MORPHODYNAMIC FEEDBACKS ON DELTAIC COASTS: LESSONS FROM THE WAVE-DOMINATED DANUBE DELTA

Liviu Giosan[1]

1. Woods Hole Oceanographic Institution, MS#22, Department of Geology and Geophysics, 360 Woods Hole Road, Woods Hole, MA 02543, USA. lgiosan@whoi.edu.

Abstract: In natural conditions, the dynamics of the Danube delta coast has been largely determined by the interaction between fluvial deposition and a strong southward wave-induced longshore transport near the mouths of the river. River-mouth morphodynamics is highly nonlinear, involving multiple feedbacks on the longshore sediment transport. These include a *groin effect* of the river plume and subaqueous delta, a *shoaling effect* of the downdrift offset subaqueous delta, and a *barrier steering effect* of the downdrift barrier islands or spits. As a result, a net sequestration of sediments occurs near the river mouth that aids and speeds up delta lobe development. Downdrift of the mouth, barriers may form after extreme river floods, but also due to increased shoreline instability under high angle waves. Although river mouth processes are complex, the resulting morphology of wave-dominated delta lobes exhibits a tendency to self-organize.

INTRODUCTION

Deltas are home to a disproportionate fraction of the world's population. Moreover, a few remaining less developed deltas have some of the highest biodiversity on the planet. However, deltas are fragile geomorphic features, which can change dramatically with modest modifications in boundary conditions. Their complex morphology is the result of a dynamic equilibrium between fluvial discharge, marine energy conditions, accommodation, and the overall geological framework. Low relief makes deltas susceptible to floods, storms and sea level change, vulnerabilities exacerbated by sediment deficits following extensive river damming. Understanding the influence of

waves on deltaic coasts, in particular, is critical as deltas are increasingly becoming wave-dominated under these large fluvial sediment deficits (e.g., Ericson et al. 2006). In spite of the importance of deltas, a quantitative understanding of deltaic deposition is limited due to their intrinsic complexity (see e.g., Overeem et al. 2005).

Morphodynamics of deltaic coasts and shelves has been a less explored aspect in the evolution of deltas, although the morphodynamic paradigm has been widely used in coastal studies (e.g., Carter and Woodroffe 1994; Cowell et al. 2004). Feedbacks between the evolving morphology of a delta forced by the continuous sediment output from the river and modified by basinal hydrodynamics remain inadequately known, as are the interactions between contemporaneous lobes within a delta (e.g., Komar 1973; Wright 1985; Cowell et al. 2004) or the influence exerted by a delta on the dynamics of adjacent non-deltaic coasts and vice-versa (e.g., Penland and Suter 1989; Corregiari et al. 2005). While there has been much recent progress in understanding suspended sediment deposition from river plumes (e.g., Syvitski and Bahr 2001; Geyer et al. 2004), the dynamics of coarse sediments at river mouths (Wright 1977) has received little attention recently, in large part due to the inability of conventional techniques to provide direct reliable measurements.

Existing morphodynamic models (e.g., Komar 1973; Cowell et al. 2003) identify the *rotation of the shoreline* as the principal phenomenon associated with delta development. Shoreline rotation is responsible for changes in longshore drift along deltaic coasts. Several other hydrodynamic-morphodynamic feedback loops related to bedload sedimentation at river/distributary mouths by have been identified by Giosan et al. (2005) and are explored herein for the particular case of the Danube delta. Furthermore, numerical modeling (Ashton and Murray 2005; Ashton and Giosan 2006) suggested that shoreline instability is more to be expected on the downdrift coast of wave-dominated lobe than updrift of the feeding river mouth. A conceptual model for wave-dominated deltas proposed by Bhattacharya and Giosan (2003) is modified in here to account for this latest understanding of delta coast morphodynamics.

BACKGROUND

Danube River

The Danube river is the second largest European river after the Volga in terms of catchment area (817,000 km2) and length (2870 km) as well as water and sediment discharge. The average annual discharge reported between 1840 and 1995 is ~6240 m3/s, with the highest measured annual discharge of ~9250 m3/s in 1970 (Bondar and Blendea 2000). The peak discharge during the year occurs in late spring (Vörösmarty et al. 1998), following snowmelt and there is a factor of 2 variability between the spring (high) and the fall (low) discharge (Reschke et al. 2002).

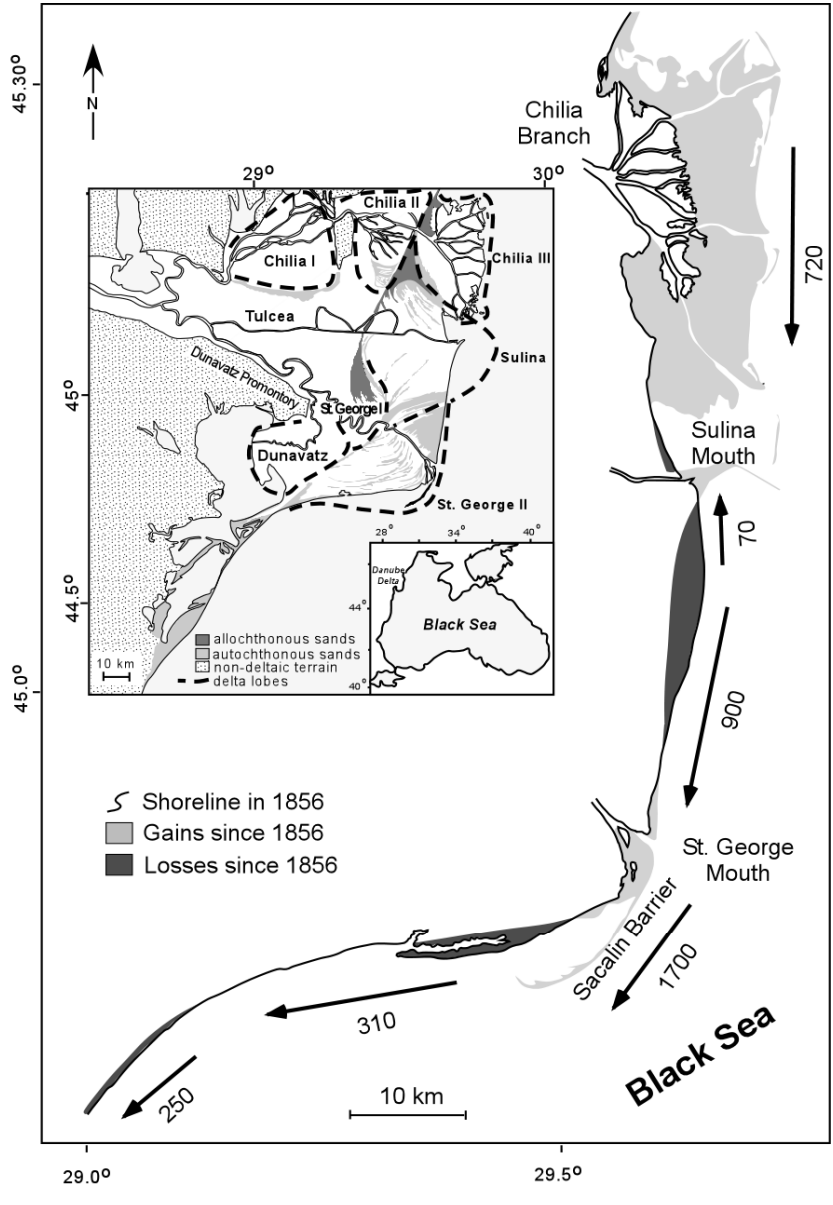

Fig. 1. Danube delta coast: shoreline changes from 1856 to 2003/05 (after Giosan et al. submitted). Cartography: S. Constantinescu. Inset: Danube delta morphology and sand facies distribution (after Giosan et al. 2006)

Extensive damming, especially in the lower basin, has reduced the suspended sediment discharge at the apex of the delta from ~67×10^6 t/year between 1921 and 1960 to ~25-35×10^6 t/year at present. The bed-load sediment discharge at the Danube mouths has been estimated to range between ~4.6 and ~5.3×10^6 t/year (Bondar et al. 1992).

In the delta, Danube splits into three main distributaries (Fig.1): the Chilia (Kilia), the Sulina and the St. George (Sf. Gheorghe). Since 1856 when the first estimates of the flow were made by the European Danube Commission, discharge through main navigation route, the Sulina arm, has steadily increased (from 7% to 19%), while St. George and Chilia have compensatorily decreased their flow (from 30% to 23% and from 63% to 57% respectively) as a consequence of sustained maintenance and improvement projects for navigation on Sulina and intensive channelization in the delta. After similar human interventions on the St. George arm in 1980's, the discharge of this distributary started to increase. Reported values for suspended and bed-load sediment discharge on the three distributaries are 55% and 57-65% for Chilia, 21% and 19-25% for Sulina, and 23% and 19%-21 for St. George, respectively (Bondar and Harabagiu 1992).

Black Sea

Danube flows and builds its delta into the Black Sea, a semi-enclosed basin connected to the World Ocean via the Sea of Marmara and the Mediterranean. Black Sea is a microtidal basin with a semi-diurnal tide with a range between 7 and 12 cm. Long term relative sea-level rise has been minimal at the Danube delta (Giosan et al. 2006), although a recent acceleration to 2.7 mm/year has been observed (Cazenave et al. 2002). The average wind speed along the Danube coast is between 5 and 6.5 m/s (Bulgakov et al. 1992). Winds from the north-east quadrant are dominant. Based on visual observations offshore Constantza, the wave regime is higly skewed (82%) arriving dominantly from the left hand side relative to the regional direction of the coast (i.e., north-east quadrant); for the 1972-1981 measurement period, the annual average significant wave height was 0.8 m, with an annual standard deviation of 1 m, and a mean period of 5 seconds (Giosan et al. 1999).

Danube Delta

Two distinct delta plain regions have been classically recognized (Antipa 1915) based on distinct morphologies defined by the distribution of channels, flood basins and lakes, and sand ridge geometries. The "fluvial delta", composed of the Tulcea, Chilia I and II, and Dunavatz lobes (Fig. 1; Giosan et al. 2006), developed in the former Danube Bay, which was probably sheltered by a barrier (Spratt 1860). The "marine delta" developed largely outside the Danube Bay and exhibits a clear wave-influenced morphology (Fig. 1). After reaching the barrier coast, Danube distributaries built four laterally offset lobes. Open-coast delta lobes are wave-dominated (Fig. 1), with the exception of the Chilia III, the youngest lobe, which shows primarily a fluvial-dominated morphology. The wave-dominated lobes exhibit an asymmetric morphology (Bhattacharya and Giosan 2003). Amalgamated beach ridges formed extensive beach ridge plains updrift (north) of (paleo)distributary mouths and are capped in places by dune fields with heights up to ~12 m (Fig. 1). Non-amalgamated beach ridges organize in barrier beach plains located

downdrift (south) of (paleo)distributary mouths. They resemble chenniers, with a succession of elongate sandy ridges separated by mud-filled marshy/lacustrine elongate depressions (Fig. 1). Beach ridges have been recognized to represent former shorelines of the delta (Bratescu 1922); their groupings in sets that are laterally juxtaposed allows the identification of the lobe development sequence for the "marine delta" (Fig. 1). Early interpretations of beach ridge juxtaposition patterns established a relative chronology for the open-coast lobes (de Martonne 1931; Zenkovich 1956). The St. George I was the first lobe built at the open-coast, followed by Sulina; subsequently, the St. George arm was reactivated developing a second lobe St. George II (Fig. 1). Chilia III is the youngest lobe built at the open coast. Based on AMS radiocarbon and optical dating, Giosan et al. (2006) have established that the "marine" part of the delta has started to develop no earlier than 5500 years BP.

Giosan et al. (1999) analyzed the longshore sediment transport pattern along the Romanian sector of the deltaic and associated lagoonal coast (Fig. 1) and found that the magnitude of the sediment drift was extremely high, with average values of ~900,000 m^3/year along sectors of the coast that are not sheltered from the eastern-northeastern dominant waves. Since 1856, when the European Danube Commission first surveyed the Danube delta coast in detail, the Chilia lobe experienced massive progradation (Fig. 1), although it has become increasingly wave dominated since 1940s (Giosan et al. 2005). The St. George lobe, with a new barrier (Sacalin) development, appears to be in a relative equilibrium, while the Sulina lobe has been reworked by waves.

MORPHODYNAMIC FEEDBACKS

Morphodynamics addresses the coupled adjustments between hydrodynamic processes, sediment transport, sedimentation, and morphology, and has become an established paradigm for studying coastal evolution (e.g., Carter and Woodroofe 1994; Wright 1985). Compared to other clastic coasts, the morphodynamics of deltas is complicated by the continuous or episodic delivery of freshwater and sediment to the coast by one or several rivers through one or multiple mouths. The solid load discharged by the river comprises of both suspended fine sediment within the river plume and coarse bed-load. Sedimentation of the coarse-grade sediments appears to be a dominant factor in river mouths evolution (Wright 1995) and further, in determining the facies architecture of wave-dominated deltas (Bhattacharya and Giosan 2003).

At the coast, delta forms a discrete subaqueous protuberance; in most cases, the protuberance is also expressed at the shoreline, which progrades relative to the adjacent coasts. From a hydrodynamical perspective, this deltaic "bulge" can be viewed as a morphological perturbation to the regional circulation system. Morphodynamic adjustments between the deltaic morphology and the fluvial and basinal hydrodynamics are most intense at the river mouths. Morphodynamics of wave-dominated deltaic distributary mouths is highly non-linear, involving multiple feedbacks between subaerial deltaic progradation, deposition on the subaqueous delta, current and wave hydrodynamics as well as wave-current interactions (Fig. 2; Giosan et al. 2005). These

feedbacks are particularly well expressed at the St. George mouth/deltaic lobe coast of the Danube delta.

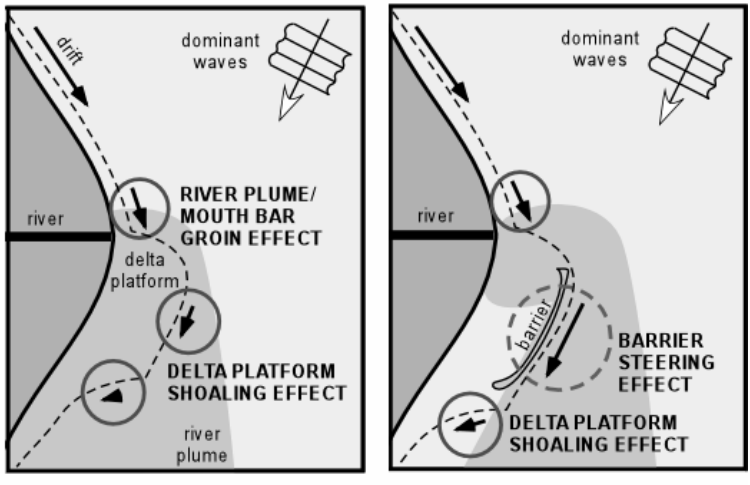

Fig. 2. Effects leading to sediment trapping on the subaqueous delta for a wave-dominated asymmetric deltaic coast with and without barrier. Convergence/divergence of the sediment drift is indicated by shortening/lengthening of arrows and continuous/dashed line circles, respectively.

Groin Effect

The morphology of the mouth shows that the submarine lobe built by the St. George branch is completely offset to the south of the mouth (Fig. 3; Constantinescu et al. submitted) in the direction of the longshore drift and the preferred orientation of the distributary's plume (Fig. 1; Bondar 1964). The coast updrift of the mouth is separated from the mouth by a subaqueous levee, it is multibarred, and evolves much like a beach on a sand-rich non-deltaic coast (Giosan et al., submitted; Vespremeanu-Stroe, A., Constatinescu, S., Ovejanu, I., Filip, F., Giosan, L., in prep., Impact of Danube high discharge events on the morphology and sedimentation at the mouth of St. George arm). Sands updrift of the St. George mouth are texturally more mature than the sands downcoast (Giosan 1993) suggesting again that fluvial material from St. George distributary does not contribute significantly to the updrift wing of the delta lobe, but instead has been built by sediment eroded from the Sulina lobe.

To explain the development of the subaqueous levee and the composition of the updrift coast, Giosan (1998) invoked the interaction between the river plume and the surface waves (Fig. 2). The convergence of the longshore sediment transport updrift of the river mouth due to this interaction has been termed as the hydraulic groin effect of the plume (Todd 1968; Komar 1973). This effect occurs regardless of the presence of suspended sediment in the plume. However, the increase in plume's density by addition of suspended sediment leads to an increase in the density contrast between the plume and the coastal waters, resulting in a more rapid breaking of the waves when they encounter the plume (e.g., Rodriguez et al. 2000). Furthermore, the subaqueous delta *per se* developed offshore the river mouth (including the subaqueous levee) also acts like an obstacle to the sediment drift (Fig. 2), much like an ebb shoal restricts bypassing of sediment downcoast (Bruun and Gerritsen 1959; Kraus 2000).

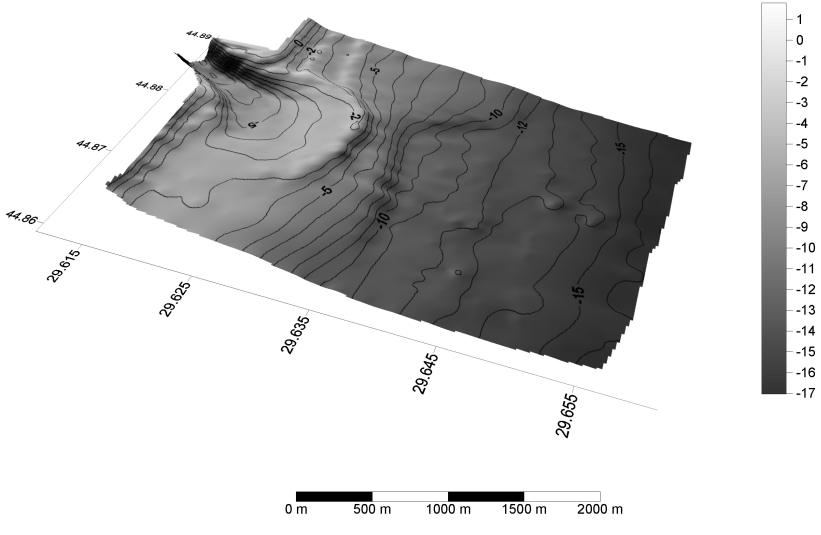

Fig. 3. DEM of the St. George mouth (after Constatinescu et al., submitted). Depth scale (in m) is on the left. Coordinates are in degrees latitude-longitude. Cartography by S. Constantinescu.

Where the longshore drift reaching the mouth is significant, a positive feedback loop develops between the progradation of the updrift coast caused by this combined groin effect of the river plume and subaqueous delta (Fig. 2), leading to a mouth that is progressively more sheltered from waves, which in turn, results in an increase in sedimentation on the subaqueous delta platform and less sand bypassing around the mouth. Sediment trapping within the delta is one of the net results of this feedback mechanism.

Shoaling Effect

On the updrift side of the mouth, the longshore drift obstructed by the river plume builds a deltaic beach ridge plain mostly of sediments brought in from updrift. Development of a subaqueous delta strongly offset to the opposite downdrift side of the mouth is accomplished with sediments brought in by the river. The asymmetry of this subaqueous delta relative to the river mouth activates another positive feedback between morphology and wave hydrodynamics (Fig. 3; Fig. 4a). The vast, shallow delta platform offset to the south of the river mouth shelters the mainland deltaic coast as waves dissipate almost completely over it. Although at a larger scale, this phenomenon is similar to the reversal of the wave-driven sediment transport on the downdrift side of ebb-shoals at inlets, due to the sheltering provided by the shoal itself (e.g., FitzGerald 1984).

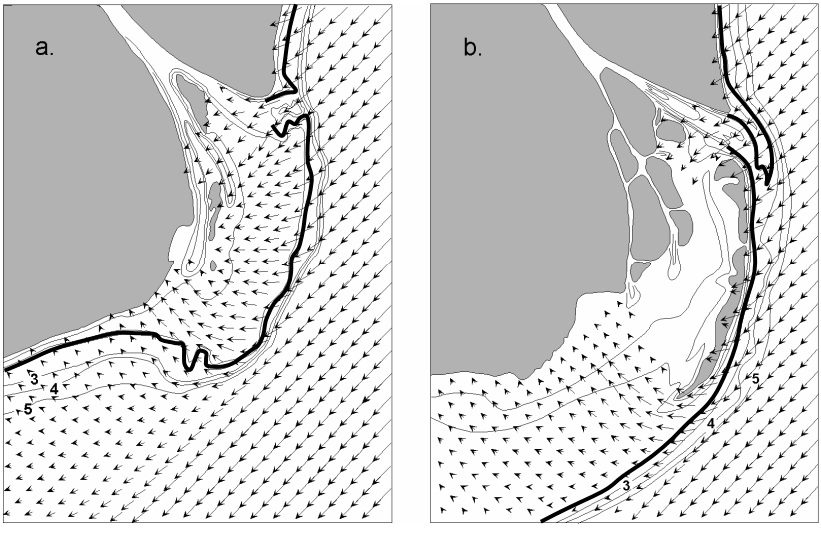

Fig. 4. Wave transformation of a typical wave field (NE from 30 m depth, with a 1 m height represent by initial arrow length and 4.5 s period; after Giosan et al. 2005) on bathymetries of St. George mouth: (a) 1856 and (b) 1935. Extent of subaqueous delta platform is shown by the 2 m depth contour (thick line). STWAVE (Smith et al. 2001) runs by F. Buonaiuto.

The convergence of the drift along the subaqueous delta is seen in modeling exercises (Fig. 4a) as waves refract and shoal less updrift of the mouth, where no the subaqueous delta is present, than downdrift of the mouth, where a massive submarine delta exists. This dynamic interaction between the morphology, with an ever expanding subaqueous delta driven by river sediment discharge, and the wave hydrodynamics acts as another positive feedback (Fig. 2), leading to larger entrapment of sands within the delta. The downdrift offset of the subaqueous delta promotes a stronger, more rapid dissipation of waves over it, than updrift of the mouth where no subaqueous delta is present; this results in more quiescent conditions favoring expansion of the subaqueous delta.

Barrier Steering Effect

Similar to other deltas (e.g., Rodriguez et al., 2000), the barrier at St. George mouth was probably built by waves reworking sediments delivered by the extreme river floods (at the end of 19th century; Bratescu 1922). By 1935, Sacalin barrier doubled in length (Fig. 4b) while rolling-over to the mainland under the influence of overwash and breaching processes (Giosan 1998). The submarine lobe appears to have continued to prograde into the dip direction until mid-19th century (Giosan et al., submitted), albeit slowly, but its slope became flatter as the delta platform retreated with the barrier island toward mainland. However, after Sacalin's emergence, the submarine lobe elongated to southwest (Fig. 4b) at a dramatic rate of over 200 m/year, compared to less than 100 m/year previously.

Wave transformations performed using the STWave model (Fig. 4b) for the case when a barrier is present show that the nearshore is steep along the barrier and incoming waves reach the coast of the island incompletely shoaled and refracted, inducing an intense longshore drift that is steered (guided) and redirected to the south by the barrier island shore (Giosan et al. 1999). This phenomenon, which we term barrier steering (or channeling) of the longshore drift, is another feedback loop developed between morphology and wave hydrodynamics (Fig. 2), contributing to the dramatic southward extension of the submarine lobe after Sacalin's emergence (Giosan et al. 2005). Development of a shallow subaqueous delta platform downdrift of the mouth allows deposition of mouth bars to be displaced offshore to the edge of the platform during floods, exposing them to a more intense wave activity. Waves elongate these bars into barrier islands fronting the delta platform via the longshore drift. As the emergent barrier becomes the new shoreline for the downdrift half of the delta, it activates this new feedback loop between the wave hydrodynamics and the delta morphology. Waves can no longer dissipate over the shallow delta platform; they reach the barrier shore incompletely refracted resulting in a steering of the longshore drift (i.e., intensification of the drift guided along the shore of the barrier); this in turn leads to a more rapid development of the subaqueous delta in the alongshore direction. This mechanism is also a positive feedback loop because as the subaqueous delta is built alongshore it advances gradually into deeper waters and, thus, immobilizes sand there rather than bypassing it to the downcoast. The barrier also keeps most of the river plume offshore of it and steers it downcoast. This steering forces sedimentation from the suspended load to aid development of the subaqueous delta at its downcoast tip into gradually deepening waters.

Shoreline Rotation and Instability

Morphodynamic models (e.g., Komar 1973; Cowell et al. 2003) identify the rotation of the delta shoreline as a phenomenon responsible for changes in the longshore drift along a wave-dominated deltaic coast. Assuming that the offshore wave regime is not significantly skewed to one side of the regional orientation of the coast, as a delta protrusion advances, the wave angle of attack increases along both sides of the mouth driving a larger drift away from the mouth. Changes in the drift magnitude can be

thought as a feedback loop between subaerial morphology of the delta and waves, which ultimately limits the growth of the deltaic protrusion.

For numerical modeling purposes, rotation is generally conceptualized as a two-dimensional problem by assuming that the nearshore profile is invariable for the entire deltaic coast. Even with such a drastic simplification, recent one-line modeling showed that, for the same sediment supply and wave energy, deltas prograde faster and attain a more pronounced aspect ratio when the proportion of high-angle waves is increased, for wave regimes that remain symmetrical relative to the regional orientation of the coast (Ashton and Murray 2005). In cases where the offshore wave direction is skewed toward one side of the coast, the shoreline instability on the downdrift delta wing is enhanced leading to the development of overwashing spits (Fig.5; Ashton and Murray 2005; Ashton and Giosan 2006). This seems to be the case for the St. George shoreline in 1856 (Fig. 1), when a spit was present on the downdrift wing of the lobe.

Fig. 5. Simulation result for deltas with a one-line model (Ashton et al. 2001; Murray and Ashton 2004;) with asymmetrical wave distribution (more waves from the left; after Ashton and Murray, 2005).

CONCLUSIONS

Based on a survey of the morphology of several deltas and/or deltaic lobes, Bhattacharya and Giosan (2003) introduced a conceptual model for wave influenced deltas that classifies them into symmetric, asymmetric and deflected types. We modify this model to account for the role played by the subaqueous delta in establishing the morphodynamic feedbacks discussed above (Fig. 5). In cases where the longshore drift is relatively strong at the river mouth asymmetry index >200; Bhattacharya and Giosan, 2003), it can interact with fluvial delivery of sediment leading to an asymmetry in the morphology and facies distribution of the delta (see above for St. George's case). Furthermore, the

shoreline instability on the downdrift delta wing could lead to the development of overwashing spits (Ashton and Murray 2005; Ashton and Giosan 2006). In the extreme case where the longshore drift is dominant over a relatively low or episodic fluvial discharge, a deflected delta develops (Fig. 6). In this case, the mouth of the river runs subparallel to the coast most of the time during the delta evolution with the river being separated from the sea by a sandy spit-levee (Wright 1985). Subaqueous deposition in this case is not localized and never reaches a volume large enough to have an effect on sediment trapping. The delta progrades as a series of randomly distributed, quasi-parallel sand spits and channel fills.

At river mouths where the net longshore sediment transport is small (asymmetry index <200; Bhattacharya and Giosan, 2003), wave-influenced deltas are symmetric in morphology and facies (Fig. 1). In this case, where the river discharges a significant suspended load besides sandy bed load, a subaqueous delta advances periodically in front of the mouth (Van Maren 2005) with beach ridges or barriers developing subsequent on both sides of the mouth. The mechanism to generate these barriers is still unclear: Van Maren (2005) believes that onshore sediment transport by wave asymmetry is responsible, while we would argue based on Giosan (1998) that river floods are probably the main mechanism for barrier nucleation and longshore transport is the mechanism responsible for their further development. However, in these cases of symmetrical deltas, both the groin effect and the barrier steering effect would apply acting on both sides of the mouth.

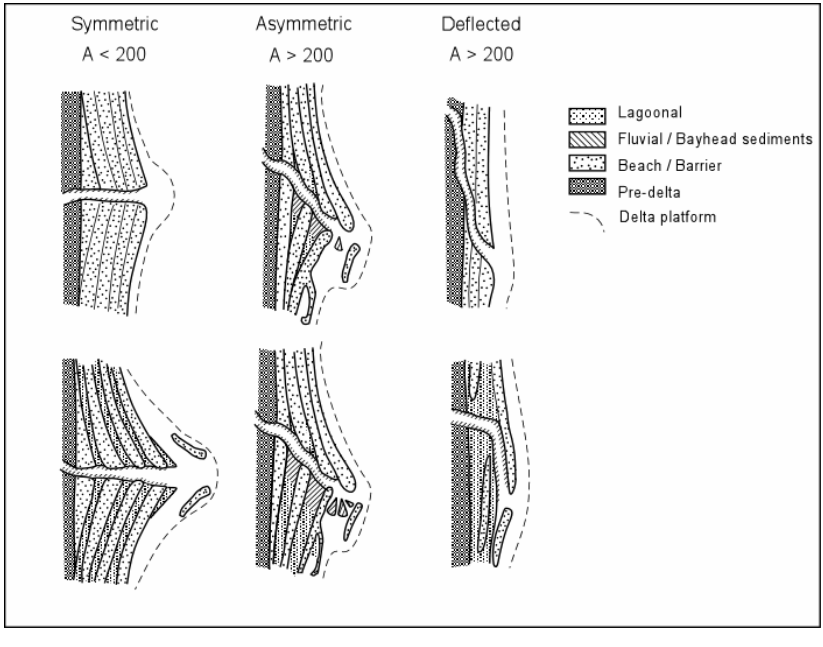

Fig. 6. Process diagram for wave influenced deltas (modified from Bhattacharya and Giosan, 2003). The upper row includes deltas preserving a lower proportion of fluvial mud compared to the cases in lower row that are more typical for rivers with high suspended load.

Asymmetric development of delta lobes has been documented around the world by Bhattacharya and Giosan (2003). In the case of the Danube delta, besides the St. George lobe, asymmetry with development of downdrift barrier occurs also on the previously fluvially-dominated Chilia lobe coast at several secondary mouths (Fig. 1), indicating a tendency to for river mouth to self-organize at various scales. The asymmetry in facies is also displayed by older marine lobes of the Danube delta (Fig. 1: Giosan et al. 2005) indicating a strong and sustained southward-directed longshore drift and suggesting that the wave-driven morphodynamics of the deltaic coast has always played a fundamental role on the entire development of the external delta plain. In conclusion, morphodynamic feedback mechanisms linked to the existence of a subaqueous delta appear to be essential in determining the morphology and facies of wave-dominated deltas and they should be considered in modeling exercises.

ACKNOWLEDGEMENTS

I thank Janok Bhattacharya, Andrew Ashton, and my Romanian colleagues S. Constantinescu, F. Filip, I. Ovejanu, and A. Vespremeanu-Stroe for good scientific discussions and help in the field and lab.

Abstract: Field observation on coastal and river mouth morphology change in Sri Lanka induced by 2004 Indian Ocean Tsunami has been carried in May 2005 by a survey team delegated by the Committee on Hydroscience and Hydraulic Engineering, Japan Society of Civil Engineers (JSCE). The survey area covers southeastern, southern and southwestern parts of Sri Lanka. It is found that dependent on the tsunami waver height and vegetation condition covering the sand surface, various level of erosion has occurred along the coast.

INTRODUCTION

Sri Lanka received extensive damage due to the Indian Ocean Tsunami caused by the earthquake that occurred off the coast of Sumatra in December 2004. In order to investigate this tsunami and related damages from the costal and hydraulic viewpoints, the Committee on Hydroscience and Hydraulic Engineering, Japan Society of Civil Engineers (JSCE) delegated its members whose majors are coastal engineering, river engineering, hydraulic engineering and hydrology (The Committee on Hydroscience and Hydraulic Engineering JSCE 2005). The present paper mostly

deal with coastal and river mouth morphology change in Sri Lamka, whereas other river-related topics, such as tsunami propagation into a river and bridge damages, have been reported elsewhere (Tanaka et al. 2007).

Several field investigations have already been carried out on tsunami run-up around the Sri Lankan coastal areas (Liu et al. 2005; Shibayama et al. 2005; Koibuchi 2005; Choi et al. 2005; Tomita et al. 2006). According to these results, it was over 10m along the east coast facing Sumatra, the source area of the earthquake. Although it gradually decrease from the southeast coast to the southwest areas, heavy human and physical damages were caused there, because there is a concentration of relatively large urban and resorts in these areas. For this reason, the rivers and the areas shown in Figure 1 were chosen as the subject of the field investigation by the JSCE survey team. Among them, the sites framed with rectangle will be dealt with herein, whereas survey results at the rest will be shown elsewhere (Tanaka et al. 2007).

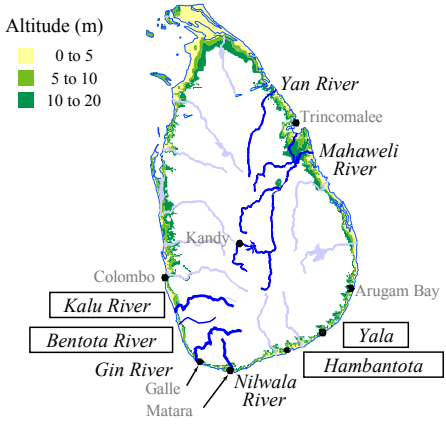

Fig.1. Study areas of JSCE survey team

SAND SPIT EROSION BY OVERTOPPING AT KALU RIVER MOUTH

The Kalu River is located in the central part of Sri Lanka, with the river basin area of 2,690m^2 with a length of approximately 100km. The Kalu River basin can be divided into the upstream valley region (Ratnapura District) and the downstream low-lying region (Kalutara District) (Komatsu et al. 2005). The difference in altitude between the mountainous land of the headwaters and the mouth of the river is approximately 2,250m, but since the altitude abruptly drops from 2,250m to 14m in the first 36km from the riverhead, much of the river channel has a steepness of only approximately 1/5,000. Along the sandy coast in Sri Lanka, elongated sand spit can commonly seen at river entrances due to predominant longshore sediment movement (The Committee on Hydroscience and Hydraulic Engineering JSCE 2004). The Kalu River is one of typical examples of Sri Lankan river with 3km long sand spit as seen in Figure 2.

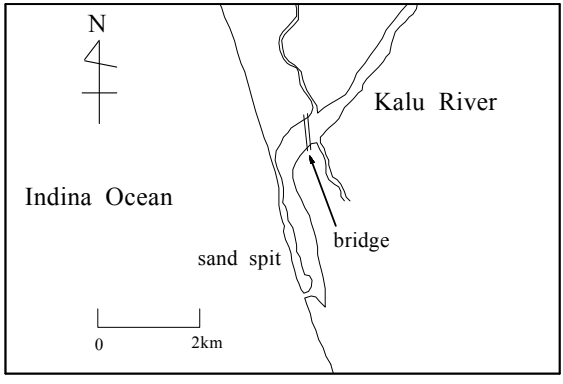

Fig. 2. Mouth of the Kalu River

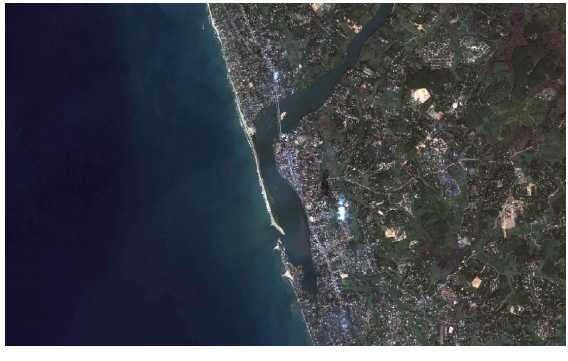

Photo 1. Satellite image at Kalu River before tsunami
(Hitachi Software Engineering Co., Ltd. 2006)

Photo 1 and Photo 2 respectively show satellite images before and during the Indian Ocean Tsunami around the sand spit at the Kalu River, located on southeast coast of Sri Lanka. Photo 2 indicates the instant of tsunami backwash, when the waterline in the upper part of the image advanced seaward by 340m. It is also seen that at the river entrance, strong seaward current from the river formed a flow pattern of turbulent jet spreading in the sea area. Although the breaching of the sand spit did not occur on the sand spit in Photo 2, the field survey revealed that there was slight erosion on the sand spit as seen in Photo 3 and Photo 4. Since the spit surface is covered with the dense vegetation, tsunami wave energy was dissipated during overtopping. It is noted tat sediment deposit in Photo 4 is similar to overwash caused by wind-generated waves (e.g., Ritchie and Penland 1990).

The tsunami height in coastal area in Kalutara, which is located near the river mouth, was 3.5m above MSL (Koibuchi et al. 2005). On the other hand, the field investigation showed that the height of the sand spit was 2.6m. From this result, it is estimate that the maximum of overflow depth was about 0.9m during the tsunami. In addition, it is reported by Tanaka et al. (2007) that the tsunami propagated further upstream along the Kalu River up to 20km from the river mouth, and that there is possibility of soliton fission occurrence in the river according to witness of workers along the river, although field data recorded by a water level gauge could not be obtained.

(Hitachi Software Engineering Co., Ltd. 2006)

Photo 3. Erosion of sand spit by tsunami overtopping

Photo 4. Sediment intrusion due to wave overtopping on Kalu River sand spit

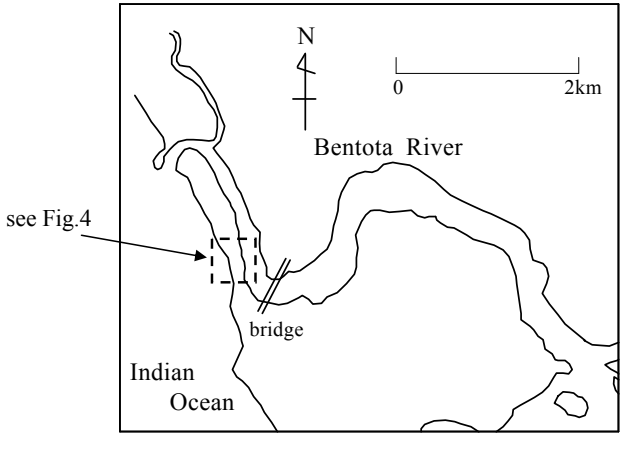

Fig. 3. Map of Bentota River mouth

SAND SPIT BREACHING AT BENTOTA RIVER MOUTH

Bentota is one of the most attractive beach resort area in Sri Lanka, located about 65km south of Colombo on the southwest coast. Similar to the Kalu River, predominant longshore sediment movement has formed a narrow spit of land almost 2km long as illustrated in Figure 3, which is the main beach area and resort hotel center for the Bentota area.

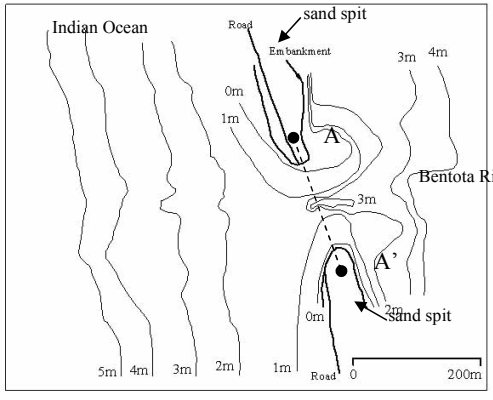

Fig. 4. Breached sand spit at the Bentota River mouth

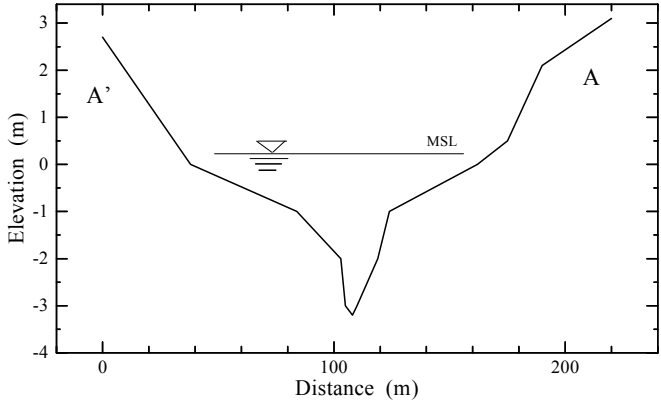

Fig. 5. Cross-section of breached sand spit (A-A' section)

On the contrary to the Kalu River, a sand spit at the Bontota River mouth was breached completely. Since several resort hotels are located near the tip of the sand spit beyond the eroded section, it was highly required to recover the access road going to the hotels. Thus, in order to make a plan for recovery work, detailed bathymetric survey has been performed immediately after the tsunami in January 2005, as shown in Figures 4 and 5. It is seen that very severe erosion occurred up to 4m deep below MSL and 200m wide, although there might have sediment intrusion into the breached section due to wind-generated waves before bathymetry surveying in January.

Photo 5. Recovery of breached sand spit by sand fill

When the present surveying was carried out in May 2005, the breached section has already been artificially filled with sand as shown in Photo 5.

SAND DUNE EROSION DUE TO OVERTOPPING IN HAMBANTOTA

Hambantota is a town in southern coastal area of Sri Lanka (Figure 6). It is also the capital of the district Hambantota in the Southern Province of Sri Lanka. Severe erosion of sand dune was observed at three places in the coastal area of Hambantota depicted in Figure 6. The tsunami height in this area was about 10m (Koibuchi 2005), whereas the sand dune is about 8m high. Thus, it is estimated that the overtopping water depth that caused severe erosion was about 2m above the dune crest.

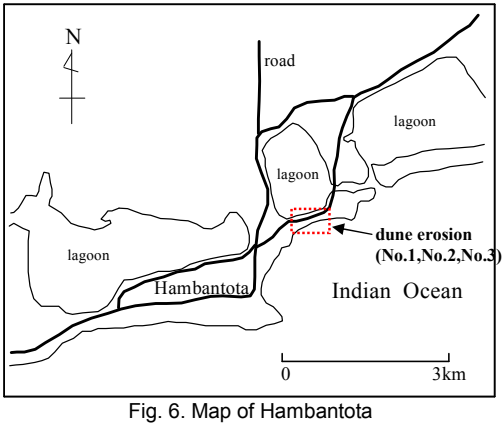

Fig. 6. Map of Hambantota

Photo 6. Dune erosion by tsunami overtopping (No.1)

Photo 7. Dune erosion by tsunami overtopping (No.2)

Each site of severe erosion will hereafter be referred to as No.1, No.2 or No.3 from the westernmost one. Photo 6 shows No.1 erosion taken from the lagoon side behind the dune. According to an interview to local people, although a scouring hole was created behind the dune at No.1 by strong overflowing water, it has already been filled up with debris caused by the tsunami disaster before the present field survey. Most severe erosion can be seen at No.2 site shown in Photo 7; a scouring hole filled with water still exists behind the dune as seen in Photo 8, with a partial landfill with debris after tsunami. Meanwhile, Photo 9 shows No.3 erosion, which is quite similar to No.2, but no scouring hole was formed.

Photo 8. Dune erosion by tsunami overtopping (No.2)

Photo 9. Dune erosion by tsunami overtopping (No.3)

EROSION IN YALA

Investigation for the damages in Yala National Park was carried out mainly around the beach where 50 people including 8 Japanese were killed (Figure 7). The height of the tsunami in this coastal area was 7-7.5m, judging from the withered leaves in the trees. Some trees were ruptured at around the height of 2m, and sand surface near the lodge and the trees was eroded up to the depth around 0.6m (Photo 10 and Photo 11).

Photo 12 and Photo 13 show the damages of the road, which also acts as an embankment for a small reservoir behind the lodge. The tsunami ruptured the embankment as can be seen in Photo 12. In the ruptured area in Photo 12, there was a channel on the beach that had not existed before the occurrence of the tsunami. The water in the channel was stagnant at the time of the field investigation, and its mouth facing the sea was already closed due to sediment deposit by waves.

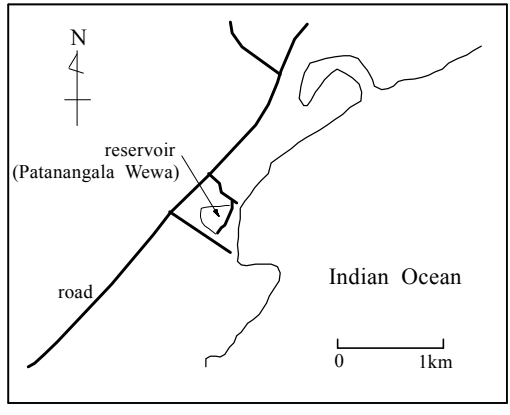

Fig. 7. Map of Patanangala in Yala area

Photo 10. Beach erosion by tsunami in Yala

Photo 11. Beach erosion around a tree

Photo 12. Breaching of reservoir embankment

Photo 13. Severe erosion of seaward surface of embankment

It is noted that shoreward surface of the embankment was more severely eroded than landward surface as illustrated in Photo 13. The mechanism of such a different erosion patter on the both surface may be as follows:

(1) Figure 8(a) illustrates on-offshore cross-section from the sea to the reservoir before the tsunami occurrence.
(2) During the run-up of tsunami waves, water level rise occurred too quickly to allow erosion on the both surface of the embankment. (Figure 8(b))
(3) After reaching the highest water level, the water stored in the reservoir drained gradually, while the water level in the sea had descended more quickly. The large difference of water level inside and outside of the reservoir caused strong overflowing current, resulting in severe erosion on the seaward surface of the embankment as seen in Photo 13 (Figure 8(c)).

(4) After breaching of the embankment due to overflow, a channel connecting the reservoir and the sea was created by the strong seaward current (Figure 8(d)).

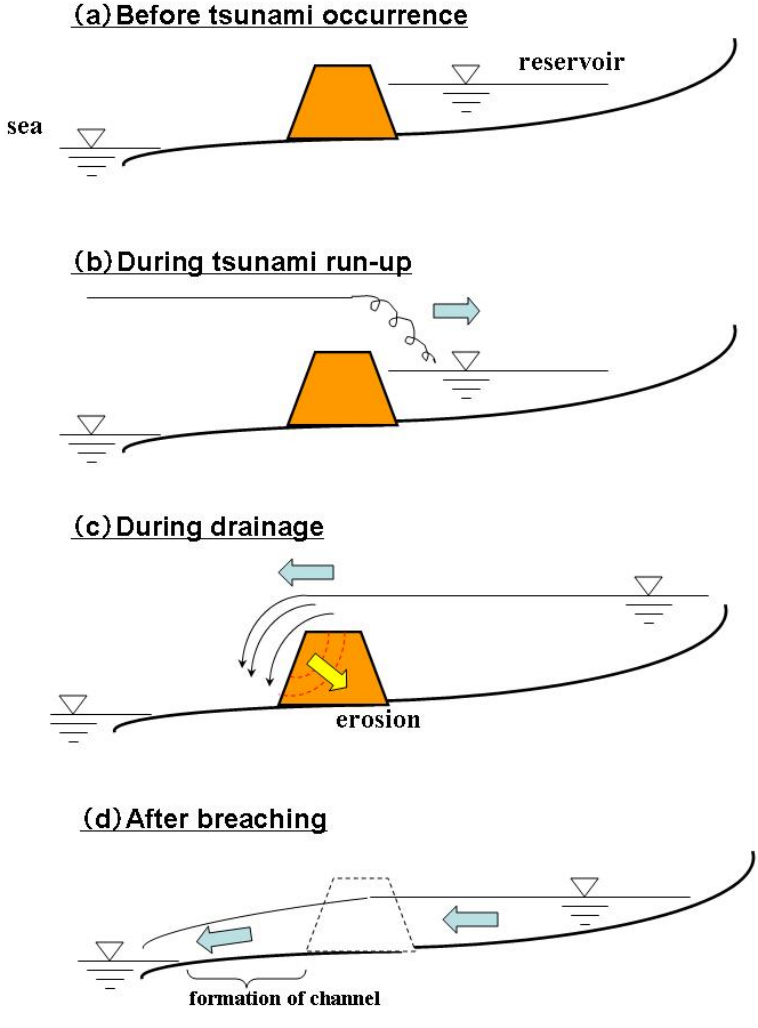

Fig. 8. Mechanism of erosion on seaward slope surface of embankment

CONCLUSION

This study highlights erosion of sandy coast and sand spit at a river mouth in Sri Lanka due to the 2004 Indian Ocean Tsunami, based on a field investigation by JSCE survey team.

At the Kalu River mouth, slight erosion was induced on the sand spit by tsunami overtopping, while at the Bentota River mouth, the spit was breached by strong current by tsunami. Such a different response in river mouth morphology change may depend on the tsunami height, the geological formation around the river mouth and on the characteristic features of the river. Furthermore, dune erosion in Hambantota coast and embankment erosion in Yala are surveyed. In particular, a role of return flow is discussed in connection with slope erosion of embankment in Yala.

ACKNOWLEDGEMENTS

The authors would like to express their grateful thanks to Foundation of River and Watershed Environment Management for their financial support to the present field investigation. The authors' appreciation should be extended to Lanka Hydraulics Institute (LHI) for their kind offer of the bathymetric data, Japan International Cooperation Agency (JICA) and various other organizations and institutions for their kind assistance in conducting the field investigation.

Abstract: Recent multi-beam, backscatter, and bottom sediment data demonstrate that a large sand sheet was formed in the inner shelf by the reworking of the Merrimack River lowstand delta and braid plain (12 kya) during the Holocene transgression. Seismic data reveal the presence of widespread channel cut-and-fill structures landward of the delta suggesting that much of the sand sheet consists of braided stream deposits. These features map into several sets of cut-and-fill structures, indicating the avulsion of the primary river channels, which creates the lobes of the paleo-delta. Truncations of these cut-and-fill structures suggest that the braid plain deposits were probably reworked during the Holocene transgression and may have contributed sand to developing barriers that presently border the Merrimack Embayment.

INTRODUCTION

Global warming is causing increased melting of ice caps and mountain glaciers and the expansion of surface ocean waters, which is accelerating sea-level rise (SLR). The 2001 IPCC Report predicted SLR by 2100 to be between 48 and 88 cm (Church 2001). Concurrently, riverine supply of sediment to the coastal zone in northern latitudes has diminished due to dam construction and natural depletion of glacial sediment sources. The lack of new sand sources has led to pervasive beach erosion and shoreline retreat not only in New England, but throughout the US and the world. Thus, the potential sand reservoirs of the inner continental shelf and the mechanisms of sand exchange between beaches and barriers and the offshore are vital topics of research for the coastal community (Pilkey and Field 1972). Presently, the pathways, volumes, and net direction of sand exchange between the nearshore zone and offshore (the inner shelf) are not known (Morton et al. 1994). However, if shoreface sand is being lost to the inner shelf sand sheet, as suggested by several recent studies (e.g. Gayes et al. 1997; Swift and Thorne 1991), then the coastal zone and the populations and infrastructure it supports ($3 trillion along the US East and Gulf Coasts alone (USGS 2006)) may be under serious threat from accelerated SLR.

To investigate the reworking of nearshore sediments in a regime of accelerated SLR, it is crucial to understand the processes that govern the origin and distribution of sand bodies on continental shelves. To understand the source and behavior of these sediments, it is important to understand both their sedimentologic history and the present processes driving sediment transport. This paper presents a preliminary analysis and interpretation of nearly 4,000 km of shallow seismic data from the nearshore region of the Merrimack Embayment in the western Gulf of Maine and provides a sedimentologic framework for developing an evolutionary model of the 34 km-long barrier system within the embayment.

Physical Setting

The Merrimack Embayment in the Gulf of Maine is a mixed-energy, tide-dominated coast, extending from Cape Ann in northern Massachusetts north to Great Boar's Head in New Hampshire (Figure 1). It is the longest barrier island chain in Massachusetts (approximately 34 km long) with a backbarrier system consisting primarily of marsh and tidal creeks that often open to small bays near the inlet openings (Smith and FitzGerald 1994). The barrier islands are pinned to bedrock or glacial promontories with the tidal inlets are situated in drowned river valleys (FitzGerald et al. 2002). The Merrimack River heads in the White Mountains of New Hampshire with a catchment of approximately 13,000 km^2. The river drains regions dominated by granitic plutons, the weathering of which produced extensive sandy glacial deposits. Sediments discharged from the mouth of the Merrimack are subsequently reworked in a southeasterly alongshore direction as a result of strong northeasterly storm waves associated with Northeasters (FitzGerald et al. 2002).

Stone et al. (2004) used a variety of data to construct a sea-level curve that incorporates a rheological model for the region (Koteff et al. 1993). Following the Wisconsin sea

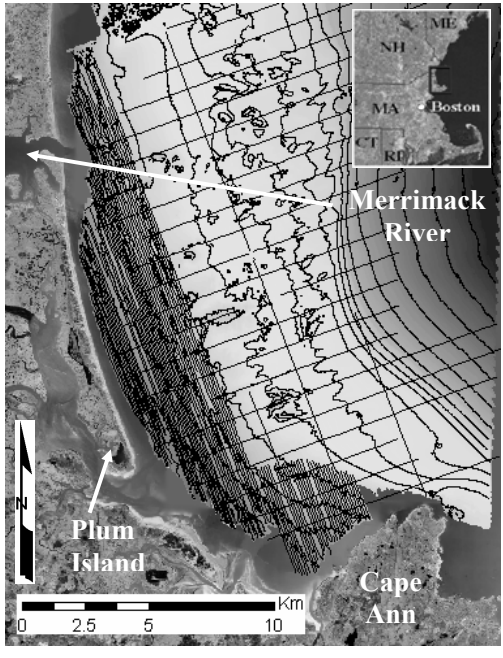

Fig. 1. Study area in northern Massachusetts. Offshore study area shown in grayscale bathymetry with black isobath lines (contour interval = 5m). Parallel track lines (black) run shore parallel with shore normal tie lines.

level highstand (+33m) at ca.17,000 cal yr. BP, this region experienced rapid isostatic rebound resulting in a -45 m lowstand at 12 kya. During this time, the Merrimack River deposited a large delta that is currently located approximately 6 to 7 km offshore and trends parallel to the present coast (Oldale et al. 1983; Edwards 1988). The paleo-delta is 20 km long, 4 to 7 km wide, up to 20 m in thickness and contains about 1.3 billion m^3 of sediment (Oldale et al. 1983, 1993). Earlier seismic records showed that eastwardly-dipping delta foresets were truncated during the early Holocene transgression of this region (Oldale et al. 1983). Much of the surface of the delta exhibits a ravinement surface that is inferred to be a time transgressive unconformity formed during the Holocene marine transgression and subsequently overlain by beach or bar deposits (Oldale et al. 1983). Edwards (1988) described these sandy deposits as a discontinuous, planar, palimpsest shelf surficial sand sheet of varying thickness and in disequilibrium with present-day processes. Edwards (1988) also reported "linear ridges" that he hypothesized formed during the transgression or as post-transgressive features; i.e. either degraded barriers that formed as sea level rose and sediments were reworked in an onshore direction or active shoreface-connected ridges that form in the present day in response to peak flow conditions during northeasters.

Several papers have since reexamined the formation and evolution of the barrier system in relation to the offshore paleo-delta (Oldale et al. 1993; FitzGerald et al. 1994). However, these efforts have relied on the interpretation of limited (2 km spacing) seismic data and only 4 vibracores that provided little information on the detailed morphology and nature of the sub-bottom stratigraphy. Recent multi-beam, shallow

seismic, and bottom sediment data provide new evidence for the partial reworking of the paleo-delta deposits that continues to the present time.

METHODS

During February - March 2004, September 2005, and September 2006 the sea floor of the Merrimack Embayment (323 km^2 area) from the nearshore zone to about 17 km offshore was mapped using single beam, multibeam, and side scan sonar. Additionally, 3,857 km of shallow seismic track lines were taken in the study area using an Edgetech SB-512 CHIRP sub-bottom profiler. Shallow seismic track lines were primarily oriented shore parallel and were taken within the first 1-2 km of the present shoreline (depths of less than 30 m) with 100 m spacing between lines (Figure 1). Several sets of shore normal lines with approximately 750 m spacing were also taken.

Analysis of backscatter data was used to select the position of more than 100 bottom videos and sediment samples, collected simultaneously with the seismic data. Videos and grain size data were used to ground truth the backscatter image, allowing identification of features such as the sand sheet and areas in the vicinity of bedrock outcrops. Shallow seismic data were georeferenced and analyzed using ESRI's ArcGIS Desktop software package. Cut-and-fill features in the shallow seismic profiles were traced across profiles and mapped throughout the study region.

RESULTS

Shallow Seismic Surveys

The locations of shallow seismic profiles analyzed in this section are given in Figure 2. Shallow seismic data from the paleo-delta region exhibit pervasive shallow, seaward dipping reflectors that become tangential with the sediment bottom in an offshore direction. In most cases, the surface of the clinoforms are truncated and overlain by thin flat-lying deposits. Track lines normal to the coast show a consistent pattern of seaward dipping clinoforms and a pronounced ravinement surface, confirming previous observations that the upper portions of the delta were eroded during the Holocene transgression (Figure 3). However, it is still not known how much of the upper delta was removed during the reworking process.

Shore parallel profiles reveal the existence of channel cut-and-fill structures in the region onshore of the paleo-delta. These features trend in an E-W direction and are commonly several meters in thickness, varying in width from about 25 to several hundred meters. Several large sets of cut-and-fill features range from 500 to 600 m wide and 10 to 15 m deep. Shore normal seismic lines confirm the nearly shore normal orientation of these features. In some locations, the orientation and geometry of these features closely resembles that of underlying bedrock surfaces (Figure 4). Several of the cut-and-fill features exhibit structures interpreted as the result of river terracing; i.e. sets of parallel horizontal reflectors on either side of a deeper incised channel (Figure 5). Within any given region, the spatial distribution of cut-and-fill features varies from a highly organized network to a random distribution. However, several examples exist of a single structure retaining an identical geometry across numerous parallel profiles representing hundreds of meters in a shore normal direction (Figure 6).

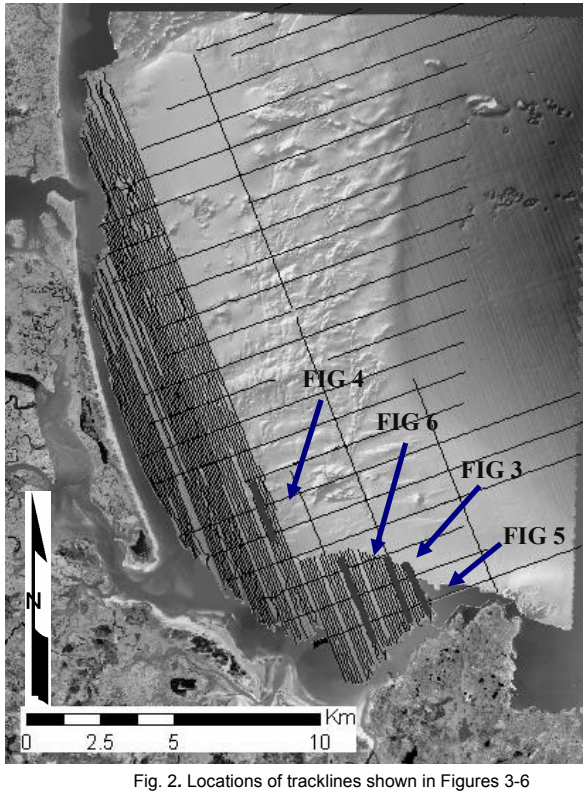

Fig. 2. Locations of tracklines shown in Figures 3-6

A continuous, near-horizontal reflector, interpreted to be an erosive ravinement surface, overlies the cut-and-fill features. This layer is in turn overlain by several (3-8) meters of sediment, interpreted to be Holocene deposits (Figure 3). Generally, the thickness of this Holocene layer decreases in a shoreward direction, resulting in a shallowing of the ravinement surface in the profiles. In the nearshore profiles the channel cut-and-fill features loose their distinct character and are not ubiquitous. In the most nearshore profiles, the cut-and-fill features breach the subsurface and appear to be within a zone of active reworking. These changes in the character of the sub bottom likely reflect reworking during the Holocene.

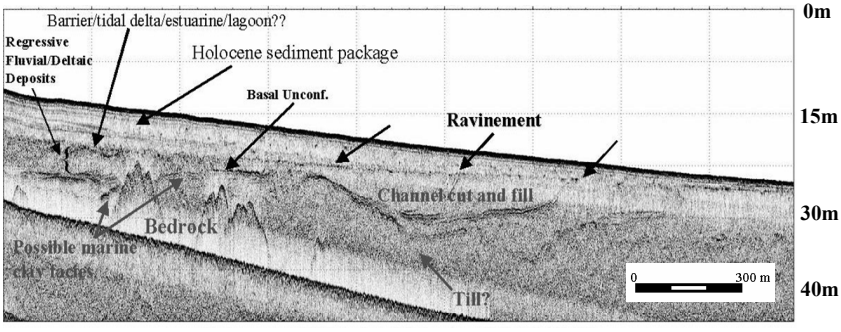

Fig. 3. Sample shallow seismic line indicating general features seen in both shore normal and shore parallel transects (Seismic shot L101f1).

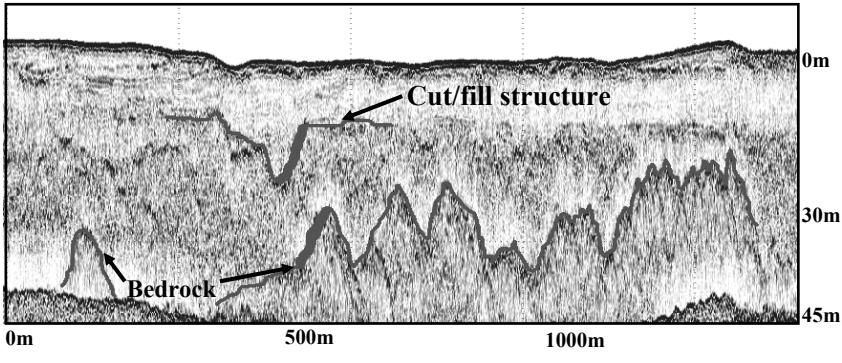

Fig. 4. Sample shallow seismic line indicating a channel cut-and-fill structure overlying bedrock. The bolded lines highlight the close correlation between the geometry of the bedrock and the side of the channel (Seismic shot L5f2).

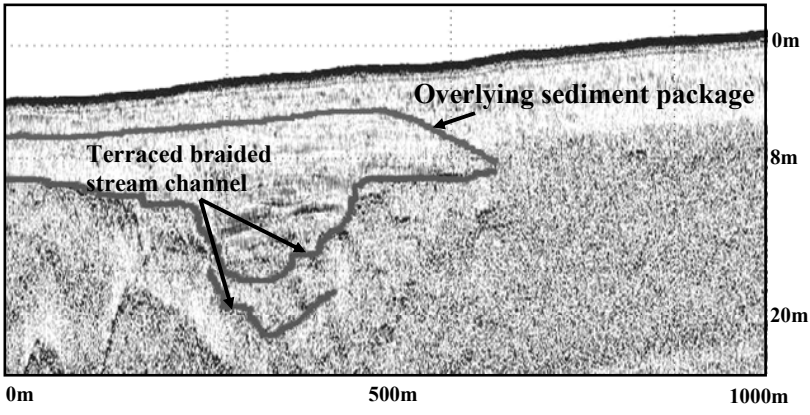

Fig. 5. Evidence of terracing in channel cut-and-fill structures (Seismic shot L106f1).

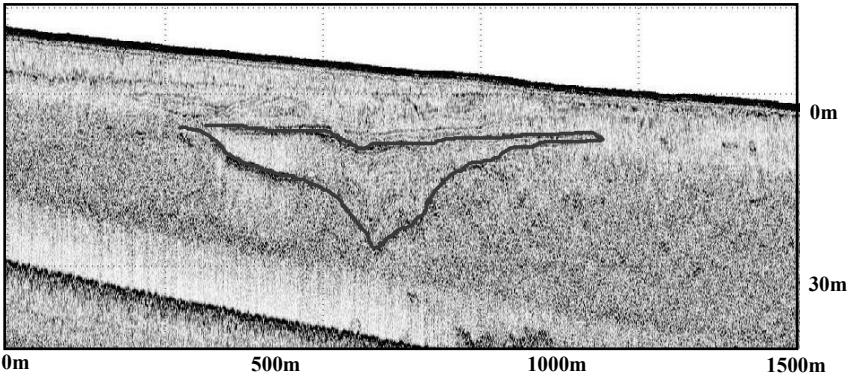

Fig. 6. Example of typical channel cut-and-fill feature mapped near Cape Ann. The form exhibited in this feature is easily traced across several parallel track lines (Seismic shot L97f5).

Channel cut-and-fill structures identified in sub bottom profiles were mapped onto a surficial bathymetric map of the Merrimack Embayment (Figure 7). Three sets of shore normal channel cut-and-fill structures are identified. The southern set continues towards the Parker River Inlet at the southern end of Plum Island (Set A, Figure 7). A central set tracks towards the northern end of a remnant drumlin at the southern end of Plum Island (Set B, Figure 7). The northern-most set trends toward the center of Plum Island near a

low marshy region (Set C, Figure 7). Additionally, at the very southern end of the Merrimack Embayment there is some evidence of a forth set of cut-and-fill features that trend towards the present-day Ipswich River Inlet.

ANALYSIS AND DISCUSSION

Braided Stream Deposits

Seismic profiles of the region of the Merrimack Embayment inshore of the paleo-delta reveal an irregular basement overlain by channel cut-and-fills, flat lying reflectors, and acoustically transparent regions. Bedrock outcrops extending through the sediment surface increase in extent to the north. Our records and those collected by Oldale et al. (1983) suggest that glacial and bedrock topography strongly controlled the course of the river system while it was delivering sediment to the lowstand delta. Presently, bedrock outcrops continue to stabilize much of the lower river and estuary region.

The earlier studies of the Merrimack Embayment (Oldale et al. 1983; Edwards 1988; Oldale et al. 1993) did not report the pervasive channel cut-and-fill features characterizing the region landward of the delta. However, the channel cut-and-fill structures observed in our seismic profiles suggest that the delivery system conveying sediment to the delta consisted of a braided stream complex. Moreover, the size and morphology of the paleo-delta suggest that the delta was deposited in a series of lobes indicating significant river migration and/or avulsion (Figure 7). Present-day topographic evidence supports this conclusion. A ridge landward of the backbarrier marsh west of Plum Island may have controlled drainage landward edge of potential drainage (Figure 7).

Edwards (1988) postulated that distributary drainage through the paleo-Merrimack occurred at or near the present-day mouth of the Merrimack River. Sediment would have been deposited along northern end of paleodelta and then reworked to the south to form the southern lobe. However, evidence from this study indicates that paleo-drainage of the Merrimack River was indeed to the south through various avulsion channels. Few cut-and-fill features are seen near the present-day mouth of Merrimack River; however thick (>20 m) layering of sediment overlying bedrock indicates a large input of sediment from the present-day Merrimack River.

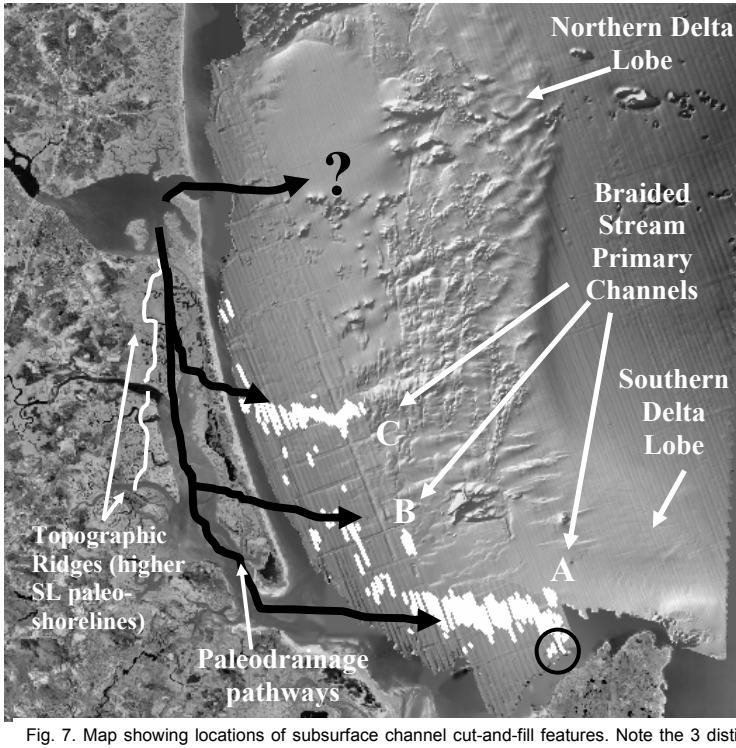

Fig. 7. Map showing locations of subsurface channel cut-and-fill features. Note the 3 distinct sets of features denoting possible locations of braided streams, labeled A-C. The possible forth set of features is circled just north of Cape Ann. Edwards (1988) identified a braided stream complex directly offshore of the present-day mouth of the Merrimack River, however, no channel cut-and-fill features were mapped in that location from data in this study.

Formation of the Merrimack Embayment Barriers and Subaqueous Sand Sheet

Surficial sediments in the Merrimack Embayment have been substantially reworked during the Holocene, as indicated by the existence of a broad sand sheet (18km x 7km) extending from approximately 2 km north of Cape Ann to 4 km north of the mouth of the Merrimack River and from the nearshore (-10 m) to the paleo-delta front (-45 m). This sand sheet consists of silty sand in the outer reaches near the delta and coarse-grained sand further inshore. An expansive (32 km^2), featureless coarse-grained sand deposit is centered off the Merrimack River. Fine-grained sand overlies this deposit in many locations, although it is not continuous, and forms asymmetrical bedforms (Hein et al. 2007).

Notably in shoreward regions, channel cut-and-fill features are truncated suggesting that the braided stream deposits themselves were reworked during the Holocene marine transgression. Shallow seismic profiles show a basal unconformity located immediately below a set of regressive fluvial / deltaic deposits. Capping these deposits is a pronounced ravinement surface, which extends from the delta to the nearshore of the Merrimack Embayment, indicating extensive reworking of the fluvial-deltaic lithosome during the Holocene transgression.

Granularmetric analyses indicate that the delta sediments are bimodal containing poorly sorted silt and fine sand components, which is characteristic of fluvio-deltaic sediments (Giosan and Bhattacharya 2005). Cores through the paleo-delta generally show intercalated silty clays and fine to medium silty sands. The upper 20 to 30 cm of the cores consists of medium sand with coarse pebbles and shell fragments (Edwards 1988). The cores that extend between 3 and 8m confirm that the delta is composed largely of fine-grained sediments, unlike the sediments that comprise the sand sheet.

The sediments composing the broad Merrimack Embayment sand sheet are likely sourced from the braided stream deposits that were reworked during the Holocene transgression and not from the delta itself. Furthermore, though FitzGerald et al. (1994) postulate that the reworking of paleo-delta sediments contributed to the formation of Plum Island and the other barriers in the Merrimack Embayment, it is likely that these coarser braided stream deposits were the true offshore source for any barrier sediments. The sand sheet and barriers were likely generated during the Holocene transgression when shoreface processes reworked both delta and braided stream deposits. Additional sand may have been derived from the Merrimack River (FitzGerald 1994).

CONCLUSIONS

1. New shallow seismic data indicate a widespread system of channel cut-and-fill structures inshore of the Merrimack paleo-delta having a depth of 5-10 m and an apparent width of 25 – 300 m.

2. The channel geometry and spatial extent of the cut-and-fill features are consistent with those of braided streams. Several distinct sets of channel cut-and-fill features represent avulsion of the primary distributary channel of the paleo-Merrimack River.

3. This braid plain system was responsible for delivering a large volume of sediment (1.3 billion cubic meters) to a multi-lobate lowstand delta during late Pleistocene (12 kya, at -45 m, Oldale et al. 1983).

4. Sediment comprising this braid plain was reworked during the Holocene transgression and likely contributed sediment to the present day barrier system in the Merrimack Embayment.

ACKNOWLEDGEMENTS

This study was funded by the Minerals Management Service of the US Department of the Interior and Massachusetts Coastal Zone Management. The authors would like to extend our appreciation to Bror Jonsson of Boston University and Brian Andrews, Seth Ackerman, and the rest of the team at the USGS Science Center for Coastal and Marine Geology in Woods Hole, MA for their assistance in the collection and processing of the raw data. Additional thanks to the crews of the R/V Connecticut (Groton, CT) and the F/V Venture (Gloucester, MA).

THE USE OF HISTORIC TOPOGRAPHY FOR THE CHARACTERIZATION OF TIME-DEPENDENT GEOMORPHIC CHANGE AND SEDIMENT DELIVERY

David A. Jaffe[1]

Abstract The Santa Clara River, draining one of the largest watersheds in Southern California (1,634 sq-mi [4,232 sq-km]), is a major source of coastal sediments. Future development on the watershed has the potential to alter sediment delivery and cause erosion both along the coast and within the River. Unfortunately, long-term, historic sediment transport data is unavailable for Santa Clara River. Because of the paucity of the available data, an alternative means of determining a baseline geomorphic and sediment delivery condition is needed.

Time dependent geomorphic change was calculated based on topographic data dating from 1906 to 2005. At least one cross-section was chosen for each hydraulically distinct subreach of the study area. A sectional analysis based on elevation change of the bed (area computation of the section) was conducted to determine time dependent geomorphic change. Analysis finds that sections show geomorphic change between 1947 and 2005 ranging from -8.0 to 3.1 feet (-2.44 to 0.95 m).

INTRODUCTION

The following technical investigation provides a detailed and focused evaluation of the long-term stability of the Santa Clara River for the reach between Interstate 5 and the Los Angeles-Ventura County Line (7.0 miles [11.3 km])(Figure 1). The Santa Clara River fluvial system extends from Acton, California in the east to the Pacific Ocean, the River's natural terminus, in the west. The River is a major source of coastal sediments along Southern California beaches. Both historical and future development along the River within the study reach has the potential to modify the fluvial response of the watershed through changes in the runoff and reduction in the sediment supply from the developed areas. Until approximately the 1960's, development in the watershed upstream of the study reach was primarily agricultural, however, more recent development has been

suburban housing and commercial uses. Future modifications to the river system and uplands have the potential to modify the fluvial operation of the floodplain and cause changes to the stream mechanics. These changes to fluvial mechanics have the potential to impact the delivery of sediment to the coast. The intent of this analysis is to evaluate changes in the floodplain fluvial operation over the long-term, and estimate the extent to which these changes have been a function of riverine and uplands development.

Modifications to the river system are measured as bed adjustment in feet. Positive adjustment indicates bed aggradation while negative adjustment indicates bed degradation. Of the several types of adjustment, only long-term adjustment is considered in this study. Long-term adjustment consists of fluvial processes that occur over many rainy seasons and contribute fluctuation of bed elevation of a river or creek.

The primary objective of this study is to develop the technical engineering analysis to assess river bed impacts from potential modifications of fluvial operation from long-term watershed development west of Interstate 5.

PREVIOUS STUDIES

Three sediment transport studies have been conducted within the study reach between Interstate 5 and the Los Angeles/Ventura County line in the last 25 years. The first study conducted by Sikand Engineering was submitted in June 2000, and revised November 2004. The primary focus of the study was the long-term degradation of the river bed. Grain size distribution plots indicate poorly graded sand with gravel and a D_{50} of approximately 1 mm in the vicinity of the Castaic Creek confluence. The study found that for seven subreaches in the present condition, the bed is in steady state, but that the proposed conditions are expected to cause minimal degradation (an average of one foot [0.3 m]) in some subreaches and minimal aggradation (an average of three feet [0.9 m]) in some subreaches. The study also analyzed the historical record of gage data at the county line from 1953 to 1993. By comparison, USGS data (*Sediment Discharge in The Santa Clara River Basin, Ventura and Los Angeles Counties, California*) notes in Table 3 that in 1971 at 1470 cfs (41.6 cms), 99% of the transport was silt at the county line. It is important to note that the results of this study were not accepted by Los Angeles County Department of Public Works (LADPW), and the comments on the last review of the study in 2004 were not addressed.

The second study produced by Simons, Li, and Associates (SLA) and submitted November 1990, sought to provide information for flood and fluvial process management in the Santa Clara River from Soledad Canyon to Castaic Creek. The study included multiple tasks including data collection, quantitative analysis and mathematical modeling, and other assignments. For the portion of the River downstream of Interstate 5, the bed was found to be adjusting between -0.1 to +1.0 feet (-0.03 to 0.31 m). The study notes that the River appears to be in “pseudo-equilibrium” and “shows no trend toward either aggradation or degradation and significant lateral migration of the channel is not apparent.” The SLA report was reviewed in detail by LADPW and response to comments made, however, the report was not revised to obtain final LADPW approval.

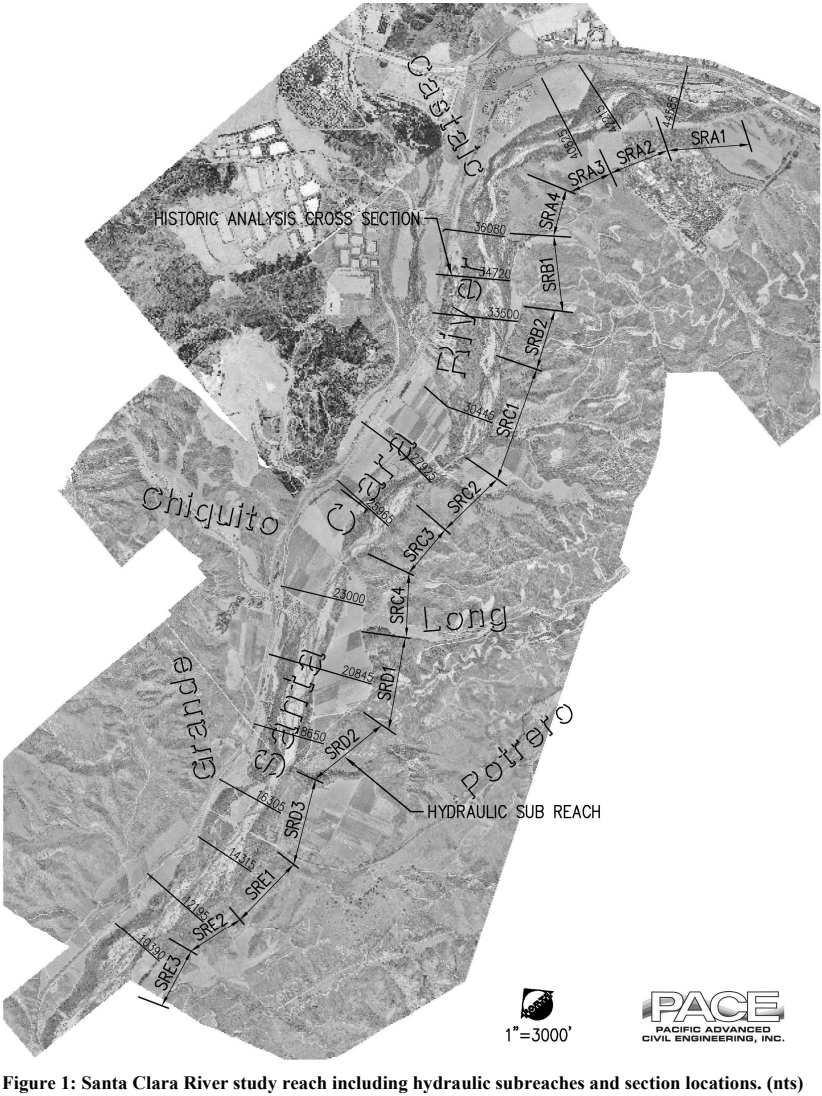

Figure 1: Santa Clara River study reach including hydraulic subreaches and section locations. (nts)

The final study was conducted by the United States Geological Survey and completed in August 1979. The study sought to determine the sediment discharge in the Santa Clara

River Basin in Los Angeles and Ventura Counties using sediment trap (1968-1975) and historical discharge data (1928-1975). Sediment data was collected for the period 1967 to 1975 at the Los Angeles/Ventura County line. During the short-term period (1968-1975), total sediment discharge was 63.5 million tons (5.76×10^{10} kg), 59.5 million tons (5.43×10^{10} kg) of which was carried in suspension. Coarse sediment accounted for 28% of the total sediment discharge (17.7 million tons [1.61×10^{10} kg]). Transport of the majority of sediment occurred during only a few days of flood flow each year (55% of the total sediment within 2 days and 92% within 53 days). Sediment deposited in reservoirs resulted in a 6% reduction of sediment to the River basin during the historical period (1928-1975) and 12% during the period most affected by dams (1953-1975). Castaic Creek interception of sediment reduced the amount of sediment in the River by another 2% from 1928-1975 and 4% from 1953-1975. It is not clear how these reductions are directly related the completion of the Castaic Creek Dam because it was not completed until 1971.

SEDIMENT CHARACTERIZATION AND ANALYSIS

To characterize the sediment of the river bed and by extension the possible bed load of sediment during discharge events, a sediment grain size analysis was conducted. The goal of the analysis is to gain a statistical representation of the size distribution of soil components of the river bed.

Sediment collection for the Santa Clara River along the study reach was conducted by Allen Seward Engineering Geology, Inc. Eighteen samples were collected along the river with a five samples taken at the tributaries. The relevant sampling locations are compiled in Table 1. All sampling was conducted using grab samples of the upper foot of the active or recently active portion of the bed. At least three samples at different locations within a sampling station were taken at each River sampling location.

For this study, no fine material is included in analysis because fine material is generally transported as wash load, which is not of concern here. Distribution data has been averaged on a station by station basis. Averaging is accomplished by taking the mean of the three samples from a given station. Averaging provides a single representative sediment grain size distribution for a given station that can be used for analysis. Plots of the mean grain size distribution for each sampling station are presented in Figure 2.

A review of the raw gradation curves indicates that most samples are comprised of poorly graded sands with gravels and silts. The D_{50} values for all samples ranged from 0.25 to 4.67 mm with an average of 0.80 mm. The averaged D_{50} values range from 0.50 to 1.00 mm. Additionally, previous SLA study noted above also found similar sandy characteristics, however, the average grain size was found to be approximately D_{50}=1.30 mm, somewhat more coarse that the current sampling. An armoring layer was not observed in field measurements, Seward field studies or SLA boring logs.

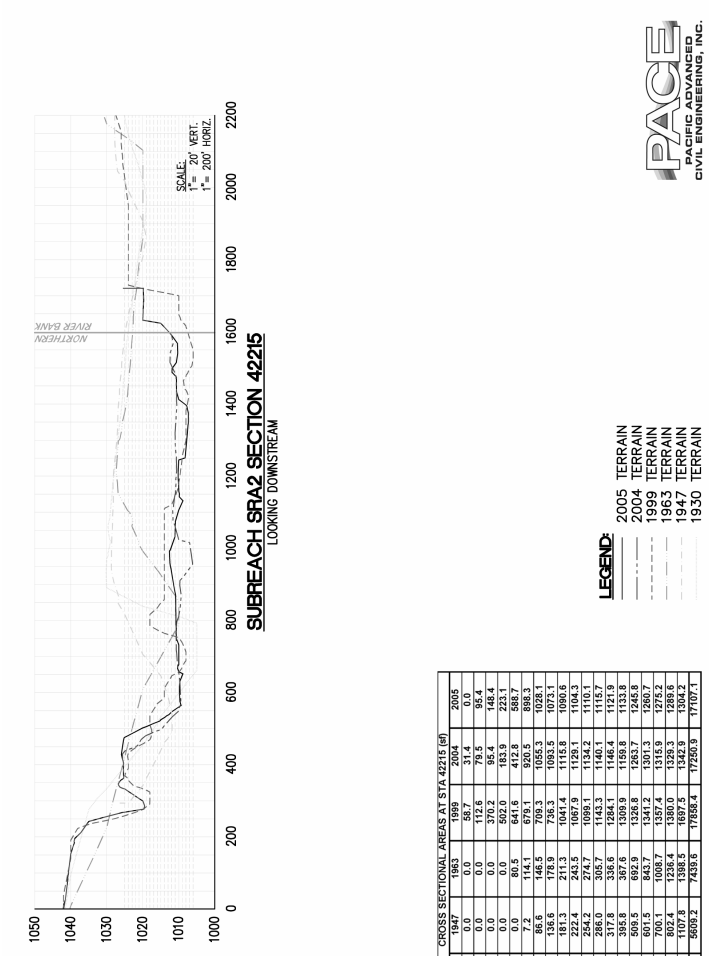
LONG-TERM ADJUSTMENT

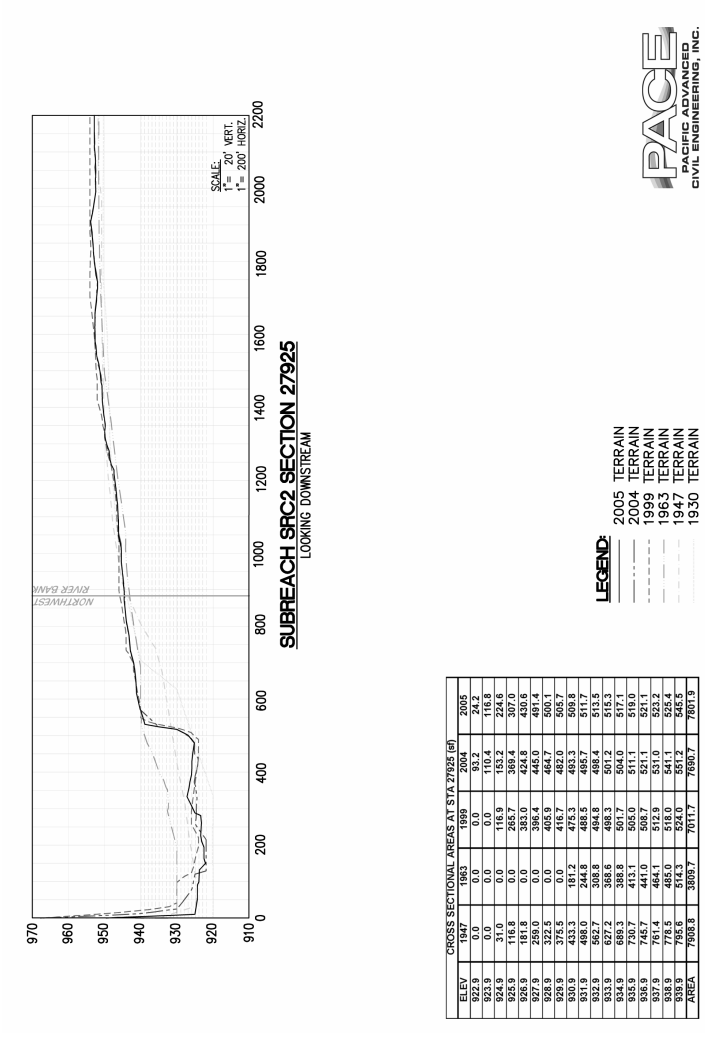


Long-term adjustment was calculated based on historical records in the form of topographic data. First, topographic data dating from 1906, 1930, 1947, 1963, 1999, 2004 and 2005, was obtained and digitized. This was accomplished by determining a common coordinate system and creating contour lines within the study area. Topographic data was available in several formats including digital elevation maps (1999, 2004, 2005), topographic surveys (1963) and quad maps (1906, 1930, 1947). Digital elevation maps were only adjusted for horizontal location. Cross-sections were next cut at the locations of select numerical model sections for each historical topography (Figure 1). At least one cross-section was chosen for each hydraulically distinct subreach based on engineering interest. The sections chosen are section 10390, section 12195, section 14315, section 16305, section 18650, section 20845, section 23000, section 25965, section 27925, section 30445, section 33500, section 34720, section 36080, section 40825, section 42215, and section 44585. Section 36080 is actually in SRB1 not SRA4, although it was chosen since it is directly upstream of a tributary and near the proposed Commerce Center Drive Bridge. Areas of the 1947, 1963, 1999, 2004 and 2005 sections are calculated and these areas are used to calculate the average change in bed elevation over time. The 1930 topography is not used to calculate average change in bed because of the impacts of the failure of the St. Francis Dam in 1928. The 1906 topography is excluded from this study because it of insufficient resolution. To calculate the area of a given cross-section the lowest historical point on the section is determined and the area of each vertical foot (0.31 m) of the section in one-foot (0.31 m) intervals is calculated, as shown in Figure 3a-c, for each topography. (Space restrictions prevent the publication of all 16 sections so the upstream, middle and downstream sections are presented and discussed below for brevity.) The area of a section is the sum of the one-foot area intervals, also shown in Figure 3a-c. All areas for a given section have a common toe and top from which the area is calculated. The relative average change in depth for a given section and topography is calculated as the area divided by the top width, where the top width is taken as the width of the upper most one-foot (0.31 m) area. The top width in this sense is not a hydraulic characteristic but a physical one, which along with the sectional area determines the maximum capacity of the section. Moreover, the calculated depth is a relative physical value based on the section area and represents an average physical characteristic of the section as a whole.

