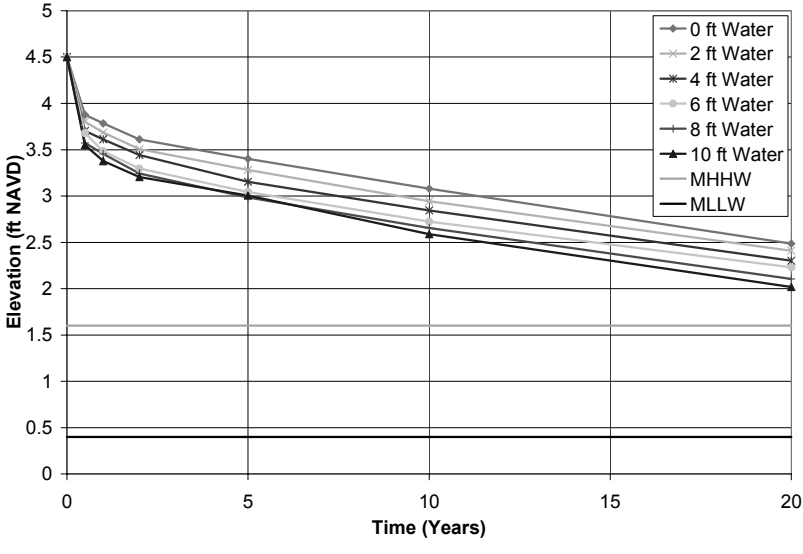

Figure 7. Settlement of Marsh Fill Containment Dike in Various Water Depths

Settlement calculations predicted the dike is likely to settle as much as 0.8 feet within the first six months immediately following dike construction. Examining the results of the Bay Joe Wise wave analysis, the proposed primary marsh dike elevation of 4.5 feet NAVD should be sufficient to protect the marsh fill from storms of a magnitude less than or equal to that of the average two-year storm events. Since the fill should be completely

dewatered within a six month time period, this should provide a reasonable amount of protection to the fill until it is settled in place.

Marsh Platform

A similar analysis was performed to determine the optimal design elevation of the marsh platform, 2.6 feet NAVD, for achieving the Project's design objective for marsh construction, that is, achieve an elevation such that the marsh fill elevation lies within this zone through the majority of the 20 years. Figure 8 presents the results of this analysis. Although the marsh fill elevation generally remains above MHHW until Year 5, it remains above MLLW for the 20-Year design life.

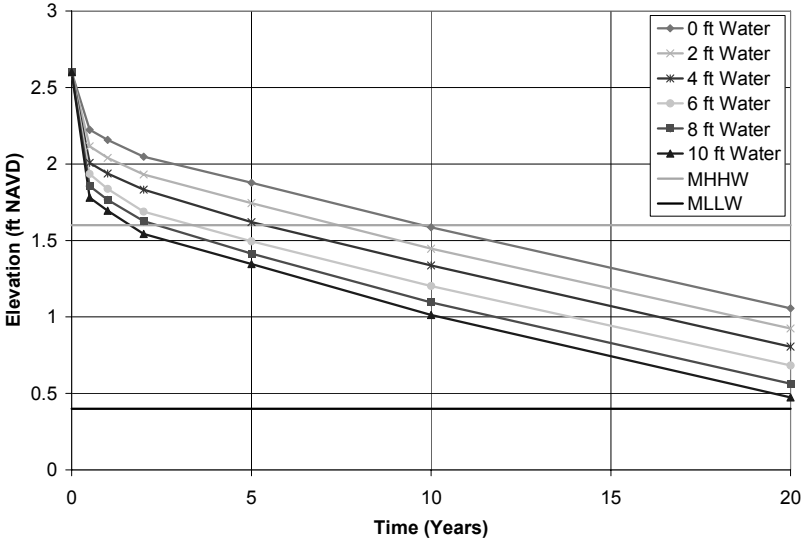

Figure 8. Settlement of Marsh Fill in Various Water Depths

Material Sources and Alternatives

The primary marsh containment dike will be approximately 16,000 linear feet long and require approximately 526,000 cubic yards. There are three (3) sources of material for dike construction. They are the inlet ebb shoals, interior channels, and Bay Joe Wise sediments. Field work was accomplished during Project design to sample the inlet ebb shoals and interior channels (SJB Group and CEC, 2005). Based on visual observations, the sediments are comprised primarily of fine sand with silts and clays and should be suitable for dike construction. STE (2004) determined the bay sediments are also suitable for dike construction.

CONCLUSION

Coastal Louisiana is disappearing at alarming rates resulting in the loss of pristine and unique estuarine systems, wildlife habitats, and recreational and commercial fishing; not to mention the decline in opportunities to mine oil and gas reserves and safely transport and distribute these valuable resources to the country. The state has embarked on its Coast 2050 program to hold the line and offset a significant amount of these impacts. The program includes dozens of marsh restoration projects to stabilize the integrity of the barrier shorelines. Key design steps in these projects include the siting, form and function of containment dikes to hold hydraulically placed fill within the marsh platform, and target elevations of the dikes and marsh platform to achieve environmental benefits based success criteria. The guidelines presented herein are recommended to the designer to enhance their understanding of the geotechnical data collection and sediment analyses required to properly design these key project components and achieve the success criteria. A case study is presented demonstrating the design of the marsh creation component of a Barrier Island Restoration project within the Barataria Basin wherein many of the guidelines were applied in the containment dike and marsh platform design. The project is slated for construction in 2007.

ACKNOWLEDGEMENTS

The authors thank the staff of LDNR's Coastal Engineering Division and National Marine Fisheries Service for their valuable input on marsh restoration design processes and blending of engineering principles with the biology and ecology of healthy marshes. Further, the authors thank the staffs of Coastal Engineering Consultants and consulting partner, SJB Group of Baton Rogue, Louisiana, for their support and contributions to this paper and to the Coast 2050 restoration program.

Abstract: Ice-rafting of sediment is a major winter process in New England coastal marshes, increasing in intensity northwards. A survey of ice rafts conducted across three back-barrier salt marshes characterizes and quantifies sediment loads. The mean concentration of sediment in ice rafts increases to the north: 10.4g/L at Nauset, MA; 20.3g/L at Essex, MA, and 26.2g/L at Wells, ME. Inorganic sediment dominates 70% of ice rafts sampled. Ice raft dispersion across the marsh surface, while highly stochastic, is influenced by tidal amplitude, channel network density, meteorological conditions, and marsh surface elevation. A numerical model of ice-rafted sediment deposition on New England salt marshes is derived. Mechanisms of ice raft sediment incorporation and dispersion, conceptual models of ice raft formation, and estimates of the relative magnitude of vectors are presented, with implications for the vertical accretion of northern marshes in a regime of rising sea level.

INTRODUCTION

Winter processes such as ice-rafting are an important sedimentation vector to northern high marsh environments. Ice rafts are a secondary sedimentation process, redistributing sediment within the back-barrier system. The transfer of inorganic sediment from tidal creek bottoms, tidal flats, and pannes to the marsh surface plays a critical role in the geomorphic evolution of the marsh, and may be a key factor in the survival of northern marshes in a regime of accelerated sea-level rise.

Background

Differences between northern and southern marshes may result from processes directly or indirectly attributable to climate (Chmura et al., 1997; Pennings and

Bertness, 1999; Morris et al., 2002). Shorter summers and a lower angle of incident sunlight reduce the growing season, and most marshes experience complete winter die-off of above-ground vegetation north of Cape Cod. Progressively longer winters increase the magnitude of cold-weather processes northward along the New England coast (Fig. 1). Despite the current global warming trend, winter processes may remain significant on northern marshes. Climate trends from the past 55 years at Portland, ME, show an increase in monthly mean minimum temperatures for all months (mean = +3.16°C) except January, which has become colder on average (-0.88°C)(data from NCDC, NOAA). Shorter winters that are nevertheless more severe are another unexpected effect of global warming that may impact sedimentation and bioproductivity on the marsh surface.

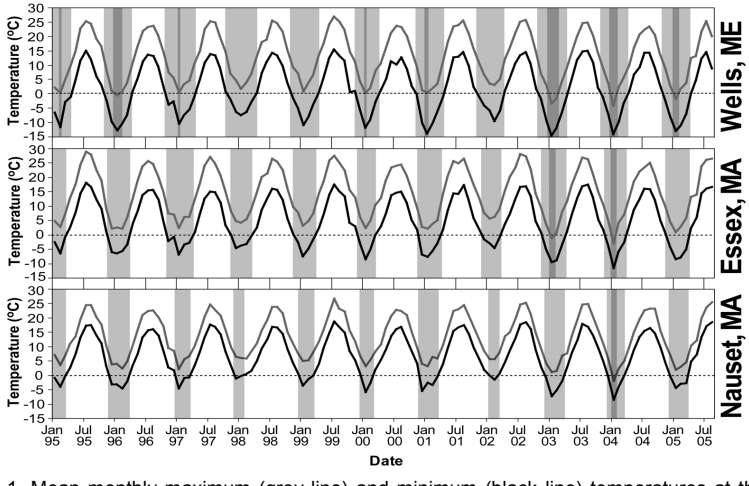

Fig. 1. Mean monthly maximum (grey line) and minimum (black line) temperatures at three New England field sites. Grey bars denote periods when mean daily minimum temperatures for the month were ≤ 0°C; darker grey bars indicate monthly mean maxima were ≤ 0°C. Data from NCDC (National Climatic Data Center), NOAA (National Oceanic and Atmospheric Administration).

Recently more attention has been focused on the role that winter ice plays in northern salt marshes (e.g. Ewanchuk and Bertness, 2003; Chmura and Hung, 2004; van Proosdij et al., 2006). Ice rafts deliver a large amount of sediment to the marsh surface in late winter or spring at break-up (Gordon and Desplanque, 1983; Wood et al., 1989; Dionne, 1988, 1989, 2000; Chmura et al., 1997; Ollerhead et al., 1999; Pejrup and Andersen, 2000; Chmura et al., 2001; Staats et al., 2001; Davidson-Arnott et al., 2002; van Proosdij et al., 2006). Ice-rafted sediment was found to significantly influence both the sediment budget and the morphology of intertidal and supratidal salt marshes in studies attempting to quantify this process (Dionne, 1989; Ollerhead et al., 1999; Pejrup and Andersen, 2000; Argow, 2006). Several of the mechanisms by which this sediment is incorporated into ice rafts in New England back-barriers differ from those described in the literature of open coasts. These processes may be specific

to these sub-environments of northern back-barriers: platform-type marshes dominated by high marsh, tidal flats in sheltered, enclosed embayments, tidal creek bottoms and creek banks, and tidal pools or pannes.

In intertidal environments, sediment may be frozen in a layer 10 to 15 cm thick onto the base of ice cover on mudflats or marshes, and later lifted and transported by ice (Gordon and Desplanque, 1983; Dionne, 1988, 1989, 1993; Chmura et al., 2001a). Blocks of ice may be stacked, partially melted, and re-frozen to create layered ice-rafts, observed on several marshes (Gordon and Desplanque, 1983, Dionne, 1988, 1989; Wood et al., 1989; Ollerhead et al., 1999; Pejrup and Anderson 2000; van Proosdij et al., 2006; Argow, 2006). At higher latitudes thick ice buildup on the surface of the marsh is capable of ripping up sections of marsh surface peat during break-up (Gordon and Desplanque, 1983; Dionne 1988; 1989), or planing off peat blocks from the leading edge of a fringing marsh (Pejrup and Anderson, 2000; vanProosdij et al, 2006), contributing to the erosion of the marsh and creating pannes on the marsh surface. In New England, the geomorphic effects of ice reported in the literature include ice-rafting as a mechanism of salt marsh colonization or expansion (Redfield. 1972; Richard, 1978). Ice-shearing of vegetation has also been observed (Redfield, 1972; Hardwick-Witman, 1985; Hardwick-Witman, 1986; Roberts and Robertson, 1986; Bertness, 1999; Ewanchuk and Bertness, 2003).

This paper presents observations of freezing and sediment entrainment processes on three New England marshes and provides conceptual models for ice raft formation and characterization. The thickness of ice deposits formed in situ on the surface of the marsh is discussed relative to elevation and geomorphic features. Data from surveys of representative ice-rafts stranded on three salt marshes in February, 2005 serve to characterize the nature of ice rafts and ice-rafted sediment in this region. The data and these models have implications for larger-scale processes on the marsh surface, such as the development of salt pannes, the evolution of tidal creeks, salt marsh expansion and colonization, and near-term coastal evolution in response to climate change.

Study Areas

Three representative back-barrier salt marshes were selected at different latitudes in New England to explore the variation in intensity of winter processes based on climatic differences. Webhannet River marsh (hereafter referred to as "Wells marsh"), located at 43°18'N in Wells, Maine, is a 7-km^2 back-barrier salt marsh formed behind a stabilized, highly-developed barrier island (Fig. 2). Essex River and Castle Neck River marsh ("Essex marsh") represents the southerly extent of the large barrier complex developed along the shore of the Merrimack River Embayment, and is located at 42°40'N on the north-facing coast of Massachusetts west of Cape Ann. The total area of the back-barrier is approximately 4645 acres (18.8 km^2). Nauset marsh, located between Eastham and Orleans, Massachusetts on the Atlantic shore of Cape Cod at 41°50'N, is a back-barrier marsh and lagoon system covering 2335 acres (9.45 km^2).