Several events within the available historical record (1930 to present) have had an impact on the River bed and fluvial mechanics. These events include failure of the upstream St. Francis Dam, construction of bridges spanning the River, agricultural infill along the River banks, and periodic burning of surrounding vegetation during forest fires. These different historical events can be placed into two categories: the St. Francis Dam failure in 1928, and those both prior to and following Dam failure. The most significant historical event in the formation of the present bed condition was the aforementioned failure of the Dam. The consequence of this event is tied to the River's recovery from the erosion caused by the extremely high flow of floodwater (1.7×10^6 cfs [4.8×10^4 cms] at the dam-break). Within the project reach, the failure of the Dam appears to have resulted in the severe scouring of the bed in some locations. Placement of bridges does not appear

to have had a measurable impact on long-term bed characteristics, except for very local characteristics. The Interstate 5 Bridge has not been outflanked by bed migration since its construction. Moreover, despite narrowing of the bed locally, bridge placement does not appear to have led to general bed degradation on the River as a whole. Periodic fires have burned the flora of the watershed historically, and as recently as the summer of 2006. Fires are important to changes of the River bed because these fires deplete vegetation stalks and root systems that hold soil in upland areas, thereby leading to increased erosion on slopes and increased sediment delivery to creeks and rivers. Agricultural fills are also important to the historic River fluvial mechanics because the fills limit the extent to which the River may migrate, and in turn cause vertical erosion of the creek bed. LADPW has noted that lateral erosion of agricultural fill has occurred periodically although no data is presently available to date to gage the extent or depth of this erosion. Certainly, the volume of agricultural fill laterally eroded is not sufficient to prevent vertical bed erosion.

Table 2a shows the long-term historical cross-sections area from 1947 to 2005. The table lists the area for each historical section in a given subreach. The table also lists the difference between historical sections (e.g. 1947 section 23000 area – 2005 section 23000 area). Table 2b shows the historical cross-section average depth and average depth change by section and year. As noted above, the average depth is the area of a given section by year divided by the section geometric top width for that year. The difference between historical areas is also shown. It is important to note that the vertical elevation for each section is the same.



Section 42215 (SRA2) appears to have greatly down cut and widened since 1947, degrading an average 8.1 feet (2.47m) along the section. Some of the observed long-term change may be related to the presence of the theme park and water treatment facility on the bank at this location. In recent years (1999-2005), the creek appears to have become relatively stable: area has increased from 17946 to 17101 over the period (Figure 3a). The River is relatively wide at this location although a bend is present. Development has occurred on both banks with agricultural development on the north bank and the Magic Mountain theme park on the south bank. Historical development may have led to the observed degradation, although at present the bed appears to be stable or degrading only slightly. The impacts of woody vegetation in this section may have played a role in the recent degradation. Finally, the 2004-2005 winter was very wet and high flows were present on the River. During the heavy storms of December 2004 and January 2005, approximately 4.4 acres (17,806.2 m^2) of the south bank was lost to the Santa Clara River. Some of the single-season degradation may possibly be attributed to this event. The features located at station 775 and 1325 in the 1999 topography are expected to be related the aerial surveying methodology.

2 - STA 36080 was chosen to represent sra4 because the downstream confluence is of particular engineering interest to that subreach

3- STA 44585 1947 area uses 1963 data since 1947 data is not available.

At section 27925 (SRC2), the upstream degradational trends diminish and historic topographic data begin to indicate a bed that is fluctuating about a mean (Figure 3b). Section 27925 is quite narrow and adjacent to historic agricultural practice. The channel

at this section is confined between steep bluffs on the left bank and tree-lined agricultural embankments on the right. Data in Table 2b indicate that the section has degraded 4.4 feet (1.34 m) over the period of record and 0.3 feet (0.09 m) during 2005 season. A relatively low-radius bend in the River is also present here.

Section 10390 (SRE3) illustrates 3.1 feet (0.95 m) of aggradation from 1947 to 2005 and 0.5 feet (0.15 m) of degradation between 2004 and 2005 (Table 2a). In this subreach, the River is relatively very wide and braided. Little woody vegetation is observed on the banks and steep bluffs dominate both banks, although a small farm plot sets the bluff on the right bank back. Figure 3c indicates that the bed is recovering from scouring related to the 1928 dam break. The observed feature in the 1999 and 2004 topographies at station 625 appears to be the south bank of the thalweg.

Based on the above analysis and Table 2, sections above approximately 25965 appear to be degrading, while sections below appear to be stable or fluctuating around a mean elevation. This may be the result of historic development within the overbank areas or owing to the presence of the generally narrower, winding channel bed in the upstream portion of the study reach. The lower portion of the study reach is relatively flat, broad and straight.

With historical topography from successive years, estimates of single-season change can be developed. The 2004-2005 rain season was wet on Santa Clara River with strong rain events occurring on already saturated soils both in December 2004 and January 2005. These events produced very high discharges on the River (≈ 50-year return period discharge). Topography from before and after these events provides a tool to estimate the impacts of a single large-discharge event, in general, and single season cumulative impacts. The 2004 and 2005 beds are described in Table 2a-b and Figure 3a-c. The table and figures illustrate that the bed elevations show alternating degradation and aggradation. Degradation ranges from 0.1 to 2.3 feet (0.03 to 0.70 m), on average, with most degrading sections changing less than one foot (0.31 m), on average. Aggrading sections change from 0.2 to 0.7 feet (0.06 to 0.21 m), on average. More sections degrade than aggrade. The pattern of aggradation and degradation over the single season does not appear to be a function of proximity to a river confluence.

CONCLUSION

This technical study provides an evaluation of the long-term stability of Santa Clara River between Interstate 5 and an area generally west of the Los Angeles/Ventura County line. Future development along the River within the study area has the potential to modify the fluvial mechanics of the River. This sectional-area-based analysis evaluates changes to the river bed and in the floodplain fluvial operation over the long-term despite a paucity of available historical data.

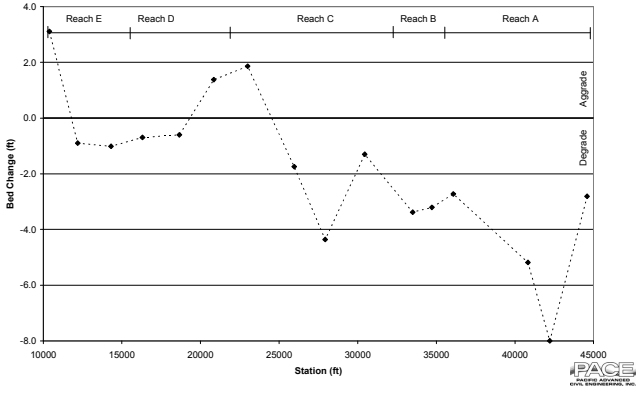

Figure 4: Santa Clara River Historic Long-term Bed Elevation Change

Three sediment transport studies were previously conducted within the study reach in the last 25 years. The first study conducted by Sikand Engineering (June 2000, and revised November 2004) was to provide a sediment transport analysis for the Santa Clara River and to determine the possible effects of future development on river bed stability. The second study, produced by SLA (November 1990), sought to provide information for flood and fluvial process management in the Santa Clara River. The final study was conducted by USGS, whereby the study collected sediment data from 1967 to 1975 at three sites in the Santa Clara River basin including the Los Angeles-Ventura County line. The study estimated long-term sediment discharge by applying the sediment and water discharge relationship observed from 1967 to 1975.

Long-term adjustment was calculated based on historical records in the form of topographic data. Topographic data dating from 1906, 1930, 1947, 1963, 1999, 2004 and 2005, was digitized. Cross-sections were cut at the locations of select modeling sections for each historical topography. At least one cross-section was chosen for each hydraulically distinct subreach. Areas of the 1947, 1963, 1999, 2004 and 2005 sections are calculated and the areas of the 1947, 2004 and 2005 bed are used to calculate the average change in bed elevation over time. The 1930 topography is not used to calculate average change in bed because the trends in bed change that occurred during this year occurred immediately following the failure of the St. Francis Dam upstream of the project site, while the 1906 data is of insufficient resolution for inclusion. Several events within the available historical record (1930 to present) have had an impact on the River bed and fluvial mechanics. These events include failure of the upstream dam, construction of bridges spanning the River, agricultural infill along the River banks, and periodic burning of surrounding vegetation during forest fires. The most significant historical event in the formation of the present bed condition was the failure of the Dam. Within the project reach, the failure of the Dam appears to have resulted in the abrupt scour of the bed.

The sectional analysis finds that some historical sections (SRD2, SRD3, SRE1, SRE2) show little change between 1947 and 2005 suggesting an approximate equilibrium state for these subreaches. Between 1947 and 2005, 0.5, 0.7, 1.0, and 0.8 feet (0.15, 0.21, 0.31, and 0.24 m), respectively, of cumulative degradation appears to have occurred on these sections. A combination of limited development on the banks and local topographic features are possible causes for the limited degradation. It should be noted that the degradation observed on these reaches is similar to that predicted by the Sikand (2000) study, but the opposite of that predicted by the SLA (1990) study where aggradation of approximately 1 foot (0.31 m) was expected. Upstream sections SRA1 to SRC3 (SRC2: Figure 3b) show continuous degradation over the period of record from 1947 to the present. Degradation ranged from -1.3 feet (0.40 m) at section SRC1 to -8.0 feet (2.44 m) at Section SRA2 (Figure 3c). This degradation appears to be caused by a combination of local topography, development of the banks, and local scour related to bridge placement. Three sections, SRC4, SRD1 and SRE3 (Figure 3c) aggraded cumulatively between 1947 and 2005 by 1.9, 1.4, and 3.1 feet (0.58, 0.43, and 0.95 m) on average, respectively. While it is unclear why the observed aggradation occurred, it is presently believed to be the result of bed recovery from the 1928 St. Francis Dam failure combined with affects of local topography. By way of comparison with previous studies the SLA (1990) study predicted aggradation of approximately 1 foot (0.31 m) while Sikand (2000) predicted degradation, as noted above.

Degradation seems to be more prevalent on the upper half of the study reach while mild fluctuations about a mean are more apparent on the lower half. This appears to result from the relatively steep, narrow, winding upper portion of the study reach versus the relatively flat, wide, braided channel in the lower portion of the study reach of the River. Agricultural activities occurred, primarily in downstream sections but in upstream sections as well, so some of the observed channelization may have resulted from these activities. Non-agricultural development is more prevalent on the banks of upper portion of the study reach and this development may contribute to the observed degradational trends, also.

In general, the data presented here suggests that erosion has increased on the study reach over the period of historical record. Data suggest that the observed erosion has resulted from impacts to the floodplain by development. It is not clear from this study, however, if the increased scour is localized or if the increased scour will impact sediment delivery at the coast. Certainly the implication here is that continued development of the banks will reduce the sediment from uplands, increasing bed scour, and reducing delivery to the coasts unless future development sediment inflows are managed carefully.

Abstract: Box cores collected on the Louisiana continental shelf immediately following Hurricanes Lili (2002) and Katrina (2005) allow comparison of sediment event layer formation on the actively accreting Mississippi delta adjacent to Southwest Pass (Katrina) and the Atchafalaya delta (Lili). Post-Katrina box core sites in water depths of <40 m show evidence of an erosional surface at the sediment-water interface, indicating the water depth that critical erosion stresses are found in these large storms. Erosional deflations from Katrina and Lili ranged from 2-15 cm, controlled by water depth (shallower caused greater incision) and degree of consolidation of the pre-existing seabed sediments. In water depths of >25 m, post-Katrina cores display event layer deposition 1-25 cm thick above the incision surface: post-Lili cores from the Atchafalaya show similar thicknesses dependent on proximity to the storm path, but also extending into shallower water (shallowest station sampled was 4 m).

INTRODUCTION

Tropical cyclones, because of the enormous wave orbital velocities and strong mean flows they create in the benthic boundary layer, may have a disproportionate impact on the transport, deposition and burial of sediments on continental shelves where they are active. Study of the shelf seabed response to tropical cyclones, whether erosional, depositional, or a combination of the two, is complicated by the wide range of sediment types and shelf geometries that are present in areas prone to these storms, as

well as the individual nature of storm tracks, pressures and wind fields. River-dominated continental shelves are generally the only shelf type where modern fine-grained sediment deposition is taking place on the inner to mid shelf region (Nittrouer and Wright, 1994; McKee et al., 2004) most impacted by storm-induced waves and surges. As such, large reservoirs of soft sediments are available for mobilization in these areas, which may have significant implications for controlling the geometry and location of the shelf sediment depocenter. Previous investigations of tropical cyclone seabed response have involved the examination of a shelf area immediately following the event in an area recently studied for another purpose. This before-and-after approach aids in minimizing a complicating issue—definitively identifying the sediment deposit or erosional surface associated with the storm.

On October 3, 2002 the southwestern coast of Louisiana was struck by Hurricane Lili, a tropical cyclone that took a northwesterly route across the Gulf of Mexico and reached Category 4 status with maximum winds of 232 km/h (125 knots) and a minimum pressure of 940mb at 0000 GMT on October 3rd, before weakening to Category 2 status at landfall 13 hours later (Fig. 1). Beginning 4 days after landfall, a

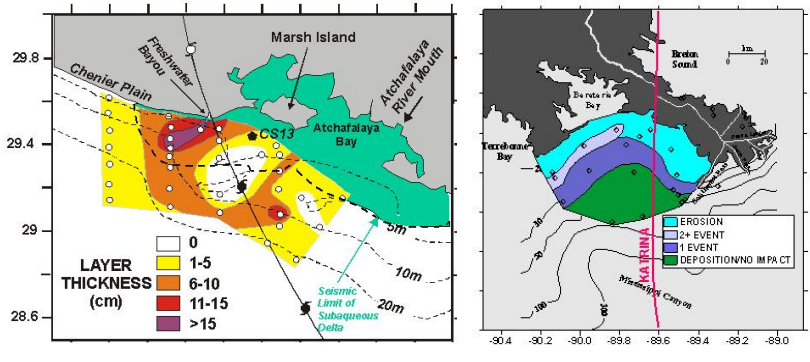

Figure 1. Thickness map of the Lili event layer on the Atchafalaya Shelf (left). Path of the center of the eye is shown. Box core locations are also shown as white circles and the LSU Coastal Studies Institute monitoring platform #3 is plotted. The seismic limit of the Atchafalaya subaqueous delta is from Neill and Allison (2005). The extent of the post-Katrina event layer and box core locations, shown in the panel at right, are relative to the storm path. Areas are divided into 1) a region where shelf incision and no event layer were found (Erosion), 2) a region where shelf incision was followed by deposition of an event layer (1 Event), 3) a region similar to the 1 Event zone but where stacked earlier (Ivan) and/or later (Rita) event layers were also preserved (2+ Event), and 4) a deeper region where no shelf incision was observed and event layers were documented or no impact was observed (Deposition/No Impact).

seabed box coring cruise was conducted on the inner shelf in the area of storm passage. This area, which includes the Atchafalaya subaqueous delta and adjacent inner shelf offshore of the West Louisiana Chenier Plain, has been the subject of recent sediment transport and accumulation studies (Allison et al., 2000; Draut et al., 2004; Neill and Allison, 2005; Kineke et al., 2006). The core data collected on this

cruise on the R/V *Longhorn*, combined with meteorological, sea surface and water column current data over the period of the storm from a nearby observational platform (Fig. 1) operated by Louisiana State University's Wave-Current-Surge Information System for Coastal Louisiana (WAVCIS) provided a unique opportunity to examine fluid and flow characteristics of the storms and the seabed response over a heterogeneous shelf inner shelf of modern muds and relict (sandy) deltaic shoals. The sedimentology and organic geochemistry of the Lili storm deposits have been reported previously in Allison et al. (2005) and Goñi et al. (2006).

The landfall of Hurricane Katrina along the southeastern Louisiana coast on August 29, 2005 provided an opportunity to conduct another early response study of this deltaic coast to a tropical cyclone: in this case immediately west of the main Mississippi shelf. Hurricane Katrina made landfall in Louisiana as a transitional Category 3-4 storm, after having reached Category 5 status on 28 October. A coring and seismic cruise on the R/V *Longhorn* was carried out over this area of the Barataria Bight (Fig. 1) on 1-6 October. This area has been analyzed recently for sediment accumulation and surficial seabed mobility (Corbett et al., 2004; Corbett et al., 2006), allowing a comparison with recent, but pre-storm, seabed character. These studies have shown that modern mud accumulation is focused further offshore along this section of the coast relative to the Atchafalaya shelf. The primary objective of the present paper is to outline the erosional and depositional response of the Mississippi deltaic shelf (15-70 m water depth) to Hurricane Katrina, and to compare these seabed response results with the earlier Lili dataset, which was collected, processed and analyzed utilizing the same methods.

OBSERVATIONS

The 18 box cores collected on the Katrina cruise were subsampled with tray cores and x-rayed for stratigraphy with a portable x-ray machine at 15 mA//70 keV. X-radiographs show that the sample sites can be divided into four categories based on A) the presence or absence of an irregular, basal erosional surface that marks the transition from pre-storm (below) and Katrina event layer (above) deposits (Fig. 2), and B) the presence or absence of a fining-upward event layer attributable to the storm. As in the Lili studies, this event layer was attributed to Katrina based on the relatively homogenous (when corrected for grain size variations) activity of the particle-reactive, short-period radiotracer ^{7}Be (half life = 53 days), which tends to be high in activity on river-derived particulates, and, secondarily, on the fining upward stratigraphy. The event layer and erosional basal surface was interpreted in the Lili deposit (see Allison et al., 2005) as being a result of seabed erosional deflation during the period of maximum wave heights and onshore, surge-induced currents, followed by gradual reduction in water column energies with passage of the eye onshore. This waning phase would be marked by re-deposition of particles suspended by the storm and runoff of additional particles from the land surface, associated with the surge backflow. Gradual reduction of energies would result in fining upward stratigraphy, with a sharply coarser basal layer above the erosional surface (Fig. 2). In several Katrina cores, this coarse basal layer reached 5-7 cm thick and was marked by x-

bedding in the sands—indicative of bedload transport of sandy lags from the erosion of the underlying seafloor.

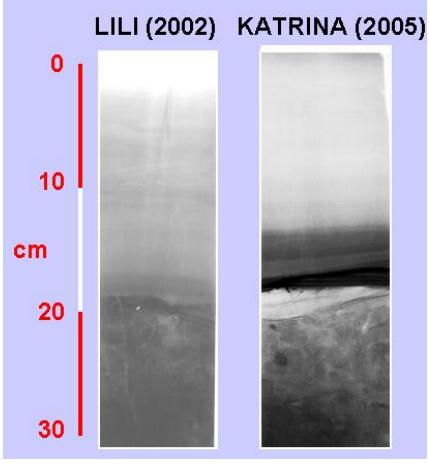

Figure 2. X-radiograph positive images (dark=coarser) of box core subcores showing characteristic examples of the event layer stratigraphic record left by Hurricanes Lili and Katrina. In both cases, a basal incised surface of pre-storm deposits is bound at about 19 cm depth in the cores. Above this surface is a basal deposit of coarser material: in the case of the Lili deposit, this is a thin (2 cm) sandy silt, while the Katrina deposit is a laminated sand 5 cm thick. The difference is ascribed to the limited sand available for reintroduction by seafloor incision in the Atchafalaya subaqueous delta versus the sandier deltaic deposits on the inner-mid Mississippi deltaic shelf. Above this basal layer is a massive to laminated, low consolidation, silty clay deposited in the waning phase of the storms in both cases.

The zonations shown in Figure 1 for the Katrina event strongly correlate with water depth. In water depths of less than about 25 m, box cores showed no event layer preservation and an erosional sediment surface. These cores were uniformly composed of relatively highly consolidated and burrowed muds. At three of these sites, were were able to compare box core X-radiographs from the post-Katrina cruise with those collected at the same locations in May 2005 by a NOAA-funded, Texas A&M University hypoxia study (Steve DiMarco, lead PI). Using subbottom layers, we were able to measure seafloor deflations of 2, 3, and 8 cm, presumably due to the storm, with the deepest erosion at a site closer to Southwest Pass and underlain by more recent Balize lobe sediments, rather than older, more consolidated Lafourche lobe sediments at the sites further west. Seaward of 25 m to about 40 m water depth, the basal erosional surface was covered by a fining-upward event layer of similar morphology to the Lili event layer (Fig. 2). At two of the three sites shown as "2+ Events" in Fig. 1, the surface of the Katrina deposit was incised by a later, erosional surface-event layer packet we attribute to the impact of Hurricane Ivan which made landfall at the Texas-LA border the week prior to our cruise and caused large waves as far eastward as our study sites. Potentially, this event also contributed to the seabed deflation thicknesses mentioned above. At all three "2+ Event" sites, the Katrina deposit was underlain by another erosional surface-event layer packet that is probably associated with Hurricane Ivan in 2004. It is uncertain why this multiple deposit is observed in this zone at water depths (20-25 m) that in adjacent regions (Fig. 1) show no event layer preservation, but may be related to water and sediment emitted from the exits from adjacent Barataria Bay. Seaward of about 40 m water depth, no incision surface was observed, suggesting that combined wave-current

shear stresses were below critical erosion stress at these water depths during the storm. In several of these sites, an event layer was still observable in X-radiographs as a change in fabric (grain size), supported by the presence of ^{7}Be activity. No event layer was recognizable in some of these deeper sites, which may indicate that fabric changes were too subtle with underlying sediments, or that no storm deposition took place, and only normal, ^{7}Be penetrations of a few centimeters were present due to bioturbation. A more widespread mapping of these deeper sites was carried out further west of the present study area by a second, NSF-funded and simultaneous cruise on the R/V *Hatteras* (Goñi and Corbett, PI's). This study (Walsh et al., 2006) recognized a Katrina event layer as far west as the Atchafalaya shelf, where it overlapped with a more substantial Rita event layer, and as deep as the floor of Mississippi Canyon.

CONCLUSIONS

Several conclusions about the impact of tropical cyclones on river-dominated continental margins can be drawn from an examination of the event layers formed by Hurricane Katrina and from comparison with the earlier Lili dataset. They are:

1) Katrina generated seafloor incision in the Barataria Bight to water depths of about 40 m. The removal of surficial sediments down to a relict fluvio-deltiac material up to several thousand years old at inner sites suggests that tropical cyclones are a primary mechanism for keeping most of the inner shelf (<20 m) swept from modern sediments, despite the large flux of Mississippi-derived particulates moving alongshore in the westward-flowing coastal current. Further, this deflation by successive storms over decades, likely is a major additional factor generating retreat of inactive Mississippi deltaic lobe headlands. While winter cold-fronts also likely contribute to this on the innermost shelf and shoreface (<10 m), significant wave heights (<2 m) during these events are generally too small to generate resuspension at greater depths.

2. The deposition of an event layer on shallow (5-20 m) areas of the Atchafalaya shelf after Hurricane Lili, where only erosion is observed in the Katrina event at these water depths, suggests a wave-seafloor feedback, where the presence of extensive soft muds on the Atchafalaya subaqueous delta dissipates sufficient wave energy that deposition can take place in the waning phase of the storm. This is evidence of the important role that soft muds play protection of adjacent shorelines from wave attack during tropical cyclones. Significant deposition of an event layer in deeper water from Katrina than was observed during Lili is likely a function of the offshore-oriented vector of particle transport in the waning phase. The lower gradient Atchafalaya shelf requires particles to traverse greater distances prior to settling relative to the Barataria Bight to reach equivalent water depths.

3. Interannual preservation of tropical cyclone event layers on river-dominated continental margins, such as could be utilized for studies of paleo-hurricane frequency and intensity are likely to be limited to 1) areas of active subaqueous lobe

deposition, 2) water depths sufficient to avoid total incision by subsequent winter and tropical storms, and 3) areas that are sufficiently shallow that a basal erosional surface is formed, which aids in identification of the storm event layer.

Abstract: As part of an ongoing cooperative effort between USGS, NASA and USACE, the barrier islands within the right-front quadrant of Hurricane Katrina were surveyed with airborne lidar both before and after landfall. Dauphin Island, AL was located the farthest from landfall and wave runup intermittently overtopped its central and western sections. The Gulf-side of the island experienced severe erosion, leaving the first row of houses in the sea, while the bayside accreted. In contrast, the Chandeleur Islands, LA did not experience this classic 'rollover'. Rather, the island chain was completely stripped of sand, transforming a 40-km-long sandy island chain into a discontinuous series of muddy marsh islets. Models indicate that storm surge likely submerged the entire Chandeleur Island chain, at least during the latter part of the storm. The net result was destructive coastal change for the Chandeleur Islands, while Dauphin Island tended to maintain its form through landward migration.

INTRODUCTION

On August 29, 2005, Hurricane Katrina made landfall on the Mississippi delta as a Saffir-Simpson Category 3 storm. Earlier, it had reached Category 5 intensity in the central Gulf of Mexico but fortunately weakened as it approached land. Regardless, Hurricane Katrina—with winds at landfall estimated at 110 kts—was the most costly and one of the five most deadly hurricanes in United States history (Knabb et al., 2005).

The U.S. Geological Survey (USGS), National Aeronautics and Space Administration (NASA) and U.S. Army Corps of Engineers (USACE) are working together to quantify the changes forced by Katrina along the coast of the northern Gulf of Mexico, focusing on the chain of barrier islands from Louisiana to Alabama within the hurricane's right-front quadrant (Fig. 1). Our primary tool is airborne lidar that over the past decade has revolutionized the quantification of coastal change by surveying hundreds of kilometers of coast in hours with high spatial data densities. For example, USGS, NASA, and USACE were able to survey, before and after landfall, the impact zones of all four hurricanes that came ashore in or near Florida in 2004 (Sallenger et al., 2006). For more information about the USGS, NASA, and USACE extreme storms research effort, including preliminary results from other 2005 hurricanes (e.g. Rita), see: http://coastal.er.usgs.gov/hurricanes/

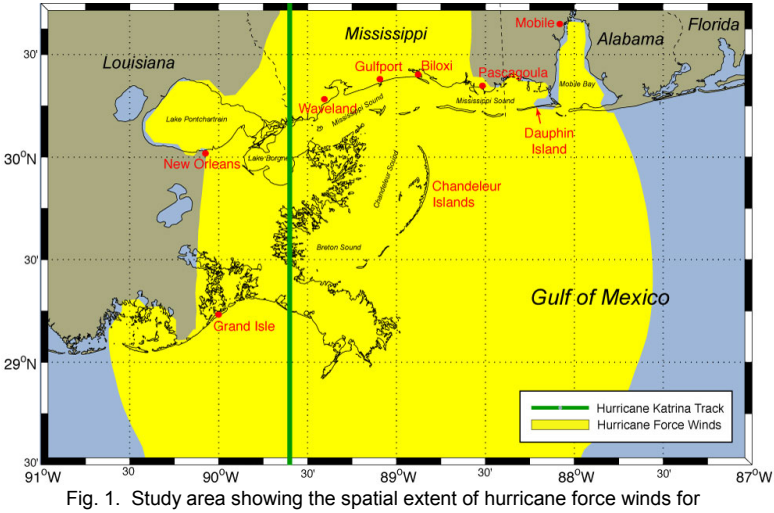

Fig. 1. Study area showing the spatial extent of hurricane force winds for Hurricane Katrina. Wind fields were calculated by NOAA's Hurricane Research Division, Miami, Florida.

METHODS

Two different lidar systems were used to survey the study area before and after landfall of Hurricane Katrina: U.S. Navy and USACE CHARTS (Compact Hydrographic Airborne Rapid Total Survey) and NASA EAARL (Experimental Advanced Airborne Research Lidar; Wright and Brock, 2002). In addition, the USGS acquired pre- and post-storm oblique aerial photography and video to assist in interpreting the lidar data.

Lidar—once an acronym for "light detection and ranging" and now an accepted word, like radar—typically acquires estimates of ground elevation with spatial densities of about one shot every square meter within a swath width of several hundred meters. Multiple surveys of a 70-km long reach of coast on the same day have shown vertical

accuracies of elevation estimates of about 15 cm RMS for another NASA lidar: Airborne Topographic Mapper (Sallenger et al, 2003). Both CHARTS and EAARL should have comparable accuracies for topography. They are also designed to obtain bathymetry, although the post-Katrina survey, collected several days after landfall, encountered water too turbid to allow sufficient laser penetration for accurate measurements of depth.

OBSERVATIONS

In this paper, we compare and contrast hurricane-induced coastal changes on developed Dauphin Island, Alabama, near the outer extent of hurricane force winds, to changes on undeveloped Chandeleur Islands, Louisiana, located relatively close to landfall (Fig. 1). Further, to help put the extreme changes during Katrina into perspective, we compare them to changes from other recent hurricanes, such as Ivan in 2004 and Lili in 2002, for which we have acquired comparable lidar surveys.

Dauphin Island, Alabama

In May 2004, lidar topography of a central section of Dauphin Island showed a narrow barrier island with four rows of houses and a central road, the road appearing in the topography as a depression below the surrounding sand (Fig. 2A). Category-3 Hurricane Ivan came ashore east of this area on September 16, 2004. Even though on the weak side of the storm, Dauphin Island experienced overwash sufficient to fill the depression containing the road (Fig. 2B). An elevation difference map shows this accretion (in shades of green), as well as erosion on the Gulf-side of the island (in shades of red; Fig. 3A). The houses were not removed from the topographic data; hence in the difference map, lost houses appear as red (erosional) rectangles. Within this central section, ~17 houses were lost as a result of Hurricane Ivan.

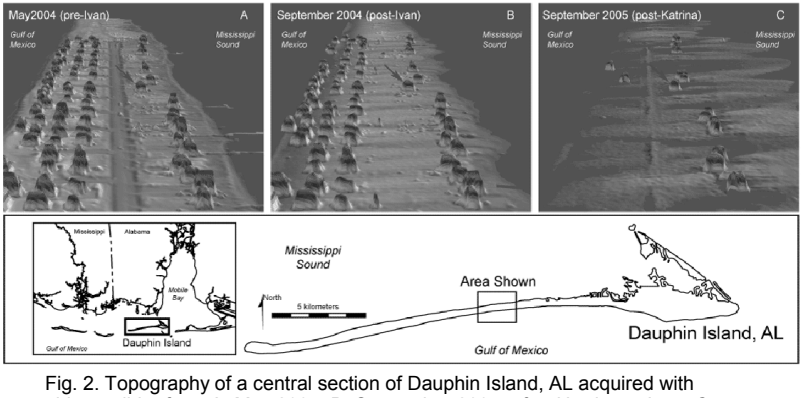

Fig. 2. Topography of a central section of Dauphin Island, AL acquired with airborne lidar from A. May 2004. B. September 2004, after Hurricane Ivan. C. September 2005, after Hurricane Katrina. The hotter colors are higher elevations. The highest elevations here are the roofs of houses. In each map, the red arrow points to the same house.

The post-Katrina topography shows a more extensive coastal-change response (Fig. 2C), as the island width was completely overwashed from Gulf to bay (Fig. 3B). The pattern is the same as for Ivan, with erosion on the Gulf-side of the island and accretion farther landward, but the scale of change was far greater during Katrina. On the Gulf-side of the island, sand was eroded from under the first row of houses leaving their pilings stranded in the water. Overwash extended into the back bay where sand was deposited building the island landward. In the classic sense for a barrier island, it 'rolled over' or migrated, like a large bedform. Over 100 houses were destroyed in the section shown (Fig. 3B) and most of their remains were likely swept with the sand into the back bay.

Chandeleur Islands, Louisiana

Hurricane Lili came ashore west of the Chandeleur Islands in 2002 and forced a similar overwash regime as observed on Dauphin Island, where waves transported sand from the Gulf-side of the island to its central part (Fig. 4). Note that the island eroded on its Gulf-side, but remained intact as a barrier island. Lili was a relatively weak storm, Category 1, generating a maximum storm surge along the Chandeleurs of only 0.6 m, according to NOAA SLOSH model simulations.

In contrast, Hurricane Katrina, with an average storm surge along the Chandeleurs of 3.2 m, forced a very different response than overwash. The sand was completely removed from the subaerial island (Fig. 5), including dunes that in places reached ~6 m high before the storm. Discontinuous marsh islets were left in the storm's wake (Fig. 6), with maximum elevations of approximately 2 to 3 m. Post-Katrina surveys were collected several days after landfall and, by that time, what remained of the Chandeleur Islands no longer satisfied the definition of sandy barrier islands.

Discussion

Along the Chandeleurs, at some point during Katrina, the storm surge (3.2 m) was likely greater than the post storm elevation of the remnant muddy islets (2-3 m), creating the inundation regime of Sallenger (2000). Under these conditions, the islands were continuously underwater (as opposed to being intermittently overtopped by waves during overwash.) It was a submerged shoal and the currents that removed the sand would have been driven by gradients in sea level across the island. Such gradients would have varied in direction and strength as the counterclockwise circulation of the storm moved past the island.

A major research question is where the removed sand was transported during the storm: landward of the island into the back bay? or offshore of the island into the Gulf? We hope to address this question through modeling the currents across the island and working with USGS and University of New Orleans colleagues who are conducting coring and sampling studies on and offshore of the Chandeleurs after Katrina.

CONCLUSIONS

The processes causing coastal change to barrier islands at varying distances from Katrina's landfall were different. Near the outer limits of hurricane force winds, surge

and wave runup were high enough that waves intermittently overtopped the island, forcing it to rollover. Closer to landfall, storm surge was sufficient to submerge the island and all sand was removed from its surface. Under this inundation regime, the system changed destructively, diminishing in size, compared to normal overwash regime, when the island would have maintained its overall dimensions.

MODELING DUNE RESPONSE USING MEASURED AND EQUILIBRIUM BATHYMETRIC PROFILES

Laura A. Fauver[1], David M. Thompson[1], Asbury H. Sallenger[1]

1. U.S. Geological Survey, Florida Integrated Science Center, 600 Fourth Street South, St. Petersburg, FL 33701, USA. lfauver@usgs.gov.

Abstract: Coastal engineers typically use numerical models such as SBEACH to predict coastal change due to extreme storms. SBEACH model inputs include pre-storm profiles, wave heights and periods, and water levels. This study focuses on the sensitivity of SBEACH to the details of pre-storm bathymetry. The SBEACH model is tested with two initial conditions for bathymetry, including (1) measured bathymetry from lidar, and (2) calculated equilibrium profiles. Results show that longshore variability in the predicted erosion signal is greater over measured bathymetric profiles, due to longshore variations in initial surf zone bathymetry. Additionally, patterns in predicted erosion can be partially explained by the configuration of the inner surf zone from the shoreline to the trough, with surf zone slope accounting for 67% of the variability in predicted erosion volumes.

INTRODUCTION

Long-term coastal erosion along the east and gulf coasts of the United States is exacerbated by short-lived, high-intensity extreme storm events. The hurricane seasons of 2004 and 2005 produced eight major hurricanes (Category 3 or higher) that made landfall on U.S. coastlines, causing extensive shoreline retreat, dune erosion, and coastal overwash events (Sallenger et al., 2006). Coastal engineers and planners typically use numerical beach erosion models such as SBEACH to predict coastal change due to extreme storms. SBEACH is a two-dimensional, cross-shore model that takes into account the pre-storm beach profile, as well as wave heights and periods, water levels, and wind speeds.

This study focuses on the sensitivity of SBEACH to the details of pre-storm bathymetry. Recent SBEACH studies have utilized light detection and ranging (lidar) data for the

pre-storm topography, while an equilibrium shape was used to represent the profile seaward of the shoreline (Fauver, 2005). Advances in lidar technology now allow the measurement of nearshore bathymetry with lidar sensors developed by the Naval Oceanographic Office (NAVO) and the U.S. Army Corps of Engineers (USACE) (Wozencraft and Lillycrop, 2003). In this study, the SBEACH model is tested with two initial conditions for pre-storm bathymetry, including (1) measured bathymetry from lidar, which is referred to as "Case A", and (2) calculated equilibrium profiles, which is referred to as "Case B."

The SBEACH model takes into account the shape of the pre-storm beach and offshore profile, as well as the hydrodynamic conditions of the storm. At each time step, wave height and water level profiles are calculated between the offshore boundary and the shoreline, and are utilized to calculate sediment transport rates across the profile (Larson and Kraus, 1989; Larson et al., 1989). Calculations of wave height in the surf zone are sensitive to water depth, and therefore pre-storm bathymetry can play an important role in model accuracy (Kraus and Wise, 1993). Traditionally used as a proxy for real bathymetry, equilibrium profiles decrease monotonically with depth, whereas many beaches along U.S. coastlines are known to display bar configurations. Nearshore bars cause waves to break seaward of the shoreline, dissipating energy offshore and lessening the impact of the storm. Additionally, observed surf zone profiles can display significantly different slopes than modeled equilibrium profiles, which affects the distance from the shoreline at which the wave breaks and the rate of energy dissipation across the nearshore zone.

BACKGROUND

Study Area

The study site is a 1.2 km stretch of shoreline within the city of Destin, FL on the Gulf of Mexico coastline (Figure 1). The selected area is an undeveloped stretch of coast within Henderson State Park, which consists of recreational public beaches and several inland parking lots. The park is characterized by continuous, linear sand dunes with a mean peak elevation of 5.0 m (σ = 0.4 m). On September 16, 2004, Hurricane Ivan made landfall in Gulf Shores, AL as a Category 3 hurricane. Hurricane force winds extended 140 km to the east of landfall, with the study area falling within the outer edge of these limits. The NOAA Hurricane Research Division's (HRD) H*Wind grids provide a maximum surface wind speed estimate of 65.8 kts directly offshore of the study site.

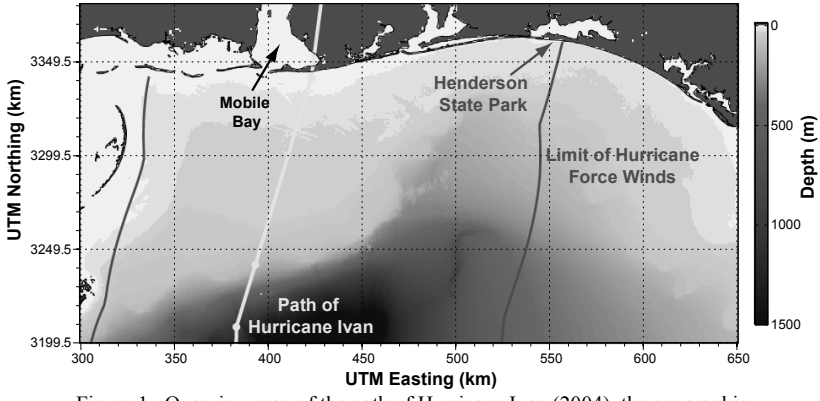

Figure 1. Overview map of the path of Hurricane Ivan (2004), the geographic extent of hurricane force winds, and the location of Henderson State Park.

Lidar measurements show that offshore of Henderson State Park, a non-rhythmic, three-dimensional sandbar was positioned approximately 150 m from the shoreline (Figure 2). Within the western portion of the study area, the bar is attached to the shoreline over a distance of approximately 120 m in the longshore direction. Along this section of shoreline, the surf zone slope is shallower than the surrounding area, and a bar and trough configuration is not detectable in cross-sectional profiles. Within the study area, the mean bar height and width are 1.1 m and 87.6 m respectively (σ = 0.5 m and 23.1 m). The mean water depth at the bar crest is 2.6 m below mean sea level.

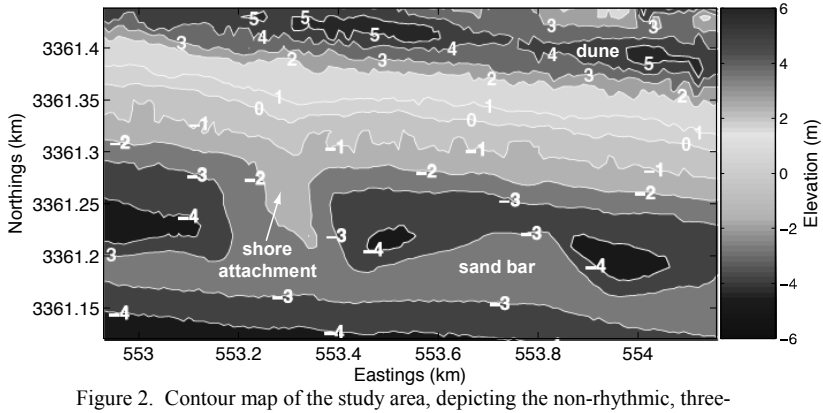

Figure 2. Contour map of the study area, depicting the non-rhythmic, three-dimensional bar configuration.

Model Description

SBEACH is a macroscale beach erosion model, invoking sediment transport over length scales of meters, and time scales of hours (Larson and Kraus, 1989; Larson et al., 1989).

At each time step, input values of offshore wave height and period are used to calculate the cross-shore wave height profile. A two-dimensional form of the conservation of energy flux equation is used to compute wave heights from the offshore boundary to the shoreline:

$$\frac{d}{dx}(F\cos\theta) = \frac{k}{d}(F - F_s) \tag{1}$$

where F is wave energy flux, F_s is the energy flux of a stable wave, θ is the local wave angle, k is the wave decay coefficient, and d is total water depth including surge and setup. Additionally, the location of the break point is determined by an empirical equation for the value of γ, the ratio of wave height to water depth at which the wave breaks.

The wave height calculations obtained from Equation 1 are used to compute sediment transport rates, which are applied to the conservation of mass equation in order to calculate profile change. Within the surf zone, sediment transport rates are calculated with the empirical formula:

$$Q_s = K\left[D - D_{eq} + \frac{\varepsilon}{K}\frac{dh}{dx}\right] \tag{2}$$

where Q_s is the sediment transport rate, D is wave energy dissipation, D_{eq} is the energy density required to maintain the instantaneous profile form, K is the transport rate coefficient, ε is an empirical coefficient, and dh/dx is the local bed slope. Model calibrations were performed to determine best-fit values for the coefficients in Equation 2, including $K = 1.0\text{x}10^{-6}$ m^4/N, and $\varepsilon = 0.0045$ m^2/s. The wave energy dissipation term D is proportional to the wave height squared, and therefore the sediment transport rate is directly affected by the surf zone bathymetry.

METHODS

Measured and Equilibrium Profiles

Lidar surveys were flown along the Florida panhandle coast in May 2004, four months before Hurricane Ivan made landfall in Alabama. Topographic data were collected with the Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system, and bathymetric data were measured with the Scanning Hydrographic Operational Airborne Lidar Survey (SHOALS) sensor. Surveys were flown in a cooperative research agreement USACE, NASA, and the USGS. Cross-shore profiles were extracted from the lidar data set every 20 m along the beach, and used as the initial profile conditions for SBEACH model runs of Hurricane Ivan. A total of 61 profiles along 1.2 km of beach were used to evaluate the SBEACH model.

Two sets of initial bathymetric profiles are used to evaluate the sensitivity of SBEACH to the configuration of the surf zone. The first set of profiles consists of topographic data from CHARTS lidar, as well as the measured bathymetric lidar data. These profiles

display a bar and trough configuration along most of the study site. A notable exception occurs within the western portion of the study area where the bar is welded to the shoreline, creating a more planar nearshore profile. Profiles taken from bathymetric lidar and the corresponding SBEACH results will be referred to "Case A."

The second test case consists of equilibrium profiles calculated using a standard $h=Ax^{2/3}$ offshore profile as described by Dean (1977). Topographic data from lidar was appended with the calculated equilibrium profile seaward of the shoreline. The shape of the profile is dependent on median grain size, which is measured to be 0.33 mm at mean high water (Taylor Engineering Inc., 2003). For the remainder of this paper, these equilibrium profiles and corresponding SBEACH results will be referred to as "Case B."

Along a majority of the study site, the Case A profiles exhibit a wide bar and a steeper surf zone slope than Case B profiles (Figure 3a, Figure 4). The slope of the inner surf zone, measured from the shoreline to the deepest section of the trough, ranges from 0.017 to 0.045 for Case A. In contrast, profile slope is uniform about a mean of 0.025 for Case B equilibrium profiles. A shallower slope and smaller bar volumes are observed on Case A profiles that are located where the longshore bar attaches to the shoreline and fills in the deep trough (Figure 3b, Figure 4). Due to this attachment, the volume of the bar also decreases in this same location.

The two working hypotheses for these test cases are that (1) the bar-type configuration of the Case A profiles will produce statistically significant differences in SBEACH model results when compared with results from Case B profiles, and (2) the longshore variations in Case A bathymetry will lead to longshore variability in the modeled erosion signal. In contrast, the homogeneity of the Case B bathymetry is expected to contribute to a relatively uniform longshore erosion signal.

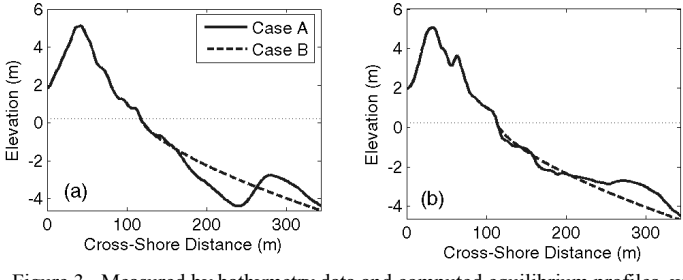

Figure 3. Measured by bathymetry data and computed equilibrium profiles, where (a) depicts a profile displaying a large offshore bar, and (b) is an example of a profile where the longshore bar has attached to the shoreline.

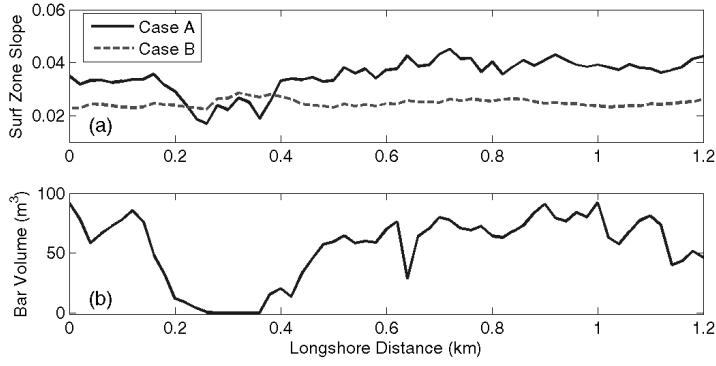

Figure 4. Alongshore variation of (a) surf zone slope as calculated from the shoreline to the deepest point of the trough, and (b) bar volume. A noticeable decrease in surf zone slope corresponds to the location where bar volume is at a minimum.

Wave Height and Water Level

The SBEACH model was initialized with time series of wave height, wave period, water level and wind speed. No wave buoys or tide gauges were located near the study area, and therefore waves and water levels for Hurricane Ivan were modeled with Delft3D (Thompson et al., 2006). A time series of nearshore water levels was extracted from the Delft3D model results 2 km offshore of the study site, in order to avoid boundary affects associated with land. These water levels were used as input values for the SBEACH model runs (Figure 5). Wave heights for SBEACH model runs were extracted offshore of the study site at a depth of 20 m, which is intermediate water depth for the given storm conditions (Figure 5).

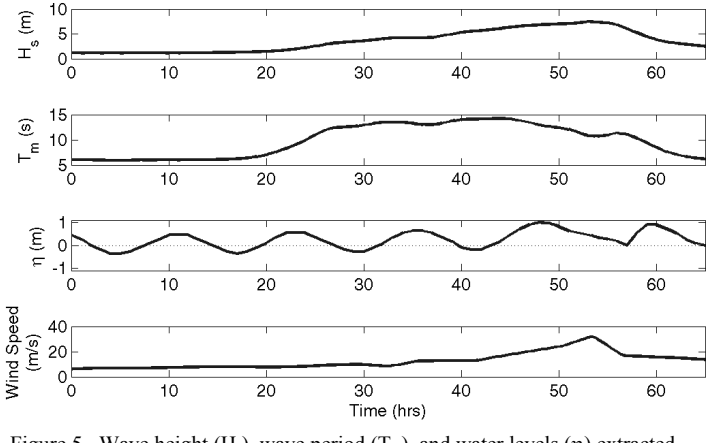

Figure 5. Wave height (H_s), wave period (T_m), and water levels (η) extracted from Delft3D model runs, and wind speeds extracted from HRD H*Wind grids.

RESULTS

SBEACH model runs were completed for each of the two sets of pre-storm profiles described in the previous section, including measured bathymetric profiles (Case A) and equilibrium profiles (Case B). Results can be divided into two groups, those for barred profiles and those for non-barred profiles. SBEACH model results for a barred profile are plotted in Figure 6, with the area of profile change enlarged in the right panel. The SBEACH model predicts greater profile change over the Case A (bar) profile, as opposed to the Case B (equilibrium) profile. This result is consistent throughout the study area for profiles with a bar-type configuration. SBEACH model results are plotted for a non-barred profile in Figure 7. For non-barred profiles, SBEACH model results converge for Case A and Case B.

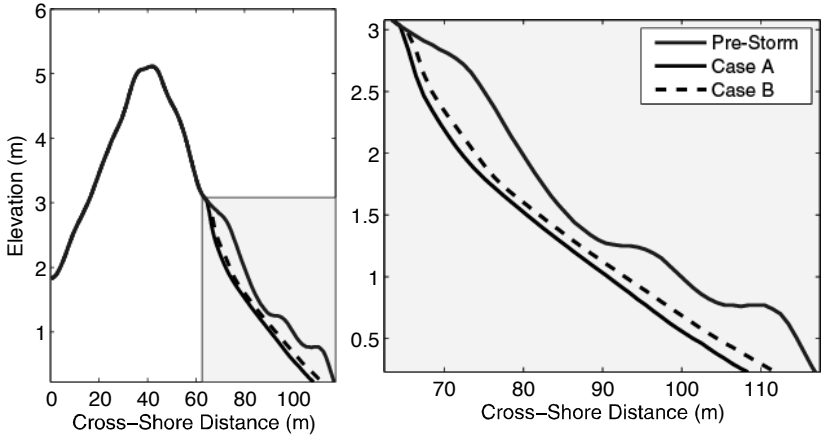

Figure 6. Comparison of SBEACH model results for the two test cases. The pre-storm profiles are the same as shown in Figure 3a, which has a distinct offshore bar and is typical of a majority of the study site.

Two calculations were used to quantify differences in model results. The first calculation is the root-mean-square (RMS) vertical difference between the two predicted profiles, measured between the shoreline and the dune crest:

$$RMS = \left[\frac{1}{N} \sum_{i=1}^{N} (z_{i,A} - z_{i,B})^2 \right]^{1/2} \tag{3}$$

where z_A is the elevation of the Case A predicted profile, and z_B is the elevation of the Case B predicted profile. For all profiles tested, the mean RMS value is 0.13 m, with a standard deviation of 0.04 m (Table 1). This result is considerably less than originally expected, given the large differences in initial bathymetric configuration. However, when the results are separated into barred and non-barred profiles, the

mean values of RMS are 0.14 m and 0.06 m respectively. These mean RMS elevation differences are statistically different at the 95% confidence level.

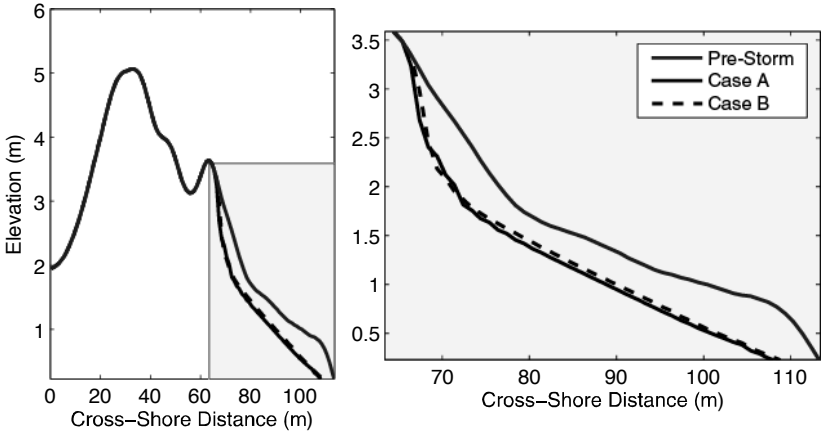

Figure 7. Comparison of SBEACH model results for the two test cases. The pre-storm profiles are the same as shown in Figure 3b, which has a shallow slope and planar nearshore profile, corresponding to the shoreline attachment of the offshore bar.

The second calculation is of the gross volume difference (GVD) between the two predicted profiles, measured from the shoreline to the dune crest:

$$GVD = \sum_{i=1}^{N} \left| z_{i,A} - z_{i,B} \right| dx \tag{4}$$

where *dx* is the horizontal distance between elevation points (set at 0.1 m). The mean value of GVD for all of the profiles is 6.0 m^3/m, with a standard deviation of 2.1 m^3/m. For barred and non-barred profiles, the means are 6.4 m^3/m and 2.7 m^3/m respectively. These means are also significantly different at the 95% confidence level. Calculations of RMS and GVD confirm that model results for Cases A and B converge over the non-barred profiles where initial bathymetry is similar, and diverge over barred profiles where bathymetric differences are more pronounced.

Table 1. Mean statistics describing differences in model results for Cases A and B.

Profiles	Mean RMS (m)	Std RMS (m)	Mean GVD (m^3/m)	Std GVD (m^3/m)
All profiles (N=61)	0.13	0.04	6.0	2.1
Barred (N=54)	0.14	0.03	6.4	1.6
Non-barred (N=7)	0.06	0.03	2.7	2.5

In order to address the question of longshore variability in the erosion signal, a quantitative measurement of erosion is established. Gross volume change (GVC), a proxy for total erosion volume, was calculated between the shoreline and the dune crest:

$$GVC = \sum_{i=1}^{N} \left| \hat{z}_i - z_{i,pre} \right| dx \tag{5}$$

where $\hat{z}$ is the elevation of the predicted profile, and z_{pre} is the elevation of the pre-storm profile. In the longshore direction, an interesting pattern emerges in the predicted erosional signal (Figure 8). For Case A results, a significant drop in GVC is displayed within the western half of the study area, in the location corresponding to the shoreline bar attachment. In this area, no bar is present and surf zone slopes are shallow due to the filling in of the trough. Beyond this area where the bar-type configuration persists, the predicted GVC signal is relatively consistent. For Case B results, the erosion signal is uniform along the entire study area. These results conform to the original hypothesis, which stated that greater longshore variability in erosion was expected for Case A results, due to longshore variations in initial surf zone bathymetry.

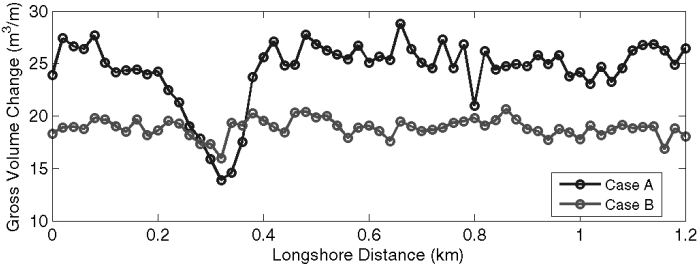

Figure 8. Longshore patterns in predicted GVC are shown for the two test cases.

DISCUSSION

The SBEACH model results show that more erosion was predicted on Case A profiles displaying a bar-type configuration, as opposed to Case B profiles with an equilibrium profile form. This result seems contrary to conventional wisdom, which says that for barred beaches, waves will break over the bar and dissipate energy, therefore producing less erosion on the subaerial profile. For Case B, energy should dissipate gradually over the equilibrium profile in the surf zone, allowing greater wave heights closer to shore and hence greater erosion of the subaerial beach. The results from this study do not fall in line with this hypothesis, and therefore modeled wave height profiles are inspected for further insight. Modeled wave heights are extracted from SBEACH at the time of maximum offshore waves (Figure 5). The cross-shore wave height profile is plotted with the corresponding beach profiles modeled by SBEACH in order to examine patterns of breaking over nearshore bathymetry. Results are shown for both a barred profile (Figure 9) and a non-barred profile (Figure 10).

Over the barred-profile, waves break slightly over the bar and then reform over the trough. Alternatively, dissipation of energy is gradual and decreases monotonically moving towards the shoreline over the corresponding equilibrium profile. Landward of the trough, the Case A and Case B wave height profiles diverge due to differences in surf zone slope. The steeper slopes associated with Case A profiles allow waves to break closer to the shoreline, producing greater erosion on the subaerial beach. In contrast, over a non-barred profile, the Case A and Case B wave height profiles are not significantly different from one another (Figure 10).

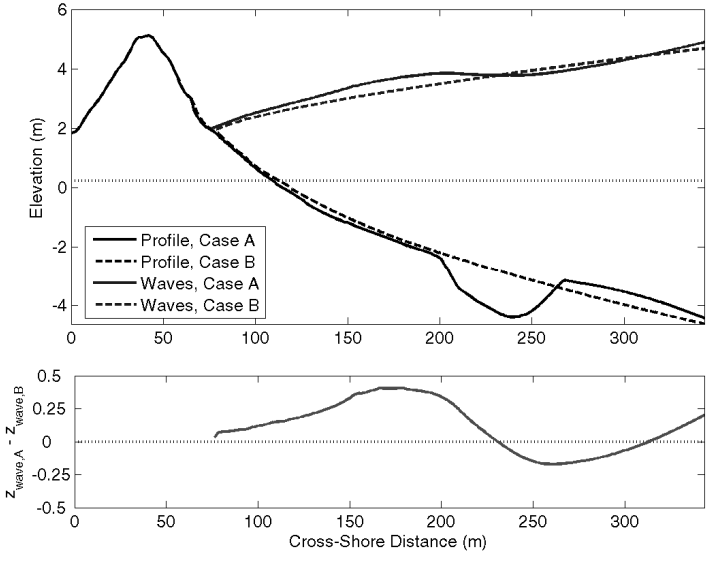

Figure 9. SBEACH predictions of wave height and profile shape at the time of maximum wave height (53 hrs) for a barred profile. Near the shoreline, wave heights are greatest over the measured bathymetry, which exhibits a bar and a deep trough. Nearshore wave heights are smaller over the equilibrium profile, due to the shallower surf zone slope.

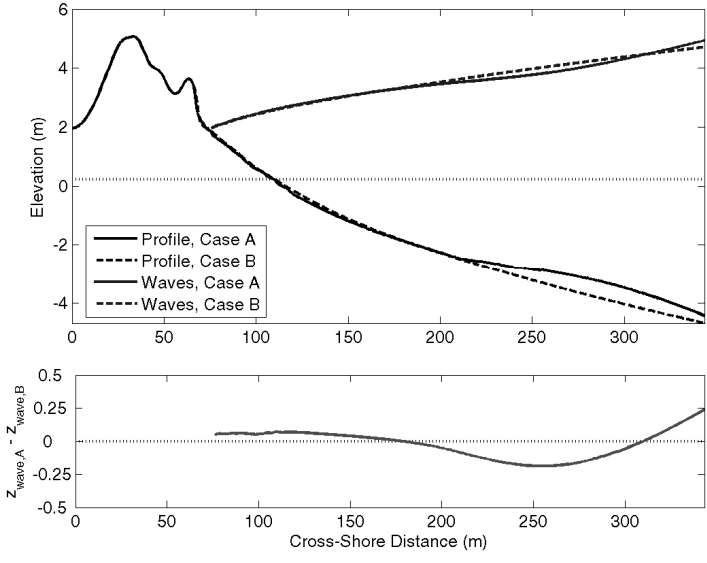

Figure 10. SBEACH predictions of wave height and profile shape at the time of maximum wave height (53 hrs) for a non-barred profile. Near the shoreline, wave heights are comparable for both test cases, due to the similarity in surf zone configuration.

Predictions of GVC were compared to surf zone slope and bar volume, in order to determine potential relationships between bathymetry and model predictions of erosion. Plots of GVC and slope show a linear relationship with an r^2 value of 0.67, which is significant at the 95% confidence level (Figure 11a). Results are clustered into two groups, with ample spread observed within each group. The first group contains those profiles with low slopes, including all of the Case B equilibrium profiles, and those Case A profiles with a non-barred configuration. These profiles display lower predicted GVC values than the second grouping. The second cluster of profiles are Case A profiles with a bar-type configuration and higher slopes and correspondingly higher GVC values.

Alternatively, the relationship between bar volume and predicted GVC (plotted for Case A only) shows no significant trend (Figure 11b). This result suggests that the bar did not play a significant role in the erosion of the subaerial profile. This finding is explained by the modeled wave height profiles which show minimal breaking over the bar and immediate reformation over the deep trough (Figure 9).

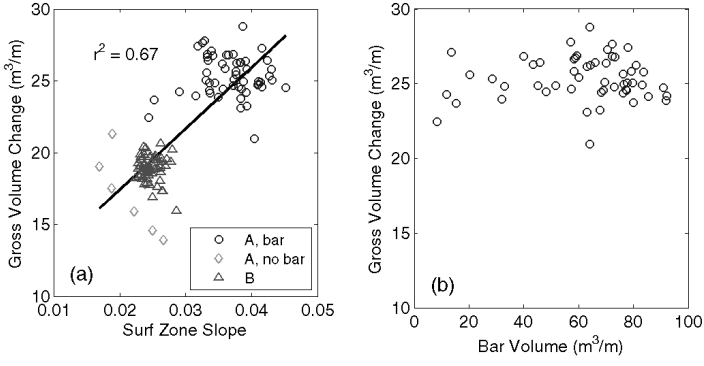

Figure 11. (a) GVC as a function of pre-storm surf zone slope for both test cases. The calculated r^2 value of 0.67 is significant at the 95% confidence level. (b) GVC as a function of bar volume, showing that in this specific case, bar volume is not a significant variable in affecting erosion of the subaerial profile.

CONCLUSIONS

Model results for Cases A (measured bathymetry) and B (equilibrium profiles) converge over non-barred profiles where initial bathymetry is similar, and diverge over barred profiles where bathymetric differences are more pronounced. The mean volume difference between the two predicted profiles was 6.0 m^3/m, which is smaller than expected based on differences in initial surf zone bathymetry. When this calculation is separated into barred and non-barred profiles, the respective means of 6.4 m^3/m and 2.7 m^3/m are significantly different at the 95% confidence level. Additionally, longshore variability in model predictions is observed for Case A profiles. The surf zone configuration changes sharply over a 120 m wide attachment of the bar to the shoreline, which occurs within the western half of the study area. The predicted erosional volumes drop sharply in this region, to as little as half of the predicted erosion on surrounding profiles (Figure 8). In contrast, predicted erosion is uniform throughout the study area for Case B model results. Patterns in predicted erosion can be partially explained by the configuration of the inner surf zone from the shoreline to the trough, with surf zone slope accounting for 67% of the variability in predicted erosion volumes (Figure 11a).

The predicted erosional volume on the subaerial profile was consistently greater for Case A results than for Case B results. This observation is contrary to the original hypothesis, which suggested that waves would break over the bar and dissipate substantial energy seaward of the beach, therefore producing less erosion on the subaerial profile. While the bar was expected to play a significant role in erosional trends, no relationship emerged in a comparison of bar volume and gross volume change (Figure 11b). Inspection of modeled wave heights over barred profiles shows that waves break minimally over the bar, and immediately reform landward of the bar over the deep trough (Figure 9). Over the equilibrium profile, wave heights decrease gradually over the monotonic profile form. Modeled wave height profiles for Cases A and B diverge

significantly landward of the trough. The divergence is caused by differences in surf zone slope, which allows larger waves to shoal closer to the shoreline over Case A profiles. Accordingly, the specific configuration of the profile, including the height and depth of the bar, the depth of the trough, and the surf zone slope will all play important roles in determining the magnitude of erosion predicted by SBEACH.

ACKNOWLEDGEMENTS

Many thanks are due to Peter Howd (USGS), Hilary Stockdon (USGS), and Chantal Donnelly (University of Lund) for lending their expertise in statistics and dune modeling. Karen Morgan, Kristy Guy, and Charlene Sullivan of the USGS were all instrumental in processing lidar data and profiles used in this study. Lidar surveys were performed in cooperation with Jeff Lillycrop of the U.S. Army Corps of Engineers and the Naval Oceanographic Office. This work is funded under the USGS Hurricane and Extreme Storm Impact Studies project, which is part of the USGS National Assessment of Coastal Change Hazards.

Abstract: The landfall of Hurricane Rita in 2005 significantly altered physical and morphological characteristics along the southwestern Louisiana coastline and interior marshes. An excessive storm surge event linked to Rita resulted in widespread, storm-induced overwash deposits in Cameron and Vermilion Parishes, Louisiana. These deposits superseded prior deposits and were aligned parallel to predominant flow patterns associated with the storm's counter-clockwise circulation. These responses became more pronounced farther west and culminating at eyewall impact. Excessive salinity levels resulting from salt-water intrusion severely impacted local vegetation several kilometers inland and over the longer term may exacerbate the loss of vegetation that retards coastal erosion and attenuates waves and storm surge during high-energy events. Massive water levels introduced onshore by surge remained locally ponded several weeks after the hurricane; however, morphological patterns along the coastline had begun facilitating the return flow of water and sediment to the Gulf of Mexico.

INTRODUCTION

A significant coastal sediment transport and storm surge event occurred along the southwestern Louisiana shoreline concurrent with the landfall of Hurricane Rita on September 24, 2005. This hurricane, which made landfall as a Category Three storm near the Texas/Louisiana border, significantly altered coastal sediment transport patterns through (1) the effects of a strong storm surge, and (2) the post-storm return flow to the

Gulf of Mexico of elevated water levels within inland bays and marshes. Additionally, coastal morphology was influenced by post-storm beach recovery as indicated by bar welding to the lower shoreface only several weeks after the passage of Hurricane Rita.

Research by the Coastal Studies Institute of Louisiana State University revealed sand overwash deposits and evidence of excessive storm surge and salt-water intrusion along the southwest Louisiana coast. These responses became more pronounced farther west and closer to eyewall impact near the Texas/Louisiana border. Excessive salinity levels resulting from salt-water intrusion severely impacted local vegetation both along the coast and several kilometers inland. These impacts may locally exacerbate existing problems linked to coastal erosion through the loss of vegetation that retards coastal erosion and attenuates waves and storm surge during high-energy events.

Storm surge associated with the passage of Hurricane Rita infiltrated tens of kilometers inland. Ponded surge water remained trapped even several weeks after Hurricane Rita struck the southwestern Louisiana coast. However, distinct return flow patterns of water and sediment were observed along the southwestern Louisiana coastline, which indicate active processes by which excessive water volume returns to the open Gulf.

STORM HISTORY AND SEA STATE

Hurricane Rita began as a tropical depression just east of the Turks and Caicos Islands on September 17, 2005 and intensified steadily over the next several days as it moved westward through the Florida Straits. The eye of Hurricane Rita passed approximately 50 miles (80 km) south of Key West, Florida on September 20 and thus missed the U.S. mainland as it approached southern Florida as a Category 2 hurricane on the Saffir-Simpson scale. However, upon entering the Gulf of Mexico, Rita intensified rapidly and attained Category 5 status and a peak sustained wind strength of 175 mph (78 m/second) within only 24 hours. The barometric pressure recorded during this phase of the storm reached 897 millibars, the third-lowest ever recorded for a tropical system in the Atlantic Basin at that time. This pressure reading simultaneously displaced to fifth-lowest the 902 millibar minimum pressure measurement from Hurricane Katrina recorded only one month earlier (National Hurricane Center, 2005; Knabb et al., 2006). However, both of these measurements were subsequently displaced one level lower in October 2005 by Hurricane Wilma, which yielded the lowest barometric pressure ever recorded to date in the Atlantic Basin, at 882 millibars (Pasch, et al., 2006).

Wind and wave conditions during Hurricane Rita were measured by a series of buoys maintained by the National Data Buoy Center. While still at sea in the Gulf of Mexico, the eye of Rita passed approximately 2 miles (3 km) southeast of Buoy 42001, the data buoy closest to the path of the storm (Figure 1). A barometric pressure of 926 millibars was recorded at 6:00 PM (2300 Z) on September 23, about 8.5 hours prior to landfall. The maximum significant wave height measurement was 38 feet (11.6 m), sustained winds were measured at 100 mph (45 m/second), and maximum gusts were measured at nearly 136 mph (61 m/second) approximately 7 hours prior to landfall. As Rita neared the coast, C-MAN station SRST2, located near Sabine Pass on the upper Texas coast

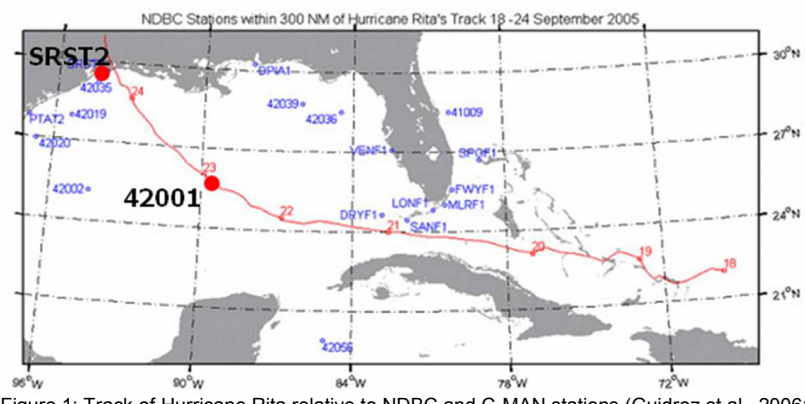

Figure 1: Track of Hurricane Rita relative to NDBC and C-MAN stations (Guidroz et al., 2006; reprinted by permission of the GCAGS whose permission is required for further use)

(Figure 1), recorded a barometric pressure of 951 millibars at 1:00 AM on September 24 (approximately one hour prior to landfall).

Hurricane Rita weakened as it approached the north-central coast of the Gulf of Mexico on September 23, eventually becoming a Category 3 hurricane as it made landfall. The hurricane moved ashore between Sabine Pass and Johnson's Bayou, Louisiana early on September 24 with sustained winds of 120 mph (54 m/second). Concurrent with its onshore arrival and wind field, Rita initiated a substantial storm surge east of its center that reached a maximum of 18-20 feet (5-6 m). Rita then weakened rapidly as it continued northward through east Texas and western Louisiana, eventually turning northeastward and merging with an advancing cold front on September 26, 2005.

OBSERVATION METHODS

A helicopter overflight was taken to observe post-hurricane coastal conditions along practically the entire south-central and southwestern Louisiana coastlines and interior marshlands (Figure 2). The coastal flight path began near the Atchafalaya and Wax Lake Delta, extended westward toward Marsh Island and Vermilion Bay, and concluded at Sabine Pass in Cameron Parish, Louisiana. An interior marshland flight pass was then made that extended eastward from Sabine Pass and continued through Cameron, Calcasieu and Vermilion Parishes. Digital photos were taken throughout the trip as were a constant stream of video data that provided a continuous record of the entire trip. Photos were calibrated to a GPS to ensure accurate positioning of each picture so that sedimentologic and morphologic changes detected in potential follow-up trips could be accurately calibrated to those from this original flight.

RESULTS

Several unique phenomena were observed during the overflight. Massive overwash deposits were observed on the backside of many beaches along the coast. These became

Figure 2: Helicopter overflight route, southwestern Louisiana, October 16, 2005 (satellite image available at http://www.geology.com/satellite/louisiana-satellite-image.shtml)

more pronounced farther west and culminated near where the eye moved ashore at Johnson's Bayou. In addition, excessive storm surge and salt-water intrusion also became more evident farther west as indicated by the loss of vegetation in inland marshes as well as the catastrophic infrastructure and property loss in locations such as Holly Beach and Cameron. Scour effects and sediment re-distribution patterns were also noted, particularly in association with several series of rock jetties located just offshore from the southwestern Louisiana coast. Despite the destructive nature of the phenomena observed, the initial phases of post-storm recovery were also detected, primarily through bar welding to the lower shoreface as sediment was being reworked from offshore by post-storm waves.

Storm Surge and Return Flow Observations

Overwash deposits were observed in western Vermilion Parish and continued westward through most of Cameron Parish. These overwash deposits were typically located approximately 30-50 feet (9-15 m) behind the immediate coastline and were approximately 40 feet (12 m) wide (Figure 3). In many cases, ripple beds were detected on top of overwash deposits, indicating significant wave-induced currents. In other cases, overwash deposits were seen as distinct lobes in tandem with distributary patterns that appeared to consist of relatively finer-grained, muddier material (Figure 4).

However, overwash was not detected continuously along the coast. This fact may stem from either the lack of an initial, sand-sized offshore sediment supply or from localized variations in coastline morphology. In some cases, distinct incision events were detected across a broad mud apron along the immediate shoreline and seemed to indicate evidence of return flow of water and sediment to the Gulf of Mexico (Figure 5). These dendritic-shaped patterns continued from the shoreline southward to a hinge point just offshore where they appeared to bifurcate and form subaqueous channels directed offshore. Although significant onshore sediment movement occurred during Hurricane Rita, this evidence indicates that steady, post-storm sediment and water movement had been taking place in the offshore direction.

Figure 3: Overwash deposits, eastern Cameron Parish, Louisiana (inset shows rippled overwash deposits and return flow features)

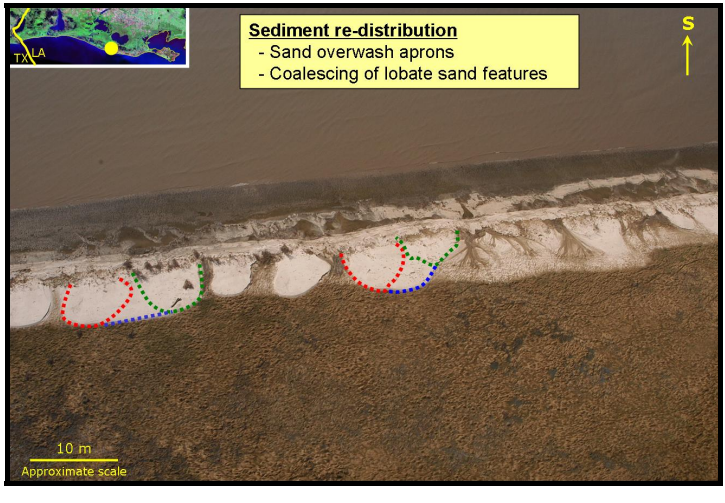

Figure 4: Lobate sand overwash deposits, Vermilion Parish, Louisiana (Guidroz, et al. 2006; reprinted by permission of the GCAGS whose permission is required for further use)

Hurricane Rita generated a significant storm surge event that resulted in substantial salt water intrusion, much of which occurred as far as 25 miles (40 km) inland. Evidence for this intrusion was noted by several different means. First, severe vegetation loss was noted during the October 2005 overflight, primarily through marsh grass that had been

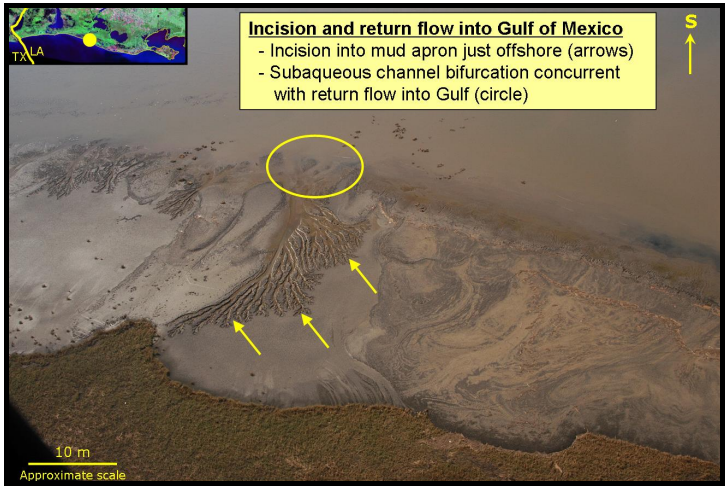

Figure 5: Drainage and return flow channelization, Cameron Parish, Louisiana (Guidroz, et al. 2006; reprinted by permission of the GCAGS whose permission is required for further use)

killed off through saline seawater intolerance. Second, numerous debris fields were observed, particularly near Cameron and Holly Beach, Louisiana and all were aligned in a southeast-northwest direction, indicating how surge had transported both beach and man-made material parallel with the hurricane's predominant counter-clockwise flow. Third, ponded water, remaining from the surge event three weeks earlier and trapped from re-entering the Gulf by localized topographic relief, was also clearly evident along the coast (Figure 6). Fourth, a series of high-water observations was undertaken by staff from the LSU Hurricane Center to visually observe storm surge water level heights based on markings from debris and water levels carried inland by storm surge.

Storm Surge Water Levels

Field observations of high water marks along the coast and inland for several kilometers were obtained by the LSU Hurricane Center (LSUHC; Figure 7) and the Federal Emergency Management Agency (FEMA; Figure 8; URS Group, Inc., 2006). Both data sets are in generally good agreement. Maximum water levels associated with Rita were observed at 14-15 feet (4-4.5 m) at Cameron and slightly farther to the east (all elevations were measured relative to NAVD88). Inland along the margins of Calcasieu Lake, storm surge was significantly attenuated, and high water marks ranged between 3-10 feet (1-3 m). To the east as far as Vermillion Bay, storm surge water levels remained significant and high water marks of up to 12 feet (3.7 m) were measured.

High-water surge observations noted in the field were compared to publicly available numerical models (SLOSH and AdCirc; FEMA, 2005, Figure 9). The datasets generally agree on the relative intensity of storm surge along the immediate southwestern Louisiana coast although the FEMA model consistently under-predicted surge levels at

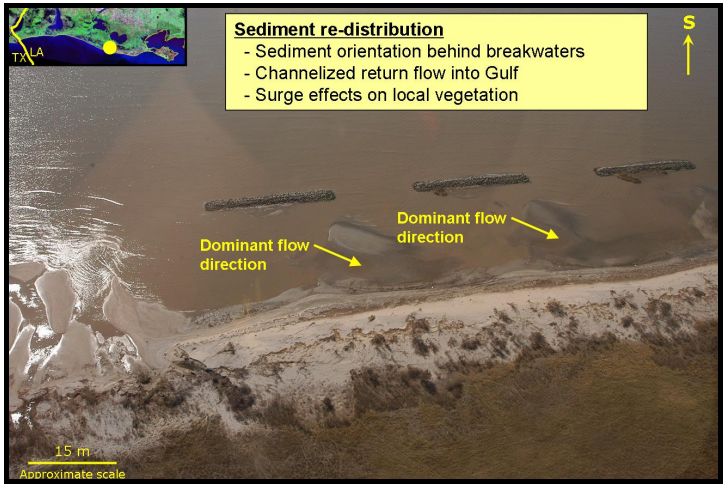

Figure 6: Channelized return flow features, Vermilion Parish, Louisiana (Guidroz, et al. 2006; reprinted by permission of the GCAGS whose permission is required for further use)

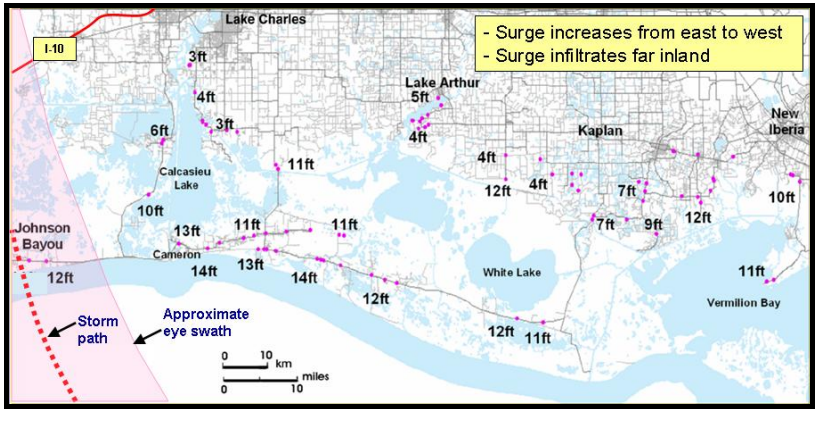

Figure 7: LSUHC high-water mark field observations, southwestern Louisiana (Guidroz, et al. 2006; reprinted by permission of the GCAGS whose permission is required for further use)

the coast. Inland, however, the model results diverged greatly. The FEMA model, which was run in hindcast mode, vastly over-predicted surge levels inland. The latter may be a direct function of the inability of these models to account for differences in bottom friction between water and marsh.

West of the eyewall impact along the upper Texas coast, storm surge levels were much lower compared to areas east of eyewall impact in southwestern Louisiana. The counter-

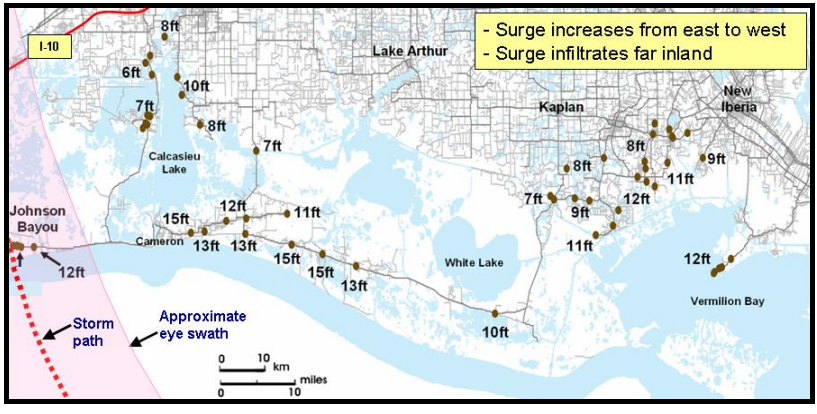

Figure 8: FEMA high water mark field observations, Hurricane Rita, southwestern Louisiana (URS Group, Inc., 2006)

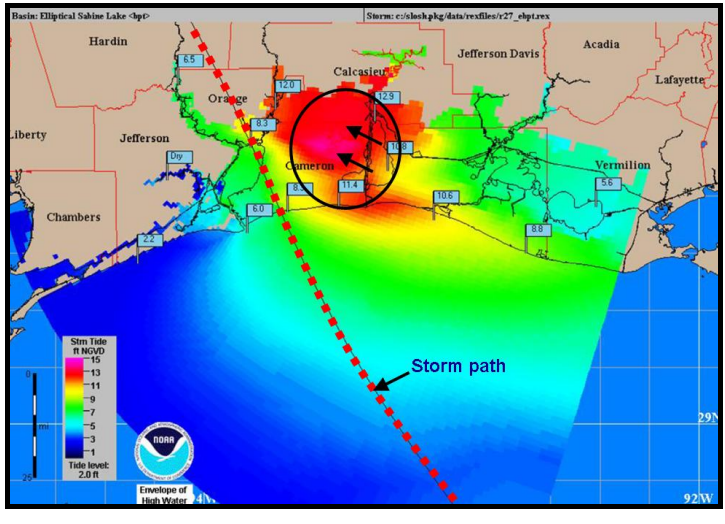

Figure 9: SLOSH model, Hurricane Rita (URS Group, Inc., 2006; available at http://www.fema.gov/pdf/hazard/flood/recoverydata/rita)

clockwise circulation associated with Rita resulted in a primary wind field along the upper Texas coast from the north and northeast. This flow direction suppressed any excessive surge events and therefore minimized morphologic effects west of the point of eyewall impact. Preliminary observations along the upper Texas coast have confirmed these findings (King, personal communication, 2006).

LONG TERM CONSEQUENCES

Since 1901, at least 55 tropical storms and hurricanes have made landfall within Louisiana, implying a long-term average of one storm about every-other year (Stone et al., 1997). However, storm frequency along the central and southwestern Louisiana coasts is nearly twice that of eastern Louisiana with a peak in activity usually occurring

in the month of September. The relatively high frequency of storms along this section of the Gulf coast therefore exerts a cumulative effect on and can significantly alter coastal geomorphology from year-to-year. Previous sand overwash deposits have been noted along the southwestern Louisiana coastline (Williams, 2006) as driven by excessive storm surge events. However, post-storm adjustments to these effects also play a critical role. As an example, post-storm recovery has been previously documented along several Louisiana barrier islands after Hurricanes Juan (1985), Danny (1985) and Gilbert (1988; Stone et al., 1999; Guidroz et al., 2006). Although post-storm recovery depends upon the degree of damage and the availability of sediment within the coastal system, more investigation is needed to further quantify the full effects. This overflight was only the initial investigation into documenting destruction and recovery effects; follow-up observations are required to adequately address the pace and efficiency of future beach recovery.

CONCLUSION

The observations noted in the aftermath of Hurricane Rita demonstrate several distinct phenomena prevalent within the coastal environment after severe storms. Storm surge, combined with post-storm water and sediment return flow back to the open Gulf, can greatly influence sediment patterns along and adjacent to nearshore and inland coastal areas. The observations made during the study will serve as the basis for future investigations to document longer-term effects on local sediment distribution patterns as a result of Hurricane Rita. However, these effects may be interrupted, and possibly delayed, by future tropical cyclones that impact the north-central and northwestern Gulf of Mexico coasts.

ACKNOWLEDGEMENTS

The authors would like to thank BP America, Inc. for underwriting costs associated with this overflight. We also thank the Coastal Studies Institute of Louisiana State University for their support in arranging overflight logistics. Xiongping Zhang and Felix Jose of the Coastal Studies Institute acquired digital photo images and video data during the flight that were used in assembling this paper.

Abstract: Ship Shoal, a shore-parallel elongate sand shoal and a remnant of a late Holocene active delta has a unique heterogeneous sedimentary feature strongly affected by winter storms and fluvial sediment input from the Atchafalaya River. The interaction between fluvially derived sediment and subsequent deposition on the shoal has not been quantified; implications for hydrodynamic modeling are profound given that the shoal surface vacillates between sand and fluid mud. Thus, attenuation effects on waves and currents vary greatly. The results of a field survey undertaken during spring flood and winter storm periods showed that during fair weather, river-borne sediments transported to the shoal, forms a distinct fluid mud layer. Bottom sediments were re-suspended and transported by storm-induced waves and prevailing northerly/southerly

trends of currents over the shoal during the period. Data presented here suggest that the high sediment transport during the storms and the ephemeral deposition of fine-grained sediments could form transient sediment distribution on the shoal without leaving any modern sedimentary records, as reported by recent core surveys.

INTRODUCTION

Much of the Louisiana continental shelf is characterized by fine-grained sediment due to fluvial inputs from the Mississippi and Atchafalaya rivers, their distributaries, and frequent hurricane and winter storms. Submerged transgressive sand shoals off Louisiana, which are remnants of past active deltas, form thick sandy sequences on the inner shelf (Penland et al., 1986).

Physical processes along the Louisiana coast are strongly affected by high energy events such as hurricanes and quasi-periodic winter storms. The muddy coast along western Louisiana also causes unique physical process responses (e.g. Sheremet and Stone 2003; Sheremet et al., 2005; Stone et al., 2006) as well as biological processes (e.g. Stone et al. 2006). Recent articles demonstrate the effects of the Mississippi and Atchafalaya River plumes on the Louisiana continental shelf, based on hydrological and geological surveys and satellite image analysis (e.g. Allison et al., 2000; Walker and Hammock, 2000; Bentley, 2002).

It is now well documented in the scientific literature that coastal Louisiana has experienced substantial wetland loss and beach/barrier island erosion due to high rates of subsidence, storms, shortage of sediment supply from adjacent fluvial systems and human intervention such as dam and levee construction. Federal and state governments are exploring potential sand sources offshore to restore eroding barrier islands and beaches (Drucker et al., 2004). Offshore sand resources have been considered one of the highest priorities for sand resources for coastal restoration given proximity to the target areas and for sand quality (Drucker, B., pers. com.). Ship Shoal, which is a remnant of the paleo-Maringouin delta, located 20 km offshore Isles Dernieres, is a high priority target sand resource to aid in the restoration of the Isles Dernieres Barrier Chain (Drucker et al., 2004). Numerous studies of the area have been undertaken particularly in terms of geological and physical processes (Penland et al., 1986; Pepper, 2000; Stone et al., 2006). Studies of the physical processes include wave-climate, bottom boundary layer, and sediment transport processes based on field surveys and spectral wave model studies (Pepper 2000; Stone et al. 2004). These studies concluded that waves substantially transform as they

propagate over the shoal by comparing the result of pre- and post-sand mining scenarios (Stone et al., 2004). Although they provide detailed mechanisms of hydrodynamics and non-cohesive sediment transport at the shoal, recent surveys suggest that the area has a complex sedimentary environment, which has not previously been researched. To fully understand the mechanism of wave-bottom sediment interactions and sediment transport processes, field surveys and numerical modeling studies were conducted and a synopsis of the data are presented here. The overall purpose of this paper is to describe wave and current dynamics affecting the bottom boundary layer, and sediment transport over the shoal during a field survey conducted in Spring 2006.

DATA AQUISTION

During spring flood and the winter storm season, an array of oceanographic instrumentation was deployed at three locations along the northern and southern

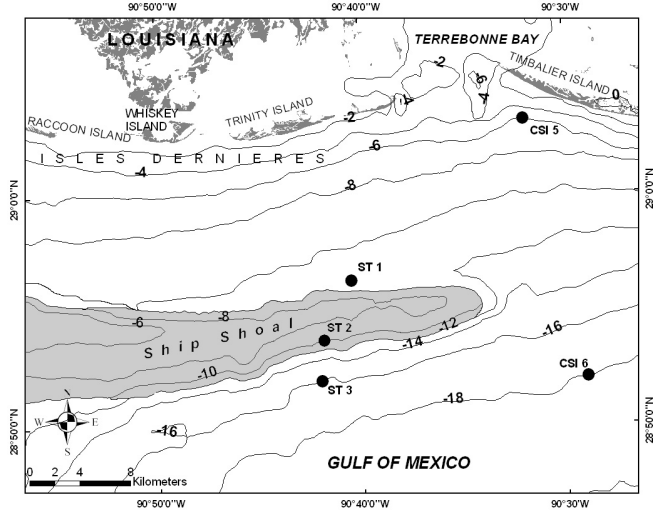

Figure 1 Map of 2006 survey stations, ST1, ST2 and ST3

edges of the shoal and the crest of the shoal, to collect wave, current and suspended sediment concentration data (Figure 1). The instruments at the middle station (ST2) consisted of a 1.5 MHz SonTek^{R} pulse-coherent Doppler profiler, a Druck^{R} pressure sensor, and two D&A^{R} optical backscatter sensors. A 5.0 MHz SonTek^{R} Acoustic Doppler Velocimeter and a ParoScientific^{R} pressure sensor were deployed at both

edges of the shoal (ST1, ST3). Two D&A^R optical backscatter sensors were also deployed at the north station (ST1). Each instrument system was tethered to nearby oil platforms for a robust deployment.

DATA ANALYSIS

Significant wave height, peak wave period, and dominant wave direction were calculated from pressure and current data based on the spectral method by Earle (1995) (see also Stone et al. 2006). Directional wave spectra were calculated by the PUV method using DIWASP, a Matlab package (DIWASP, 2001).

Suspended sediment concentration (hereafter referred to as SSC) was estimated from the data collected using optical backscatter sensors (hereafter referred to as OBS) after calibration using water and sediment samples taken from the stations by ponar grab. The calibration studies were conducted at the CSI field support facility. Bottom sediment samples were incrementally added to distilled water in a black bucket and stirred using a hand-held electric agitator. OBS sensors were immersed in the bucket and measurements were taken for 2 minutes. Water samples were taken after the OBS measurements and were filtered; the SSC were estimated from the weight of the dried sediments and the water volume (Stone et al., 2006).

SSC was also estimated from the ADV and the PCADP single frequency acoustic backscatter intensity with appropriate calibration. The acoustic backscatter intensity is a by-product of the PCADP and the ADV, and is proportional to the SSC estimated from the OBS. This method includes inevitable noise because the backscattering is affected by various parameters such as sediment type, size and composition. All are difficult to quantify by single frequency backscatter sensors and there remain limitations associated with optical and acoustic instruments (Hamilton et al., 1998). In spite of these limitations, estimating the relative sediment concentration profile based on the acoustic backscatter intensity is a cost-effective method which enables us to monitor the SSC trend over time. A more detailed method of estimating the SSC from the OBS and the PCADP/ADV is presented in Stone et al. (2006). The SSC at ST3 was estimated from the relationship between the OBS and the ADV backscatter intensity at ST1.

Wave orbital velocity, shear velocity, shear stress, and apparent bottom roughness were calculated to examine boundary layer dynamics. For the calculation of shear velocity and shear stress, four methods were used: (i) linear wave theory, (ii) log-linear method, (iii) Reynolds stress method, and (iv) quadratic stress law method (Sternberg, 1972; Komar, 1976; Pepper, 2000). Critical shear stress for non-cohesive

sediments was calculated by the Shields parameter combined with the modified Yalin parameter (Pepper, 2000). The critical shear stress for cohesive sediments is difficult to specify and needs further laboratory experiment to determine parameters which are site-specific (Mehta et al., 1989). Mean critical shear stress for erosion and deposition is suggested to be 0.15 N/m^2 and 0.1 N/m^2, respectively, based on a wide variety of studies in the U.S. and was used in this study (DHI, pers. com.).

RESULTS AND DISCUSSIONS

Meteorological and hydrological characteristics

Tropical cyclones (i.e. hurricanes and tropical storms) and extra-tropical storms (i.e. winter storms) are the two important meteorological events that affect the Louisiana coast. Particularly, frequent passage of winter storms between October and April causes cumulative effects on waves, hydrodynamics and sediment transport along the Louisiana coast because of their frequency, compared to less frequent landfall of tropical cyclones (Pepper, 2000; Stone et al., 2004; Kobashi et al., 2005). Generally, as cold fronts approach the coast, strong southerly winds can generate significant wave height on the shelf from 3-5 m, barometric pressure shows a marked decrease and thus characterizes the pre-frontal phase. After the front passes, air temperature abruptly decreases and wind direction changes from the southern to northern quadrants representing the post-frontal phase. The above described trend is evident in the time series of wind data obtained from a nearby meteorological station, WAVCIS CSI-6 (90° 29' W, 28° 52' N) (Figure 2 left). The dominant wind direction is 173 degrees (i.e. wind from SSE), which is a common characteristic during the fair weather conditions and a force to generate longshore current, generally directed westward, off south-central Louisiana (Figure 2 right).

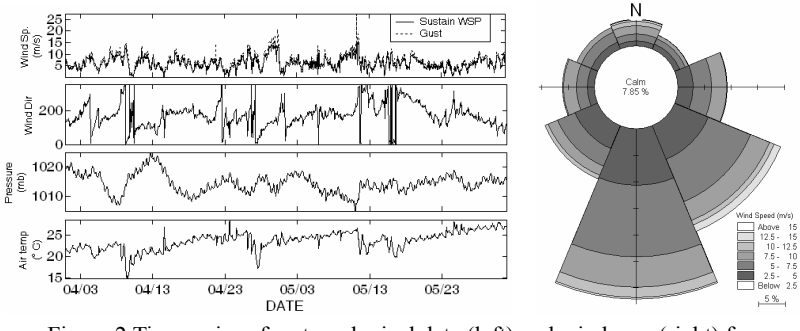

Figure 2 Time series of meteorological data (left) and wind rose (right) from WAVCIS CSI-6

Significant amounts of fluvial sediment discharged from both the Mississippi and Atchafalaya rivers, and distributaries, are also highly significant in introducing sediment to the shelf thereby playing an important role on hydrological processes that affect physical and biological processes on the Louisiana inner continental shelf. In the study area, maximum river discharges of 310,000 cubic feet per second (cfs) were recorded at Simmesport located upstream on the Atchafalaya River on March 30th, 2006 and 250,000 cfs on May 8th, 2006, resulting in significant influxes of muddy sediments along the western/south-central Louisiana coast (Stone et al., 2006).

Bottom sediment characteristics

Bottom sediments collected during a biological cruise conducted for the entire shoal that included ponar grabs along the eastern flank of the shoal before and after bottom boundary layer equipment deployment (Figure 3, shaded triangles), show a unique shoal sedimentary environment. Bottom sediment grain size distribution for the entire shoal, surveyed in late May, 2006, shows that the grain size is finer along the western part of the shoal than its eastern flank; we attribute this to the influence of fluvially derived material from the Atchafalaya River (Figure 3, left).

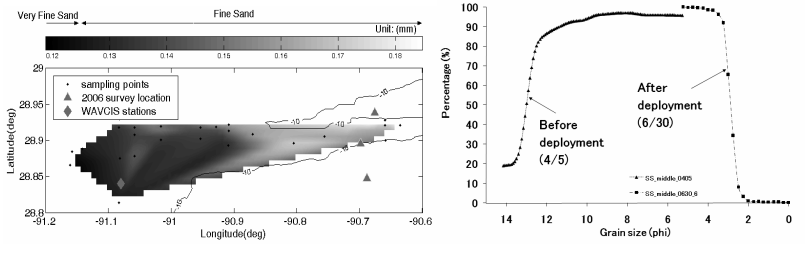

Figure 3 Mean grain diameter for the entire shoal (samples taken May 25th, 2006) (left) and grain size distribution taken before and after the deployment (right)

Bottom sediment taken from the eastern portion of the shoal shows a dramatic change in sediment grain size before and after the deployment (Figure 3, right). Sediment sampled before the deployment was mainly clay with a median grain diameter of 2 microns, probably originating from the Atchafalaya River; sediment sampled after the deployment was fine sand with a median grain diameter of 143 microns, suggesting the effect of sediment reworking due to storm-induced waves. This unique behavior of the bottom sediments was not found during previous field surveys undertaken along the western flank of Ship Shoal in January, 1998 (Pepper, 2000). The fine

grained sediments from the Atchafalaya River are usually transported west due to a longshore coastal current (Wells and Kemp, 1981). However, during winter storms, strong southerly wind-induced currents with sufficient sediment supply can transport this fine grained sediment to the south/southeast, occasionally reaching Ship Shoal (Kobashi et al., submitted). Such a sediment dispersal pattern was confirmed by satellite imagery obtained during our deployment and also reported by Walker and Hammock (2000).

Wave characteristics

During the cold frontal passages, pre-and post-frontal phases have a significant effect on the wave field along the northern Gulf. Lower frequency waves dominate the spectrum during pre-frontal conditions. As winds veer to the north, higher frequency waves occur in the bays/estuaries and wave energy levels drop significantly on the shoreface (Figure 4d,e). Waves can become higher after the storms because of relatively strong southerly wind induced by a high pressure system covering the area (e.g. April 10th, 2006) (e.g. Pepper, 2000; Kobashi et al., 2005).

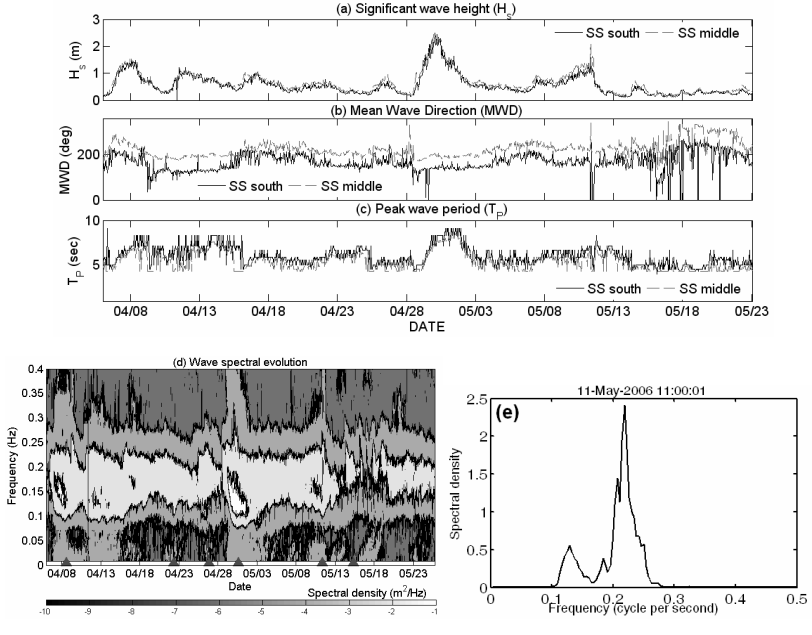

Figure 4 (a-c) Time series of wave parameters, (d) Wave spectral evolution, (e) spectral distribution during a post-front. Triangles show passage of cold fronts.

Current velocity and circulation patterns

Bottom currents are strongly affected by local bathymetry and associated turbulence as well as currents due to tides. Current direction near the bottom is different from that at the surface, suggesting current modulation due to local bathymetry, wave-induced turbulence, or wind-induced Ekman transport. Currents due to tides are generally small (i.e. less than 5 cm/s) and strong currents occur during winter storms. The strong northeast/southwest osciallation of current direction during winter storms is clearly apparent in Figure 5, and is associated with the rotating storm wind direction. During fair weather, currents are weak and highly variable when compared to storm conditions; however, surface currents were often westward (not in the figure) due to longshore currents driven by prevailing south-easterly waves. In addition to the longshore currents, tidally-induced currents when combined with higher energy waves during winter storms result in additional currents with a period of around 5 to 10 days, a mean frequency consistent with winter storms.

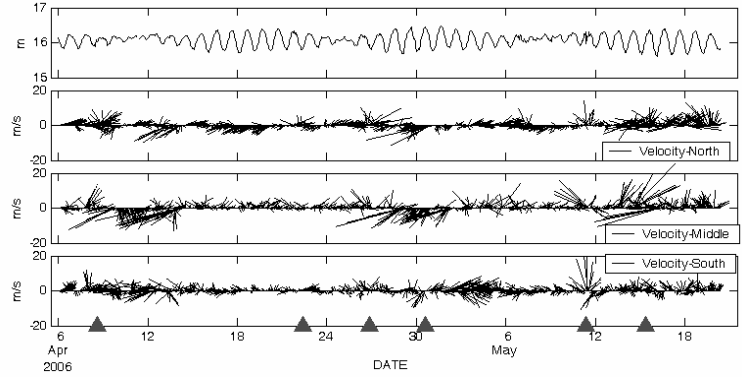

Figure 5 Stick vector of bottom current velocity at each station. Triangles indicate passage of storms

Suspended Sediment Concentration

Suspended sediment concentration is also strongly associated with winter storms. Figure 6 shows that high sediment concentrations occur during winter storms at all three stations, suggesting that strong storm-induced waves cause high bottom sediment re-suspension compared to that during fair weather. Particularly, during late April, high concentration of suspended sediments associated with a storm occurred. At ST1, SSC attained saturation level and lasted approximately 2 days. At ST2 and ST3, high SSC also occurred during the waning phase of the storm as well as during

the pre-frontal stage, suggesting the occurrence of substantial deposition of cohesive sediments (The latter is discussed in more detail below). High SSC during April 8th and May 10th shows the input of river-borne sediments from the Atchafalaya River, also confirmed by satellite images and altimeter data during this period (Kobashi et al., submitted).

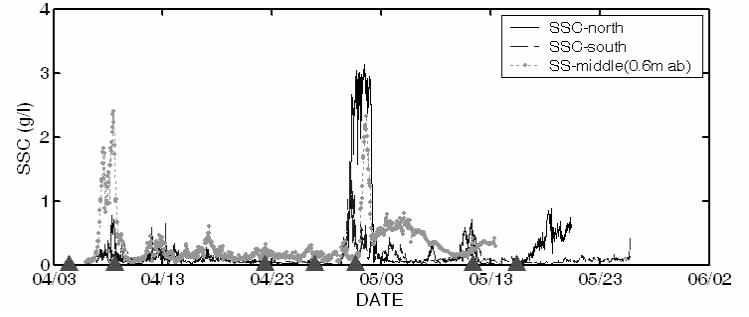

Figure 6 Time series of sediment concentration at each deployment station. Triangles indicate passage of storms.

Bottom boundary layer parameters and sediment flux

Shear velocity and shear stress are high during winter storms. Bottom orbital velocities associated with winter storms attained a maximum of 60 cm/s during a storm in late April (Figure 7). The periods of high orbital velocity, shear velocity, and shear stress match those of the high SSC shown in Figure 6.

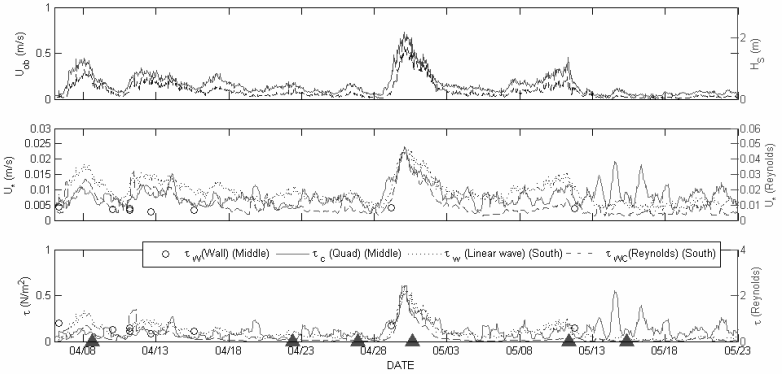

Figure 7 Time series of bottom boundary layer parameters: (a) wave orbital velocity (Uob), (b) shear velocity (U*), and (c) shear stress (τ) during the deployment at the middle station

The sediment flux, calculated by the product of horizontal velocity and sediment concentration, is shown in Figure 8. The direction of sediment transport is different among stations, and is significantly influenced by current direction. Northerly/southerly currents during winter storms drive the highest transport in the region, although current direction is dependent on other factors such as local bathymetry and tides. It is evident that in-situ observation of sediment flux is much higher than non-cohesive sediment transport derived numerically (not in the figure). It is also evident sediment flux occurs during fair weather, a finding that contradicts the results of previous work (e.g. Wright et al., 1997).

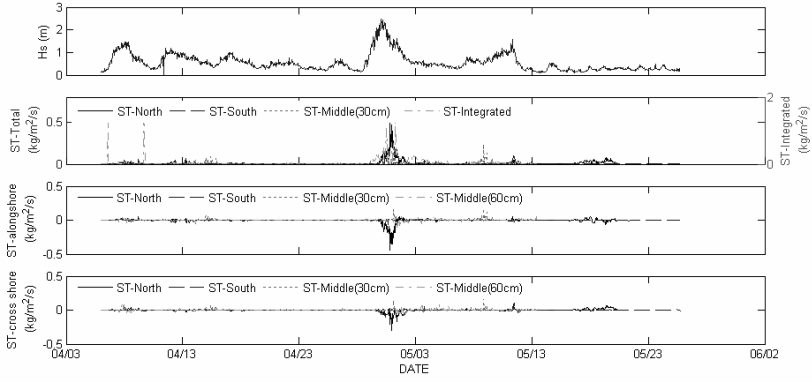

Figure 8 In-situ sediment transport measurements for each deployment station

Resuspension, mixing, and settling processes of fluid mud during a storm

Waves, currents, and sediment transport are intensified by winter storms, and the bottom sediment of the shoal uniquely varies during these events. Figure 9 shows the time series variation of bottom boundary layer parameters and SSC during a storm which passed the region in late April, 2006. Wave height reached approximately 2.5 m during the pre-frontal phase, consistent with a maximum wind speed of 18 m/s. When wave height reached approximately 1 m, the shear stress exceeds the threshold for sediment re-suspension (i.e. τ_{ce}), which is consistent with the increase of bottom SSC (Figure 9c). Bottom sediments are re-suspended strongly during the pre-frontal phase (Re-suspension period), causing highest sediment transport during the storm because of high horizontal velocity. Subsequently, the transport rates decrease due to decreased horizontal velocity and an increased vertical velocity causing vertical mixing during the storm passage (Mixing period). During the waning phase of the storm, substantial sediment deposition occurs in spite of the high sediment transport

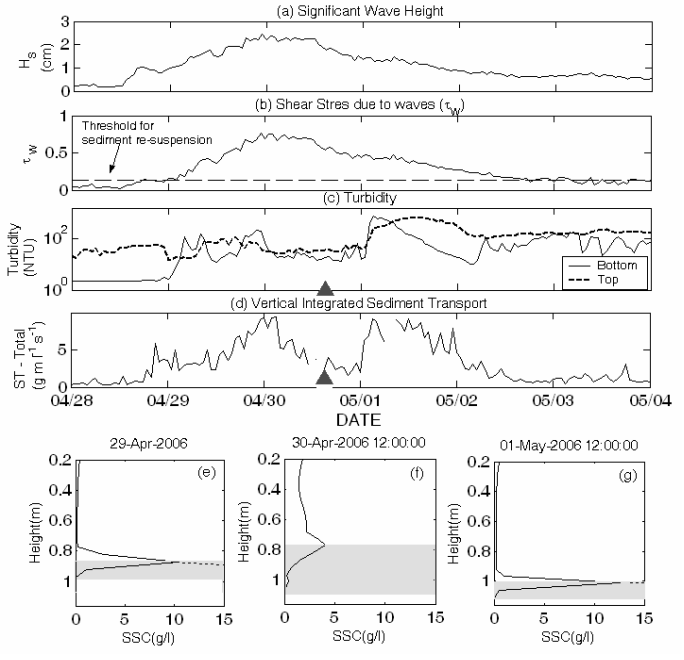

Figure 9 Time series of (a) significant wave height, (b) shear stress due to waves, (c) turbidity, (d) vertical integrated sediment transport, (e)-(g) sediment concentration profiles. Triangles indicate passage of a storm

rates (Settling period). The SSC profile in Figure 9 (e, f, g) demonstrates the above. Prior to storm passage, the peak sediment concentration was measured near the bottom, suggesting the existence of a fluid mud layer (SSC>10 g/l) delivered by hyperpycnal flows originated from the Atchafalaya River. The peak of the SSC strongly decreased below the lutocline since the acoustic signal was strongly attenuated below it (cf. Traykovski et al., 2000). The high frequency acoustic pulse cannot penetrate consolidating muddy bed or sandy bed below fluid mud. Based on this, the thickness of the layer was estimated to approximate between 10 and 15 cm (Figure 9e-g, shaded area). The high value of the SSC disappeared during the storm peak and the peak of the SSC shifted upward, suggesting the layer was vertically diffused due to high vertical velocity. During the waning phase of the storm, the fluid mud layer was re-established. However, the layer is highly unstable according to the SSC profile during the deployment (not in the figure). It is implied that this unstable

layer, which can easily be re-suspended, could not be settled long enough to become consolidated, because of the frequency of the winter storms. Allison et al. (2000) demonstrated that sediment cores taken on the southwest of Ship Shoal had no modern sedimentary records, implying these muddy sediments on the sandy relict sediments cannot become consolidated hard mud bed without leaving any modern sediment records as reported by the recent core surveys at the southwest of the shoal.

There are few data available to prove this hypothesis. It is still unclear as to the fate of this transient mud sediment covering the sandy bottom. Surveys will be undertaken to examine bottom sediments using box cores and underwater cameras to better understand mud distribution during various seasons. Also, the ongoing modeling studies of waves, currents and cohesive sediment transport should provide a more comprehensive analysis of the shoal and its unique processes, which are important to the physical and biological processes of the study area, and for future sand dredging activities.

CONCLUSIONS

To examine wave-climate and wave-bottom interactions over a heterogeneous shoal, field surveys were conducted and the following results were obtained. (I) Bottom sediments on the shoal vary substantially depending on fluvial sediment inputs and winter storms; (II) The north-south trend in current direction during storms suggests a dominant sediment transport direction during the deployment; (III) Rates of transport for cohesive sediment is much higher than those numerically derived non-cohesive sediment transport during the deployment; (IV) A fluid mud layer is formed during fair weather on the shoal and is re-suspended, mixed and re-deposited during storms, implying fine-grained sediment are ephemeral resulting in no sedimentary records on the deposited sediments previously reported by Allison et al. (2000).

ACKNOWLEDGEMENTS

This study is funded by the U.S. Minerals Management Service, Department of Interior and Louisiana Department of Natural Resources. The authors would like to thank CSI field support crews for assisting in the field survey. Yuliang Chen assisted with cartography.

Abstract: Here we present data indicating the complexity and highly variable response of barrier islands and beaches to the impacts of tropical cyclones and winter storms along the northern Gulf of Mexico. Data indicate that (1) barrier islands can conserve mass during catastrophic hurricanes; (2) less severe hurricanes and tropical storms can promote rapid dune aggradation and contribute sediment to the entire barrier system; (3) cold fronts play a critical role in the post-storm adjustment of the barrier by deflating the subaerial portion of the overwash terrace and eroding its marginal lobe along the bayside beach through locally generated, high frequency, steep waves; and (4) barrier systems along the northern Gulf do not necessarily enter an immediate post-storm recovery phase, although nested in sediment-rich nearshore environments. The fluid mud environment off west Louisiana coast plays a significant role in damping wave energy associated with tropical cyclones. However, no significant surge attenuation appears apparent. It is anticipated that these findings will have important implications for the longer-term evolution of coastal systems in the northern Gulf of Mexico.

INTRODUCTION

Recent data suggest that the North-central Gulf of Mexico coast has undergone an increase in the number of tropical cyclone landfalls over the past decade. Louisiana State University and the USGS have monitored the Florida panhandle and Alabama coast since the mid 1990's using airborne LIDAR and field surveys. The resultant data sets provide a unique time series capturing morphological change and post-storm adjustment due to three powerful events (Opal, 1995, Ivan, 2004 and Katrina, 2005), weaker hurricanes and numerous tropical storms. It is the objective of this paper to identify, quantify and elucidate storm responses and post-storm adjustment along a heterogeneous and geologically complex coastal region. The concept of "barrier mass conservation" is further examined. Study sites along the Florida panhandle (A on Fig. 1), Mississippi, (B) and south-central Louisiana (C, D and E) are used to investigate the effects of geological variability on storm response. The significance of locally generated, high frequency waves in estuaries/bays during winter storms is also investigated and interpreted within the context of short-term coastal evolution.

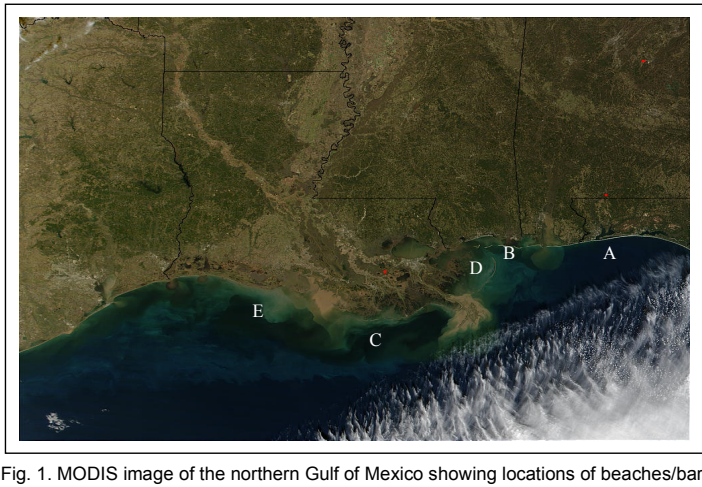

Fig. 1. MODIS image of the northern Gulf of Mexico showing locations of beaches/barriers monitored during the study program discussed in text.

GEOLOGICAL VARIABILITY

In an otherwise tectonically stable region of the northeastern Gulf of Mexico, the coast appears to be storm dominated and undergoing a reduction in sediment volume in the sub-aerial barrier unit, a phenomenon that appears attributable to storm dominance (barrier islands off Mississippi coast are the typical example, location B on Figure 1).

Along the Louisiana coast, barrier islands are routinely breached and/or stripped of their coarser (fine sand) fraction of sediment that overlays an organic, silty-muddy, cohesive core (location C on Figure 1). While the sand veneer is typically infused into the finer-grained bay sediments, the organic and fine-grained core material is exposed due to turbulence associated with storm waves. This response was noted after Hurricane Andrew (1992) (Stone and Finkl, 1995), Tropical Storm Isidore (2002) and Hurricane Lili (2002) (Stone et al., 2003; Allison et al., 2005). Larger chains that constitute those barriers west of the modern delta were not significantly impacted by either Hurricane Katrina or Rita (2005) (Stone et al., 2005; Guidroz et al., 2006; 2007). Similar to during Hurricane Ivan (2004), the Chaundeleur Islands (location D on Figure 1) were severely breached during Hurricane Katrina (2005).

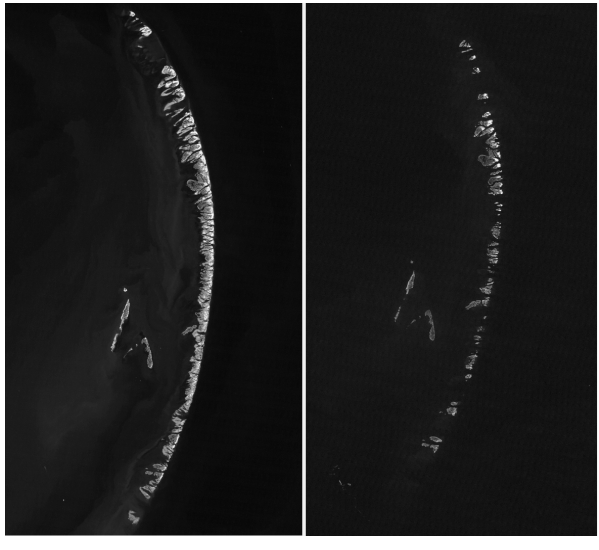

Fig. 2. Chandeleur Islands, Louisiana, before hurricane Katrina, on 13 October 2004 (left) and after, 16 September 2005. Images courtesy of USGS.

West of the Atchafalaya delta (location E on Figure 1) a predictable response occurred along the Chenier plain and the coast farther west during Hurricanes Lili (2002) and Rita (2005). Fine sand was eroded from the upper shoreface and beach and deposited on the adjacent marsh surface as a well defined veneer which widened considerably to between 100-150 m west towards the point of landfall near the Louisiana-Texas border. Guidroz et al., (2006; 2007) reported extensive damage to the coastal marsh vegetation, even up to 25 km inland, due to super elevated storm surge associated with Hurricane Rita. Overwash deposits and evidence of excessive

salt water intrusion were observed for the Cameron and Vermilion Parishes, (Figure 3) southwestern Louisiana. However, the aerial observation study also reported initial post-storm beach recovery, within a matter of two weeks from the day of landfall. Significant contrasts in post-storm adjustment are evident over decadal time-scales on contrasting the sediment rich Florida-Alabama coast and the barriers of South-central Louisiana. Longer-term monitoring along the Florida coast implies post-storm adjustment can take up to 10 years for recovery of approximately 75% of the sediment budget after major events (e.g., Hurricanes Frederic, 1979 and Opal, 1995) (Stone et al., 1999). Although post-storm adjustment of the Louisiana coast is

Fig. 3. Holly Beach, Louisiana, before Hurricane Rita, on 16 June 2001 (upper) and after, 28 September 2005. Images courtesy of USGS, Coastal Hazard Team.

considerably slower, infusions of sand from updrift and offshore sources are apparent. Nevertheless, the multi-decadal increasing trend in storminess is causing a distinct down-turn in the sediment budget.

FIELD DATA

As a case study, topographic and bathymetric surveys have been conducted for a 6 km stretch along the western half of Santa Rosa Island (location A, Figure 1) over a 10 year period. Altogether 30 surveys were conducted since February 1996 and pre and post storm island morphology associated with all major storm events were monitored during this decade long field study program. The details of the transects and the methodology adopted are given in Stone et al., (2004). The morphological evolution of the island in terms of change in volume of sediments is presented in Figure 4. For uniformity, shoreline location was defined as NGVD zero. To study the different responses of the various sub-environments, the cross-island profile was divided into four sections as follows: Gulf beach (foredune to -1.5 m NGVD), dune (foredune to bay beach dune), bay beach (dune to Mean Low Water), and bayside platform (MLW- -1.5 m NGVD).

STORM IMPACTS ON MORPHOLOGY

Stone et al., (2004) described in detail the post-storm morphological adjustment of the island after Hurricane Opal (1995). The study revealed that approximately 90% of the sediment eroded from the foredune-beach-nearshore environment was deposited as expansive overwash deposits on the interior and bayside flanks of the barrier. The barrier increased by an average of approximately 40 m in width along the bay side suggesting that the system conserved mass during Hurricane Opal. As a consequence of this mass conservation response, the Gulf side shoreline of the island retreated an almost equal distance. During the ensuing 2 years this newly deposited wedge of material along the adjacent bay was significantly reworked by northerly waves during the post-frontal phase of cold fronts which resulted in a significant shoreline recession (Stone et al., 2004). The response of north facing beaches/nearshore to these high-frequency steep waves generating in the bay during winter time are discussed in more detail later in this paper.

The time series volume change data for the study area over the period February 1996 – August 2005 is given in Figure 4 and Table 1. These data include the signatures of 7 storms and 10 cold front seasons, which contained over 300 winter storms. Even though the impact of Tropical Storm Josephine resulted in a net loss of sediments from the system, the barrier immediately regained sediment during the period November 1996 and July 1997. Due to the sustained southerly winds during Hurricane Danny a significant amount of sediment migrated from the nearshore and was re-desposited on the berm and overwash platform. The increased vegetation density during the summer also helped the re-deposition of sediment. Prior to

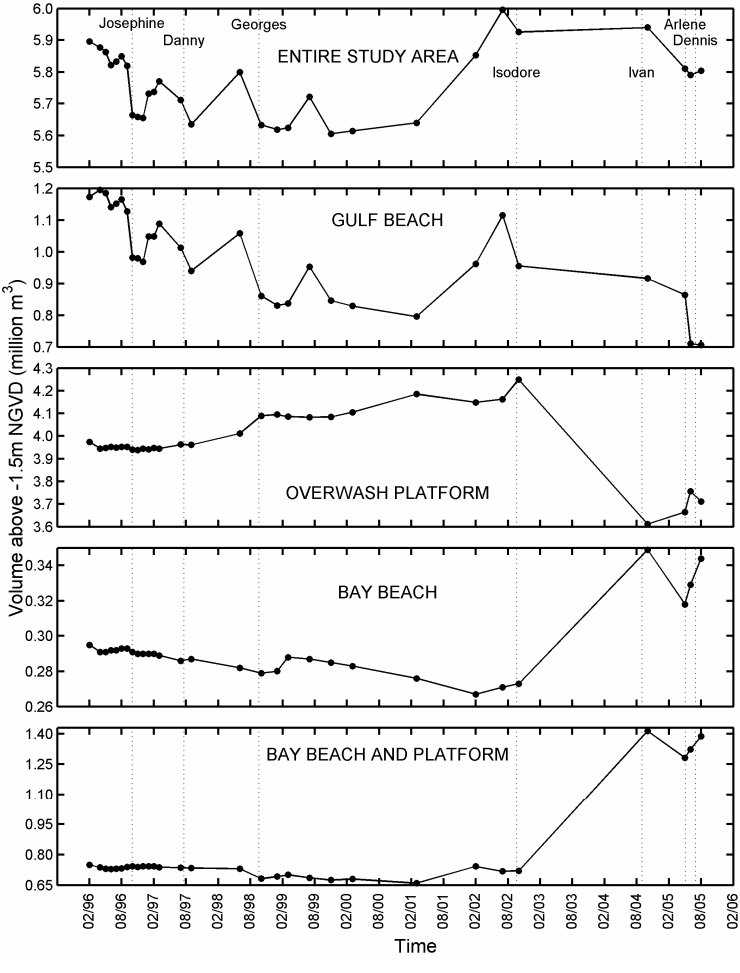

Fig. 4. Volume change for each of the barrier sub-environments from 2/96-8/05 at the Santa Rosa Island site, west Florida.

landfall of Hurricane Georges, the barrier went through a phase of sustained accretion, particularly along the gulf beach. The impact of this storm resulted in the migration of considerable volumes of sediment, eroded from the berm, across the

island to form a series of overwash terraces. This resulted in a considerable reduction in the volume of sediments in the gulf beach environment. This downward trend in gulf beach volume was reversed after May 2001, six years after landfall of Hurricane Opal. However, Tropical Storm Isidore (September 2002) again reversed that trend

and subsequently, the gulf beach has been undergoing a sustained erosional phase which was exacerbated by the land fall of Hurricane Ivan (2004), Tropical Storm Arlene (2005) and Hurricane Dennis (2005). As per our latest survey in August 2005, the sediment volume along the gulf beach was at its lowest level during the entire span of the study period.

The overwash platform, however, has been following a different trend over this decade of monitoring. Beginning May, 1997, two years after landfall of Opal, the overwash platform had been showing a steady increase in volume, mainly at the expense of episodic migration of sediments from the nearshore and beach, driven by sustained southerly waves and storm surge associated with the occasional hurricanes and tropical storms. However, a conspicuous downturn in volume occurred with the landfall of Hurricane Ivan in September 2004. For the track and other meteorological details of the Hurricane Ivan, see Stone et al., (2005). Persistent southerly waves and storm surge associated with landfall of Hurricane Ivan, a category 3 hurricane, resulted in substantial transport of sediment from the dune and overwash platform to the bay beach/nearshore. In addition, the island breached across the study area at a few locations and channels occurred in the backshore area. However, contrary to the gulf side environment, the overwash platform had been gradually gaining in sediment volume since Fall 2004 and underwent erosion during Hurricane Dennis (July 2005).

As discussed in Stone et al., (2004), the bay beach is susceptible to frequent cold front generated winter storms and the morphodynamics of this environment are variable. During our survey period, the bay beach sediment volume increased since 2002. Apparent increases in the volume of sediment were observed immediately after landfall of Hurricane Ivan. Sediments reworked from the gulf shore and overwash platforms were redistributed and deposited on the bay beach and the adjacent platform during this event. However, these sediment deposits were reworked by the northerly waves associated with winter cold fronts and a net reduction in volume was observed until the land fall of Tropical Storm Arlene (2005). The trend had been reversed and the net sediment volume in this environment was increasing until our last survey.

DISCUSSION

Influence of Storms on Morphodynamics

Data indicate the importance of overwash events in supplying sediments to the bayside beaches along Santa Rosa Island, and the importance of cold fronts in rapidly eroding the overwash deposits and causing a significant amount of deflation on the subaerial portion of the barrier. These data have added significantly to our

understanding of the longer-term morphological maintenance of barrier islands in the Gulf and the importance of extratropical and winter storms (see Figure 5). Few studies have been conducted on the post-storm adjustment phase of barrier islands. Moreover, those that have been conducted (cf. Sexton and Hayes, 1991; Dingler and Reiss, 1995) are limited to annual topographic surveys, which significantly reduce the resolution of morphological recovery of the barrier system. Profiles are typically conducted during the same month in successive post-storm years, restricting conclusions to the net amount of sediment deposited on the barrier during the post-storm phase (Dingler and Reiss, 1995).

Given that >90% of sand comprising largely the subaerial barrier mass at the Florida study site could be accounted for after two severe hurricanes, the implications are highly significant for (a) the source of material during post-storm recovery, and (b) the prevailing concepts that sediment eroded from, in particular, the upper shoreface during storms, is transported offshore to the continental shelf and lost from the barrier system. These issues have not been adequately addressed in the barrier island literature. In addition, these preliminary data have potentially significant bearing on the application of existing models to the upper shoreface-foreshore (see Swift 1976; Swift et al., 1985).

Barrier islands along the northern Gulf of Mexico are oriented generally east-west from southern Louisiana to the Florida panhandle (Fig. 1). North-facing beaches on the bay side of these barrier islands are particularly susceptible to wave attack during northerly winds, which generally accompany the passage of cold fronts. Significant erosion has been observed in areas where the adjacent fetch in the sound or bay is relatively long (Stone and Morgan, 1993; Chaney and Stone, 1996; Armbruster et al., 1995; Armbruster, 1997).

During winter seasons, three distinct end-member type cold fronts impact the northern Gulf of Mexico (Lewis and Hsu, 1992; Pepper, 2000; Pepper and Stone, 2004): 1) the mid-latitude cyclone; 2) the Arctic surge; and 3) the Gulf cyclone. The extratropical weather systems produce local variations in wind direction, intensity, and duration, and thereby significantly affect wave and sediment transport processes along the back-barrier beach. Fronts cross the northern Gulf approximately 30 times each year and with the exception of tropical storms and hurricanes, are the only known natural mechanism to generate relatively high waves in these bay/sound environments. A common regional weather phenomenon accompanying the passage of cold fronts is the strong post-frontal northerly wind. Due to the sheltering effect of the island, southerly winds are not capable of generating high waves along the back-barrier beach. Influences of the Gulf swell are minimal except in the vicinity of the

tips of the islands and inlets. Strong northerly winds, therefore, constitute the primary driving force for modifying the bayside barrier beach system.

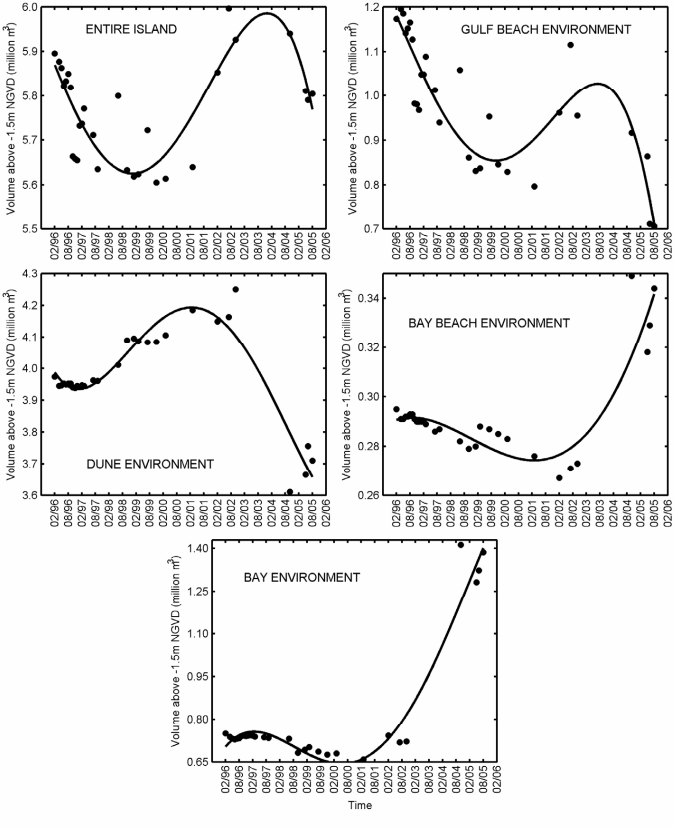

Fig. 5. Time series of volumetric change along the northern Gulf for 3 sub-environments and the entire barrier system 1996-2006 with an applied fourth order polynomial curve to identify apparent trends.

The general morphological characteristics of these back-barrier beaches are fundamentally different from the features developed by storm overwash processes (Schwartz, 1981; Otvos, 1982), which are critical to the origin and supply of sediment to these systems (Stone, 1998). These differences indicate the existence of

a general mechanism/s governing the dynamics and morphological maintenance of the back-barrier beach.

Post-Frontal Forcing

It is reasonable to assume that due to the sheltering effect of barrier islands along the northern Gulf (Stone and McBride, 1998), nearshore sediment transport along the back barrier beach is not significant during southerly winds. Where the northerly wind has a long fetch and is capable of generating relatively high waves, water-level setup occurs. Our work to date indicates that the strong northerly wind is the primary energy supply to the back-barrier beach in terms of significant sediment transport and morphological change. We acknowledge the longer-term role of relative sea level rise in these areas but take the position that the critical forcing mechanism/s for mobilizing and transporting sediment are a primary function of wave-current and wind forcing. The area is microtidal and thus, tidal currents play a lesser role in sediment resuspension in shallow water.

The frontal event has distinct meteorological and sea state signatures associated with its pre- and post-frontal phases. In Figure 6 we present a time series of wind speed (A), wind direction (B) and significant wave height (C) for a frontal passage in December 2002. The data were obtained from a WAVCIS (www.wavcis.lsu.edu) metocean station located at the 6 m isobath in Mississippi Sound, north of West Ship Island. Winds blow from the south prior to arrival of the front at the site and reach a maximum speed of approximately 7 m/s. Southerly wind speeds decrease as wind direction veers clockwise to the north over a matter of a few hours (B). Wind speeds rapidly increase across the Sound and peak at approximately 13.5 m/s. During the pre-frontal phase, wave heights are low in the Sound, <0.2 m (C), due to the sheltering effect of West Ship Island. Wave response to wind forcing is rapid and heights of 0.6 m are attained. Spectral evolution of the wave field is presented in Figure 7 and illustrates that energy is concentrated in the higher frequency bands due to wind veering to the north. Northerly winds persist for several days and maintain high wave energy levels along the north-facing beach resulting in erosion. As wind speed decreases wave energy levels show a concomitant decrease and winds veer clockwise to the east during this phase, resulting in extremely low wave energy conditions in the Sound. These data support the contention that winter cold fronts play the key role in north-facing beach erosion over short-term time scales. The prevalence of fronts over the northern Gulf explains the continued loss of sediment from the bay beach as presented earlier. What is less clear, however, is the actual pathway of sand transport during these events. Our data indicate that sediment is being removed from the foreshore during post-frontal events. The transport and ultimate fate of the material eroded is not yet understood. Our preliminary data indicate a sequence of events during the post-frontal northerly winds. The existence

of the commonly observed erosional scarp extending along the high water mark, and the flat extensive platform indicates to us, a significant contribution of sediment transported from the upper shoreface, offshore. The mechanisms driving this apparent offshore sediment transport are poorly understood.

Implications for Short-term Barrier Evolution

The data presented suggest that weaker hurricanes, such as Danny and Georges, can rework considerable amounts of sediment to the berm and relict overwash terrace. Bay beach accretion through overwash or aeolian deposition is short lived however, and frontal passage during the ensuing winter typically results in net loss to the system. This sequence of events implies that the barrier crosses a threshold initiated by a catastrophic storm, e.g. Ivan, and over the shorter-term, barrier degradation results due to net sediment loss from the system in its entirety. Storms such as Lili and Rita resulted in little beach erosion due to wave attenuation across the muddy inner shelf along western Louisiana.

CONCLUSIONS

Several important conclusions have been reached based on the data presented here: (1) where the inner shelf is comprised of cohesive sediments (fine silts and clays), typical of western Louisiana, pronounced wave damping and attenuation results in minor beach erosion. A clearly defined erosional-depositional couplet is a typical response during storms where fine sand eroded from the beach is overwashed across the interior marsh and an eroded marsh surface is exposed in the foreshore. What is not known, however, is the role of these cohesive sediments in surge attenuation. This is an important question that should be addressed by numerical modelers using data from carefully designed experiments involving in situ observations; (2) low-lying barrier islands, vulnerable to overwash, can conserve mass during catastrophic hurricanes (e.g., Hurricanes Opal and Ivan); (3) less severe hurricanes can promote rapid dune/berm aggradation and contribute sediment to the entire barrier system; (4) cold fronts play a critical role in the post-storm adjustment of the barriers by deflating the subaerial portion of the overwash terrace and eroding its marginal lobe

along the bayside beach; (5) considering seasonal time scales, post-storm recovery along the Gulf-facing beach/nearshore is not immediate and did not occur at some of the study sites until approximately 6 years after several events; and (6) bay facing beaches showed a continued decline in volume throughout the entire study period, a phenomenon we attribute to locally generated high frequency waves due to the passage of cold fronts along the northern Gulf of Mexico. There remains a need for field experiments to determine the source(s) and mechanisms responsible for sedimentation in these environments over various time and spatial scales and the development of models that elucidate the morphosedimentary dynamics of other mid-latitude, micro tidal barriers.

Abstract: The morphologic and volumetric changes of the dune foot, beach and inner nearshore zone over a major storm are studied on Egmond beach. The shoreline configuration of this beach showed an alongshore variation of embayments and horns, with an alongshore spacing between 400 and 700 m and a cross-shore amplitude of about 25 m. The response of the dune foot and intertidal beach was closely coupled to this alongshore variation, with major changes in the embayments (more reflective conditions) and small changes at the horns (more dissipative conditions). Overall, the upper beach and dune foot were eroding and flattened and the lower intertidal beach was accreting. The inner nearshore slope showed a steepening and a landward movement of e.g., the -3 m depth contour. The mechanisms that caused the changes are discussed and coupled to observed water levels in the nearshore. These water levels altered and shifted the location of the transformed waves (asymmetric waves, breaking waves, bores and swash) in a cross-shore direction over the profiles

INTRODUCTION

The beach is the transition zone for sediment exchange between the dunes and the nearshore. Under accretive conditions with low- to moderate wave energy conditions in the nearshore, these beaches tend to grow in height and width due to successive onshore migration of intertidal bars, which may merge to the upper beach (see for a recent overview Masselink et al., 2006). During onshore winds, part of this accumulated

sediment will be further transported to the dunes by wind. However, under erosive conditions with a high influx of wave energy and a dissipative nearshore, the dunes often erode by incoming waves and much of the sediment on the upper and intertidal beach is transported to the inner nearshore zone. This intense wave action near the dune foot is caused by an increase of the mean water levels over the beach due to extra surge levels by the passage of a depression track (area of low air pressure), wave set-up and wave run-up. The offshore sediment transport of beach sediments is enhanced by undertow (bed return flows).

We studied the impact of an extreme storm on a sandy beach located at Egmond, the Netherlands. The paper will show results of the morphologic and volumetric changes of the beach and nearshore during an extreme storm event. The analysis is based on daily bathymetric surveys of the beach (DGPS) and 2 bathymetric surveys of the nearshore (WESP) over a 16 days period. Special emphasis is paid to the alongshore variations that might be caused by the variations in the initial observed alongshore morphology with alternation of beach horns and embayments. The alternations had a length scale between 400 and 700m. The mechanisms that caused the changes are discussed and coupled to observed water levels in the nearshore. These water levels altered and shifted the location of the transformed waves (asymmetric waves, breaking waves, bores and swash) in a cross-shore direction over the profiles, and might be responsible for the observed patterns.

FIELD SITE: EGMOND, THE NETHERLANDS

The field site at Egmond, the Netherlands is located at the central part of the Dutch coast (Figure 1). This is a mixed energy coast, influenced by waves and tides. The coastline is exposed to waves coming from S-SW to N directions. The mean annual offshore wave height is 1.3 m with wave periods of about 5 s. The mean semi-diurnal tidal range is 1.65 m and increases towards 2.1 m during spring tides. The tidal curve is asymmetric with a 4-h flood period and an 8-h ebb period. The tidal current direction is towards the N during flood and towards the S during ebb.

The area has two nearshore bars and an intertidal bar on the beach. These nearshore bars have their crest typically around -3 m (outer) and -2 to -2.5 m (inner) below mean sea level. The bar crests experience a net offshore migration, with generation in the inner nearshore and decay in the outer nearshore (e.g., Ruessink and Kroon, 1994; Wijnberg and Terwindt, 1995). The slope between the -1 m and -8 m depth contours is between 1:35 and 1:60. The outer bar is slightly crescentic in alongshore direction to relatively straight. The inner bar crest has a crescentic shape during low- to moderate wave conditions and straightens during storms . Weak rip channels can develop in the inner sub-tidal bar with a variable alongshore spacing of 200 to 500 m. The intertidal beach is between 50 and 100 m wide and often shows cell topography with intertidal bars, feeder channels and drainage rips. The intertidal bar often shows a landward migration and is flattened during storms (e.g., Masselink et al., 2006). The slope of the intertidal beach varies between 1:10 and 1:50.

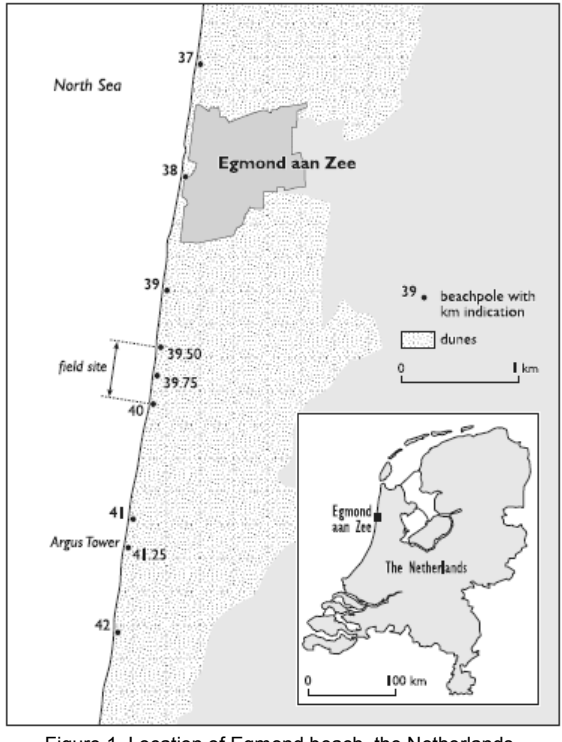

Figure 1. Location of Egmond beach, the Netherlands.

Figures 2 and 3 show the alongshore alternation of more dissipative bar horns (shoreline salients) and more reflective embayments. The typical alongshore length scale is about 400 to 700 m. The mean grain size of the intertidal beach sediments ranges between 250 and 300 μm and shows an offshore fining trend to 200 μm in the outer nearshore.

Figure 2. Argus video-image of Egmond beach with the alternation of horns and embayments on 21 October 2002 (Low-tide image with small waves breaking on the inner nearshore bar; Alongshore coordinate of camera position is 41.25 km; View to the N, decreasing alongshore coordinates)

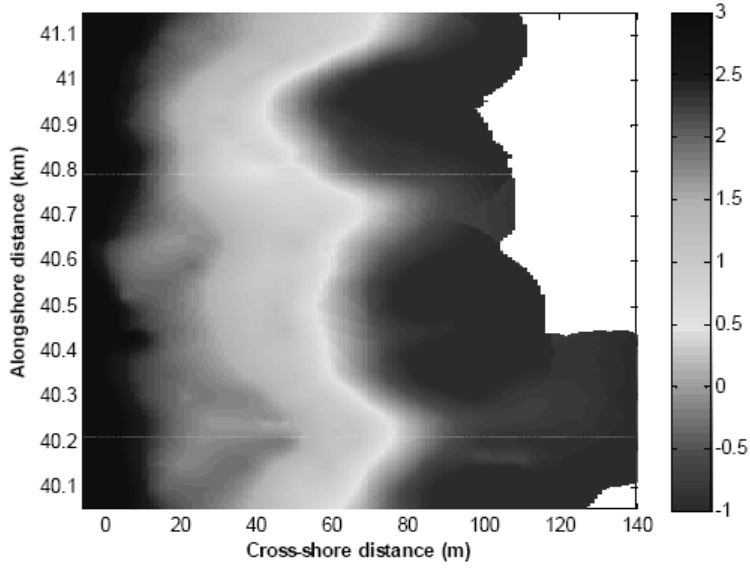

Figure 3. Beach survey with a DGPS of 21 October 2002 (see Figure 2)

CHARACTERISTICS OF THE MAJOR STORM EVENT

The studied storm event occurred on Sunday 27th of October 2002 (Figure 4). The event was registered as the fourth storm of the last 100 years along the Dutch coast (communication Royal Netherlands Meteorological Institute, KNMI). The maximum wind speed at the coastal station of IJmuiden, some 15 km S of Egmond beach, showed mean velocities over 25 m.s^{-1} and came in from the SW to W directions during the peak (270 degrees; shore normal). The wave height (*Hm0*) at about 8 km offshore reached maximum values over 6 m. The peak of the storm coincides with low-tide in the afternoon. The maximum surge level in the outer nearshore zone, computed as the difference between the measured water level and the predicted tidal level, was almost 2 m. The combination of SW to W wind and wave directions (relatively small fetch over the North Sea), and the peak at low tide caused relatively low values of the measured water levels above mean sea level. The duration of measured and predicted water levels over the storm event and over the period between two nearshore bathymetric surveys are presented in Figure 5 (left and right panel, respectively). Maximum water levels during the storm were about 2.3 m above mean sea level (≈ 0 m Dutch Ordnance Level).

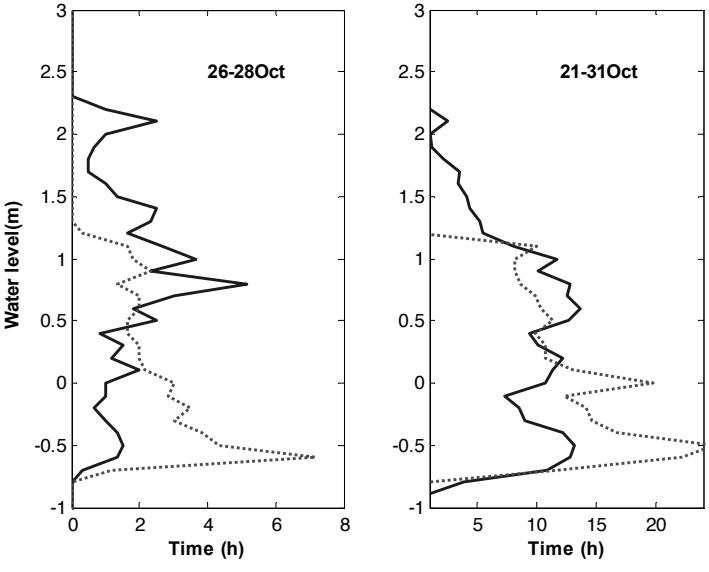

Figure 5. Water levels on the beach during the storm period (left panel) and the period between two WESP measurements (right panel). Solid line is measured water level in the nearshore; dotted line is predicted tidal water level.

MORPHOLOGIC RESPONSE OF THE BEACH AND NEARSHORE

Two bathymetric surveys of the dune, beach and nearshore area were used to describe the morphologic response of the storm event. These surveys were made on October 21st and 31st 2002 with the WESP, an amphibious vehicle with a height of 11 m. Most cross-shore profiles were measured from +3 m MSL, just above the dune foot, towards the -5m depth contour during the first survey and the -3 m depth contour at about 230 m from the dune foot during the last survey. The latter survey could not be extended further offshore, due to loose sediments in the trough landward of the outer nearshore bar. The alongshore spacing of the cross-shore profiles was about 50 m. and the total alongshore coastal stretch was 3.5 km from beach pole 39.00 km in the N towards beach pole 42.50 in the S. All profiles were made equidistant (cross-shore spacing of 0.1 m) and smoothed with a moving average method (window size of 10, which means 1 m average) in order to remove measurement spikes and small scale bed forms. The results are focused on the stretch between 39.10 km and 40.75 km where alongshore embayments and horns were observed (see Figures 2 & 3 and Aagaard et al., 2005).

The changes of the contour lines at the dune foot (+2.5 m), near the high water mark (+1.0 m) and halfway the intertidal beach at mean sea level (+0 m) are presented in Figure 6 (left panel). The dune foot showed an alternation of seaward and landward changes with a weak rhythmic pattern along the shore. The upper beach near the high

tide mark also showed an alongshore alternation, but the overall pattern was landward migration. However, the +0 m contour line showed an opposed trend with a majority of changes pointing in a seaward direction. This meant that there was an overall flattening of the upper beach that induced deposition halfway the intertidal beach. The changes of the contour lines in the inner nearshore (-2.0 m and -3.0 m) are presented in Figure 6 (right panel). Despite the large variation in the alongshore direction, the overall pattern was a slight seaward movement of the -2 m contour line and a landward movement of the -3 m contour line. This caused a steeper slope of this area during the storm.

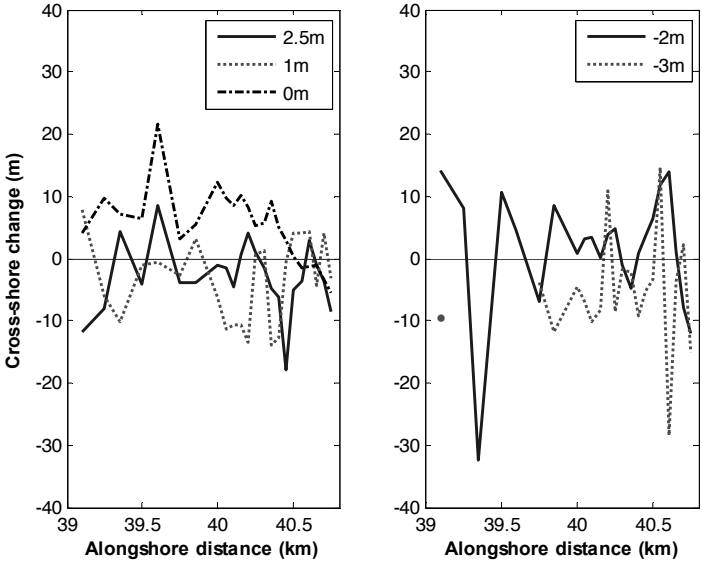

Figure 6. Alongshore variation of changes in contour lines between 21 and 31 October 2002. Left panel shows dune foot and intertidal beach contours, right panel shows inner nearshore contours.

The slopes of the upper part of the cross-shore profiles, between the dune foot (+2.5 m) and halfway the intertidal beach (+0 m), and of the lower part between +0 m and the -2 m depth contour in the inner nearshore is presented in Figure 7 (left panel). The slopes of the upper part were much steeper and showed a large alongshore variation with 2 flatter areas at 39.35 km and 40.25 km at the position of horns. Most of these slopes decreased over the storm event and the upper part of the cross-shore profile thus flattened. The slopes of the lower part were smaller, hardly showed any alongshore variation and steepened in most cases. The alongshore variation of the slopes for both the upper beach and lower beach and nearshore decreased during the storm event. However, alongshore variation in slopes of the upper beach was still significant.

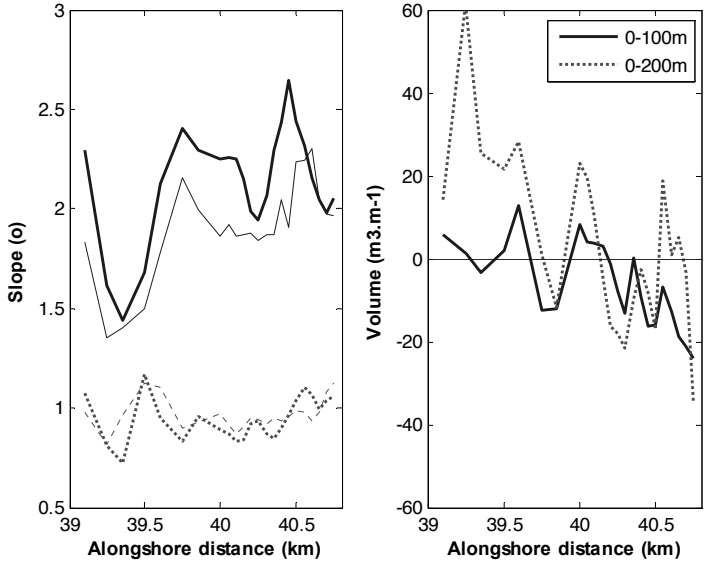

Figure 7. Alongshore variation of the slopes (left panel; thick line is 21 Oct, thin line is 31 Oct; solid line is between 2.5 and 0m contour lines, dotted line is between 0 and -2m contour lines) and volumetric changes (right panel; solid line is beach and dotted line is beach and nearshore) between 21 and 31 October 2002.

The volumetric changes on the upper beach were computed between the cross-shore position at x = 0 m (initial dune foot at +2.5 m) and the cross-shore position at x=100 m. The total changes in this cross-shore area are presented in Figure 7 (right panel). The volumetric changes showed a clear alongshore variation with a rhythmic pattern between accretion and erosion. Besides, the northern part (lower numbers of the alongshore distance) was more accretive than the southern part. The volumetric changes between x = 0 m (initial dune foot at +2.5 m) and the cross-shore position at x=200 m (inner nearshore) is also presented in Figure 7 (right panel). The alongshore variation of an alternation between erosive and accretive profiles was similar and in the order of 400 to 600 m. However, the absolute values of these volumetric changes were larger.

Daily bathymetric surveys of the dune foot, and the upper- and intertidal beach were measured with a DGPS system. The cross-shore profiles were about 100 to 150 m long and the alongshore spacing was 50 m. The alongshore coastal stretch measured 1100m, between alongshore beach positions 40.05 km and 41.15 km. The measured data were interpolated and computed to a regular grid with a spacing of 1 m. An example of intertidal beach bathymetry is presented in Figure 3. The alongshore alternation of steeper embayments and flatter horns was clearly visible. This pattern remained very prominent until the beginning of the storm. Bed level changes of the detailed surveys

around the storm, between 28th and 25th October 2002, are presented in Figure 8. The patterns were similar to those observed in WESP surveys over the 10 days period. The dune foot was heavily eroded and showed an alongshore variation that corresponded with the location of the horn-embayment structure (see Figure 3). The highest dune foot erosion rates were observed at the location of the embayments. Most of these eroded sediments and those of the upper beach were deposited on the lower intertidal beach. This induced an overall flattening of the whole area and a destruction of the intertidal barred features. However, visual observations of aeolian sediment transport during the peak of the storm from the upper beach and dune foot into the dune area were made, pointing at an extra loss of sediment over the landward boundary of the cross-shore profiles. Bed level changes of the detailed surveys after the storm, between 31st and 28th October 2002, are presented in Figure 9. Immediately after the storm, the intertidal morphology changed again towards a barred situation. This is also presented in the cross-shore profile evolution in Figure 10. The upper part of the beach and the dune foot were now landward located of the active profile, due to the reduced wave energy and surges levels (see Figure 4). The intertidal bar was generated in the upper intertidal area, between +0.5 and +1 m, and the seaward flank of this bar steepened. The profile adjustments of the storm were largest in the embayments. The initial profile here was steeper, while the initial profile of the horn profiles were already very flat and dissipative.

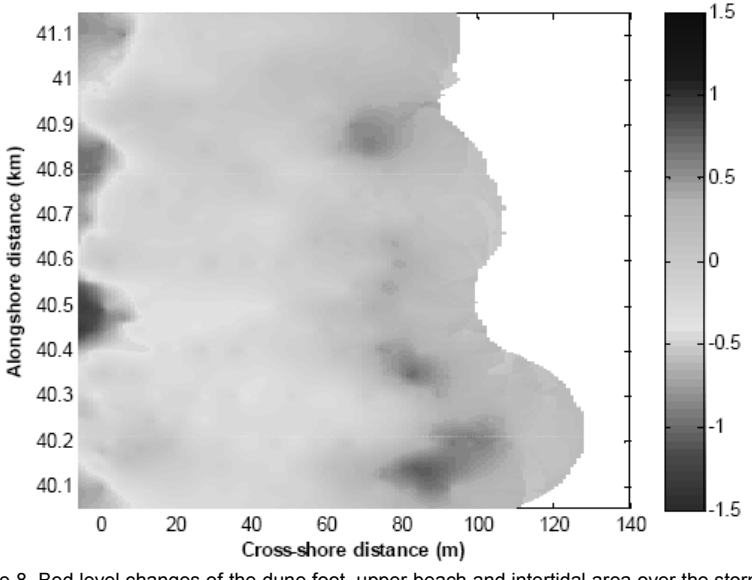

Figure 8. Bed level changes of the dune foot, upper beach and intertidal area over the storm. Changes are in m between 25th and 28th October 2002, positive values = accretion.

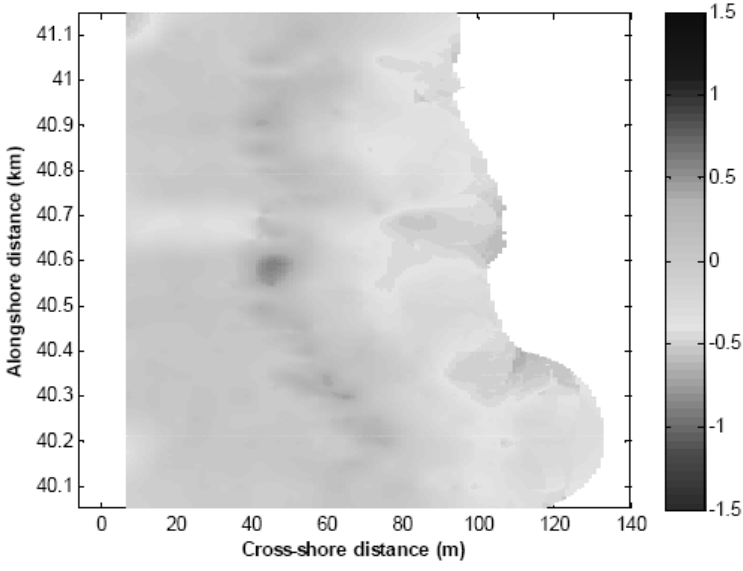

Figure 9. Bed level changes of the dune foot, upper beach and intertidal area after the storm. Changes in m are between 28th and 31st October 2002, positive values = accretion.

DISCUSSION AND CONCLUSIONS

The cross-shore response of the dune, beach and nearshore morphology along an embayment and horn differed. Quite often, the beaches on the horns were less steep (more dissipative) and showed hardly any morphologic changes during storms (Figure 10), where the beaches along the embayment showed erosion of the upper part and accretion on the lower intertidal beach and in the inner nearshore trough (see also Aagaard et al, 2005).

The causes of the different profile response were probably due to these initial cross-shore profile configurations. The wave transformation over the flat sloping beach at the horn was more dissipative. The water levels on the upper and intertidal beach were not extreme and the dune foot was especially eroded behind the embayments (Figure 8). The slope of the upper and intertidal beach hardly adjusted at the horn location and the overall lowering was probably caused by a slightly larger component of the undertow driven offshore mean sediment flux during high tide over the onshore directed sediment flux due to propagating bores and swash over very shallow water (with relative wave heights in the order of 1, see Masselink et al., 2006; Aagaard et al., 2005).

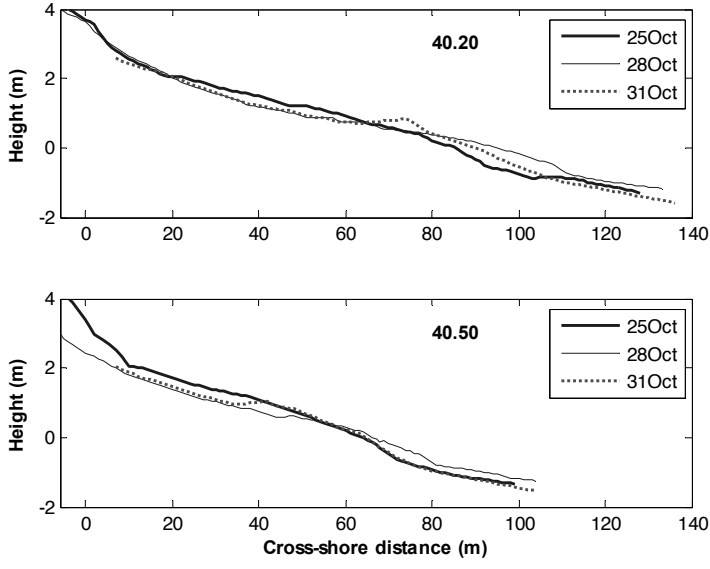

Figure 10. Profile adjustments at the location of a horn (upper panel; alongshore location 40.20km, see Figure 3) and at the location of an embayment (lower panel; alongshore location 40.50km).

The pattern of upper beach erosion and lower intertidal beach accretion during the storm (Figure 8) and generation of an intertidal bar at the upper intertidal beach after the storm (Figure 9) showed that a lot of the eroded sand stayed in the area (see also Figure 6 left panel) and was transported onshore after the storm. The mechanism responsible for this intertidal bar generation at the upper intertidal beach were initiated by the dissipation of incident wave energy over shallow water with a major role for surf zone bores. The tidal water levels altered and shifted the location of the transformed waves (from deep to shallow: asymmetric waves, breaking waves, bores and swash) in a cross-shore direction over the profiles. The actual location of this intertidal bar was probably determined by the duration of the swash and surf zone bore processes at the distinct position of the cross-shore profile (Masselink et al., 2006).

The alongshore variability of horns and embayments survived the storm event, despite the different morphologic and volumetric behavior at its units. The horns stayed almost at the same positions. However, the whole pattern was less pronounced in a cross-shore direction. The coupling between the alongshore variations with a length scale of 400 to 700 m in these crescentic patterns of the shoreline configuration to the alongshore configuration of the crescentic nearshore bar at about 400 m offshore could only be made for a restrictive area S of the Argus tower (see Figure 1; no data presented). The

bar was alongshore straightened during the storm, as generally described in Van Enckevort and Ruessink (2003), but the alignment still remained crescentic. The data set was unfortunately too small to correlate the alongshore alignments of the outer nearshore bar with the shoreline configuration.

STORM PATTERNS AND CLIMATIC TRENDS BASED ON WATER LEVEL FLUCTUATIONS: DUCK, NORTH CAROLINA, USA

Joan Pope[1]

1. U.S. Army Engineer Research and Development Center, Ft. Belvoir, Alexandria, VA, 22315, USA. Joan.Pope@hq02.usace.army.mil

Abstract: A twenty-year (1978-1998) record of open-coast atmospherically-induced water level fluctuations at the US Army Engineer Field Research Facility (FRF) at Duck, NC has been analyzed and correlated to the occurrence of both cyclonic and frontal storms. The time-series and statistical clustering of water level excursions from the predicted tide have been analyzed. The analytical technique and findings presented here reveal significant information on the characteristics of individual storm surge hydrographs and on both short and long-term climatic trends. A classification model for characterizing storm hydrographs is presented along with selected statistical summaries of water level and storm trends. The techniques presented here provide a simple method for assessing climatic variability and storm cycle trends using frequently available continuous tide records. A Storm Intensity Index parameter, bases solely on water level deviations is presented. This study suggests an approach to link shoreline evolution to metrological patterns.

INTRODUCTION

The U.S. Army Engineer Field Research Facility (FRF) at Duck, North Carolina has one of the most comprehensive, long-term process-response coastal data sets in the world (including local meteorology, water levels, waves, and beach profiles) (Savage and Birkemeier, 1987; Birkemeier, Savage, and Leffler, 1988). As such it offers the opportunity to consider decadal correlation patterns between water level events and beach evolution trends. It is also a site that is exposed to a variety of both tropical and extratropical storms. The classic concept of a storm surge is of a single well-defined peak rise in the water level (lasting several hours). However, an analysis of the

atmospherically-induced water level fluctuations in the FRF record reveal a variety of hydrographs including; sustained rise in the water surface lasting days to a week or more, periods of water depression (i.e., a "draw-down"), or vacillations in the surface demonstrating sequences of rises and draw-downs of the water surface in response to the shifting wind patterns of an extratropical storm and/or the passage of multiple lows.

The tide record from the FRF was used to extract atmospherically-induced deviations from the predicted tide (called "storm surge" throughout this paper). Selected events were compared to the regional meteorological record and correlated to either the occurrence of frontal passages, extratropical lows, or tropical storms; both near and far field. Time-series correlations between the FRF water level record and local weather conditions were used to understand local verses regional influences and the sensitivity of the event to wind directionality. Individual events were extracted from the record and parameterized. Each water level event has been characterized (duration, magnitude, range, etc) and classified. Through this process statistical summaries were developed that were used to identify climatologically-driven patterns of seasonal, annual, and decadal event clustering.

Coastal process analyses rarely consider the role of water level fluctuations as a suite of individual events or as cumulative trends in inducing cyclic geomorphic changes to the beach and nearshore. This work provides a foundation for linking annual and long-term meteorological trends to spatial and temporal patterns of water level fluctuations and the role of storm surges in promoting conditions of beach instability. Thus it is but one step in the process of assessing the cumulative effect of storm clustering in driving longer-period beach dynamics and coastal morphodynamic trends. It is further proposed that storm surge data, easily extracted from the tidal record, has value in assessing climate variability and trends. This analysis could assist coastal scientists in understanding the temporal influence of atmospherically-driven water levels in controlling beach evolution.

THEORY

Both tropical and mid-latitude cyclonic storms can affect the mid-Atlantic coast (Dolan and Davis, 1992; Davis, Dolan, and Demme, 1993). Tropical cyclones form between the equator and the Tropics of Cancer (Northern Hemisphere) and Capricorn (Southern Hemisphere) over warm ocean waters. The most intense tropical cyclones (wind speeds in excess of 120 km/hr) develop a distinctive 3-dimensional wind field and a central eye and are called either hurricanes in the Atlantic and eastern Pacific or typhoons in the western Pacific and Indian Ocean. Mid-latitude cyclones usually develop along the front of a high latitude (cold) air mass that is displaced into lower and warmer latitudes (specifically, between the polar circles and the tropics). Instability along the front associated with strong horizontal temperature gradients between the warm and cold air masses promotes the development of a perturbation, which becomes a wave, then a low pressure cell, and finally a fully developed cyclonic storm. Other commonly used names for mid-latitude storms are "non-tropical" or "extratropical" storms. Along the Atlantic seaboard of the United States they are commonly called "Nor-easters." These two major

populations of cyclones have different climatology, genesis, dynamics, structures and impacts to the coast (Perry and Walker, 1977; Bowden, 1983; Pugh, 1987).

The first distinction for the two classes of Earth's large-scale atmospheric cyclones; tropical and non-tropical, is the latitude of their genesis. In general, tropical cyclones originate in the tropics (between 23.5^0 N and S), while non-tropical, mid-latitude storms originate outside the tropics (between the 23.5 and 66.7^0 parallels). There are a number of other distinctive aspects between the two storm populations. Table 1 is a simplified summary that compares several major characteristics as well as the implications to the coast. Hurricanes are self-contained and self-maintaining cyclones that move (relatively) independent of synoptic scale air masses, while extratropical storms are usually generated and move along fronts between cold and warm air masses. The primary energy source for hurricanes is the latent heat released during the formation of heavy rains in convection cells, while the primary energy of extratropical storms is derived from the thermal contrast between two air masses. Hurricanes are well-organized storms with very steep pressure gradients and tight, circular isobars, near the eye.

Although, typically smaller then an extratropical storm, hurricanes are more intense (lower central pressures, steeper pressure gradients, and higher wind speeds). The typical hurricane has a diameter of about 650km, (less than half the size of a mid-latitude storm), will have maximum sustained surface winds in excess of 33 m/sec (74mph), and sea level central pressures of 950mb or less. Hurricanes are an intense warm-core low that occur during the warm summer and early fall. Extratropical storms have a cold core and, although they can occur year round, their frequency and intensity peaks during the winter and near-winter months (for the hemisphere of interest). Extratropical storms tend to move eastward within the mid-latitude westerlies. Hurricanes tend to move westward within the tropical trade-winds until they cross the 23^{rd} parallel and into the mid-latitudes where zonal winds steer the hurricane toward the east. A typical hurricane season will spawn in the order of ten storms, while a hemispherical winter weather pattern may generate hundreds of extratropical lows. Thus, the typical extratropical cyclone is a less intense, longer lasting; but more frequent event that can affect a large area and redistribute a lot of sand along a beach.

Both tropical and extratropical storms can induce long wave fluctuations in the sea surface that impact the shore as a surge. These atmospherically-induced water level fluctuations extend the cross-shore impact zone of the wave field beyond that of the astronomical tide, causing instability (i.e., disequilibrium) to the beach profile. Most dramatic changes to the coast happen during storms in response to how the surge hydrograph distributes the wave field across the shore. The role of a single, major storm surge in causing large quantities of sand transport, coastal retreat, dune breaching, channel shoaling, and changes to the nearshore slope and profile are well established throughout the literature. However, extratropical storms generating lesser maximum surge events (particularly when of long duration or clustered) can accumulate a significant total quantity of elevated water levels and may have a greater affect on the beach profile.

Table 1. A Generalized Comparison of Tropical vs. Extratropical Storms

CHARACTERISTICS	TROPICAL	EXTRATROPICAL
Location of Cyclogenesis	Tropics, over Warm Ocean Waters	Mid-latitudes, over Land or Water
Size	Smaller (10-100's of Km)	Larger (100-1000's of Km)
Pressure Gradient	Extreme and Steep	More Subdued
Sustained Winds	Higher (<74mph)	Lower
Frequency of Impact to an Area	Decadal or Greater	Yearly or less
Structure	Well-organized (Defined Core), Self-contained	Disorganized, Affiliated with a Cold Front
Forward Speed	Faster	Slower
Period of Impact to an Area	Hours	Days
Classic Impact Locations	US East and Gulf Coasts, Caribbean, Pacific Ocean Islands, Australia, Indian Ocean	US East & Pacific Coasts, East Coast Canada, Great Lakes, North Europe, Mediterranean, etc.
Storm Surge	Steep, High, Short-lived Peak (i.e., Hours), Moves with Storm	Broad, Flatter, Lasting Days, May Move with or Propagate Away from Storm Center
When Occur	Summer-Early fall	Late Fall, Winter, early Spring
Primary Beach Impact Damages	Inundation – Flooding Inlet formation, Overtopping of dunes Transport of sand toward back beach	Retreat of the shoreline, significant loss of sand from beach berm, Sand transported offshore

Redundant weather patterns can trigger multiple lows impacting the same area resulting in week to month or longer sequences of water levels deviations from the predicted. For example, the record analyzed during this study record included as many as 5 or 6 water level events in a single month, with 75% or more of the days in that month experiencing greater then predicted water level ranges. The result is a long period of sustained high water and greater beach dynamism. An Intensity Index parameter for measuring the total cumulative water-level effect of an event or over a period has been developed for this study.

Storm-induced water-level fluctuations are more complex in both their manifestation and in their impacts than that suggested by the generally accepted use of a single water elevation parameter (usually the “maximum surge”). There is a direct relationship between the storm meteorology (particularly location, size, duration, and wind and pressure fields) and the characteristics of the water level fluctuation.

METHODOLOGY AND ANALYSIS

The methodology used in conducting this study required the following steps:

1) Acquire and process water level data including the filtering of the data to one hour increments and calculating the residual water level by subtracting the predicted tide from the measured water level.
2) Analyzing the database to identify and extract periods of excursion from the predicted water levels that complied with the criteria used in this study. Each became a sequentially numbered storm event.
3) Examination of individual storm events to characterize particular classes of surge hydrographs. A subset of the storms was compared to the meteorological conditions of the time to interpret the relationship between the meteorological event and the surge hydrograph.
4) Parameterize each storm event as to maximum or minimum peak, duration, and the area of the hydrograph (total meter hours).
5) Conduct a comparative trend analysis to examine seasonal and yearly trends.

Water Level Data

The National Ocean Service (NOS) of the National Oceanic and Atmospheric Administration (NOAA) maintains hundreds of water-level monitoring ("Tide Stations") throughout the United States (Harris, 1981). Some of the oldest, continuously operating, tidal stations in the nation, are located along the mid-Atlantic through New England coast (i.e., Boston Harbor, MA initiated in 1921; Sandy Hook, NJ in 1910; Atlantic City, NJ in 1911; and Sewells Point, Hampton Roads, VA in 1927). However, many stations have been established, abandoned, and then re-established at other location with extensive data gaps. Also of concern is that the majority of these stations are in protected waters within harbors or bays where a storm surge would be locally modified by the geometry of the bay and the orientation of the bay/harbor-mouth. The selection of a tide station for a study of storm-induced water level fluctuations should be based upon an analysis of the station's data history, exposure to storm surges, and availability of meteorological data.

The 20-year tide record at the FRF at Duck, NC was selected for the analysis presented here. The FRF is a unique source for continuous, synoptic data (representing each data class of coastal interest including beach changes) since 1981. In addition to this extraordinary and well-maintained database, the FRF has the additional advantage of being subject to both tropical and extratropical events. The tide station at the FRF is located at the end of a 560m long reinforced concrete pier at the approximate 7-m depth contour. Water level data collection started in August 1978. However, during the first couple of years (1978-1979) the gage experienced some technical difficulties and there are windows of invalid data and a tendency to fail during storms. Although water level data collection continues at this site, only data through December 1998 is included in this analysis. Water level is recorded at 6-minute intervals however; the data was filtered to 1-hour increments for the purposes of this analysis.

Selection of Storms

A suite of 351 extratropical and hurricane storms which have impacted the mid-Atlantic at Duck, North Carolina between 1978 and 1998 have been extracted from the water level record based upon elevation and duration of the residual surge (measured water level – predicted water level) according to the following criteria.

A Positive storm surge must have a:

1) Maximum residual water level greater then 0.299 m lasting at least 12 hours, or
2) Maximum residual water level greater then 0.599m lasting at least 8 hours, or
3) Maximum residual water level greater then 0.899m lasting at least 6 hours.

A Negative storm surge must have a:

1) Minimum residual water level less then -0.299 lasting at least 12 hours, or
2) Minimum residual water level less then -0.599 lasting at least 8 hours.

Levels complying with these criteria need not be continuous, but shouldn't drop below +0.25m or above -0.25m for more then a few hours. The plus or minus 0.299m as well as the 12 hour discriminating criteria for identifying a storm were developed after a complete review of the water level record and though comparison with both the meteorological and wave record. Any water level deviation from the predicted that fell between 0.299 and –0.299 is considered as insignificant in causing a change in the excursion of the wave climate across the profile. The 12-hour criteria encompasses one tidal cycle. The higher peaked, shorter criteria tend to capture the near field and direct hit tropical storms.

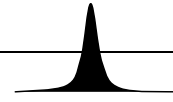
A total of 351 individual storm events were identified and selected for analysis during the period 1978-1998. The predicted astronomical tide was extracted from the actual water level hydrograph producing the storm hydrograph. Several statistics were extracted for each event including the maximum and minimum surge elevations and duration of the greater then 0.299m deviation from the predicted tide. In addition, a parameter was specifically developed for this analysis that is the total area of the hydrograph in units of meter-hours. This parameter provides a single metric of the storm's duration and intensity.

Storm Characterization and Analysis

Of the 351 storm surges examined only Hurricane Gloria, (1985) and Hurricane Bob (1991) were close to matching the idealized hydrograph shape of a steeply rising and falling hydrograph with a strong single peak. These were the only two direct hit hurricanes in the database. An example of the complexities associated with surge hydrographs are those that oscillated between positive and negative surge peaks over a water level range of 1.5 meters. A number of hydrographs displayed multiple surge peaks; either two or three significant peaks several days apart or even a frequent cyclic peaking pattern with a 12-hour periodicity (often found to be in phase with the falling astronomical tide).