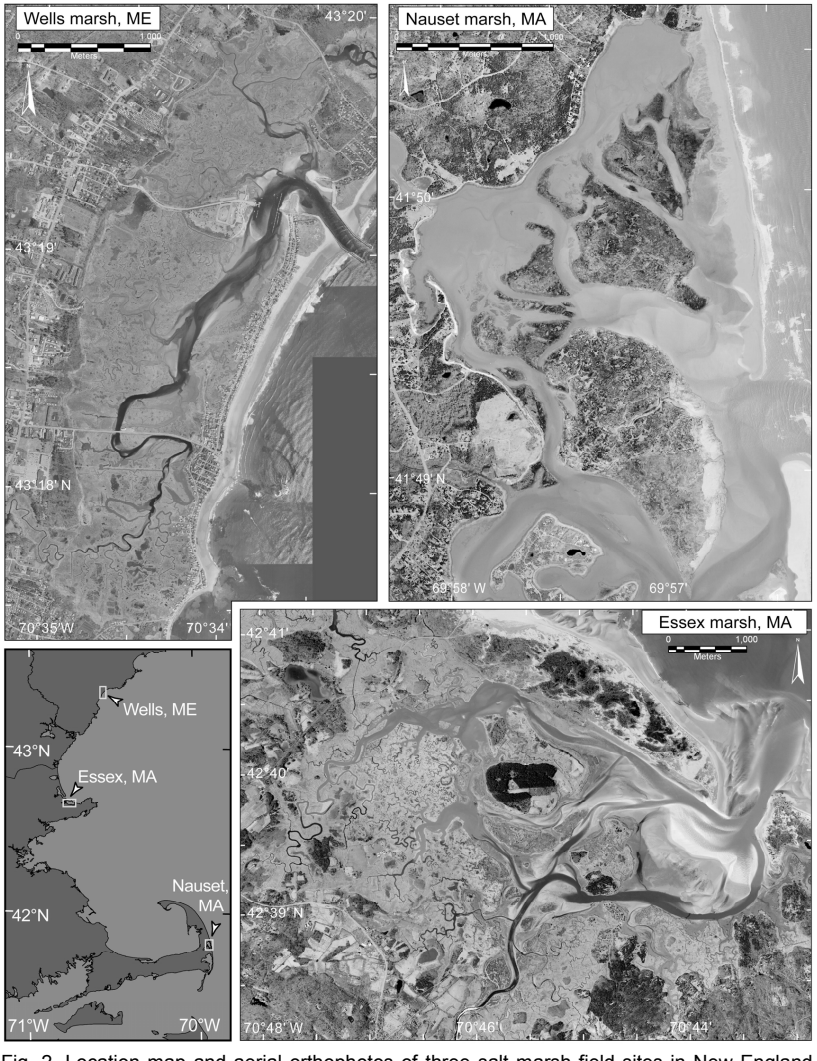

Fig. 2. Location map and aerial orthophotos of three salt marsh field sites in New England. Photo scales are per photo. (Apr 2001 photos from: Maine, Massachusetts State GIS).

All three marshes experience semi-diurnal tides and are lower mesotidal (Wells =2.7m, Essex =2.8m, Nauset =1.9m). The salt marshes are dominated by high marsh species (*Spartina patens, Distichlis spp, Juncus spp,* short form *S. alterniflora*)(Nixon and Oviatt, 1973; Nixon, 1982) and are deeply incised by tidal creeks. These supratidal expanses are completely flooded only ~3-6 days per tidal cycle (based on comparison of NOAA NOS data and modal surface elevation). Flood tidal waters

carry a modest suspended sediment load to the marsh surface in New England, generally an order of magnitude less than that reaching most southern wetlands (3.4—17.2 mg/L in the Webhannet River estuary, Wells, ME)(Ward, 2004). This mineral sediment influx, together with the accumulation of organic material due to the bioproductivity of *Spartina spp*., is an essential mechanism for vertical accretion of salt marshes, and helps to determine whether they will keep pace with rising sea level or be inundated (Reed, 1995; Callaway et al., 1996).

Climate variation between the sites is reflected in several quantifiable parameters. Over the last decade, the severity and duration of the winter season increases consistently to the north among the study locations (Fig. 1). During winter 2004-05 (Dec-Mar), Wells marsh experienced 53 days when the maximum air temperature did not exceed freezing, and 163 days when minimum temperatures were at or below 0º C. Mean air temperature was -4.1º C, comparable to the 20 year average (NCDC, NOAA; Wells NERR). In comparison, Essex marsh experienced 29 days when temperature maxima were ≤ 0º C, 138 days of minima ≤ 0º C. Mean winter temperatures = -1.38 ºC (2004-05, NCDC, NOAA). Near Nauset marsh, the southernmost site, records of minimum air temperatures indicate 87 days ≤ 0º C, maxima ≤ 0º C on 23 days. Nauset marsh experienced a mean temperature of 0.8º C over the winter of 2005-05 (data from NCDC, NOAA). Total snowfall received was 90.2cm at Wells marsh, 100.3cm at Essex marsh, and 14.5cm at Nauset marsh. These data give some indication of the different climate regimes of the three study sites and the expected magnitude of winter processes at each.

METHODS

Shore-fast ice (formed on and frozen to marsh surface) thickness was measured in early February, 2005, following a ten-day cold spell. A hand auger was used to take replicate (n=3x5) measurements at ~50 m intervals along upland-normal transects at each study site. Elevation was derived from LIDAR and TOTAL station data. 100 representative ice rafts were observed and sub-sampled along upland-normal transects at each study site after break-up in early March, 2005. Ice and incorporated sediment were weighed and sediment characterized by dominant sediment type based on grain size and composition. The average bulk density of aggregate samples was determined. Numerical relationships between physical and spatial parameters were determined using MSExcel and Matlab.

RESULTS

Ice thickness

Greatest thickness of shore-fast ice on the high marsh surface is observed at elevations closely corresponding to mean high water (MHW), and ice deposit elevations range from 1.25—1.46m above MSL (NAVD 88). Analysis of LIDAR elevation data for the Webhannet River estuary reveals that modal elevations for the back-barrier region as a whole are between 1.3—1.4 m above MSL, near the elevation of MHW (Fig. 3).

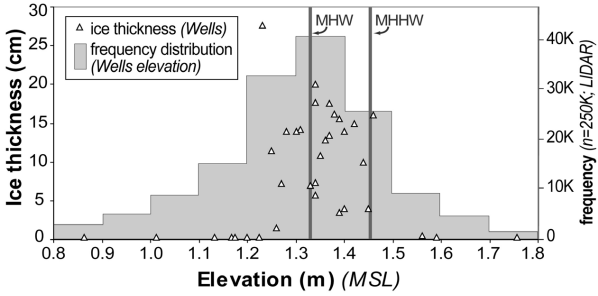

Fig. 3. Relationship between shore-fast ice thicknesses (Feb 2005) and marsh surface elevation at Wells marsh, ME. Histogram shows relative proportion of marsh surface area per elevation in the intertidal zone (LIDAR data, NOAA). All non-zero sample sites are located on high marsh (defined by plant species).

Ice-raft survey

Over 90% of the ice-rafts sampled on three New England marshes exhibited layering when the ice textures were closely examined. Most rafts showed regelation textures within layers. In this survey, relatively few (17%) had measurable sediment layers (>0.5 cm thick) frozen between ice layers, but nearly all (97%) had visible sediment adhered to the base. Mean thickness of ice rafts observed at the study sites varied; Wells and Essex were comparable, while Nauset ice rafts were thinner (22.5, 25.4, and 11.7 cm, respectively; Table 1). Similarly, mean thickness of the individual layers observed in ice rafts at Wells and Essex marshes was comparable (8.3 and 7.8 cm, respectively; mean 3 layers per raft), while Nauset rafts had fewer and thinner layers (4.7 cm, 2 layers per raft). The thickness of the ice rafts was positively correlated to the number of visible layers at all sites (r^2=0.72). At all sites, most rafts exhibit 2-3 layers (Table 1).

Sediment concentration in ice rafts varies within (0.1-190.1 g/L_{ice}) and between sites, generally increasing northward (10.4-26.2 g/L_{ice}; Table 1). The modal 50% of ice rafts had relatively low concentrations of sediment relative to the carrying capacity of

sea ice (Fig. 4a). The top 10% of ice rafts having the highest sediment concentration define a trend roughly equivalent to the wet bulk density of fine sand (1.35 g/cm^3), although the sediment incorporated into those rafts was not exclusively sand (Fig. 4b).

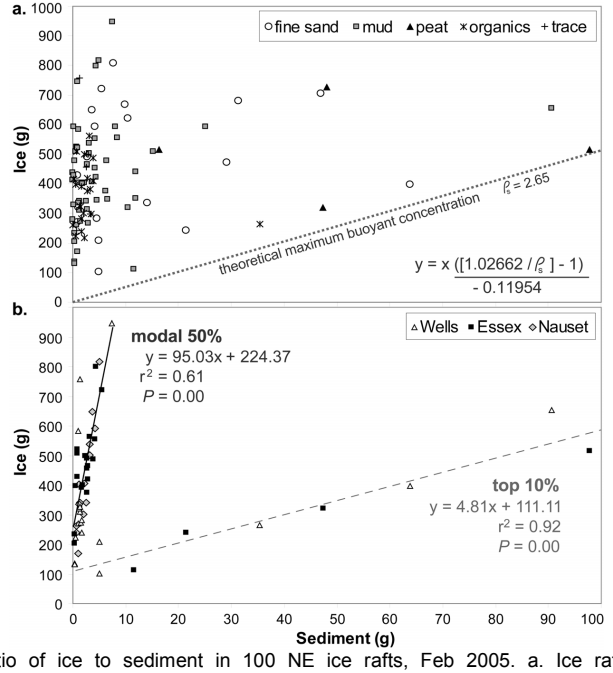

Fig. 4. Ratio of ice to sediment in 100 NE ice rafts, Feb 2005. a. Ice raft sediment concentration, classified by sediment type. Grey dotted line represents theoretical maximum sediment concentration in neutrally buoyant ice rafts, based on seawater at 3ºC and 33.5 ppt salinity (ρ_{sw}=1.03g/cm^3), density of sea ice (ρ_i=0.91 g/cm^3), and maximum density of incorporated sediment (quartz; ρ_s=2.65 g/cm^3). b. Solid line represents regression through points within the modal sediment/ice concentration (1-8 g/L; 50% of total points); dashed line represents regression through the top 10% of rafts based on sediment concentration.

Sediment incorporated into each ice raft was removed and characterized. Fifty-four percent of ice rafts sampled were silt-dominated (mud; Fig. 5a)(BD_{wet}=1.1 g/cm^3). Fine sand concentration decreased southwards (Fig. 5a,b)(BD_{wet}=1.35 g/cm^3). Peat, characterized by a cohesive, well-developed root mat and low wet bulk density (BD_{wet}=0.8-1.2 g/cm^3) was least commonly sampled in ice rafts at all sites (Fig. 5a), but made up the greatest total concentration of sediment at Essex marsh (Fig. 5b). No clear relationship between sediment type and concentration in ice rafts could be determined (Fig.4a,5b). However, patterns emerge when ice-rafted sediment concentration and type are compared to spatial parameters on the marsh surface. Sediment concentration decreases logarithmically with increasing distance from the nearest creek for all sites (y = -8.5 ln(x) + 41.6, r^2=0.68 (Nauset marsh); Fig. 6).

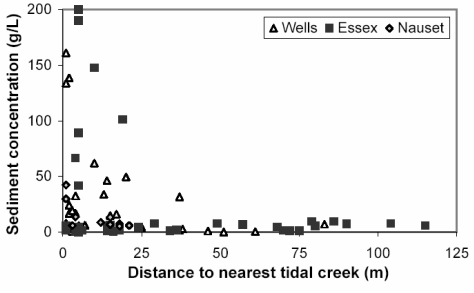

Fig. 6. Inverse relationship between distance to the nearest tidal creek on the marsh surface and the amount of sediment incorporated in surveyed ice rafts at three study sites.

DISCUSSION

Ice thickness measurements

Nauset marsh had the thinnest measurable ice deposits and the least total surface area covered by ice, as would be expected at the most southerly study site. Thicker shore-fast ice deposits were observed at Essex marsh and Wells marsh, correlating to the amount of snowfall at each site. Shore-fast ice deposits were thickest in the mid-to-fore marsh, near the leading edge of the geomorphically-defined high marsh platform, at elevations close to MHW (Fig. 3). This finding agrees with observations from northern climates (Nova Scotia; van Proosdij et al., 2006). At lower elevations, frequent tidal inundation prevents build-up and regelation of snow; at higher elevations, wind may remove drier snow.

During our on-going study of New England marshes, no fresh scars that seemed attributable to ice-plucking of peat from an unbroken marsh surface have been observed, as has been reported farther north (Dionne 1988, 1989; Gordon and Desplanque, 1983). Shore-fast ice on salt marshes in the Bay of Fundy (45 º49'N) has been reported at thicknesses up to 1.5 m (Ollerhead et al., 1999); resultant ice rafts are certainly capable of tearing up and transporting even large tufts of peat at break-up (Dionne, 1976, 1984, 1988). It may be that shore-fast ice on New England marshes rarely if ever reaches the thicknesses required to generate enough buoyancy to rupture an undisturbed, healthy *Spartina* root mat. However, numerous instances of ice-plucking from the edges of creeks and pannes and in otherwise disturbed areas have been observed at temperate latitudes; this process of peat incorporation into ice-rafts

is addressed in the conceptual models of ice raft formation and sediment incorporation which follow.