There is a first order relationship between the resultant surge and whether or not the generating storm was a tropical or extratropical event. There is also a linkage between

the characteristics of the surge and whether or not the storm was a local meteorological event or a remote event. Storm surges that do not mirror changes in the local atmospheric pressure or wind field are those that are spawned and maintained by remote, and probably regional scale storms. Figure 1 was developed based upon a review and characterization of the 351 surge hydrographs analyzed through this study. Figure 1 dramatically illustrates a range of curve geometries including flat (little peakedness), several well-defined peaks, and negative peaks (drawdowns). These are each related to the meteorological event associated with that hydrographic signature. There is a significant range in surge duration (i.e., from 1 to 10 days) and variability as the storm meteorology evolves and changes location relative to the surge measurement site.



STORM TYPE	CLASSIC EXAMPLE STORM	GENERALIZED SURGE STATISTICS			CONCEPTUAL SURGE HYDROGRAPH SHAPE
		Trend	Max peak	Dur	
Direct-hit Hurricane	Hurricane Gloria Sep 26-28 1985	+	<1.0m	6-12hr	
Passing Hurricane	Hurricane Edouard Aug 29 –Sep 3 1996	++	<0.3	1-2 days	
Near-field, Minor Extratropical	VERY FREQUENT EVENT	+	<0.3m	1-2 days	
Local Low Extratropical	FREQUENT Oct 23-26 1982	-+-	0.3-0.6m & >-0.3m	1-2 days	
Regional Extratropical	Mar 6-14 1989	+++	<0.6m	3-4 days	
Sequential Local Extratropicals	Dec 8-18 1989	-+-+-	0.3-0.6m & >-0.3m	5-8 days	
Sequential Regional Extratropicals	Oct 28- Nov 12 1991 Halloween Storm	+++0+++	<0.6	2-3 weeks	
Anti-cyclone (High) or Inland Low	Mar 13-18 1993 Storm of the Century	---	-0.3 to >-0.6	2 –3 days	

Figure 1. Classes and characteristics of storm hydrographs extracted from FRF record

Statistical Analysis

Parameters were developed per storm and per month. Figure 2 illustrated the summary statistics per storm, while Figure 3 is presented for per month. In all cases the parameters refer to the atmospheric surge elevation as the residual once the predicted tide has been removed from the measured water level. Maximum and Minimum values are the highest and lowest surges that occurred that during that month or per storm. Duration is the total number of hours that the storm surge elevation exceeded either plus or minus 0.299 m. An Intensity Index parameter is presented as meter-hours (m-hr). This parameter represents the area of the surge hydrograph during which the water rose or fell greater then 0.299 from the predicted tide. This parameter is the best single indicator of both the "intensity" of a storm and the "storminess" of the month.

Figure 2 compares water level parameters per storm. Figure 2a illustrates that most storms last less then 50 hours and produce less then a 0.6m rise in the water level. The longest duration storms are major regional extratropicals that can produce surges between 0.6 and 0.9m and last over 150 hours (6-8 days). These are significant beach erosion events. Most of the higher surge events are associated with hurricanes that move through the region fairly quickly. This comparison of duration to maximum surge height is not necessarily a good indicator of significant storms as it doesn't capture the duration of the highest water levels. Figure 2b and 2c is better at discriminating the more significant coastal events than Figure 2a.

For example, the highest Intensity Index (m-hr) event on record was Storm #335, which occurred February 3-10, 1998. This storm produced a maximum surge of 0.91 m, with a duration of 163 hours and an Intensity Index of 53.4 m-hr. There are storms that lasted longer and storms that produced higher surges. But this single storm dominates as the most intense on record as can be seen in Figure 2c. The second most intense on record is Storm #190 which occurred October 28- November 2, 1991. This storm lasted 120 hours, produced a peak surge of 1.01 m, and an Intensity Index of 38.14 m-hr. It was immediately followed by Storm #191, which occurred November 8-12, 1991, lasting 97 hours, producing a maximum surge of 0.933m, and intensity of 16.67 m-hr. There are few events that trigger a draw-down of the water level and these tend to be of short duration. The single most significant draw down event was Storm #225, which occurred March 13-16, 1993 associated with an extratropical low that traveled west of the FRF along the eastern seaboard (Kocin, et al., 1994). This actually caused a 0.56m draw down of the water level.

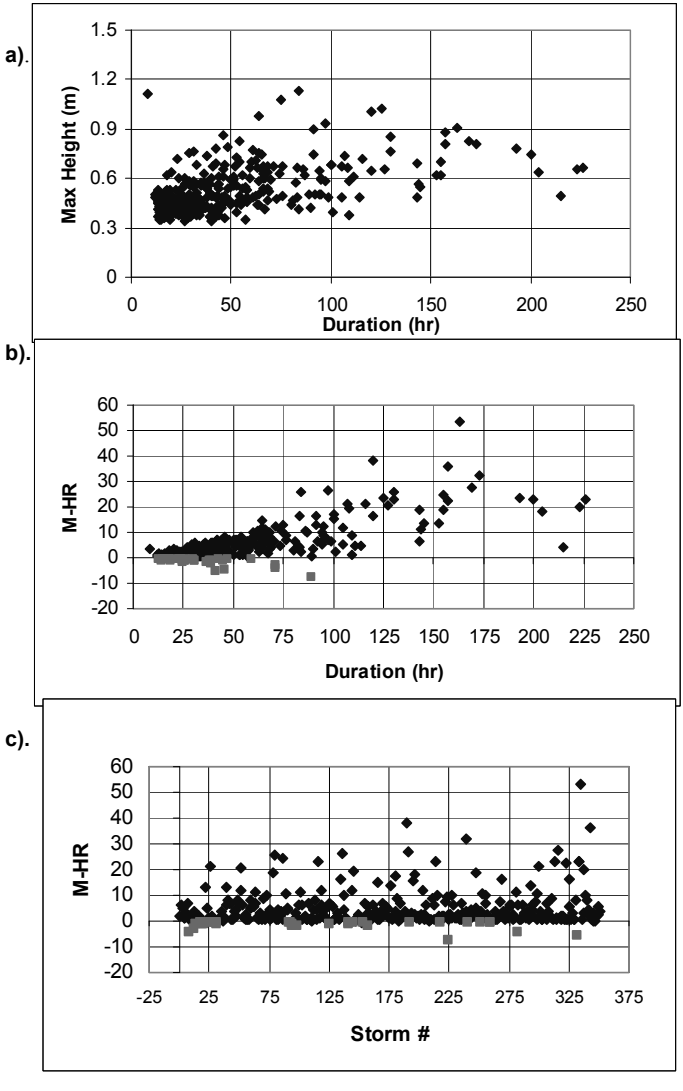


Fig. 2. Comparison of water level parameters for all 351 storms extracted from the FRF data set 1978-1998. Diamonds document each storm that had a positive surge while squares document each storm with a negative surge. Graph a) correlates maximum surge to duration. Graph b) compares the area under the curve (meter-hours) to duration. Graph c) demonstrates the trend of storm hydrograph area over time. Each storm is numbered sequentially with Storm #1 on Jan 1, 1980 and Storm #351 on Dec 30, 1998.

Figure 3 demonstrates the seasonality of these storm events. Figure 3a shows that surges of greater then 0.6 m or draw downs of the water surface greater then 0.3 m can occur during any month. However, Figure 3b, which compares the total number of hours of surge per month, and Figure 3c, which uses the m-hr intensity index parameter clearly indicates a tendency for the stormiest months to be from October through April. February tends to be the stormiest with 216.4 m-hr of surge, followed by October with 200.9 m-hr of surge. The highest recorded surge, 1.129 m, is actually associated with an extratropical storm, April 11-15, 1988. The next highest is 1.112 m with Hurricane Gloria, September 29, 1985. The least stormy month is July with only a single storm during the 20-year period, resulting in 147 hours of surge and an index of 6.2 m-hr.

Total storm intensity index (m-hr) per year is demonstrated in Figure 4. This figure suggests both a cyclical trend to the occurrence of stormy years and a tendency of increasing storminess over the 20-year record for this site. The years with the most storms are 1983, 1997, and 1998, with nineteen storms each. When considering the storm intensity index, 1991 is added to the list of the stormiest years. A storm intensity index of 212.6 m-hr was computed for 1998, 157.8 m-hr for 1991, 152.6 m-hr for 1997, and 131.0 m-hr for 1983. The quietest years on record are 1980-1982, 1986, and 1990; each year with a storm intensity index of less then 50 m-hr.

Discussion

The analysis presented here demonstrates the dynamism of meteorological patterns as they influence coastal processes. It also advances a relatively simple technique for documenting meteorological trends, critical in the evolution of the coast. As the position and intensity of the jet streams and the ocean temperature change, different air masses dominate a region influencing the genesis and evolution of storms. Meteorological conditions that tend to generate either tropical or extratropical storms are likely to spawn sequential storms resulting in a temporal clustering of higher energy events impacting a particular region. The greatest impact of this analysis may be in illustrating how, through the readily extractable parameter of water level excursions, the storm history for a region can be assembled.

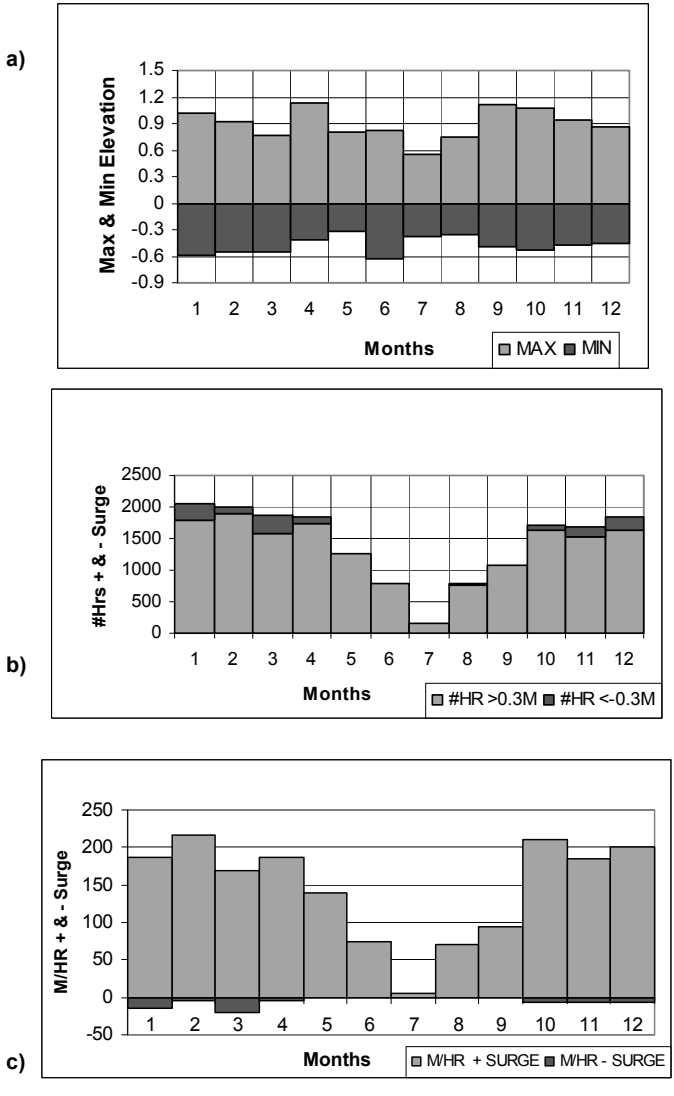

Fig. 3. Monthly statistics based upon all 351 storms extracted from the FRF data set 1978-1998. Graph a) documents the single occurrence maximum and minimum (negative or draw down) peaks experienced during that month over the 20 year record. Graph b) documents duration, cumulating the total hours during that month of storm surge influences over the 20 year record. Graph c) illustrates the total cumulative meter-hours of surge impact per month.

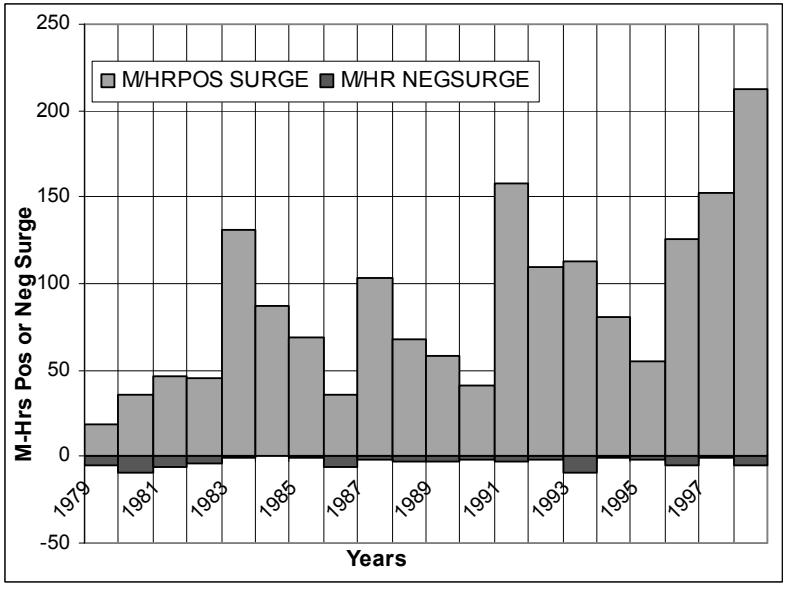

Figure 4. Storm Intensity Index (meter-hours) per year over the 20-year water level record for the FRF.

CONCLUSION

Storm surges number amongst the deadliest and most destructive of all natural disasters. They kill, flood the land, damage the coastal infrastructure, create and destroy inlets, erode beaches, and disrupt ecological systems. Yet their study has generally been limited to the high profile, direct-hit hurricanes which quickly overwhelm coastal communities. The work presented here provides a foundation for consideration of the full storm surge record including lower surge, but longer duration, and clustering of more minor events. Very little analytical work has been conducted on the range of characteristics, evolution, and impacts using prototype surge data. The study proposes an analytical approach and also a mechanism to correlate storm induced water level fluctuations as a means for better understanding trends in coastal evolution.

HINDCASTING POTENTIAL HURRICANE IMPACTS ON RAPIDLY CHANGING BARRIER ISLANDS

Hilary F. Stockdon, David M. Thompson, and Asbury H. Sallenger, Jr.

U.S. Geological Survey, Center for Coastal and Watershed Studies, 600 4th St. South, St. Petersburg, FL 33701, USA; hstockdon@usgs.gov

Abstract: Hindcasts of the coastal impact of Hurricane Ivan on Santa Rosa Island, Florida, using a storm-impact scaling model that compares hurricane-induced water levels to local dune morphology, were found to have an accuracy of 68% in predicting the occurrence of one of four impact regimes: swash, collision, overwash, and inundation. Errors were overwhelming under-predictions of the regime where the observed response was more extreme than had been expected. This is related to the evolution of the profile during the storm. Mean pre-storm dune elevations decreased by 1.9 m over the 75-km long island as most of the dunes were completely eroded during the storm. Dramatic morphologic change during a hurricane makes barrier islands more vulnerable to overwash and inundation than will be predicted based on pre-storm dune parameters. Incorporation of the timing of rising water levels relative to storm-induced profile evolution is required to improve model accuracy.

INTRODUCTION

In recent years, several large hurricanes have made landfall in the United States resulting in extensive damage to coastal communities and dramatic change to natural coastal systems including beaches, barrier islands, and wetlands. When Hurricane Ivan made landfall in Gulf Shores, Alabama, on September 16, 2004 much of the coastline of Alabama and the Florida panhandle experienced significant coastal change (Sallenger et al. 2006). In Orange Beach, Alabama, a 5-story condominium collapsed after the dune supporting its foundation was completely eroded by large waves. Just west of landfall in Pine Beach, Alabama, parts of the island were flooded during the storm, and a 1.8-m deep channel was scoured across its entire width. On

Santa Rosa Island, Florida, located over 55 km east of where Ivan came ashore, sand dunes were completely eroded and much of the 73-km stretch of island was overwashed. In order to mitigate the impact of these intense storms on existing and future Gulf and Southeast Atlantic barrier island communities, predictions of the coastal response to an approaching storm are essential.

One method for determining the likely mode of coastal change on barrier islands during a hurricane is to make use of a storm-impact scaling model that compares the elevations of local beach morphology and extreme water levels expected during a storm (Sallenger 2000). Based on these elevations, four storm impact regimes are defined, and within each the processes and magnitudes of coastal change are unique (Stockdon et al. in press). When extreme water levels (R_{high}), defined as the sum of storm surge, astronomical tide, and the 2% exceedence level for runup, are confined to the beach face, the system is within the *swash* regime and the magnitudes of coastal change are minimal. When R_{high} reaches the elevation of the base of the dune (D_{low}) the beach enters the *collision* regime, which is characterized by dune erosion. If R_{high} exceeds the crest of the dune (D_{high}) the beach will *overwash*, and sand will be transported landward, resulting in increased shoreline erosion and beach volume loss (Stockdon et al. in press). The most extreme regime, *inundation*, occurs when the storm-induced still water level (R_{low}), defined as the sum of wave setup and storm surge, exceeds the elevation of D_{high}. At this point, the island is continually submerged, and cross-island flows dominate the physical processes responsible for morphologic change.

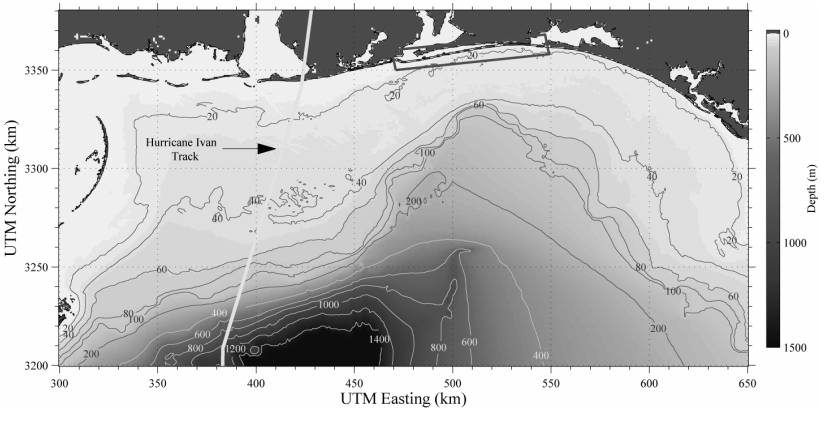

Fig. 1. Bathymetry grid (1-km x 1-km) for modeling wave and surge conditions during Hurricane Ivan along the northern Gulf of Mexico from eastern Louisiana to western Florida. The box shows the location of Santa Rosa Island, FL.

The predictive accuracy of this model is tested by hindcasting the spatially-variable coastal response of Santa Rosa Island, Florida, to the landfall of Hurricane Ivan on September 16, 2004 (Fig. 1). Santa Rosa Island is a 73-km long barrier that encompasses the communities of Pensacola Beach, Navarre Beach, and Okaloosa Island, as well as a portion of Gulf Islands National Seashore. Most of the island was subjected to hurricane-force winds (> 119 m/s) during the storm and, therefore, experienced striking morphologic change in response to large waves. The magnitudes of storm-induced shoreline change varied substantially along the length of the island: shoreline retreat of over 40 m was observed in some locations while change in adjacent areas was near zero.

METHODS

Hindcasts

Hindcasts of the coastal response to Hurricane Ivan were made every 20 m along the island by comparing measurements of pre-storm dune morphology to modeled water-level elevations. Storm surge and the nearshore wave climate were simulated using the Delft3D model (Delft 2003). The model domain consisted of a 2-km x 2-km grid with a nested 1-km x 1-km grid located closer to the study area (Fig. 1). The model was run for 66 hours beginning ~53 hrs before the storm made landfall. Observed winds and atmospheric pressure input were obtained from NOAA's Hurricane Research Division. Tides were simulated by inputting tidal constituents extracted from the TPXO6.2 global tide model (Egbert and Erofeeva 2002) at four points along the boundary of the Delft3D model domain. Wave heights and periods were verified in deep water using measurements collected at NOAA's National Buoy Data Center (Thompson et al. 2006).

The offshore wave height at each time step was extracted from the 20-m depth contour and, in conjunction with lidar-based measures of pre-storm beach slope, converted to the 2% exceedence elevation for wave runup, R_2, using the empirical formulation of Stockdon et al. (2006). Storm surge and astronomical tides, η, were extracted along the shoreline position, as defined by the mean-high-water (MHW) tidal datum. Hurricane-induced total water levels, R_{high}, were calculated every 20 m along the island as the sum of R_2 and η. Still-water levels, R_{low}, during the course of the storm were calculated as the sum of η and wave setup, also modeled empirically using offshore wave conditions and local beach slope (Stockdon et al. 2006).

The pre-storm elevations of the dune base, D_{low}, and crest, D_{high}, were extracted every 20-m along the island from a May 2004 lidar survey conducted by the US Army Corps of Engineers using the Naval Oceanographic Office CHARTS instrument. When a dune was not present, the height of the berm was taken as D_{high}. The elevations of D_{high} varied considerably along the island: mean, μ, D_{high} was 3.27 m while the standard deviation, σ, was 1.17m (Fig. 2).

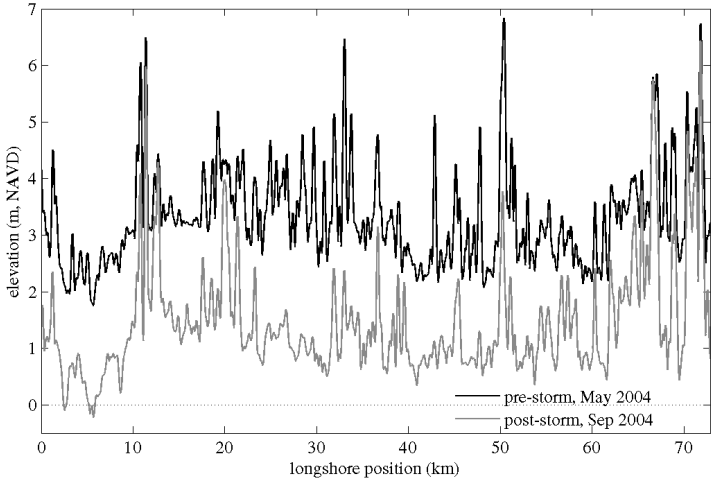

Fig. 2. Elevation of the dune crest, D_{high}, before (May 2004) Hurricane Ivan and of the same cross-shore position following the storm (Sep 2004). Mean elevation decreased by 1.9 m to 1.4 m.

To hindcast the impact regime expected during Hurricane Ivan, modeled water levels were compared to elevations of pre-storm dune morphology. When $R_{high}>D_{low}$, the beach was expected to fall in the collision regime and experience dune erosion; when $R_{high}>D_{high}$, the beach was expected to overwash (Fig. 3a); and when $R_{low}>D_{high}$, the beach was expected to inundate or breach (Fig. 3b). Examining the threshold quantities (R-D) at each time step of the progression of the storm reveals the time when thresholds were exceeded, as well as the magnitude and duration of exceedence (Fig. 3a). The spatial variability of the expected regime (Fig. 3a) is overwhelmingly due to an associated variability in beach morphology, which is included in the model both directly, through the elevation of dune parameters, and indirectly, through the beach-slope-dependent estimates of wave runup.

Observations

Hurricane-induced coastal change and the observed impact regime were quantified by comparing the May 2004 morphology to that measured three days after landfall, on September 19, 2004, using the NASA EAARL lidar. The observed impact regime was designated every 20-m along the beach by comparing cross-shore profiles of island topography. Locations showing dune erosion exceeding a 2.5 m^3/m threshold were classified to be within the collision regime. Areas with a decrease in dune elevation exceeding 1 m were identified as locations of overwash. Because overwash deposits extended into the bay behind the island where volumes of transported sediment could not be measured, objective measures of this regime were subjectively verified using lidar difference grids and post-storm aerial photography. Finally,

cross-shore profiles with peak post-storm elevations less than MHW (0.23 m NAVD) were likely submerged during the storm and, therefore, classified as falling within the inundation regime. Over 89% of the island was observed to have overwashed during the storm. Inundation was limited to a narrow area on the low, western end of the island and limited areas between longshore locations, y, = 38 - 41 km.

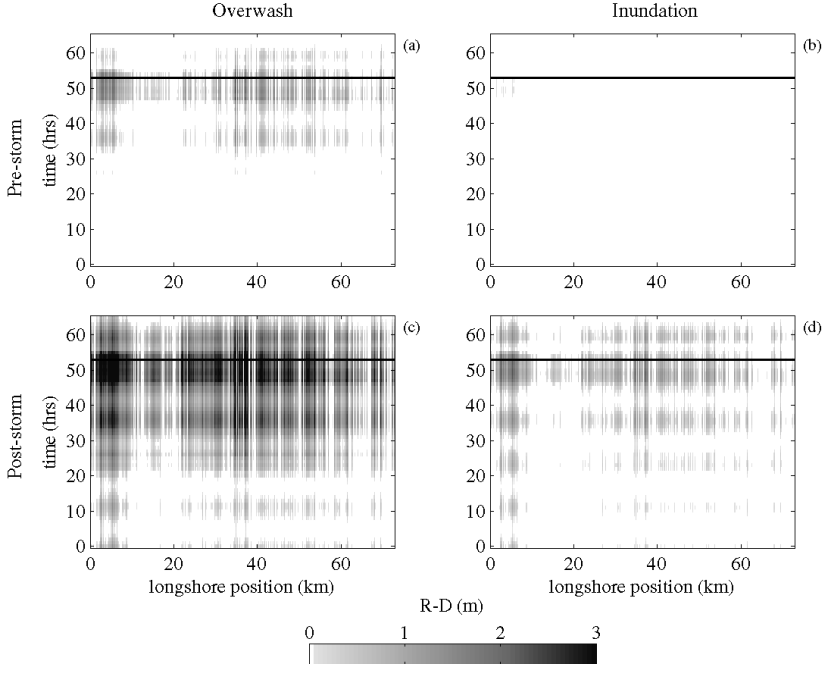

Fig. 3. Space-time plots of the predictive quantity for determination of the overwash (R_{high} – D_{high}, left column) and inundation (R_{low} – D_{high}, right column) regimes at all locations along Santa Rosa Island, Florida, for all time steps of the wave and surge modeling (66 hours), based on pre-storm (top row) and post-storm (bottom row) morphology. The black horizontal line marks the time of Hurricane Ivan's landfall. White areas indicate where R - D <= 0, meaning an area was not likely to be in that particular regime.

RESULTS

To evaluate the predictive accuracy of the model, the observed regime was compared to the hindcast regime at the time the maximum R_{high} was observed, which for most locations was the time of landfall. Mean modeled R_{high} along Santa Rosa Island was 3.55 m and the standard deviation was 0.37 m (Fig. 4). Elevated water levels in the central portion of the island result from higher runup in an area with steeper beach

slopes. Storm surge, which remained relatively constant (μ = 0.98 m, σ = 0.14 m) along the island, represents only 27.7% of the total water-level signal, with wave runup (swash and setup) contributing the remaining 72.3% (Fig. 4).

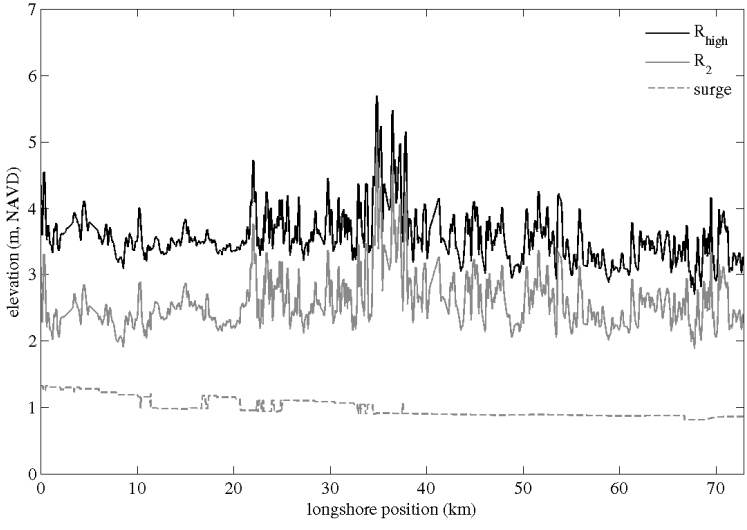

Fig. 4. Elevations of wave runup (R_2), storm surge, and total hurricane-induced water level (R_{high}) along Santa Rosa Island, Florida, as modeled during the peak of Hurricane Ivan.

The majority of the 73-km stretch of island (69.9%) was predicted to overwash while 28.2% of the island was predicted to experience dune erosion and only 1.9% was expected to inundate (Fig 3b). Comparisons to observations show an overall accuracy of predicting one in four regimes to be 68%. However, accuracy for a particular regime varied considerably. A confusion matrix that explicitly shows the number of correct predictions, *Nc*, total observations, N_o, and total predictions, N_p, for each regime can be used to examine regime-specific accuracies (Table 1). Positive predictive power, *P*, calculated as (N_c/N_p * 100), defines the probability that a particular regime will occur if predicted by the scaling model. Model sensitivity, *s*, is defined as (N_c/N_o * 100) and represents the probability that a particular regime was classified correctly. High sensitivity for the collision and overwash regimes (s = 77.2% and 72.4%, respectively) indicate the model's ability to identify locations most susceptible to dune erosion and overwash. Positive predictive power of 90.3% within the overwash regime shows that there is a high probability that an area predicted to overwash will, in fact, do so.

DISCUSSION

The majority of the hindcast errors were associated with the under-prediction of the response, such as the prediction of collision (dune erosion) in locations that experienced overwash. These errors may arise because a time-dependent process (profile evolution during a storm) is being examined using a non-time-dependent model. During a high tide 17 hours before the storm made landfall, water levels at the shoreline exceeded the elevation of the dune crest along 35.7% of the island. Five hours before landfall, R_{high} exceeded D_{high} at over 67% of the longshore locations, a total length of ~49 km. The dunes along these sections of the island (consistently between y = 2 - 7 km and intermittent locations between y = 35 - 60 km) were likely being overtopped for a full tidal cycle before the hurricane made landfall.

At a location near the middle of the island, y = 35 km, the time series of R_{high} modeled throughout the storm's approach show extreme water levels exceeding the crest of the dune for ~30 hrs (Fig. 5). While the total hurricane-induced water level remained high for many hours, this area was not predicted to inundate because the pre-storm D_{high} was higher than R_{low}. However, the profile changed dramatically over the course of the storm as the sand dune was completely eroded, making this location more vulnerable to extreme coastal change as the storm continued (Fig. 6). At y = 35 km, the maximum elevation was reduced by 1.1 m to 2.1 m, resulting in a post-storm dune elevation that was lower than the peak R_{low} (Figs. 5 and 6). Therefore, it is likely that this location was inundated at some time during the storm.

Likewise, many locations that were not vulnerable to overwash based on the pre-storm morphology showed substantial dune erosion as a result of the storm. The mean elevation at the cross-shore position of D_{high} decreased by 1.9 m (σ = 1.0 m), creating areas that were more vulnerable to overwash (Fig. 2). The increased vulnerability can be visualized by examining the predictive quantity for overwash (R_{high}-D_{high}) using the post-storm morphology rather than the pre-storm (Fig. 3c). While this parameter

cannot be used as a hindcast, it provides a qualitative look at the likely impact regime experienced during the storm, particularly at the time of landfall when the beach had already evolved in response to more than 20 hours of elevated water levels. When the post-storm morphology is considered, 92% of the island was shown to have conditions that were favorable for overwash, in closer agreement to the 89% that was observed to have overwashed. In some locations, such as the western 7 km of beach, peak water-level elevations exceeded the post-storm dune/berm elevations by 3 m.

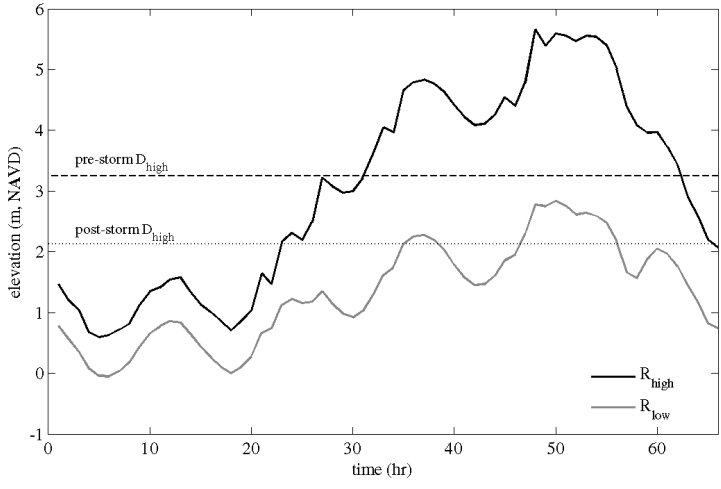

Fig. 5. Time series of modeled R_{high} and R_{low} during Hurricane Ivan at a single location (y = 35 km) along Santa Rosa Island. Horizontal lines indicate the elevations of the dune crest, D_{high}, before (3.25 m) and after (2.13 m) the storm.

The long duration of increased water levels contributed to significant profile evolution; however, the period of time that water levels exceeded threshold conditions did not directly correlate to the magnitudes of shoreline or beach volume change and, therefore could not explain the spatial variability of the observed coastal change. This is likely because, as a result of the storm, 43% of the island had conditions favorable for inundation (Fig. 3d). In the inundation regime, portions of the island are underwater and cross-shore flows will dominate the processes of sediment transport. During these extreme conditions, wave-driven processes such as swash and setup are not expected to scale with transport or the resulting coastal change.

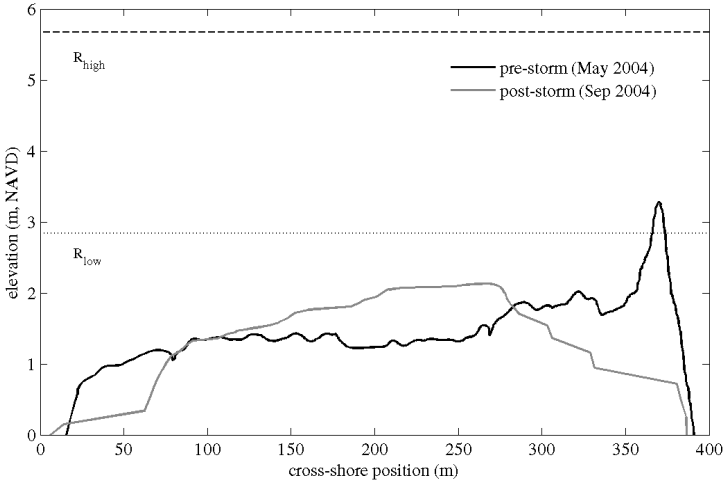

Fig. 6. Cross-shore profiles measured before (May 2004) and after (Sep 2004) the landfall of Hurricane Ivan. Cross-shore distance increases offshore with the Gulf of Mexico located to the right. Horizontal lines show the maximum value of R_{high} (5.67 m) and R_{low} (2.83 m) reached at this location during the storm.

In order to more accurately predict the type of coastal change expected during a hurricane, models will need to include information about the duration of elevated water levels and the magnitude of the difference between R_{high} and D_{high}. Of particular importance is the timing of water level increases relative to that of changes in beach morphology.

CONCLUSION

A storm-impact scaling model was used to hindcast the potential coastal impact of Hurricane Ivan on Santa Rosa Island, Florida. Comparisons to lidar-based measurements of coastal change and classification of regime indicate that the model has an overall accuracy of 68% in predicting one in four regimes. Based on measures of model sensitivity and positive predictive power, performance was best within the overwash regime where 72% (s) of overwashed locations were correctly predicted to do so, and there was a 90% (P) probability that an area predicted to overwash would respond as such. Most of the errors were an under-prediction of the impact regime. This is likely due to the evolution of the profile during the course of the storm. Seventeen hours before the storm made landfall, hurricane-induced total water levels exceeded the elevation of the dune or berm crest along 35.7% of the island. During the next high tide, five hours before water levels peaked, as much as 67% of the coastline was expected to be overwashed by waves and surge. Comparison of pre-storm morphology to that measured three days after the storm made landfall reveal large changes to the profile shape as storm waves eroded most of the sand dunes

along the beach. The mean elevation at the cross-shore position of pre-storm D_{high} was reduced by 1.9 m to 1.4 m, making this area more vulnerable to extreme coastal change as the storm slowly moved onshore. The predictive quantity (*R-D*) calculated using a post-storm measure of D_{high} shows that, because of significant erosion during the course of the storm, portions of the island likely entered a more extreme regime than expected based on the pre-storm morphology. In order to more accurately predict the mode of coastal change during a hurricane, models will need to include information about the duration and timing of increases in total water levels relative to profile evolution during the storm.

ACKNOWLEDGEMENTS

The lidar data were collected through a joint program between USGS, NASA, and USACE. We would like to thank C. Sullivan, J. Wozencraft, P. Howd, K. Morgan, and L. Fauver for technical assistance with data processing. This work was funded by the USGS Coastal and Marine Program's National Assessment Project.

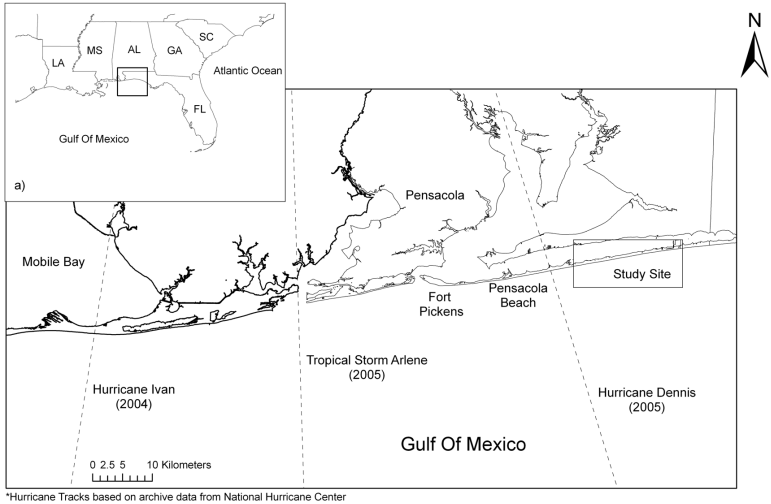
Abstract: Hurricane Ivan, a Category-3 hurricane, came ashore near Gulf Shores, Alabama, on September 16, 2004. Santa Rosa Island, Florida, was within the Northeast quadrant of the storm and subject to surge heights in excess of 3 m. As a result the area suffered significant sediment loss (>200 m^3 m^{-1}) and widespread overwash and breaching. Morphological changes were quantified by comparing LIDAR images collected before and after landfall. In general, the morphological changes exhibited an alongshore variation at a range of scales (<1 km), consistent with the variation in foredune height prior to the storm. Using multivariate statistics it is found that this variation not only depends on the height of the foredune (relative to the surge elevation) but also on the alongshore extent of the dune and the presence and relative location of the secondary dunes. This alongshore variation will affect the recovery of the dunes, reinforcing the observed patterns.

INTRODUCTION

Hurricanes and tropical storms produce elevated water levels and large waves, capable of eroding the beachface and causing overwash and barrier breaching. In general, the impact of a storm on a barrier island depends on the elevation of the storm surge relative to the vertical geometry of the coast, which in turn depends on the extent and height of foredune development (Thieler and Young, 1991; Sallenger, 2000).

Alongshore variations in dune morphology can force alongshore patterns in overwash and breaching during storms (Morton and Sallenger, 2003). While dunes along Cape Hatteras are relatively continuous, variations in dune height (in excess of 8 m) have



been noted at scales of kilometers to tens of kilometers (Elko *et al.*, 2002). Wetzell (2003) showed that the alongshore variation in storm impact was consistent with the variation in dune height and the Storm Impact Scale of Sallenger (2000). In areas where there is frequent and extensive overwash the dune field tends to develop as a mosaic of alongshore patches that vary in age and composition (Stallins and Parker, 2003). While the dunes will obstruct overwash penetration, surge water may be forced into the intervening areas of low elevation, which can become washover conduits (Morton, 2002). It is reasonable to expect that the concentrated flows within these conduits could impact adjacent foredunes through lateral erosion, which could increase overwash penetration where dune height is variable.

In recent years, Santa Rosa has been impacted by Hurricane Ivan (2004), Tropical Storm Arlene (2005), Hurricane Dennis (2005) and Hurricane Katrina (2005). During Hurricane Ivan, the dunes on Santa Rosa Island were again reduced in height through direct wave erosion and overwashing. It is hypothesized that the morphological response to Hurricane Ivan was conditioned by the alongshore variation in the height of the dunes that had recovered following Hurricane Opal (1995). The purpose of this study is to examine how the alongshore variation in dune height and extent affected the morphological response of Santa Rosa Island to Hurricane Ivan and the redistribution of dune and beachface sediment between the nearshore and overwash deposits.

STUDY SITE

Santa Rosa Island is a narrow sandy Holocene barrier island extending over 80 km in length, from East Pass near Destin in the east to Pensacola Pass in the west (Figure 1). The second-longest barrier island on the U.S. Gulf Coast, Santa Rosa Island is separated from the Pleistocene mainland coast by Santa Rosa Sound, a continuous lagoon 3 km wide in the west and tapering to less than 400 m in the east (Kwon, 1969). Although some scholars ascribe the origin of the island to erosion of a central Pleistocene "core" and longshore redistribution of sediments (Otvos, 1982), others (Stone, 1991; Stone *et al*., 1992; Stone & Stapor, 1996) attribute longshore sediments derived by bluff erosion east of Destin as contributing most to the island's formation. The island reached its present form by 3000 bp, and it has been characterized by overall transgression since then. On the basis of dated peat and tree stumps, Stone and Morgan (1993) estimated a landward shift of "one island width" over the past 800 years (cited in Otvos, 1997). This translates to a long-term shore retreat rate of about 2 ft/yr at the site of present-day Pensacola Beach.

Santa Rosa Island is microtidal, with an average tidal range of 0.43 m (Armbruster, 1997). In addition to strong wave action on the Gulf side, especially during tropical storms and hurricanes, the island experiences back-barrier shoreline erosion due to wind-driven waves generated by winter polar outbreaks. As a result, the roll-over effect commonly associated with transgressive island systems is largely absent, except following intense hurricanes that generate extensive overwash activity.

*Hurricane Tracks based on archive data from National Hurricane Center

Fig. 1. Map of study site showing location relative to the tracks of Hurricanes Ivan and Dennis and Tropical Storm Arlene.

Historically, Santa Rosa Island has been been struck by relatively few hurricanes, especially throughout most of the 20th century. In spite of hurricanes in 1906, 1916,and 1926 (when Santa Rosa Island was unpopulated), the island's shoreline position remained relatively stable from 1920 to 1993 (Foster *et al.*, 1999; Stapor, 1975).

Short-term shoreline changes have, on the other hand, been rather dramatic since 1995 because of the passage of several hurricanes and tropical storms, e.g. Erin (1995), Opal (1995), Georges (1998), and various tropical storms. Such changes have been well documented (e.g. Leadon *et al*., 1998; Leadon *et al.*, 1999; Liebens, 2000, and unpublished analyses by Olsen & Associates).

METHODOLOGY

Changes to the barrier morphology were quantified by comparing LIDAR images collected immediately before and after landfall using cross-shore transects spaced 50 m alongshore. The cross-shore geometry of the island was examined using empirical orthogonal function (EOF) analysis to identify to reduce the topographic data into common forms. EOF analysis is similar to principal component analysis, except that the variability structure is examined through space rather through time. The relationship between the primary modes of the pre- and post-storm topographic data was examined through canonical correlation analysis (CCA). This test is used to

investigate whether or not there are patterns that occur simultaneously in two different data sets and to describe the nature of those patterns.

RESULTS

A comparison of the pre- and post-storm alongshore variation in foredune elevation is provided in Figure 2. The foredune height exhibited considerable variability alongshore and was in some cases discontinuous with an average elevation above-sea-level of ~4.3 m prior to the storm. Through spectral analysis, it is found that the variation in dune height is periodic, with statistically significant spectral peaks at 9, 14, 31 and 76 transects. The average elevation within the foredune area was reduced to 2.3 m, with remnant dunes remaining only where relatively large continuous dunes had been present. The post-storm elevation data also exhibits an alongshore periodic variation at 31 and 76 transects and relatively muted variations at 9 and 14 transects.

The average pre- and post-storm cross-island profiles are presented in Figure 3. The net change in sediment volume ranged from an erosion of 238 to 43 m^3 per unit width of beach. The largest net losses of sediment (>150 m^3 per unit width of beach) were coincident with the location of breaches, which were observed where the dune crest elevation (based on a 9-point moving average) is at a minimum and close to the surge elevation (Figure 2). The crest of the dune at these locations would have been overtopped early in the storm and would have focused overwash that would eventually precipitate a breach. The breaches were reactivated during Hurricane Katrina (2005) and are activated during frontal storms that coincide with high tide.

The amount of sediment removed per unit width of beach exceeded 45% at the breach sites and ~20% on average. The loss of sediment is considerably larger than the volumetric changes presented by Stone *et al.*, (2004) for Hurricane Opal, although sediment volumes in that study were considered to a depth of 1.5 m on both the Gulf and Sound side of the island. Except for the breach areas, the amount of sediment lost from the profile does not exhibit a clear relationship with the pre-storm elevation of the foredune. This suggests that the height of the foredune is not the only control on the redistribution of sediment between overwash and erosion offshore.

Empirical Orthogonal Function (EOF) Analysis

In both the pre- and post-storm data, the first 5 modes were found to be statistically significant (ρ<0.05), with the percent of the total variance explained being 65 and 75% respectively. The primary eigenmode (E1) for the pre-storm morphology explains 21% of the variance and shows a secondary dune (positive factor weightings) ~170 m landward of the average primary dune (Figure 4a). Secondary dunes are also indicated by positive factor weightings for E3 and E5, at 67 and 117 m landward of the primary dune respectively. The second eigenmode (E2) explains 14% of the variance and exhibits negative factor weightings in the vicinity of the beachface and positive factor weightings on the landward slope of the primary dune.

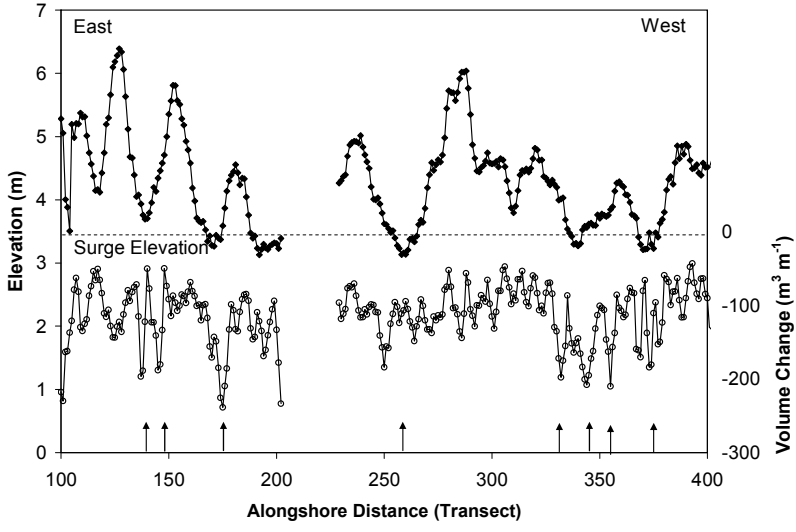


Fig. 2. Alongshore variation in dune height modelled using a 9-point moving average and the volume change between the pre- and post-storm profiles. Also shown with the arrows are the locations where breaches were observed.

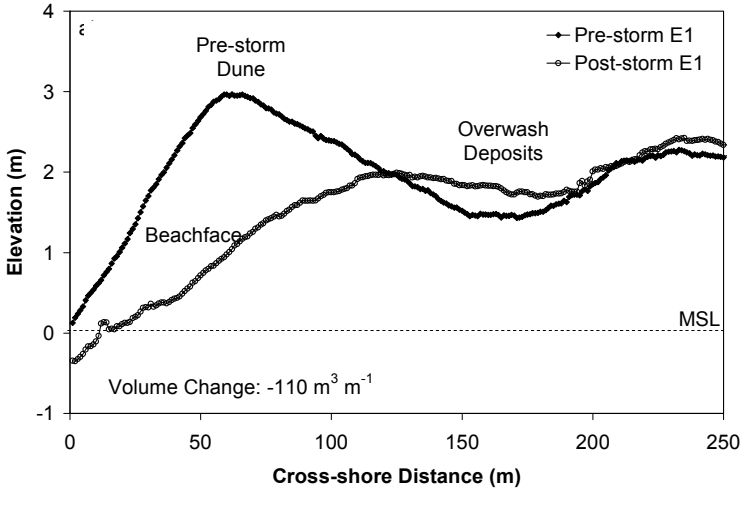

Fig. 3. Pre- and post-storm average cross-island profiles with major morphological features identified.

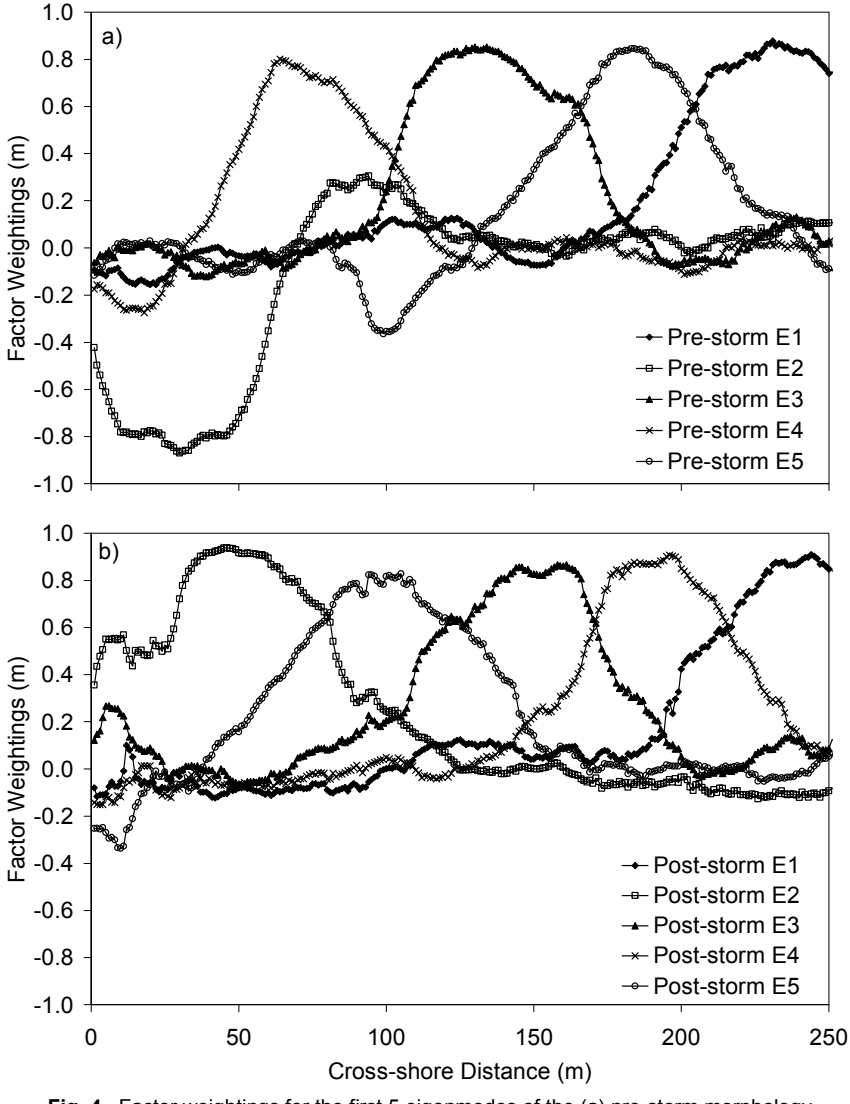

Fig. 4. Factor weightings for the first 5 eigenmodes of the (a) pre-storm morphology and (b) the post-storm morphology.

This profile is characterized by a single foredune that is ~20 m landward of the average foredune position and a relatively extensive foreshore and backshore. The fourth eigenmode (E4) has positive factor weightings at the crest of the foredune and is characteristic of a foredune that is ~0.80 m larger than the average dune (Figure 3).

In the post-storm morphology, 26% of the total variance is explained by E1and 25% of the variance is explained by E2. The primary eigenmode (E1) for the post-storm morphology exhibits positive factor weightings in the backbarrier similar in position and amplitude to the primary eigenmode for the pre-storm morphology (Figure 4b). Remnant secondary dunes are also apparent, to varying degrees, in the profiles for E3 and E4. The location and amplitude of these dunes is consistent with E3 and E5 for the pre-storm morphology. The second eigenmode exhibits positive factor weightings and accretion in the vicinity of the beachface, characteristic of either less beachface erosion or accretion relative to the average post-storm profile (Figure 3).

Canonical Correlation Analysis

As observed in the EOF analysis, there are similarities in the factor weightings of the pre- and post-storm morphology. Canonical correlation analysis between the factor scores for the pre- and post-storm morphology yields a correlation of 0.73 (ρ<0.05). Results of the analysis are presented in Table 1. The negative correlation (-0.79) between the pre-storm E2 and post-storm E2 is a reflection of how overwash penetration is inversely related to dune height and that significant overwash penetration and even breaching are observed in areas of low dune height (areas with a negative pre-storm E2). The positive correlation between pre-storm E4 and post-storm E5 is a reflection of increased beachface erosion and sediment loss to the offshore with increasing dune height. Overwash penetration is relatively small and in some cases absent where there is a strong positive pre-storm E4 (large dunes). The additional correlation between pre-storm E4 and post-storm E2 suggests that large dunes adjacent to smaller dunes (or areas where dune are absent) can be eroded through lateral erosion.

Table 1. Canonical correlation coefficients (*r*) between the pre- and post-storm profiles, with the largest coefficients (strongest relationships) highlighted.

		Post-storm Profiles

DISCUSSION

It has been well demonstrated in previous studies that the response of a barrier island to an extreme storm depends not only the local magnitude of the storm but also the pre-storm morphology (e.g. Sallenger, 2000; Morton, 2002). The models developed in these studies provide reasonable estimates of storm impact (see Wetzell, 2003), but

the models only provide a first approximation based largely on foredune height and there is a need for verification in the prototype. In the present study, LIDAR data is used to examine how the response of Santa Rosa Island to Hurricane Ivan was directed by the pre-storm geometry. Results suggest that (to the first order) the morphological response partly varies with the height of the foredune relative to the elevation of the storm surge, which supports the storm impact model of Sallenger (2000).

The pre-storm height of the foredune exhibited considerable variation alongshore and the variation in the morphological response and profile volume exhibited a similar variation. Prior to the storm, the alongshore variation in the foredune height exhibited periodic variations at 76, 31, 14 and 9 transects. The larger-scale variations remained strong following the storm while the smaller-scale variations were significantly weaker following the storm. If the impact of this storm depended only on the relative elevations of the dune and storm surge, then these small-scale variations would have been maintained and potentially reinforced with larger and sustained impacts where there were small dunes. It is reasonable to expect that the absence of these small-scale variations following the storm is a result of lateral dune erosion and that the scale of variation that is removed (or weakened) by the storm depends on the magnitude and duration of the storm. As noted in a number of studies, surge water can be forced into areas with low dune heights (Morton, 2002) and the fast flowing water within these conduits is capable of eroding the dunes laterally.

The morphological response and redistribution of dune sediment was also found to depend on the cross-island geometry. Where there were no secondary dunes overwash and sediment erosion offshore were primarily dependent on the height of the foredune (Sallenger, 2000), which was the general case in the eastern section of the study site (transects 115 through 181). Numerous secondary dunes were observed in the western section of the study site (transects 229 to 400) with a periodicity of 38 transects. Where the primary and secondary dunes were closely spaced overwash was restricted and sediment erosion offshore was increased. This situation was analogous to having a large wide foredune (Thieler and Young, 1991). As the separation between the primary and secondary dune increased, overwash penetration was not restricted and the amount of sediment eroded offshore was reduced.

While the island appears to be uniformly covered an overwash terrace the results of this study have shown there to be considerable alongshore variability in the morphological response and redistribution of dune sediment. This variation will ultimately affect the recovery of the dune system, such that there will be alongshore variation in the height and extent of the next foredune. If the frequency of extreme storms increases the alongshore variation will be reinforced and the dunes will develop a mosaic of alongshore patches that have a cross-island orientation (Stallins and Parker, 2003). The secondary dunes on Santa Rosa Island are remnant features that not only survived Hurricane Ivan but had also survived Hurricane Opal in 1995. The alongshore periodicity of these features (~30 transects) is consistent with the

alongshore periodicity in the height of the foredune, suggesting that the alongshore response of the island is directed by a persistent variation in the island geometry that is a reflection of the storm frequency (Stallins and Parker, 2003).

CONCLUSIONS

While it has been well demonstrated in previous studies that the response of a barrier island to an extreme storm depends on the pre-storm morphology, these models only provide a first approximation based on foredune height. Results from the present study suggest that the morphological response not only depends on the foredune height but also on the presence and relative location of secondary dunes and breaks in the crest. Where there were no secondary dunes, overwash and sediment erosion offshore were primarily dependent on the height of the foredune. Where the primary and secondary dunes were closely spaced, overwash was restricted and sediment erosion offshore increased, analogous to having a large wide foredune. As the separation between the primary and secondary dune increases, overwash is not restricted and the amount of sediment eroded offshore is reduced. The alongshore variation in morphological response will ultimately control the recovery of the dune system, such that the alongshore variation in dune height and extent may redevelop and direct the response to the next extreme storm.

Abstract: The hydrodynamic response of Terminos Lagoon to the passage of Hurricane Isidore is presented. The field data analysis shows the changes of the hydrodynamic currents in the Carmen and Puerto Real inlets, as well as the water level elevation in the marine front and the interior of the Terminos Lagoon, due to the storm surge from the ocean, and the large fresh water discharges from land to the lagoon. Finally a brief interpretation of the system behavior is made, showing that in spite the large distance between the lagoon system and the hurricane trajectory (250 km), important effects in the hydrodynamics and sediment transport rates were reported. The identification of the hydrodynamic and sediment transport response to extreme events can help to better understand the physics of such systems, and can be applied to water quality and mass transport studies in semi-enclosed coastal bodies.

INTRODUCTION

Inlet hydrodynamics in coastal lagoons are complex. They result from the interaction between the fluid motion and the bottom floor, which often has a complicated spatial distribution (channels, bars, deltas, platforms…). The fluid motion is in turn generated both by currents (tidal-induced, wind-driven, wave-generated, river flow...) and by waves, which propagated at frequencies ranging from a few seconds to several hours or more.

The tide, propagating from deep to shallow water, suffers a distortion process (energy transfer to higher frequency components, energy loss energy due to friction), which

increases when the tide enters and propagates in a semi-closed body as can be a coastal lagoon. This distortion produces an imbalance between the flood and ebb tidal prisms, favoring the generation of residual currents. The variation of these residual currents over time is responsible for the net circulation through the inlet and for the net transport of silts and sand.

The hurricane Isidore to affect the variation in the hydrodynamic circulation, in all Terminos Lagoon. In order to analyze the effects of waves and storm surge on inlet dynamics, a series of projects have been conducted, including field measurements (waves, currents, suspended sediment), mathematical and numerical modeling. This study consists of numerical simulations of hydrodynamics response of the lagoon system and the changes of hydrodynamic system in Puerto Real inlet, flow (ebb).

STUDY AREA

The Terminos Laggon coastal system is located in the coastal plains of the State of Campeche. It communicates with the Gulf of Mexico through two natural inlets, Carmen and Puerto Real inlets, east and west of the Carmen barrier island, respectively, and Sabancuy Inlet, a small artificial inlet, 43 km northeast from Puerto Real Inlet. The system is composed by a main water body with 4.5 m average depth and a surface area of approximately 1,700 km^2, and a series of adjacent lagoons, some of which are the deltas of rivers entering the main lagoon (see Fig. 1), with a total surface area of 800 km^2. The flood area, up to the +1.0 m relative to the mean sea level, is 4,000 km^2 large.

The climate is tropical humid and is characterized by three stations, regulated by the rain intensity: little precipitation (March to May), heavy rains (June to October), and intermediate precipitations with strong northerly winds or Nortes (November to February). The average yearly precipitation is 1,805 mm (David et al., 1998), and the yearly evaporation has been estimated to be 1,512 mm, which give an average effective input, considered uniformly distributed over the entire system, of 23 $m^3.s^{-1}$. The predominant winds are moderate with north-northeast and east-southeast wind speeds lower than 5 $m.s^{-1}$, except during the Nortes season, in which frontal passages can have average sustained north-northwest wind speed in excess of 12.5 $m.s^{-1}$ (Mancilla et al., 1980).

Most of the fresh-water input to the system comes from three rivers (see Fig. 1): Palizada river with monthly-averaged discharges ranging from 115 to 510 $m^3.s^{-1}$ (288 $m^3.s^{-1}$ yearly average), Candelaria and Mamantel rivers, whose discharges occur in the Panlau lagoon, and range monthly from 23 to 197 $m^3.s^{-1}$ (72 $m^3.s^{-1}$ yearly average), and Chumpán river with discharges ranging from 0.3 to 50 $m^3.s^{-1}$ (18 $m^3.s^{-1}$ yearly average). The tide in the area is mixed-diurnal (Marina, 2001), with the diurnal components being the largest, as shown in Table 1. The average amplitude is 0.424 m, the high high water is 0.923 m and the low low water is –0.662 m, with respect to the mean water level (0.000 m). According to measurements of the water level fluctuations at the inlets and an intermediate point between the inlets (St. 12 in Fig. 1), the phase lag of the tide as it propagates inside the lagoon is important, as shown in Table 2. For instance, the high O_1

tide occurs 1.7 hours later at Carmen Inlet and 5.01 hours later at Station 12. It can be seen that the propagation of the tide is from northeast to southwest in that zone of the Gulf of Mexico. Furthermore, the propagation experiences selective dampening inside the lagoon, as a result of higher friction and energy transfer from one component to another.

Location and Description of Oceanographic Equipments

In order to gather oceanographic data in the Terminos Lagoon, the Coastal and Ports Engineering Group (GICP) of the Engineering Institute of the UNAM and the Federal Electricity Commission (CFE) placed two oceanographic equipments to collect current and wave data, in the Puerto Real Inlet (GICP) and Carmen Inlet (CFE). Additionally, water level elevation data was collected with the Navy tide gage (SEMAR, 2001), located in the oriental margin of Carmen Inlet. During the campaign, hurricane Isidore stroke the coast of Yucatan (Fig. 2), which was recorded by the three instruments.

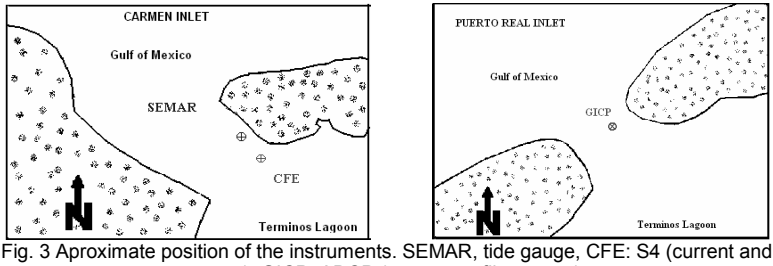

Fig. 3 Aproximate position of the instruments. SEMAR, tide gauge, CFE: S4 (current and waves), GICP: ADCP (current profile, waves).

NUMERICAL MODEL

Numerical simulations of the tidal dynamics in the system, using RMA-2V (Donnell et al., 1997), a vertically integrated finite-element model that solves the non-linear momentum and continuity equations, complemented with COPLA-2DH (COPLA-RD, 1998), a wave parabolic model for the wave propagation under the presence of currents, were performed in order to estimate the flow characteristics at the inlet. Finally, the bedload and suspended load sediment transport at different locations was computed by means of a combined wave-current bottom boundary layer flow model (e.g., USACE, 2001).

WAVE PROPAGATION

The wave propagation includes both inlets, with 1 and 3 m height waves whit 6 and 12 second period, respectively approaching from the North, which is the more common wave direction, according to the directional spectrum analysis of the data (Mantilla, 2004).

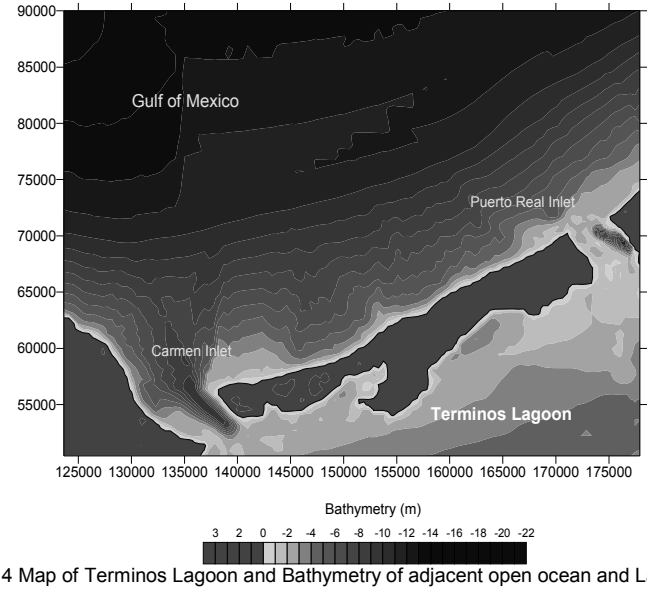

Fig. 4 Map of Terminos Lagoon and Bathymetry of adjacent open ocean and Lagoon.

In order to obtain the form of the wave and induced current characteristics at the Inlets, a model was used to propagate the waves, as shown in the following figures.

In the case of the 1m waves at Carmen Inlet (Fig. 5), the model results show that the induced currents, between 0.2 and 0.5 $m.s^{-1}$, are oceanward in the western boundary of the inlet and lagoon ward in the eastern section. In turn, the Puerto Real Inlet presents increasing induced currents after the waves pass the ebb delta and become more nonlinear (Fig. 6).

The effect of increasing the wave height in Carmen Inlet is that all the induced current becomes flood-oriented (Fig. 7). The increase of wave height and period in Puerto Real Inlet produces simply an increase in the induced current (Fig. 8).

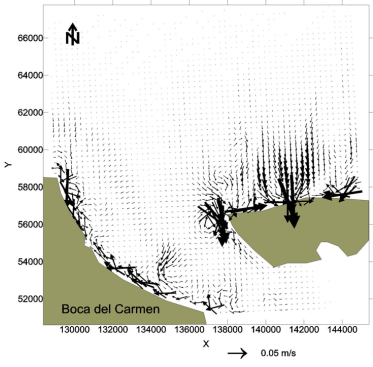

Fig. 5 Wave-induced current velocity vectors at Carmen Inlet with 1m waves (period=6s)

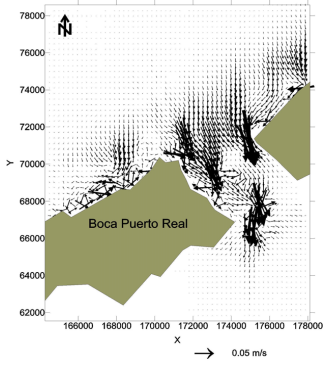

Fig. 6 Wave-induced current velocity vectors at Puerto Real Inlet with 1m waves (period=6s)

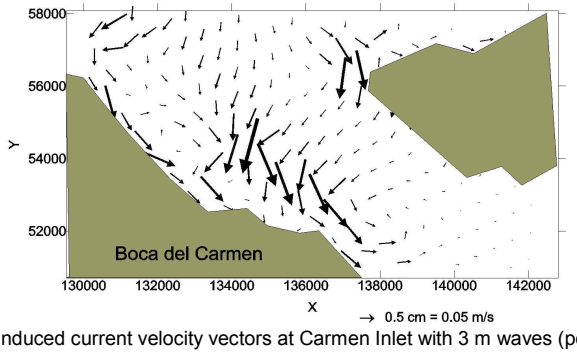

Fig. 7 Wave induced current velocity vectors at Carmen Inlet with 3 m waves (period = 12 s)

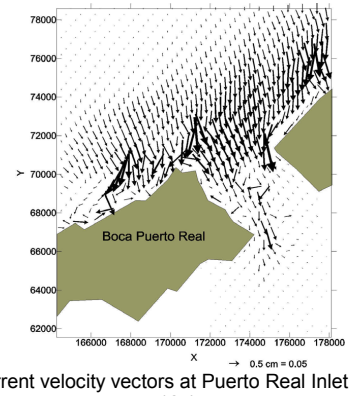

Fig. 8 Wave induced current velocity vectors at Puerto Real Inlet with 3 m waves (period = 12s).

LONG PERIOD CURRENTS

The modeled current velocities across the inlets were computed as the weighted average for the nodes of the cross-section, as shown in Fig. 9.

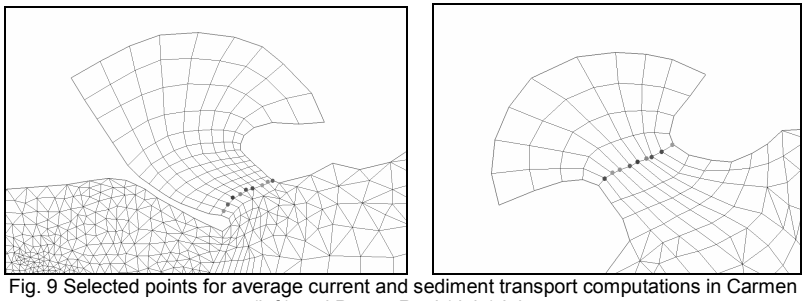

Fig. 9 Selected points for average current and sediment transport computations in Carmen (left) and Puerto Real (right) Inlets.

The hydrodynamic results include the effect of river discharges, and tide for a 20 day period encompassing the days during which Hurricane Isidore stroke the area. The tide gauge in Carmen and Puerto Real Inlets are shown in Fig. 10 and Fig. 11.

The hydrodynamic results to Carmen and Puerto Real Inlets was obtained by RMA2 Model implemented, next figures show the cross sectionally average flow velocity, in both cases flow negative is flood and positive ebb.

Although Fig. 10and 11 show stronger flood currents at both inlets, a closer analysis of the discharger (e.g., Espinal 2002) indicate that Carmen Inlet is a net exporter of water on normal conditions (before Isidore). While Puerto Real Inlet is a net import of water before on normal conditions.

Indeed, these same figures show that Carmen Inlet presented stronger and longer ebb flows during a small fraction of the first part of the Hurricane surge (22/09) but in fact remained directed to the lagoon (flood) during most of the Hurricane passage (Fig. 10). Inversely, the flow through Puerto Real Inlet was ebb oriented most of the duration of the Hurricane surge (Fig. 11). In other words, there was a reversal of the flows, Carmen became net importer of water, and Puerto Real net exporter.

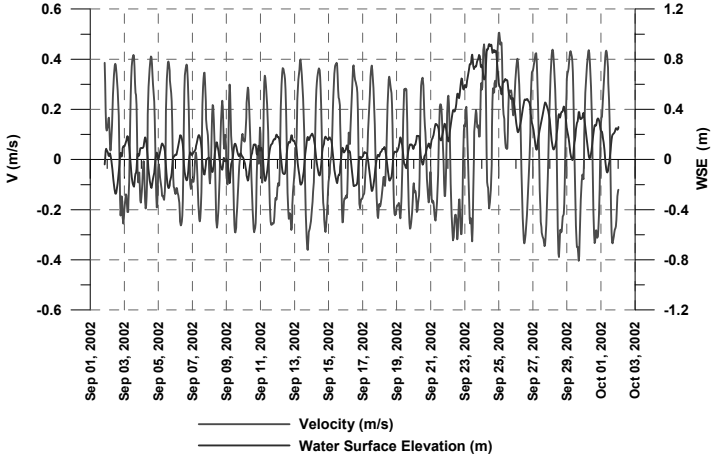

Fig. 10 Water surface elevation and cross-sectionally averaged flow velocity in Carmen Inlet (negative is flood).

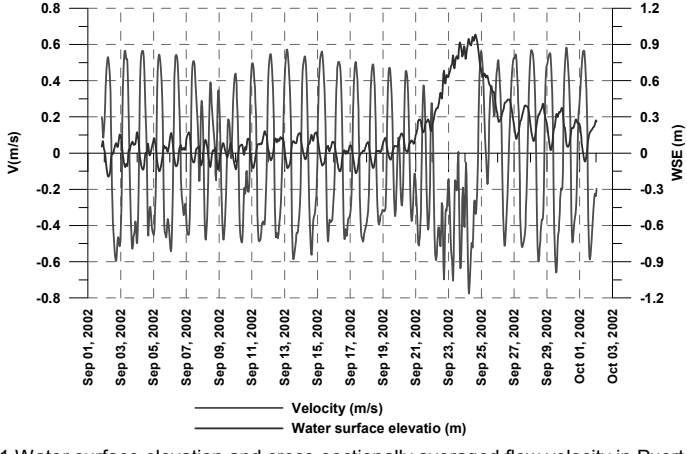

Fig. 11 Water surface elevation and cross-sectionally averaged flow velocity in Puerto Real Inlet (negative is flood)

Fig. 12 shows the current profile data at the Puerto Real site, during the passage of Hurricane Isidore. These data confirm the water export at Puerto real, found also in the model results presented above.

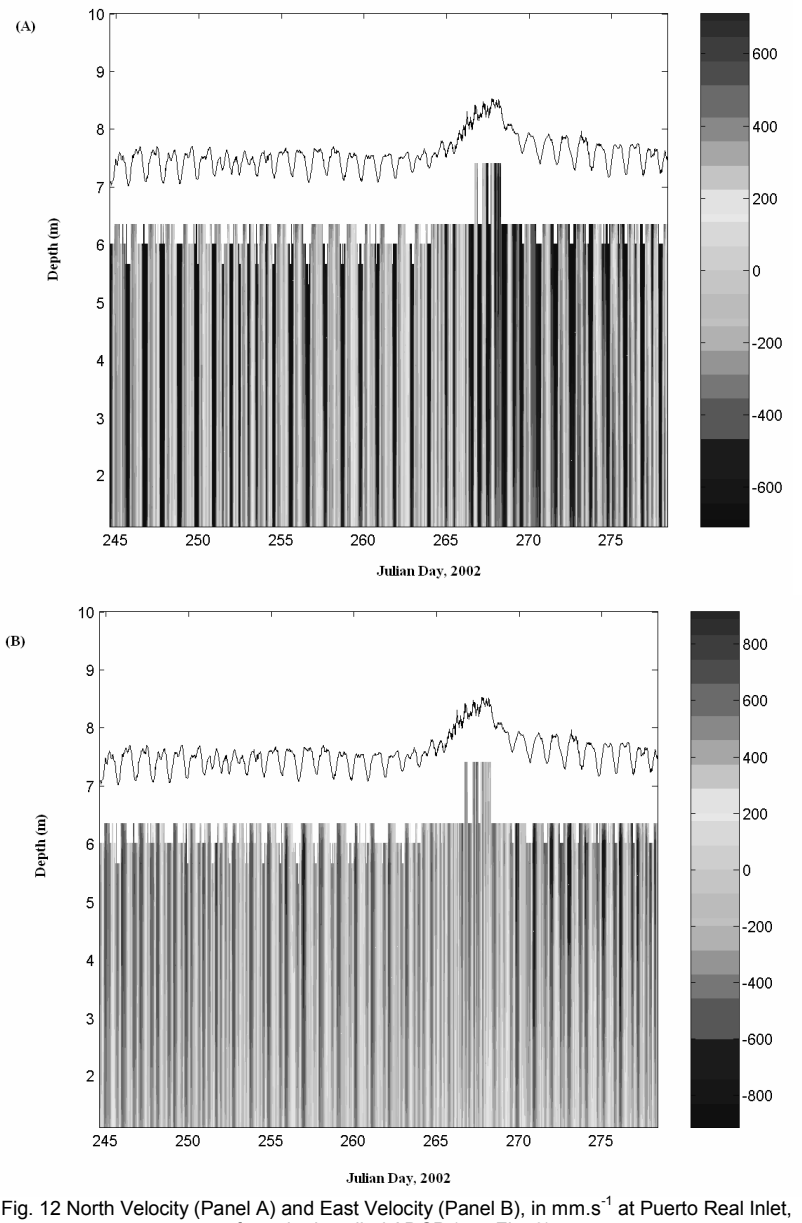

Fig. 12 North Velocity (Panel A) and East Velocity (Panel B), in mm.s^{-1} at Puerto Real Inlet, from the installed ADCP (see Fig. 3).

SEDIMENT TRANSPORT ACROSS THE INLETS

The transport of non-cohesive material is calculated by means of a combined wave-current bottom boundary layer flow model computed whit two conditions of wave and long period currents to normal and storm surge conditions (Hurricane Isidore) and rivers discharge.

The modeled effect of the Isidore Hurricane on the sediment transport rates at Carmen Inlet can be observed in Fig. 13 and at Puerto Real Inlet in Fig. 14.

The peaks are generally more uniform in all cross section, both inlets increased sediment transport rates, associated whit stronger velocity gradients presented during hurricane Isidore.

What can be seen from these figures is that the sediment transport rate (in $m^3.s^{-1}.m^{-1}$) during the passage of Hurricne Isidore decreased at Carmen Inlet and Increased at Puerto Real Inlet. In other words, and according to the hydrodynamics shown previously, Carmen imported small amounts of sand during Isidore, and Puerto Real exported large amounts of sand during that same period.

Although a thorough analysis of the effects of waves on sediment transport can be done analytically, this example simply shows the importance of considering waves when studying the morphological evolution of coastal features as inlets. In Terminos Lagoon, especially in the flood dominant Puerto Real Inlet, the wave effects on sediment transport are considerable. The large sediment transport capacity obtained when considering waves in this inlet is consistent with the observed morphologic evolution.

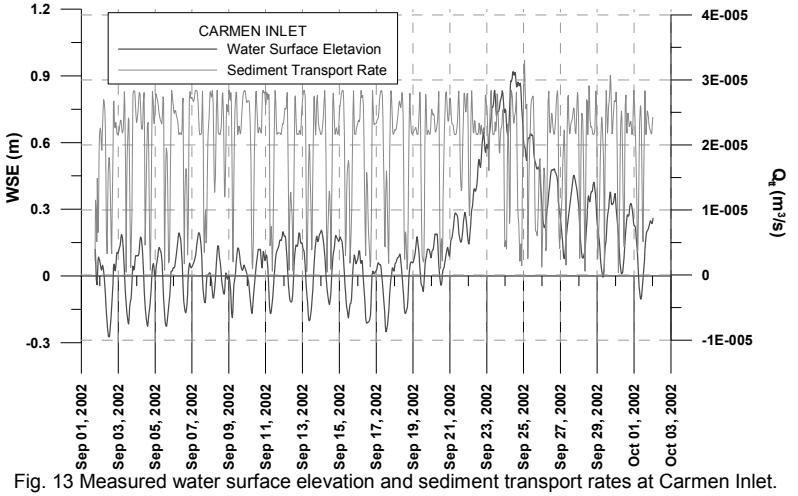

Fig. 13 Measured water surface elevation and sediment transport rates at Carmen Inlet.

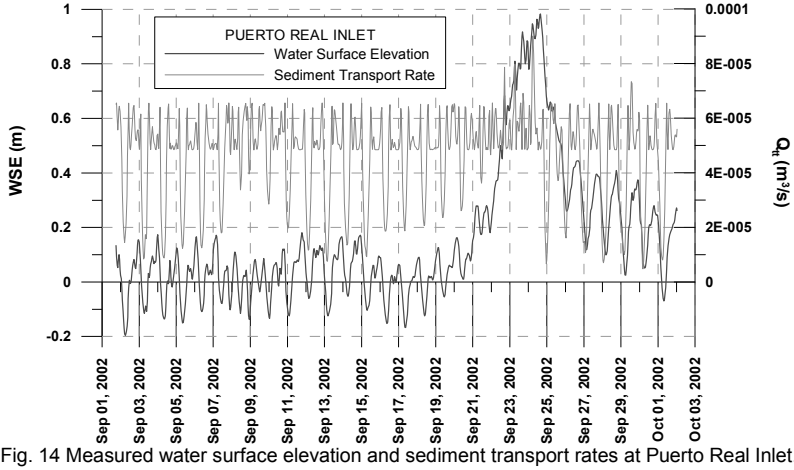

Fig. 14 Measured water surface elevation and sediment transport rates at Puerto Real Inlet.

CONCLUSION

The following conclusions can be made:

Terminos Lagoon is protected in a natural way by the configuration of the Gulf of Mexico and the Orientation of the Lagoon System.

Given the measured and modeled currents for the period of the passage of Hurricane Isidore, the water surface elevation increase that occurred at both inlets may have not been caused only by a storm surge, but also by large volumes of freshwater discharged by the rivers and surface runoff.

The storm surge can increase the rates of sediment transport, but for the case of Carmen Inlet it seems that the sediment transport decreased.

The combination of field data with modeling can be a useful tool to understand hydrodynamic and morphodynamic responses in coastal environments affected by large storm events.

Abstract: Quantitative estimation methods for tsunami damage to houses and humans are proposed in consideration of beach transformation and dike failure. Case studies were conducted for Kochi Coast, Japan, where dike subsidence caused by earthquake motions, topographical change by tsunami, and dike failure by toe scouring is expected. Damage to houses and humans on land increases with dike subsidence and dike failure, and public awareness of evacuation had a significant influence on the extent of human damage. The methods used in this study quantitatively evaluated the mitigation of tsunami damage achieved by making coastal dikes earthquake- and tsunami-resistant, and raising the level of evacuation awareness.

INTRODUCTION

Coastal areas in Japan are at risk of tsunami disasters although concrete-armored dikes are distributed along the long shoreline. The central and prefectural governments have conducted tsunami damage estimations assuming non-failure of coastal dikes during earthquake and tsunamis. However, even concrete-armored dikes could fail by strong earthquake motions or large tsunamis, resulting in tremendous damage to coastal zones. Dike subsidence caused by earthquake motions and dike failure by scouring should be taken into account in tsunami damage estimation in order to determine the most effective measures for tsunami damage mitigation. Moreover, topographical change caused by tsunamis should also be considered because tsunami runup transforms river-mouth bars that act as breakwaters and erodes sandy beaches that form the foundation of coastal dikes.

We propose a method for estimating tsunami damage to humans and houses taking into consideration beach transformation and dike failure, as shown in Figure 1.

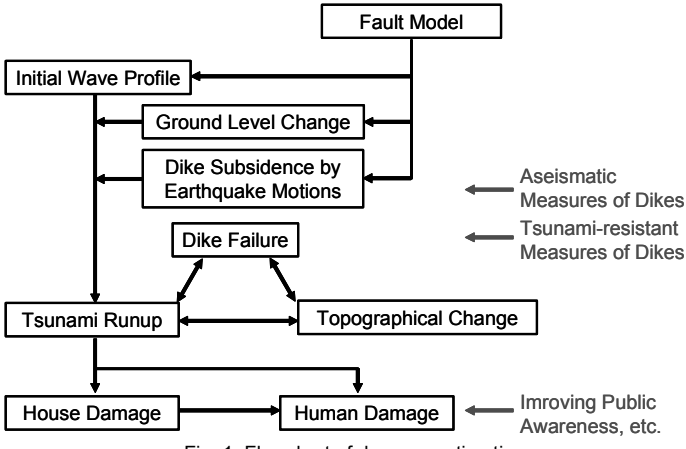

Fig. 1. Flowchart of damage estimation

TSUNAMI SIMULATION

Calculation Method

Case studies were conducted for Kochi Coast, Kochi Prefecture, Japan, where huge tsunamis generated by large-scale earthquakes are expected in the near future. Tsunamis were simulated using a fault model in which the Tonankai and Nankai Earthquakes occur at the same time as shown in Figure 2. Table 1 shows conditions for the case studies, which were taken into account in the tsunami simulations based on nonlinear long-wave equations. Grid size of calculation was refined from 2700 m to 11 m. Initial tide level was set at the mean monthly-highest level (0.945 m above the mean sea level in Tokyo Bay). Gates and sluices were assumed to be closed in the simulations.

Dike subsidence caused by earthquake motions was calculated using dynamic FEM analysis for the case in which the Tonankai and Nankai Earthquake occur at the same time (magnitude 8.6). In this analysis, the effects of concrete covering coastal dike were ignored for the Nino District (east of the Niyodo River) because the seaward slope of the dike is not covered with much sand. On the other hand, for the Nii District where considerable sand covers the seaward slope, the effects were taken into account. Therefore, dike subsidence was estimated at 3.44 m for Nino and 0.09 m for Nii. Besides this, the ground level was expected to fall by about 2 m on the Kochi Coast because of the earthquake. The post-earthquake crest height of the coastal dike was estimated to be T.P. +4.39 m (4.39 m above the mean sea level in Tokyo Bay) for Nino and T.P. +8.02 m for Nii.

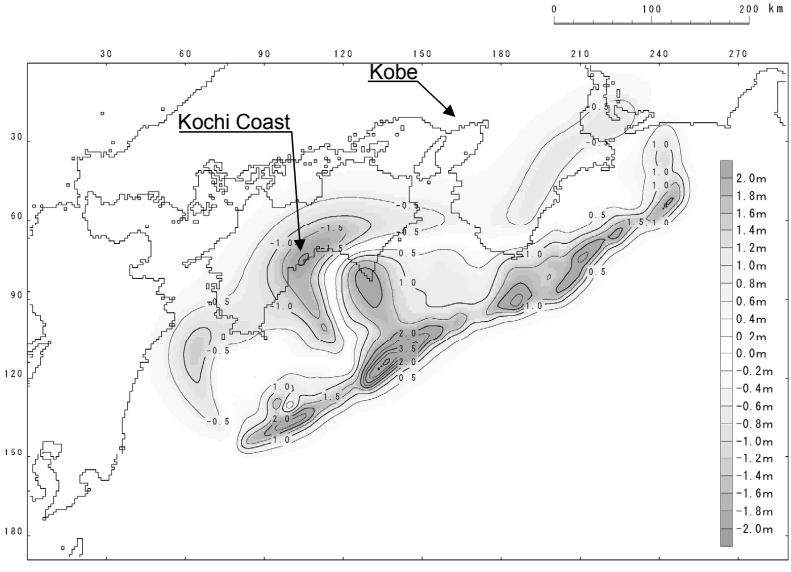

Fig. 2. Change in ground level (source: Central Disaster Prevention Council)

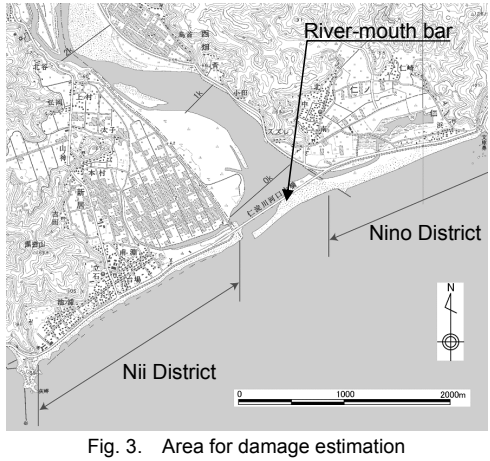

Fig. 3. Area for damage estimation

Table 1. Conditions for case studies

Case	Dike subsidence	Topographical change	Dike failure
A1	No	No	No
A2	Yes	No	No
B3	Yes	Yes	No
B4	Yes	Yes	Yes

As shown in Figure 4, tsunami simulation considering dike failure was conducted after that without dike failure in order to estimate the timing of failure. According to Takahashi et al. (1993), topographical change caused by tsunami was calculated using Brown's equations with bottom friction force based on Manning's formula, and the continuity equation proposed by Watanabe et al. (1984).

$$Q_s = \frac{u_*^5}{(\sigma/\rho - 1)^2 g^2} \frac{10}{d} \tag{1}$$

$$u_* = \sqrt{\tau/\rho} \tag{2}$$

$$\tau = \rho g n^2 (u^2 + v^2) / D^{1/3} \tag{3}$$

where Q_s = sediment transport rate; u_* = friction velocity; σ = sand density; ρ = water density; g = gravity acceleration; d = grain size; τ = sheer stress; n = Manning's roughness; u and v = horizontal velocity; and D = total water depth. Thickness of sand layer was set at 0 for grids corresponding to coastal dike because the dike is covered with concrete. Median grain size and pore ratio in the model were set at 2 mm and 0.4, respectively. Total scour depth was calculated by adding time series of scour depth to topographical change caused by tsunami, because scouring due to overflow is a dominant cause of topographical change near coastal dikes. Scour depth was calculated using the equation proposed by Noguchi et al. (1997) and the overflowing rate at the coastal dike. We assumed that the crest height of the coastal dike lowered to initial ground level near the coastal dike when ground level near the coastal dike fell to the residual water level in the coastal dike (T.P. +0.54 m).

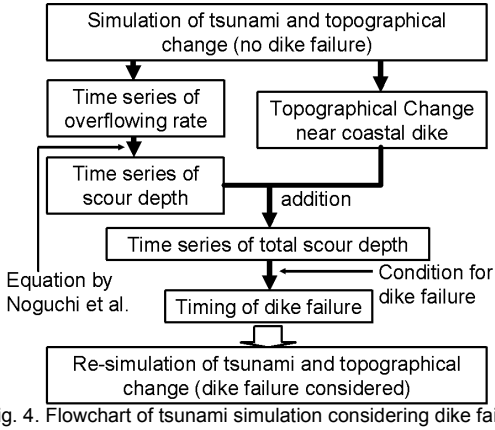

Fig. 4. Flowchart of tsunami simulation considering dike failure

Results of Calculations

Figure 5 shows the calculation results for water level and velocity in front of the coastal dike at Nino District for Case B3. The water level reached a peak (6.53 m) about 30 minutes after the earthquake, and fluctuated after the peak. Overflowing

occurred only near the peak water level, resulting in strong landward flow. The results indicate that only the first wave overtopped in Nino District. As for Case B4, the dike failed 33 minutes after the earthquake. The dike failure lowered the maximum water level by increasing the overflowing rate as shown in Figure 6, and increased the velocity after the second wave. On the other hand, overflowing did not occur in Nii District because dike subsidence was very small.

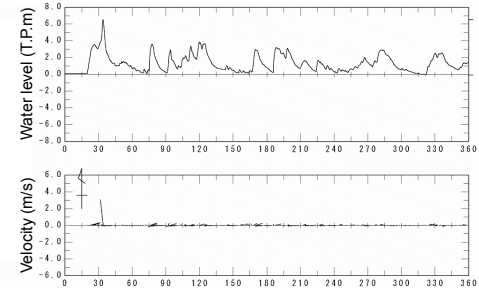

Fig. 5. Water level and velocity in front of coastal dike at Nino District (Case B3)

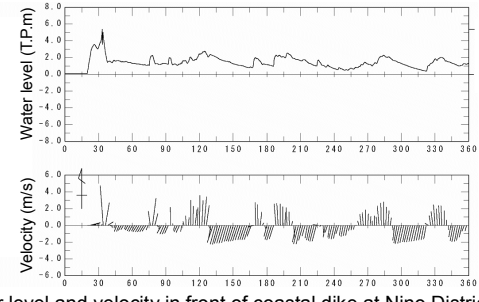

Fig. 6. Water level and velocity in front of coastal dike at Nino District (Case B4)

Figure 7 shows the maximum water level in each case. In Case A1, the maximum water level reached 7 -8 m in Nino and Nii, about 6 m seaward of the river-mouth bar, and less than 5 m in the Niyodo River because of the river-mouth bar. In Case A2 when dike subsidence was taken into account, the maximum water level in front of the coastal dike at Nino was about 1 m lower than that in Case A1. In Case B3 when topographical change and dike subsidence were considered, the maximum water level lowered by about 1 m on the river-mouth bar, but rose slightly in the river. In Case B4 in which even dike failure was assumed, the water level rose on the land in Nino, and inundation area expanded slightly.

Figure 8 shows the maximum water depth in each case. In Case A1, the maximum water depth was more than 6 m in front of the coastal dike in Nii and Nino, and more than 4 m on the river-mouth bar. In Case A2 in which dike subsidence was taken

into account, the maximum water depth exceeded 2 m in low areas of the hinterland. In Case B3 in which topographical change was also considered, the water depth was larger on the river-mouth bar than that in Case A2. In Case B4 in which dike failure was also considered, the maximum water depth on the land increased more.

Figure 9 shows the maximum velocity in each case. In Case A1, the velocity exceeded 5 m/s at the upstream side of the river-mouth bar during tsunami runup, and at the cutoff of the river-mouth bar during tsunami drawdown. In Case A2, the velocity on the land reached a peak of more than 5 m/s during tsunami runup. As shown in Cases B3 and B4, consideration of topographical change and dike failure increased the velocity on the land.

Figure 10 shows the extent of topographical change in Cases B3 and B4. A tendency to erode near the coastal dike and to accumulate in low areas of the hinterland was shown. Tsunami runup moved the river-mouth bar upstream, and tsunami drawdown caused accumulation off the cutoff of the river-mouth bar and off the point of dike failure. At the tip of the river-mouth bar, the ground level lowered by 2 m or more.

DAMAGE ESTIMATION

Estimation Method

Major damage functions for houses and human were selected from past tsunami damage estimations conducted by prefectures and the Central Disaster Prevention Council of Japan. House damage was estimated using Kanagawa Prefecture's damage functions (wooden houses, heavily destroyed: water depth > 4 m, partially destroyed: water depth > 2 m) and those of the Special Investigation Committee on the Tonankai and Nankai Earthquakes in the Central Disaster Prevention Council (as well as many prefectures) as shown in Table 2. Human damage was estimated using house damage or the maximum water depth with three functions shown in Table 3. In the method used by Kanagawa Prefectures, etc., the death toll and the number of injured people was estimated based on damages caused by the Tonankai Earthquake (1944) and Nihonkai-Chubu Earthquake (1983), respectively. Casualty estimation in the method used by Shizuoka Prefecture, etc., and the death rate in the method used by the Central Disaster Prevention Council were based on damage caused by the Hokkaido-Nanseioki Earthquake (1993). In the Central Disaster Prevention Council's method, four cases were set considering the difference between general and "tsunami" earthquakes in human behavior, and public awareness of evacuation. "Tsunami" earthquakes correspond to earthquakes which generate rather large tsunamis for small earthquake motions. The ratio of persons who did not complete evacuation varied with tsunami arrival time, which was set at a value for 33 minutes after the earthquake (average time of dike failure in the simulation).

Table 2. Criteria for evaluating house damage

Damage	Water depth	
	Wooden houses	Non-wooden houses
Heavily damaged	$H \geq 2.0$ m	-
Partially damaged	$1.0 \text{ m} \leq H < 2.0$ m	-
Slightly damaged	$0.5 \text{ m} \leq H < 1.0$ m	$H \geq 2.0$ m
Inundation below floor level	$H < 0.5$ m	$H < 0.5$ m

Table 3. Criteria for evaluating human damage

Method	Death toll	Number of people injured
Kanagawa Prefecture, etc.	$0.072(N_t+0.5N_c)^{1.018}$ N_t: Number of houses heavily damaged N_c: Number of houses partially damaged	Heavily injured: $0.00001074(N_t+0.5N_c)^{1.961}$ Slightly injured: $0.00004510(N_t+0.5N_c)^{1.961}$
Shizuoka Prefecture, etc.	$0.0424\exp(0.1763r_h)$ X (Population) r_h: $(N_t+0.5N_c)$/(Number of houses)	Heavily injured: $0.0340r_h$ X (Population) Slightly injured: $0.0822r_h$ X (Population)
Central Disaster Prevention Council (CDPC)	People evacuate: (Population affected) X (Ratio of persons who do not complete evacuation) X r_d People not evacuate: (Population affected) X r_d r_d =0.0282exp(0.2328 X (Water depth))	

Results of Estimation

Figure 11 shows the estimated number of damaged houses. The maximum water depth was less than 4 m for all cases, so that the number of houses partially damaged estimated using Kanagawa Prefecture's method was equal to the number of houses heavily damaged using the Central Disaster Prevention Council's method. In the results obtained with the Central Disaster Prevention Council's method, the number of houses heavily or partially damaged was 39 for Case A2 (dike subsidence considered) and 148 for Case B4 (dike subsidence, topographical change and dike failure considered), while only one house was inundated in Case A1. Dike subsidence and dike failure increased the water depth and flooded area on land, which greatly influenced the extent of house damage.

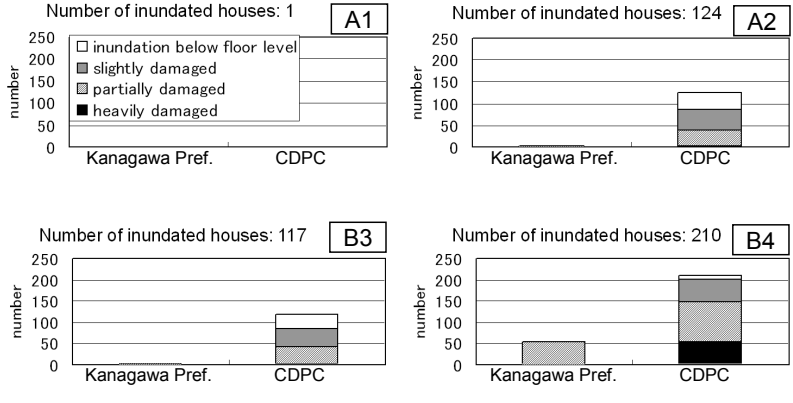

Fig. 11. Estimated house damage

Figure 12 shows the human damage estimated using the methods shown in Table 3. In the results obtained with Kanagawa Prefecture's method, the death toll was almost 0. In the results obtained using Shizuoka Prefecture's method, casualties increased with the number of houses damaged, reaching 90 for Case B4. In the results obtained using the Central Disaster Prevention Council's method, the death toll was very small when public awareness of evacuation was high, because the ratio of persons who evacuated was high and that of persons who did not complete evacuation was low. On the other hand, when public awareness of evacuation was low, the death toll for tsunami earthquakes was about two times that for general earthquakes, because the ratio of persons who did not complete evacuation was high. This indicates that improved public awareness of evacuation has a mitigating effect on the extent of human damage.

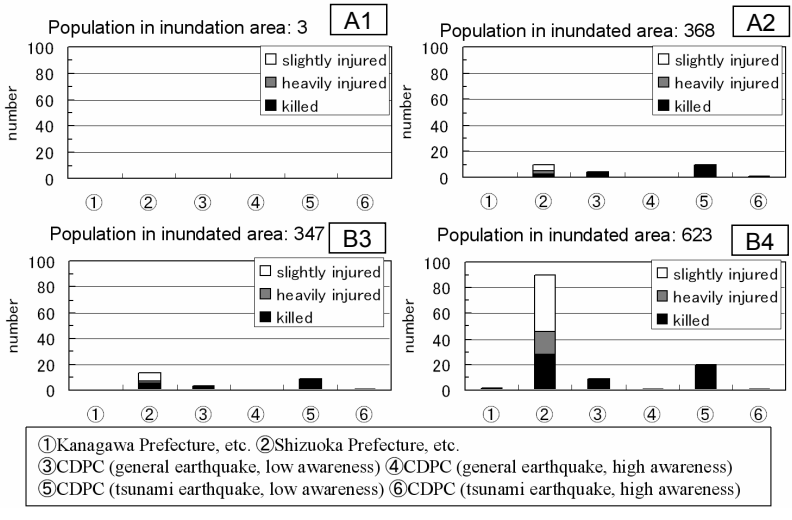

Fig. 12. Estimated human damage

CONCLUSIONS

As described above, the extent of damage to houses and humans on land was increased by dike subsidence and dike failure, and public awareness of evacuation had a significant influence on human damage. The methods used in this study quantitatively evaluated the mitigation of tsunami damage to humans and houses achieved by making coastal dikes earthquake- and tsunami-resistant, and raising the level of evacuation awareness.

ACKNOWLEDGEMENTS

We thank Kochi Office, Shikoku Regional Bureau, Ministry of Land, Infrastructure and Transport, for survey on earthquake-resistance of coastal dikes.

Abstract: A study of morphological response and development of beaches which were affected by the earthquake and the tsunami on 26th December 2004 has been conducted at two selected coastal sections of Banda Aceh, Indonesia. A simplified principle adopted from one-line shoreline theory in a geospatial analysis utilizing identified shoreline features across the foreshore zone is applied. The analysis yields a rough estimation of the shoreline and sediment volume changes since the tsunami. After the severe impact as revealed by a significant chaotic shoreline retreat, the morphological development in the following 6 months has shown that about 15% of the total sediment loss due to the tsunami on the northwest coast has further been eroded, while 60% of that on the west coast has been compensated by accretion. This leads to a conclusion that different coastal characteristics show different responses to, and developments after the tsunami.

INTRODUCTION

On 26th December 2004 at 7:58 hr. local time (i.e. North Sumatra Time = GMT + 7 hours), South-East Asia was hit by an earthquake with a magnitude of at least 9.0 (Stein and Okal, 2005), which generated tsunami waves. Being only 150 km away from the epicentre, the earthquake and the resulting tsunami destroyed almost everything in the coastal region of Banda Aceh and lead to a dramatic change of the coastal morphology.

Another big earthquake (8.7) subsequently occurred on 28th March 2005 at 23:09 hr local time (Anonymous, 2006) which epicenter was near Simeulue Island, ca. 300 km south of Banda Aceh. The earthquake caused severe land subsidence in the area around Banda Aceh, i.e. about 2 m at the west coast and about 0.3 – 0.6 m at the northwest coast (e.g. Gibbons and Gelfenbaum 2005). The tsunami caused extensive inland inundation, severe coastal erosion and large tsunami deposits inland (Jaffe et al. 2006).

The objective of the present study is to quantify the coastal morphological changes in response to the earthquake and the following tsunami waves and to determine how the morphology has developed since then. The importance of the present study is twofold: one, to quantify the magnitude of the changes and development in time; and two, to understand how the coast responses to this impact. In the present study, these phenomena are presented through an alongshore shoreline variability analysis and a volume change of the beach profiles over a relatively short term period (< 1 year).

This paper starts with a general description of the coastal zone of Banda Aceh followed by a more detailed assessment of the two selected areas. A qualitative description of the morphological changes due to the tsunami and the development since then is also included. Subsequently, the methods applied and their relevance to the objectives of the study is discussed. This is followed by descriptions of data analysis, shoreline features identification and the net volume change concept. The results of the applied methods are subsequently discussed and the paper ends with some general conclusions derived from the study.

STUDY AREA

To understand in more detail of the morphological changes in response to such a huge scale of disaster, we observe two small spatial scale coastal sections (~ 1 to 4 km) on the study area. Each coastal section has a different morphological characteristic. Here, we have to choose the part of the coast which has the best data quality. Our choice falls on the Ulee Lheue (reads: *Oo le le*) beach which is located on the northwest coast and Lampuuk beach (reads: *Lampoo ook*) which is located on the west coast of Banda Aceh. The lengths of the coastal sections are ca. 1 and 4 km, respectively. A map showing the overall study areas is presented in Fig. 1.

Ulee Lheue Beach, Northwest coast

Before the tsunami, almost the entire Ulee Lheue beach was protected by seawalls (Fig. 1b). They were constructed to protect the backshore from flooding during spring tides

and from severe wave attack. Moreover, the northwest coast had also subjected to significant erosion in the past few years before the tsunami. A short stretch of the beach remained open for recreational purposes near the Ferry port. The average elevation of the backshore was about 1.5 to 2.0 m above lowest low water level. This narrow coast separated a coast-parallel lagoon system from the sea.

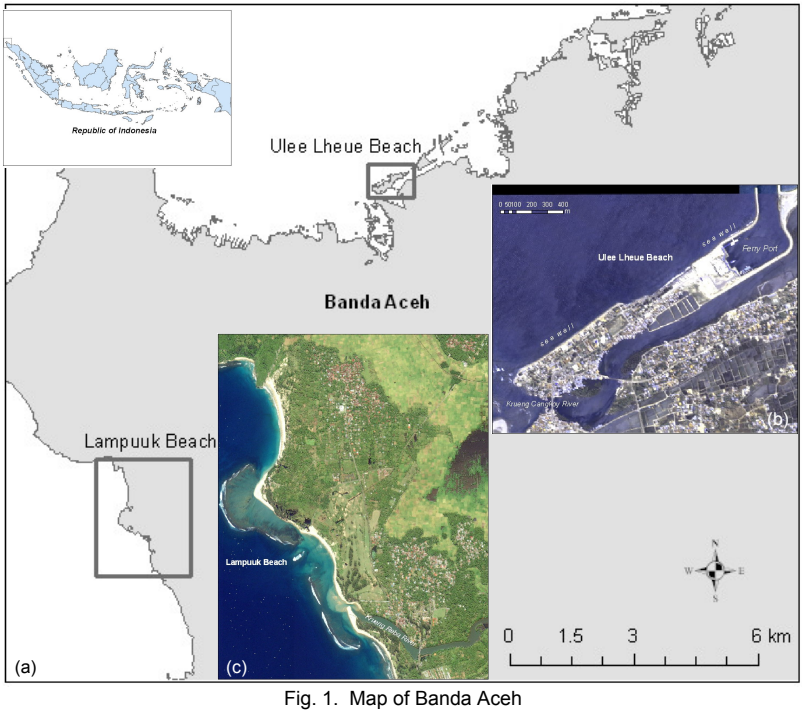

Fig. 1. Map of Banda Aceh

Since the tsunami, this low-lying northwest coast suffers from permanent inundation due to the breaching of its narrow sandy beach. It connected the lagoon and wetland area behind the beach with the sea. The breached beach was transformed into small barrier islands (Fig. 1a). The length of these barrier island formations ranges between 0.2 and 1.7 km. Recently, the active long shore transport seems to be inter-connecting the islands by the formation of the sand spits.

Based on a coastal survey on the northwest coast of Banda Aceh conducted in 2003 (Meilianda, et al. 2006), the wave climate was pre-dominantly coming from northwest (54%) during the northwest monsoon (June – October) and from northeast (40%) during the southeast monsoon (January - May). The significant wave height was 1.00 m with a peak period of 2.4 seconds. The tidal range of the coastal area of Banda Aceh is around 1.73 m high. The sediment transport was pre-dominantly in the west-to-east direction.

Lampuuk Beach, West coast

The west coast is a type of white sandy coast. The coastal plain is generally a higher ground above the mean sea level with beach slope between 1:30 and 1:100. It is bounded with coast-parallel ridges and some small promontories. The west coast has a persistent long shore sediment transport from south to north direction. The significant wave height is about 2.5 m with a period of 5 seconds. We assume the tidal range in this area to be similar to that at the northwest coast of Banda Aceh.

The impact of the earthquake and the tsunami is revealed by the trim line of the stripped-off vegetation along the feet of hills and headlands/promontories caused by tsunami waves attack. The shore-parallel dune system along the northern part of the west coast was also cut-back, some were flattened, and inlet mouths were eroded (widened). Recently, significant accretion is taking place along the west coast. This evident from the development of the dunes or elevated beaches which at some places overtopped the coastal roads. Closure of the inlet mouths occurs along the west coast. This effect is caused by the accreting beach development in front of them.

Lampuuk beach is located between a small headland on the north and Krueng Reba River mouth on the south of the west coast (Fig. 1c). An off-shore coral reef system exists in the middle of this 3.3 km coastal stretch. Sand bars were also found along the pre-tsunami's west coast. In our study, we extend the coverage length to another half kilometers to the south of the river mouth in order to observe the development in the vicinity of the inlet.

METHODS

An overall indicator for coastal problems is often concentrated to shoreline positions and trends, being used either by the scientists, coastal engineers or coastal managers. In many geospatial studies, it is common to represent coastal morphological development by rate of changes of comparative single or multiple shoreline positions (White and El Asmar, 1999; Solomon, 2005; Trebossen et al. 2005). These approaches may give an impression of changes in terms of horizontal position changes due to erosion-accretion processes. Alternatively, a quasi-three dimensional approach can be applied, for instance by comparing before and after coastal profiles using cut/fill methods (Zhang, et al., 2005) or a volumetric method (Morton et al., 1995).

Tides fluctuate on the foreshore between Mean Low Water Level (MLWL) and Mean High Water Level (MHWL). In the present study, we focus our observation on the foreshore zone. In this zone, the position of the waterline fluctuates continuously. We call the indicator of these different water level positions as 'shoreline features'. The measure to detect coastal morphological changes due to an extraordinary impact like a tsunami and the development since then is the net of erosion or accretion between the initial and later state of the morphology after the tsunami.

Data Analysis

Monitoring a morphological development in the geospatial studies requires information of the horizontal and vertical positions of a coastal feature (e.g. shorelines, coastal roads,

etc.) relative to the coordinate system to be used. From this information we can quantify, for instance, the distance and elevation of a feature. The data sources representing this information are, however, scarce in the present study. This is particularly the case for elevation data, such as topographic and bathymetric contours. Consequently, there is a gap of information needed for studying the morphological development in this particular area. To fill in this gap, we use any information contained in the available data sources, which in this case consists of four types: i) ortho-rectified aerial imagery; ii) satellite imagery; iii) tidal chart; and iv) coastal topographic contour. The details of the data sets are given in Table 1. All data uses Lowest Low Water Level (LLWL) as the datum (± 0.00 m).

Table 1. Image Acquisition and the Corresponding Tidal Elevation

Image data	Notation	Date	Local time	Tidal elevation*	Tidal stage
IKONOS sat. imagery	T_0 (west)	13 Jan 2003	11:12:39	0.7	MLWL
IKONOS sat. imagery	T_0 (northwest)	23 Jun 2004	10:54:29	0.5	MLWL
IKONOS sat. imagery	T_1	29 Dec 2004	10:55:41	1.2	1 hour to MHWL
Aerial Photograph	T_2	06 Jun 2005	ca. 08:30:00	1.5	MHWL
Coastal topographic	T_2	06 Jun 2005	ca. 08:30:00	1.5	MHWL

* Tidal chart source is from Hydro-Oceanographic Service of Indonesian Navy.

An ortho-rectified aerial imagery of Banda Aceh was obtained from an airborne survey conducted by the Norwegian Agency for Development Cooperation (NORAD) on behalf of the Survey and Mapping Agency of Indonesia (Bakosurtanal). The data has already been through a high standard image rectification process. This imagery is used as our base-map to register and to geo-reference other imageries and topographic data.

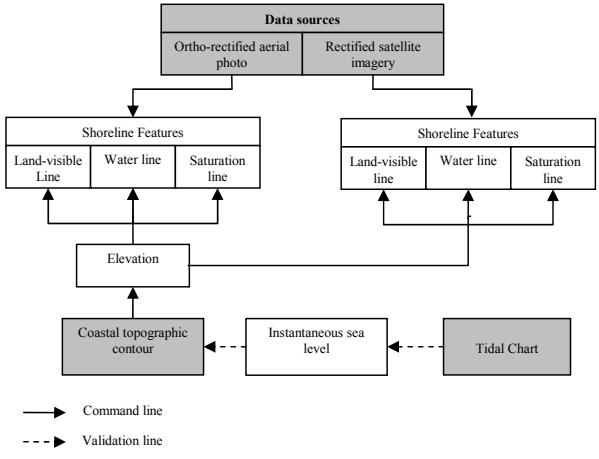
The topographic contour of Banda Aceh city was derived from this imagery and verified with ground control point surveys conducted by Japan International Corporation Agency (JICA). The contour line interval is 0.5 m which enables the careful study of the new developments along the coast.

High resolution IKONOS satellite images were provided by the International Institute for Geo-information Science and Earth Observations (ITC) in Enschede, The Netherlands. The multi-spectral IKONOS satellite imagery consists of 3 bands; i.e. red, green and blue. The images have been resampled to 2.5 m spatial resolution. These high resolution satellite images were enhanced to improve the appearance of the discernible features. Here, a minimum-maximum type of stretching for the three image bands was used. As the result, the water- and saturation lines were becoming more discernible.

Shoreline Feature Identification

To get an idea of which elevation each shoreline indicators represents, the first attempt is to overlay the image (with the identified shoreline features) with the coastal contour map.

The next step is to determine the instantaneous tidal stage of the image using a tide chart.



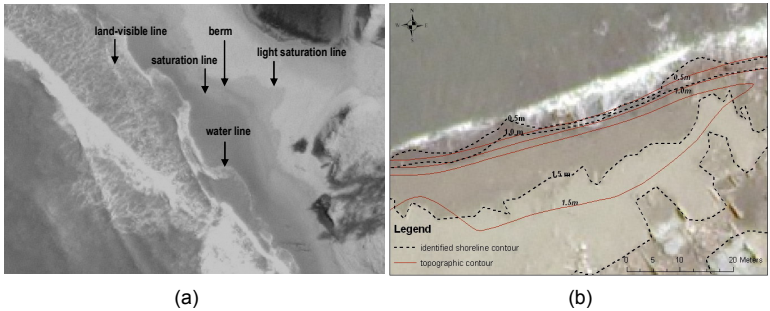


Fig. 2. Scheme of data source usage for shoreline feature identification and its validation

Boak and Turner (2005) stated that a shoreline feature is used as a proxy to represent the 'true' shoreline position. The proxies consist of three types: a feature that is visibly discernible in coastal imagery, the intersection of a tidal datum with the coastal profile, or a shoreline feature that is not necessarily visible to the human eyes but is based on the application of image-processing techniques. The choice for either one of these techniques in a shoreline analysis study very much depends on the data source and the chosen shoreline definition. Shoreline features in the present study are determined visually using the available data. Figure 2 shows the process of shoreline features identification in this study.

(a) (b)

Fig. 3. (a) Shoreline features. (b) Identified shoreline features based on the contour map and discernible features, validated by the tidal chart.

Figure 3 shows that to extract shoreline features from different kinds of image sources one has to treat each of them uniquely, either because of the image characteristics and

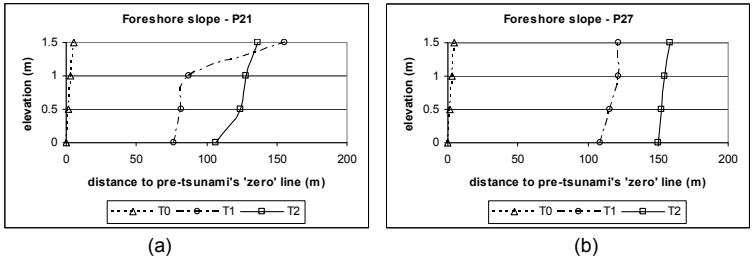
acquisition, or because of the tidal stage at the moment.

Here, the aerial photograph was used as the basis to identify the shoreline features. The high quality of the image (which was resampled to 0.3 m spatial resolution) enables the identification of the instantaneous shoreline dynamics. There are at least four different shoreline indicator features, which are as following (see also Fig. 2 and 3a):

- *Light saturation line*; the border line of maximum run up of the area which has smaller groundwater content and is not affected by the run-ups.
- *Saturation line*; the border of the area which is saturated by the groundwater (a similar feature was termed 'groundwater exit point' by Boak and Turner, 2005). The tone of sand color of this area is dark grey or dark brown, depending on the type of beach material.
- *Water line*; the border line of the instantaneous water body, which appears in green or blue color tone.
- *Land-visible line*; the border line of the water body where the submerged land just below the water is still visible.

By overlaying the contour map on top of the image, one can observe which contour elevations from the coastal contour map coincides with the interpreted shoreline features in the foreshore zone of the image. These were subsequently validated using the corresponding tidal stage. The tidal chart indicated for the time of image acquisition (see Table 1) was at MHWL which elevation was charted at +1.5 m from the datum.

The contours of the topographic map are generated from interpolation of several ground control points across the coastal area. We identify the elevation of the shoreline features by the proximity to the contour patterns. The line of these features shows that the alongshore variability which may, for example, be due to the formation of beach cusps. The contour of +1.5 m falls into the area of groundwater saturation which appears as a dark color of sandy beach. This feature is clearly discernible, especially along the accreting beach with a gentle slope. The saturation with groundwater is probably the result of a high intensity of water fluctuations due to wave run-ups. Therefore, we take the +1.5 m contour as representative for mean high water level (MHWL). This is confirmed by the tidal chart which showed that it was high tide (MHWL) with a water level of +1.5 m at the photograph's acquisition time.



Based on the contour map, the (instantaneous) water line is approximately following the contour elevation of +1.0 m. To identify this particular line is quite tricky because of either it is the 'true' instantaneous waterline (still water level) or the waterline in motion (e.g. run-ups and breaking waves). The color tone of this area (i.e. green or blue color tone for the 'true' waterline) in this case becomes an important control in order to avoid the confusion.

It turns out that due to the high tide the position of the +0.5 m contour falls into the watered area, although the color tone of land is still visible just below the water (mixture color of green-blue and brown). We observed that this feature is continuously connected

alongshore, sometimes in combination with the on-shore wave breaks. The light saturation line is not taken into account because this feature belongs to the instantaneous wave run-ups.

At this stage, from the four shoreline features, there are only three features left which we were able to validate using the other data sources (tide charts and contour map). These are: i) the saturation line (i.e. elevation +1.5 m); ii) the water line (i.e. elevation +1.0 m); and iii) the land-visible line (i.e elevation +0.5 m). These validated features is subsequently used as the reference to identify the shoreline features for the other images in order to complement the contour line information which is not available for the whole area studied.

The minimum boundary was set to the elevation ± 0.00 m. Since we study the foreshore zone, we assume that the elevation ± 0.00 m can be obtained by extending the slope of the foreshore, that is from the identified shoreline features (elevation of +0.5, +1.0 and +1.5 m). From here, the shoreline position as well as the steepness of the foreshore slope change in time can be observed.

(a) (b)

Fig. 4. Examples of foreshore slope of early and 6 months after the tsunami at Ulee Lheue Beach. (a) Profile P21 (b) Profile P27. (See also Fig. 6a)

Figure 4 shows the foreshore slope change which also correlated to shoreline positions of two examples of the beach profiles. Here, we used the elevation zero line of the pre-tsunami as our reference. Shoreline positions of the pre-, early after- and 6-months after tsunami with respect to the pre-tsunami's elevation zero are denoted by T_0, T_1 and T_2, respectively (see also the data acquisitions correspond to the notations in Table 1 on page 5).

Concept of Net Volume Change

The shoreline feature identification has revealed the visual observation of the impact and the development since the tsunami. The subsequent attempt is to measure the magnitude of those changes. We adopt the principle of the one-line shoreline theory. The principle assumes that the coastal profile advances or retreats in response to shoreline accretion/erosion, while conserving its shape (Fig. 5). This means that the active part of the coastal profile identified by the height (H) is kept constant and the horizontal variable ΔY detects the changes of shoreline position. The magnitude (volume) of sediment loss ($Q_1<Q_2$) or gain ($Q_1>Q_2$) is subsequently obtained by multiplying the trapezoidal profile

with the distance (ΔX) between two profiles alongshore.

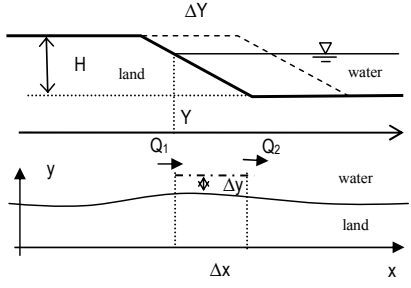


Fig. 5. Principle of one-line shoreline model.

We calculate the volume changes for two pairs of foreshore profiles by using the cut/fill operation in the spatial analyst tool in the Arc View software, which are: (1) the difference in sediment volume between the situation early after the tsunami and the pre-tsunami situation (T_1-T_0); (2) the difference in sediment volume between the situation 6 months after the tsunami and the pre-tsunami situation (T_2-T_0). Subsequently, we subtract volume (2) with volume (1) resulting in a loss or gain of sediment volume in the months after the tsunami.

ANALYSIS ON MORPHOLOGICAL RESPONSE AND DEVELOPMENT OF THE BEACH AFTER THE TSUNAMI

In this chapter we discuss the results from the applied methods to analyze the beach morphological changes and development in response to the earthquake and tsunami. The nature of the study gives a rise to some uncertainties. Uncertainties arise particularly from the fact that a simplified concept is used (i.e. one-line shoreline theory), and from a limitation of the presently available data, which is only valid for the foreshore zone.

Ulee Lheue Beach, Northwest coast

The morphological development of Ulee Lheue beach shows the erosion along with the re-distribution of sediment alongshore. The shoreline was retreating on average as far as 73 m from the pre-tsunami's shoreline. During the following 6 months the shoreline continued to retreat, resulting in an average distance from the pre-tsunami's shoreline of as large as 84 m.

We observe that a considerable portion of the beach sediment was eroded due to the tsunami. It may be brought outside the system, dumped over the coastal area during the tsunami, or transported off-shore within the active coastal zone. Profiles P1 to P6 in Fig. 6c show a small amount of volume change (erosion) between the pre-tsunami and both post-tsunami periods. This may be because the profiles are located in a semi-protected area in Krueng Cangkoy River mouth (see Fig. 1b). Profiles P14 and P19 reveal significant erosion in the development period after the tsunami (Fig. 6b), while in between the two profiles, the sediment seems to be re-distributed alongshore, as revealed

by the accretion on the profiles P11, P13, P17 and P18. Another interesting phenomenon is that the breached lands started to re-connected by sand accumulation between profiles P24 and P27. A graphic in Fig. 6c depicts these phenomena by the trend of alongshore erosion and re-distribution of sediments since the tsunami (comparison of the chaotic line due to the tsunami and the smoothed line of the development since then; see also Fig. 6b).

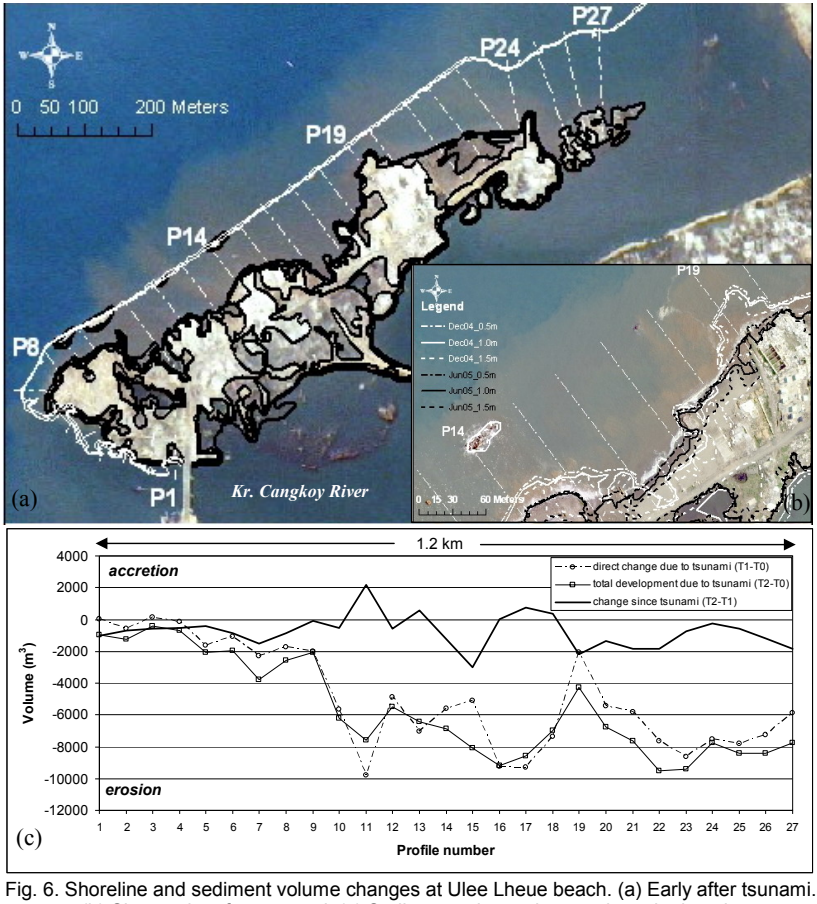

Fig. 6. Shoreline and sediment volume changes at Ulee Lheue beach. (a) Early after tsunami. (b) Six months after tsunami. (c) Sediment volume change along the beach.

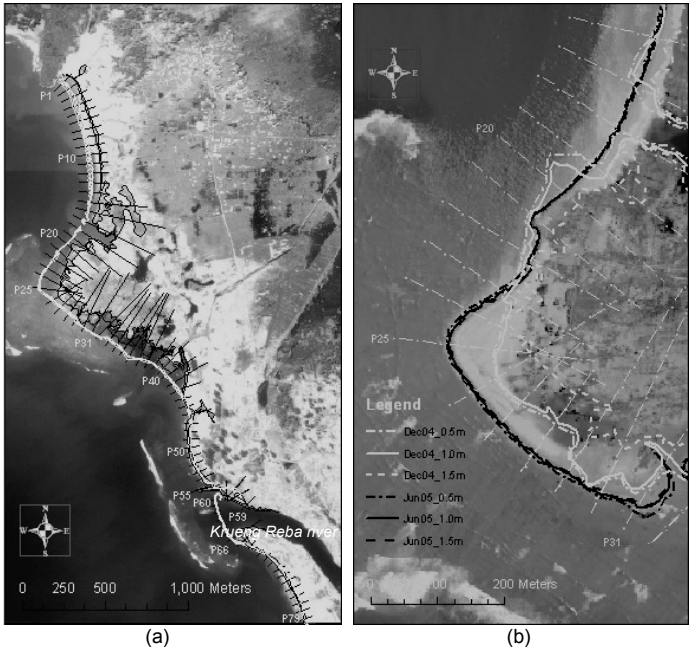

The longshore transport seems to be pre-dominant on this particular coast which was indicated by the sediment re-distribution alongshore. There is no clear tendency of which direction the distribution is pre-dominant. Perhaps it is due to the fact that there are two opposite directions of the prevailing seasonal wave directions corresponding to the

monsoonal climate which influence the coast, as mentioned earlier in this paper.

The total amount of sediment loss in the initial response to the tsunami (T_1-T_0) and after six months (T_2-T_0) is 1.31x10^5 m^3 and 1.5x10^5 m^3, respectively. This implies that the development of the coastal section within 6 months after the tsunami was a further erosion, equals to 15% (1.9x10^4 m^3) of the sediment loss due to the tsunami.

Lampuuk Beach, West Coast

The morphological response of the west coast represented by Lampuuk beach reveals a similar effect of the chaotic shorelines (the black lines in Fig. 7a). Impact to the inlets is more obvious on this coastal section.

(a) (b)

Fig. 7.Shoreline changes at Lampuuk beach. (a) Early after tsunami. (b) Six months after tsunami.

The shoreline was retreating as far as 77 m early after the tsunami. In the following six months the shoreline was advancing on average 40 m with respect to the pre-tsunami's shoreline. Furthermore, Fig. 7 shows a significant difference of the morphological changes and development between profile P1-P44 and P45-P79. Figure 8 shows the trend of accretion during the 6 months of development after the tsunami (see also Fig. 7). This phenomenon is considerably different from what has occurred on the northwest coastal section (Ulee Lheue Beach).

Coastal section P1-P44 was heavily eroded due to the tsunami, while the adjacent part, i.e. P45-P79 was less eroded. We understood that coastal section P1-P44 was a non-protected sandy beach with a gentle slope, while the adjacent coastal section on the south was a beach with dune formation of ca. 10 m high above the ground, coastal protections such as beach revetment and training jetties were constructed in the vicinity of Krueng Reba river mouth (P51-P60). As the matter of fact, during our field visit in May 2005, we observed that the sea conifer trees behind the section P51 to P55 survived from the tsunami, and the beach revetment in front of them was still intact.

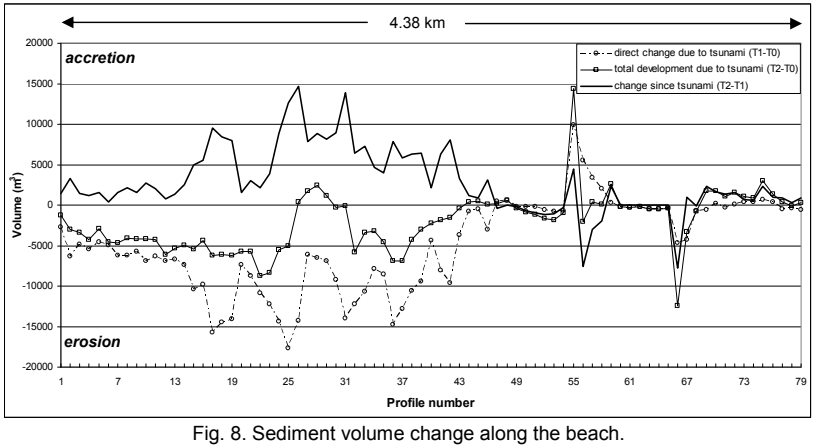

Fig. 8. Sediment volume change along the beach.

These different coastal settings may be the reason of different responses to the tsunami observed between coastal sections P1-P44 and P45-P79. Development of the morphology in the following 6 months shows the beach was accreting.

The small inlets at the profile P17 and P 18 used to be an inland depression behind the sandy beach in the pre-tsunami time. Due to the tsunami, the beach strip in front of this coastal feature was breached to form a small inlet. The beach on the vicinity was also flattened, as revealed by the elevation of the contour line in Fig. (7b). Morphological development during the following 6 months shows a tendency of considerable accretion, as can be seen from the positions of the contour lines (see the comparative white and black contour lines in Fig. 7b). Another interesting phenomenon is also observed on the beach promontory between profiles P20 and P40. The tip of the promontory was oriented northward during the development period.

Local discrepancy of the volume change appears in the graphic in Fig. 8 between profiles P55 to P66. This can be explained by the fact that at profile P55 there was training jetty which had not yet been constructed in our pre-tsunami's data (13 January 2003). Meanwhile, the profile P60 to P65 belong to the pre-tsunami's sand spit in front of Krueng Reba River mouth. Profile P66 shows the shifting of sand spit during the

morphological development after the tsunami.

The pre-tsunami's Krueng Reba river mouth was narrow with seasonal openings. Due to the tsunami, the instable part of the sand spit (profile P60 to P66) was breached and the river mouth was widening. Evidence of accretion that was taking place along the beach can also be observed on the Krueng Reba river mouth. The shift formation at the southern sand spit in recent development was oriented towards the river course. It suggests that besides the pre-dominant long shore sediment transport (south-north direction), the cross shore transport may also contribute to the beach/dune development; perhaps during the extreme wave condition where the spit was pushed inland and no significant discharge flowing in the river course. Furthermore, as mentioned in the earlier chapter, the dune formation was beginning to form again along the beach.

The overall impression of the development of the beach morphology after the tsunami not only occurred in the longshore direction but also in the cross shore direction. This process leads towards new beach equilibrium. The total amount of sediment loss in the initial response of the tsunami and in its development is 3.8×10^5 m^3 and 1.6×10^5 m^3, respectively. The volume of net change reveals that 2.2×10^5 m^3 or about 60% of sediment budget has been gained back into the beach stretch within 6 months.

CONCLUSION

We quantified the morphological response and development of beaches that were affected by the earthquake and the tsunami on 26th December 2004. It covers a small spatial scale (~ 1 to 4 km) of two different beach settings on the northwest and west coast of Banda Aceh city. Quantification of time-dependent shoreline features within the foreshore zone using a simplified principle adopted from one-line shoreline theory is applied. Three data sets of consecutive dates before, early after and several months after the event were used. After the severe impact as revealed by a significant chaotic shoreline retreat, the morphological development within the following 6 months has shown further erosion (about 15% of the sediment loss due to the tsunami) on the northwest coast. Meanwhile, 60% of the sediment loss on the west coast due to the tsunami has been compensated by accretion in the months after the tsunami. This leads to a conclusion that different coastal characteristics show different responses to and different developments after the tsunami. The nature of the study gives rise to some uncertainties. Uncertainties arise particularly from the fact that a simplified concept is used (i.e. one-line shoreline theory), and from a limitation of the presently available data, which is only valid for the foreshore zone. This uncertainty has hampered our effort to incorporate land subsidence quantifications, which we are looking forward to in our future study.

ACKNOWLEDGEMENTS

We address our acknowledgement to Bakosurtanal for providing the ortho-rectified aerial imagery, the coastal topographic map, and other supporting information under NORAD grant, distributed by SIM-centre, BRR, Banda Aceh. We also address our thanks to the Water Resource department of ITC, the Netherlands, for providing facility on image

processing and the satellite imagery data, and for providing the supervision (by Dr. Ben H.P. Maathuis; who is also the co-author in this paper). This study is made possible by the fund of Asian Development Bank (ADB) through the TPSDP Project of the Higher Education Department of Republic of Indonesia, and the University of Twente, the Netherlands.

DUNE MORPHOLOGY AS AN INDICATOR OF PALEOTSUNAMIS

James R. Goff[1]

1. National Institute of Water & Atmospheric Research, PO Box 8602, Christchurch, NEW ZEALAND. j.goff@niwa.co.nz.

Abstract: Analysis of modern and past tsunamigenic features from within New Zealand and around the world have identified a suite of tsunami-related geomorphological features in dune systems including; Pedestals - remnant sections of dune ridge separated by scoured areas; Hummocky topography/Sand sheets - formed landward from pedestals (hummocky topography is the old, weathered equivalent of sand sheets); Parabolic dune fields - remobilised sand sheets landward of pedestals; Low Profile Sequences - post-tsunami feature indicative of changes to coastal sediment budget.

The type of features formed by a tsunami, and the ability to detect and interpret tsunami geomorphology by LIDAR (and also in the field) hinges on the interactions between five key criteria; the availability and type of sediment (e.g. sand/gravel); embayment type; a prograding or eroding coast; small or large accumulation space; and whether there is a wet or dry landward environment.

INTRODUCTION

New Zealand sits astride the boundary between the Pacific and Australian Plates (Figure 1). To the north in the Tonga-Kermadec-Hikurangi trench, the Pacific Plate is subducting from the east at a rate of 40 mm/yr. To the south in the Puysegur trench, the Australian Plate is being subducted from the west with a convergence rate of 35 mm/yr. In the centre of New Zealand, the plates are locked. This unique tectonic setting provides a wide range of potential tsunamigenic sources (Walters et al. 2006).

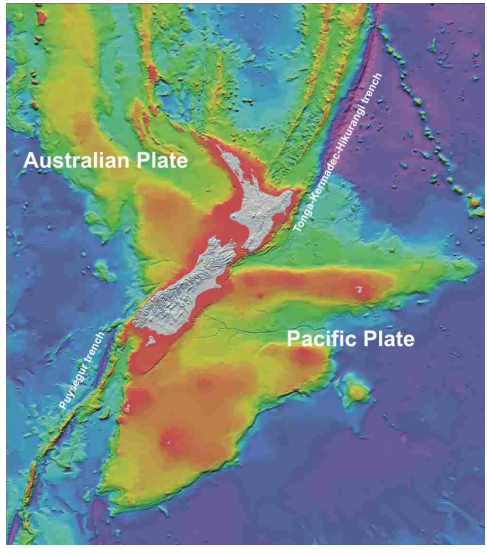

Fig. 1. New Zealand – showing key tectonic associations

An historical tsunami database for New Zealand records over 40 tsunamis (Berryman 2005). Additionally, a recently developed prehistoric tsunami database contains records from over 200 sites with details of more than 30 Holocene palaeotsunamis (Goff 2006). These geological signatures of tsunamis provide clues to a hazard that is poorly understood from historical records alone. Indeed, in northeast Japan, western North America, Norway, and Scotland, tsunami deposits serve as warnings of unusually large tsunamis (Nanayama et al. 2000; Atwater et al. 2005a; Bondevik et al. 2005). Tsunami deposits also afford estimates of tsunami recurrence (Pinegina et al. 2003; Cisternas et al. 2005; Kelsey et al. 2005), and can yield constraints on tsunami flow depth and velocity (Jaffe and Gelfenbaum 2002; Atwater et al. 2005b).

Researchers have also studied *tsunami-scour fans*. These form where a tsunami cuts a breach, or cleans out an existing one, through a beach ridge. Using material scoured from the breach, the tsunami builds a fan as it emerges from the breach. These combined features of erosion and deposition (scour and fan) were noted on opposite sides of the Pacific Ocean as by-products of the tsunami associated with the giant Chilean earthquake of May 22, 1960 (Kitamura et al. 1961; Bourgeois and Reinhart 1989; Atwater et al. 1999). Still other examples of tsunami scours have been reported from Kamchatka (MacInnes et al. 2005).

Similar features have been noted in New Zealand (Goff et al. in press). Unlike those reported by researchers in Chile, Japan, and the US, the New Zealand features are part of a geomorphological association purported to have been created by palaeotsunamis.

These include Hummocky Topography situated landward of coastal dune systems (Figure 2) and Pedestal features often associated with either hummocky topography or overwash deposits (Figure 3).

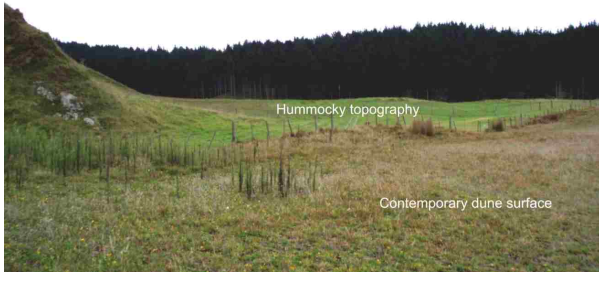

Fig. 2. Whangaruru North – hummocky topography inland of contemporary dune system (Photo: J. Goff).

Fig. 3. Great Barrier Island – resistant pedestal surrounded by palaeotsunami deposit (pebbles) – hummocky topography visible in distance (Photo: Scott Nichol, University of Auckland).

If such features can be identified centuries later by remote sensing, they can potentially be used to study the tsunami hazard on coastlines which have little or no historic record. With its high spatial density of data points (typically ~ 1-2 m) and accurate ground elevation fixes (typically to within a standard error of 0.15 m), LIDAR delivers topographic information that theoretically should be adequate to identify hummocky topography, pedestals, and scour-fan features if they have been preserved within the landscape.

FEATURES OF TSUNAMI GEOMORPHOLOGY

The 2004 Indian Ocean tsunami provided clear evidence that a large tsunami is required to leave a marked geomorphological signal in the landscape. The topographic extent of this signal is generally governed by antecedent sand supply (Figures 4 and 5).

Fig. 4. Sri Lanka: Top – large scale pedestals on sand-rich coast; Bottom – small scale foredune pedestals on sand-poor coast (arrows indicate pedestals). Smaller features are produced on coastlines with a reduced sand supply (Photos: J. Goff).

Fig. 5. Sri Lanka: Top – thick sand sheet landward of large scale pedestal formation shown in Figure 4 for sand-rich coast; Bottom – thin sand sheet landward of small scale foredune pedestals shown in Figure 4 for sand-poor coast (Photos: J. Goff).

The preservation of geomorphological features is affected by subsequent sand supply. Assuming similar post-tsunami conditions, in sand-rich areas there would be rapid rebuilding of coastal dunes and loss of pedestal topography, only the largest pedestals remain exposed. There are several variables, however:

1. Post-tsunami sand supply may be severely reduced if the tsunami entrains all available offshore sand (above and often considerably below storm wave base) and transports it inland. Subject to subaerial processes, this probably removes it from the coastal sediment transport cycle for some considerable time. Evidence of sand removed from the system would be preserved inland.

2. Post-tsunami sand supply may be severely reduced if the tsunami transports large quantities of sand from the shore and nearshore seaward beyond the normal storm wave base. This effectively removes it from the coastal sediment transport cycle. There would be no terrestrial evidence of the sand removed from the system.

3. Post-tsunami sand supply may increase markedly if the tsunami was generated by a large, local earthquake that led to large quantities of new sand being routed into the coastal zone from rivers (a delayed pulse can also occur in arid areas where years may pass between the earthquake and the next major rain event).

4. Other factors unrelated to tsunamis may affect sand supply conditions, such as extreme climatic events or anthropogenic land clearance.

Event magnitude and spatial extent are also important controls on tsunami generated morphology ("large" events are assumed to be in the region of 10m runup or greater). We believe that inundation by region-wide events would cause multiple breaching of dune systems as opposed, for example, to the isolated tsunami-scour fans. In other words, they would create multiple tsunami-scour fan assemblages during one inundation. The assemblages would include remnant dune ridges, or *pedestals*, between each breach, and the individual overwash fans would coalesce to form *sand sheets* that may or may not be mobile depending upon aeolian and dune swale conditions. This overall concept is not new. Minoura and Nakaya (1991) modelled the effects of tsunamis on a sandy barrier coastline and described the results in morphological terms.

Tsunamis in shallow water have the potential to carry large amounts of sediment. Tsunami overwash of dune ridges can reduce their height, create multiple breaches, transport eroded sediment into dune slacks (reworked aeolian dune sand and offshore sediments), and deposit a sand sheet across the landward topography – wet or dry. Dunes can also be remobilised by the passage of a tsunami (Bryant, 2001). If the sediment volume carried is large then, according to Bryant (2001) "a raised back barrier may form from coalescing overwash fans or small lagoons may be completely infilled. If these surfaces are not covered by seawater or quickly vegetated, they may be subject to wind deflation, with the [*landward*] formation of parabolic dunes (if the prevailing wind is onshore). Alternatively, sub-aerial processes may weather the sand in situ, developing a

hummocky topography. Bryant (2001) makes the point that storms tend to only surge through gaps in dunes, sporadically depositing lobate fans that rarely coalesce or penetrate far inland. This is a key difference generally, but there is room for confusion in areas of low accumulation space (e.g. in a small pocket beach, there may be insufficient accumulation space for more than one lobate fan and two pedestals).

Conceptual models

A series of conceptual models were developed to consider the major variables discussed above – namely sand supply and accumulation space. Examples are shown below (Figures 6-9).

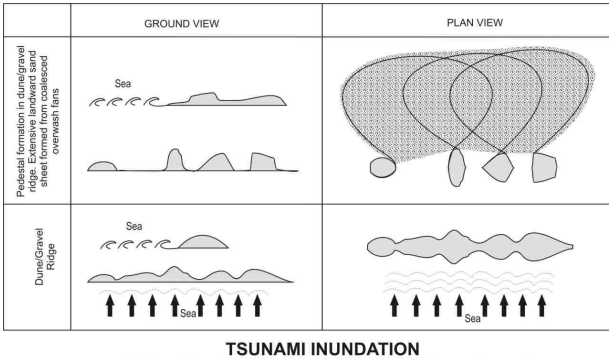

Fig. 6. Pedestal and overwash fan formation from tsunami inundation – light grey shading = in situ dune sand.

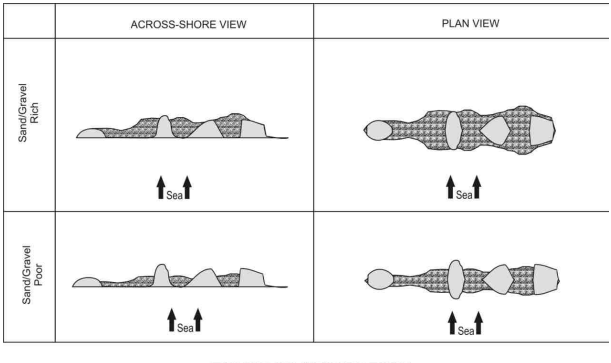

Fig. 7. Pedestal development over time in different sand supply conditions. Light grey shading = in situ dune sand, dark mottled shading = new sand supplied to the dune system following inundation.

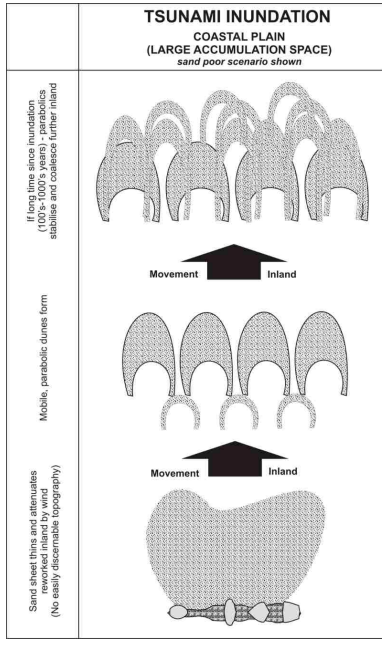

Fig. 8. Sand sheet–parabolic dune development (bottom to top of diagram) with large accumulation space AND dry ground conditions (in wet conditions the sand sheet is immobile and weathers). These are sand-poor conditions.

METHODS

For our analysis, LIDAR text files containing thinned ground strikes were read through a series of software packages to produce Triangulated Irregular Networks (TINs). Several edge detection techniques were then used to automatically identify possible features (refer to Goff et al, in press for full details of the methodology). Sites identified using these techniques were visited to geologically groundtruth the identified features.

STUDY AREA

We selected a series of sites along the coastline of the Otago region, New Zealand (Figure 1). A recent review of geological and archaeological information for the Otago coastline suggests that tsunami inundation has occurred since human occupation in the 13th century (Goff, 2006). If inundation did occur, it would seem likely that this was a rare event in the Holocene. The reasoning behind this assumption is that there are no obvious active local or regional earthquake sources thought to be significant enough to generate a large tsunami. Otago's coastal geomorphology may therefore prove useful for recognising tsunami inundation because only few (one?) large events have occurred

during the Holocene. If more that one large tsunami inundation has occurred, it is possible that they would have been infrequent enough to be recognisable as a separate suite of features.

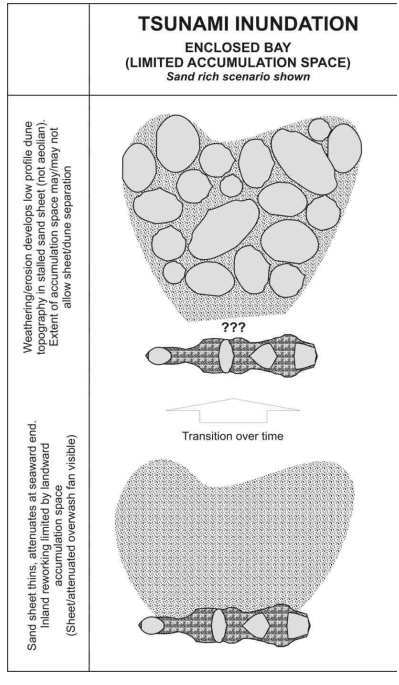

Fig. 9. Sand sheet–hummocky topography dune development with limited accumulation space AND wet/dry ground conditions. The upper section of the figure represents the formation of hummocky topography through time – the light grey shaded areas represent remnant small, low-profile dunes

RESULTS

We briefly discuss data from one site, Long Beach. Full details on this and other sites is available in Goff et al. (in press). The LIDAR image for Long Beach initially revealed a small embayment with two distinct sets of dunes. A fragmented landward set of higher elevation dunes, and an intact seaward group of lower elevation dunes, are separated by a wide, low-profile sequence of sand. The seaward dune system started to form around 1863 (Anderson, 1981). Our initial interpretation of the LIDAR image is shown in Figure 11. There is a section of well-defined hummocky topography landward of the higher elevation dunes. The fan of hummocky topography splays into a small wetland formed where a stream ponded behind the dunes. This pedestal-hummocky topography association is interpreted as tsunami geomorphology. Long Beach contains an important archaeological site that shows evidence of having been "washed by the sea" (Leach and

Hamel, 1981). During our groundtruthing survey (Figure 12), the evidence for "washing" by the sea was found to be a layer of pebbles and sand approximately 20 cm thick. In similar geomorphological associations elsewhere in the country, this type of sedimentary unit has been defined as a tsunami deposit (e.g. Nichol et al., 2004). Perhaps the important point to make here is that there is no other process capable of depositing such a sedimentary sequence - it is not diagnostic of a storm deposit (Goff et al., 2004).

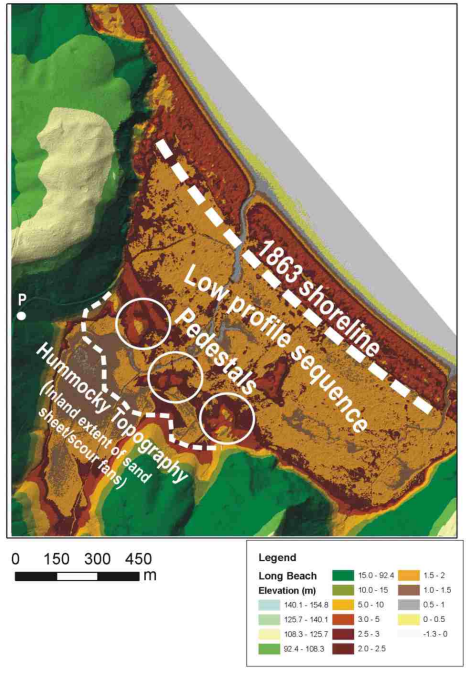

Fig. 11. Long Beach: Interpretation (P = Photo point for Figure 12)

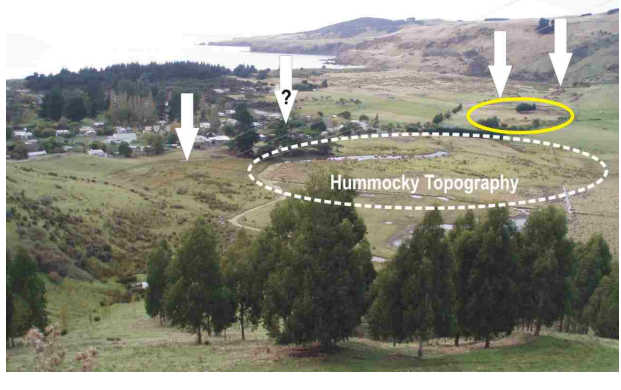

Fig. 12. Long Beach viewed from the NW. White arrows indicate remnant pedestals on the spit. The yellow ellipse is the archaeological site. The sand sheet/fan can be seen in the centre of the photo extending into the wetland (Photo: J. Goff).

DISCUSSION

Allowing that a coast has been subject to tsunami in the recent geological past, the ability to detect and interpret their geomorphic signature from LIDAR data, and also in the field, hinges on the interaction between five key criteria.

1. Availability and type of sediment (sand/gravel):
The spectrum of sediment availability ranges from sediment-rich to sediment-poor. In sediment-rich environments, tsunami geomorphology is more likely to be rapidly buried by incoming post-event material (10's of years). This is particularly pertinent for pedestals. In a sediment-poor system, geomorphology is more likely to be preserved for a much longer period (10^2-10^3 years).

2. Embayment type (n.b. – cliffed coasts were not a focus of this study):
Tsunami geomorphology in semi-enclosed embayments can be exposed to reworking by tidal and fluvial processes, whereas the latter are the main problem in small estuaries. Smaller pocket beach type embayments, such as Long Beach, which often have small streams and/or wetlands ponded behind coastal dunes, are more likely to preserve the features of tsunami geomorphology. This is because neither coastal nor fluvial processes are sufficiently energetic to rework tsunami-emplaced geomorphology.

3. Prograding/eroding coast:
An eroding coast is unlikely to preserve the complete geomorphological record of past tsunamis. Over time, the record will be lost. A prograding coast is more likely to preserve the geomorphology.

4. Small/large accumulation space:
A restricted landward accumulation space limits the development of tsunami geomorphology. On the other hand, there is less likelihood of post-tsunami remobilisation of the sand sheet (e.g. by wind, estuarine currents), thus hummocky topography is more likely to develop and be preserved (e.g. Long Beach). Differentiation of hummocky topography from conventional dune ridge formation will be complicated if multiple tsunami inundations add fresh sand volumes. Large accumulation spaces provide the potential for the development of tsunami geomorphology and the creation of remobilised sand dune phases as landward parabolic dune systems (e.g. Kapiti-Horowhenua coast – the conventional genesis of these dune systems is considered to be as a result of remobilisation caused by land clearance, although dune ages do not coincide – refer to Hawke and McConchie (2006) and Goff and McFadgen (2006) for opposing views). Where there is abundant space, sand sheets will most likely spread further and be thinner..

5. Wet/dry landward environment:
A wet landward environment (e.g. backshore swamp/pond) will stabilize inwashed sand . This is most likely to weather (in situ) over time to form low profile hummocky

topography. Since many dune systems are often associated with some form of ponded or blocked drainage system, low profile hummocky topography closely linked to a pedestal landscape would seem to be the most likely geomorphological association related to tsunami inundation. This is not always the case however, and dry landward environments could enable remobilisation of sand with the possible formation of a parabolic dune field or hummocky topography some distance landward of the original dune source.

CONCLUSIONS

LIDAR data analysis supplemented with brief ground surveys can identify the geomorphic signature of past large tsunamis. The type of geomorphological features and the chances of finding them depend largely upon the geomorphic setting. It is therefore important to know what to look for and where to look.

ACKNOWLEDGMENTS

This work was funded as part of NIWA's Capability Fund (Project CISA065) allocation from the Ministry of Research, Science & Technology. I am most grateful to Dr. Stephen Swabey of Otago Regional Council for permitting us to use coastal LIDAR imagery and their aerial photograph database for this project.

SEDIMENTOLOGICAL CHARACTERISTICS OF REGIONAL-SCALE WASHOVER DEPOSITS CAUSED BY HURRICANE IVAN

Mark H. Horwitz[1], Ping Wang[1]

1. Department of Geology, University of South Florida, 4202 E. Fowler Ave., Tampa, FL 33620, USA. mhorwitz@mail.usf.edu; pwang@cas.usf.edu

Abstract: Washover deposits induced by Hurricane Ivan are examined along a 260-km stretch of northern Florida coast. Initial response to the overwash event is dominated by dramatic nearshore, beach, and dune erosion. Eroded sediment is in-turn redistributed landward across the barrier-island profile. Distinct sedimentological characteristics of the washover deposits are recognized in different barrier-island sub-environments. Deposits on the beach are bound by a basal erosional surface, and exhibit planar seaward-dipping stratification. Over the barrier interior, preservation of fresh, in-place vegetation below the washover indicates that limited erosion occurred prior to washover deposition landward of the foredune. Washover deposits over the interior platform are characterized by horizontal to sub-horizontal stratification. Increased accommodation space landward within flooded interior wetlands and the back-bay yields substantially thicker washover deposits characterized by steeply inclined sigmoid and tabular foreset stratification. Back-bay deposition locally accounts for 120 m of landward bayside-shoreline migration.

INTRODUCTION

Ivan, a strong category 3 hurricane, made landfall near the Florida-Alabama border on September 16, 2004 accompanied by extreme wind and wave energy. The storm induced regional-scale overwash extending as far as 260 km east of the storm's landfall position. Overwash occurs when water levels become elevated due to a combination of storm-surge and wave run-up, inducing cross shore flow landward beyond the beach-berm crest (Shepard, 1973). The process yields both erosional and depositional features, the latter referred to as washover deposits (Schwartz, 1975). Low lying barrier islands along the northern Florida coast are particularly vulnerable to overwash.

Notwithstanding the long-term gradual effects of deflation, the overwash process provides a primary mechanism for rapid and episodic redistribution of sediment landward across the barrier profile. Sedimentation can extend well into the back-bay resulting in landward barrier migration. Ivan induced regional-scale overwash produced a broad spectrum of impacts ranging from beach and dune erosion along the distal reaches of the storms wind-field, to inundation proximal to the storm center. The range of impact can be attributed to spatial and temporal variations in the magnitude of storm related forcing and antecedent morphologic and biologic conditions of the barriers and beaches. The broad range of overwash impact generated by Ivan provided a unique opportunity to study the sedimentological characteristics of regional scale washover deposits.

This study integrates trenching, coring, topographic profile survey, aerial photo, and ground penetrating radar (GPR) data in order to examine the sedimentological characteristics of washover deposits associated with Hurricane Ivan. The objectives of the study were: (1) to examine erosional and depositional characteristics of regional washover deposits, (2) to characterize their spatial distribution patterns in both the cross-shore and long-shore directions, and (3) relate the above to antecedent morphologic and biologic conditions of the barriers and beaches. These data should provide valuable insight into coastal response to intense storm events.

STUDY AREAS

The northwestern Florida coast, commonly referred to as the Florida Panhandle, is a low energy, wave dominated coast, punctuated by a discontinuous chain of barrier islands (Fig. 1). The region is considered micro-tidal with a range of less than 0.5 m (Morang, 1992). Significant wave heights average around 1.2 m during the winter months and 0.8 m during the summer. The 85-km long Santa Rosa Island is the westernmost Panhandle barrier. The island is oriented roughly east-west and has a maximum width of ~1- km. Further to the east, barrier-island orientations range from northwest to northeast, paralleling a broad Pleistocene headland. Owing to the additional sediment supplied by the headland, eastern Panhandle barrier-island widths can reach several km, with the wider portions of the islands being comprised of a sequence of beach ridges. Overall, relief on the barriers rarely exceeds 10 m.

Sediment along the Florida Panhandle coast is comprised of compositionally and texturally homogeneous quartz sand, 75% of which lies within the 0.2 to 0.4 mm grain-size fractions (Stone and Stapor, 1996). Shell-debris content is low, rarely exceeding 5%. Dark heavy minerals are common in the sediments and tend to concentrate in distinct laminae providing a basis for distinguishing bedforms and stratification.

This study examines seven sites located along a 260-km stretch of the Panhandle coastline, extending from Santa Rosa Island on the west to St. George Island on the east (Fig. 1). Santa Rosa Island hosts the four westernmost sites, which include from west to east, Fort Pickens Park (FP), Navarre Beach (NV), Eglin Air Force Base (EG) and Beasley Park (BP). The Inlet Beach (IB) site is located along a central Panhandle mainland stretch of beach, and the two eastern sites are located on St. Joseph Island (SJ)

and St. George Island (SG). The sites were chosen based on: (1) areas with limited anthropogenic modification, (2) proximity to the storm center, and (3) degree of morphologic and biologic diversity.

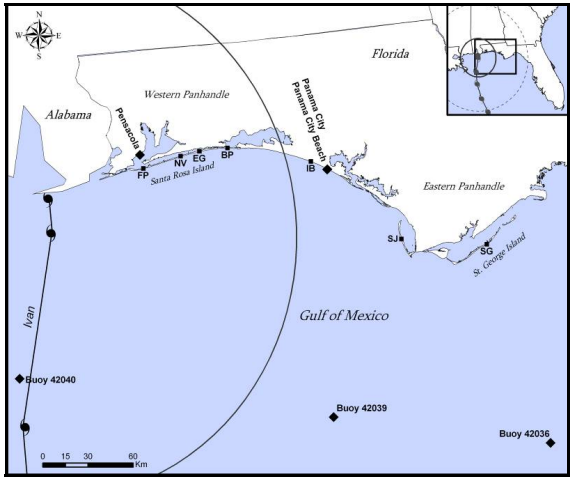

Fig. 1. Map showing track of Hurricane Ivan, wave and tide gauges (diamonds), and study sites (squares). The solid arc represents the extent of sustained hurricane force winds, and the dashed arc (in the insert) sustained tropical storm force winds at landfall.

The barrier-island study sites are characterized by a range of sub-environments (Fig. 2) which include, from bayside to Gulf: (1) mature woody vegetated dunes, (2) low-lying interior marsh and ephemeral wetlands, (3) broad flat interior platforms and hummocky dune fields (likely previous washover platform), and (4) a continuous to semi-continuous foredune ridge system populated with grassy vegetation, which merges seaward with the backbeach. The IB site, located along mainland beach is bound on the west by an artificially maintained narrow sinuous tidal inlet channel and on the east by residential development.

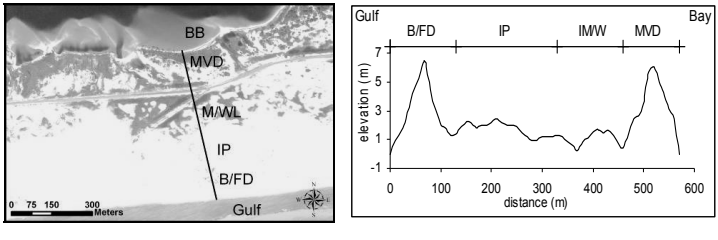

Fig. 2. Schematic showing typical northern Florida barrier island sub-environments. Sub-environments include; beach and foredune (B/FD), interior platform and hummocky dune-field (IP), interior marsh and wetlands (IM/W), mature vegetated dunes (MVD), and back-bay (BB).

Spatial variation of storm impact along the studied stretch of coastline was substantial. Employing the impact scale proposed by Sallenger (2000), inundation dominated the westernmost FP site. The NV site marks the transition from inundation to overwash, while overwash dominated the EG site. The BP site lies along the transition from overwash to collision regime, with scarping of higher dunes, erosion of lower dunes, and overwash penetrating inter-dune regions. East of the BP site, collision and swash regime dominated, with impact largely limited to beach erosion and dune scarping.

HURRICANE IVAN STORM CONDITIONS

On September 2, the ninth tropical depression of the 2004 hurricane season formed in the east Atlantic. Over the course of the next 24 hours, the storm intensified into Tropical Storm Ivan. Following a westerly course, Ivan further intensified into a Category 5 hurricane. On September 13, following passage through the Yucatan Channel, Ivan began a northwest track through the Gulf of Mexico, weakening slightly to Category 4, and eventually making landfall on September 16, as a strong Category 3 hurricane at Gulf Shores, Alabama, near the Florida-Alabama border (Fig. 1). The storm came onshore with extreme wind, wave, and surge.

Sustained tropical storm strength winds extended 475 km from the storm center, with sustained hurricane force winds extending 170 km (Fig 1). Significant and sustained surge was measured over a large area (Fig. 3). At the Pensacola tide gauge, the highest surge measured was 2.1 m above the Mean Low Low Water (MLLW), exceeding the gauge capacity. At Panama City Beach, the highest surge measured was 2.0 m above MLLW, nearly 4 times the typical tidal range. Surge levels exceeding 1.5 m (MLLW) persisted for over 10 hours (Fig. 3). Measured surge levels do not include contributions from wave setup and swash runup. Based on elevations of beach-profile changes, Wang et al. (2006) suggested that wave setup and swash runup account for ~50% of the total elevated water level during Ivan impact.

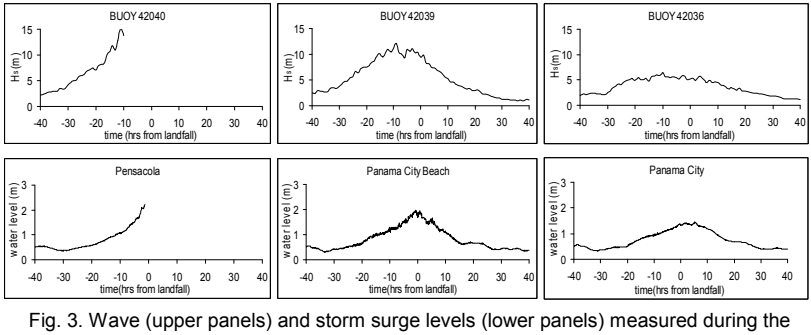

Fig. 3. Wave (upper panels) and storm surge levels (lower panels) measured during the passage of Ivan. Locations of the wave buoys and tide gauges are shown in Fig. 1. Water levels are relative to MLLW. Zero hour on time axis represents time of landfall.

Extremely high waves were measured offshore at the NDBC wave buoys. Shortly before landfall, 16-m waves were measured at the westernmost gauge 42040 (Fig. 3), which

apparently, was rendered inoperable. At gauge 42039, 220 km to the west, the highest wave measured was 12 m. Further east, at gauge 42036, the highest wave recorded was 6.4 m. Wang et al. (2005) measured wave heights higher than those reported by the NDBC buoys, with maximum wave height (H_{max}) reaching 28 m near Ivan's center. Overall, the highest waves at all three buoys were measured shortly before landfall.

METHODOLOGY

Coring, trenching, and GPR imaging were used to study the sedimentary characteristics of the Ivan washover deposits. Overall, 25 cores, 41 trenches, and approximately 30 line-km of GPR data were surveyed. Pre- and post-storm beach/dune and cross-island profiles were surveyed using an electronic total station and the data were referenced to NGVD 29 (National Geodetic Vertical Datum), which lies approximately 0.2 m below present sea level along the Panhandle region. At the BP, IB, SJ, and SG sites, profiles were surveyed 2 days prior, and 10 days following Ivan's landfall. Access limitations prevented pre-storm data collection west of the BP site. Core, trench and GPR data collection was initiated in October 2004, and continued during the 8 month post-storm period. During that period of time no appreciable storms impacted the studied region.

Sediment cores were obtained by driving a 7.6-cm diameter aluminum pipe into the subsurface with a sledge hammer. This procedure can penetrate up to 2 m below surface. Similar procedures of core description and sampling as used by Sedgwick and Davis (2003) were used here. Trenches of various shapes (e.g., T- or L-shape) and sizes (up to 6 m long and 1.5 m deep) were excavated in order to examine detailed sedimentological characteristics of the washover deposits. GPR transects were scanned adjacent to select trenches and core locations for ground truthing.

While traditional trenching and coring techniques provide valuable insight into detailed sedimentary characteristics, the methods are limited in spatial coverage. GPR, when employed in conjunction with coring and trenching can greatly expand spatial coverage, allowing for characterization of: (1) detailed internal sedimentary architecture, (2) transitional sedimentary features over a larger area, and (3) larger scale sedimentary features that may not be evident through single point data collection methods. GPR is a non-invasive geophysical technique which utilizes high-frequency electromagnetic (radar) waves to measure changes in the dielectric properties of earth materials. Abrupt changes in the dielectric properties of sediment layers (e.g., composition, texture, and porosity) result in some energy being reflected back to the ground surface, where it is recorded by a receiving antenna. The principals of GPR are discussed in detail by Daniels et al. (1988) and Davis and Annan (1989). Numerous studies describing the application of GPR in sedimentological studies are available in the literature (e.g., Jol et al., 1996; Bristow and Jol, 2003; Neal et al., 2003; Neal, 2004).

The GPR profile data were collected using a Sensors and Software Noggin SmartCart, equipped with a 250 MHz antenna and 100 V transmitter. Common mid-point (CMP) gathers were conducted at selected locations with a PulseEKKO 100 with a 200 MHz antenna and 400 V transmitter. The SmartCart data were collected in common offset

mode with the antenna separation fixed at 0.3 m, using a 0.05 m step size. Transect locations were established with a WAAS enabled GPS (Global Positioning System). The transects were surveyed for topographic control. The GPR data were processed using Sensors and Software EKKO Mapper software. All data were dewowed and scaled. Since imaging continuity of stratigraphic horizons and sedimentary structures were the primary goals of the GPR survey, an AGC (Automatic Gain Control) gain was applied employing max gain and pulse width settings of 400 and 1, respectively. This AGC gain settings tend to equalize signals by scaling in a manner inversely proportional to the signal strength. While some relative amplitude information is lost in this process (e.g., contrast between high and low amplitude reflections); lower amplitude reflections are enhanced, allowing better imaging of sedimentary structures. Common mid-point (CMP) gathers conducted at the NV, EG and BP sites yielded average signal travel velocities of 0.12 - 0.13 m ns^{-1} in the unsaturated sands, and 0.06 m ns^{-1} for the saturated sands below the water table. These velocities were used in the GPR interpretation, and depth scales were adjusted accordingly.

At the Santa Rosa Island sites, GPR penetration was on the order of 2 m. This relatively deep signal penetration can be attributed to the presence of a significant freshwater aquifer on the island as well as favorable sediment characteristics (medium quartz sands). Overall, data quality was good, and resolution was sufficient to image detailed sedimentary features observed in the cores and trenches. In contrast, at the central Panhandle IB site, shallow saline groundwater yielded rapid signal attenuation and nominal results. Owing to the limited cross shore extent of overwash along the eastern Panhandle, GPR surveys were not conducted at the SJ and SG sites.

Radar reflection profiles were interpreted following the techniques and terminology described by Neal (2004). The configuration and continuity of reflections provided the basis for establishing: (1) radar surfaces (radar boundaries), interpreted to represent depositional breaks, e.g., washover unit contacts, and (2) radar facies, interpreted to represent internal sedimentary structure. Interpreted profiles were correlated with sedimentary features observed in cores and trenches. This study focuses on the sedimentary characteristics of the Ivan washover deposits. Sedimentary units lying below the storm layer were not examined in detail.

RESULTS AND DISCUSSION

Pre and post-storm topographic surveys illustrate dramatic morphologic changes induced by Ivan extending over 260 km east of the storm center (Wang et al., 2006). The event yielded a broad spectrum of depositional as well as erosional features. These features are described within a spatial framework employing beach and barrier sub-environments as illustrated in Fig. 2.

Backbeach and Foredune Sub-environments

Representative pre- and post-storm profiles from the SG, IB and BP sites are shown in Fig. 4. Profile SG1 (Fig. 4a) illustrates typical backbeach and foredune response to the Ivan erosion and overwash event. Net erosion along the profile amounted to 20 $m^3 \cdot m^{-1}$,

with erosion reaching a maximum elevation of 2.7 m NGVD. A trench excavated along the backbeach revealed a 27 cm thick storm deposit here referred to as berm washover. The base of the washover is marked by antidunal bedforms punctuated by dark heavy mineral rich convex-up laminae (Fig. 5), and an abrupt transition from distinctly darker pre-storm bioturbated sediment to light colored quartz sand. The basal bedforms are overlain and truncated by horizontal to gently seaward dipping layers suggesting aggradation during the subsiding phase of the storm.

Further to the west, at the IB site, similar but more severe foredune and beach erosion were measured. Along the easternmost profile IB1 (Fig. 4b), net erosion amounted to 37 $m^3 \cdot m^{-1}$, with scarping of the foredune reaching a maximum elevation of 4.4 m NGVD (or roughly 4.2 m above MSL). A series of trenches excavated along the backbeach revealed a thickening seaward berm washover unit, 15 to 25 cm thick, characterized by horizontal to gently seaward dipping layers, overlying a sharp basal erosional surface (Fig. 4b), similar to the above SG site.

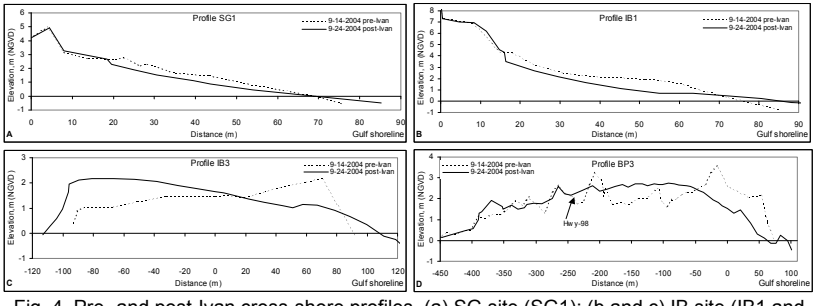

Fig. 4. Pre- and post-Ivan cross-shore profiles. (a) SG site (SG1); (b and c) IB site (IB1 and IB3); (d) BP site (BP3).

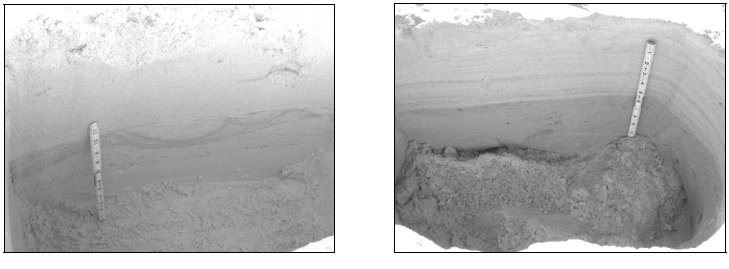

Fig. 5. Trenches excavated along profiles SG1 (left) and IB1 (right).

Located roughly 1-km to the west of IB1, profile IB3 (Fig. 4c) illustrates a significantly different pre-storm beach morphology. The site is characterized by a steep pre-storm shoreface and beach, which merges landward into broad flat platform (previous washover platform). Dunes are absent, and the beach and platform are bound on the west and north by a tidal inlet. Erosion along IB3 extended up the beach 75 m from MLW, yielding a net

loss of 40 $m^3 \cdot m^{-1}$ of sediment. Washover deposition further landward over the platform amounted to 75 $m^3 \cdot m^{-1}$, nearly twice the amount of sediment loss, suggesting longshore sediment transport may have contributed to the washover sediment supply. This is in contrast to the situation at BP site discussed in the next section.

Further to the west, along the eastern end of Santa Rosa Island, at the BP site, erosion dominates seaward of the foredune ridge. Along profile BP3 (Fig. 4d), the foredune ridge, with a pre-storm elevation of 3.6 m NGVD, was completely eroded, representing 76 $m^3 \cdot m^{-1}$ of sediment loss. Trenches excavated along the backbeach revealed a thickening landward berm washover deposit 20 to 33 cm thick, characterized by the horizontal to gently seaward dipping layers.

Fig. 6 shows a 270-m long shore-perpendicular GPR profile scanned at the BP site. The profile extends landward from the Gulf shoreface (left side), traversing the back-beach, foredune, interior platform, and interior marsh sub-environments. The profile contains: (1) a continuous undulating reflection lying between 0.5 and 1.6 m (labeled Iv) traceable across the entire profile, interpreted to represent the radar boundary separating the Ivan washover from pre-Ivan sediment; (2) semi-continuous horizontal and inclined, parallel to sub-parallel reflections overlying Iv representing internal structure within the Ivan washover deposit (Ivan radar facies); and (3) a continuous near horizontal reflection cutting across inclined reflections which represents the water table (labeled wt). Seaward inclined reflections imaged between 15 and 35 m correlate with layering observed within the berm washover. Between 70 and100 m, an eroded section of the foredune ridge was imaged. Reflective patterns suggest the Ivan washover thins substantially over the eroded dune and thickens rapidly landward. A general increase in accommodation space landward of the foredune would account for these patterns.

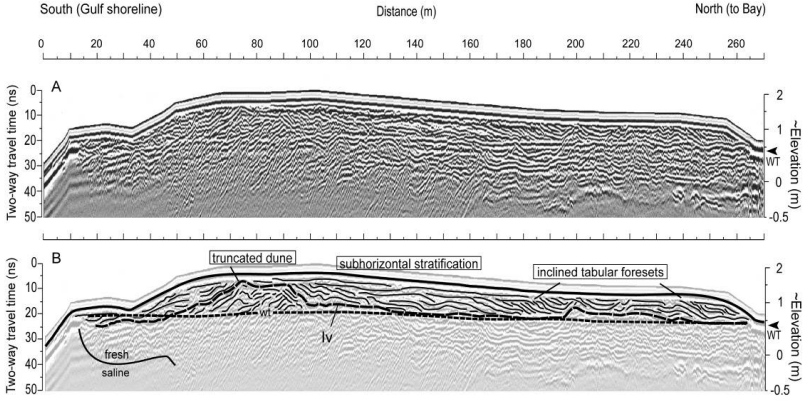

Fig. 6. Shore-normal GPR transect (upper) and interpreted profile (lower) at BP site.

Interior Platform and Hummocky Dune Field Sub-environment

In terms of aerial extent, the interior platform and associated hummocky dune field represent the largest portion of the barrier-island. This sub-environment is likely

washover from previous storms with recovering dunes. As shown in profile BP3 (Fig. 4d), erosion over the interior platform was largely focused to dunes lying above 2.5 m NGVD, with washover deposition dominating the lower elevations. Deposition along the profile amounted to 75 $m^3 \cdot m^{-1}$. This is roughly equal to the 76 $m^3 \cdot m^{-1}$ eroded from the beach and foredune along the profile, and suggests that while a significant volume of sediment redistribution occurs during an overwash event, overall barrier mass can be conserved. The average thickness of platform washover deposits based on 20 cores and trenches was 62 cm, with a maximum of 105 cm measured at the EG site. The washover is characterized by heavy mineral-rich horizontal to subhorizontal layers. The heavy minerals concentrate within the finer grain-size fractions (0.125 - 0.3 mm), and tend to form distinct laminae. Fresh, in-place and nearly upright grasses preserved along the base of the washover (Fig. 7) suggest erosion along the pre-storm surface was limited, and much less severe than the erosion on the backbeach and foredune areas.