Ice raft survey

Ice raft thickness and layering is believed to be primarily a function of seasonal conditions, and varies from year to year. During the 2005 study, most ice rafts contained 2-3 layers (Table 1). The consistent pattern of layering of the ice rafts at all sites suggests a mechanism of formation governed by repetitive, cyclical processes, such as tidal processes, precipitation patterns, or daily temperature fluctuations. The number of layers may indicate the approximate duration of the ice-raft forming process relative to these cycles. The quantity of sediment incorporated into ice rafts is highly variable (Fig. 4); however, ice-raft sediment concentration increases as both the number of layers and total thickness of the raft increase (Table 1), suggesting that the incorporation of sediment into ice rafts also may be related to ice-raft layering, and be governed by the same cyclical processes, such as tidal fluctuations.

Most ice rafts surveyed were carrying relatively low concentrations of sediment (Fig. 4). Comparing the mass of sediment incorporated in ice rafts to the mass of the ice reveals that the majority of ice rafts contain more than 100 times the mass of ice relative to sediment (Fig. 4a). Therefore, the sediment concentrations of most sampled ice rafts fall well below the theoretical maximum concentration based on physical parameters, indicating that few rafts are at the carrying capacity for sediment. In fact, due to its low bulk density (as low as 0.80 g/cm^3 when saturated with seawater), peat can be ice-rafted even when dramatically out-weighing the ice component of the raft, a phenomenon often observed in the field (Fig. 7).

Fig. 7. Ice raft stranded on high marsh 1.5m from the creek bank in the mid-back marsh, Wells marsh, late Feb 2004. The ice raft contains a thick basal layer of low marsh peat, a layer of organics (ice-sheared *S. patens*), a thick, muddy fine sand layer (upper), and several trace layers (arrows). Lens cap for scale (circled).

Numerical Model of Ice Raft Sediment Concentration

Given the relative densities of ice, sediment, and cold seawater (3ºC, 33.5 ppt), surveyed ice rafts easily carry observed sediment loads (Fig. 4). Interestingly, the top 10% of ice rafts based on sediment concentration form a statistically significant trend ($r^2 = 0.92$, $P = 0.00$; Fig. 4b). These results may be taken to suggest the maximum amount of sediment that can realistically be incorporated into ice rafts transported

onto New England marshes. This "maximum carrying potential" is described by the relationship:

$$M_i = 4.8\ M_s + C, \quad (1)$$

where M_i is the mass of ice in the ice raft, M_s is the mass of frozen sediment, and C is a constant most likely dependent upon climate. This trend is quite similar to the limit of maximum theoretical sediment concentration described earlier (Fig. 4a).

If we consider the modal 50% of rafts based on sediment concentration (1-8 g/L), we derive a more conservative estimate for the quantity of sediment carried to the marsh surface by ice-rafting. A trend through this subset of the data yields a relationship wherein:

$$M_i = 95\ M_s + C \quad (2)$$

(r^2=0.61, C is a constant equal to 224 for New England)(Fig. 4b). This relationship may be useful in providing very rough estimates of the amount of sediment that is being transported to the marsh surface over a winter season by ice rafting, based on aerial and ground surveys of stranded ice rafts, which observe volume. Based on the volume of ice rafts deposited on a New England marsh:

$$M_s = 0.01\ V_i - C \quad (3)$$

where C = 2.36 for northern New England.

Classification and Origin of Ice-rafted Sediment

Despite the fact that the majority of all ice rafts sampled were carrying predominantly mud (Fig. 5a), nearly equal total masses of ice-rafted mud and fine sand were measured (Fig. 5b), due to the higher bulk density of sand and the observed tendency of sand layers in sampled ice rafts to be thicker, whereas mud laminations were often quite fine (Fig. 7). A sand-rich sediment layer implies that these ice rafts incorporated sediment in a sandy creek bottom or tidal flat (Fig. 8). Such sand-bottomed creeks and sheltered intertidal flats are present at all three study sites.

Fig. 8. A nearly-melted ice raft deposits a 5 cm thick layer of sandy sediment on the high marsh surface at Essex marsh, mid-Feb, 2004. The muddy fine grey sand texturally and compositionally matches sediment in the bed of a nearby tidal creek.

When peat was observed in ice rafts at all sites, the dense root mat tended to create an unusually thick sediment layer relative to the thickness of the ice raft (Fig. 7), accounting for the high mass of peat recovered from relatively few ice rafts. Peat can be frozen into ice rafts most readily at locations where the root mat has already been disturbed, such as slumping creek banks or the edges of salt pannes or pools. These environments are common in New England marshes.

Most ice rafts at all three sites carried sediment dominated by mud, suggesting that they formed in environments with muddy substrate. Two types of mud-dominated sediment were observed in ice rafts: a sandy mud with few organics and occasional

shells, and an organic-rich mud bearing rare *S. alterniflora* rhizomes and often characterized by a blackened anaerobic zone. The sandy mud is similar in grain size and composition to sediment found in the channels of the distal or upper reaches of tidal creeks at all sites. Organic-rich mud is characteristic of sediment found in low marsh ramps at the leading edge of the marsh and in slumped or gently sloping areas along major creek banks, both environments present at all sites.

Most ice rafts bearing "organics" (15% of total) included dense mats of sediment-laden algal matter, commonly found in pannes, ponds, and disturbed areas on the high marsh (Fig. 9). Rafts from frozen pannes are common; solid ice excavated from a panne on Essex marsh in January, 2005 revealed algal mats adfrozen to the ice layer. Sediment removed from pannes via ice-rafting is observed at all sites (Fig. 9). Some rafts contain sheared vegetation (5%) from stranding on the marsh surface (Fig. 7).

The four types of sediment incorporated in ice rafts suggest four potential sources from within the back-barrier environment: tidal flats, creek beds, creek banks, and salt pannes. Sediments from each of these sub-environments of the marsh are incorporated into ice rafts via different processes, described in conceptual diagrams of ice-raft formation.

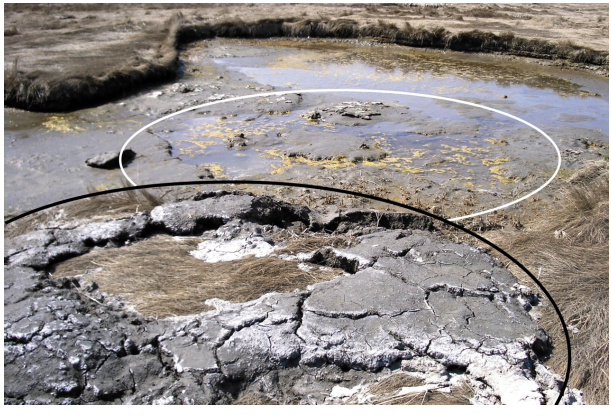

Fig. 9. Muddy algal-rich sediment lifted from the bottom of a nearby panne by ice rafting and deposited on the high marsh on Essex marsh, Apr 2005 (black circle). The upper surface of the muddy deposit is covered by algal mat and gastropods. Visible in the panne in the background is a scar closely matching the contours of the ice-rafted sediment deposit (white circle).

Ice Raft Dispersion

The concentration of sediment in surveyed ice rafts decreases sharply with increasing distance from the nearest creek (Fig. 6), suggesting that ice rafts laden with greater volumes of sediment may not travel as far from their probable source as may clean drift ice. Sandy ice rafts stranded closest to tidal creeks. Muddy ice rafts, formed primarily in mid-to-back marsh creeks and drained pannes, stranded at elevations of 1.2-1.4m above MSL (NAVD'88). This is a narrow range compared to sandy rafts, which were stranded at elevations between 0.9-2.0m, and rafts carrying dominantly organics, which stranded at 0.7-1.6m. Peat and algal rafts were found closer to salt pannes and ponds, as were many rafts bearing mud containing sparse S. *alterniflora* rhizomes.

Conceptual models

Conceptual models are based on data and observations over the period 2002-06 and describe processes of ice raft formation in distinct environments on the marsh surface: shallow tidal flat, creek bottom, creek bank and salt panne.

Tidal Flat Model: In northern marshes, the leading edge of the high marsh is often cliffed, abutting tidal flats. In winter, surface seawater freezes in sheltered embayments with limited wave activity, forming a layer of drift ice. As tide ebbs, sea ice strands on the tidal flat. A layer of sediment freezes to the bottom of the ice blocks. Ice is re-floated on next flood tide, and then strands and fractures repeatedly during successive tides until spring flood occurs. Note that peat calving at the leading edge of the marsh may also become frozen to ice rafts. During a spring tide event, the ice will raft onto the marsh surface. With the ebb tide, many ice rafts are stranded on the surface of the marsh, where in spring they melt and deposit characteristic sediment (Fig. 8). Ice rafts originally formed from drift ice may also become trapped in creeks, repeating the cycle of sediment adfreezing and layering until finally being rafted onto the marsh surface, into the embayment, or melting. Rafts may float out the inlet to open water.

Creek Bed and Bank Models: In summer, sub-surface flow drains peat to creeks (Fig.10a; arrows). In winter, sub-surface seepage builds up a layer of ice on creek banks and beds (Fig.10b,c) in a period of ~two weeks of freezing temperatures (drift ice requires shorter periods but colder temperatures to form). Limited daily melting contributes to thicker ice deposits on banks by increasing sub-surface flow (Fig.10c). Ice fractures due to micro-slumping or creep of the underlying peat and hydraulic pressure of tidal waters. Water continuously seeps from the peat, freezes onto the banks and bed, and, during flood tide, may break free as a sediment-laden ice raft (Fig.10b,d). During neap tides, ice may strand on the channel bottom and freeze to an additional layer of ice and sediment (Fig. 7). During spring tides, ice may raft onto the surface of the marsh with flood tides (Fig.10d), sometimes traveling great distances from the nearest creek (up to 500 m observed) before stranding. Ice in these rafts does not exhibit regelation textures, and sediment may range from mud to gravel, depending on the location and configuration of the creek channel.

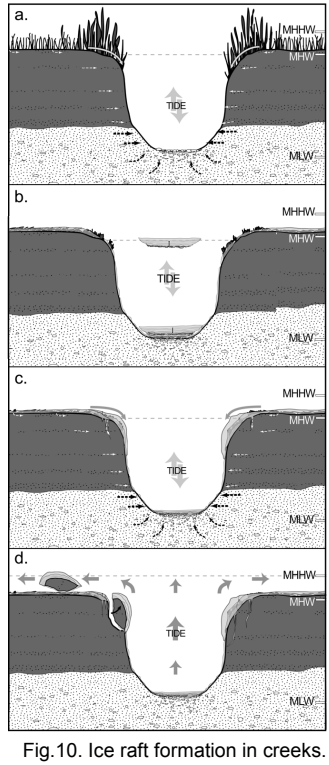

Fig.10. Ice raft formation in creeks.

Ice raft formation is an effective, possibly dominant, mechanism of tidal creek enlargement on northern New England salt marshes. This

process transfers sediment from creek banks and beds to the marsh surface, expanding tidal creeks and increasing vertical relief. Due to flood dominance of tidal creek channels (Leonard et al., 1995; Blanton et al., 2002; Davidson-Arnott et al., 2002), tidal sediment moves headward and replaces ice-removed sediment. Peat lost from creek banks, however, is not replaced in the same fashion; creek widening results. If sea level remains constant or rises very gradually, channel infilling may lead to shallowing as tidal currents slow, allowing colonization of intertidal creek-edge ramps by *S. alterniflora*, eventually narrowing the creek. In a time of rapidly rising sea level, however, enlarged channels will facilitate conduction of increased tidal flow through the marsh, and creek widening will continue.

Panne Model: The high marsh surface of New England marshes is marked by the presence of numerous small ponds and shallow, waterlogged depressions, herein collectively referred to as salt pannes (Erwin et al. 2004)(Fig.11a). During cold winters, these pannes freeze over; shallow pannes may freeze to depth (Fig.11b,c). This process forms ice rafts when ice and incorporated sediments are fractured and buoyed from the panne by flood tides (Fig.11d). Rafts may be identified by the particular sediment carried: a basal layer of sediment-laden algal mat and smaller clumps or ribbons of high-marsh peat torn from the edge of the panne. The formation of ice rafts effectively deepens and widens existing pannes on the marsh surface (Fig.11e). In disturbed areas, this mechanism of ice raft formation may also be responsible for panne initiation.