GPR data over the interior platform (Fig. 6) show radar boundary Iv as a continuous horizontal to undulating reflection. The undulations appear to reflect hummocky dunes preserved along the pre-storm surface (Fig. 7). The Ivan radar facies is characterized by semi-continuous horizontal to slightly inclined landward reflections that downlap onto Iv. The reflective patterns illustrate a rapid thickening of the washover landward of the eroded foredune.

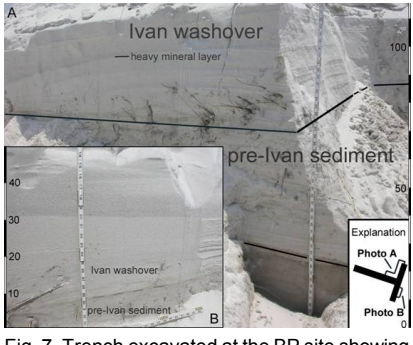

Fig. 7. Trench excavated at the BP site showing interior platform washover deposition occurring over a low-lying hummocky dune.

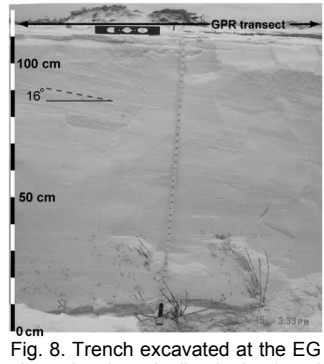

Fig. 8. Trench excavated at the EG site showing inclined landward tabular foreset stratification and marsh grasses along basal contact.

Interior Marsh and Ephemeral Wetlands Sub-environment

This sub-environment typically occupies low lying portions of the barrier islands, making it particularly susceptible to flooding during overwash. The pre-storm surface tends to be populated with marsh grasses, and in the case of ephemeral ponds, thin algal mats may develop along surface. The organic rich nature of the pre-storm sediment makes distinguishing the cleaner quartz sand washover deposits relatively straightforward.

Numerous existing studies (e.g. Schwartz 1975; 1982) have described the development of inclined tabular foreset bedding during washover deposition into lagoons and

washover ponds. Bedding features of this nature were apparent in both the trenches and GPR profiles examined in this study. At the EG site, a trench excavated along the margins of an active interior marsh (Fig. 8) exposed inclined landward tabular foreset bedding developed during progradational washover deposition into the flooded marsh. Fresh in-place marsh grasses extending up from the pre-storm surface indicate limited erosion occurred prior to washover deposition. Increased accommodation space within the low-lying wetlands yields an increasingly thicker washover relative to the seaward sub-environments, with washover thicknesses commonly approaching 1.20 m.

The GPR profile shown in Fig. 9 was scanned adjacent to the EG trench, and shows the Iv radar boundary extending across the profile at depths ranging from 0.8 to 1.2 m. The Ivan radar facies is characterized by semi-continuous inclined landward reflections that downlap onto Iv. Similar inclined reflective patterns were observed along the landward end of the BP GPR profile (Fig. 6), and correlate with washover deposition into a flooded interior marsh. The inclined reflections observed on the BP GPR profile however, are overlain by a series of semi-continuous horizontal to sub-horizontal reflections more consistent with platform type radar facies. The reflective patterns as well as trench data indicate that within the marsh-wetland sub-environment, inclined landward tabular foreset bedding translates upward into horizontal layering frequently. This transition of bedding features suggests a temporal variation in the mode of washover deposition. Initial deposition within the flooded wetlands occurs in a progradational manner as bedload sediment cascades down the terminal slope of the washover lobe. The in-filling of the accommodation space and the resulting increased elevations prompts a renewal of washover platform type aggradation yielding the overlying horizontal bedding. This aggradation should be dominated by sheet flow and suspended-load transport modes in shallowing water.

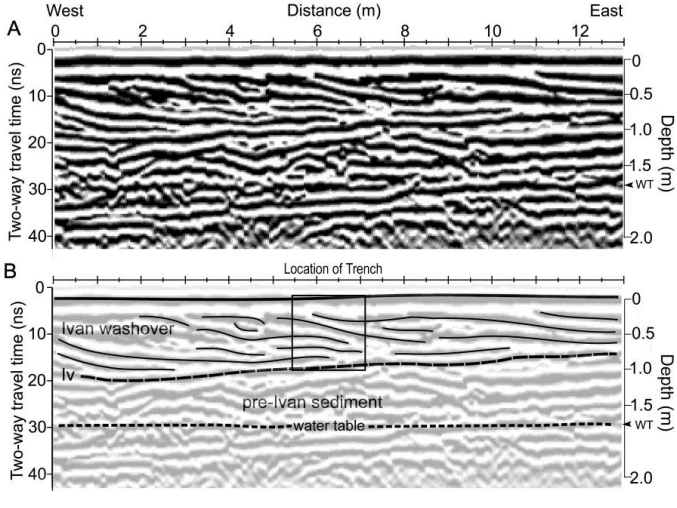

Fig. 9. GPR transect scanned adjacent to the trench (box outline) shown in Fig. 8.

Mature Vegetated Interior Dunes and Inter-dune Sub-environment

Along the western Panhandle, mature vegetated and less active interior dunes are commonly found landward of, or flanking the interior platform. The dunes rarely exceed 10 m in height, and frequently host woody plant species such as Scrub Live Oak and Myrtle, with vegetation commonly extending down to the inter-dune region. At the NV site, washover deposition occurred within the woody vegetated inter-dune region yielding a 45-cm thick deposit (Fig. 10a). The lower 15 cm of the washover is a massive layer containing abundant organic fragments and randomly disseminated dark heavy minerals, and is overlain by a series of thinner heavy mineral rich horizontal layers containing minor amounts of organic debris. A sharp boundary separates the washover from the organic rich pre-storm sediments. Numerous coarse woody roots and branches extend up from the pre-storm surface, suggesting that limited erosion occurred in the inter-dune region prior to washover deposition. The GPR transect scanned adjacent to the trench shown in Fig. 10 shows a continuous horizontal reflection at a depth of 0.5 m (labeled Iv) which correlates with the base of the of the Ivan washover unit. The Ivan radar facies is represented by a series of semi-continuous horizontal to sub-horizontal reflections. Numerous discrete hyperbolic reflections lying both above and below Iv represent coarse root and branch material.

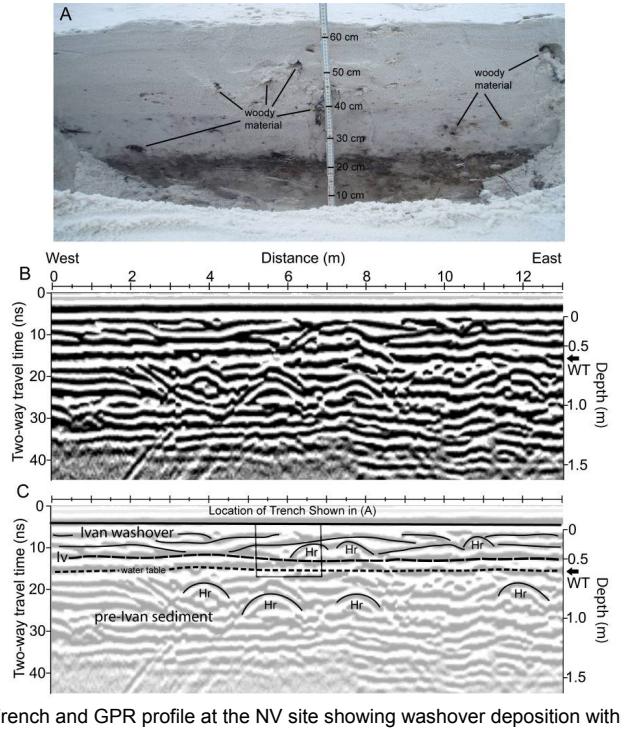

Fig. 10. Trench and GPR profile at the NV site showing washover deposition within vegetated inter-dune sub-environment.

Back Bay Sub-environment

The morphological characteristics of the bayside beach along the Panhandle coast include a narrow and steep shoreface and a shallow platform, typically less than 1.5 m deep extending up to several hundred meters into the bay (Stone et al., 2004). This platform, also referred to as low-tide terrace (Nordstrom, 1992), is common along estuary beaches worldwide. Ivan induced washover deposition into the back-barrier bay at the western FP, NV, and EG sites. Overwash into the back-bay took two forms. Along narrow sections of the barrier, where mature vegetated dunes are largely absent and the interior platform dominates the profile, inundation resulted in laterally continuous bayside washover deposition, in places amounting to 120 m of landward bayside shoreline migration. Along wider sections of the island, where mature dunes populate the bayside shoreline, deposition was largely confined to narrow shore normal runoff channels 50 to 80 m wide, yielding discrete washover tongues extending up to 100 m into the back-bay.

Landward progradation of the bayside shoreline is clearly evident when comparing the pre- and post-storm aerial photos of the FP site (Fig. 11c,d). A GPR profile scanned over the pre-storm bayside beach shoreface (Fig. 11a,b) shows an abrupt downwarping of Iv between 30 and 35 m which correlates with the pre-storm shoreface. Gulfward of the shoreface, the washover is characterized by semi-continuous subhorizontal reflections characteristic of washover platform radar facies. The platform facies merges landward (bayward) into steeply inclined sigmoid reflections lying tangential to Iv. Owing to the increased accommodation within the back-bay, washover thicknesses increase substantially, ranging from 1.5-2.0 m.

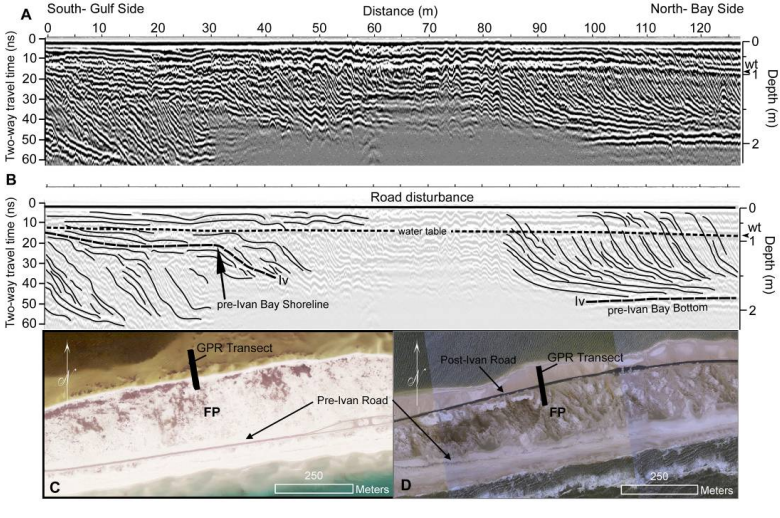

Fig. 11. GPR transect scanned at FP site, and pre- (C) and post-Ivan (D) aerial photos.

It is worth noting that along the Gulf side of the above GPR profile, below Iv, steeply inclined landward reflective patterns downlap onto a high amplitude landward dipping

reflector. The reflective patterns indicate an earlier phase of progradational deposition into the back-bay, suggesting that overwash constitutes a major process driving landward barrier island migration.

CONCLUDING SUMMARY

Regional overwash induced by Hurricane Ivan along the northern Florida coast yielded a range of spatially distinct erosional and depositional features. Nearshore beach and foredune response is initially dominated by erosion. Subsequent deposition over the beach, here referred to as berm washover, is characterized by basal high flow regime bedforms (e.g., antidune) or a sharp planar erosional surface overlain by horizontal to gently seaward dipping planar bedding. This berm washover deposits suggest aggradation occurred during the subsiding phase of the storm after the initial erosion. Owing to the limited accommodation space over eroded sections of the beach and foredune, the berm washover tends to be relatively thin.

Sediment eroded from the foredunes is in-turn transported landward and deposited across the entire barrier profile. Barrier response landward of the foredune is largely depositional; with limited erosion occurring in the low-lying areas as indicated by the widespread preservation of in-place vegetation below the washover deposits. Washover deposits over the interior platform and hummocky dune field are characterized by horizontal to subhorizontal inclined landward bedding. These bedding features correlate with horizontal and subhorizontal reflective patterns observed in the GPR data. Landward thickening of the interior platform washover can be attributed to a general landward increase in accommodation space.

Washover deposition within the flooded interior marsh and wetland sub-environment, coupled with increased accommodation space, yields thicker washover deposits. The washover is characterized by distinct inclined landward tabular foreset bedding that often translates upward into horizontal to subhorizontal inclined landward bedding. This transition of bedding features suggests a change in the mode of sediment transport and deposition. Initial deposition within the wetlands occurs in a progradational manner as bedload sediment cascades down the steep terminal slope of the washover lobe. The in-filling of the wetland depression and the resulting increased elevations prompts a renewal of washover platform type aggradation yielding the overlying horizontal bedding. This aggradation is believed to be dominated by sheet flow and suspended-load transport modes in shallowing water.

Proximal to Ivan's center, along narrow portions of Santa Rosa Island, inundation resulted in substantial washover deposition into the back-bay, in-places amounting to 210 $m^3 \cdot m^{-1}$ accumulation yielding up to 120 m of landward barrier migration. GPR reflective patterns indicate washover deposition within the back-bay is dominated by progradational sigmoid and inclined tabular foreset stratification. Owing to the significantly increased accommodation space, washover thicknesses within the back-bay commonly approach 2 m. Overall, the thickness of washover deposits is strongly controlled by the accommodation space.

Abstract: The 2004 Indian Ocean tsunami caused major landscape changes along the southwest coasts of Sri Lanka that were controlled by the flow, natural topography and bathymetry, and anthropogenic modifications of the terrain. Landscape changes included substantial beach erosion and scouring of return-flow channels near the beach, and deposition of sand sheets across the narrow coastal plain. In many areas tsunami deposits also included abundant building rubble due to the extensive destruction of homes and businesses in areas of dense development. Trim lines and flow directions confirmed that shoreline orientation and wave refraction from embayments and rock-anchored headlands locally focused the flow and amplified the inundation. Tsunami deposits were 1 to 36 cm thick but most were less than 25 cm thick. Deposit thickness depended partly on antecedent topography. The deposits were composed of coarse to medium sand organized into a few sets of plane parallel laminae that exhibited overall upward fining and landward thinning trends.

INTRODUCTION

A U.S. led multi-discipline multi-national survey team was dispatched to Sri Lanka two weeks after the 2004 Indian Ocean tsunami to conduct a rapid reconnaissance investigation of the impacts of this catastrophic event. The purposes of the survey were to obtain eyewitness accounts and to make observations and measurements regarding tsunami impacts that would likely be altered by the post-tsunami cleanup and reconstruction that began immediately (Liu et al., 2005, Goff et al., 2005). Nearly all of the post-tsunami field surveys conducted in Sri Lanka focused on the wave characteristics, water levels, and inundation distances (Wijetunge, 2006). In contrast, the U.S. led team also collected data to characterize the tsunami deposits. The types of tsunami data collected were water levels and wave run-up elevations (Fig. 1), flow

depths, inundation distance from the shore, and flow directions. Water level is the water elevation above a sea level datum, wave runup is the maximum elevation of water on the land, and flow depth is the water level minus the land elevation. Geological observations included geologic setting, nearshore topography, erosional and depositional changes, and tsunami deposit characteristics. This report summarizes the general morphological changes and sedimentological observations along the southwest coasts of the country between Colombo and Yala.

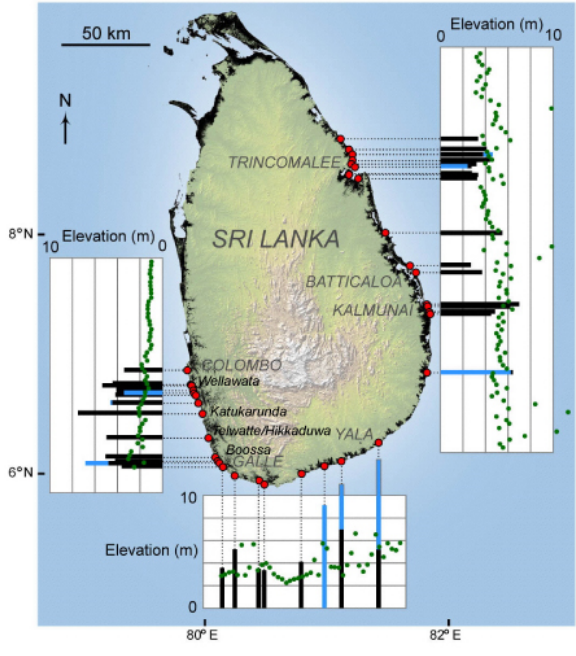

Fig. 1. Water levels in Sri Lanka associated with the 2004 tsunami. Measured tsunami runup (gray bars) and maximum wave heights (black bars). Gray-filled dots show the sites of elevation measurement. After Liu et al. (2005).

GEOLOGICAL SETTING

The island of Sri Lanka consists primarily of a Pre-Cambrian bedrock core that makes up the Central Highlands surrounded by lowlands and a fringing coastal plain composed of alluvial deposits (Swan, 1985). Long barriers with sandy beaches and interior lagoons occupy embayments between headlands that are bluff outcrops of resistant rock. Wave-cut platforms and other expressions of submerged outcrops extend offshore along much of the southwest coast (Swan, 1985). The lengths of sandy beach are greatest on the east and southeast coast but diminish to the west where cliff headlands are more common. These first-order morphological features controlled tsunami impacts such that the headlands blocked tsunami inundation and

prevented interior damage, whereas the embayments focused the waves and increased the limits of inundation and runup (Fig. 1).

The southeast coast of Sri Lanka near Yala is characterized by relatively wide zeta-curved sandy beaches and adjacent narrow coastal plains offset and separated by rock-anchored headlands and points. Small inlets that are connected to bays or lakes and associated upland drainages also bound coastal segments. Sand dunes are locally well developed on the southeastern beaches of Sri Lanka where sand supply is abundant and the climate is relatively dry. Sand dunes are largely absent on beaches of the southern and west coasts as a result of higher rainfall in the region. Beaches are composed predominantly of fine to coarse quartz sand with variable amounts of carbonate material consisting of shell and fragments of coral reef. Beach erosion was a serious problem for many Sri Lankan communities even before the tsunami. At some locations, shoreline stabilization structures such as gabions, riprap revetments, groins, and segmented breakwaters were heavily damaged or rendered ineffective by the tsunami.

2004 INDIAN OCEAN TSUNAMI

On December 26, 2004, rupture along a 1200 km segment of a megathrust fault west of northern Sumatra produced a magnitude 9.1 earthquake. The great subduction zone earthquake, which lasted for several minutes, deformed the seafloor an estimated 15 m (Lay et al., 2005) and generated a tsunami that propagated throughout the Indian Ocean, causing widespread destruction of coastal communities in 11 countries.

One of the countries hardest hit by the tsunami was Sri Lanka, owing to its location directly in the path of the highest waves and separated from the tsunami-generating source by only deep water. In Sri Lanka, where the tsunami arrived about 2 hrs after the earthquake, eyewitnesses reported that the first wave was a minor surge that flooded beaches but caused little damage to the infrastructure. The initial positive wave was followed by a large negative wave that caused the sea to withdraw several hundred meters, exposing the seafloor and coral reefs offshore. About 10 to 15 minutes later, the second positive wave struck causing most of the casualties and catastrophic impacts. North of Galle, a third wave was reported several hours after arrival of the first waves, indicating that the later wave followed a longer path, probably having been reflected off the Maldives or India (Liu et al., 2005).

TSUNAMI IMPACTS

In Sri Lanka, the low coastal areas with ocean-facing sand beaches provide easy access to the sea for commercial fishing and recreation. Consequently, they are densely developed and occupied by businesses and residences that are vulnerable to tsunami hazards. Most of the fatalities and structural damage from the 2004 tsunami occurred within a few hundred meters of the shore. Primary tsunami impacts at selected sites along the southwest coasts of Sri Lanka are summarized in Table 1. The following accounts, organized from northwest to southeast (Fig. 1), present the morphological impacts and deposit characteristics where the data are most complete. At all trench sites, tsunami deposits were sampled at 1 cm intervals.

Table 1. Summary of 2004 Tsunami Impacts on Southwest Coasts of Sri Lanka

Location	Primary Impacts	Max. Flow Depth m	Deposit Composition	Max. Thick. cm
Wellawatta*	Inundation, minor deposition	1.5	sand	7
Mt. Lavinia	Inundation, minor deposition	1.5	sand

* Tsunami deposits examined at these locations are described in the text.
† Thickness increased by artificial topography

Wellawata

South of Colombo, the densely developed communities of Wellawata and Mount Lavinia are characterized by straight and continuous sand beaches, which are approximately 30 m wide between the high water line (HWL) and the vegetation line. A narrow rock platform about 200 m offshore acts as a local breakwater for incoming waves. The coastal plain is an extension of the backbeach that gradually increases in elevation landward. Tsunami impacts along this coastal segment were primarily inundation, minor deposition, and slight damage to the infrastructure. Maximum flow depths were 1.5 m and inundation extended about 350 to 400 m inland from the beach where the waves generally were unrestricted by buildings. Sand was deposited as a washover sheet that extended about 30 m inland from the backbeach to the railroad embankment that runs parallel to the shore.

At Wellawata, eleven deposit thickness measurements were made along a cross-shore transect. The measurements showed that the tsunami washover sheet systematically increased and decreased in thickness landward from the HWL, ranging from 2 cm at 21 m, to 7 cm at 24 m, to 1 cm at 30 m, and pinch out at 31.7 m. The 7 cm deposit consisted of plane parallel laminations organized into two laminae sets, each about 3.5 cm thick (Fig. 2). The lower unit was composed of medium sand with abundant heavy mineral laminations and a slight upward fining of mean grain size. The upper unit also was composed of upward-fining medium sand that bracketed the same range of mean grain sizes as the lower unit, but did not contain the well defined segregation of heavy mineral laminations. Both of the laminae sets were moderately well sorted with sorting systematically improving upward. The tsunami deposits contrasted both

in color and texture with the older underlying deposits, which consisted of poorly sorted, very coarse orange sand and gravel (Fig. 2).

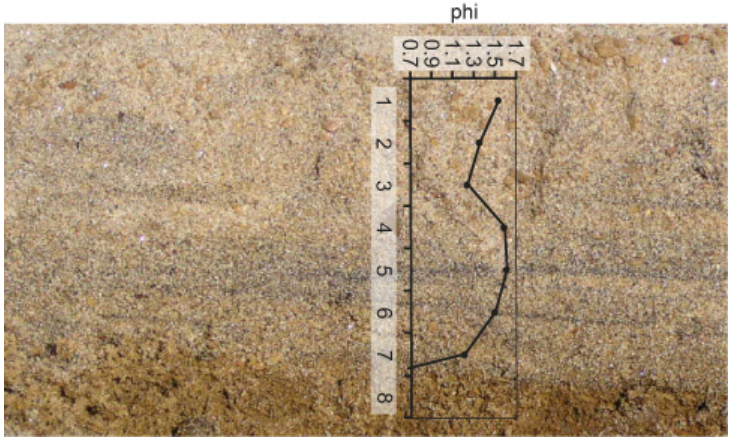

Fig. 2. Trench exposure at Wellawata located 24 m from the high water line.

Katukurunda

At Katukurunda, a broad lagoon separates a low narrow sand spit (150 m wide) from the mainland. The spit, which was approximately 1 m above sea level and developed with a three-story hotel complex and houses, was completely overwashed by the tsunami that generated a maximum flow depth of approximately 3.5 m. Beach width is highly variable owing to a field of offshore segmented breakwaters, each about 180 m long. The beach is about 140 m wide where it is attached to a breakwater as a tombolo and less than 25 m wide where the shore is unprotected between breakwaters. Post-tsunami observations were made at a site immediately landward of one of the breakwaters that was so severely damaged that rocks extracted from the structure were incorporated into the tsunami deposit.

On the low spit between the beach and hotel complex, rows of planted palm trees formed topographic highs, whereas the gaps between the trees formed topographic lows. The trees interfered with tsunami flow and scour increased around the tree bases. The tsunami washover sand deposits conformed to the landscaped topography and were thin around the tree root balls and relatively thick between them. A trench located 61 m from the HWL and between adjacent rows of trees showed that the tsunami deposit was 36 cm thick (Fig. 3).

The deposit was composed of medium to coarse sand that appeared to be homogeneous at the base and organized into plane parallel laminations toward the top. Vertical textural trends demonstrate that the tsunami deposit was organized into four units, each exhibiting upward-coarsening/upward-fining textural trends. Each component of each couplet was roughly equal in thickness and the couplets were

progressively thinner from bottom to top. The uppermost two couplets, each about 4 cm thick, consisted of clean sand laminae overlain by heavy mineral laminae. Within the deposit were two rip-up clasts about 3.5 cm in diameter composed of organic-rich sand derived from the underlying pre-tsunami soil, which was texturally finer than the tsunami deposit. Cobbles and small boulders (50 cm b axis) excavated from the offshore breakwater were scattered across the coastal plain close to the beach (Fig. 4). Concentration of the boulders at the surface indicated that they were probably part of the late-stage tsunami load that was mobilized and deposited after initial sand deposition.

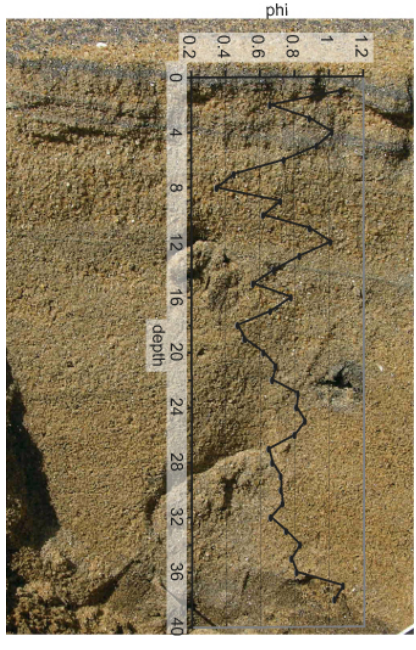

Fig. 3. Trench exposure at Katukurunda located 61 m from the high water line.

Telwatte

Low coastal plain elevations near Telwatte and an estuary mouth at North Hikkaduwa amplified tsunami inundation and led to near total destruction of buildings within 100 m of the sea. This coastal segment has a moderately wide beach (~70 m) and does not have a nearshore rock platform to protect the coastal infrastructure, such as the platform observed farther to the south at South Hikkaduwa. The sandy coastal plain near Telwatte is moderately wide, extending 0.5 to 1 km inland from the beach to a partly filled arcuate lagoon. The beach is relatively straight, long, and continuous, but it also is steep, narrow, and armored with riprap and short groins that protrude about 1 m above sea level. The coastal highway, which is located about 15 m from

the erosional backbeach scarp, and some houses were constructed on a low sand ridge that dominates the topography about 60 m inland from the beach. The ridge

Fig. 4. Small boulders on the Katukurunda beach emplaced by the 2004 tsunami.

influenced tsunami flow, the resulting morphological impacts, and the thicknesses of the tsunami deposits. Erosion and transport were the dominant processes across the ridge where flow depths were about 2 m. Deposits consisted of small coastal-structure boulders emplaced between the seaward edge of the ridge and the road, thin patches of sand, and accumulations of building rubble near and landward of the bare foundations that formerly supported buildings. The rapid tsunami flow and abrupt increase in water depth at the landward edge of the ridge produced a hydraulic jump that scoured pits roughly parallel to the ridge. Landward of the ridge and pits, tsunami deposits formed a sheet of sand and debris that extended inland more than 50 m.

Two trenches, each approximately 110 m from the HWL, exposed well sorted to moderately sorted medium to coarse sand 10 to 20 cm thick above an organic-rich soil. The soil zone was substantially coarser and more poorly sorted than the overlying tsunami deposits. The 10 cm tsunami deposit (Fig. 5) was organized into 3 laminae sets. The basal 4 cm were faintly laminated medium sand that exhibited upward-fining and upward-coarsening textural trends. A well-defined, possibly erosional surface of coarse sand and gravel formed the base of the second upward-fining laminae set, which was 2 cm thick. The third set was faintly laminated and upward fining to uniform in texture.

Where the Telwatte deposit was 20 cm thick it consisted of medium to coarse sand organized as plane parallel laminations into three laminae sets. Each laminae set was

about 6 cm thick. The basal laminae set, which was in erosional contact with the underlying dark brown

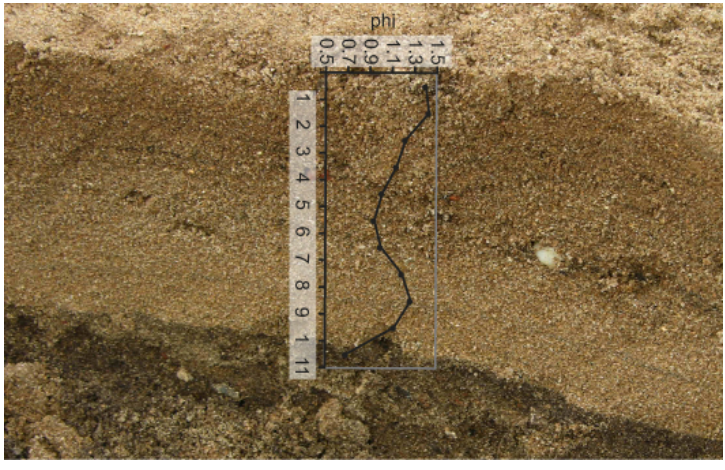

Fig. 5. Trench exposure at Telwatte located 110 m from the high water line.

organic-rich soil, was capped by a 0.5 cm unit marked by two faintly developed lamina enriched in heavy minerals. The intermediate and upper laminae sets were similar in grain size and composition; both contained pebble size clasts of masonry building material, but they were distinguishable by the slightly darker color of the upper unit.

South Hikkaduwa

The shore planform and beach dimensions at South Hikkaduwa are irregular owing to the presence of rock outcrops and a wave-cut shore platform at the toe of the sand beach. Although the beach typically is less than 10 m wide and embayed over distances of 150 to 200 m, it is densely developed with well-constructed commercial buildings including hotels and other businesses. The rock platform provided substantial protection from the tsunami and limited the impacts to beach erosion and deposition of a washover sheet and minor damage to buildings located between the beach and the coastal highway. Trapped debris and bark scars on trees indicated that flow depths across the backbeach and washover sheet were about 2.3 m, although there was evidence that the undulating rock platform influenced the runup, by focusing wave energy where there was a gap in the platform.

Tsunami deposits at Hikkaduwa exposed in a trench about 30 m from the HWL were 16 to 23 cm thick, and composed of well-sorted plane parallel laminated coarse sand with some shell fragments overlying a brown organic-rich sandy soil (Fig. 6). The tsunami deposit was organized into two laminae sets each about 8 cm thick and each exhibiting upward-fining textural trends. Upward-fining textures also characterized

the entire deposit. A slightly coarser lamina with some gravel separated the two laminae sets. Heavy minerals were disseminated throughout the deposit and were not concentrated into individual lamina as in other tsunami deposits.

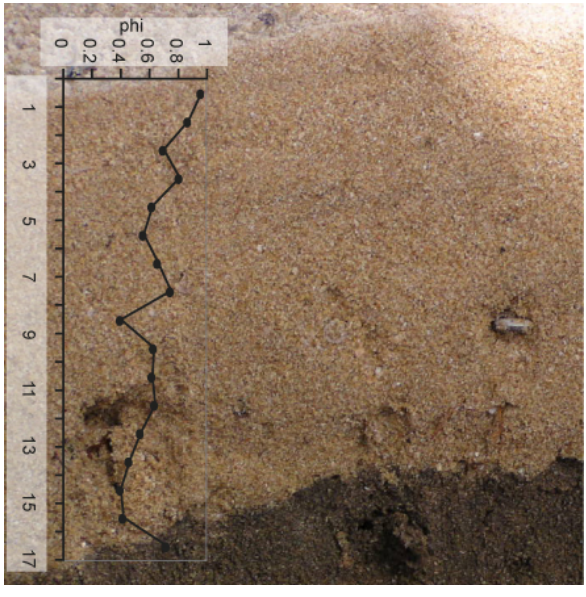

Fig. 6. Trench exposure at Hikkaduwa located 30 m from the high water line.

Boossa

Rock outcrops offshore and along the shore near Boossa create an irregular, slightly embayed shore platform that locally alters wave characteristics and produces variable beach dimensions. Locally increased wave heights and steepness were confirmed by the many surfers who favor the beach at Boossa for their sport. The steep narrow beach is about 10 m wide and only 10 to 100 m from the coastal highway. The tsunami eroded the beach, creating a scarp of densely matted tree roots and destroying houses that had been constructed near the coastal highway. Bent metal poles and broken concrete posts along the railroad tracks indicated both onshore and offshore flow directions. Maximum flow depths were about 1.5 m. Eyewitnesses reported that the first wave was low and moved rapidly, but the second wave, which came about 15 minutes later, was the most destructive.

Inundation by the tsunami produced a thin sand sheet and building rubble that covered the flat coastal plain near the shore at Boossa. Loading from pedestrian traffic had extensively modified the depositional surface and possibly the internal structure of the sand deposit. A trench located approximately 28 m from the HWL revealed 5 cm of homogeneous coarse sand overlying a dark organic-rich soil (Fig.

7). The sand was moderately well sorted and the minor vertical changes in mean grain size defined two slightly upward-coarsening units, each about 2 cm thick.

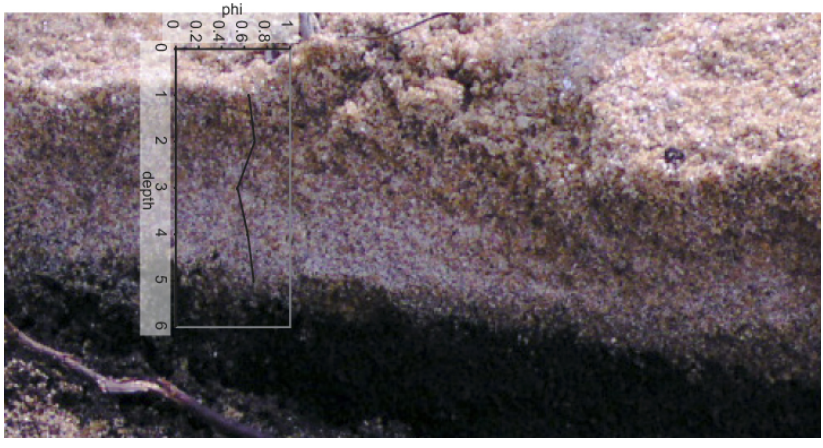

Fig. 7. Trench exposure at Boossa located 28 m from the high water line.

Yala

The shore of southeast Sri Lanka near Yala (Fig. 1) has a zeta-shape that is controlled by irregularly spaced rock promontories and embayments where minor local rivers cross the beach. As a result of this configuration, the shoreline is oriented slightly northeast, whereas embayed offsets face east. The coastal plain is about 2 km wide and relatively flat except for an ancestral dune ridge that is about 11.5 m high and 300 to 400 m inland from the modern beach and dune ridge. Grasses and shrubs stabilize the modern dune ridge, which is as much as 4 m high. Shore-parallel patterns on satellite images suggest long-term coastal plain progradation; however, field observations along the southern coast of Sri Lanka indicate a recent prolonged phase of beach erosion before the tsunami.

The unusual coastal setting, shoreline orientation, and refraction of the westward propagating tsunami wave produced a complex flow pattern at Yala that involved nearly simultaneous onshore (north) and alongshore (west) flow. West of the Yala study site, tsunami inundation extended more than 2 km inland where elevations were low along the estuary. The onshore and alongshore flows produced complex flow patterns that caused the destruction of two substantially built eco-tourism resort complexes. Destruction of one of the resorts (Fig. 8) was facilitated by intentional removal of the foredune ridge during resort development. Rubble derived from destruction of the buildings was incorporated into some of the more inland tsunami deposits. Open coast tsunami flow depths of 4.6 m were estimated at several sites from the heights of broken branches and debris trapped in trees, whereas a runup height of 12.5 m was measured from debris in shrubs on the ancestral dune ridge where flow depth was only about 1 m. Sand grains imbedded in surface pits of a

rough iron post near the beach indicated that the transported sand load in the water column extended at least 1.9 m above the pre-tsunami land surface.

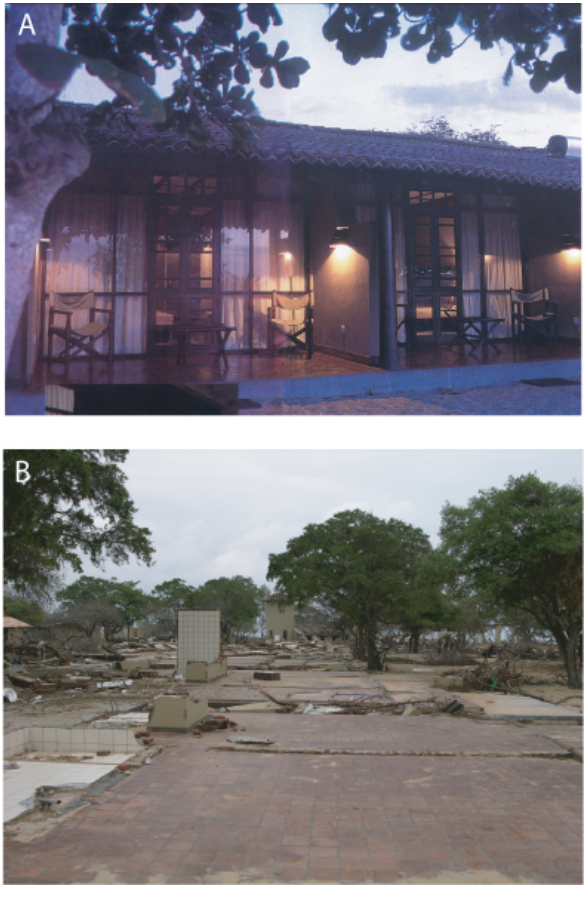

Fig. 8. Yala Safari Resort before and after the Indian Ocean tsunami.

The largest morphological changes observed at this site were erosion of the beach by onshore flow and scouring of incised channels near the beach by the return flow. Two weeks after the tsunami, a sand bar overwashed at high tide was rapidly migrating onshore to partly replace the sand lost during beach erosion and to fill the return flow channels (Fig. 9).

Tsunami erosion and inundation were exacerbated where the dunes had been removed intentionally and were minimized where the dunes were unmodified. Absence of the tsunami deposit in the lee of the dune ridge and bent grass and a small

boat resting on top (Fig. 9) demonstrated that the dune ridge was barely overtopped by the waves and it protected the area immediately landward from onshore flow.

Fig. 9. View at Yala of beach-recovery sand bar migrating onshore after the 2004 tsunami.

Three trenches, two sediment cores, and six supplementary depth measurements along a cross-shore transect at Yala were used to characterize the tsunami deposit. The overall landward-thinning deposit ranged in thickness from 19 cm near the beach, to 22 cm in the middle of the sand sheet, to 2.5 cm near the toe of the ancestral dune ridge. Re-construction of the pre-tsunami topography indicated that the thickest tsunami deposits were located in former topographic lows and the thinnest interior deposits were over former topographic highs including an unsealed road bed that was buried by the tsunami deposit.

The trench located 300 m from the HWL exposed 22 cm of plane parallel laminated well sorted to moderately well sorted sand. The sand was medium and coarse in texture and was found overlying an erosional basal contact and underlying truncated foreset stratification (Fig. 10). This deposit was visually subdivided into 3 units that were bounded by laminae of concentrated heavy minerals. The basal unit consisted of 12 cm of coarse-fine sand couplets composed of clean sand and heavy mineral laminations. The middle unit consisted of 5 cm of clean sand, whereas the upper 5-cm unit consisted of clean sand and heavy mineral couplets. The upper unit represented scour and fill deposits that decreased in thickness seaward. These late stage deposits probably were associated with a component of seaward-directed return flow. Sediment textures in the trench recorded four different vertical trends commencing with the basal 7-cm upward-coarsening trend overlain by 10 cm of relatively uniform

mean grain sizes. These trends were followed by 3-cm and 2-cm upward-fining trends that were separated by the finest textures in the tsunami deposit.

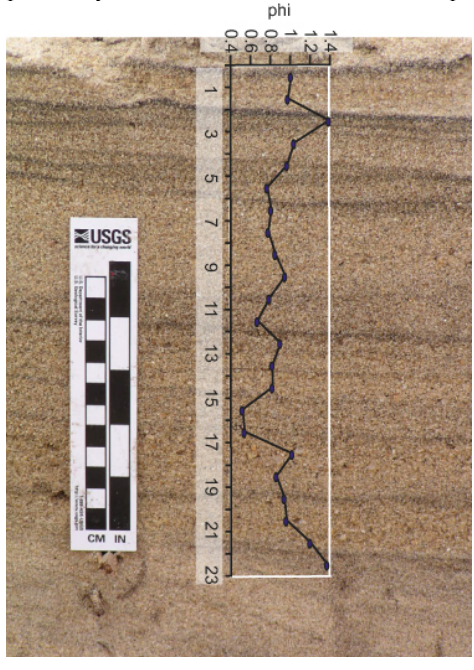

Fig. 10. Trench exposure at Yala located 300 m from the high water line.

DISCUSSION AND CONCLUSIONS

Field observations, trench measurements, sediment samples, and topographic profiles at sites spanning more than 250 km of the southwest coast of Sri Lanka provided a basis for interpreting the erosional and depositional phases of the tsunami event. The data show that sand deposits from the same tsunami event are highly variable in thickness, inland extent, geometry, and vertical textural trends. Deposits ranged in thickness from 1 to 36 cm but most were less than 25 cm thick. Local cross-shore variability in deposit thickness was partly related to antecedent topography with the deposits thinning over former topographic highs and thickening in topographic lows. The thickest deposit (36 cm at Katukurunda) was an artifact of a topographic low created by planted trees. The topographic dependence and upper limits on tsunami deposit thicknesses are consistent with those reported by Morton et al. (2007).

In Sri Lanka, the thin tsunami deposits tended to be homogeneous, whereas the thickest deposits exhibited better stratification, more laminae sets, greater textural variability, and more complex vertical textural trends. Visual subdivision of sandy tsunami deposits in the field only partly agrees with more detailed textural trends identified using mean grain size and sorting at 1 cm intervals. Vertical trends in mean

grain size included upward fining, upward coarsening, uniform, and highly variable. The most common vertical textural trend was upward fining. Cross-shore thickness measurements of the tsunami deposit at the two sites farthest apart where flow depths were the greatest (Yala) and least (Wellawatta) showed overall landward thinning. Comparison of the lowest laminae of the tsunami deposits and underlying soils indicated that the tsunami deposits are not texturally similar to the soils and therefore the soils are not the likely sources of the tsunami deposit sediments. Where present, the tsunami deposits have compositions and textures similar to the adjacent beaches and nearshore sediments from which they were derived. At several sites along the southern shore of Sri Lanka between Galle and Tangalla, there was very little sediment transported onshore. These sedimentological differences reflect the local influences that controlled the availability of sand and hydrodynamic characteristics of tsunami flooding.

At most tsunami impact sites in Sri Lanka, overland flow, sediment transport, and deposition were complicated so there is no simple direct correlation with the number of significant waves and the number of laminae sets or vertical textural trends in the deposits. Except for general spatial and textural trends such as landward thinning and upward fining, it does not appear that there are predictable geometric or textural patterns for these tsunami deposits.

Abstract: Tsunamis frequently leave a characteristic sediment deposit on the inundated land surface, which can be interpreted to deduce some of the features of the original tsunami wave. A simple trajectory-based theory of the tsunami hydrodynamics and sediment dynamics is presented here, yielding expressions for the landward variations in thickness and sediment composition of the deposit. Each grainsize contribution to the deposit thins linearly landwards, with the sediment run-up limit increasing with decreasing grainsize. The expressions can be fitted to observed sedimentary characteristics to deduce the run-up height and distance of the water. Example applications of the theory are given for the 1929 "Grand Banks" Tsunami, and the Holocene Storegga Slide Tsunami. Reconstruction of palaeo-tsunamis can help with assessments of present day risks from tsunamis.

INTRODUCTION

Evidence can be found at many locations around the world of thin layers of sand that are attributed to deposition by tsunamis. These have been observed after modern tsunamis, and can also be found in the recent geological record as evidence of tsunami inundation in the past. They typically run some 100s of metres inland of the (historic) shoreline and are up to some 10s of centimetres thick. Typically, they comprise a fine to medium sand with only small amounts of fine silt and clay, in a layer that thins from the shoreline landwards (e.g. Smith *et al.* 2004; Matsutomi *et al.*

2001; Dawson and Shi 2000; Moore 2001). Detailed grainsize analysis of vertically subdivided borehole samples generally reveals a pattern of landward fining, with upward fining in one or more sequences (Smith *et al.* 2004). Observations following modern tsunamis have shown that the height and landward extent of inundation by the water extend further than the limit of the sediment deposits (Tuttle et *al.* 2004) .

The aim of the present paper is to devise a simple mathematical model that contains the main physical (hydrodynamic and sediment dynamic) processes needed to predict the behaviour described above. The derived equations describing the characteristics of the sediment deposits are expressed in terms of the main descriptors of the coastal profile, the sediments and the tsunami hydrodynamics. Previous research workers have devised physics-based methods to re-construct the maximum inundation depths (Smith *et al.*, in press), maximum velocities (Jaffe and Gelfenbaum, in press), and characteristic velocities and depths together (Moore *et al.*, in press). The present approach extends these and other analyses (e.g. Matsutomi *et al.* 2001; Dawson and Shi 2000) by including a fuller description of the tsunami dynamics, while remaining mathematically tractable. A major motivation for this work is to facilitate re-construction of palaeo-tsunamis to assess the present-day risk of tsunamis at coastal sites, using the rationale outlined by Jaffe and Gelfenbaum (2002).

DERIVATION OF THEORY

Conceptual model

The scenario considered is sketched in Figure 1, which also shows the notation used. In order to keep the model mathematically tractable, a number of simplifying assumptions have been made. Everything is taken to be constant in the along-shore direction (1D assumption), and only the inundation flow onto and off the dry land is considered. The land surface is assumed to be plain and non-erodible, with a slope of 1:m. If R_z is the maximum run-up height of the water, then the maximum horizontal run-up distance is $R_w = mR_z$ from the still-water shoreline (SWL).

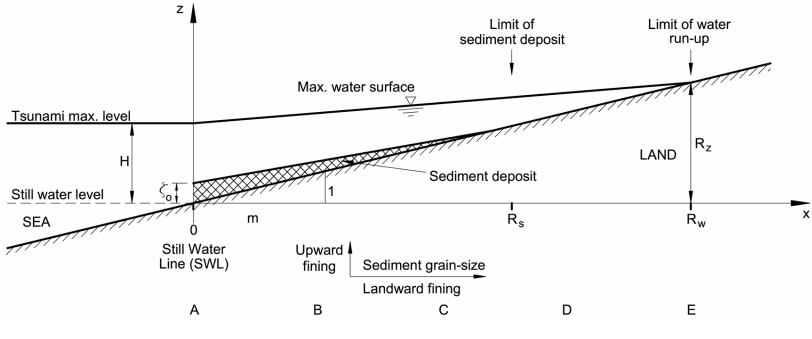

Fig. 1. Schematic of cross-section through land surface, with tsunami inundation and deposits. Snapshot at time $t = \gamma T$. ζ_o is deposit thickness at SWL.

Considering first the *hydrodynamics* of the tsunami wave, the maximum depth of inundation is assumed to decrease linearly with distance x from the SWL, from a depth H at $x = 0$ to zero at the maximum run-up point (Figure 1). The water depth $h(0,t)$ at the SWL (Point A in Figure 1) is assumed to increase with time linearly to H during the uprush ($0 < t < \gamma T$), then decrease linearly with time during the backwash ($\gamma T < t < T$), where T is the total time that the SWL is inundated (Figure 2a).

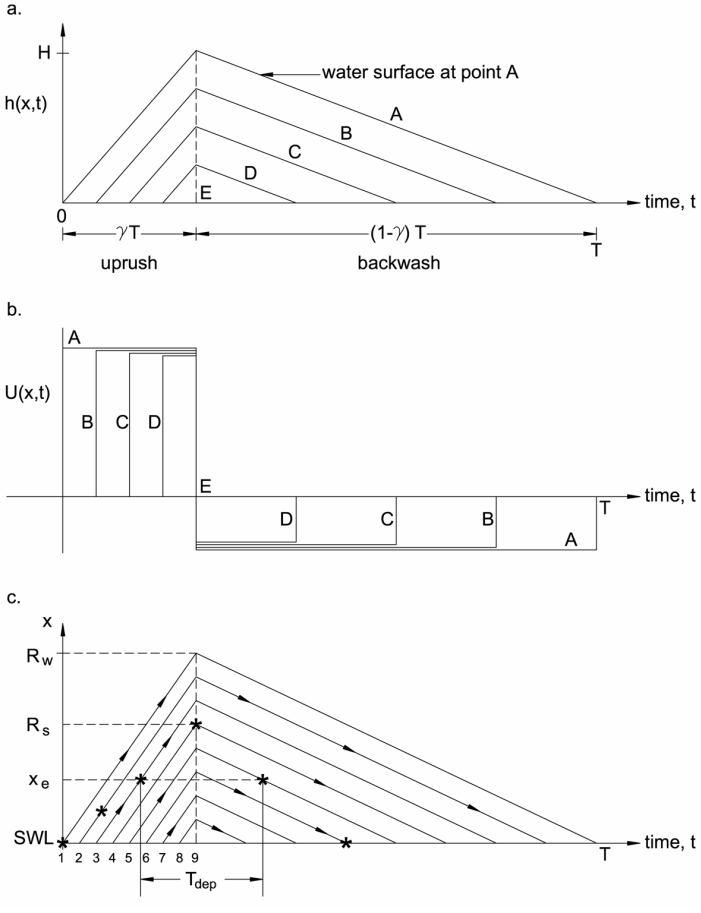

Fig. 2. Idealised tsunami characteristics for modelling purposes. (a) Depth variation with time at points A – E on Fig. 1. (b) Velocity variation with time at points A – E on Fig. 1. (c) Trajectories of water particles as distance (x) inland of SWL versus time for 9 different times of crossing the SWL. R_w and R_s are the horizontal run-up limits of water and sediment respectively, * marks points at which sediment deposition ceases for each trajectory, and T_{dep} is the duration over which sediment is deposited at example point x_e.

The time-variation of the water-level $h(x,t)$ at points between A and E also increases and decreases linearly with time, and the inundation durations decrease linearly with x from T at Point A to zero at Point E (Figure 2a). The time-lag between the time of maximum inundation at Point A and at the successive Points B to E is ignored, i.e. maximum water-level occurs everywhere at time $t = \gamma T$. Depth-averaged water velocities $U(x,t)$ are derived from the prescribed depths via the continuity equation (Figure 2b).

Next, considering the *sediment dynamics*, the wave is assumed to be heavily charged with suspended sediment eroded from the sea bed when it arrives at the SWL (Point A). The concentration (dry mass per unit volume) here is taken as constant (C_o) through the depth due to intense turbulent mixing, and constant in time over the uprush period $t = 0$ to γT during which sediment is advected onshore. Initially, the sediment is treated as having a single grain-size with settling velocity w_s. This is easily extended later to multiple grain-sizes. Judging from the observed thicknesses of deposits, the concentrations of suspended sediment must be very large (some 10s or 100s of kg/m^3), so that the downward settling flux $w_s C_o$ of sediment greatly outweighs the re-erosion flux. Accordingly, for the purpose of this simple model, the re-erosion flux is neglected. The settling is treated as if the sediment was in a moving settling column, i.e. the settling flux is given by a constant value of $w_s C_o$ until all the sediment in that water column has been deposited. This ignores the re-distribution of sediment vertically by turbulence. The thickness of the sediment deposit is assumed to be much thinner than the inundation depth, so that the changing bed elevation during the inundation does not significantly affect the hydrodynamics.

Mathematical model

A brief summary of the derivation of the model is presented here. The full mathematical derivation is available from the first author on request. Following Borthwick *et al.* (2005), the continuity equation is expressed in the form:

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} = 0 \tag{1}$$

where the volumetric flux q of water (per unit shore-wise width) is given by: $q = Uh$ and q, U and h are all functions of x and t. From the prescribed form of depth time-series shown in Figure 2a, it can be seen that $\partial h/\partial t$ is a positive constant during the period $t = 0$ to γT, and a negative constant during the period $t = \gamma T$ to T. Solution of Eq. 1 during the uprush phase leads to a velocity that is constant in time and space (Figure 2b):

$$U_{up} = \frac{R_w}{\gamma T} \tag{2}$$

Likewise, during the backwash phase the velocity is also constant:

$$U_{back} = -\frac{R_w}{(1-\gamma)T} \tag{3}$$

Consider the nine trajectories of water particles shown in Figure 2c. Because of the assumptions made, the water depth remains constant along any trajectory. Thus

trajectory 1 is the locus of the wetting and drying line, has depth $h(x,t) = 0$, and reaches inland to the run-up limit R_w. Trajectory 3 starts at time $t = \gamma T/4$, has depth $h(x,t) = H/4$, and reaches inland to $x = (3/4)\,R_w$. Trajectories 5 and 7 have depths $H/2$ and $3H/4$, and reach inland distances $x = R_w/2$ and $R_w/4$ respectively. Trajectory 9 has a depth H, but because it starts (and finishes) at time $t = \gamma T$, it does not travel inland at all.

Applying the assumption that the sediment settles as it would in a settling column, the time taken for all the initially-suspended sediment to settle onto the bed, with settling velocity w_s, is h/w_s. Thus trajectories with greater depths will deposit sediment for longer times. Conversely, as seen above, these trajectories are also the ones with the shorter durations (from crossing the SWL on the uprush to re-crossing it on the backwash), and have the shorter penetrations inland. In Figure 2c, the point at which all the suspended sediment has been deposited is marked * on each trajectory. Trajectory 1 has zero depth, so all sediment is dropped immediately. Trajectories 2 and 3 have progressively greater depths, and complete the deposition at progressively later times and further distances inland. Trajectory 4 just completes its deposition at time $t = \gamma T$, when its distance inland is a maximum and it is about to return with the backwash. This distance, denoted R_s, is the maximum run-up distance for sediment deposition. Trajectories 5 and 6 are sufficiently deep that sediment is not only deposited during the uprush, but also through part of the backwash. Trajectory 6 just completes its deposition by the time it returns to the SWL. Trajectories 7 and 8 deposit sediment through their entire uprush and backwash journeys and carry some sediment back out to sea. Trajectory 9 does not carry sediment onto the land.

Now consider an arbitrary fixed point x_e on the land surface (see Figure 2c). No sediment arrives at point $x = x_e$ until trajectory 3 arrives. All the subsequent trajectories deposit sediment at $x = x_e$ until trajectory 5, which completes deposition on the backwash at $x = x_e$. Trajectory 6 deposits sediment briefly at $x = x_e$, but trajectories 7 and 8 do not even reach $x = x_e$. The time during which sediment is deposited T_{dep} extends from the time trajectory 3 reaches x_e on the uprush to the time trajectory 5 reaches x_e on the backwash. Moreover, with the settling column assumption, the rate of deposition during this time is constant $= w_s C_0$, so that the total mass of sediment deposited at point $x = x_e$ throughout the inundation is $w_s C_0 T_{dep}$. This applies to all points x_e between $x = 0$ and R_s, with T_{dep} decreasing landwards.

The run-up distance for sediment, R_s, can be related to the run-up distance for water, R_w (Figure 1), as follows. Suppose that trajectory i (which crosses the SWL at time $t = t_i$) is the one that just completes deposition at the time of velocity reversal, $t = \gamma T$ (marked as trajectory 4 on Figure 2c). Because depth at the SWL ($x = 0$) increases linearly with time during the uprush, the depth of this trajectory is:

$$h_i = \frac{t_i}{\gamma T} \cdot H \tag{4}$$

The time during which the trajectory is moving landwards is $(\gamma T - t_i)$, and this is equal to the time taken to deposit all the sediment, h_i/w_s. Thus:

$$\gamma T - t_i = \frac{h_j}{w_s} \tag{5}$$

Since the velocity on the uprush is given by Eq 2, the maximum distance R_s inland that sediment is deposited is (making use of Eqs. 2, 4 and 5):

$$\begin{aligned} R_s &= U_{up}\left(\gamma T - t_i\right) \\ &= R_w \cdot \frac{1}{w_s \gamma T / H + 1} \end{aligned} \tag{6}$$

For convenience, write $\alpha = \frac{w_s T}{H}$. Then the run-up of sediment R_s is related to the run-up of water R_w by the relationship

$$R_s = \frac{R_w}{1+\alpha\gamma} \tag{7}$$

Now calculate the thickness, ζ_o, of sediment deposited at the SWL ($x = 0$). Consulting Figure 2c, sediment starts to be deposited at $x = 0$ by trajectory 1, and finishes depositing at the end of trajectory 6. Denote this final depositing trajectory as trajectory j, which crosses the SWL on the uprush at time $t = t_j$, and reaches the SWL again on the backwash at time $t = t_k$. The trajectory has a depth h_j, and hence deposits all its sediment in a time h_j/w_s which is equal to the duration ($t_k - t_j$) of the trajectory. Thus:

$$t_k - t_j = \frac{h_j}{w_s} \tag{8}$$

The depth is given by (see Eq 4)

$$h_j = \frac{t_j}{\gamma T} \cdot H \tag{9}$$

and t_k is related to t_j by the respective velocities of uprush and backwash. The distance travelled inland is equal to U_{up} ($\gamma T - t_j$) on the uprush, and distance travelled back to the SWL is equal to $|U_{back}|$ ($t_k - \gamma T$) on the backwash. Equating these, and making use of Eqs 2, 3, 8 and 9 leads to:

$$\begin{aligned} t_k &= T - \frac{(1-\gamma)}{\gamma} \cdot \frac{\alpha\gamma T}{1+\alpha} \\ &= T \cdot \left[\frac{1+\alpha\gamma}{1+\alpha}\right] \end{aligned} \tag{10}$$

This gives the time $T_{dep,0} = t_k$ during which sediment is deposited at $x = 0$. Since sediment is deposited continuously at the rate $C_0 w_s$ through time $T_{dep,0}$, the mass deposited per unit area of bed at $x = 0$ is $C_0 w_s T_{dep,0}$. If the (dry) bulk density of the deposited sediment is ρ_B, where a typical value is $\rho_B = 1600\text{kg/m}^3$, the thickness deposited, ζ_o, is (using Eq. 10)

$$\zeta_o = \frac{C_0 w_s T}{\rho_B (1+\alpha)}(1+\alpha\gamma) \tag{11}$$

and, since $w_s T = \alpha H$,

$$\zeta_o = \frac{\alpha(1+\alpha\gamma)}{1+\alpha} \cdot \left(\frac{C_0}{\rho_B}\right) \cdot H \tag{12}$$

A full mathematical analysis following the same principles outlined above, and extended to all points inland, gives the distribution of the thickness $\zeta(x)$ deposited decreasing with distance x inland of the SWL according to the linear relationship:

$$\zeta(x) = \zeta_0\left(1 - \frac{x}{R_s}\right) \quad \text{for } x \le R_s, \text{ and 0 for } x > R_s \tag{13}$$

where ζ_o is given by Eq (12), R_s is given by Eq (7), and $\alpha = \frac{w_s T}{H}$.

Interpretation

The analysis given above enables the distribution of the thickness of sediment deposit, $\zeta(x)$, left by a single tsunami wave to be predicted for a wave of maximum height H at the SWL, with a period T from the time of first wetting to final drying at the SWL, in which the uprush occurs during a fraction γ of that period.

The deposit has a maximum thickness ζ_o occurring at the SWL, given by Eq 12. For a very fine-grained sediment (clay or fine silt), w_s is very small so α is very small and ζ_o tends to zero. Thus very fine sediments are hardly deposited at all, because they stay in suspension throughout the inundation. For coarser-grained sediment (coarse silt or sand), w_s is larger so α is larger, and the thickness ζ_o increases with grain-size (for a given concentration C_0). The thickness of the deposit is proportional to the concentration of suspended sediment just offshore of the SWL, and increases with the proportion γ of time occupied by the uprush. For very coarse-grained sediment, α is large and ζ_o tends to a value of $\alpha\gamma C_0 H/\rho_B = w_s(\gamma T)(C_0/\rho_B)$; in other words, all the suspended sediment is deposited during the uprush (γT) near the SWL.

The thickness of deposit tapers inland linearly with distance (x) from the SWL, as given by Eq 13, up to the sediment run-up distance R_s. Beyond this, no sediment is deposited, even though the water runs up further, to a distance R_w. R_s is smaller than R_w by a factor $(1+\alpha\gamma)$ as given by Eq 7. Thus, for a given γ, the larger that α is (coarse sediments), the shorter the sediment run-up. Very fine sediments will extend almost to the limit of water run-up, but gravel and coarse sand will be deposited closer to the SWL. For a given sediment size, the run-up distance R_s decreases as the proportion γ of time occupied by the uprush increases.

Mixed sediments

If interactions between different grain-sizes of a mixed sediment are ignored, Eqs 13, 7 and 12 can be applied separately to different grain-size fractions. Each fraction (subscript n) will have a characteristic settling velocity w_{sn} and characteristic value of α_n (for a tsunami of given H and T), and will have a concentration C_{on} just offshore of the SWL.

As an illustration, consider the case of a tsunami with a wave height of $H = 5$m, period $T = 10$ minutes, and uprush occupying 2.5 minutes ($\gamma = 0.25$), striking a coast that has a slope of 1:m = 1:30. The wave has entrained sediment characterised as follows into three grain-size fractions, each having a concentration of 20kg/m^3 (total concentration = 60kg/m^3). The fractions are, using subscripts $n = 1, 2, 3$:
Finest 1/3, represented by $d_{16} = 0.1$mm, with $w_{s1} = 0.006$m/s and $C_{01} = 20$kg/m^3
Middle 1/3, represented by $d_{50} = 0.2$mm, with $w_{s2} = 0.02$m/s and $C_{02} = 20$kg/m^3
Coarsest 1/3, represented by $d_{84} = 0.4$mm, with $w_{s3} = 0.053$m/s and $C_{03} = 20$kg/m^3

Suppose that the run-up height of the water is $R_z = 8$m, so that the run-up distance is $R_w = 8 \times 30 = 240$m. Using Eqs (12) and (7) for each fraction:

Fine sediment: $\alpha_1 = \dfrac{0.006 \times 10 \times 60}{5} = 0.72,\ \zeta_{01} = 0.031m,\ R_{s1} = 203m$

Medium sediment: $\alpha_2 = \dfrac{0.02 \times 10 \times 60}{5} = 2.4,\ \zeta_{02} = 0.071m,\ R_{s2} = 150m$

Coarse sediment: $\alpha_3 = \dfrac{0.053 \times 10 \times 60}{5} = 6.4,\ \zeta_{03} = 0.140m,\ R_{s3} = 93m$

When the three fractions are added together, it is seen that they form a landward-fining sequence. In addition, since the coarse fraction is deposited first, and the fine fraction last, at any point, they will form an upward fining sequence. The composition of each upward fining sequence could be calculated by an extension of the mathematical analysis that would give the time-sequence of deposition for each fraction at each point.

APPLICATION 1: THE 1929 "GRAND BANKS" TSUNAMI

On November 18th, 1929, a magnitude $M_s = 7.2$ earthquake on the Grand Banks south of Newfoundland triggered an offshore landslide that developed into a turbidity current moving down the Continental Slope and out onto the Abyssal Plain, cutting twelve trans-Atlantic telegraph cables. The resulting tsunami was observed from Newfoundland to the Caribbean, being felt most strongly on the south coast of the Burin Peninsula, southern Newfoundland. The tsunami run-up rose to 13m above the normal tide level in St. Lawrence, and to about 10m at Taylor's Bay, both south-facing bays. Widespread devastation took place on the Burin Peninsula and 28 persons lost their lives (Tuttle *et al.* 2004, Ruffman and Hann 2006).

The site from which the samples analysed in this paper were obtained is at Taylor's Bay, on the south side of the Burin Peninsula (Figure 3). At Taylor's Bay, a sand and gravel barrier circa 200m long encloses a small lagoon, landward of which an area of low-lying, largely peat-covered land, up to 20m above local datum, widens to nearly 1km behind the lagoon, then progressively narrows for circa 500m inland. The site is of particular interest for studying the effects of the tsunami because there are records of the arrival of the waves across the barrier and into the low-lying area and of the destruction caused, so that there is anecdotal evidence of the anatomy of the event (Tuttle *et al.* 2004). However, the particular value of the site lies in the extensive deposit of sand which was deposited by the tsunami and which is found a few cm

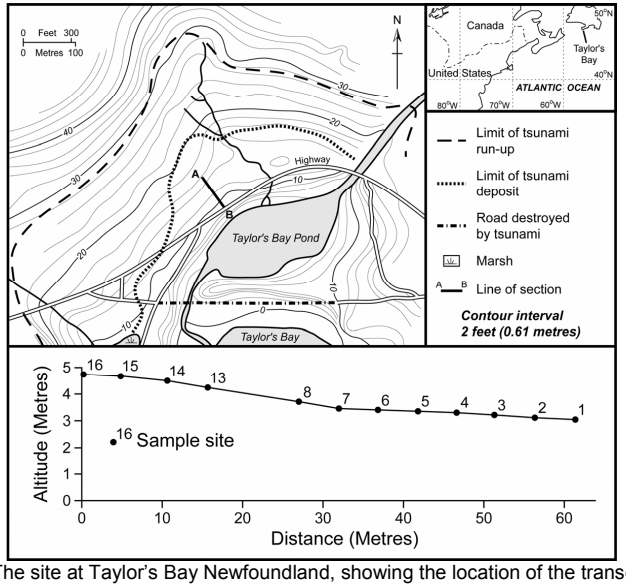

Fig. 3. The site at Taylor's Bay Newfoundland, showing the location of the transect from which samples were taken, together with the possible limits of tsunami run-up and deposit. Based partly on Tuttle *et al*.. 2004.

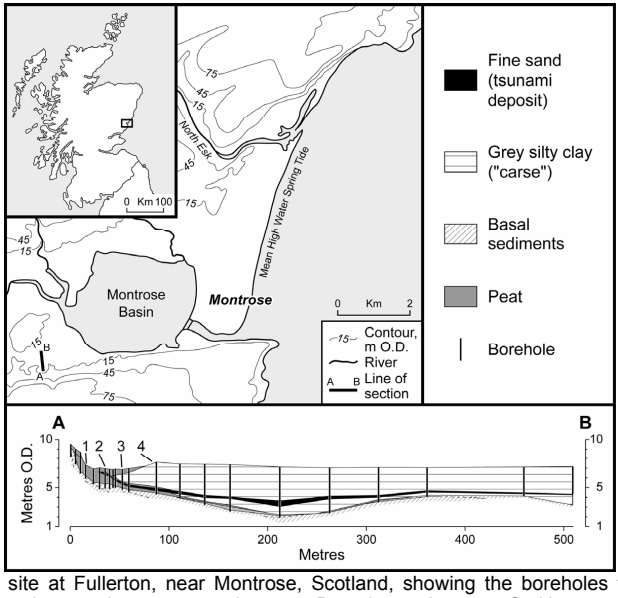

Fig. 4 The site at Fullerton, near Montrose, Scotland, showing the boreholes from which tsunami sand samples were taken. Based partly on Smith *et al*.. 2004.

beneath the surface of the peat. In recent work Moore *et al.* (in press) showed that the layer becomes thinner and fines landwards in general terms.

Monoliths from the peat containing the sand layer were taken at 5-10m intervals from the lagoon to the inland limit of the deposit (Figure 3). The location of each monolith was surveyed and its altitude levelled to local datum. On return to the laboratory, the sand layer at each monolith was sampled in contiguous 1cm slices and these samples analysed using a Malvern 2000 Mastersizer laser granulometer. Analyses involved pre-treatment using an acid digest to remove all organic matter, following the approach of Smith *et al.* (2004). The samples were obtained in August 1995 with the assistance of the Ottawa office of the Geological Survey of Canada and Erik Nielsen of Winnipeg, and analysed at Brighton University by Professor Callum Firth courtesy of Geomarine Associates Ltd.

Application of theory

The theoretical analysis can be applied to the twelve monolith samples taken along the shore-normal transect shown in Figure 3. The aim is to predict the water run-up distance from the observed sediment depositional characteristics. The SWL is taken as the shore of Taylor's Pond from extension of the line of section. The gradient of the land over this region increases landwards, with a mean gradient of about 1:22.

The Malvern granulometer gave results from each 1cm slice from each monolith as percentages of the total mass of sediment found in each of five grain-size fractions. The grain-size fractions with the largest masses of sediment were found to be those for 500-2000μm, 177-500μm, and 44-177μm, and these were chosen for the theoretical treatment. The percentages in all the slices for each monolith for a given grain-size fraction were summed, to give the percentage of sediment at that location attributable to that fraction. This was converted to give the contributions from each fraction to the thickness of deposit at that location. These are plotted for each of the three fractions and for the twelve locations in Figure 5a. Despite some scatter, due presumably to topographic features, it is seen that the thickness of each fractional deposit thins landwards. Linear trends have been fitted by least-squares regressions. From the trend-lines, the coarsest fraction (500-2000μm) has a thickness at the SWL of 3.4cm and a run-up distance of 115m. The corresponding figures for the medium fraction (177-500μm) are 4.1cm and 130m, and for the finest fraction (44-177μm) are 0.7cm and 166m. Thus, the run-up distances of the sediments (from the trend-lines) are greater for the finer sediments as predicted by the theory.

The settling velocities of the median diameters of each fraction (1000, 297, 88μm) are 0.114, 0.0368 and 0.00442 m/s for the coarse, medium and fine fractions respectively, using the formula of Soulsby (1997, Eq. 102) and assuming sea-water at 10°C and 35ppt with sediment density of 2650kg/m^3. Eq 7 can be applied to each fraction, yielding three equations in two unknowns, namely R_w and the quantity $B = \gamma T/H$ (with dimensions of inverse velocity), since the three values of R_s and w_s are known. A fitting procedure leads to an optimum value of B = 4.2s/m and R_w = 163m. The predicted run-up height is thus 163/22 = 7.4m above the local datum

(estimated tide level at the time of the tsunami). This compares with an observed run-up height from direct observations at the time of the tsunami of about 8.8m at this location (Tuttle *et al.* 2004) as seen in Figure 3.

APPLICATION 2: THE HOLOCENE STOREGGA SLIDE TSUNAMI

The Holocene Storegga Slide tsunami occurred around 8000 sidereal years BP. It is believed to have been generated by submarine sliding on the Continental Shelf and slope off South West Norway. The cause of the slide is unknown, but could have been due to crustal movement at the close of the last glaciation as Scandinavia became relieved of its ice burden (e.g. Smith *et al.* 2004).

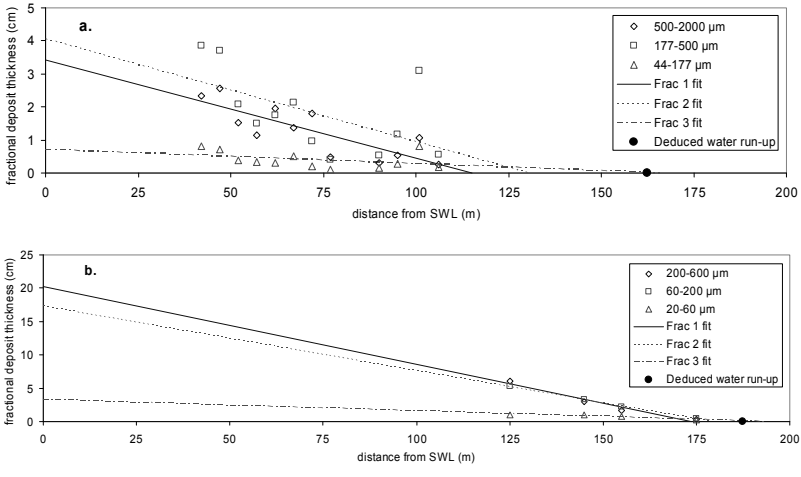

Fig. 5. Observed landwards variation of fractional deposit thickness, and fitted lines, for three grainsize fractions from (a) Taylor's Bay, Newfoundland, (b) Fullerton, Scotland.

The effect of the slide was to generate tsunami waves which inundated coastal areas as far apart as Iceland, the Faeroes, much of the Norwegian west coast, Scotland and northern England. At the time, sea surface levels lay up to 15m lower in the area (e.g. Mörner, 1980), but because of differential crustal depression following glaciation, relative sea levels across the coastlines involved were variable. The tsunami deposited in particular a distinctive layer of sand, normally less than 0.5m thick, across coastal peat, mudflat and saltmarsh. Subsequently, the layer was buried beneath later deposits of peat and coastal sediments. The layer is best preserved in former coastal inlets, usually gullies and small estuaries.

The sand layer at all sites was identified and sampled from shallow boreholes, using hand operated coring equipment. On return to the laboratory, contiguous 1cm samples were prepared for particle size analysis by removing all organic matter. Analysis was undertaken in a previous study by Shi (1995) using a Malvern 2600 laser granulometer as detailed by Smith *et al.* (2004).

The site used for this application is Fullerton (Figure 4), which lies at the western edge of the Montrose Basin, where a gully circa 1km long occurs in Late Glacial raised coastal terraces, to seaward of which raised Holocene estuarine sediments form an extensive surface. The tsunami sand layer can be traced along the gully and across its axis, and the sand has been analysed in four boreholes at the southern and of the transect. Two upward-fining sequences can be distinguished, but only the upper one is used in the present analysis as it is better defined. The site was described in Smith *et al.* (2004).

Application of theory

The theoretical analysis of the Fullerton section followed the same approach as for the Newfoundland example. Here, there were only four boreholes available. The origin of the *x*-coordinate (SWL) was taken at the lowest point on the section of the base of the sand layer, at about 210m on the section in Figure 4 where the elevation is 3.0mOD. The mean gradient of the land is about 1:30. The three grain-size fractions used in the analysis were 200-600μm, 60-200μm and 20-60μm. Roughly 10% of the sediments were finer than 20μm, but these were not used in the analysis. The thicknesses at the SWL, and the sediment run-up distances, taken from fitted lines (Figure 5b) for the coarse, medium and fine grain-size fractions were 20.3cm and 174m, 17.3cm and 179m, and 3.3cm and 194m respectively. The calculated settling velocities were 0.0447, 0.00682 and 0.000709m/s. The optimum values from the fitting procedure were B = 2.6s/m and R_w = 188m. The predicted run-up height is thus 188/30 = 6.3m above the assumed SWL, giving a total run-up height of 9.3mOD. In this case, there are no observations of water run-up, and the theory provides an estimate for an otherwise unknown quantity.

DISCUSSION

It is seen in both applications that the predicted run-up limit of the water is roughly equal to the projected limit of the finest sediment fraction. This is because the theory essentially equates the water run-up to the run-up of sediment with zero settling velocity, and the settling velocities of the finest sediments in both applications are very small. At Taylor's Bay, the observed water run-up height (about 8.8m) is rather larger than the predicted value (7.4m). This might be due to the simplifying assumption of no re-erosion of sediments in the theory, whereas in reality a thin layer of fine sediment deposited by the uprush could be eroded during the backwash.

Other departures of the idealised theory from the field situation include: (a) the actual topography is much more complex (gullies, ponds, ridges, vegetation) than the assumed smooth plane of constant slope, (b) laboratory experiments (O'Donoghue *et al.*, in press) show that the depth and velocity of a wave running up a sloping beach exhibit roughly parabolic and saw-tooth time-variations respectively, instead of the linear and constant time-variations respectively used in the simple theory, (c) the settling-column assumption for the sediments is an over-simplification. In practice, the sediment responds to a balance of erosion, deposition and diffusion processes.

In principle, a more sophisticated fitting technique between the theory and the data could be used. This could include the vertical grain-size variations, and might allow other tsunami characteristics such as wave height and period, water velocities, and suspended sediment concentrations to be deduced. However, the value of performing such a fitting would depend on how closely the idealisations of the theory conform to the geographical realities of individual sites.

The best way to overcome the deficiencies of the simple model would be to add sediment dynamics to a detailed numerical model of the tsunami hydrodynamics such as those of Borthwick *et al.* (2005) and O'Donoghue *et al.* (in press). This could model the two-dimensional flow patterns around complex topography, as well as the offshore sediment erosion, and the transport, deposition, re-erosion, convergence and divergence of sediment transport onshore. Optimisation of the input parameters such as height and period of the offshore wave could be performed to give a least-squares fit to the observed sediment thicknesses and grain-size compositions to achieve a full re-construction of depths, velocities and durations at all inundated points. More realistic tsunami inputs, such as multiple interacting waves, could also be modelled.

CONCLUSIONS

This analysis yields an equation for the maximum sediment run-up distance (R_s) in terms of the water run-up distance (R_w), and two additional parameters $\alpha = \frac{w_s T}{H}$, and γ = ratio (duration of uprush)/(duration of backwash) at the SWL. Here H is the height of the tsunami wave, and T the duration of inundation, at the SWL. A second equation gives the maximum deposit thickness (at the SWL) ζ_o in terms of α, γ, H, C_0 and the bulk density of the deposited sediment. The derived variation in thickness of the sediment deposit is found to decrease linearly with landward distance, from ζ_o at the SWL to zero at distance R_s. Applying the model with a range of grainsizes yields the following features, which agree with observations:

- The thickness of the deposit decreases uniformly with distance from the SWL
- The limit of the sediment deposit falls well short of the water run-up limit
- The landward extent of the sediment deposit increases with decreasing grain-size, so that the net result is a landward fining of the sediment
- Very coarse sediments are all deposited close to the SWL.
- Very fine sediments are almost entirely swept back out to sea
- Because of differential settling velocities, an upward fining sequence is formed
- Successive tsunami waves can give rise to multiple upward fining sequences

The theory has been applied to sediment samples from Newfoundland deposited by the 1929 "Grand Banks" tsunami, where the water run-up distance and height are known from observations at the time. Reasonably good agreement between predicted and observed run-up were found. The method has also been applied to sediment deposits in Scotland resulting from the Holocene Storegga Slide tsunami to deduce the water run-up distance and height, which in this case are not known. Thus

here the new method allows additional information to be deduced from the sediment deposits.

Abstract: In numerical simulation of tsunami, the changing topography must be taken into account for some specific problems such as run-up over coastal dunes. In this paper, a numerical model for tsunami flooding over movable topography is presented. The model is based on the Boussinesq-type equation coupled with the sediment advection equation and existing empirical formulas for sediment transport. Laboratory experiment is conducted for the model verification on fixed bed, while its performance on movable bed is examined through comparison with available data. Finally, the dune erosion induced by tsunami is discussed on the basis of the model results.

INTRODUCTION

Coastal dunes are natural bedforms caused by wind and wave motions. They run parallel to the shoreline close to the beach and thus have an important role to protect land against potential ravages by storm waves or tsunami. A typical case was observed by authors in Hambantota, a city located in south coast of Sri Lanka, after the December 2004 Indian Ocean Tsunami. East part of the city has large-scale dunes along shoreline and hence suffered minor damages due to tsunami flooding. On the other hand, other part of the city without dunes or with small-scale dunes experienced serious damages. Since dunes undoubtedly reflect large part of flow energy, it is

essentially important to evaluate such protective effects against severe external forces such as tsunami.

Although numerous computational studies have been carried out on Tsunami flooding, only little studies focused especially on the tsunami hydraulics around dunes. The main difficulty in numerically solving the transient flow may be treatments of discontinuous phenomena such as breaking or hydraulic jump. In addition to the complexity of the flows, dry/wet boundary must be considered, which is usually troublesome. Conventionally empirical formulas are employed on an ad-hoc basis to overcome those difficulties. However such an approach may fail or degrade the accuracy due to arbitral choice of associated parameters.

In recent years, Shock Capturing Schemes have been widely used to solve hyperbolic problems. The schemes were first derived for scalar convection equation and then generalized for system equations by a technique known as approximate Riemann solver (Roe 1981). They are explicit schemes with conservative and shock capturing properties and higher order accuracy can be attained by giving the numerical dissipation required to maintain monotonicity of the solution. In the field of hydraulic engineering, the employment of the schemes to nonliner shallow water equation has become very popular especially in transient flow problems such as Dam break flow (Zoppu and Roberts 2002) or swash zone hydrodynamics (Brocchini 2001). In most cases the results show better agreements with experiments than those of conventional schemes.

Another important feature is that dunes are highly erodible under huge momentum of tsunami rushing from sea. If some part of dunes were washed out at initial stage of flooding, the ability of dune to reflect tsunami would become considerably small. The flow-induced sediment transport and the morphological change must be taken into account to accurately predict the flow rate over dunes. However, little is known about sediment transport induced tsunami partly because real-time field measurements are impossible. Moreover, only few data are available in physical experiments with limited spatial scales (Kobayashi and Lawrence 2004).

The objective of the present study is to develop a numerical model which can simulate tsunami flooding over erodible sand dunes and to investigate the ability to protect land from inundation via application of the model. The model is based on 1D Boussinesq-type equation coupled with sediment advection equation. Existing formulas for sediments exchange through bottom boundary are used for model closure. TVD-MacCormack Scheme(Vincent et al. 2001), which is classified as Shock Capturing Schemes, is employed with Roe's approximate Riemann solver to integrate the governing equations. The model performance on fixed bed is verified through comparison of the results with available data obtained in physical experiments carried out in the present study. For the case of movable bed, the model results are compared with data of Kobayashi(2004)

The paper starts with a description of numerical model. This is followed by a verification of the model. Finaly the protective effect of dune against Tsunami flooding is discussed on the basis of model results. The paper ends with some conclusions and brief remarks on future work.

MODEL DEVELOPEMENT

Nonlinear shallow water equation is used in many literatures for the simulation of tsunami on the assumption of hydrostatic pressure. Another equation widely used in coastal engineering is Boussinesq-type equation which accounts for dispersion effects due to non-hydrostatic pressure. Since dispersion term has an role of anti-steepeing, simulation based on NSWEs predicts wave breaking far offshore. In addition, the present target is flow around dune with steep slope so that vertical acceleration can not be negligible. For this reason, Boussinesq-type equations are employed in the present study.

Sediment transport is modeled on the basis of advection equation with bottom boundary condition specified by a balance of upward and downward sediment flux. Horizontal diffusion term is not explicitly introduced since the equation is integrated with Shock Capturing Scheme, in which numerical diffusion is automatically given to preserve monotonous distribution of sediments in horizontal direction. For the upward flux, which is entrainment of sediment from bed layer, total-load sediment is computed with a single formula.

Mass conservation equation of water and sediments must be fully coupled since time-scale of the bed level change is not smaller than that of water surface. Thus, at every time step, bed level change is considered in the calculation of the flow. Although the effects of horizontally varying concentration and momentum transfer due to sediment exchange are also significant in the simulation of highly concentrated flow(Cao et al. 2004), they are not taken into account here.

Governing Equations

Governing equations described above can be written as

$$\frac{\partial(h)}{\partial t}+\frac{\partial(uh)}{\partial x}=-\frac{\partial z}{\partial t} \tag{1}$$

$$\frac{\partial(hu)}{\partial t}+\frac{\partial}{\partial x}(hu^2+\frac{1}{2}gh^2)=-gh(\frac{\partial z}{\partial x}+s_f)+S_d \tag{2}$$

$$\frac{\partial(hc)}{\partial t}+\frac{\partial(huc)}{\partial x}=E-D \tag{3}$$

$$\frac{\partial z}{\partial t} = \frac{D - E}{1 - p} \tag{4}$$

where x = cross-shore coordinate positive in the seaward direction; h = total depth; u = depth averaged velocity; z = bed level; c = depth averaged sediment concentration; E = entrainment of sediment from bed layer; D =deposition flux of sediment; g = gravitational acceleration; s_f = friction slope; S_d = wave dispersion due to non-hydrostatic pressure; and p = prosity of bed material.

There are various formulations for the dispersion term S_d . In the present study, nonlinear dispersiton term derived for the large Ursell number is considered.

$$S_d = \frac{\partial}{\partial x}(\frac{h^3}{3}P_1 - \frac{h^2}{2}P_2) + \frac{\partial z}{\partial x}(\frac{h^3}{2}P_1 - hP_2) \tag{5}$$

where

$$P_1 = \frac{\partial^2 u}{\partial x \partial t} + u\frac{\partial^2 u}{\partial x^2} + (\frac{\partial u}{\partial x})^2 \tag{6}$$

$$P_1 = \frac{\partial z}{\partial t}\frac{\partial u}{\partial x} + \frac{\partial}{\partial t}(u\frac{\partial z}{\partial x}) + u\frac{\partial h}{\partial x}\frac{\partial u}{\partial x} + u^2\frac{\partial^2 h}{\partial x^2} \tag{7}$$

The dispersion term is identical to that of Peregrine(1967) if higher order terms of u are neglected from (6) and (7).

Model Closure

Empirical formulations of friction force and sediment exchange through bed are required for model closure. For the friction slope, conventional formulation is used,

$$s_f = \frac{n^2}{h^{4/3}}u\sqrt{u^2} \tag{8}$$

where n= the Manning roughness.

The entrainment of sediment from bed layer is calculated using total-load formula of Engelund and Hansen(1967),

$$E = 0.05\frac{u^2}{h}\left(\frac{\rho d}{(\rho_s - \rho)g}\right)^{1/2}\left(\frac{\tau_{be}}{(\rho_s - \rho)gd}\right)^{5/2} \tag{9}$$

where ρ = density of water; ρ = density of sediment; d= grain size and τ_{be} = effective bottom shear stress. To account for gravity effect due to bed slope, streamwise component of gravitational force is added to bottom shear stress by Wu(2004)'s method,

$$\tau_{be} = \tau_b + \lambda \tau_c \frac{\sin\theta}{\sin\beta} \tag{10}$$

where τ_b = bottom shear stress; τ_c = critical shear stress; θ = the bed angle with the horizontal; β = repose angle; λ = coefficient related with flow and sediment condition as well as bottom slope.

The deposition flux is evaluated with a general expression

$$D = w_s c_a = w_s \alpha c \tag{11}$$

where w_s = settling velocity of sediment; c_a =sediment concentration nearbed; α = the adaptation coefficient. For α, different values are used by many researchers. In the present study, α =2 is selected following Cao et al.(2004).

Numerical Scheme

Governing Equations are solved by a finite difference scheme with shock capturing property. TVD-McCormack (Vincent 2001) scheme is employed in the present study. The scheme is flux limited version of MacCormack scheme which has been widely used for hyperbolic equations. Non-physical oscillation associated with the classical MacCormack scheme is suppressed by correcting the flux to satisfy TVD (Harten 1983) condition. The reason for choosing this scheme is its superiority to keep the integration of source term in second order not like in other schemes. To describe the numerical scheme, governing equations are rewritten as follows

$$\frac{\partial Q}{\partial t} + \frac{\partial F}{\partial x} = S_1 + S_2 \tag{12}$$

$$Q = \begin{bmatrix} h \\ hu \\ hc \end{bmatrix} \tag{13}$$

$$F = \begin{bmatrix} hu \\ hu^2 + \frac{1}{2} g h^2 \\ huc \end{bmatrix} \tag{14}$$

$$S_1 = \begin{bmatrix} (D-E)/(1-p) \\ -gh(s_0 + s_f) \\ E - D \end{bmatrix} \tag{15}$$

$$S_2 = \begin{bmatrix} 0 \\ S_d \\ 0 \end{bmatrix} \tag{16}$$

The present numerical integration process can be divided into three steps.