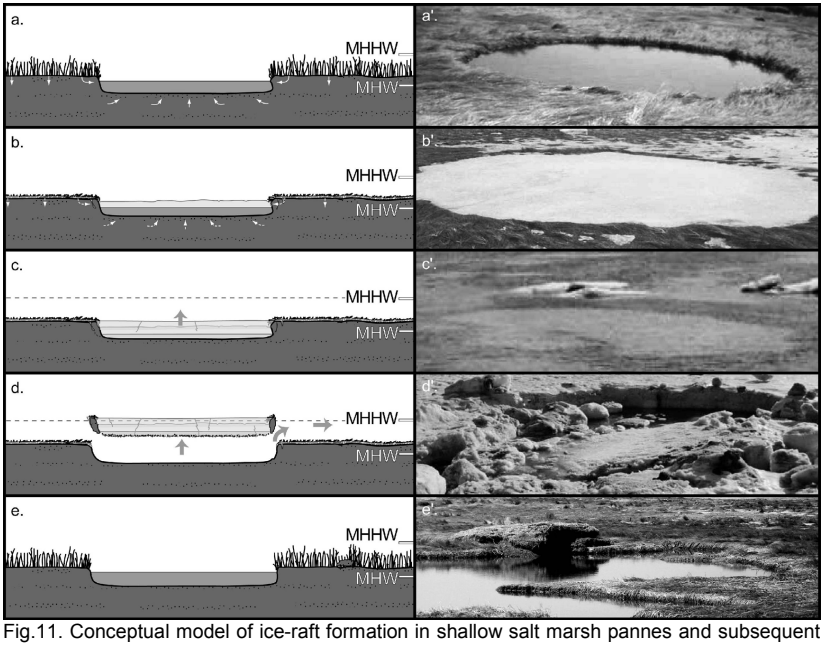

Fig.11. Conceptual model of ice-raft formation in shallow salt marsh pannes and subsequent panne enlargement. Letter primes are representative photos (2003-2005).

Relative magnitude of the four processes of intra-marsh ice-raft formation

Each of these mechanisms of ice raft formation is active in New England marshes, but their relative importance in the sediment budget varies. By considering the percentage of diagnostic sediment types contained in surveyed ice rafts (Fig. 5a,b), a rough measure of the magnitude of these processes at each study site can be obtained.

At Wells marsh, ~50% of ice-rafted sediment was fine sand, suggesting ice raft formation in large creek bottoms and tidal sand flats. Rare peat rafts suggest that ice was not as effective at removing peat from channel sides over the 2005 winter season, relative to previous observations. Sixteen percent of rafts bore organics, and most likely formed on the marsh surface and in pannes. Nearly 30% of the sediment carried in ice rafts was dominated by mud, most likely adhered to ice rafts in the upper reaches of tidal creeks, farther from the main source of sand (Wells inlet).

Essex marsh, where 30% of ice-rafted sediment was peat, has man-made ditches in the study area wherein peat from the sides is actively slumping and available to ice rafts. Over half of ice-rafted sediment appears to come from tidal channels or tidal flats, and little evidence of algal mats from salt pannes was observed in this study; however, due to ditching, relatively few pannes mark this section of the marsh.

Nauset marsh ice rafts bore little sediment, and were dominantly silty or muddy. Nauset tidal channels are generally sand-bottomed, suggesting that most ice-rafts formed in the muddier shallow reaches of the marsh distal to the inlet. Panne ice raft formation was represented. Few sandy rafts were sampled, due to the short ice season and relatively open hydraulics of the system, inhibiting channel ice-raft development.

CONCLUSIONS

Ice rafting of sediment is a secondary process of sedimentation in the back-barrier; rafts move sediment from tidal flats, creeks and pannes to the surface of the marsh, aiding vertical accretion. The volume of ice rafted onto the high marsh surface can be used to estimate the total quantity of ice-rafted sediment deposited on the marsh. Despite global warming, ice processes remain relevant as winters become shorter but more severe.

While research worldwide has led to significant advances in our understanding of salt marsh processes and our ability to numerically model these complex systems, there remains some disconnect between our general understanding of marsh processes and their application to coastal systems in northern latitudes. Differences in morphology and climate are responsible for variations in the physical, chemical and biological processes of the salt marsh at a variety of time scales, from a single tidal cycle to historical or Holocene records (e.g. physical processes: Davidson-Arnott et al., 2002; Argow and Fitzgerald, 2006; van Proosdij et al., 2006; biological processes: Bertness and Ewanchuk, 2002; Morris et al., 2002; Chmura and Hung, 2004). These differences can result in significant deviation from what is considered the “norm” in wetlands processes, and should be accounted for in models seeking to predict coastal response to sea-level rise in northern temperate latitudes, including New England.

Abstract: The Nauset barrier spit breached during a strong Northeast storm in January 1987, creating a new tidal inlet. Nauset Beach has historically undergone an approximate 135 year cycle of spit elongation followed by breaching and new inlet formation. The creation of the tidal inlet resulted in dramatic changes to the hydrodynamic processes within the Pleasant Bay estuarine system including an increase in tidal range, tidal currents, formation of ebb and flood tidal deltas, and an increase in wave energy transmitted into the previously quiescent back-bay region. A notable change was a loss of fringing salt marsh within the estuary. In the 10 year period after the breach there was a 14% decrease in fringe marsh followed by a 5% and 12% increase during the next 11 years. Since 1998, the Town has removed approximately 482,000 yd^3 of dredged material that has been used to maintain unarmored important Town beaches along the interior shoreline.

INTRODUCTION

Tidal inlets play an important role in the dynamics of the coastal ecosystems because they provide conduits for nutrients and fauna both into and out of the lagoon or estuary they serve. The efficiency of the conduit often dictates the relative health of the estuarine ecosystem. If the tidal inlet efficiently flushes the estuary there most likely is an adequate flow of oxygen and nutrients into the estuary resulting in healthy populations of Submerged Aquatic Vegetation, fish, shellfish, and other wetland resources that are important to the socio-economic viability and health of the estuarine ecosystem.

Additionally, the tidal inlet often provides an important navigation access to ports and harbors for commercial and recreational vessels. Historically, many of the inlets within the United States provided vital links for commerce carriers and fisherman to access trade routes and fishing grounds that lay off the nearshore areas of the coast.

Tidal inlets are often unstable if the longshore littoral transport exceeds that natural flushing capability of the tidal inlet. If this condition occurs and the tidal inlet is commercially important it is often artificially maintained by structures, by dredging, or a combination of both. Many estuaries within the United States are served by a single tidal inlet. However, when a second inlet forms in a single inlet system, the system normally becomes unstable and one of the inlets will close because the dominant inlet successfully captures tidal flows and reduces the tidal volume and velocities within the tidal channel served by the secondary inlet. This instability may go on for years however, eventually, one of the inlets gains dominance and the secondary inlet closes. When a new inlet opens or an old inlet closes there may be significant changes within the back-bay system. These changes may include impacts to navigation, shoreline orientation (both within the back-bay area and on the open coast), and expose previously sheltered areas of the back-bay shoreline to significant amounts of wave energy. These changes can have significant social, environmental, and economic impacts to the back-bay estuarine region.

This was the case when a new tidal inlet formed during a northeaster in Chatham, MA on January 2, 1987 (Figure 1). This storm was not a storm of record nor was it particularly damaging along much of the coast of New England. However, the storm breached the Nauset Barrier Beach forming a new tidal inlet. The formation of this inlet had been predicted by scientists however, the breach caught most people and state agencies by surprise and therefore, they were unprepared for the changes that occurred after the inlet formed. While the consequences of New Inlet have been far ranging and profound, this paper will concentrate on the effect of New Inlet on the fringe marsh resources within the back-bay area and the problems associated with maintaining navigation channels within this dynamic and ever changing system.

SETTING

The study area for this project is within the Pleasant Bay Estuary in Chatham, Massachusetts, located on Cape Cod (Figure 2). Nauset barrier beach forms a continuous strip of barrier beach free of any coastal engineering structures or other impediments to sediment transport. This uninterrupted section of beach extends approximately 17 km from Nauset Inlet to New Inlet. Prior to the formation of New Inlet the barrier beach extended an additional 8 km to the south (Figure 1). This southern 8 km of the barrier beach was cut off after the formation of New Inlet and transformed that section of the barrier beach into a barrier island. Nauset barrier beach provides protection to Chatham Harbor, Bassing Harbor, Crows Pond, Ryder's Cove, Pleasant and Little Pleasant Bays. Additionally, within the estuary there are many rivers, creeks and islands that provide a wide diversity of habitats. The entire estuary comprises approximately 2,833 ha of open water habitat (Pleasant Bay Management Alliance, 1998).

Fig. 1. Chatham Harbor showing the pre- and post breach conditions and New Inlet

Fig. 2. Study location, Chatham, Massachusetts on Cape Cod

There are an additional 467 ha of salt marsh within the estuary. However, approximately 142 ha of 467 ha of salt marsh is composed of fringing salt marsh while the rest resides in larger tracts and is not characterized as fringing salt marsh. Nauset Barrier Beach

protects the estuary from the waves and storm surge associated with the Atlantic Storms that frequent Cape Cod during the fall, winter, and spring seasons. During the January 2, 1987 northeast storm the Nauset Barrier Beach was initially breached by an overwash that flowed water only at high tide. The overwash area was approximately 1 meter wide and could be stepped across however; the overwash rapidly grew in size over the next several months until today it now measures approximately 1.3 km in width. The geologic history of the Nauset Barrier beach was studied by Giese (1988). He predicted that the barrier beach would be breached and would break-up and reform a number of times prior to migrating to the south. Weishar *et al*. (1989) and Weishar and Fields (1993 and 1994) used Giese's model to make predictions on how the back-bay shoreline would respond to the rapidly changing inlet morphology.

The formation of New Inlet and subsequent morphological changes associated with the inlet resulted in many changes within the back-bay system. The tide range increased approximately 0.5 m within the first year after the inlet formed (Wilhelm 1989). The tide range within the estuary increased because after New Inlet formed, approximately 8 km of narrow sinuous tidal channel that connected the estuary to the Atlantic Ocean was eliminated thus; reducing tidal friction and the length the tide had to travel to reach Pleasant Bay. However, the formation of New Inlet also allowed more wave energy to travel directly into the estuary from the Atlantic Ocean. Previously these areas had been sheltered by the barrier beach and as a result, large lengths of the shoreline previously protected were now subject to direct wave attack during severe storms. As New Inlet grew in size and dominance, it eventually captured all of the tidal flow from the old Chatham tidal inlet. As New Inlet increased in size, new tidal channels formed along with large flood- and ebb-tidal shoals (Stauble 2001). The change in wave energy and increase in tide range created many changes within the estuary however, this paper is going to address only the changes induced by New Inlet on the loss of fringing salt marsh, navigation, and shoreline erosion mitigation. The fringe marsh and dredge management areas are shown in Figure 3.

CHANGES IN SALT MARSH RESOURCE

Prior to the formation of New Inlet, much of the Pleasant Bay Estuary had a fringing marsh that varied in width from a ½ m to 10 to 12 m. The fringing marsh is primarily composed of *Spartina alterniflora* that grows in the region between the Mean- and High-Tide lines and is positioned between the open water of the estuary and the glacial bluffs and coastal banks that frequent the shoreline within the estuary. The fringing marsh is an important resource within the estuary because it provides habitat diversity, sequesters nutrients, provides refugia for small fish and crustaceans, and provides food in the form of detritus for primary producers.

Prior to the formation of New Inlet the coastal bluffs and banks that are composed of glacial till and outwash were largely unarmored, well vegetated and stable. A typical transect would begin at the top of the coastal bank and progress seaward and cross a well vegetated stable bank slope to the toe of the bank.

Fig. 3. Location diagram showing the Pleasant Bay estuary, the fringe marsh study area, and the dredge management area including New Inlet

The transect would continue seaward from the toe of the bank across a narrow sand beach and then across a narrow strip of fringe marsh into the intertidal region.

The formation of New Inlet along with the increase in tidal range had a profound effect on the stability of the coastal banks and the viability of the fringing marsh. In some areas, the fringing salt marsh was eroded directly by the increase wave energy that traveled through the New Inlet however; these areas were confined to the region near the opening of New Inlet.

In most of the estuary, the increase in tidal range allowed locally wind generated waves to reach further landward. The combined action of increased tide range and storm surge allowed the locally generated wind waves to reach higher on the beach and in most cases reach the toe of the coastal bank. As a result, many of the fringing salt marshes were subjected to more frequent wave attack from larger waves and were inundated for longer periods of time. While increasing the tide range and inundation time will not kill the salt marsh, it will weaken the *Spartina* species until it can readjust to the new dynamic

regime. The increased tidal range permitted waves to reach the base of the previously stable coastal banks and bluffs during even moderate storms. As a result, the previously stable coastal banks began to erode which inundated the fringing marsh with sediment. The combination of the weakened plants, longer tidal inundation, and covering with relatively large amounts of sediment resulted in a loss of fringing salt marsh within the estuary. The change in the salt marsh resource associated with the formation of New Inlet had been observed but not previously been quantified. In order to quantify the observed change in the fringing salt marsh resource a sub-section of the Pleasant Bay estuary was chosen for study. The study area was located within the lower portion of the estuary and was composed of Bassing Harbor, Ryder's Cove, and Crows Pond (Figure 4). The study area has an open water area of approximately 146 ha and approximately 9 ha of fringing salt marsh. This area was chosen because it is a confined series of embayments that offered a well delineated study area, the wetland resources are dominated by fringe marsh, and it is characteristic of the rest of the Pleasant Bay estuary. A series of vertical aerial photographs were obtained that included coverage beginning before the formation of New Inlet and spanning the 21 year period between the 1984 and 2005 vertical aerial photographs (Table 1).

Fig. 4. Fringe marsh study area and location of sub-embayments

Table 1. Date and scale of vertical aerial photographs used in this study

Date	Data Source	Scale	Comments
1984	Col-East	1:6,000	
1994	MAGIS web site	1:48,000	
2000	Town of Chatham (East Coast Mapping)	1:6,000	
2003	MAGIS web site	1:2,500	Not used; photos acquired at or near high tide
2005	Town of Chatham (James W. Sewall Co.)	1:12,000	

The 2005 and 1994 aerial photographs were obtained from MAGIS and were georectified. The 1984 and the 2000 aerial photographs were scanned, imported into ArcMap, and georectified. We researched other sources of aerial photography to obtain additional coverage however, these were the only time series available. Once all photographs were georectified, Arc Map was used to create polygons of fringe marsh. The results of the analysis are shown in Figure 5. There was a relatively extensive fringing marsh within the study area prior to the formation of New Inlet. After New Inlet formed, the dynamics within the estuary changed and as a result the fringe marsh area declined from 90,207 m^2 to 77,435 m^2.

While the decline in fringe marsh between 1984 and 1994 is dramatic it may have been more extensive because the only set of vertical aerial photographs for the Pleasant Bay estuary available after the formation of New Inlet were acquired in 1994, 10 years after the formation of New Inlet. The decline may have been more extensive immediately after the hydrodynamics changed within the estuary and the fringe marsh may have already been recovering by 1994. Even taking this short-coming into account the trend in the data is clear. After the breach there was a decline in the aerial coverage of fringe marsh. We hypothesize that the fringe marsh decline stopped and began recovering because the eroding coastal banks had either been armored or had reached a new dynamic stability by 1994 thus, eliminating the episodic covering of the fringing salt marsh with sediments eroded from the banks. Additionally, the increase in tidal range provided additional area for the fringing salt marsh to expand into because the tide range between Mean- and High-Tide lines increased vertically by approximately 0.75 ft. This increase in vertical range provided additional area for the *Spartina alterniflora* to expand into where there was either beach or other relatively flat areas to colonize.

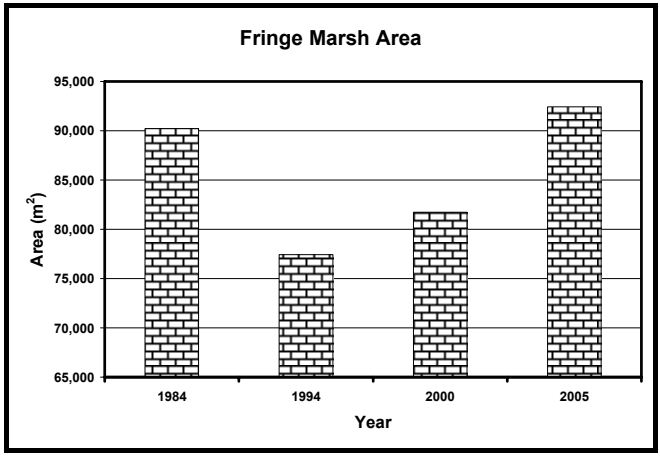

Fig. 5. Results of the fringe marsh analysis showing the decrease in fringe marsh area after the formation of New Inlet and subsequent growth of fringe marsh within the study area

NAVIGATION

The formation of New Inlet relocated the primary opening through Nauset Barrier beach approximately 8 km to the north. The opening of New Inlet also created a new shorter navigation channel and new ebb- and flood-shoals. As the system adjusted to the new hydrodymics, the flood shoal grew rapidly, rapidly changed position, and increased in volume (Stauble 2001). This situation presented challenges for the Town to manage dredging for navigation, mooring, and constructive use of dredged material.

Navigation within Chatham Harbor is critical because Chatham has one of the largest commercial fishing industries in New England and Chatham's municipal Fish Pier, which is its primary fish offloading facility, is located just over a mile north of New Inlet. Chatham's close proximity to some of the prime northeast fishing grounds provides the opportunity to travel to and from the fishing areas in a single day. Chatham's fishing fleet is comprised of about 60 to 70 smaller "day-boats" typically in the 9 to 15 m class with drafts between 1 and 2.4 meters. Additionally, the US Coast Guard, Station Chatham, also maintains vessels at the Fish Pier because it provides the most direct route to the Atlantic Ocean for search and rescue operations. The ability for fishing boats to make single day fishing trips results in higher prices for their fishing catch. Therefore, maintaining the navigation channel to Aunt Lydia's Cove is of vital importance for the commercial fishing fleet and the US Coast Guard utilizing the Fish Pier.

Soon after the break in Nauset Beach, the traditional navigation channels were overwhelmed with sediment from two sources. Sand already within the harbor system was now becoming more mobile due to the increase in tidal velocities and wave energy. In addition, significant volumes of new sand were being swept into the harbor from the outer littoral system creating new shoals which migrated as a unit into the harbor (Fitzgerald and Montello 1993, Liu *et al*. 1993, Stauble 2001). This resulted in drastic changes in the form and location of the traditional channels and limited the ability of the fishing vessels to traverse the shoals to enter and exit the harbor.

In the late 1980's, US Army Corps of Engineers (USACE) initiated studies to investigate the impacts of the break on the surrounding shorelines and navigation channels, and examined the potential for federal interest for corrective strategies. Ultimately, the USACE developed a small draft (-2.5m MLW by 30.5m) federal navigation project (Section 107) for Aunt Lydia's Cove to maintain fishing fleet access to the Fish Pier. The object of the dredging project was to provide navigation access into Chatham Harbor and to the Fish Pier through the rapidly changing flood shoal morphology (Figures 1 and 6; Stauble 2001, Fitzgerald and Montello, 1993). Access over the outer bar (ebb-tidal) delta, while still difficult at certain tidal conditions, was not included in the authorized project.

The location of the 1995 initial federal dredging maintained the channel entrance at its historic position. The initial dredging of the federal project was completed in 1995 with approximately 120,000 cubic yards (yd^3) of material removed by a hydraulic cutterhead

dredge from the old entrance channel as well as the more sheltered mooring basin located to the west of Tern Island (Figure 6).

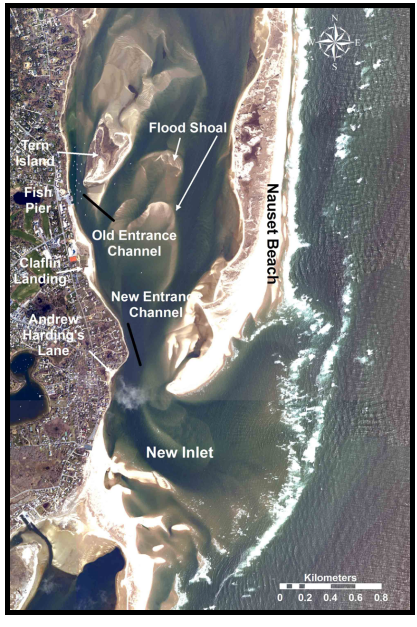

Fig. 6. Location of dredged channels, Fish Pier and beach nourishment areas

The dredged material was clean fine sand and disposal was upland on the adjacent Tern Island which had been historically used as a disposal site for smaller dredging projects. Dredging of the channel was difficult because the channel was infilling with freshly supplied sand even while the dredging was underway. Ultimately this channel completely shoaled and was closed to navigation within approximately 6 months. The USACE did not return for maintenance dredging until June of 2000 when the special purpose hopper dredge "Currituck" instead of a hydraulic dredge was used to dredge the navigation channel through the flood shoal. The Currituck has subsequently been providing annual spring maintenance since 2000 removing from 30,000 yd^3 to over 95,000 yd^3 of sand from the navigation channel on a typical annual cycle.

Prior to the return of the USACE dredge Currituck in the Spring of 2000, the morphology and history of the flood shoal was re-evaluated to develop dredging strategies to improve the longevity of the navigation channel. In addition, given the ongoing erosion of many of the vulnerable surrounding shorelines, a dedicated effort was made to re-utilize the dredged sand for beneficial re-nourishment. The goal was to develop a comprehensive Channel/Sand Management Plan that enabled flexible dredging and disposal strategies that would be more responsive to highly dynamic shoal

morphology and changing hydrodynamic conditions. The Channel/Sand Management Plan acknowledged the highly mobile nature of the flood shoal, and identified a "zone of potential dredging" in lieu of a fixed channel footprint. This approach did not restrict the dredging to set channel coordinates and instead allowed the dredging to be more mobile and follow actual or potential natural channel positions. This plan proved to be a more effective strategy from the perspective of both channel longevity and cost effectiveness.

The first significant dredging following the USACE initial project completion in 1995 was conducted in March 1998 utilizing the Barnstable County 14-inch hydraulic cutterhead pipeline dredge "Codfish". This was the first time that the navigation channel was substantially relocated to take advantage of the change in flood shoal morphology (Figure 6). Specifically, the channel was relocated to take advantage of developing marginal ebb dominated channels along the western edge of the flood shoal adjacent to the mainland shoreline. These ebb dominated channels were dredged to enhance flow through the dredged cut to encourage natural tidal action to assist in reducing sand from depositing into the channel. This strategy has been successfully implemented for the past several years for both the local and federal dredging efforts.

As the flood shoal complex continued to evolve, increasing quantities of sand were transported northward into the Fish Pier access channel and the mooring basin. This condition threatened to deny commercial and private fishing boats access to both the Fish Pier and the mooring basin. Twice yearly dredging was often required to keep the channels open sufficiently for the fishing fleet due to the rapid infilling of the channel and mooring basin (Table 2).

Table 2. History of dredged material quantities and location of disposal by year

AUNT LYDIA'S COVE DREDGING SUMMARY					
Date		Dredge Type	Dredge Location	Total QTY	Disposal Location
1995		ACE: Cutterhead	Mooring Basin	120,000	Tern Island
1998	Mar	Mechanical	Entrance	1,000	Tern Island
	May	County-Cod Fish	Entrance	9,300	Direct Pumpout to Claflin (5K); truck haul to asst'd Landings (4K)
	May	County-Cod Fish	Mooring Basin	1,500	Town Landing
	Oct	County-Cod Fish	Entrance	9,000	Direct Pumpout to Andrew Hardings
1999	May	County-Cod Fish	Entrance	9,800	Direct Pumpout to Andrew Hardings
	Oct	County-Cod Fish	Entrance	6,000	Direct Pumpout to Andrew Hardings
2000	May	County-Cod Fish	Mooring Basin	9,800	Direct Pumpout to Claflin (1.8K) ; truck haul to asst'd landings (8K)
	May	ACE-Currituck	Entrance	30,000	Sub-acqueous: Outside bar
	Oct	County-Cod Fish	Mooring Basin	8,400	Direct Pumpout to Claflin
2001	June	ACE-Currituck	Entrance	60,000	Sub-aqueous: Outside bar & Inside bar near shore
2002	Mar	County-Cod Fish	Mooring Basin	8,300	Direct Pumpout to Claflin (2K); truck haul to asst'd landings (6.3K)
	June	ACE-Currituck	Entrance	60,000	Sub-aqueous: Outside bar & Inside bar nearshore
2003	June	ACE-Currituck	Entrance	60,000	Sub-aqueous: Inside bar near shore
2004	June	ACE-Currituck	Entrance	50,000	Sub-aqueous: Inside bar nearshore
	Oct.	County-Cod Fish	Entrance	10,200	Direct Pumpout to Andrew Hardings
2005	June	ACE-Currituck	Entrance	97,000	Sub-aqueous: Inside bar nearshore
	Oct.	County-Cod Fish	Entrance	2,100	Direct Pumpout to Claflin
			Mooring Basin	8,000	Direct Pumpout to Andrew Hardings
2006	May	ACE-Currituck	Entrance	42,400	Sub-aqueous: Inside bar nearshore
			TOTAL QTY	**602,800**	**cubic yards**

Total to Tern Island: 121,000 cys
Total to Andrew Hardings: 43,000 cys
Total to Claflin: 19,300 cys
Total to Town Landings: 19,800 cys
Total to Sub-aqueous: 369,400 cys

Notes: ACE - Army Corps of Engineers

The Town quickly realized that the appropriate dredging strategy would be to use the Currituck for removal of larger volumes of sand from the primary entrance channel while utilizing the Cod Fish for supplemental dredging in the entrance channel when necessary and to maintain the relatively small mooring basin where the larger Currituck was unable to maneuver. It should be stressed that the volume of material that was removed by either the Currituck or the Cod Fish was more often a reflection of the funding available at the time of each project than the true need or actual volume that should have been removed. The Town had limited funds to apply to these projects and significant efforts were devoted to maximize the effectiveness of the dredging to conserve these resources. In addition, the USACE, Currituck had a limited window of time to work on-site, and their goal was to remove the maximum amount of sand from the most severely shoaled channel sections in the allotted time period rather than maintaining the overall project dimensions.

Given the highly dynamic nature of the flood shoal and sediment movement, the Town's dredging strategy has been to identify the most critical areas for dredging to provide for the greatest navigation channel longevity. As the flood tidal shoal continued to evolve, the shoal and channel morphology was frequently reviewed to incorporate a more creative approach that included a form of advanced maintenance dredging that incorporated the following:

- Shifting the orientation of the channel and dredged cut to facilitate natural tidal flushing.
- Dredging of deposition basins adjacent to the channel to trap sand prior to entering the channel.
- Over-depth dredging to provide greater capacity of the channel for shoaling.
- Over-dredging along the leading edge of the flood shoal adjacent to channel in anticipation of rapid infilling.