Predictor Step

$$Q_i^p = Q_i^p - \frac{\Delta t}{\Delta x}(F_{i+1}^n - F_i^n) + \Delta t S_{1,i}^n \tag{17}$$

$$z_i^p = z_i^n + \Delta t \frac{D_i^n - E_i^n}{1-p} \tag{18}$$

Corrector Step

$$Q_i^c = Q_i^n - \frac{\Delta t}{\Delta x}(F_i^p - F_{i-1}^p) + \Delta t S_{1,i}^p \tag{19}$$

$$z_i^c = z_i^n + \Delta t \frac{D_i^p - E_i^p}{1-p} \tag{20}$$

TVD Step

$$Q_i^{n+1} = \frac{1}{2}(Q_i^p + Q_i^c) - \frac{\Delta t}{\Delta x}(F^T_{i+\frac{1}{2}} - F^T_{i-\frac{1}{2}}) + \Delta t S_{2,i}^n \tag{21}$$

$$z_i^{n+1} = \frac{1}{2}(z_i^p + z_i^c) \tag{22}$$

where F^T is correction flux. The predictor and the corrector steps are fully explicit, while TVD step should be implicit because the integration of the dispersion term ,which contains time derivatives of the variables, is included. If the bed level z and water depth h at new time step are approximated as solutions of the predictor and corrector step, (21) become tridiagonal about velocity u so that Thomas argorithm can be applied. If long propagation of wave is concerned, integration of the dispersion term should be improved.

The correction flux F^T is calculated by the conservative flux of the first order upwind scheme and second order lax-wendroff scheme as follows

$$F^T_{i+\frac{1}{2}} = (1-\Phi)(F^{UP}_{i+\frac{1}{2}} - F^{LW}_{i+\frac{1}{2}}) \tag{21}$$

where Φ is the flux limiter function which ensure the scheme is total variation diminishing (TVD). As solution become discontinuous, Φ approaches to zero so that numerical dissipation associated with the first order upwind scheme is introduced to eliminate spurious oscillation. F^T can be evaluated by using Roe's apporoximate

Riemann solver. The detailed description of how to calculate F^T is available in many literatures. (Vincent et al. 2001).

MODEL VERIFICATIONS ON FIXED BED

Laboratory experiments were performed in a wave flume with 30cm width, 80cm height and 30m length to obtain data for verification of the present model on fixed bed. As shown in Fig 1, the flume has a piston-type wavemaker at one end and constant slope of 1/30 at the other end. Water depth in flat bottom region is 20.0 cm. The toe of sloping beach is located 13m from wavemaker and sloping beach has length of 600cm to shoreline. The experiment conditions are shown in Table1. In case of U1, U2 and U3, solitary waves with different wave height are generated to observe wave run-up over uniform sloping beach. D1 and D2 are the cases in which dune-like structure having trapezoidal cross-section with different heights are installed at 50cm landward from the still water shoreline. In the present experiments, water surface elevations are measured by capacitance–type wave gauge every 10cm from the toe of the sloping beach up to maximum run-up point. Since number of wave gauge is limited, the measurement is conducted in several runs and the displacement of wave generator is recorded together for later synchronization of all data.

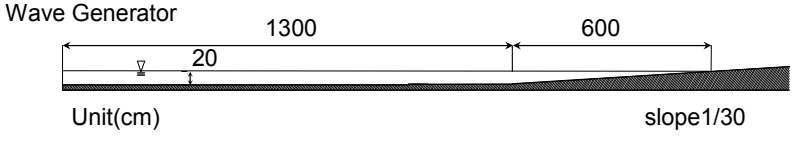

Fig. 1. Wave flume

Table 1. Experimental Conditions

Case	Wave Height, cm	Ratio of Wave Height to Water Depth	Bottom Topography
U1	5.0	0.25	Uniform Slope
U2	3.2	0.16	Uniform Slope
U3	1.8	0.09	Uniform Slope
D1	3.2	0.16	Dune(4cm height)
D2	3.2	0.16	Dune(6cm height)

Runup over Uniform Slope Beach(U1, U2 and U3)

The experimental and corresponding computational results of wave deformations over sloping beach for the case U1 , U2 and U3 are shown respectively with markers and lines at every 2.0 seconds in Figure 2. The line Z=0cm indicates still water level and the slope starts from X=300cm. In the computation, two different flux limiters

called Minmod and Superbee were employed for the flux correction. They are respectively the flux limiter giving the maximum and minimum numerical dissipation in the extent of TVD region (Sweby 1985). In order to make comparison easier, the offshore experimental data are given as the incident boundary condition of the simulations. The computational results reproduce the wave shoaling and breaking as well as formation of bore with excellent accuracy for all cases. The differences between two limiters become evident for the case of larger wave height. Superbee limiter preserves steeper wave profiles just before wave breaking, but underestimates the dissipation associated with the breaking.

Figure 3 shows wave run-up and backwash over sloping beach, which are subsequent profiles of Figure 4. In the figure, only results with Minmod limiter is shown for legibility since there is slight difference between two limiters. Bore formed after breaking collapses during run-up phase and thus the potential energy converted into kinematic energy. Therefore the flow velocity rapidly increases to rush water upward. After wave reaching its maximum run-up point, the backwash starts to form hydraulic jump around X=800cm. The computational results show good agreements with physical data except that waves are overestimated near the front during run-up for all cases. This may be because of the simple formulation of friction force as effects become dominant in small water depth.

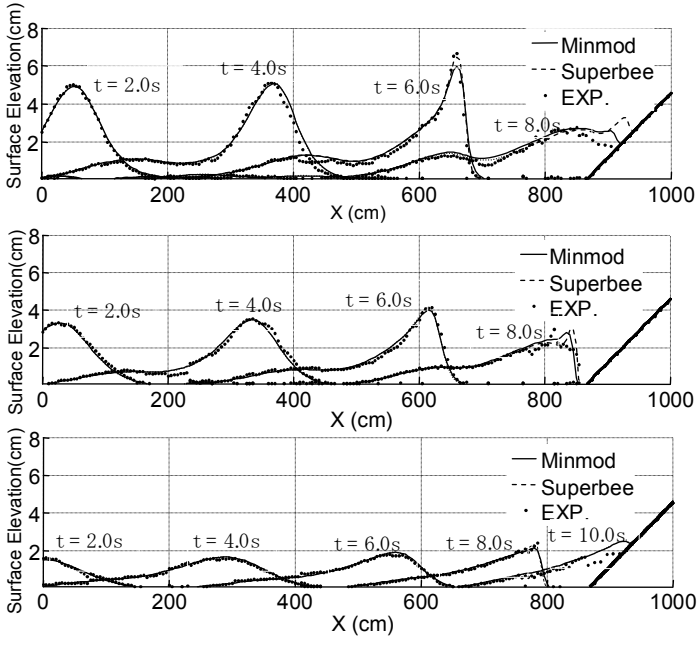

Fig. 2. Computed and experimental results of wave propagations over sloping beach

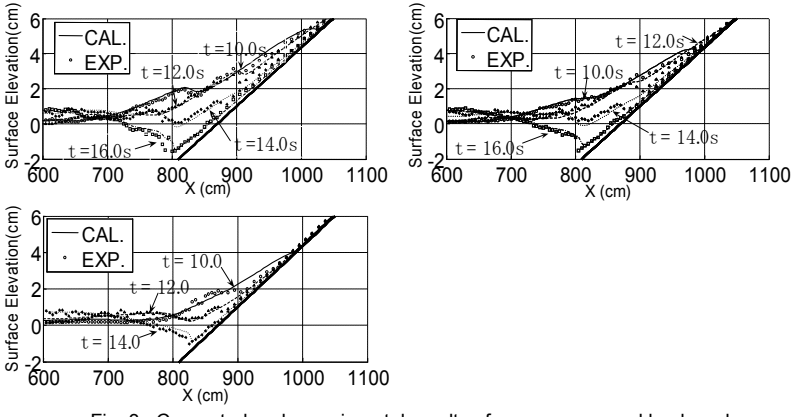

Fig. 3. Computed and experimental results of wave run-up and backwash

Runup over Dunes on sloping beach (D1 and D2)

Figure 4 shows the result for the case D1 and D2 with corresponding numerical results. Water surface profiles around dune-like structure at three different time stages are plotted. For the case D1, hydraulic jump is formed immediately after the wave front reaching the dunes while some amount of water overflows landward. In contrast, the wave is perfectly reflected by the dune-like structure if the height is larger in case of D2. Hence, it is confirmed that dune-like topography evidently has protective effect against tsunami if it is not erodible. From these figures, it is also confirmed that the present model reasonably predicts the run-up over dune-like topography.

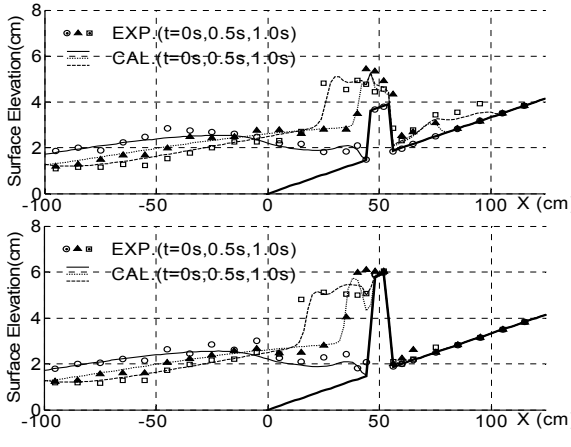

Fig. 4. Computed and experimental results of wave run-up over dune-like topography

MODEL APPLICATIONS ON MOVABLE BED

As described in former section, only few physical data is available for sediment transport due to tsunami. One of them is recently obtained by Kobayashi and Lawrence (2004). They conducted laboratory experiments in wave flume to investigate the beach profile change induced by breaking solitary wave. In order to examine the performance of the present model on movable bed, computations are carried out under the same conditions as adapted in the experiment. In the experiment, beach with initial slope of 1/12 was exposed to solitary wave with the wave height 0.216m. The grain size, measured settling velocity, porosity and the specific gravity of sand are 0.18mm, 2.0cm/s, 0.4 and 2.6 respectively.

Figure 5 displays the computed beach profile after 4 times exposition to the solitary wave. The experimental result shows the significant erosion at foreshore and the deposition seaward of still water shoreline as results of the wave plunging and subsequent strong downwash. The computed result well reproduces such a tendency and shows a good agreement in a quantitative sense.

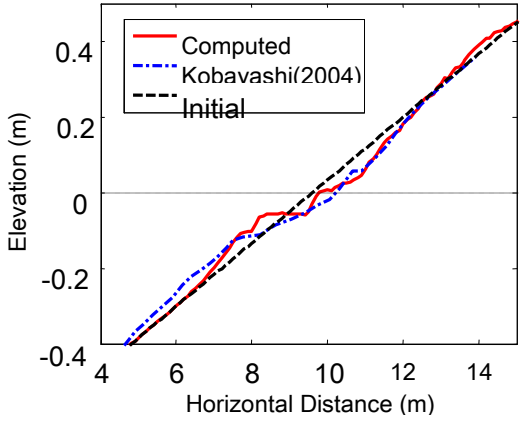

Fig. 5. Beach deformation induced by solitary wave

In order to investigate the beach deformation process in detail, the evolutions of water surface, bed level, velocity and the sediment concentration profiles during run-up and backwash are respectively displayed in Figure 6-8. Since a discussion with single wave is preferable, the incident wave height is increased to 0.35m to magnify the sediment transport. All figures start from the instance of furious breaking of the solitary wave approaching the shore. At this moment, the rapid transition from potential to kinematic energy produces a large velocity and thus the considerable amount of sediments are picked up from the bottom layer. The highly concentrated flow rushes up to the maximum run-up point losing its speed due to gravitational

effect and energy dissipation. Hence the entrainments become smaller than the deposition at certain height where sand is slightly accumulated as shown in the second figure. At the next moment, the flow changes its direction to initiate the backwash. During this stage, the flow velocity is accelerated by gravity so that the foreshore goes through the erosion again. Subsequently the suspended load settles down seaward of the still water shoreline.

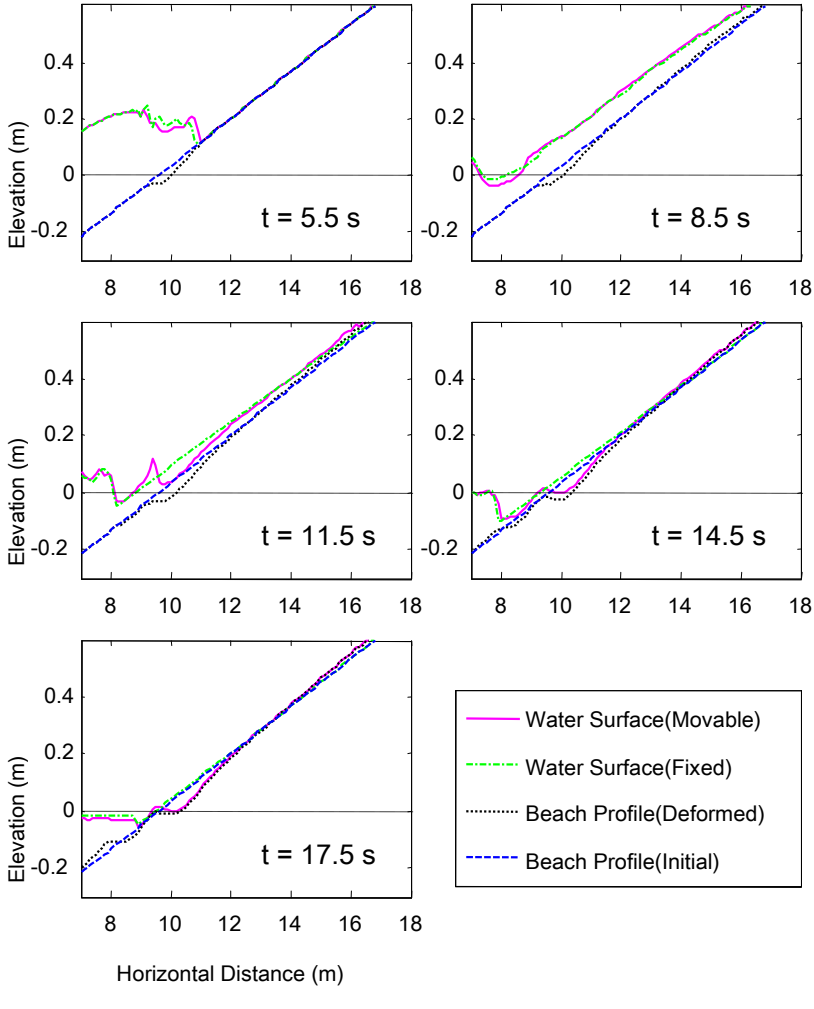

Fig. 6. Water surface and beach profile during run-up and backwash

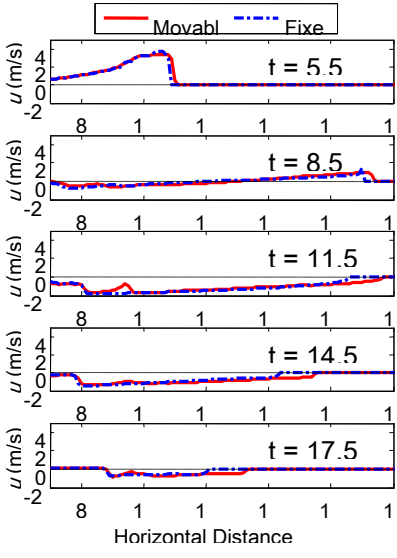

Fig. 7. Velocity profiles

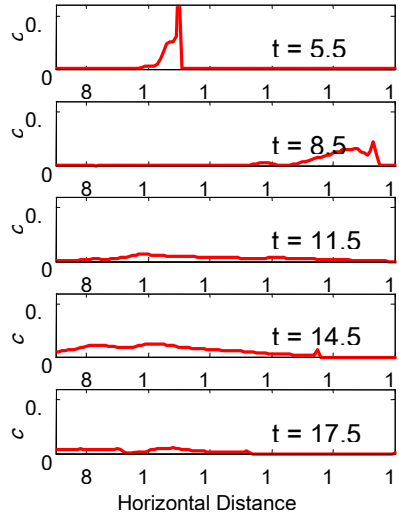

Fig. 8. Sediment concentration profile

TSUNAMI RUNUP OVER ERODIBLE SAND DUNE

Tsunami run-up over erodible dune is computed by the present model and the protective effects are discussed on the basis of the results. Dunes with different cross-section are introduced landward of shoreline on the beach with the same conditions as used in previous section. The shape of the dune is simply given with sech-squared profile. The region landward of the dunes is set as a flat bottom to avoid backwash from landside which makes the phenomena much more complicated.

A typical result from the computations is shown in Figure 9. The evolution of water surface and bed profiles around dune is plotted along with that from fixed-bed computations at 5 different times. Once waves overtop the dune, landside of the dune is severally eroded due to the flow descending along the downslope and the suspended sediments are later deposited on the flat bottom landward as shown in Figure 9. This is common to all the numerical tests especially with dunes having steep slope on landside. It is also confirmed by comparison of two results on fixed-bed and novable that the type of erosion does not significantly affect the overflowing rate. On a steep downslope, sand particle can move with smaller velocity due to gravitational effect. Once the landside of dune is eroded at lower part, its slope become steeper and such an effect become more significant. Consequently it results in large erosion. These results from the present computations are in accordance with

the observation of the real eroded dunes carried out by one of the authors in Sri Lanka. As shown in Figure 10, the landside of dunes, which experienced the overflow during 2004 Indian ocean tsunami, is violently scoured. The photograph on left hand side was taken from top of the dune, while one on right hand side shows landside of the dune.

CONCLUSION

A numerical model for simulation of tsunami flooding on movable bed is developed on the basis of Boussinesq-type equation coupled with sediment advection equation. The model has conservative and shock capturing property so that the flow containing discontinuities such as breaking or hydraulic jump can be handled without any special treatments. The model results are compared with available data both on fixed bed and movable bed. For the case of fixed bed, the model results show excellent agreements with the various experimental data relevant to solitary wave. Although verification is limited, the model outputs qualitatively reasonable results on movable bed problems such as tsunami run-up over dune. Since there are some empirical parameters to be determined, large-scale laboratory experiments must be conducted on movable bed for further improvement of the model.

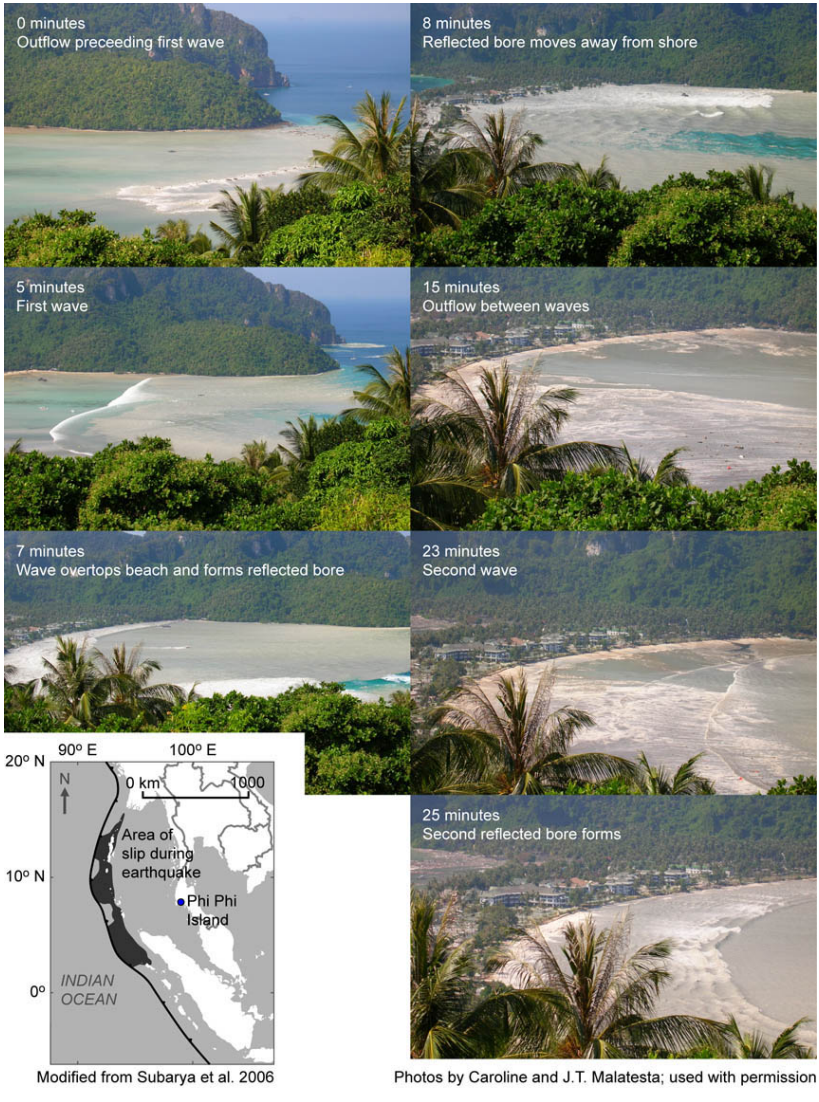
Abstract

Where a steep slope blocks an inrushing tsunami, the tsunami commonly reverses direction as a reflected bore. A simple method for relating vertical and horizontal variation in sediment size to output from numerical models of depth-averaged tsunami flow yields predictions about the sedimentary record of reflected bores:

- Near the reflector, a abrupt slowing of the flow as the reflected bore passes is recorded by a normally graded layer that drapes preexisting topography
- At intermediate distances from the reflector, the deposit consists of a single normally graded bed deposited preferentially in depressions, possibly including a sharp fine-over-coarse contact. This contact records a brief period of erosion as the front of the reflected bore passes
- Far seaward of the reflector, grading in the deposit includes two distinct normally graded beds deposited preferentially in depressions separated by an erosional unconformity. The second normally graded bed records the reflected bore

INTRODUCTION

Geologists seeking paleo-tsunamis typically target beach plains and coastal marshes for study because they are good preservational environments. In the millennia since global sea levels stabilized in the middle Holocene, many beach-ridge and tidal-marsh plains have been building seaward. Some of these plains, which are vulnerable to attack by tsunamis, terminate at former sea cliffs or other steep slopes.



Depending on the width of a coastal plain and on the height and wavelength of a tsunami, strong flooding may or may not extend all the way to a steep inland limit. If fast-moving water does reach a steep slope at the end of the plain, it will likely form a reflected bore. The 2004 Indian Ocean tsunami reflected off beaches in Thailand (Fig. 1), and incoming tidal bores crossed exposed tidal flats to reflect off the shores of a macrotidal estuary in Alaska (Fig. 2b-d).

Nonlinear numerical tsunami run-up models predict the formation of reflected bores. In cases where a tsunami hits a steep slope at the landward limit of a horizontal plain, the reflected bore is one of the most prominent features in velocity time series—nearly as prominent as landward moving wave fronts (Fig. 2a).

As tsunamis flood beach plains, they usually carry marine sediment and leave it in a layer across the landscape. These tsunami deposits vary substantially in structure. Some deposits, such as the 1998 Papua New Guinea tsunami deposit (Gelfenbaum and Jaffe, 2003) and the 1992 Nicaragua tsunami deposit (Higman and Bourgeois, in press) have been characterized as quite simple—just one or two normally graded beds. However, even in these cases, variation in thickness, basal grain size, and rate of grading occurred through the deposit. For more complex deposits such as those from the 2004 Indian Ocean tsunami (Moore et al., 2006; Jaffe et al, 2006) and the 2001 Peru tsunami (Jaffe et al., 2003)) multiple layers are common, and grading within layers varies from normal to inverse. The number of layers in these deposits can vary both over hundreds of meters where the variation might be explained by large-scale evolution of the tsunami flow, and over a few meters where it more likely reflects local factors such as small variations in pre-existing topography.

In this paper, we explore grading predicted via simple flow sorting approximations (Fig. 3), to describe the expected grading for a simple reflected bore scenario (Fig. 4) and to interpret output from numerical tsunami inundation models (Figs. 5-6). By combining these approaches, we produce synthetic tsunami deposit structures.

Our ultimate objective, beyond this paper's scope, is to use the observed bedding of tsunami deposits to learn about paleo-tsunami flow conditions. For example, the spatial variation in grading in paleo-tsunami deposits may be used to determine whether the paleo-tsunami did impinge on a reflecting slope. Because the interaction of a reflected bore with the incoming wave is dependent on height and wavelength of the tsunami, it may be possible to interpret the characteristics of the paleo-tsunami from its deposits when the reflected bore was formed.

METHODS

In general, faster flows carry coarser sediment, and deposits form in areas of slowing flow. Thus coarse grains are observed in river beds in the mountains and fine sediments in flat areas, and deposition occurs in concave basins or where flows expand at delta fronts.

We apply this same conceptual model, here called the flow sorting approximations, to explain grading in tsunamis (Fig. 3)(originally applied to turbidites by Kneller, 1995). As the flow speed varies, the size and amount of sediment carried varies as well. When moving quickly, the flow will carry more and coarser sediment, and when it slows it will carry less and only the finest of available sediment. Deposition is assumed to be a function of whether the water passing over a point on the bed is slowing down or speeding up. This total time derivative of speed can be broken into a temporal and spatial term:

Total
Temporal Spatial

$$\frac{d|u|}{dt} = \frac{\delta|u|}{\delta t} + |u|\frac{\delta|u|}{\delta x}$$

where u is velocity, |u| is speed, t is time, and x is horizontal distance in the direction of the flow. Note that this latter definition is unusual in that the direction in which x increases changes each time the flow direction changes. The partial derivatives in space and time are defined at or across a single point (Eulerian perspective), while the total derivative is defined following an individual water particle (Lagrangian perspective). Although the *temporal* term—the change in speed at a given point—determines the change in grain-size distribution present in the flow, it is the sum of this term and the *spatial* term that determines whether deposition occurs. For example, where the flow brings progressively slower water past a point on the bed, it will usually be depositional. However, if the flow is speeding up through space to the point where the water experiences a *total* increase in speed then it will be erosional. Because we assume that the grain size of the sediment in the flow decreases along with flow speed, a normally graded deposit will be formed in this case. If the flow is speeding up, it will usually be erosional, but if there is some local variation in the bed such as a depression that leads to slowing through space, the water will experience a *total* decrease in speed and, because we assume that the grain size coarsens with increasing speed, an inversely graded sediment will be deposited.

The flow sorting approximations treats flow speed as the main variable controlling sediment sorting and deposition. A more thorough treatment would require tracking the variables more directly responsible for controlling sedimentation, such as bed shear stress and turbulent mixing in the water column. As a result of the simplifications the flow sorting approximations make, they do not resolve time-lags related to timescales of deposition and erosion.

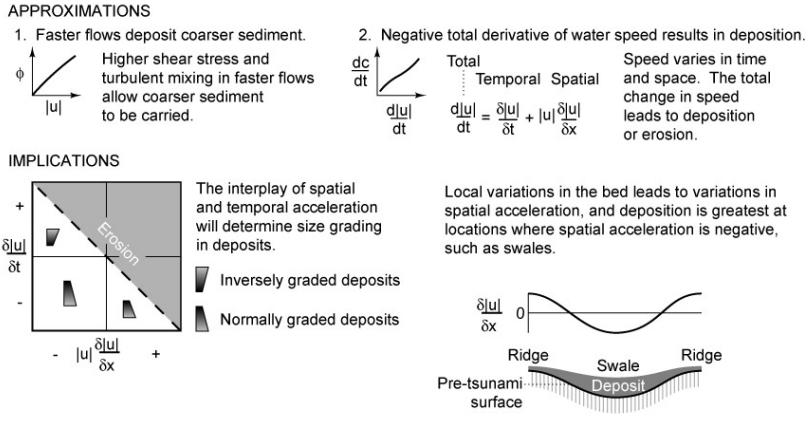

Figure 3 Flow sorting approximations

Here we present interpretation of output from two depth-integrated, nonlinear shallow -water wave models implemented for tsunami inundation: Coulwave (Lynett et al., 2002) and Delft3D (Stelling and van Kester, 1994). Though these models vary in the way they resolve moving limit of inundation and other important details, they both have been shown to accurately model most aspects of tsunami inundation. We are using them only to resolve general patterns of flow. In each case we run modeled waves across a horizontal plain with a slope at its landward limit.

In the next section, we present three realizations of bore reflection. The first is a qualitative sketch that describes some essential features of bore reflection using simplified (generally linear with discontinuities) time-series for speed and total change in speed (Fig. 4). The second presents numerical results from Coulwave for a single positive wave reflecting off a 2% slope (Fig. 5). The third presents numerical results from Delft3D for a wave train that reflects off a vertical wall (Fig. 6).

RESULTS

Reflected Bore

Figure 4 outlines the sequence of events as a tsunami crosses a beach plain and reflects off the distal slope. Figure 4a shows a simple profile of this sort, and 4b traces the paths of water particles across this beach plain. In 4b each water particle is averaged through depth, and separates constant volumes of water. Defined in this way, the water paths show the sudden change in direction that occurs with the passage of a reflected bore, generating a clear division between two distinct time-space domains. 4c shows a cartoon of the wave shape as the wave moves inland, and

4d shows the change in speed, velocity, and total derivative of speed through time. These variables can be combined using the flow sorting approximations to produce the time-grading diagrams in 4e.

This time-grading diagram emphasizes the evolution of the reflected bore's depositional pattern as it moves from the reflector. Near the reflector it starts fast and drops abruptly to very slow, dumping all the coarser sediment out of the water column. At intermediate distances from the reflector, the flow becomes abruptly more erosional, but it does not change in what grain size it is delivering to the deposit. Finally at locations far from the reflector the deposit records two distinct jumps in speed followed by gradual waning, each as a normally graded bed. The first bed records the inflow, the second records the outflow following the reflected bore. With some improvements in realism in 4f, the time-grading diagram can explain why the deposit varies depending on local topography. In lows, a more negative spatial derivative of speed leads to deposition even at times when the flow is erosional elsewhere. Finally 4g shows a deposit, both with and without annotation, that could be produced by this cartoon tsunami.

Figures 5-6 show a similar compilation of information for the Coulwave and Delft3D model runs. These are more realistic than the cartoon in figure 4, but are also likely to include complexities that are a function of the particular realization of fluid dynamics used in these models.

Deposit

Distal (near reflector) deposit: To form a reflected bore, a tsunami must be flowing quickly when it reaches the reflector. Given the flow sorting approximations, this fast flow will be carrying relatively coarse sediment. Because the tsunami slows continuously across the beach plain it will be depositing a continuously aggrading, normally graded sheet of this sediment. However, this deposit has only a moment to begin forming before the flow is abruptly stopped by the passage of the reflected bore. Relatively fine sediment rains out of this stilled water (Fig 4e, 5e, location A).

The flow sorting approximations fail to account for time lags in deposition from settling, dissipation of turbulence, and reversal of the boundary layer. As a result of these time lags, the abrupt drop in flow speed is recorded by a more gradual normal grading in the deposit. This normally graded deposit distinctly drapes topography, unlike deposits of more nearly steady flows that lap onto ridge crests. In the absence of larger incoming waves or strong reflector-parallel currents, it is likely that this drape will survive later reworking because later currents are expected to be weak. After the formation of this drape, gradually withdrawing water will leave a thin deposit that may be normally or inversely graded, possibly including discontinuous minor unconformities (Fig 4f, 5f, location A).

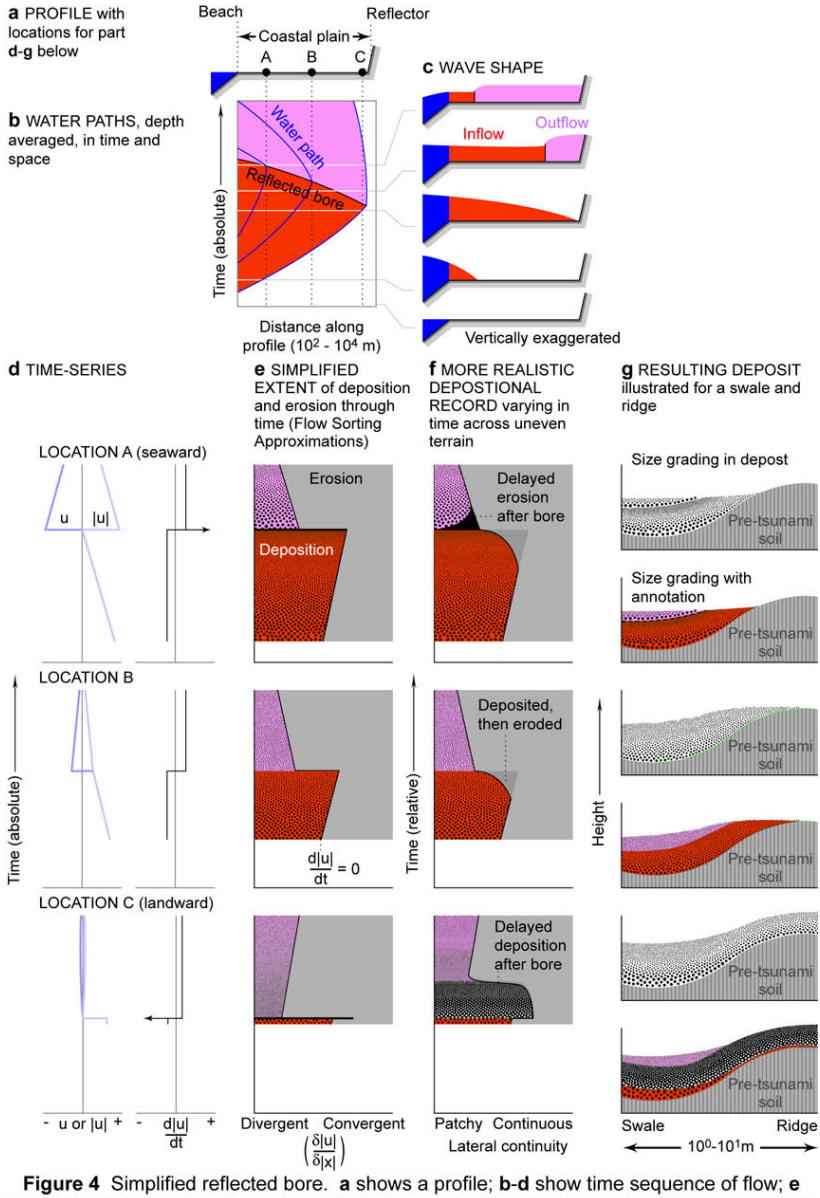

Figure 4 Simplified reflected bore. **a** shows a profile; **b-d** show time sequence of flow; **e** and **f** show the spatial extent of depositional record; and **g** shows the deposit implied by **f** on a local swale and ridge.

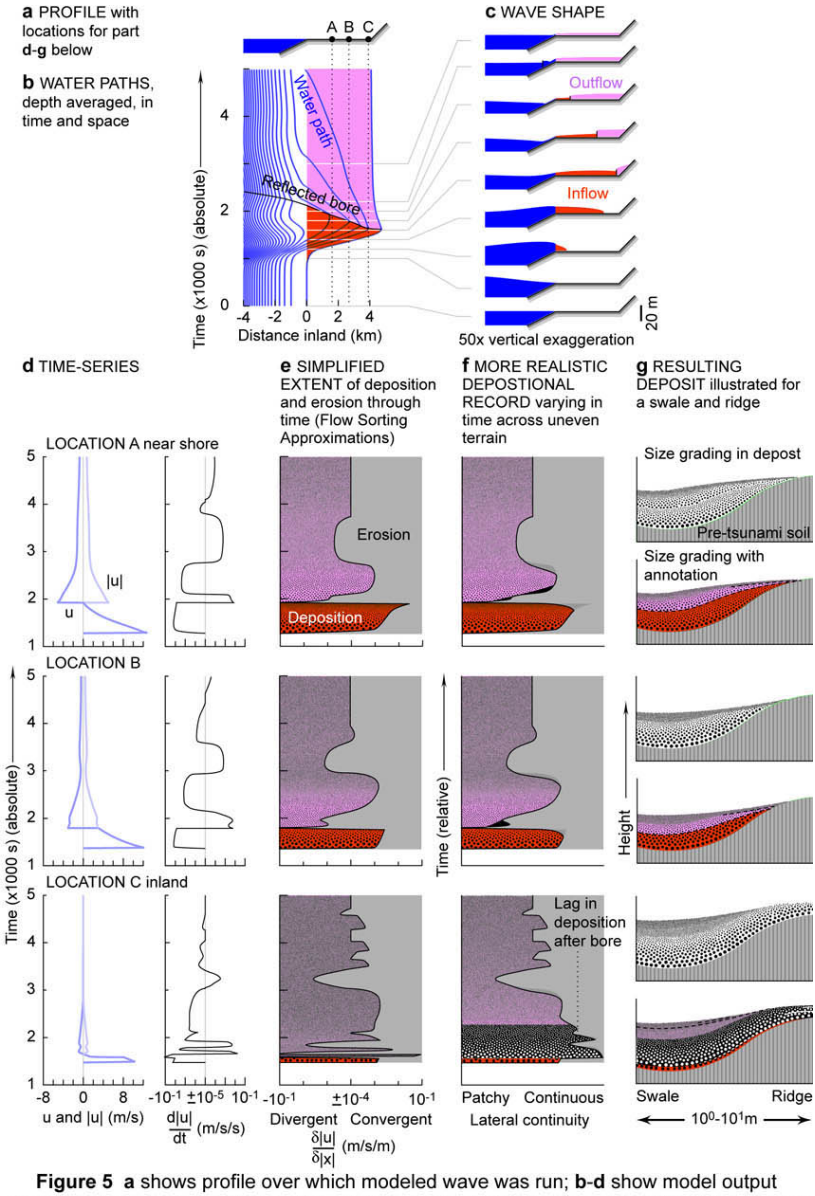

Figure 5 **a** shows profile over which modeled wave was run; **b**-**d** show model output (Coulwave); **e** and **f** show the spatial extent of depositional record; and **g** shows the deposit implied by **f** on a local swale and ridge.

Middle (between reflector and beach) deposit: The abrupt decrease in landward flow that distinguishes the distal deposit also occurs in more seaward locations. However, in these cases the magnitude of the change in flow is greater than the flow's speed, so the flow reverses and its speed (the scalar rate of motion relative to the bed) drops less than the flow velocity (the degree to which the flow is moving landward). There is some point where the abrupt decrease in landward velocity corresponds to no change in flow speed. Given our flow sorting approximations, there will be no abrupt change in grain size at this point, but there is likely to be a change in the total temporal derivative of speed that changes the spatial pattern of deposition on the bed. For example, a period of erosion can be recorded as an abrupt fine-over-coarse contact (figure 5e, location B). Allowing for time-lags in deposition and erosion scarcely alters this expected stratigraphic sequence (Fig 4f, 5f, location B).

Proximal (far from reflector) deposit: Where the arrival of the reflected bore occurs long after the passage of the leading tsunami front, there is time for the flow to slow down and possibly even stop or reverse before the reflected bore arrives. The slowing of the flow is recorded by a normally graded bed. When the reflected bore arrives the flow is again strong and slowly weakening, leaving a second normally graded bed (Fig. 4e, 5e, location C).

The reflected bore partially erodes the uppermost part of the first normally graded bed before deposition of a second normally graded bed. Because the flow needs time to entrain enough sediment to reach its transport capacity, the arrival of the reflected bore lags the beginning of deposition at this location (Fig. 4f, 5f, location C). The sediment in the reflected bore is limited to what can be eroded from the pre-existing tsunami deposit and pre-tsunami soil—provenance that may provide aid in distinguishing the reflected-bore deposit from that of a successive incoming wave or surge. Otherwise, a second normally graded bed may closely resemble the deposit of a second surge.

Most tsunamis includes multiple large waves. In these cases later waves may encounter water from earlier waves and form landward propagating bores. Also, multiple reflected bores will form. This multiplicity of flows is likely to produce the kinds of complexity shown in Fig. 6.

DISCUSSION

Many tsunami deposits have fairly simple structure, typically normally graded and thinning and fining landward (e.g. Gelfenbaum and Jaffe, 2003). These cases may be examples where the tsunami did not form a reflected bore. The most prominent expected record of a reflected bore is a relatively fine grained layer that thickens toward the reflector. However, detailed documentation of tsunami deposit structure, including lateral variability in layering, could provide evidence even of more subtle reflected bores, and allow one to untangle the signals of multiple bores and reflected bores crossing the beach plain. For example, in the 1992 Nicaragua deposit (Higman and Bourgeois, in press), a deposit in a lagoon with a steep slope at its landward limit includes a sharp contact where finer sediment overlies coarser

sediment, often associated with both heavy mineral laminae and concentrations of clay rip-ups (Fig 7). This feature may record the passage of a reflected bore.

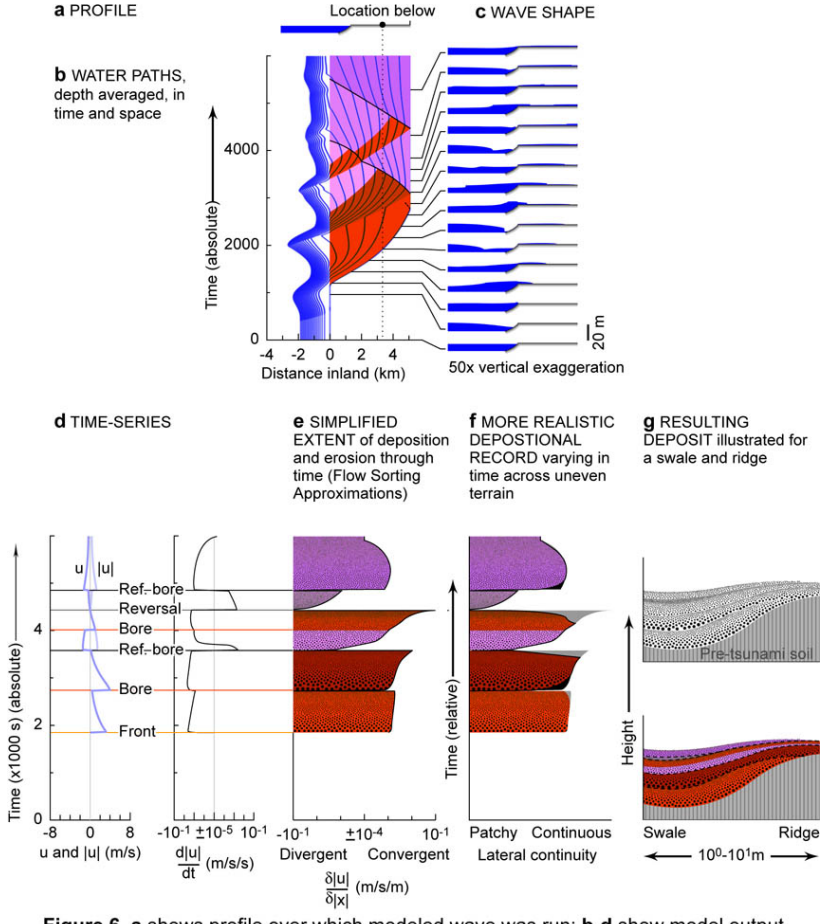

Figure 6 **a** shows profile over which modeled wave was run; **b**-**d** show model output (Delft3D); **e** and **f** show the spatial extent of depositional record; and **g** shows the deposit implied by **f** on a local swale and ridge.

The analysis presented here also provides a road-map for understanding other features of tsunami deposits. A number of non-linear shallow-water wave inundation models have been developed. These have been most widely used to estimate run-up values for tsunamis, but to achieve this they include dynamics that might be interpreted to better understand depositional patterns. Here we predict depositional signatures of reflected bores implied by numerical model output. We base our interpretation on a simple flow sorting approximation, along with some basic

sedimentary geology. This same procedure, preferably augmented by more sophisticated sedimentation models, could be used to predict deposition from other features in a tsunami, for example steep fronts propagating over dry ground or deposition in pot-hole lakes.

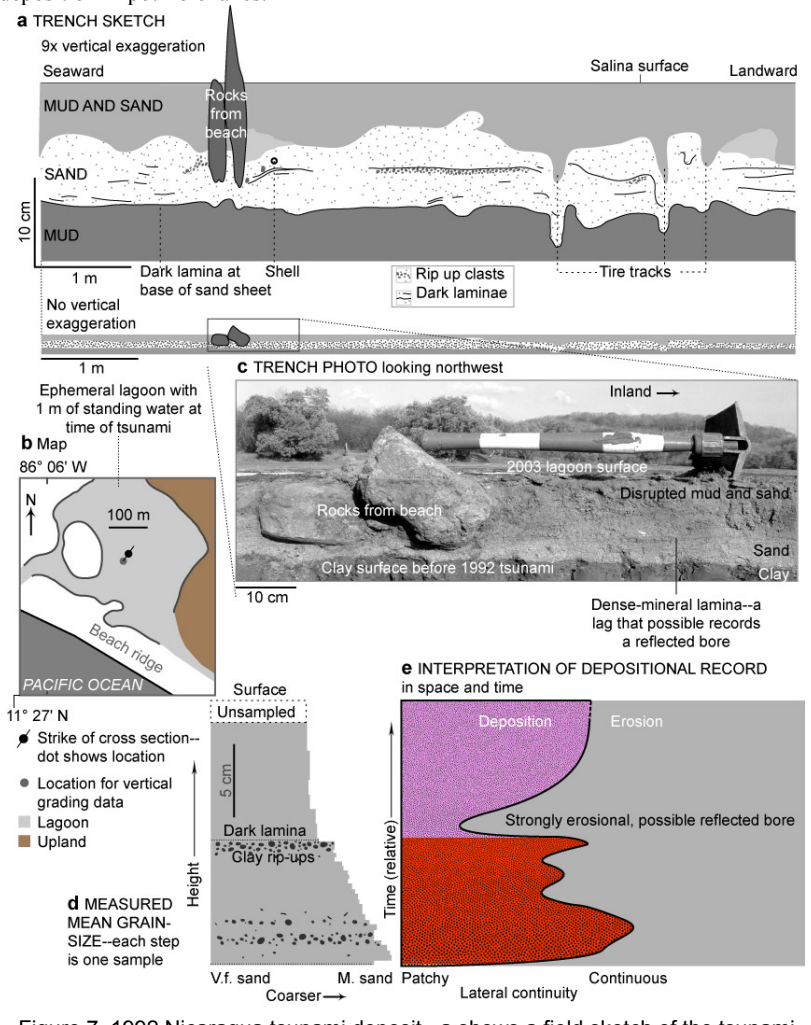

Figure 7 1992 Nicaragua tsunami deposit. **a** shows a field sketch of the tsunami deposit. **b** shows a map of the lagoon where the trench was dug. This lagoon rises steeply on its landward limit, making it a setting where a reflected bore is likely to form. **c** shows a photo of the trench. **d** shows measured vertical grading. **e** shows an interpretation of this deposit compiling measurement and sketch data in the style of figs. 4-6.

CONCLUSIONS

In a tsunami deposit that includes a record of a reflected bore, depositional patterns are likely to vary with location along a profile between the sea and the reflector: near the reflector, a thick normally graded drape; at intermediate distances from the reflector, a normally graded deposit possibly including a sharp contact; and far from the reflector, two normally graded beds.

These predicted features should be detectable in paleo-tsunami deposits, and we have seen similar features in modern deposits in settings where reflected bores are likely to form.

Beyond reflected bores, our methods could be applied to many features of tsunamis and their deposits. These qualitative tools for reading the paleo-tsunami record could greatly improve our understanding of tsunami hazard and of the events that generate tsunamis.

ACKNOWLEDGEMENTS

This manuscript was substantially improved by suggestions from Brian Atwater and Brian Collins. Also thanks to Caroline and J.T. Malatesta for permission to use their incredible photographs in figure 1, and to Andrew Mattox for his photos in figure 2 and for his unparalleled efforts as a field assistant.

Abstract: Field measurements from Sumatra of tsunami wave height, erosion and deposition form a comprehensive data set that is tested against the Delft3D tsunami inundation and sediment transport model. Relative agreement between measured and modeled maximum water levels and sediment erosion and accumulation provides confidence that the model is reasonably characterizing the important processes of tsunami inundation. Adding a component to account for vegetation, the model is used to explore the effects of fringing mangrove forests on tsunami inundation and sedimentation. In model experiments, mangrove forests modify the water levels and flow speeds reached during tsunami inundation. Simulations with a mangrove forest result in sedimentation in the forest and not erosion, as occurs in the base case with no forest. This difference in sedimentation is important because the change in profile shape increases wave energy reflection off the beach and decreases wave energy penetration onto land.

INTRODUCTION

In recent years there has been a renewed interest in examining the beneficial effects of coastal defense structures in mitigating tsunami hazards. After the 2004 Indian Ocean tsunami, coastal managers, engineers and scientists have been asking if natural or man-made coastal structures could have helped reduce tsunami damage and casualties in

countries such as Sri Lanka, Indonesia, and Thailand. Whereas a tsunami warning system would have been beneficial for locations somewhat distant from the tsunami source, for locations so close to the source that a warning system would not have had enough time to be effective, education and coastal defense structures are viewed as important alternatives. For many years, the man-made coastal structures (seawalls and breakwaters) along the Japanese coast have played an important role in protecting the coast from tsunami hazards. Problems associated with man-made structures, such as high construction and maintenance costs, and modification of the natural environment are causing some managers to seek natural defense structures, such as coral reefs, sand dunes, or coastal forests (Figure 1) to complement their mitigation strategies.

Figure 1. Fringing mangrove forests, like this one near Simelue Island west of Sumatra, may reduce tsunami impact. The lower roots are exposed because of coastal co-seismic uplift.

Mangrove forests are known to provide coastal protection against normal wind waves and tidal currents, but the extent to which coastal forests reduce loss of life or protect coastal structures during tsunami inundation is less well known (United Nations Food and Agriculture Organization web site). Coastal forests can reduce tsunami impacts by 1) acting as a barrier against floating objects (e.g., boats, debris), 2) reducing tsunami impact such as inundation distance, wave height, or flow speed, 3) providing structures for people to climb or cling to during a tsunami, and 4) promoting development of dune

formation during fair-weather conditions (Harada and Imamura, 2005). Recent laboratory and numerical studies examine the reductions in tsunami energy associated with characteristics of coastal forests such as forest density, trunk diameter, tree height, and forest width (Harada and Imamura, 2005).

While the extent to which coastal forests act to reduce tsunami impacts are beginning to be elucidated, the associated sediment transport and morphological change around and within these forests have not been studied. For example, if a mangrove forest reduces tsunami flow speeds, what will the resulting sediment transport be in and beyond that zone? Will the reduced flow speed modify the sediment transport enough to cause different patterns of coastal erosion and sedimentation? This manuscript describes numerical simulations of tsunami inundation, sediment transport, and morphological change with and without fringing mangrove forests. The model presented here includes feedback between the flow, sediment transport, and morphological change, through regular bed updating. Prior to testing the effect of the fringing mangrove forest, the tsunami sediment transport model is validated with field data collected on the coast of Sumatra, Indonesia after the December 2004 Indian Ocean tsunami.

TSUNAMI INUNDATION AND SEDIMENT TRANSPORT MODEL

Model

The modeling approach employs the Delft3D-FLOW module to simulate the coastal flooding and the "online" sediment transport capabilities to calculate the erosion and deposition of sediment. Delft3D-FLOW has been shown to accurately simulate the propagation of the Indian Ocean tsunami away from the earthquake source (Vatvani et al., 2005). The hydrodynamics model solves the non-linear shallow water equations in 2D or 3D on a staggered grid with a finite difference scheme (Stelling and van Kester, 1994). A special solver is employed to handle rapid wetting and drying for use when simulating flooding and which has previously been validated for modeling dam-break waves and rapid inundation of dry areas (Stelling and Duinmeijer, 2003). Sediment transport is calculated by solving the conservation of mass equations within the flow module. This model has been tested against flume and analytical solutions and shown to be applicable under typical coastal sediment transport conditions (Lesser et al., 2004). Both bedload and suspended load transport are calculated using the transport formula of van Rijn (1993). Convergences and divergences of sediment transport are accounted for at each grid cell and result in deposition and erosion of sediment on the bed (Lesser et al, 2004). The model has been used successfully in a variety of coastal and estuarine settings to simulate sediment transport and morphological change for both event and long-term morphological evolution (Roelvink, 2006; Lesser et al., 2005; Gelfenbaum et al., 2003) but has only recently been tested under the conditions of tsunami inundation (Gelfenbaum, et al., 2006).

The model is used here to simulate the tsunami inundation at Kuala Meurisi, along the west Sumatra coast. A fine-scale rectangular grid extending from about 2 km offshore to 2 km landward of the shoreline, the extent over which accurate bathymetric and topographic data were obtained is used. Grid size varies from 10 m at the shoreline and

at the steep slope near the landward limit of inundation to 20 m in areas of slowly varying bottom elevation. A simulation time step of 0.3 s was necessary to minimize instabilities in the modeled water level. The earthquake rupture and sea-floor displacement are not simulated. Instead, a deep-water boundary condition along the outer boundary of the numerical domain was obtained from the Vatvani et al (2005) coarser-scale tsunami propagation model. The water-level time series from the Vatvani model is composed of numerous waves that leads with an initial trough that has an amplitude of -4 m in 18 m water depth at the offshore model boundary.

Field Data

As part of an International Tsunami Survey Team (ITST), field data of tsunami inundation and sediment deposits were collected in April 2005 along the west Sumatra coast. At several sites the ITST collected eyewitness accounts, topographic profiles, tsunami wave heights, inundation distances, tsunami deposit thickness, sediment samples for grain size analysis, and nearshore bathymetry (Jaffe et al., 2006). Topographic profiles were measured along shore-normal transects with a hand-held laser range finder and surveying rod with prism. Elevations were collected relative to water level at the time of the survey and later corrected to mean sea level. Tsunami wave heights were estimated by measuring the elevations of the highest freshly broken branches or of debris in trees left standing after inundation. Where possible, several water-level indicators were measured on nearby standing trees with the laser range finder and averaged. Small pits were dug along each transect to identify if the tsunami had eroded the surface or left a sedimentary deposit at that location. Where a tsunami deposit was found, its thickness was measured and sedimentary structures, vertical variation in grain size, and number of layers were noted. Samples of the tsunami deposit were collected for laboratory grain-size analysis. Nearshore bathymetric data were collected along cross-shore transects with a digital echo sounder to measure the water depth and GPS for horizontal position. The data were later tide-corrected to mean-sea level.

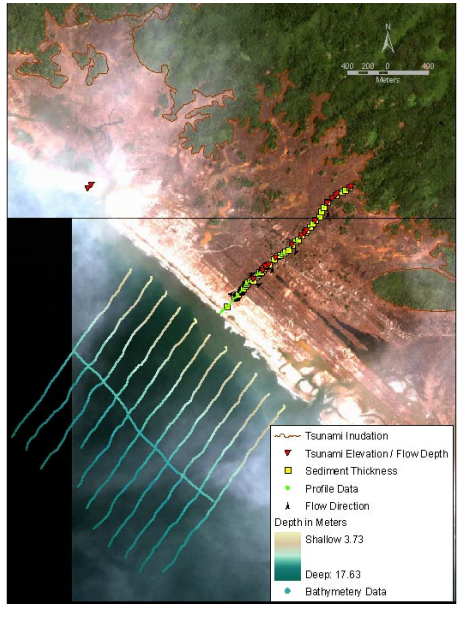

Figure 2. Satellite image of Kuala Meurisi with location of nearshore bathymetry, onland topography, water level, and sediment thickness measurements

At Kuala Meurisi, a site approximately 100 km south of Banda Aceh which will be used to test the model, a tsunami wave 15 m high inundated nearly 2 km across a coastal plain that was only 3-4 m above sea level. Eyewitnesses reported that the first wave arrived on land approximately 15-20 minutes after the earthquake, that the second and third wave arrived before the previous wave had completely receded, and that the third wave was the largest. The nearshore bathymetric data reveal a smooth shoreface profile to 18 m water depth, with a longshore bar at about 12 m depth and a concave shape up to 5 m. The bathymetric and topographic data were merged requiring interpolation between 5 depth m and the shoreline. Several trees remained standing across the coastal plain in the vicinity of this transect and reveal tsunami wave heights up to 15 m above mean sea level 1 km from the shoreline. The tsunami inundation extended 12 m up a hillside at a distance of 2 km from the shoreline.

The tsunami eroded the beach face and left a deposit that varied in thickness across the coastal plain from less than 1 cm to 34 cm. Comparison of satellite images from approximately 1 year before the tsunami and a few days after the tsunami suggest the shoreline moved approximately 75 m landward as a result of erosion during the tsunami and co-seismic subsidence, locally estimated to be 1-2 m. By the time of the ITST field survey, a new beach had formed along the shoreline with sand brought onshore (or perhaps alongshore) from fair-weather waves. During the field survey, moderate sized waves and average high tides combined to produce overwash of the dune and landward migration of the beach berm. Close to shore, the tsunami deposit includes one to three layers of sand above a dark brown soil. The sandy deposits are commonly normally graded and thin landward to muddy sand while a mud layer above the tsunami sand thickens. The deposit thickness consistently varies with local topography, thinning along ridges or local highs and thickening in the swales or low-lying areas. This pattern is characteristic of tsunami deposits and consistent with patterns observed in Papua New Guinea (Gelfenbaum and Jaffe, 2003) and in Sri Lanka (Goff et al., 2006) and other locations in Sumatra (Jaffe et al., 2006; Moore et al., 2005). The measurements at Kuala Meurisi of tsunami wave height, topography and bathymetry, and tsunami erosion and deposition form a comprehensive data set with which to test a tsunami inundation and sediment transport model (Figure 2).

Base Model Verification

Model simulations show several waves inundated the low-lying coastal plain of Kuala Meurisi, consistent with eye-witness accounts. Modeled maximum water levels at every cross-shore location fall within the scatter of field estimates of maximum wave height (Figure 3). Model and field data both give a runup of 12 m, the elevation of maximum landward inundation. Field estimates of maximum wave height in the center of the coastal plain may be somewhat higher than the model predicts, likely a result of uncertainties in the offshore boundary condition. Bottom roughness is set higher along the sub-aerial plain than for the part of the profile below mean sea level.

The sediment transport model predicts erosion of sediment along the beach. Accumulation of sediment occurs in an offshore bar and on land, across the coastal plain

(Figure 4). Sediment accumulation of up to 60 cm is predicted on land compared to measured deposit thickness of up to 34 cm. For this comparison, only one grain-size class (800 microns) is simulated yet sensitivity analyses show that deposit thickness is highly dependent on grain size. Both model simulations and field data show thicker deposits in local topographic lows or swales and thinner deposits (or erosion) on local topographic highs or ridges. The relative agreement between measured and modeled maximum water levels and sediment erosion and accumulation in the Kuala Meurisi case provides confidence that the model is reasonably characterizing the important fluid mechanics and sediment transport processes of tsunami inundation. By adding a component to account for vegetation, the model can be used to explore the effects of fringing mangrove forests on tsunami inundation and sedimentation.

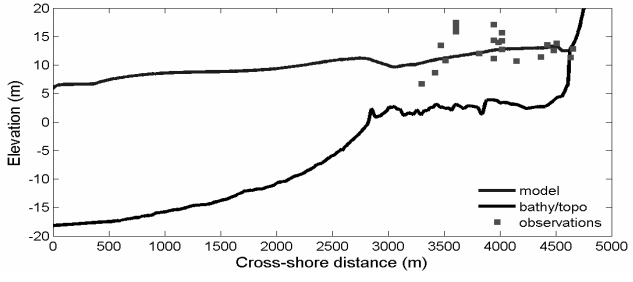

Figure 3. Cross-shore variation in maximum water level measured in the field (red squares) and modeled (blue line) after inundation of the tsunami.

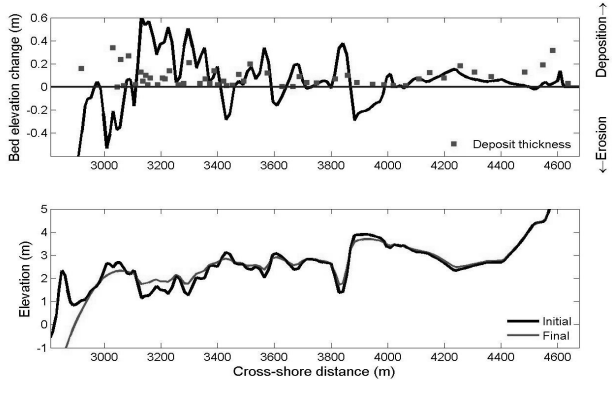

Figure 4. Model and data comparison of bed elevation change (erosion and deposition) along the beach and coastal plain at Kuala Meurisi. In top panel, red squares are measured tsunami deposit thickness and the black line is the model prediction. In lower panel, the thick black line is the initial topographic profile in the simulation and the thin red line is the final, predicted profile.

Mangrove Forest Parameterization

The influence of mangroves on the flow is included in the momentum equation by defining an extra force based on vegetation characteristics. Vegetation will lead to an extra resisting force acting on the flow. Following Baptist (2005) and Uittenboogaard (2003), the vegetation in Delft3D is modeled as a group of parallel, staggered or randomly arranged rigid vertical cylinders (stems) with homogeneous properties. The resistance force F per unit area can be expressed as:

$$F(z) = \tfrac{1}{2}\rho_0 \int_0^k C_D m(z) D(z) |u(z)| u(z) \qquad [N/m^3] \qquad (1)$$

Where:
ρ_0 = density of water
k = plant height
$C_D(z)$ = drag coefficient
$m(z)$ = cylinder density per unit area
$D(z)$ = cylinder diameter
$u(z)$ = time averaged, horizontal flow velocity

This parameterization is similar to the relation used by Mazda et al. (2005) and Wu et al. (2001). Vertical variations in the force generated by mangrove forests can be large due to the root-trunk-canopy structure of the tree. The flow velocity profile is assumed to be uniform inside the vegetation field. The continuity equation is corrected with the volume that is encompassed by the cross-sectional plant area.

In 3D simulations, all parameters in Eq. 1 are functions of the vertical coordinate z. In 2D simulations, the velocity u is uniform over the depth (depth averaged velocity), but C_D, m, D can still be a function of the vertical coordinate (i.e. the water level). When the water level rises above the vegetation height the influence of the vegetation (in the momentum and continuity equations) is reduced accordingly.

Table 1. Mangrove forest parameters for model experiments

Simulation	Mean Height, m	Stem diameter, m	Stem density, /m^2
Ma1	3	0.15	0.3
Ma2	3	0.15	0.6
Ma3	3	0.15	1.0

For the cases to be examined in this paper, the plant height and stem diameter are held constant and the stem density is varied from 0.3 to 1.0 stems/m^2 (Table 1). The width of the fringing mangrove forest in the numerical simulations is 175 m, with short transition zones on the seaward and landward edges of the forest (Figure 5). Although the actual

mangrove forest characteristics for the islands off Sumatra are slightly different, the parameters chosen for these numerical experiments allow examination of the influence of mangrove forests on coastal sediment transport during tsunami inundation. Model simulations include sandy sediment offshore and on the beach with a mean grain size of 400 microns and muddy sediment on land with a mean size of 50 microns. These sizes were chosen because they approximate the sediment sizes of the underlying soil and overlying tsunami deposit found near a mangrove forest (Figure 6).

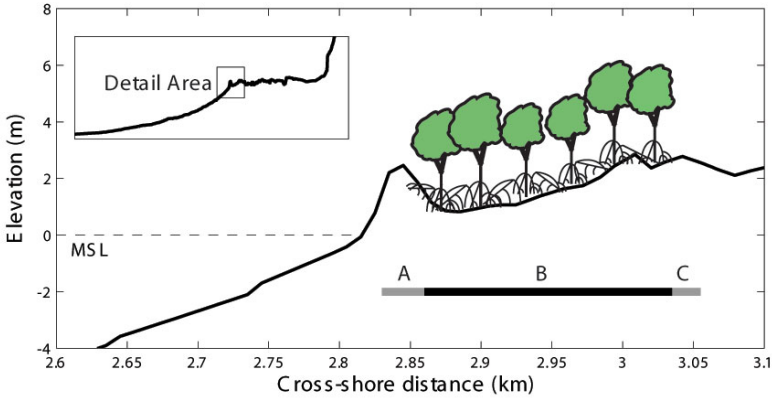

Figure 5. Location of the fringing mangrove forest along the coastal profile. Zones A and C are transition zones and zone B has stem densities of 0.3, 0.6, or 1 /m^2.

Figure 6. Photographs of sandy tsunami deposit overlying muddy organic rich soil in the vicinity of a mangrove forest.

MODEL RESULTS

A fringing mangrove forest can modify the maximum water level reached during tsunami inundation (Figure 7). Increasing the mangrove density decreases the maximum water

level across the coastal plain and the run-up. The maximum water level reached during the simulation, at a location approximately 200 m landward of the mangrove forest, is 80-91% of the maximum water level with no mangrove forest (the base case). Greater mangrove densities in the forest induce a greater reduction in water level.

Likewise, there is a reduction in maximum flow speed in the tsunami both within and landward of the mangrove forest. The flow reduction depends on several factors, and varies not only with mangrove density, but also from the first wave in the wave train to the last. The reduction in speed from the base case (no mangrove forest) varies from 49-91%. The greatest reduction in flow speed occurs for the third wave in the series (the largest in this simulation), in which the flow varies from 66-49% of the base case as the plant density increases.

The modified hydrodynamics have a significant impact on the sediment transport and resulting coastal morphological change (Figure 8). Both the onrushing wave and the seaward withdrawal result in erosion of the beach in the base case with no mangrove forest. Each of the simulations with a mangrove forest results in sedimentation in the zone of the forest and not erosion. This changes the amount of sedimentation further landward on the coastal plain, but more importantly, changes the profile shape, increasing wave energy reflection off the beach and decreasing wave energy penetration onto land. Deposition within the mangrove forest increases with increasing plant density, and deposition landward of the forest is less than in the base case with no forest.

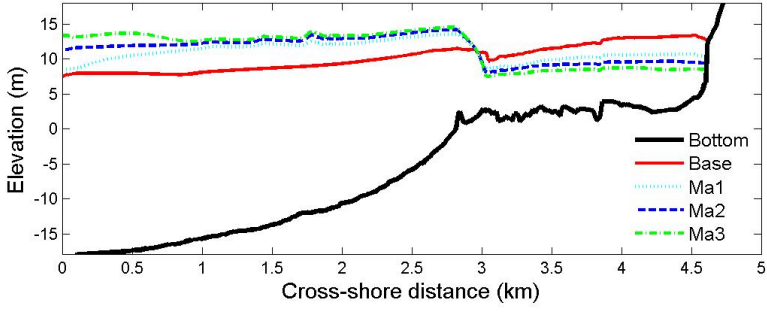

Figure 7. Cross-shore variation in predicted maximum water level for the base case and three cases with varying mangrove stem densities (see table 1 for explanation of cases).

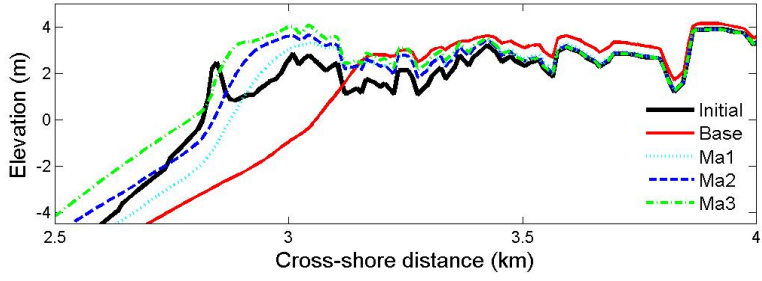

Figure 8. Cross-shore variation in predicted bed elevation for the base case and three cases of varying mangrove stem densities (see table 1 for explanation of cases).

CONCLUSION

Coastal communities at risk from tsunami inundation can benefit from a variety of man-made and natural defense structures. How helpful a particular coastal defense may be depends on many factors, and a validated process-based numerical model can be a very powerful tool in assessing the efficacy of various defense strategies. For "soft" defense structures such as sand dunes or fringing coastal forests, the feedback between the hydrodynamics, sediment transport, and morphological change can be critical. Laboratory experiments or models with fixed beds may not capture the important morphological changes that result from tsunami inundation, and that could have a significant impact on interpreting the usefulness of a particular structure. In the case of a fringing mangrove forest, the forest itself may modify the hydrodynamics and sediment transport enough to change the shape of the coast. In the example forest simulated here, the forest causes the beach to aggrade instead of erode, modifying the energy exchange as the tsunami impacts the coast.

ACKNOWLEDGEMENTS

Funding for this work came from the U.S. Geological Survey, Coastal and Marine Geology Program. We appreciate the efforts in the field of Andrew Moore, Robert Morton, Peter Ruggiero, Lori Dengler, Brentwood Higman, Widjo Kongko and Eko Yulianto. We also thank Andrew Stevens for assistance with the figures. Dirk-Jan Walstra and Edwin Elias contributed valuable conversations and Doug George and Andrew Stevens provided constructive comments to improve the manuscript.

Abstract: The coast of the western part of The Netherlands changed from a transgressive, tide-dominated system, characterised by tidal inlets and tidal basins, into a prograding barrier coast, between 5500 BP and 3200 BP. Ypenburg, SW of The Hague, is situated on the seaward boundary of a transgressive tidal basin which evolved from a predominantly subtidal into a intertidal flat area. During this evolution the landward expansion of the basin stopped. The seaward side of the tidal flat area was reworked and built-up by waves; it formed a transgressive barrier. The limited thickness of the wave-dominated deposits and the lack of shells of open-marine molluscs indicate that this coast line was sheltered from open North Sea conditions. The infilling of the tidal basin and the associated decreasing tidal channel are the onset of coastal regression. The formation of a beach barrier further seaward was the start of coastal progradation.

INTRODUCTION

The Holocene coastal evolution of the western part of The Netherlands changed in nature from transgressive to regressive around 5000 BP (BP means years Before Present). Initially, this area was an open coast, with barriers, tidal inlets and tidal basins, that was shifting landward as a result of rapidly rising relative sea level and insufficient sediment supply. After a decline in the rate of relative sea-level rise (RSLR) after 6000

BP, the tidal basins were filled in with sediment and the tidal inlets gradually closed. The coastal system changed into a series of prograding beach barriers. Until recently, this major change in evolution had not been studied in detail.

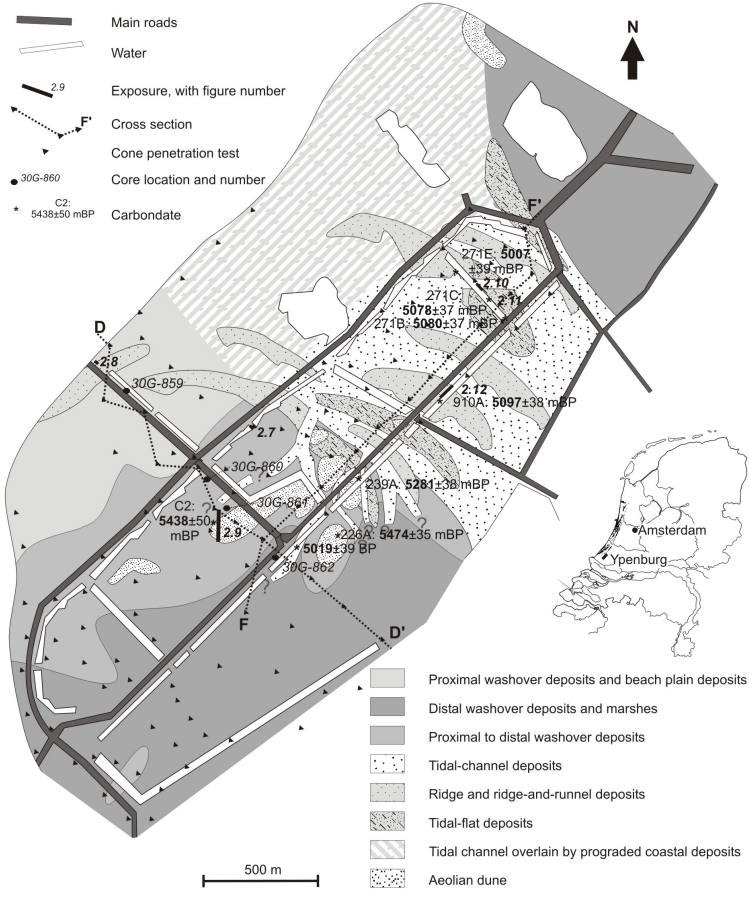

Fig. 1. Detailed map of the surface geology of the Ypenburg area. The top of the sand body in the western part is classified as 'proximal washover deposits'. The barrier series west of Ypenburg is indicated in the small-scale map of The Netherlands.

Ypenburg, a former military airfield, is situated on the boundary between the tidal back-barrier deposits of the transgressive coastal system and the beach-plain and beach-ridge deposits of the subsequent prograded coastal system (Fig. 1). In the subsurface of the Ypenburg area the remnants of the transition from the transgressive coastal system to the prograding coastal system are preserved. The expansion of the city of The Hague in recent years necessitated the transformation of Ypenburg into a suburb. The period of preparation for construction of this area allowed for a study of the deposits that were formed during this shift from transgressive to regressive coastal evolution. An extensive set of Cone Penetration Tests (CPT's) collected for foundation of constructions, temporary trenches, and other data provided an excellent opportunity to study the deposits in this area. Furthermore, Neolithic finds, including a well preserved burial site, triggered extensive archeological research, which provided additional subsurface data and facilitated geological research.

The morphology of transgressive coastal systems depends on the relative magnitude of waves and tides, and on the morphology of the substrate (see Boyd et al., 1992, for discussion and an overview). In general, the preservation potential of transgressive deposits from the seaward edge of the coastal system is very limited, because this part is constantly being eroded in the course of coastal retreat. Deposits from the landward part of the coastal system may escape erosion during transgression, and can be found in the shoreface and shelf sequence (Nummedal and Swift 1987). Prograded coastal sequences are abundant on many modern coasts. The preservation potential of prograded coastal deposits is high compared to that of transgressive coastal systems. A shift from transgression to progradation may results in the preservation of some transgressive deposits from the seaward side of a coastal system. In many cases the shift from transgression to progradation is associated with a shift from tide- to wave-dominated deposition (Davis and Clifton 1987), in most cases caused by the closure of the tidal inlets.

Aim of This Paper

The aim of this paper is to describe the change from a transgressive coastal system into a prograding barrier system on the basis of the analysis of the deposits at Ypenburg, and to summarize this transformation in a conceptual model. This paper will not present the detailed sedimentological analysis of the deposits, since this is partly done in an earlier publication (Cleveringa and Van der Spek 2000), which will be complemented by a paper in preparation.

Large-Scale Evolution of the Holland Coast

The Holland coast changed from an open, tide-dominated system, characterised by tidal inlets and tidal basins, into a prograding barrier coast dissected by the mouths of distributaries of the rivers Rhine and Meuse, between 5500 BP and 3200 BP. This evolution was triggered by the decrease in the rate of relative sea-level rise (RSLR) after 6000 BP to 0.3-0.4 m/century (Fig. 2), which tipped the balance between the creation of

sediment accommodation space by RSLR and sediment supply; the basins expanded less rapidly, allowing the sediment supply to infill the tidal basins (see Beets et al. 1992, and Beets and Van der Spek 2000, for more information). Sediment was supplied by the reworking of the North Sea bed, which included older coastal deposits and Early-Holocene deposits of the river Rhine. The major part of the sediment load of the river Rhine at that time was caught in the alluvial plain; no bed load reached the coastline (Beets and Van der Spek 2000).

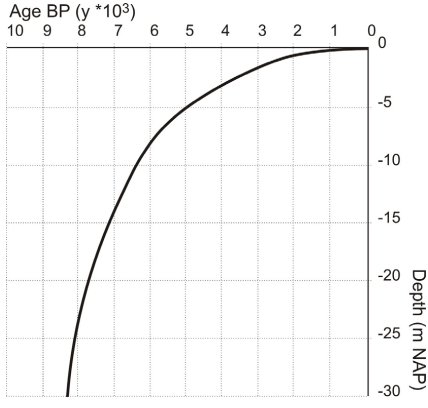

Fig. 2. Trend curve of Holocene relative sea-level rise in the western Netherlands.

When the relative sea level was rising rapidly, intertidal shoals were found bounding the tidal channels. Further away from the channels, where insufficient sediment was deposited, subtidal lagoons with predominant mud deposition existed. Going landward, these lagoons graded into freshwater swamps where peat was formed. With ongoing RSLR these basins expanded landward, leading to coastal erosion and consequent coastal retreat. The coastal retreat caused shoreface erosion which wiped out most of the traces of the former tidal basin deposits. Only the infill of deeply incised tidal inlets and channels escaped this erosion (Rieu et al. 2005).

Infilling with sediment of the tidal basins led to decreasing tidal prisms and, consequently, decreasing tidal inlet and channel dimensions. Finally, the inlets were closed. After closure of the tidal inlet, a stretch of coast started to prograde by formation of beach barriers. The latter were separated by beach plains. The beach barrier series near The Hague is over 8 km wide. This evolution was hitherto not known in detail. The data collected at Ypenburg allowed for a detailed analysis of the mechanism of inlet closure and the associated barrier formation.

Geological Setting of Ypenburg

The study area is located (south)east of The Hague, and borders the suburbs of Rijswijk and Voorburg. The area has been in use as a military airbase and until recently it was inaccessible for geological research. The airbase was closed in the 1990's and the area has been developed as a suburb of The Hague.

East of Ypenburg back-barrier sediments consist of sandy tidal-channel deposits with adjacent mud-flat deposits. The tidal channel system stretches eastward for about 12 km (Van der Valk 1996; De Gans et al. 1998). The back-barrier deposits form part of the transgressive coastal system.

West of Ypenburg the coastal stretch consists of a westward-thickening wedge of prograded coastal-barrier deposits (Van Straaten 1965; De Mulder et al. 1983; Roep et al. 1983; De Gans et al. 1998). The surface morphology of this area is dominated by a series of beach ridges and beach plains. Directly west of Ypenburg the oldest and most landward beach ridge is found, separated from the more westward ridges by a broad beach plain. The ridges are covered with low dunes, while the plains form lows which have subsequently been filled with peat. The most western part of the beach-ridge and beach-plain area is covered with high and relatively young dunes. The beach-ridge pattern can be traced 12 km to the northeast, up to the former mouth of the Old Rhine near Katwijk and Leiden. This branch of the Rhine was the main Rhine outlet from approximately 4300 BP until about 2900 - 2600 BP, when the Vecht became the active branch of the Rhine (Törnqvist 1993; Berendsen and Stouthamer 2001).

The deposits at Ypenburg can successfully be correlated with the succession found in a temporary exposure c. 3 km southwest of Ypenburg that has been described by Van der Valk (1996). This pit was deeper (down to 8 m - NAP) than any of the trenches in the Ypenburg area. The sandy coastal deposits in the construction pit are the equivalent of the sandy deposits in the western part of Ypenburg.

METHOD

Data on the subsurface of the Ypenburg area are derived from four undisturbed cores, numerous hand drillings, sections from trenches and pits, and a large number of cone penetration tests (CPT's). Cone penetration tests measure the resistance of the subsurface to vertical stress (cone resistance, indicated in Fig. 3) and torque stress. The ratio between vertical stress and torque stress gives a friction parameter. The combination of cone resistance and the friction parameter is a measure of the lithology (Amorosi and Marchi 1999, and references therein). Coarser sediment grain sizes cause higher resistance- and friction values. The inferred lithology from the CPT's can be verified with the lithology found in the continuously-core boreholes and sections from trenches. In this way CPT's can be used for stratigraphic correlations and sedimentological interpretations (Westerhoff et al. 1987; Beets et al. 1996; Amorosi and Marchi 1999). The top of the sedimentary sequence could be studied and sampled for radiocarbon dating in ditches and trenches dug for pipelines, cables, and dewatering

purposes. During preparation of the construction sites, extensive peat layers, including fossilized fully-grown oak trees, were removed, revealing the morphology of the original coastal landscape. This morphology included small-scale eolian dunes which showed abundant archeological traces and artefacts, reflecting intensive inhabitation.

Mollusc shells and tree leafs were collected from cores and trenches to determine the time of deposition with AMS radiocarbon (^{14}C) dating. Where possible, in-situ doublets of *Scrobicularia plana* were collected. Otherwise, doublets or undamaged single shells with remnants of the periostracum (the tissue covering the living shell) were taken. The doublets of *Scrobicularia* were found in living position within the sediment. All other shells were transported to their final resting-place, so their age is higher than the age of the site of deposition. However, the presence of periostracum on the selected shells indicates that transport and reworking can only have been limited. Therefore, radiocarbon ages will not deviate too much from the actual ages of deposits. The tree leafs were found within a clay layer among numerous other leaves and plant remains. The perfect condition of the leaves suggests that they have not been transported over a long distance and that their age is similar to the age of the sediment in which they were buried. A series of 38 shell samples and 1 tree leaf was dated. All ^{14}C ages on shells were corrected for the marine reservoir effect, which is 402 years for the North Sea. Ages are given in radiocarbon years BP (Before Present) throughout the text.

RESULTS

Geometry of Sediment Bodies

The CPT's facilitated the mapping of the extension and thickness of sand bodies in the area under study. In Fig. 3 two cross-sections are shown that were based on the CPT's. All CPT's show an abrupt increase in cone resistance around 15 – NAP. This jump indicates the top of the sandy Pleistocene deposits. All overlying deposits are of Holocene age. From East to West the following architecture is found. In the eastern part of cross-section D-D' (CPT's yp-65 and yp-PB8) continuous low friction values are found, indicating a sequence of about 10 m of muddy / clayey deposits with a very low sand content. In the western part of the cross-section a thick sand body is found from 12 m below NAP (NAP is the Dutch ordnance level called Nieuw Amsterdams Peil) upwards. This sand body can be traced to the east, in which direction it becomes thinner and less sandy. The CPT's yp-112 to 121 show interfingering of the thinning sand layers with the fine-grained deposits.

In the northern part of Ypenburg, another sandy sequence is found (cross-section F-F'; from yp-41 northwards). Within this sand body the CPT's yp-43 and yp-116 show highly variable resistances, indicative for alternations of sand and clay layers, reaching down to over 20 m. This pattern indicates the fill of a channel that has cut into the underlying Pleistocene sediments.

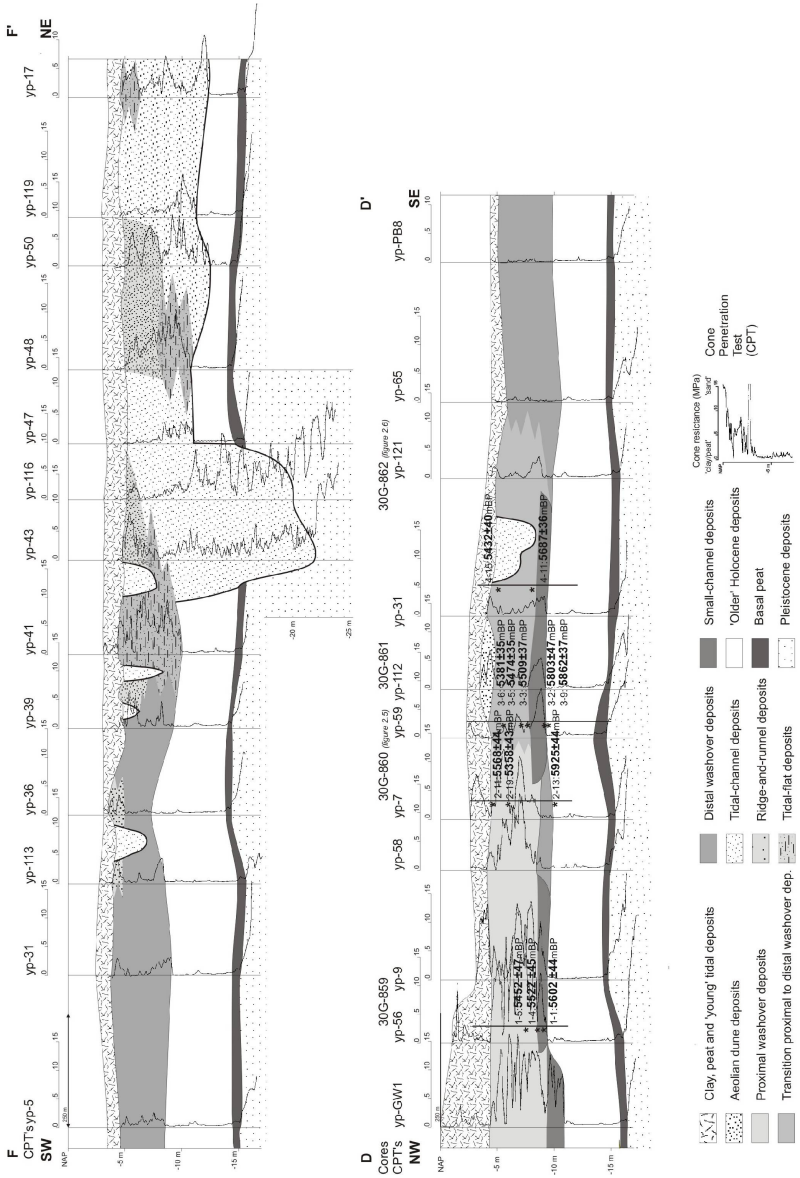

Fig. 3. Cross-sections normal (D-D') and parallel (F-F') to the paleo-shoreline at Ypenburg. The cross-sections are based on CPT's and four cores. See Fig. 1 for location.

Four continuously cored drilholes have been made along cross-section D-D' in order to sample all relevant deposits.

Sedimentary Sequence

This section describes the elementary characteristics of the deposits in the subsurface of Ypenburg, *viz.* lithology, major sedimentological elements, thickness and age (based on the ^{14}C ages), followed by the interpretation of the depositional environment. These descriptions are based on the drillings and field observations. Figure 4 shows an NW-SE cross-section based on the drillings.

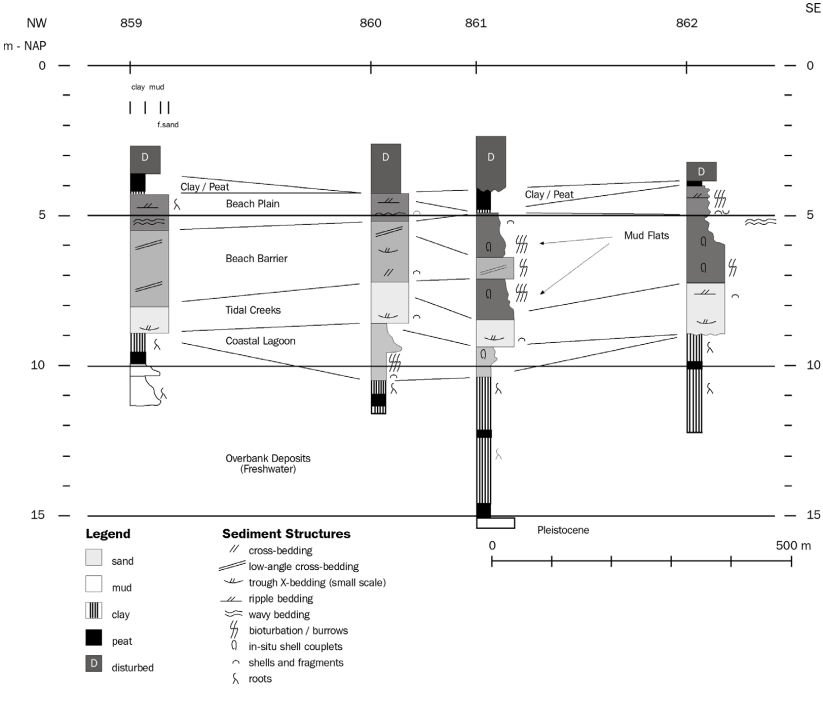

Fig. 4. Northwest-southeast cross-section of the sediment sequnce at Ypenburg, on the basis of 4 continuously-cored borings. See Fig. 1 for location.