While these strategies have proven reasonably effective at maintaining navigation access to the Fish Pier, the highly dynamic nature of the flood shoal and the entire inlet and flood/ebb shoal complexes have created a littoral environment which continues to pose considerable challenges for maintaining navigation through the inlet into the Fish Pier and mooring basin.

DISPOSAL/NOURISHMENT STRATEGIES

The Town's dredging requirements provided the opportunity to constructively use the dredged sand from the navigation projects to mitigate shoreline erosion associated with New Inlet. The Town established an internal policy to re-utilize the dredged sand as beach and shoreline nourishment whenever possible. Chatham is fortunate that the dredged material from Chatham Harbor is very clean medium to fine grained beach quality sand and therefore, can easily be reused for beneficial purposes. The Town has actively renourished shorelines eroded after New Inlet formed through a variety of means including the direct pumpout of material via the pipeline dredge, truck-hauled placement of both dewatered dredged material and mined upland sand, as well as by sub-aqueous

placement of material in the nearshore (approximately -1.8 to -6.1m MLW) by the USACE split-hulled hopper dredge, the Currituck.

Dredging with the hydraulic cutterhead Codfish, has provided the opportunity to directly pump-out the dredged sand onto beaches for beneficial nourishment. There are two Town-owned beaches and/or landings within the effective direct pumpout range (approximately 1.6 or less 5 km with a booster pump) of the Codfish. These beaches Andrew Harding's Lane and Claflin Landing are Town owned landings and have not been armored. Both of these sites have undergone considerable erosion, recession and loss of public access due to the proximity to New Inlet. Therefore, both Andrews Harding and Claflin Landings were designated as priority locations for beneficial beach nourishment and dune building projects. Utilizing these two public landings provided cost effective dredge material disposal sites and helped mitigate the on-going shoreline erosion.

Since 1998 over 19,000 yd^3 of sand has been placed at Claflin Landing while Andrew Harding's Lane has received approximately 43,000 yd^3. Almost 20,000 yd^3 of additional sand was pumped to Claflin Landing but this excess material was dewatered on-site in diked containment areas and hauled by dump trucks to several other Town owned beaches and landings. Erosion at Claflin Landing has begun to stabilize over the past few years partly as a result of the continued southerly migration of the southern tip of Nauset Beach. The migration of the barrier beach has reduced the exposure of this shoreline to wave energy, thereby reducing the loss of material from the shorefront.

Andrew Harding's Lane is located closer to the inlet and it is a small "pocket beach" located between two substantial sections of stone revetments built post-inlet formation. Andrew Harding's Lane, however, continues to undergo considerable erosive losses because it is located closer to New Inlet and is directly exposed to waves traveling through the inlet from the Atlantic Ocean. The initial beach and dune nourishment projects (1999 & 2000) were able to mitigate the erosion at this location and as a result a substantial dune had begun to develop after installing sand fencing on the back-beach. However, in 2003 and 2004 the beach began to erode at a much higher rate and the shoreline receded almost to its original 1999 pre-nourishment position. The increase in erosion is attributed to increased tidal current scour due to changes in the orientation of the primary ebb and flood channels.

As changes in the configuration of the outer ebb bar system progressed, the main tidal channel became more directed onto the shore. This change in morphology caused incoming flood currents to become focused onto the nourished beach at Andrew Harding's Lane resulting in rapid loss of sediment once the sand was suspended due to wave action. Additional beach and dune nourishment projects have partially mitigated the increased erosion and have prevented complete breaching of the dune system. This heightened erosion has moderated somewhat during 2006 because the primary tidal channel once again has shifted position into a more shore parallel orientation and the associated tidal currents are not as focused onto the shoreline.

Despite the reduced erosive losses during 2006, the Town is continuing to investigate alternatives to mitigate the erosion at Andrew Harding's Lane because this is a popular small recreational beach. The opportunistic beach nourishment during ongoing dredging may not be sufficient to maintain the shoreline given the uncertainty of the frequency or scale of future nourishment dredging projects. Therefore, various structural shore protection alternatives are being considered to supplement the ongoing sand nourishment. These structures include groins, offshore breakwaters, perched beach systems, training dikes and other similar shoreline erosion mitigation measures. Based on a preliminary analysis, the use of groin-like training dikes placed at either end of the beach appear to be the most promising option. Their function would be similar to training dikes in a fluvial system, which are constructed to deflect river currents away from river banks to prevent scour. At Andrew Harding's Lane these structures would be placed to deflect tidal currents as well as provide some sheltering from waves in the lee of the structure to reduce the loss of sand. Whether the Town will ultimately choose to pursue installation of these features will be dependent upon the changing morphology and on the associated severity and rate of future erosion.

CONCLUSIONS

The formation of New Inlet produced long ranging changes within the Pleasant Bay estuary. The shorelines along Pleasant Bay have experienced a re-adjustment following the break due to the increase in tidal range which resulted in heightened erosion. These conditions initially resulted in an influx of sediment into the system as the estuarine shorelines receded and readjusted to the new hydraulic regime during the first few years after formation of New Inlet. The sediment input has decreased as these shorelines began to form a new equilibrium profile.

Several of the most dramatic changes included an initial reduction and subsequent recovery of the fringing salt marsh, transmission of wave energy onto previously sheltered shorelines, and the growth of a large flood shoal. These changes have placed the estuary in a state of flux that continues to change 19 years after the formation of New Inlet. The increase in tidal range resulted in a loss of fringing marsh within the estuary. This loss was the result of increase tide range and storm surge that allowed waves to reach higher onto the back-beach and ultimately to the destabilization of coastal banks. The initial loss of fringing salt marsh stopped approximately 10 years after New Inlet formed. The aerial coverage of fringing salt marsh has been recovering over the past 14 years and has now exceeded pre-breech conditions. We hypothesize that the increase occurred because of the additional suitable growing area associated with the increase in tide range that occurred after the formation of New Inlet.

The formation of New Inlet 8 km north of the old inlet changed the hydrodynamic conditions within Chatham Harbor. The changing conditions led the Town to develop a flexible Channel/Sand Management Plan that is a living document. The Plan continually re-assesses the shoal morphology and the location of the navigation channel. The flexibility of the Plan allows the Town to use limited resources to maximize the dredging efforts to maintain navigation to the Town Fish Pier and the mooring basin.

The beneficial reuse of dredged material has proved effective at nourishing a number of public and private shorelines throughout Chatham. The Town has also provided supplemental nourishment utilizing sand from upland sources. This sand serves as a suitable additional source of material to provide for nourishment when the sand from dredging projects is not available. Recently, the erosion at Andrew Harding's beach has begun to abate because a change in the ebb shoal morphology has changed the orientation of the inlet channel. While the Town is encouraged by this change, it is developing plans for a more permanent solution if the channel should once again change position and the erosion increases at this location.

ACKNOWLEDGEMENTS

Some funding and data support was provided by the USACE New England District and Town of Chatham. Permission to publish has been granted by the Chief of Engineers.

Foreword

The COASTAL SEDIMENTS '07 conference was organized as a technical specialty conference devoted to the physical aspects of sediment processes and morphology change in the coastal and inlet environment. Following previous conferences in the Coastal Sediments series that were held in 1977, 1987, 1991, 1999, and 2003, COASTAL SEDIMENTS'07 celebrated 30 years of the Coastal Sediments series and promoted exchange of information and views among specialists in the fields of coastal engineering, geology, oceanography, and related disciplines. The theme of COASTAL SEDIMENTS '07 was "Coastal Engineering and Science in Cascading Spatial and Temporal Scales," which established the trend of thinking and approach of the conference, as well as determined in part the composition of the papers that were presented. This theme was chosen to stimulate research devoted to the various scales of processes and their interactions at which coastal engineers and scientists must work in developing knowledge and capabilities to assist society in managing the coast under present and future conditions. Emphasis was on papers that recognize and relate to coastal morphology change of long-term consequence.

The COASTAL SEDIMENTS '07 conference returned to the site of the 1987 conference, New Orleans, Louisiana, because of the extraordinary morphologic change along the coasts of Louisiana, Mississippi, and Texas, caused by Hurricanes Katrina and Rita that struck in August and September, respectively, of 2005. In addition to the recent hurricanes, this coast is experiencing long-term natural and anthropogenic change including rapid and differential subsidence, severe reduction in renewable sediment supply, deltaic adjustment of fine-grained material, and oil and gas exploration and extraction. The theme is intended to generate papers and discussion of coastal sediment processes from the micro-scale to the regional scale at which integrated coastal design and management must be accomplished. Participants were given an overview of recent hurricane damage within the context of the long-term morphologic change in Louisiana in the Keynote Address delivered by Mr. James R. (Randy) Hanchey, Deputy Secretary of the Louisiana Department of Natural Resources.

Professor Leo van Rijn of Delft Hydraulics and the University of Utrecht, The Netherlands, accepted the 2007 Coastal Award at the Conference Awards Luncheon on May 16th. Starting in 2001, the Coastal Award has been presented every 2 years alternately at the Coastal Dynamics conference and the Coastal Sediments conference through coordination between the organizing committees of these two technical specialty conferences. The Organizing Committee of Coastal Sediments '07 joins conference participants and the extended research community in celebrating Professor van Rijn's research contributions that have greatly influenced engineers and geologists working in the areas of coastal sediment transport and morphology change.

These *Proceedings* volumes are the permanent record of the conference, containing the latest thinking and progress of the world's leading scientists and

engineers in the areas of coastal sediment transport and morphology change. The contents are a valuable source of information on coastal sediment and morphology processes ranging from basic research to case studies and lessons learned. The papers contained herein provide the most recent results and ideas in a wide range of approaches and viewpoints not assembled elsewhere in both quality and breadth. The *Proceedings* were produced in hard copy in two volumes in black and white and also provided to conference participants as a CD ROM with searchable index of PDF files in color. All papers are available to the public in PDF format via the ASCE Research Library at www.ascelibrary.org.

Three-hundred fifty abstracts were submitted to the Conference Steering Committee. On average, each abstract received five reviews, and 225 submissions were invited for development into full papers and presentation over 3 days of technical sessions. The 197 papers appearing in these Proceedings originated from approximately 24 countries, demonstrating the international scope of COASTAL SEDIMENTS '07. Each paper included in these *Proceedings* received positive peer review. Each paper is eligible for discussion in the *Journal of Waterway, Port, Coastal and Ocean Engineering* and can be nominated for ASCE awards.

The Steering Committee of COASTAL SEDIMENTS '07 gratefully acknowledges the assistance of many individuals, both known and anonymous, in the 2 years of preparations by an all-volunteer committee. Numerous individuals assisted the Steering Committee in review of abstracts and final papers. The efforts of the following persons are acknowledged: Matthew Arsenault, U.S. Geological Survey (USGS); Mark Byrnes, Applied Coastal Research and Engineering, Inc.; Duncan FitzGerald, Boston University; Guy Gelfenbaum, USGS; Cheryl Hapke, USGS; John Headland, Moffatt & Nichol; Todd Holland, Naval Research Laboratory; Peter Howd, USGS; Bruce Jaffe, USGS; Magnus Larson, University of Lund; Jeffrey List, USGS; Randy Parkinson, Coastal and Environmental Geological Consulting; Robert Morton, USGS; James O'Connell, Woods Hole Oceanographic Institution; Lisa Robbins, USGS; Vladimir Shepsis, Coast and Harbor Engineering; Donald Stauble, U.S. Army Corps of Engineers; Marcel Stive, Delft Hydraulics; Hilary Stockdon; USGS; and Curt Storlazzi, USGS.

We also thank the session moderators for agreeing to lend their time and experience to run the conference smoothly and productively. We are indebted to the tour leaders and their organizations for arranging and conducting memorable and stimulating technical trips. The "Geology of the Louisiana Coastal Zone: Implications for Coastal Management and Restoration" tour was led by Mark Kulp, University of New Orleans (UNO); Mike Miner, UNO; Duncan FitzGerald, Boston University; and Ioannis Giorgiou, UNO. The "Wax Lake-Atchafalaya Delta Complex Sedimentation, Stratigraphy" tour was led by Harry Roberts, Louisiana State University. Finally, we thank Lucy King of ASCE for assisting and often leading in conference logistics; Donna Dickert of ASCE for accurately producing the Proceedings; and Lesa Rair and Chris Hanson of COPRI for assisting with conference arrangements, including exhibitors and sponsors.

We also would like to thank our exhibitors and sponsors for Coastal Sediments 2007 for their support:

Contents

Volume One

Sediment Transport Fundamentals I

Wave-Related Transport and Nearshore Morphology 1
Leo van Rijn, Gerben Ruessink, Bart Grasmeijer, Jebbe van der Werf, and Jan Ribberink

Closed Form Solution for Threshold Velocity for Initiation of Sediment Motion under Waves 15
Hans Hanson and Benoît Camenen

Influence of Velocity Moments on Sand Bar Movement During CROSSTEX 28
Gregory Guannel, H. Tuba Özkan-Haller, Merrick C. Haller, and James T. Kirby

Development of a New Practical Model for Sand Transport Induced by Non-Breaking Waves and Currents 42
Jebbe J. van der Werf, Jan S. Ribberink, and Tom O'Donoghue

A Total Load Formula for the Nearshore 56
Benoît Camenen and Magnus Larson

Sediment Transport Fundamentals II

Longshore Sand Transport Rate Measurements Using Small-Scale Physical Models 68
Roshan Suminda Ranasinghe and Shinji Sato

Pressure-Induced Subsurface Sediment Transport in the Surf Zone 82
Ole Secher Madsen and William McKinney Durham

Tracking Sediment Particles under Wave-Current Coexisting Field 96
Yoshimitsu Tajima, Masayuki Kozuka, Masahito Tsuru, Toshimasa Ishii, Takeharu Sakagami, Kazuo Momose, Nobuo Mimura, and Ole S. Madsen

Sediment Transport in Response to Wave Groups Generated by High-Speed Vessels 110
Philip D. Osborne, Neil J. MacDonald, and Shaun Parkinson

Sediment Transport Fundamentals III

Flume Experiments under Cat-Scan to Measure Internal Sedimentological Parameter During Sediment Transport 124
Stéphane Montreuil and Bernard F. Long

The Effects of Bed Slope and Wave Skewness on Sediment Transport and Morphology 137
D. J. R. Walstra, L. C. van Rijn, M. van Ormondt, C. Briére, and A. M. Talmon

Sediment Transport off Northeast Florida Outside the Surf Zone during Hurricanes 151
Michael Krecic, Christopher Bender, and Kristen Odroniec

Longshore Transport

Geomorphic and Sedimentologic Evidence for Net Littoral Drift—A Review 165
Terry Healy

Cross-Shore Variation of Predominant Longshore Sediment Transport Rate 179
Yoshiaki Kuriyama and Hikari Sakamoto

Longshore Sand Transport Calculated by Time-Dependent Shear Stress 193
Ernest R. Smith and Nicholas C. Kraus

Sediment Budget of the Danube Delta Coastal Zone 207
Sebastian Dan, Marcel Stive, Dirk Jan Walstra, and François Sabatier

Field Measurements and Modeling of Longshore Sediment Transport 221
J. J. Williams, L. S. Esteves, M. A. Lisniowski, and H. L. S. Perotto

Sediment Transport Fundamentals IV

Infragravity Waves in Mobile-Bed Laboratory Experiments 235
Florent Grasso, Hervé Michallet, and Eric Barthélemy

Large-Scale Laboratory Modeling of Suspended Sand Concentration Fluctuations under Irregular Waves 248
Joachim Grüne, Ruben Kos'yan, Hocine Oumeraci, Igor Podymov, Reinold Schmidt-Koppenhagen, and Chris E. Vincent

Change in Longitudinal Profile Using Sand of Mixed Grain Size in Large Wave Tank and its Numerical Simulation 259
Massaya Fukuhama, Takaaki Uda, Masumi Serizawa, and Toshinori Ishikawa

Probabilistic-Deterministic Modelling of Swash Zone Morphology 272
T. E. Baldock, P. Kim Son, P. Manoonvoravong, M. P. Barnes, and J. M. Alsina

Modelling Sheet Flow Sediment Transport Using Convolution Integrals 286
P. Guard, I. Teakle, P. Nielsen, and T. Baldock

Shoreline Change Modeling

A Middle-Term Evolution Model for Beaches 300
Soledad Requejo, Raul Medina, and Mauricio Gonzalez

Model for Predicting Beach Changes on Coast with Sand of Mixed Grain Size Based on Bagnold's Concept 314
Masumi Serizawa, Takaaki Uda, Toshiro San-nami, Kou Furuike, Toshinori Ishikawa, and Takayuki Kumada

A Circulation Modeling Approach for Evaluating the Conditions for Shoreline Instabilities 327
Jeffrey H. List and Andrew D. Ashton

An Alternative Explanation for the Shape of 'Log-Spiral' Bays 341
Ryan Littlewood, A. Brad Murray, and Andrew D. Ashton

The Response of Spit Shapes to Wave-Angle Climates 351
Andrew D. Ashton, A. Brad Murray, and Ryan Littlewood

Observed Shoreline Change

Historical Shoreline Changes and Morphodynamics of Parramore Island, Virginia (1852-2006) 364
Trent M. Richardson and Randolph A. McBride

Temporal and Spatial Scales of Profile and Planform Adjustment on a Nourished Beach 378
Nicole A. Elko and Ping Wang

Shoreline Response to Dike Failure at Grand Marais Harbor, Lake Superior, Michigan 392
Rachel R. Roblin, Mohammad Dibajnia, Robert B. Nairn, and James P. Selegean

Successful Beach Modelling, Monitoring and Management for a Large LNG Facility 406
Jonathan A. Kemp, Tom C. Coates, Richard Head, and Jenny S. Harcourt

Gravel Coasts I

The Design of Stable and Aesthetic Beach Fills: Learning from Nature 420
Paul D. Komar

Variation in the Organization of Gravel-Dominated Coastal Systems: Evidence from Nova Scotia and Southern England 434
Julian D. Orford and Simon C. Jennings

Profile Dynamics and Particle Tracer Mobility of a Cobble Berm Constructed on the Oregon Coast 449
Jonathan C. Allan and Roger Hart

Mixed Sediment Beach Processes: Kachemak Bay, Alaska 463
Peter Ruggiero, Peter N. Adams, and Jonathan A. Warrick

Mixed Sand and Gravel Beach Design and Construction for Habitat Restoration 477
David Simpson, Michael Wray, John Houghton, and John Klekotka

Gravel Coasts II

Influence of Changing Management Regimes on the Morphodynamic Response of a Mixed Gravel and Sand Barrier Beach 492
Andrew P. Bradbury and Julian D. Orford

The Influence of Groundwater on Profile Evolution of Fine and Coarse Sand Beaches 506
Diane P. Horn, Tom E. Baldock, and Ling Li

Effects of Permeability on the Performance of Mixed Sand-Gravel Beaches 520
Kaiming She, Louise Trim, Diane Horn, and Paul Canning

Cross-shore and Longshore Transport of Tracer Pebbles on a Macrotidal Mixed Sediment Beach, Somme Estuary, France 531
J. Curoy, U. Dornbusch, C. A. Moses, D. A. Robinson, and R. B. G. Williams

Why Are Shingle Beaches Replacing Sandy Beaches? (Coastal Zone of NW Portugal) 545
Helena Granja and Eduardo Loureiro

Gravel Coasts III

Field Measurements of Shore Conditions to Assess Bulkhead Effects in Thurston County, South Puget Sound 561
Susan P. Tonkin, Tim Abbe, José Carrasquero, and Steve Morrison

Coral-Gravel Storm Ridges: Examples from the Tropical Pacific and Caribbean 572
Bruce M. Richmond and Robert A. Morton

Field Observations of Step Dynamics on a Macrotidal Gravel Beach 584
Daniel Buscombe, Martin J. Austin, and Gerhard Masselink

Large-Scale Scour of the Sea Floor and the Effect of Natural Armouring Processes, Land Reclamation Maasvlakte 2, Port of Rotterdam 598
Sander Boer, Edwin Elias, Stefan Aarninkhof, Dano Roelvink, and Tiedo Vellinga

Dunes and Profiles

Dune Erosion Prediction Methods Incorporating Effects of Wave Periods 612
Marcel R. A. van Gent, E. Martijn Coeveld, Hans de Vroeg, and Jan van de Graaff

Reevaluation of Equilibrium Beach Profile Scale Parameter 626
Zhanxian Wang and Robert G. Dean

Shoreface Response to Sediment Deficit 633
G. M. Kaminsky, M. A. Ferland, P. J. Cowell, H. R. Mortiz, and P. Ruggiero

Louisiana Coast

The Challenges of Restoring Louisiana Barrier Islands: From Design through Construction 647
Gordon G. Thomson, Greg M. Grandy, and Rachel Sweeney

Field Observations of Wave-Current-Sediments Dynamics, Atchafalaya Shelf, Louisiana, USA 661
Sergio Jaramillo, Alex Sheremet, and Mead Allison

Investigation of Morphosedimentary Processes on a Schematic Louisiana Barrier Island Using Process-Based Numerical Modeling 671
T. Campbell, B. de Sonneville, L. Benedet, D. J. W. Walstra, and C. W. Finkl

Restoration-Quality Sand from Ship Shoal, Louisiana: Geotechnical Investigation for Sand on a Drowned Barrier Island 685
Syed M. Khalil, Charles W. Finkl, Jeff Andrews, and Christopher P. Knotts

Mississippi River Sand for Barrier Island Restoration in Louisiana: Geophysical and Geotechnical Investigations for Sand Mining 699
Jeffrey L. Andrews, Syed M. Khalil, Charles W. Finkl, and Lindino Benedet

Mississippi River Delta

Re-Engineering the Mississippi River as a Sediment Delivery System 712
Harley S. Winer

Sediment Flux and Fate in the Mississippi River Diversion at West Bay: Observation Study 722
T. Mitchell Andrus and Samuel J. Bentley

Initial Morphologic and Stratigraphic Delta Evolution Related to Buoyant River Plumes 736
Joep E. A. Storms, Marcel J. F. Stive, Dano (J.) A. Roelvink, and Dirk Jan Walstra

Physical and Numerical Modeling of River and Sediment Diversions in the Lower Mississippi River Delta 749
Clinton S. Willson, Nathan Dill, William Barlett, Samantha Danchuk, and Ryan Waldron

A Geomorphic Process-Response Model for Chenier-Plain Evolution in Southwestern Louisiana, USA 762
Randolph A. McBride, Matthew J. Taylor, and Mark R. Byrnes

Marshes and Wetlands

Sediment Analysis for Habitat Restoration: Adaptation of Open-Coast Beach Nourishment Principles 776
Daniel J. Heilman, Joel T. Darnell, and M. Cameron Perry

Subsurface Exploration and Containment Dike Design Criteria for Coastal Louisiana Marsh Restoration 785
Russ Joffrion, Michael Poff, and Mitch Andrus

Ice Raft Formation, Dispersion and Sedimentation on New England Salt Marshes 798
Brittina A. Argow, Zoe J. Hughes, and Duncan M. FitzGerald

Effects of Large Scale Morphological Changes to a Back-Bay System 814
Lee L. Weishar, Theodore Keon, and Donald K. Stauble

Volume Two

Deltas and River Mouths

Morphodynamic Feedbacks on Deltaic Coasts: Lessons from the Wave-Dominated Danube Delta 828
Liviu Giosan

Coastal and River Mouth Morphology Change in Sri Lanka Due to 2004 Indian Ocean Tsunami 842
Hitoshi Tanaka, Kazuo Ishino, Bandara Nawarathna, Hajime Nakagawa, and Shinichiro Yano

Holocene Evolution of the Merrimack Embayment, Northern Massachusetts, Interpreted from Shallow Seismic Stratigraphy **856**
Christopher J. Hein, Duncan M. FitzGerald, and Walter A. Barnhardt

The Use of Historic Topography for the Characterization of Time-Dependent Geomorphic Change and Sediment Delivery **867**

Frank Hopf and Douglas J. Sherman

Distribution of Horizontal Distance Traveled by Saltating Sand Grains in Air 1255
Shintaro Hotta, Susumu Kubota, and Nagatomo Nakamura

Beach Stabilization Works Against Wind Blown Sand on Beaches: Experiences from Japan 1269
Susumu Kubota, Souichi Harikai, and Shintaro Hotta

Coastal Dunefield Evolution in Conditions of Limited Sediment Availability: Natural and Anthropogenic Controls on the Corralejo Dunes 1283
Herminia I. Valdemoro, José A. Jiménez, Ignacio Alonso, Paloma Lorente, and Manuel Rodriguez-Herrerias

Coastal Inlets I

Hydrodynamic and Morphologic Modeling at Sebastian Inlet, FL 1297
Gary A. Zarillo and Florian G. A. Brehin

Erosion and Channel Migration at the Shoalwater Bay Reservation, Willapa Bay, Washington 1311
Andrew Morang, David J. Mark, and Jane M. Smith

Sediment Management Plan Development for the St. Lucie Inlet, Martin County, Florida 1326
John Ramsey, Trey Ruthven, Kevin Kremkau, and Kathy Fitzpatrick

Sand Bypassing Restores Natural Processes to Assateague Island, Maryland 1340
Courtney A. Schupp, Gregory P. Bass, and William G. Grosskopf

Morphological Responses to Jetty Construction at Tidal Inlet: Lake Saroma, Japan 1354
Kentaro Hayashi, Koji Hashimoto, Takayuki Sasaki, Akihiro Honma, and Seizo Matsura

Coastal Inlets II

Morphodynamics of Texel Inlet, The Netherlands 1363
Edwin P. L. Elias and Marcel J. F. Stive

Sedimentation Patterns in a Stabilized Migratory Inlet, Blind Pass, Florida 1377
Ping Wang, David K. Tidwell, Tanya M. Beck, and Nicholas C. Kraus

Approaches to Understanding Multiple-Inlet Stability 1391
William C. Seabergh

Engineering Guidelines for the Siting of Sand Bypassing Discharges 1405
Douglass W. Mann

Shoreline Implications of Flood-Tide Delta Morphodynamics. The Case of Port Stephens (SE Australia) 1417
Ana Vila-Concejo, Andrew D. Short, Michael G. Hughes, and Roshanka Ranasinghe

Mud Coasts I

Using Simple Semi-Empirical Models for Integrated Assessment of Scenarios for a Navigation Channel. The Case of the Port of Ostend, Belgium 1431
Toon Verwaest

Sediment Processes and Mangrove-Habitat Expansion on a Rapidly-Prograding Muddy Coast, New Zealand 1441
Andrew Swales, Samuel J. Bentley, Catherine Lovelock, and Robert G. Bell

The Influence of Mud on the Inner Shelf, Shoreface, Beach, and Surf Zone Morphodynamics—Cassino, Southern Brazil 1455
Lauro J. Calliari, K. Todd Holland, Pedro S. Pereira, Rafael M. C. Guedes, and Renato E. Santo

The Hurricane Katrina Storm Surge in Mississippi 1466
Alan W. Niedoroda, Lyle Hatchett, Himangshu Das, Andrew Cox, Robert Weaver, Stephen Baig, and Shabbar Saifee

Texas Inlets

Coastal Inlets of Texas, USA 1475
Nicholas C. Kraus

Cedar Bayou—Inlet Dynamics and Engineering 1489
Vladimir Shepsis and Joshua Carter

Navigation Improvements, Mouth of the Colorado River, Texas 1502
Ronnie G. Barcak, Nicholas C. Kraus, Lihwa Lin, Ernest R. Smith, Daniel J. Heilman, and Robert C. Thomas

Long-Term Inlet Stability of a Multiple Inlet System, Pass Cavallo, Texas **1515**
Brian K. Batten, Nicholas C. Kraus, and Lihwa Lin

Morphologic Response to a New Inlet, Packery Channel, Corpus Christi, Texas **1529**
Deidre D. Williams, Nicholas C. Kraus, and Carl M. Anderson

Coastal Inlets III

Evolution of a Relocated Tidal Inlet: Mason Inlet, NC **1543**
John M. Welsh and William J. Cleary

Present Hydrodynamics of Ancão Inlet, 10 Years after its Relocation **1557**
André Pacheco, Ana Vila-Concejo, Oscar Ferreira, and Alveirinho Dias

The Influence of Tidal Prism and Vegetation on Tidal Channel Morphology: Implications for Marsh Stability **1571**
Matthew L. Kirwan and A. Brad Murray

Natural and Anthropogenic Influences on the Morphodynamics of Big Sarasota Pass, Florida **1582**
Richard A. Davis, Ping Wang, and Tanya Beck

Morphological Behavior of Seasonal Closure of Tidal Inlets **1589**
Tran Thanh Tung, Marcel J. F. Stive, Jan van de Graaff, and Dirk-Jan R. Walstra

Estuaries

The National Academies Report on Mitigating Shore Erosion along Sheltered Coasts **1601**
Jeff Benoit and Susan Roberts

Field Measurement and Modeling of Scour Pit Dynamics in a Sandy Estuary **1609**
A. G. Davies and J. M. Brown

Projection of Topographic Change of an Estuary Terrace by Horizontal 2-D Simulation Model, Considering Grain Size **1623**
Toshimitsu Takagi, Go Asano, Takushi Inukai, and Masaya Fukuhama

Examining the Contribution of Sediment Stratification to the Evolution of Seabed Morphology **1635**
S. Falchetti, D. C. Conley, and M. Brocchini

From River Basin to Barrier Reef: Pathways of Coastal Sediments **1647**
Piet Hoekstra, Ton Hoitink, Frans Buschman, Ayi Tarya, and Gert van den Bergh

Mud Coasts II

Wave Evolution on Fluid Mud Bottom **1660**
Kevin Hall and Ali Oveisy

A Fine Sediment Transport Modeling Framework and its Application to Fluid Mud Processes **1669**
Tian-Jian Hsu and Minwoo Son

Field Measurement of Fine Sediment Transport Process around Navigation Channel 1678
Yasuyuki Nakagawa and Hideo Matsumoto

Time Dependent Mud Fluidization and Irregular Wave Transformation on Muddy Profiles 1690
Mohsen Soltanpour, S. Abbas Haghshenas, and Tomoya Shibayama

Volume Three

Regional Processes I

Regional Beach/Cliff System Dynamics along the California Coast 1696
Cheryl J. Hapke and Dave Reid

Factors Influencing the Long-Term Stability of the Carbonate Sand Beaches of Mauritius 1708
Michael J. Risk, Robert B. Nairn, and Mark O. Kolberg

Evolution of Erosion Hot Spots on a Barrier Island: Fire Island, New York 1722
Kathryn Seaver, Frank Buonaiuto, and Henry Bokuniewicz

Tropical Mixed Wave/Tide Dominated Barrier-Spit System: A Case Study from NE Brazil 1731
Helenice Vital, Francisco Santos Neto, Jose S. Placido Junior, and Venerando E. Amaro

Regional Shoreline and Beach Changes in the Santa Barbara Sandshed 1740
David L. Revell and Gary B. Griggs

Regional Processes II

Engineering Activities Influencing Historical Sediment Transport Pathways at the Columbia River Mouth, WA/OR 1754
Mark R. Byrnes, Sarah F. Griffee, and Hans R. Moritz

Implementing Regional Sediment Management to Sustain Navigation at an Energetic Tidal Inlet 1768
Hans R. Moritz, Guy R. Gelfenbaum, George M. Kaminsky, Peter Ruggiero, Joan Oltman-Shay, and Doris J. McKillip

Decadal Evolution of Shoreface Geometry in South Carolina, USA 1787
B. M. Reynolds, P. A. Wren, and P. T. Gayes

Improving Statistical Validity in Calculating Erosion Hazards from Historical Shorelines 1799
Ayesha S. Genz, L. Neil Frazer, and Charles H. Fletcher

Linking Coastal Evolution and Super Storm Dune Erosion Forecasts 1813
L. M. van der Burgh, K. M. Wijnberg, S. J. M. H. Hulscher, J. P. M. Mulder, and M. van Koningsveld

LIDAR and ARGUS

***CHARTS*-Enabled Data Fusion for Coastal Zone Characterization** 1827
Jennifer M. Wozencraft, Christopher L. Macon, and W. Jeff Lillycrop

Using Topographic LIDAR Data to Delineate the North Carolina Shoreline 1837
Patrick W. Limber, Jeffrey H. List, Jeffrey D. Warren, Amy S. Farris, and Kathryn M. Weber

Exploring Rippled Scour Depressions Offshore Huntington Beach, CA 1851
Eleyne L. Phillips, Curt D. Storlazzi, Peter Dartnell, and Brian D. Edwards

A Study of Intertidal Bar Dynamics Using the Argus Video System 1865
Amaia Ruiz de Alegria Arzaburu, Suzana Ilic, and Yohama Gunawardena

Depth of Closure Derived from Airborne Laser Bathymetry 1877
William Robertson V, Keqi Zhang, and Dean Whitman

Remote Sensing

Assessing Nearshore Bar Movements during Storms Using Time-Averaged X-Band Radar Images 1886
Luciana S. Esteves, Jon J. Williams, and Paul S. Bell

Longshore Migration of Coastal Features Observed with X-Band Radar 1900
Satoshi Takewaka, El Sayed Galal, Ryosuke Matsumoto, and Shinya Sasakura

Detailed 3-D Models of New Zealand Barrier Stratigraphy Provide Insight into Coastal Evolution in Various Spatial and Temporal Settings 1910
Amy J. Dougherty and Scott L. Nichol

Swash Zone

A Formula for Longshore Sediment Transport in the Swash 1924
Magnus Larson, Ty V. Wamsley

Importance of the Swash Longshore Sediment Transport in Morphodynamic Models 1938
Yasuyuki Baba and Benoît Camenen

Direct Bed Shear Stress Measurements in Bore-Driven Swash and Swash Interactions 1947
Matthew P. Barnes and Tom E. Baldock

Limits of Beach and Dune Erosion in Response to Wave Runup Elucidated from SUPERTANK 1961
Tiffany M. Roberts, Ping Wang, and Nicholas C. Kraus

Interaction of Dune Face and Swash Zone 1975
Jaap S. M. van Thiel de Vries, Linden B. Clarke, Stefan G. J. Aarninkhof, E. Matrijn Coeveld, Rob A. Holman, Meg L. Palmsten, Ad J. H. M. Reniers, Marcel J. F. Stive, and Wim S. J. Uijttewaal

Barrier Island Breaching

Critical Width of Barrier Islands and Implications for Engineering Design 1988
Julie Dean Rosati and Gregory W. Stone

Barrier Island Vulnerability to Breaching: A Case Study on Dauphin Island, Alabama 2002
Mark Hansen and Asbury H. Sallenger

Morphologic Modeling of Multiple Barrier Island Breaches for Regional Application 2011
Kenneth J. Connell, Magnus Larson, and Nicholas C. Kraus

Breach Stability and Growth Analysis Using a Morphological Model 2025
Santiago R. Alfageme, Masood Khondker, and Rafael Canizares

Spatial Distribution of Cross-Shore Sediment Transport Rate for Berm Formation and Erosion 2037
Takayuki Suzuki, Maiko Takeuchi, Naoki Tomoda, Satomi Yamaguchi, and Yoshiaki Kuriyama

Overwash and Washover

Sediment Transport Patterns During Overwash 2049
Ana Matias, Ana Vila-Concejo, Óscar Ferreira, Brad Morris, and João A. Dias

Characterization and Modeling of Washover Fans 2061
Chantal Donnelly and Asbury H. Sallenger

Experimental Study of Overwash 2074
Billy L. Edge, Young Hyun Park, and Margery Overton

Backbarrier Evolution and Complete Overwash Occurrence 2084
Ana R. Carrasco, Óscar Ferreira, Ana Matias, and João A. Dias

Sand Bars, Beach Cusps

Geomorphic Features Shaped by Crossing Waves 2097
Robert B. Nairn and Mohammad Dibajnia

Observation and Modeling of Crescentic Bars in Barcelona Embayed Beaches 2111
F. Ribas, R. Garnier, E. Ojeda, A. Falqués, J. Guillén, and D. Calvete

Mesoscale Behaviour of Longshore Bars—Net Onshore or Net Offshore Migration 2124
Troels Aagaard and Aart Kroon

Morphological Characteristics of Rip Current Embayments on the Oregon Coast 2137
Matthew M. Dalon, Merrick Haller, and Jonathan Allan

Geologic Framework of the Long Bay Inner Shelf: Implications for Coastal Evolution in South Carolina 2151
Walter Barnhardt, Jane Denny, Wayne Baldwin, William Schwab, Robert Morton, Paul Gayes, and Neal Driscoll

Sand Waves and Channels

A Relic Sand Wave Field in a Tidal Channel 2164
Shelley J. Whitmeyer and Duncan FitzGerald

Geometric and Statistical Characteristics of Bed Forms in the Lower Mississippi River 2177
K. Kheiashy, J. McCorquodale, I. Georgiou, and E. Meselhe

Bathymetric Evolution of a Sandy Bed under Transient Progressive Waves **2191**
Blake J. Landry and Marcelo H. García

Analysis of Sebastian Inlet, FL, Morphologic Changes Using Complex Empirical Orthogonal Functions (CEOF) **2199**
Florian G. A. Brehin, Jo-Ann Rosario-Llantin, and Gary A. Zarillo

Investigating Ship Induced Scour in a Confined Shipping Channel **2213**
David Taylor, Kevin Hall, and Neil MacDonald

Beach Nourishment

Evolution of Grain-Size Distribution on Bogue Banks: Implications for Selection of Borrow Material **2229**
Timothy W. Kana

New Findings in Equilibrium Grain Size Distribution **2242**
Jordi Galofre, Raúl Medina, Gabriela Medellin, and César Vidal

Determination of Overfill Factor for Offshore Sand in Barrier Island Restoration on the Louisiana Coast **2254**
Daniel L. Bolinger, Dominic Izzo, and Edward J. Schmeltz

Broward County Beach Demonstration Project: From Beers to Beaches **2265**
Christopher Makowski, Gordon Thomson, Peter Foye, and Stephen Higgins

Beach Nourishment Evolution in the Cancún Beach, Quintana Roo, México **2279**
Diana K. Morán, Paulo Salles, A de A, José C. Sánchez, and Juan C. Espinal

Case Studies

Geomorphic Response and Elements of Sediment Budget at St. Joseph Harbor, Southeast Lake Michigan **2292**
Mohammad Dibajnia, Robert B. Nairn, and James P. Selegean

Chesapeake Bay: Headland Control Systems Performance Including Hurricane Isabel **2306**
C. Scott Hardaway, Jr. and James R. Gunn

Coastal Protection against Wind-Wave Induced Erosion Using Soft and Porous Structures: A Case Study at Lake Biel, Switzerland **2321**
Selim M. Sayah and Stephan Mai

Physical Processes Study of Goldsmith Inlet, New York **2331**
Michael J. Morgan and Nicholas C. Kraus

Dredging

Design of Navigation Channel Deepening Works Using a Morphological Model in Barranquilla, Columbia **2345**
Rafael Cañizares, Santiago Alfageme, and Tucker Mahoney

Beach Renourishment through Spoil Disposal Downdrift of a Dredged Entrance Channel **2358**
Kyle C. Spiers and Terry R. Healy