The sediment sequence starts with a basal peat layer which is overlain by clay layers, intercalated with peat layers. Locally this sequence incorporates bodies of fine-grained sands. The clay usually contains plant remains. The unit is up to 5 m thick and deposited before c. 6000 BP. This sequence is interpreted as overbank deposits laid down on the alluvial plain of the river Rhine and in the most landward, freshwater parts of tidal basins.

Locally, see cores 860 and 861 in Fig. 4, the freshwater clays are overlain by mud which can be bioturbated, grading into sandy mud / muddy sand. Layers of small-scale sand lenses occur in the mud. The fauna is dominated by the mud snail *Hydrobia ulvae*. The deposit is 1 to 2 m thick and has an age of 5800 to 5900 BP. It is the deposit of a brackish, subtidal environment, possibly a coastal lagoon.

The freshwater clays and lagoonal muds are erosively overlain by a 1 to 1.5 m thick unit of cross-bedded, fine-grained sand with clay flasers and reworked shells of the Peppery Furrow Shell *Scrobicularia plana*. Shells of the Blue Mussel *Mytilus edulis*, the Baltic Tellin *Macoma balthica* and the Cockle *Cerastoderma edule* are found as well. These sands are dated at 5500 to 5700 BP. The were laid down by migrating tidal creeks or channels, possibly in a tidal-flat environment.

In the eastern part of Ypenburg these sandy channel deposits grade upwards into strongly bioturbated (sandy) muds with in-situ (layers of) shell couplets of *Scrobicularia plana*. These muds are 1.5 to 2 m thick and 5400 to 5600 radiocarbon years old. These are mudflat deposits.

The above mentioned sand body in the western part of Ypenburg consists of predominantly (low-angle) cross-bedded and laminated fine-grained sands, intercalated with layers of ripple bedding. Shells of predominantly *Macoma*, but also of *Cerastoderma* and *Mytilus* and, to the top of the sequence, *Spisula sp*. (the Trough Shell) occur on the foresets or dispersed within the sediment. This sandy unit is up to c. 3 m thick and was dated at 5450 to 5000 BP. The type of cross-bedding indicates the influence of swash and back-wash of breaking waves during deposition of the sand. The appearance of *Spisula* towards the top is an indication for an increasing (open) marine conditions (*Spisula* is found on the open North Sea shoreface in the present-day situation). Whether these sands were laid down on tidal flats along a tidal channel in which waves could penetrate from the North Sea or on a beach, can not be determined on the basis of cores. Equivalent deposits deposits from a pit about 3 km to the southwest were described by Van der Valk (1996) as beach deposits.

Both these sands and the mudflat deposits grade into alternations of cm-thick layers of sand and mud, (sub-)horizontally laminated, that can show intercalated layers and dispersed shells of *Macoma*- and *Scrobicularia*, some bioturbation and occurrence of rootlets. The sequence as about 1 m thick and is dated at 5100 to 5200 BP. Locally, these deposits are overlain by thicker sandy units with intercalated soils. The sand-mud alternations are interpreted as high-intertidal to supratidal beach-plain deposits, locally overlain by wash-over deposits and eolian dunes.

The second sand body in the northern part of Ypenburg has not been sampled by drilling. Observations on the top of this sequence in trenches show a lateral alternation of cross-bedded and bioturbated sandy deposits interpreted as tidal flats and ridge-and-runnel structures. The latter are erosively overlain by channel-like bodies of muddy sediments

that show concentric layering. These deposits are dated at 5000 - 5100 BP. The above described sequence is overlain by a clay layer that grades into peat.

INTERPRETATION AND DISCUSSION

The sedimentary sequence starts with a basal peat layer that was formed by deteriorating drainage, a consequence of the rising sea level. The overlying root-bearing clay with intercalated peat layers indicates continued drowning of the area. Since Ypenburg is situated at the northern boundary of the flood plain of the river Rhine, it is not clear whether these sediments were deposited in an alluvial or in a tidal-basin setting. The overlying lagoonal deposits that are overlain by tidal-flats indicate the approach of the North Sea. The tidal channel that cuts down into the Pleistocene subsurface in the northern part of Ypenburg is the major tidal channel in the area. It is known as the Rijswijk-Zoetermeer channel (Van der Valk, 1996). The tidal flats were bounding this channel. With transgression waves from the North Sea could gradually penetrate into the main tidal channel, influencing the sedimentation along the channel edges. The wave-built sand body in the western part of Ypenburg suggest the existence of a SW-NE running beach. However, the limited thickness of the sand body (the wave influenced interval is 2.5 m thick at the most), and the absence of shells of *Spisula*, the most common open marine mollusc species on the Dutch North Sea coast, suggest that this beach was not subjected to wave conditions normal at North Sea beaches (NB around 5500 BP wave conditions in the southern North Sea were only slightly less energetic as today (Stive 1987; Van der Molen and De Swart 2001). This suggest a sheltered position of this beach, protected from the bigger waves, possibly by a very shallow offshore morphology. The latter can either be caused by rapid coastal retreat or by sediment supply from the southwest, were older Holocene alluvial deposits were being reworked by marine processes (Van Heteren et al. 2003; in revision).

The deposition in the tidal basin eastward of the beach and tidal flats resulted in siltation and a decreasing tidal prism. The latter caused a decrease in dimensions of the tidal channel in the northern part of Ypenburg. The channel gradually became narrower and shallower, allowing the bounding tidal flats to expand. Continued sedimentation in the tidal flats, now protected by the beach in the west, resulted in vertical aggradation into a high-intertidal to supratidal environment. Close to the beach and the tidal channel this will have been a beach plain, further basinward this will haven been a salt marsh. The vertical aggradation, despite the ongoing rise in sea level, is caused by the positive sediment balance of the area. In the beach plain wash-over occurred during storm surges. During dry spells the wind could built small-scale dunes.

The architecture of the deposits shows a sandy to muddy tidal-flat area, bounding a tidal channel. On the seaward side, these tidal flats were reworked by waves, suggesting a position very close to a tidal inlet. The main tidal channel in the northern part of Ypenburg filled in and changed into a intertidal flat area. Although ridges and runnels have been found here, it is not clear whether sand transport by waves caused longshore transport and spit formation, contributing to the infilling of the channel. The limited

wave activity caused by the sheltered position (see above) makes significant spit formation unlikely.

During the final stage of evolution, from 5200 BP onwards, a large beach barrier formed about 2 km to the west of Ypenburg. This increased the sheltered position of Ypenburg and the area east of it, enhancing sedimentation. Only after the completion of the new barrier, the tidal inlet closed, leaving the tidal flats/beach plain as a relict feature. Subsequently, the tidal basin rapidly changed into a coastal peat bog.

The change from a transgressive to a prograding coastal system, despite a rate of RSLR that was 2-3 times higher than at present, was the result of an extensive supply of sediments from the southwest, were older Holocene alluvial deposits were being reworked by marine processes (Van Heteren et al. 2003; in revision).

CONCLUSION

Ypenburg is situated on the seaward boundary of a transgressive tidal basin which evolved from a predominantly subtidal into a intertidal flat area. During this evolution the landward expansion of the basin stopped. The formation of a wave-influenced sand body indicates the position of the coast line. The limited thickness of the wave-dominated deposits and the lack of shells of open-marine molluscs indicate that this coast line was sheltered from open North Sea conditions. This sand body can be considered a transgressive barrier. The infilling of the tidal basin and the associated decreasing tidal channel are the onset of coastal regression. The formation of a beach barrier further seaward is the start of coastal progradation which eventually resulted in a barrier sequence of over 8 km wide.

ACKNOWLEDGEMENTS

We would like to thank Hans Koot, the principal archeologist of the city of Rijswijk, who led the excavations at Ypenburg for facilitating and supporting the field work. Bastian van Dijck was a great help in the field, especially during the hand drilling campaign. Our understanding of the geology of Ypenburg and its surroundings improved significantly from discussions with Dirk Beets and Bert van der Valk.

CHANGING ORIENTATION OF OCEAN-FACING BLUFFS ON A TRANSGRESSIVE COAST, CAPE COD, MASSACHUSETTS

Graham S. Giese[1], Mark B. Adams[2]

1. Provincetown Center for Coastal Studies, 3 Holway Ave., Provincetown, MA 02657, USA. ggiese@coastalstudies.org .
2. Cape Cod National Seashore, US National Park Service, Wellfleet MA 02667, USA. Mark_adams@nps.gov .

Abstract: Erosion of the 24 km-long escarpment cut into the unconsolidated Pleistocene glacial deposits of outer Cape Cod, Massachusetts, by wave action during the Holocene transgression has supplied sediment for construction of spits and barrier beaches to its north and south. The major escarpment landforms produced by the erosion are steep coastal bluffs (upper c. 20 m), beaches, and a more gently sloping shoreface (to a depth of c. 10 m). Using differential GPS methods supplemented with LIDAR data we have re-surveyed the bluff portion of the escarpment along cross-shore transects originally surveyed in 1887-1889. Comparison of the surveys indicates that the bluffs erode at an overall century-scale rate of c. 0.8 m/yr, and that the erosion rate increases alongshore north-to-south by a factor of two. We suggest that the resulting change in coastal orientation results from relative sea level rise over the outer continental shelf and associated increase in wave energy from the southeast.

INTRODUCTION

Coastal bluff erosion is significant to environmental management largely due to two concerns: the threat it poses to coastal development, and the quantity and quality of sediment that it supplies to the littoral system. These concerns have motivated recent studies of bluff retreat on both ocean coasts of the United States as well as along the shores of the Great Lakes (Young and Ashford 2006; Kelley and Dickson 2000; Jibson and Odum 1994).

The focus of this study, the eroding east-facing bluffs of outer Cape Cod, Massachusetts, lie within the Cape Cod National Seashore (CCNS), and for that

reason their impact on coastal development is a relatively minor concern. They are critically important, however, as a sediment source. The bluffs together with the adjacent beach and shoreface (which extends to depths of more than 10 m) comprise a 24 km-long escarpment cut into unconsolidated Pleistocene glacial deposits by wave action during the Holocene transgression.

Erosion of the bluffs and shoreface is the sole source of sediment, not only for the beaches along the shoreline of the escarpment, but also for the spits and barrier beaches which make up the landforms north and south of the escarpment (Figure 1). Management of these depositional features and the bays, harbors and marshes associated with them is a matter of major concern for the CCNS and the region's municipalities.

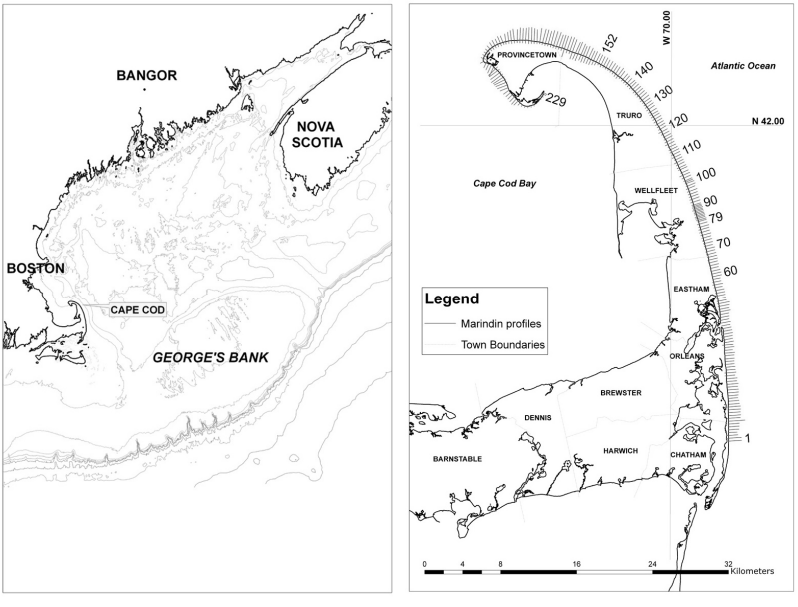

Fig.1. Cape Cod and the Gulf of Maine. The eroding bluffs surveyed in this study extend from "Marindin profile" MS56 to MS144.

While escarpment erosion appears to have been continuous throughout the transgression, construction of the depositional landforms does not, because the rates and direction of sediment transport have varied with sea level. For example, Provincetown Hook, north of the escarpment, is believed to have formed during the past approximately 6,000 years as the result of increased wave energy from the southeast due to increasing sea level over the outer continental shelf (Zeigler, et al. 1965).

Zeigler et al. (1964a, 1964b, 1965), using methods similar to (but technologically less advanced than) those described below, estimated the mean annual erosion rate of the bluffs to be approximately 0.8 m/yr over a seventy-year period. They also concluded that the bluff retreat rate remained constant alongshore for most of the escarpment. In general the reports suggested a steady state relationship between wave climate, escarpment erosion and sediment supply to landform systems to its north and south .

Pressing coastal management concerns together with restricted budgets for structural operations have motivated recent efforts to review and extend existing understanding of the physical underpinnings of sediment processes along this coast. Examples include studies of the region's beaches by O'Connell, Thieler and Schupp (2002) and of the lower shoreface and inner shelf by Poppe et al. (2006). The importance of re-examining the century-scale retreat of the bluff was recognized by Allen et al. (2001) who initiated the study which led to the present report.

METHODS

Henry L. Marindin (1889, 1891) surveyed 229 coastal profiles, normal to the shoreline of outer Cape Cod and reported latitude, longitude, azimuth and elevation for each line. For the present study, Marindin's profiles were resurveyed using Global Positioning System (GPS) receivers for navigation and measurement. To prepare the reported locations for use with GPS, Marindin's locations were converted from the original horizontal datum to the 1927 North American Datum (NAD27) by subtracting 0.6 seconds of latitude. This adjustment is based on available reference coordinates from local benchmarks (Curtis Crow, Massachusetts Division of Highways Geodesist, personal communication).

The results were then transformed to the current North American Datum of 1983 (NAD83) using ESRI ArcGIS software and loaded into Trimble differential GeoXT and Pathfinder ProXR GPS receivers for navigation. The GPS receiver's navigation mode reports distances from the origin station along the azimuth line. Distances from origin to current feature locations were recorded along each of profile (e.g., bluff crest, bluff toe, beach berm, swash zone). These distances were used to construct current profiles (without elevations) for comparison to the corresponding feature locations reported by Marindin.

Elevations were acquired for a few profiles using Trimble 5700 Real Time Kinematic GPS with a GPS base station for precise correction. Base station locations were corrected using the National Geodetic Survey's Online Positioning Service (OPUS). GPS locations were corrected using Trimble Geomatics Office software. Also, a complete set of elevations for all profiles was extracted from LIDAR data collected May 4, 2005, for the National Park Service (NPS) through a cooperative effort with NASA and the USGS Center for Coastal Studies in St Petersburg, Florida.

We report the century-scale bluff retreat in terms of change in location of the bluff

toe. The bluff toe was chosen as diagnostic of bluff retreat because it was specified in the 19th Century surveys, its position can be accurately determined in the field (the landward edge of marine deposits), and the negative feedback provided by bluff slumping produces a remarkably smooth alongshore lineation unequaled by other horizons.

RESULTS

The set of bluff toe locations as determined by our 2003-2004 survey is presented in Figure 2a. The data points with closer than usual spacing correspond to regions of special concern to the original surveyors (Marindin 1889). Larger gaps between data points occur at locations for which we encountered problems in the original data set. Two major sources of such problems were missing designations of the exact location of the bluff toe and obvious mistakes in the profile descriptive information (e.g., clearly erroneous latitude or longitude data).

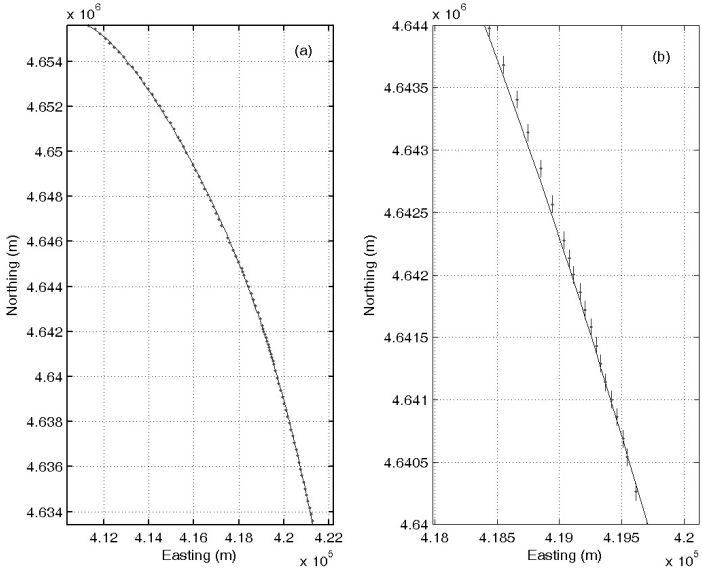

Fig.2. (a) Bluff toe locations from 2003-2004 surveys. (b) Enlargement of fitted polynomial with error bars described in text.

The general smoothness of the line of bluffs as defined by the bluff toe location is illustrated by the associated line, a fourth-order polynomial of "best fit" to the data. Deviations from the smooth curve are illustrated in Figure 2(b), which is an enlargement of one section of the first plot and includes error bars estimated to include at least 50% of the data points.

Century-scale change in location of the bluff toe was determined, as explained above, by the difference between the location of the feature along specific profiles in the 1887-1889 surveys and its location in the 2003-2004 surveys. The change was then expressed in terms of a long-term mean annual retreat rate by dividing the total change by the intervening time period. The results for specific profiles are represented in Figure 3, a scatter plot of data points plotted with respect to their alongshore distance north of the Marindin Station #1 (MS1).

Averaged over the entire length of the bluff section, 23.7 km, the mean value of the individual data points is 0.79 m/yr. However, Figure 3 indicates an overall northward decrease in bluff retreat over the time period between surveys. The oblique solid regression line represents the best approximation to the data using a linear relationship between the variables; the dashed and dotted lines are offset from the regression line by one and two standard deviation units respectively. The slope of the regression line indicates that the century-scale retreat rate decreases by approximately one-half along the section, from 1.03 m/yr to 0.53 m/yr, south to north.

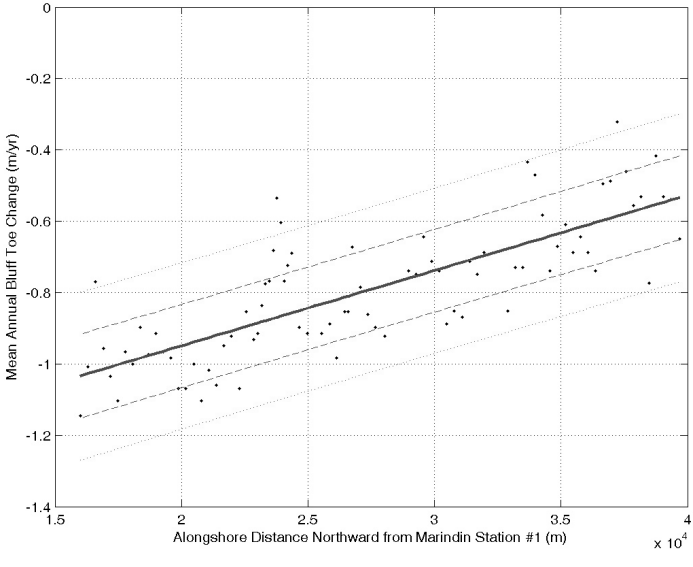

Fig.3. Scatter plot of century-scale bluff retreat rate showing linear regression line and that line extended by one and two standard deviation units.

To summarize, combining the results of our surveys during 2003-2004 with those of Henry Marindin's surveys during 1887-1889 to determine the century-scale change in the line of coastal buffs, we find that as measured at their toe they have retreated

overall at an average rate of 0.79 m/yr when expressed in terms of a long-term annual mean, and the rate of retreat varies linearly alongshore, decreasing by about one-half south-to-north over the 23.7 km section.

DISCUSSION

Coastal Orientation

While an average long-term retreat rate for the entire bluff section of approximately 0.8 m/yr is consistent with results of earlier studies (Uchupi et al. 1996), the previous results concluded that the retreat rate is constant alongshore for all but the northernmost part of the section (Zeigler et al. 1964b) in marked contrast to the present results. Nevertheless the finding of a northward decrease in bluff erosion does not come as a complete surprise. Geological reconstructions have indicated alongshore changes in coastal retreat during the Holocene (Uchupi et al. 1996), and studies of contemporary beach changes (O'Connell et al. 2002) show increasing erosion toward the south.

In addition, an alongshore change in bluff retreat rate as opposed to a constant rate may be more consistent with the overarching hypothesis of Zeigler et al. (1965): that relative sea level plays a dominant role in coastal processes along this shore by altering the depth of the extensive "Georges Bank" shoal on the outer continental shelf, thereby altering wave energy input from the southeast (North Atlantic basin). Applying this hypothesis, Zeigler et al. (1965) ascribed initiation of Provincetown Hook's development about 6,000 years ago to a reversal in direction of sediment transport, from southward to northward, resulting from submergence of George's Bank.

However, regional relative sea level has risen some 10 m since that time (Uchupi et al. 1996), presumably increasing wave energy from the southeast and thereby increasing the rate of net northward sediment flux. The expected coastal response with respect to orientation would be clockwise rotation (Giese 1964) which is consistent with the present results.

Net Sediment Flux

While such a change in the coastline orientation would provide negative feedback to counter the increased net northward sediment flux, a question arises as the relative rates of the two. The observed linear change in bluff retreat of about 0.5 m/yr over a distance of 23.7 km would produce a change in orientation of only about 1.2 degrees per 1,000 years. How would the resulting net flux decrease compare with the flux increase that would otherwise result from continuing relative sea level rise? The question has practical implications, especially in light of expected future increases in the rate of global sea level rise.

The answer requires information concerning wave climate and sediment flux not presently available as well as an analysis of the dynamics of their interaction. We

can, however, gain insight into the problem using recent LIDAR data and a simple kinematic analysis (Singh 2002).

Here we will consider the net alongshore sediment flux, that is, the net annual volume rate of alongshore transport, Qn, at a single location as the difference between the northward and southward annual fluxes at that point. Alongshore distance, y, will be positive toward the north. Were sediment volume to be conserved with no losses (sources or sinks) off- or on-shore, the alongshore gradient (i.e., divergence) of net flux, $\Delta Qn/\Delta y$, would equal the negative of the annual change in cross-shore area at that location, $\Delta A/\Delta t$.

For example, at a specific location a 1 cubic meter per year net flux increase per meter alongshore would result in a 1 square meter per year decrease in cross-sectional area, assuming sediment volume to be conserved. In our case, however, an estimated 18 % of the eroding glacial "source" material is lost offshore and does not contribute to depositional features (Zeigler et al. 1964a). Thus the relationship in this case can be expressed:

$$\Delta Qn/\Delta y = -0.82\,(\Delta A/\Delta t) \qquad (1)$$

where Qn = net alongshore sediment flux (m^3/yr); y = alongshore coordinate positive northward (m); A = cross-sectional area between successive "surveys" of individual profiles (m^2); t = time interval between successive "surveys" (yr).

To approximate $\Delta A/\Delta t$ at specific "Marindin lines" for the bluff portion of the sections, we plotted elevation vs. distance derived from the 2005 LIDAR data and compared the resulting profile with that provided by Marindin (1889). For the beach and shoreface sections, we simply translated the 1887-1889 profiles shoreward to match the profiles' bluff toe to the location of that feature as determined in our 2003-2004 surveys. Since all Marindin profiles reached at least a depth of 10 m, our submarine area calculations use a – 10m limit. Figure 4 provides an example of the method as applied to line MS100.

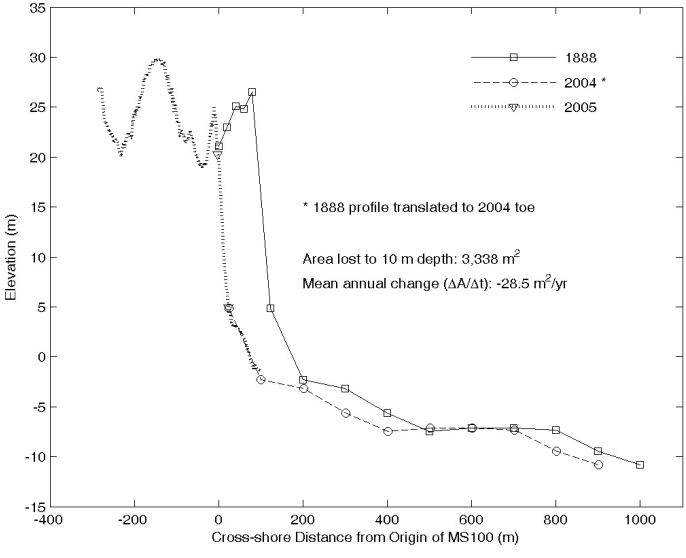

Fig.4. Comparison of cross-shore profiles at station MS100 as determined in 1888 and 2004-2005 (see text for details).

The value of $\Delta A/\Delta t$ for MS100 using this approximation is – 28.5 m^2/yr. Expressed in terms of the alongshore gradient of net flux using equation (1), this is equivalent to a $\Delta Qn/\Delta y$ value of 23.4 m^2/yr. This and the results of similar calculations carried out for several other representative lines are plotted in Figure 5. The large scatter of the values results primarily from the alongshore irregularity of bluff elevation. At MS152 (y = 42.3 x 10^3 m), the LIDAR and Marindin profiles coincide at the shoreline, marking this as the point of maximum net flux (i.e., $\Delta Qn/\Delta y = 0$).

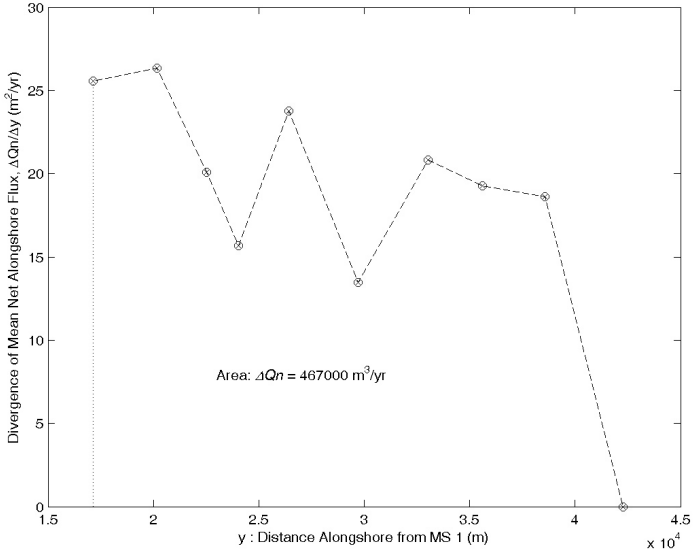

Fig.5. Scatter plot of alongshore divergence of rate of net alongshore sediment flux at selected bluff locations (see text).

Uchupi et al. (1996) estimate the total flux of sediment supplied to the Provincetown Hook as approximately 470,000 m^3/yr. Taking this as the value of the net flux, Qn, at MS152 ($y = 42.3 \times 10^3$ m) we can estimate the reduction of Qn, i.e., ΔQn, at another location southward along the bluff section through numerical intergration of $\Delta Qn/\Delta y$ over the interval of alongshore distance, Δy, between the other location and MS152.

Figure 5 illustrates that the result of this operation carried out between MS60 ($y = 17.2 \times 10^3$ m), which is near the southern limit of the eroding bluff section, and MS152 amounts to a net flux reduction of approximately 467,000 m3/yr. Despite the many approximations and assumptions employed, this suggests that at present, some 6,000 years after the submergence of Georges Bank, most if not all of the material eroded from the bluffs of outer Cape Cod is being transported northward to the Provincelands Hook. We plan to re-survey the bathymetric sections of Marindin's transects in the near future and, using these results, improve our sediment flux calculations for this section of the coast.

CONCLUSION

Results of recent surveys of the outer Cape Cod coast indicate that erosion of the section of exposed bluffs increases by a factor of two between the northern and southern ends of the section. We suggest that this increase and the resulting change in coastal orientation

are the result of continuing submergence of the Georges Bank shoal on the outer continental shelf southeast of Cape Cod. The change in orientation provides negative feedback to increased net northward sediment flux resulting from the shoal's submergence. However preliminary sediment transport calculations indicate that despite the changing orientation, most or all of the sediment supplied by bluff erosion is now transported northward.

ACKNOWLEDGEMENTS

We acknowledge the contributions of our colleague and friend, the late James (Jim) R. Allen, who initiated current resurveys of Henry Marindin's profiles and developed the initial coastal change protocol for the National Park Service's Inventory and Monitoring Program before his untimely passing.

Charles Labash of the University of Rhode Island Environmental Data Center transformed Marindin's coordinates to modern datums. Terri Smith, Dave Spang, Ben Bornstein, and Jim Gallagher provided valuable field assistance. The project has been generously supported from the beginning by the Provincetown Center for Coastal Studies, the Cape Cod National Seashore's Atlantic Research Center and the Town of Chatham. Additional community support was provided by the Cape Cod Five Cents Bank.

Abstract: An 8500-year Holocene simulation developed in GEOMBEST provides a possible scenario to explain the evolution of barrier coast between Rodanthe and Cape Hatteras, NC. Sensitivity analyses suggest that in the Outer Banks, the rate of sea-level rise is the most important factor in determining how barrier islands evolve. The Holocene simulation provides a basis for future simulations, which suggest that if sea level rises up to 0.88 m by AD 2100, as predicted by the highest estimates of the Intergovernmental Panel on Climate Change, the barrier in the study area may migrate on the order of 2.5 times more rapidly than at present. If sea level rises beyond IPCC predictions to reach 1.4-1.9 m above modern sea level by AD 2100, model results suggest that barrier islands in the Outer Banks may become vulnerable to threshold collapse, disintegrating during storm events, by the end of the next century. Consistent with sensitivity analyses, additional simulations indicate that anthropogenic activities, such as increasing the rate of sediment supply through beach nourishment, will only slightly affect barrier island migration rates and barrier island vulnerability to collapse.

INTRODUCTION

Barrier islands front a large percentage of the United States Atlantic and Gulf of Mexico Coasts. Because they are narrow and low-lying these landforms are extremely vulnerable to relative sea-level rise and storms. As sea level rises, a barrier island will respond either by migrating landward across underlying substrate to higher elevations or by disintegrating if there is no longer sufficient sand volume and relief above sea level to prevent inundation during storms. Disintegration of the Chandeleur Islands off of the

Louisiana coast during Hurricane Katrina may represent this type of threshold response whereby rapid rates of relative sea-level rise increase the vulnerability of migrating barriers allowing potentially irreversible destruction by storms to occur and ultimately leading to collapse of the barrier system. Several factors determine whether a barrier island will respond to sea-level rise by transgression or by submergence and collapse. These factors include the initial topography and morphology of the barrier, the geologic framework underlying the barrier, the availability and supply of sediment, the rate of sea-level rise, profile-response factors such as closure depth and anthropogenic modifications to the coast.

Recent predictions for the North Carolina Outer Banks, based on geologic interpretations, suggest sections of this barrier coast may collapse, becoming submerged within decades if sea level continues rising at current rates (Riggs and Ames, 2003). Our goal is to test the validity of this hypothesis by applying a morphological-behavior model, GEOMBEST, to 25-km of barrier coast expected to be among the first stretch of barrier to collapse in the Outer Banks. First, we simulate the Holocene evolution of the Outer Banks and perform sensitivity analyses to provide insight into which factors are most important in determining how the Outer Banks respond to sea-level rise. We then use the Holocene hindcast simulation as the basis for forward simulations to explore the potential response of the Outer Banks to future sea-level rise scenarios.

Study Area

The study area encompasses 25-km of barrier coast between Rodanthe and Cape Hatteras, NC (Figure 1), extending from the mainland to the shelf edge. The area is largely undeveloped including 17.5 km of National Seashore and the small towns of Avon and Salvo. The barrier island is narrow, ranging in width from 0.5 to 1.5 km and a discontinuous frontal dune provides only moderate relief across the study area. Longshore transport is to the south with a net volume of 5.9×10^5 m^3/yr lost between Oregon Inlet and Cape Hatteras (Inman and Dolan, 1989). Long-term shoreline change rates range from +2 to -4 m/yr (Morton et al., 2005).

METHODS

The Model

Because process-based models cannot yet address questions of large-scale coastal behavior, most predictions regarding future barrier island response to sea-level rise are based solely on geologic inference. Morphological-behavior models currently provide the only quantitative method for assessing how barrier islands evolve under changing conditions. These models are based on changes in sediment supply, sea-level rise and shoreface geometry (Cowell et al., 1995), but don't account for the physical processes of sediment transport. GEOMBEST (Geomorphic Model of Barrier, Estuarine and

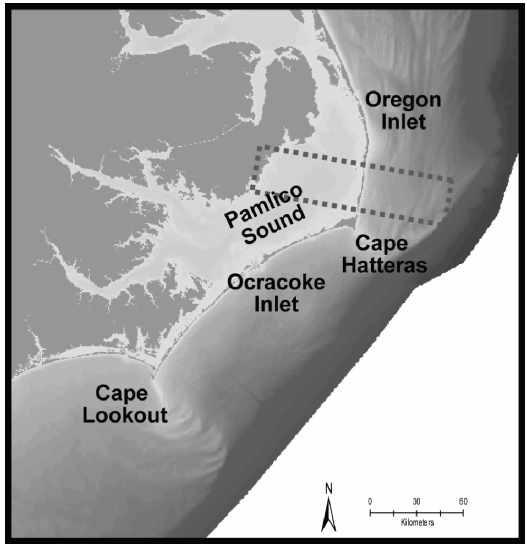

Figure 1. The study area is indicated by the rectangular box and encompasses 25-km of barrier coast between Rodanthe and Cape Hatteras, NC.

Shoreface Translations), as described by Stolper et al. (2005), is a profile-based, numerical morphological-behavior model that simulates the evolution of barrier island morphology and stratigraphy resulting from changes in sea level and sediment supply over time scales ranging from decades to millennia. The model incorporates information on the geologic framework and provides a quantitative means for testing the geometric feasibility of geologic hypotheses.

In an approach similar to that of Cowell et al. (1995), the model formulation in GEOMBEST is based on sediment conservation principles and behavior rules originating from "Bruun Rule" concepts, but with significant additional components allowing simulation of complex geological scenarios in which assumptions are relaxed, in an attempt to address concerns over the existence of equilibrium profiles (e.g., Pilkey and Cooper, 2004). The coastal tract in GEOMBEST extends from a user-defined distance offshore to the mainland and is divided into three functional realms including the shoreface, backbarrier and estuary (Figure 2). Each realm is treated separately in the model, but sediment is exchanged between them. GEOMBEST differs from other coastal evolution models by allowing specification of substrate characteristics along the coastal tract (i.e., erodibility and sand/mud ratio) and additional parameters allow for specification of open and changing sediment budgets. Morphological evolution is driven by disequilibrium between the coastal tract surface and a user-specified, equilibrium shoreface profile that maintains its vertical position

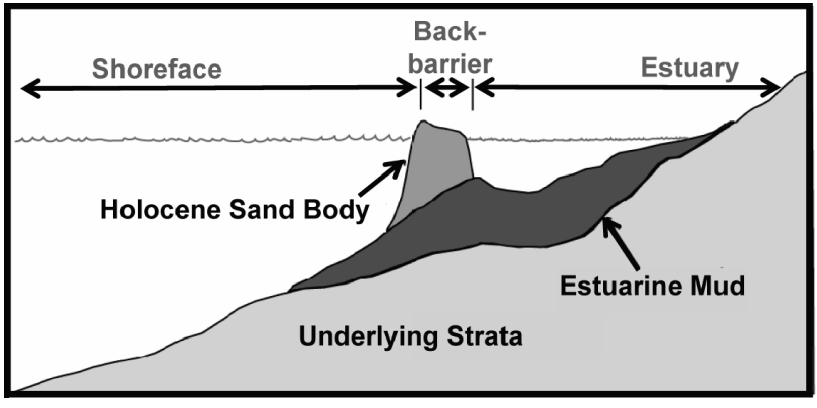

Figure 2. Cross-shore schematic showing three functional realms and stratigraphic units defined in GEOMBEST for a low-gradient barrier island coast. (After Stolper et al., 2005)

relative to sea level. Although the model drives toward equilibrium at each time step, it does not require equilibrium to be established. For example, the equilibrium profile will not be attained if the substrate is nonerodible or if sea-level rises too rapidly.

Input Parameters

The modern shelf morphology was obtained by averaging 18 alongshore transects spaced 1.5 km apart along the 25 km study area. To allow for substrate erosion, which is thought to have occurred in order to supply adequate amounts of sediment to the barrier system (McNinch et al., 1999) and which is supported by the presence of Pleistocene shells in the Holocene sand body (Wehmiller, 1999), an average of 5 m of vertical thickness was added to the modern shelf surface. Adding this layer of sediment provides an initial shelf surface across which an initial active sand body migrates landward throughout the Holocene simulation (Figure 3).

We begin the simulation with an active sand body that is approximately half the size of the Holocene active sand body currently located at the modern shoreline. Representative substrate characteristics and stratigraphy for the study area were determined for model input from cores, seismic sections and ground-penetrating radar data collected as part of a North Carolina Regional Study (Mallinson and Theiler, personal communication) (Figure 3).

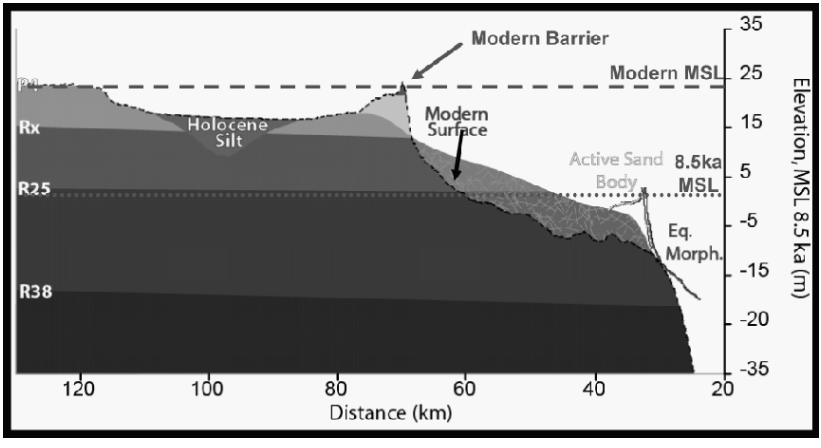

Figure 3. Stratigraphy (solid colors) and modern shelf surface (dashed black line) for the study area. 6 m of substrate is added to the modern surface (hatched area) and the active sand body (yellow) is moved offshore to create initial geometry for the Holocene simulation.

We begin the Holocene simulation 8.5 thousand years ago, when sea level was 22.5 m below modern sea level (MSL). Geometric contraints require the placement of the initial active sand body at both the shelf edge and at the farthest extent of the cape-associated shoals, which are believed to have been a major sink to the barrier island system throughout the Holocene (Pierce, 1969; Inman and Dolan, 1989; McNinch and Wells, 1999; McNinch and Luettich, 2000). Sea-level rise throughout the simulation follows the best available Holocene sea-level rise curve for North Carolina with rates of 0.5 m/100 yrs from 8.5 ka – 6.8 ka, 0.24 m/100 yrs from 6.8 – 4.2 ka and 0.15 m/100 yrs from 4.2 ka – 0 ka (Theiler et al., 2004). We assume a closure depth of 20 m based on shoreface and shelf morphology. This value agrees well with closure depths of 18.6 m and 21.6 m determined by Everts (1978) for Nags Head and Cape Hatteras, respectively. In order to bring the active sand body to its modern position while maintaining a modern sediment budget that matches closely the net loss of 5.9 x 10^9 m^3/yr reported by Inman and Dolan (1989) and to reproduce the modern shelf morphology, the sediment budget is varied throughout the simulation. The sediment budget is balanced from 8.5 ka – 6.8 ka, with 0 m^3/m/yr removed, negative from 6.8 – 4.2 ka, with 30 m^3/m/yr removed and negative from 4.2 ka – 0 ka, with 25 m^3/m/yr removed. Considered along the 25-km-long study area, the latter figure represents the removal of 625,000 m^3/yr, which comes close to the estimated net 590,000 m^3 transported to the south annually in the study area as estimated for recent decades (Inman and Dolan, 1989).

RESULTS AND DISCUSSION

Sensitivity Analyses

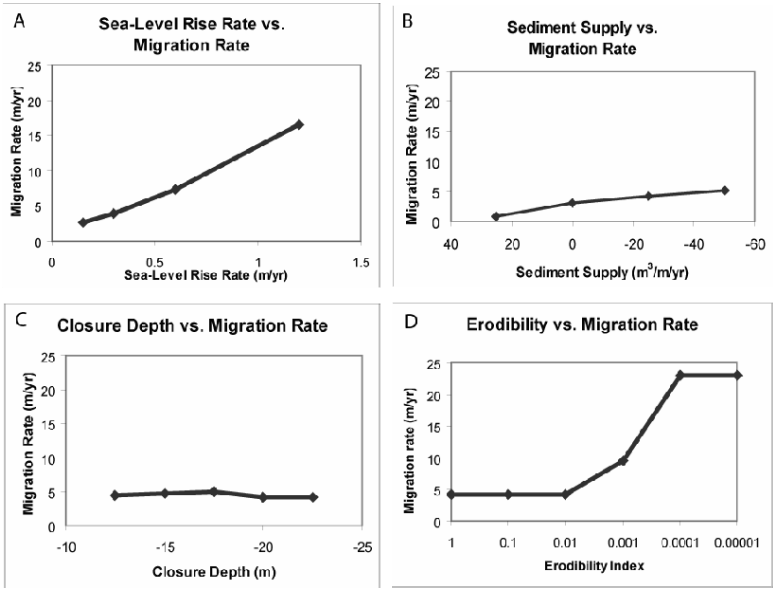

Figure 4. Results of sensitivity analyses demonstrating the effects on barrier island migration rate of changes in the rate of sea-level rise (A), rate of sediment supply (B), depth of closure (C) and substrate erodibility (D).

We explore the relative importance of sediment supply, sea-level rise rate, closure depth and substrate erodibility in determining barrier island response by varying one parameter at a time in the Holocene simulation. The relative importance of each factor is assessed by determining the degree to which changing the parameter produces a change in the rate of landward barrier island migration. Changing the sea-level rise rate by 100% from 0.3 m/100 yr to 0.6 m/100 yr produces increases migration rates 87% while decreasing the sediment budget in increments of 100% increases migration rates 40% as the sediment budget changes from balanced to -25m^3/m/yr (Figure 4). As closure depth changes from 12.5 m to 22.5 m by 2.5 m increments, migration rates change less than 6.5%. Migration rates are particularly insensitive to the erodibility of the substrate showing no change until the substrate is 1/1000 as erodible as a fully erodible unconsolidated sediment (Figure 4). Thus, given the range of sediment supply rates within the Outer Banks of North Carolina, sensitivity analyses indicate that barrier island migration rate is most sensitive to the rate of sea-level rise followed by the rate of sediment supply. Barrier island migration rate is less sensitive to closure depth and not sensitive to erodibility until the substrate is nearly nonerodible.

Holocene Simulation

The 8500-year hindcast simulation for the Outer Banks study area comes close to reproducing the morphology and stratigraphy of the modern barrier (Figures 5,6). For example, the edge of the modern shelf lies at a water depth of -11 m compared with -10 m reproduced by the simulation (Figure 6). A total of 4.5 x 10^9 m^3 of sediment is removed throughout the simulation. This sediment volume is of the same order of magnitude as the estimated volume (4.0 x 10^9 m^3) of the three cape-associated shoals (Diamond Shoal, Lookout Shoal and Frying Pan Shoal) as measured above the 12 m isobath (McNinch et al, 1999) suggesting that the volume removed throughout the simulation is reasonable. The Holocene simulation results in an average modern migration rate of -3.4 m/yr, which falls within the range of modern shoreline change rates for the study area of -4 to 2 m/yr (Morton et al., 2005), indicating that the simulation closely fits this additional observational constraint.

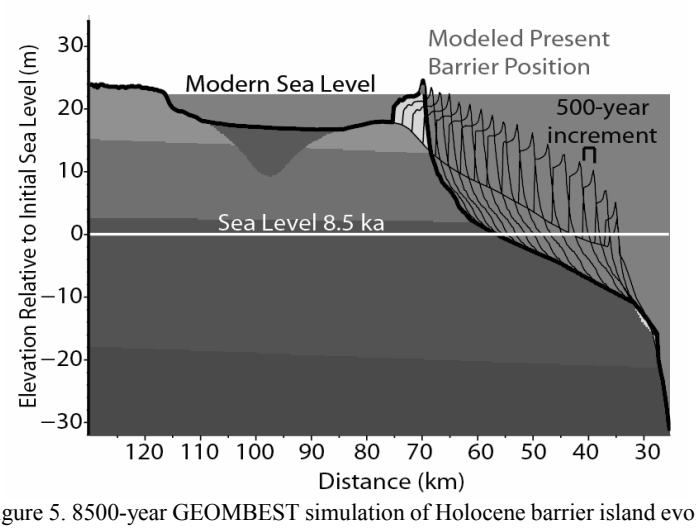

Figure 5. 8500-year GEOMBEST simulation of Holocene barrier island evolution for the study area. Pleistocene stratigraphy appears in brown. 500-year increments of time are shown as ghost traces and the final configuration of the shoreface is in bold.

Most critical to the reliability of forward simulations, for which the Holocene simulation serves as the basis, is comparison between the average modern surface (including the shelf, nearshore and active sand body), the initial surface used in the Holocene simulation, and the model-generated surface. This comparison indicates that the Holocene simulation reproduces closely the modern morphology and position of the Holocene sand body.

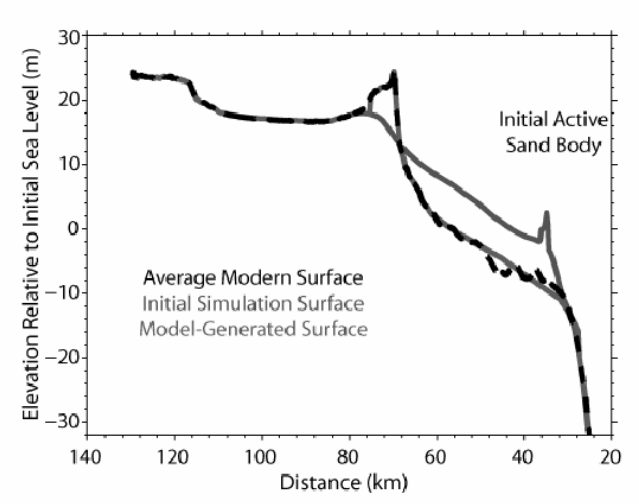

Figure 6. Comparison of the average modern surface (black dashed line), the initial surface used in the Holocene simulation (blue line), and the model-generated surface (red line).

Future Response to Sea-Level Rise

According to the Intergovernmental Panel on Climate Change (IPCC), sea level will likely rise between 0.09 and 0.88 m by AD 2100 (IPCC, 2001) unless there is a substantial reduction in greenhouse gas emissions. More recent studies suggest that IPCC estimates of sea-level rise may be too conservative and that conditions may be warm enough within the next century to cause melting of the Greenland Ice Sheet (GIS) and the West Antarctic Ice Sheet (WAIS), perhaps triggering many meters of sea-level rise (Gregory et al., 2004; Overpeck et al., 2006). If the GIS and the WAIS were to melt sufficiently, sea level could return to last interglaciation (LIG) levels of 4-6 m above present (Overpeck et al., 2006).

Forward simulations of potential barrier island response to several sea-level rise scenarios for AD 2100 start with the Holocene simulation described above and include an additional 100 years of barrier evolution with sea level rising linearly to specified elevation above modern MSL. A series of model runs based on the low- (0.09 m), mid- (0.48 m) and upper- (0.88 m) range of IPCC (2001) estimates for total sea-level rise by the year 2100, indicate future barrier migration rates of 2.3, 6.2 and 9.8 m/yr, respectively (Figure 7). The latter two results would represent an increase of up to nearly 2.5 times the fastest observed shoreline change rates in the study area, which range from 4 m of erosion to 2 m of accretion (Morton et al., 2005). Despite representing a significant increase, these rates are within the range of rates experienced by rapidly migrating barrier islands elsewhere today (Morton et al., 2004; Morton et al., 2005; Penland et al., 2005), suggesting that the barrier may remain intact even if the highest IPCC sea-level rise estimate is reached.

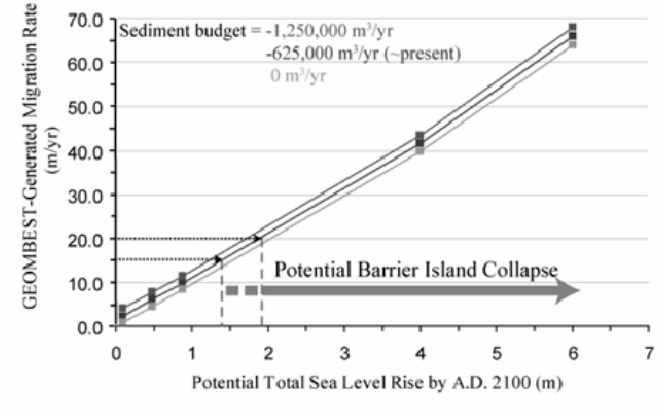

Figure 7. Model-generated barrier island migration rate as a function of total potential sea-level rise for scenarios in which the sediment budget remains similar to today, decreases by 100% and increases by 100%. The effect of an increase and decrease in sediment supply on the sea-level rise threshold is indicated by a vertical dashed green and blue line, respectively.

GEOMBEST simulations of barrier island response to 4 m and 6 m of sea-level rise by AD 2100 result in model-predicted barrier migration rates of 41 and 65 m/yr, respectively (Figure 7). These rates far exceed the highest average long-term barrier island erosion rates observed today along the Louisiana coast where the southern end of North Chandeleur Island eroded at average long-term rates of up to 18.6 m/yr (Morton et al., 2005) before disintegrating in response to Hurricane Katrina. This response to Katrina likely represents a threshold collapse whereby rapid rates of relative sea-level rise increase the vulnerability of migrating barriers allowing potentially irreversible destruction of the subaerial landform to occur during storms. In 1978, the Isle Dernieres off the coast of central Louisiana also entered into a period of rapid deterioration in response to a series of hurricanes (Williams et al., 1992) and recent measurements indicate these islands are eroding at average long-term rates of 5.2 to 17 m/yr (Penland et al., 2005). Relative sea level in Louisiana is rising 1.04 cm/yr (almost 10 times faster than the global average) (Penland and Ramsey, 1990) and sand supply is limited, making the barrier islands of Louisiana potentially viable analogs to islands that may experience similar conditions in the future. If barrier island observations in Louisiana can be applied to barriers in North Carolina, we can expect the Outer Banks to become vulnerable to threshold collapse when migration rates reach approximately 15-20 m/yr.

Model results for the five forward simulations suggest migration rates of 15 - 20 m/yr may occur if sea level rises approximately 1.4 - 1.9 m above modern MSL by AD 2100 (Figure 7). Additional simulations are consistent with the results of sensitivity analyses and suggest that changes in sediment supply plays a secondary role, modifying slightly the total sea-level rise at which barriers may become vulnerable to threshold collapse. For example, mitigating the negative sediment budget by 100% (e.g., nourishing the beaches with 625,000 m^3/year to create a balanced budget) decreases migration rates by 1.6 m/yr, which would offset barrier vulnerability to sea level rise by 0.2 m, while doubling sediment removal (from 625,000 m^3/year to 1, 050,000 m^3/year) increases migration rates by 1.6 m/yr, which would increase barrier vulnerability to sea-level rise by 0.2 m (Figure 7, green and red lines, respectively). Thus, regardless of the minor effects of possible anthropogenic modifications, our findings suggest barrier islands may become vulnerable to threshold collapse if the IPCC (2001) estimates are exceeded and sea level rises approximately 1.4 - 1.9 m above MSL by AD 2100.

CONCLUSIONS

Morphological-behavior models currently provide the only quantitative means by which to simulate barrier island evolution over long time scales. Using the morphological-behavior model GEOMBEST, we develop a Holocene simulation that closely reproduces the modern shelf and barrier morphology and provides a possible explanation for the evolution of the barrier coast between Rodanthe and Cape Hatteras, NC. Development of this simulation reveals that shoal morphology, shelf geometry and former sea levels are consistent with barrier island formation in the study area approximately 8500 years ago when sea level was 22.5 m below MSL. Sensitivity analyses suggest that in the Outer Banks, the rate of sea-level rise is the most important factor in determining barrier island migration rate and thus how barrier islands have evolved and will continue to evolve, in the future. Future simulations of barrier island response to sea-level rise, combined with modern observations, suggest that if sea-level rises ~0.9 m by 2100 AD, the Outer Banks may migrate up to 2.5 times more rapidly than at present, but will likely remain intact. However, additional results indicate that if sea-level rises beyond IPCC predictions by A.D. 2100, reaching 1.4-1.9 m above MSL, the Outer Banks may become vulnerable to "threshold collapse." Anthropogenic modifications to the sediment budget appear to only slightly mitigate increases in barrier island migration rate and vulnerability to collapse. This is consistent with the results of sensitivity analyses and may have significant implications for the future sustainability of coastal management practices.

Abstract: Rates of relative sea level rise in excess of 1 cm/yr are forcing rapid landward migration of barrier/tidal inlet systems along coastal Louisiana. Additionally, the conversion of interior wetlands to open water increases tidal prism, resulting in barrier degradation by means of increased inlet cross-sectional area and sediment sequestration in ebb tidal deltas. Historical bathymetric maps (dating to the 1880's) and up-to-date bathymetric data for Little Pass Timbalier provide a time series that shows the morphological evolution of this tidal inlet. The historical evolution includes: landward and lateral migration of its main channel (44 m/yr and 28 m/yr, respectively); changes in inlet throat geometry; and formation of a new stable ebb channel. The inlet throat cross-sectional area increased from 3,117 m^2 in 1880 to 17,510 m^2 in 2005. The ebb tidal delta is prograding seaward leaving a quasi-progradational sand body on the inner shelf as the barrier islands migrate landward.

INTRODUCTION

The Mississippi River delta plain (MRDP) is undergoing rapid relative sea-level rise (RSLR) at a rate of 0.94 cm/yr as indicated by a 57 year tide gauge record (1947-2004) from Grand Isle (Miner 2007). This high rate of RSLR coupled with the effects of tropical cyclones and passages of frontal systems results in a highly transgressive regime that has produced landward-migrating, overwash-dominated barrier systems. Moreover,

ongoing conversion of back barrier and interior wetlands to open water bays and lagoons increases tidal prisms, which in turn has enlarged the flow area of the associated tidal inlets (O'Brien 1931; 1969; FitzGerald et al. 2004). The continuing increasing bay size-tidal prism together with the landward migration of the barrier systems results in a dynamic environment within which new tidal inlets are formed and existing inlets are subject to changes in cross-sectional area (deepening and/or widening of throat) and position.

Most of the erosional and depositional changes along barrier island shorelines occur at the ends of the barrier. These changes are directly attributable to tidal inlet processes both in the inlet and along the adjacent barrier shoreline (FitzGerald 1984; FitzGerald et al. 1984). Along transgressive barrier islands, most of the landward movement of sediment occurs at tidal inlets (Armon 1979) therefore, an understanding of these tidal inlet processes is crucial to understanding transgressive barrier island evolution. In Louisiana, knowledge of inlet processes is imperative for formulating barrier stabilization projects, determining sediment budgets, and predicting future changes. Currently, large scale coastal restoration initiatives are being formulated that might require inlet management.

In comparison to many well-studied inlets, such as those along the Atlantic coast of North America, the tidal inlets of the MRDP are unique because of their location along a microtidal, transgressive coast that is dominantly fine-grained in textural character. The dominance of storm processes and overall fine-grained composition of the barriers and tidal shoals compared to the well studied inlet systems elsewhere in the world indicate that a different set of factors be considered when managing Louisiana tidal inlets.

The rapid evolution and transgressive nature of the MRDP provide an opportunity to correlate the historical morphological shoreline changes with the landward retreat, lateral migration, and avulsion of the tidal inlets. In this way, the evolution of the inlet can be traced using historical data and can be related to the actual channel morphology and depositional processes. This work will result in the development of process-response models that will be used to improve understanding of transgressive tidal inlet morphology and evolution, as well as an exploration tool for sand resource surveys and barrier/inlet system management approaches.

STUDY AREA

Little Pass Timbalier separates East Timbalier and Timbalier Islands and is the conduit for daily tidal exchange between Timbalier Bay and the Gulf of Mexico (Fig. 1). It is located approximately 90 km west of the active Balize delta complex of the Mississippi River and 100 km south-southwest of New Orleans, Louisiana. The Timbalier Islands are downdrift flanking deltaic barriers that are located west of the Caminada-Moreau erosional headland. This headland is a result of distributary progradation and delta lobe development of the Lafourche subdelta that began progradation 1,500 yrs BP (McFarlan 1961; Törnqvist et al. 1996). Approximately 300 yrs BP, the once active distributary

system waned and became reworked by marine processes to generate the erosional headland and flanking transgressive barriers (Morgan 1974; Penland et al. 1988).

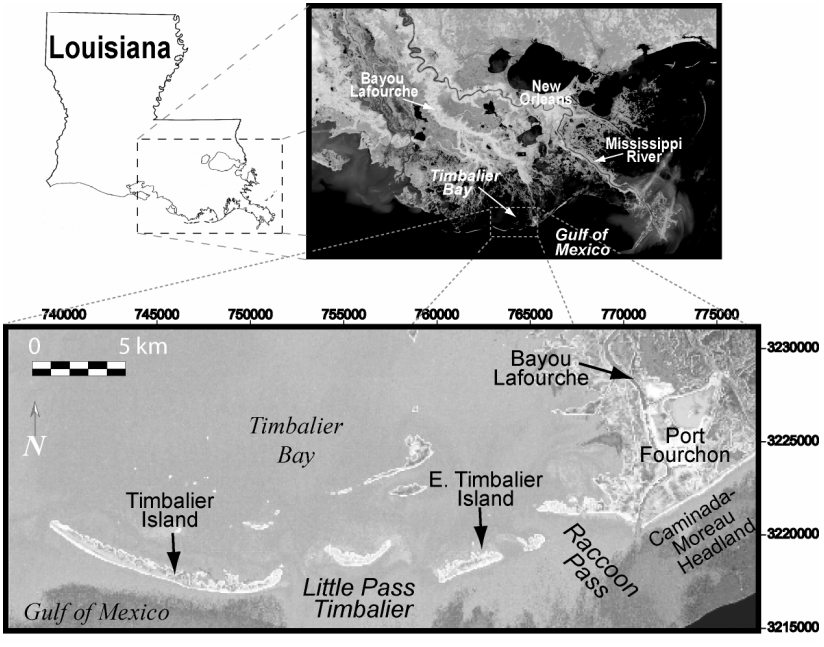

Figure 1. Little Pass Timbalier study area within the Mississippi River delta plain.

METHODOLOGY

Historical and recent bathymetric surveys are the primary datasets used in the analysis of Little Pass Timbalier. Historical surveys (dating from the 1880's –1980's) compiled by List et al. (1994) provide the framework for examining long-term trends. Details of data collection methods, processing techniques, and error assessment for the historical surveys can be found in List et al. (1994).

Recent (2005) bathymetric data of the study area were gathered using the University of New Orleans single-beam bathymetric rig mounted on the 21-foot *R/V Mudlump*. This bathymetric survey rig consists of an *Odom Hydrographics Hydrotrac* echosounder. Depth soundings are collected through a side-mounted *Odom Hydrographics* 200 kHz transducer with a beam width of 3°. The fathometer is equipped with a *Starlink Invicta* 210L differential global positioning system (DGPS) for navigation. Heave, pitch, and roll of the vessel are recorded using a *VT TSS Dynamic Motion Sensor Series-25* that is mounted vertically in-line with the DGPS antenna and the transducer. Thus, lateral offset errors between the DGPS antenna readings, transducer soundings, and vessel motion are cancelled minimizing vertical and horizontal errors in depth and navigation recordings.

The bathymetric, motion correction, and navigation data are recorded and integrated using *Coastal Oceanographics Hypack Max* hydrographic survey software.

The 2005 bathymetric data were processed using *Hypack Single Beam Editor* module and tide corrections were integrated using 6-minute interval data the NOAA tide gauge station (# 8762075) at Port Fourchon, LA. The water level elevation from the tide gauge was measured relative to mean lower low water (MLLW), a tidal datum based on the National Tidal Datum Epoch 1983 –2001.

After processing, the bathymetric data and historical datasets were used to make a series grids and ultimately digital elevation models (DEMs) for each date or time period (1880's, 1930's, 1980's, and 2005). The grids and DEMs were constructed using *Golden Software Sufer 8* contouring software. A kriging geostatistical algorithm was used to create the grid. Kriging is a distance weighting, moving average method that takes into account naturally occurring regional variables that are continuous from place to place (such as a linear bar or inlet channel), and assigns optimal weights based on the geographic arrangement of data point Z values taken from a variogram (Davis 1986; Krajewski and Gibbs 2003). Kriging was determined to be the most appropriate contouring method because it takes into account spatial characteristics of the local geomorphology and provides the best linear estimate that can be obtained from and irregular arrangement of data samples. Each DEM was then rectified and scaled relative to the other DEMs, allowing for the construction of a time series model that shows the morphological evolution of Little Pass Timbalier for the period from 1880 to 2005.

RESULTS

Inlet Morphology and Evolution

During the 1880's Little Pass Timbalier consisted of a relatively narrow, 1.5 km-wide tidal inlet with a single, 7 m-deep channel (Fig. 2) (List et al. 1994). The DEM for the 1880's indicates the presence of prominent flood and ebb tidal delta sediment bodies. The flood tidal delta was highly prominent during this early period and became less evident during subsequent stages. The flood delta morphology for the 1880's is comparable to those described by Hayes (1975) for Atlantic coast inlets and includes a flood ramp, flood channels, ebb shield, ebb spit, and spillover lobe (Fig 2). Noteworthy, is the fact that the ebb tidal delta is not as prominent at this stage as it is during subsequent stages. Ebb tidal volume for the 1880's was estimated to be 8×10^6 m^3, using the method proposed by Dean and Walton (1975). Inlet throat cross-sectional area was 3,177 m^2 in the 1880's.

Between 1880 and 1930 Little Pass Timbalier underwent a series of changes that led to breaching of the downdrift shoreline. According to U.S. Coast and Geodetic Survey maps, this process appears to have occurred prior to 1925 (U.S Coast and Geodetic Survey 1925) and possibly took place during a 1909 hurricane in which winds of 200 km/hr were recorded on the Louisiana coast and a tidal surge of 5 m was measured at Timbalier Island (Williams et al. 1992). The breaching of the adjacent shoreline resulted in an avulsion of the inlet and a displacement of the main channel 4.7 km updrift (west)

of the 1880 channel thalweg location. These changes contributed toward a widening of Little Pass Timbalier, from 1.5 km in 1880 to 8.6 km by 1930, increasing the throat cross-sectional area from 3,177 m^2 in the 1880's to 8,677 m^2. The wider inlet actually consisted of multiple channels separated by shoals, rather than a single, well-defined ebb channel (Fig. 2). The main ebb channel that formed at the site of the new breach was the deepest of the channels (7 m). Updrift, toward the east, the relict channel shoaled to 4 to 5 m and a third 4-m deep channel formed between the new breach channel and the relict channel. The ebb tidal delta of the former main channel eroded between the 1880's and 1930's (List et al. 1994), signaling a decrease in ebb current velocity in the former main channel. During that period waves reworked the ebb tidal delta sediment in a westward (downdrift) direction. The small portion of Timbalier Island that was located between the relict channel and the breach became a sand shoal, named Timbalier Shoal. Timbalier Shoal has remained ephemeral to date, becoming subaerially exposed during extended periods of calm weather and reworked to a subtidal shoal during tropical cyclone events. During the 1930's Little Pass Timbalier was characterized by a wide inlet with multiple channels separated by shoals. There were no prominent flood or ebb tidal delta deposits during this time period. Whereas the channel did migrate laterally during the period from 1880 to 1930 due to the avulsion and lateral spit migration, landward migration was approximately 1 km.

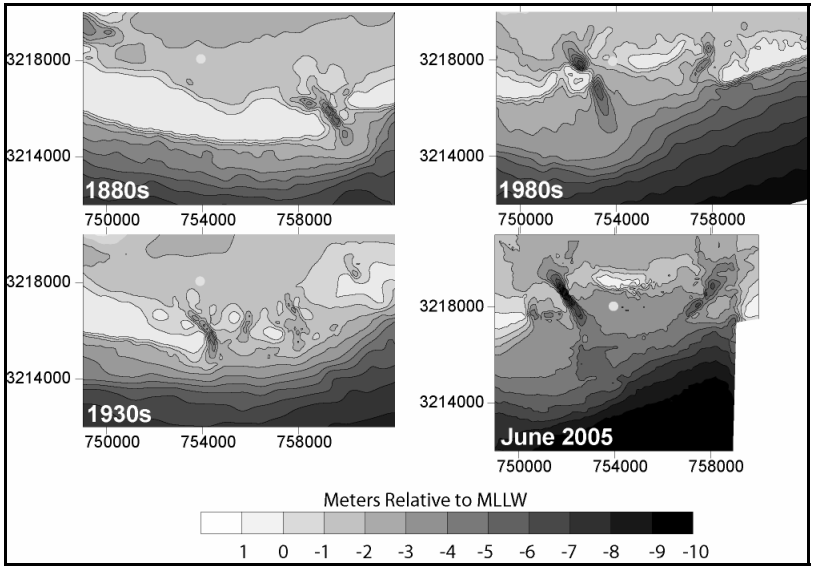

Figure 2. Morphological evolutionary model for Little Pass Timbalier. Note the yellow dot that remains geographically fixed for all time periods. Grid coordinates are in meters UTM zone 15. 1880's to 1980's bathymetric data from List et al. (1994).

Between the 1930's and the 1980's, the main channel migrated 1.9 km landward and 0.9 km laterally to the west. During the 1980's and subsequent timeframes, the inlet consisted of two ebb channels (the relict and new breach) separated by Timbalier Shoal (Fig. 4). Marginal flood tidal channels existed along the flanks East Timbalier and Timbalier islands, as well as along the flanks of Timbalier shoal. The inlet width at the throat was 7 km for the 1980's, a reduction of 1.6 km since the 1930's. However, cross-sectional area increased from 8,677 m^2 in the 1930's to 9,129 m^2 in the 1980's. During this period, Timbalier Shoal was subaerially exposed having an arcuate-shaped form built by an amalgamation of swash bars. During extensive periods of calm weather, swash bars migrate landward across the ebb tidal delta and eventually weld onto Timbalier Shoal. This phenomenon results in the vertical aggradation and subaerial exposure of Timbalier Shoal (Miner et al. 2005).

In the 1980's the two ebb channels of Little Pass Timbalier consist of differing morphologies. The deepest and westernmost channel was 7 to 8 m deep, whereas the eastern channel was 4 m deep (List et al. 1994). At the western channel site a large ebb tidal delta had become prominent since the 1930's due to increasing tidal prism (Fig. 2). The ebb tidal delta volume for the 1980's was estimated to contain 53 x 10^6 m^3 of sediment, an increase of 45 x 10^6 m^3 since the 1880's. The deepest point of the main channel did not exist at the throat during this time, but rather a large scour hole was present landward of the throat, having a depth of 8 to 9 m (List et al. 1994). According to the 1980's DEM, the easternmost channel of Little Pass Timbalier for the 1980's displayed no ebb or flood tidal delta features.

The morphology of Little Pass Timbalier reflected in the 2005 DEM is similar to that of the 1980's DEM exhibiting two ebb channels separated by Timbalier Shoal and marginal flood channels flanking the spits. However, the backbarrier scour hole disappeared and the deepest part of the main ebb channel is located at the inlet throat (Fig. 2). Dredging for the Louisiana Department of Natural Resources (LDNR) Project TE-40 Timbalier Island Dune/Marsh Restoration, resulted in the removal of approximately 3.5 x 10^6 m^3 of sediment from distal portions of the channel margin linear bar and central ebb tidal delta. This sediment was placed along the downdrift shoreline of Timbalier Island in 2004 (Shaw Coastal 2005). Of note is that between the 1980's and 2005 the ebb tidal delta ceased its progradation onto the inner shelf. The terminal lobe has since begun to retreat landward and the ebb tidal delta has broadened in a downdrift direction. Between the 1980's dataset (List et al. 1994) and the 2005 survey the inlet throat of the main channel migrated 2.1 km in a landward direction and 1.1 km alongshore to the west, and throat width widened from 8.1 km to 9.8 km. The main ebb channel increased in depth from 7 to 8 m deep in the 1980's to 9 to 10 m deep in 2005 and the secondary ebb channel deepened from 4 m to 6 m during that time. The throat cross-sectional area increased from 9,129 m^2 in the 1980's to 17,510 m^2 in 2005.

DISCUSSION

Morphologic Evolution

The morphological evolution of Little Pass Timbalier is complex and encompasses:

1) landward and lateral migration of its main channel (44 m/yr and 28 m/yr, respectively for the 1930 – 2005 time frame), 2) changes in inlet throat geometry, 3) formation of a new stable ebb channel through the combined processes of channel avulsion and breaching of the adjacent shoreline, and 4) increased ebb tidal delta sediment volume (Table 1; Figs. 2 and 3).

Table 1. Morphologic Evolution Summary

Time Period	Number of Ebb Channels	Throat Width, km	Throat Depth, m	Throat Cross-sectional Area, m^2	Ebb Delta Volume, m^3	Landward Migration, km	Lateral Migration, km
1880's	1	1.5	7	3,177	8×10^6	-	-
1930's	3	8.6	7	8,677	-	0.9	4.7*
1980's	2	8.1	9	9,129	53×10^6	1.9	0.9
2005	2	9.8	10	17,510	-	2.1	1.1

*Lateral migration due to island breach and ebb channel avulsion

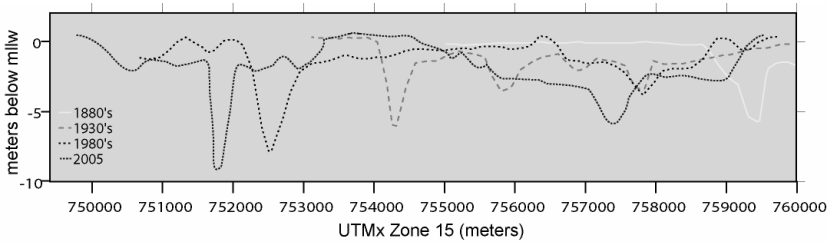

Figure 3. Shore-parallel bathymetric profiles across the Little Pass Timbalier tidal inlet throat for the years covered in this study. Profiles traverse the minimum inlet throat cross section for each period. 1880's, 1930's, and 1980's bathymetric data from List et al (1994).

Inlet channel migration and widening

Inlet throat migration is controlled by barrier landward migration in response to relative sea level rise, changes in tidal prism volume, the erodablity of the substrate (antecedent geology), longshore versus cross-shore transport processes, sediment supply, and frequency of storm impacts.

It has been established by previous tidal inlet studies along the Gulf of Mexico, Pacific, and Atlantic coasts of North America that inlet cross sectional area and bay tidal prism volume have a direct relationship (O'Brien 1939; 1969; Jarrett 1976), changes in the tidal prism volume will result in changes in inlet cross sectional area (O'Brien 1969; FitzGerald et al. 1984), and increasing tidal prism driven by wetland loss in Louisiana has resulted in increased tidal inlet cross sectional areas for the Louisiana coastal zone (FitzGerald et al. 2003; FitzGerald et al. 2004; Miner et al. 2005). At Little Pass Timbalier, increasing bay tidal prism volumes driven by backbarrier and interior land loss rates in the Timbalier/Terrebonne basin of 26.4 km^2/yr for a period from 1956 to

1990 (Barras et al. 1994) has forced this inlet widening process. Little Pass Timbalier has also increased in depth from 7 m in 1880 to 10 m in 2005 to accommodate the larger tidal prism volume (Fig. 3).

A breaching event sometime between 1880 and 1925 resulted in the formation of a second ebb channel down drift of the former inlet location. This second inlet channel has become the main ebb channel for Little Pass Timbalier and remains stable to date as part of a two-channel inlet system separated by an ephemeral shoal. Breaches and ephemeral inlets along the adjacent East Timbalier Island shoreline will eventually become stable tidal inlets in order to accommodate increasing tidal prism volume. The formation of additional tidal inlets along the Barataria shoreline in response to Barataria basin land loss has occurred during the past century as well (FitzGerald et al. 2004).

Ebb tidal delta expansion, precursory progradation, and retreat

Another consequence of the increasing tidal prism is the attendant increased volume of sediment sequestered in ebb tidal deltas (cf. Walton and Adams 1976). As the tidal prism of the Terrebonne/Timbalier basin increased between the 1880's and 1980's, the ebb tidal delta of Little Pass Timbalier enlarged by 45×10^6 m^3 and prograded onto the shelf as the barrier shoreline translated landward. This phenomenon of ebb tidal delta enlargement and seaward progradation in an overall transgressive regime has been noted by previous workers on the Louisiana coast (List et al. 1991; 1994; FitzGerald et al. 2003; FitzGerald et al. 2004). The volume increase in the ebb tidal delta occurs at the expense of the barrier islands, not only due to erosion of the tips of the barriers associated with inlet widening, but also because sand that builds the ebb tidal deltas would otherwise bypass the tidal inlet (FitzGerald et al. 2003).

During the period between 1980 and 2005 the ebb tidal delta began undergoing retreat after an initial stage of progradation (Fig. 4). This process is due to a progressive increase in the effective area of the ebb-tidal delta as it aggrades and progrades until its seaward extent is balanced by wave and shoreface erosional processes. Also, the continual landward and westward (lateral) migration of the inlet throat, where tidal current velocities are greatest, results in decreased ebb tidal current velocities along the updrift ebb tidal delta terminal lobe. The terminal lobe became starved of sediment and dominated by shoreface ravinement; forcing it to erode similarly to shoreface retreat, resulting in the transfer of sand to a downdrift lower shoreface depocenter. This proposed mechanism for ebb delta retreat and downdrift expansion after a period of seaward progradation is similar to that observed in flume experiments and stratigraphic investigations of a delta front conversion from the progradation stage to continuous retreat under constant relative sea-level rise and sediment supply as described by Muto and Steel (1992; 1997; 2001; 2002) and Muto (2001). The results are erosional processes dominating updrift portions of the ebb delta, and distribution of these sediments to downdrift flanking portions of the ebb delta, and along the adjacent downdrift shoreface.

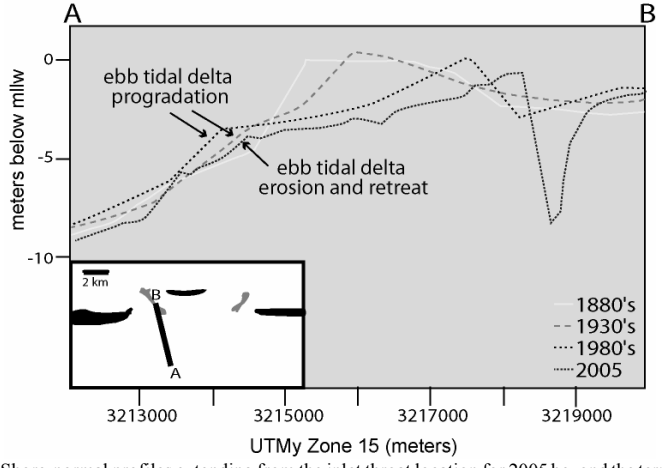

Figure 3. Shore-normal profiles extending from the inlet throat location for 2005 beyond the terminal lobe of the ebb tidal delta. 1880's to 1980's data from List et al. (1994).

Model Application

Transgressive Tidal Inlet Migration

The results of this study describe the morphological evolution of a transgressive tidal inlet that is dominated by increased throat cross-sectional area and landward channel migration. Because tidal inlet channels and inlet channel fill sequences have relatively high preservation potential during a transgression, the presence of inlet fills on the shelf have been used to document locations of relict barrier shorelines on the Atlantic shelf (e.g. Sheridan et al. 1974; Niedoroda et al. 1985). These interpretations are based on inlet fill models developed at modern inlets where lateral migration is the dominant control on inlet fill stratal geometry and sedimentary character. As shown here, the inlet migration pattern of a transgressive tidal inlet (shore perpendicular) is quite different than the laterally migrating inlet (shore parallel), and results in a distinctly different set of stratal architecture and facies successions (Miner 2007).

Shelf Sand Ridges

Lobate, shore oblique areas of accretion located offshore Timbalier Island have been identified by previous workers (List et al. 1994; Jaffe et al. 1997). However, the study conducted by Jaffe et al. (1997) did not identify a sediment source large enough to account for the accretion. A possible source for this sediment is the Little Pass Timbalier ebb tidal delta and suspended sediment transported out of the backbarrier through Little Pass Timbalier during ebbing tides. Sediment along distal portions of the ebb tidal delta is reworked by storm wave processes and deposited along the lower shoreface of Timbalier Island as shore oblique, lobate accumulations of sediment. Similar shore oblique, sediment transport trends and attendant bedforms along the middle and lower shoreface and shoreface-connected sand ridges have also been observed along the Atlantic coast (Ludwick 1978; Swift et al. 1978; Swift et al. 1985) and have been attributed to transgressive shoreface-shelf dispersal systems (Swift et al. 2003; Tillman

and Martinsen 1984), deposition as a lowstand shoreface during a forced regression (Posamentier et al. 1992), and sourced from abandoned ebb tidal deltas during a transgression (McBride and Moslow 1991; Snedden et al. 1994; 1999). The Atlantic examples are hydraulically maintained, and movement of the sediment within the ridges occurs during peak storm flow and downwelling (Wright et al. 1986; Swift et al. 1986; 2003).

Long-term landward migration of Timbalier Island combined with the enlargement and progradation of the Little Pass Timbalier ebb tidal delta resulted in the decoupling of the sediment transport pathway to the shoal from the upper shoreface and littoral systems. It has been proposed that, unlike the Atlantic lobes, the sediment transported downdrift along the lower shoreface of Timbalier Island is not lost to offshore sinks, but eventually becomes reintroduced to longshore processes downdrift at the Isles Dernieres (Jaffe et al. 1997). By the 1980's, the lateral accretion of lobes had been transported past the downdrift inlet Cat Island Pass and became a source of sediment that nourished the eastern Isles Dernieres barrier shoreline, where shoreline erosion rates are now about half of pre-bypassing rates (Jaffe et al. 1997).

During the period from the 1880's to 1980's, ebb tidal delta volume increased at Little Pass Timbalier from 8 x 10^6 m^3 to 53 x 10^6 m^3, resulting in its seaward progradation while at the same time the barrier and inlet channel system migrated landward. This morphological development is a response to increasing tidal prism. Since the 1980's, the ebb tidal delta of Little Pass Timbalier has shifted from seaward prograding to downdrift migrating. This shift results in shore-parallel downdrift growth of the ebb tidal delta and sediment transport and deposition along the downdrift lower shoreface of Timbalier Island.

A model for the formation and evolution of shoreface attached and detached sand ridges that develop from ebb tidal delta abandonment due to inlet migration or overstepping by transgression was proposed by McBride and Moslow (1991). One paradigm based on correlation between the location and orientation of existing sand ridges and the presence of relict or active tidal inlets along the modern shoreline, is that abandoned ebb tidal deltas act as an initial sand source for the generation of sand ridges (McBride and Moslow 1991). Radiocarbon age-dated vibracore and high resolution shallow seismic data collected on the New Jersey Atlantic shelf provide chronostratrigraphic evidence to support the correspondence between inlets and shelf sand ridges, however, the exact genetic process is still unknown (Snedden et al. 1994; 1999). The modern processes of transgressive tidal inlet morphodynamics at Little Pass Timbalier in which ebb tidal deltas expand and prograde seaward as the inlet channel and barrier migrate landward and their possible relationship to the formation of lobate accretionary zones along the downdrift lower shoreface along Timbalier Island have implications for the genesis of sand ridges and transgressive sand-sheets on the Holocene Atlantic (Swift et al. 2003) and northern Gulf of Mexico continental shelves (McBride et al. 2004), as well as sand sheets identified within the subsurface of the Holocene MRDP (Penland et al. 1988). A coast-wide bathymetric survey of Louisiana is currently in progress as a cooperative

study between the UNO Pontchartrain Institute for Environmental Sciences, U. S. Geological Survey, and Louisiana Department of Natural Resources. The results of this study will provide insight as to the recent depositional and erosional trends along the lower shoreface of Timbalier Island and evolution of the shore-oblique accretionary features.

CONCLUSIONS

Shoreface retreat along the barrier islands, driven by a relative rise rate of approximately 1 cm/yr, causes the Little Pass Timbalier tidal inlet system to migrate landward at a rate of 44 m/yr. Westward lateral migration of the main ebb channel is also occurring at a rate of 28 m/yr, resulting in a widening of the inlet. Widening is due in part to the fact East Timbalier Island can not accrete westward and is drowning in place due to its rip-rap lined shoreline.

The dominant control on the morphological evolution of Little Pass Timbalier since the 1880's has been increasing tidal prism driven by interior wetland loss. This has resulted in changes in inlet throat geometry (widening and deepening) and relocation of a new stable ebb channel to a site along the adjacent barrier that was breached during major storm. Increasing tidal prism has also resulted in increased volumes of sediment sequestered in the ebb tidal delta. In response to storm events and tidal prism changes, Little Pass Timbalier has evolved from an inlet having both an ebb and flood deltas in the 1880's to an inlet morphology having no prominent flood or ebb tidal delta but rather a system with multiple ebb channels separated by intra-inlet shoals by the 1930's. Most recently (1980's to 2005), the distribution of tidal channels and sand bodies reflects ebb dominance with a large ebb tidal delta and negligible flood tidal deltas.

The growth of the ebb tidal delta in a seaward direction ceased between the 1980's and 2005 and instead the ebb delta built in a downdrift direction. This downdrift dispersal of sediment explains genesis of a zone of accretion along the Timbalier Island lower shoreface, which appears to be attached to the Little Pass Timbalier ebb tidal delta. This genetic relationship between ebb tidal deltas and zones of lower shoreface accretion has implications as a possible analog for shelf sand ridge formation and transgressive sand sheet development.

Abstract: The Barataria barrier system within the Mississippi River delta plain, is experiencing some of the highest relative sea-level rise (SLR) rates in the continental USA (0.94 cm/yr). This has led to substantial wetland loss in Barataria Bay (16.9 km^2/yr, from 1935-2000). This conversion of wetlands to intertidal and subtidal environments results from several linked processes including subsidence, marsh front erosion, and catastrophic scour during large magnitude hurricanes. Increasing open water within Barataria Bay has amplified tidal exchange with the ocean. Between 1880 and 2006, an increase of 400% took place in the combined cross-sectional areas of the major tidal inlets of Barataria Bay, associated with the enlarging tidal prism. This expansion of the inlets has been at the expense of the adjacent barrier islands, evident in the concomitant progradation of the ebb-tidal deltas. Since the 1880's the ebb delta at Barataria Pass built seaward more than 2.0 km, sediment cores show that sand constitutes the upper 1-2 m of the ebb delta. Movement of sand offshore, regional subsidence and increasing bay tidal prism produce segmentation of the barriers, forming new inlets such as Pass Abel. Acceleration in eustatic sea level rise will lead to further wetland loss and thus ultimately barrier disintegration. The Barataria barrier chain will be transformed into an island-only system similar to the Isle Dernieres and Timbaliers.

INTRODUCTION

Salt marshes cover extensive areas of estuarine and deltaic environments. They are one of the most productive ecosystems on Earth, and provide a variety of essential ecosystem services to humanity (Mitsch and Gosselink 1993; Sharitz and Pennings 2006). The marsh is maintained through delicate balances between: accretion and subsidence; erosion and vegetative stabilization; and tidal prism and drainage efficiency. Salt marshes today are threatened worldwide by a forecasted acceleration in the rate of sea-level rise (SLR) (Church et al. 2001) brought on by global warming. Recent studies indicate that the acceleration is already occurring (Church and White 2006; Donnelly 2006; Gehrels 1999; Nydick et al. 1995). The destruction of wetlands may provide a powerful positive feedback mechanism for increasing greenhouse gases and global warming by converting organic matter to carbon dioxide and methane.

The fragmentation and inundation of salt marshes due to SLR are intrinsically linked to changes in the configuration and stability of barrier island systems that separate them from the open ocean. A relative rise in sea level leads to an increase in the tidal prism of the bay, expansion of tidal inlets, sequestration of sand offshore in ebb-tidal deltas and erosion of barrier islands. These changes impact the overall hydrodynamics of the inlet-bay system leading to increased erosion of the back barrier and a positive feedback causing further deterioration of wetlands (FitzGerald et al. 2003, 2004). The region becomes more susceptible to both hurricanes and the intrusion of saltwater into freshwater wetlands. As the stability of a marsh is contingent upon elevation relative to mean sea level, the ecological fabric of the marshes is also threatened (Mitsch and Gosselink 1986; Gornitz 1995).

The objective of this paper is to report our results concerning the impacts of wetland loss along the central coast of Louisiana and discuss how increasing bay area and tidal exchange have affected the morphodynamics and sedimentation trends of tidal inlets and barrier islands. Barataria Bay was chosen for this study due to the extensive historical documentation that exists for this region including wetland loss (Britsch and Dunbar 1993; Barras et al. 1994, 2003) shoreline trends (Williams et al. 1992), bathymetric changes (List et al. 1994), and relative sea level data (Grand Isle; Penland and Ramsey 1990; Miner 2007). Previous discussions of the evolution of the Louisiana tidal inlets and barriers can be found in Levin (1993), List et al. (1997), and FitzGerald et al. (2004).

Rapid Sea Level Rise

The Barataria Basin is a natural laboratory in which to study the effects of accelerated SLR because it is experiencing one of the highest SLR rates in the country (0.92 cm/yr for 1947-2006 period; Miner 2007). This rapid rate of rise is attributed to many natural and anthropogenic causes including: 1. flexure of the lithosphere due to isostatic loading and growth; 2. fault motion within Cenozoic strata; 3. sediment compaction; 4. far-field isostatic adjustment (forebulge collapse) associated with retreat of the Laurentide Ice Sheet (Mitrovica and Milne 2002), 5. incidence of hurricane and storm surges; 6. reduced sediment supply due to leveeing and channelization of the Mississippi River; 7. withdrawal of fluids associated with oil and gas production (Morton et al. 2005); and

8. eustatic sea level rise. In a recent study using radiocarbon dated basal peat, Gonzalez and Tornqvist (2006) reported that widespread subsidence in the lower Mississippi delta appears to be unrelated to fault motion, but that glacio-isostasy may be a significant contributor. This is in addition to the process of locally significant sediment compaction, which is suggested to take place most rapidly above thick, recently deposited deltaic sediments (Penland and Ramsey 1990).

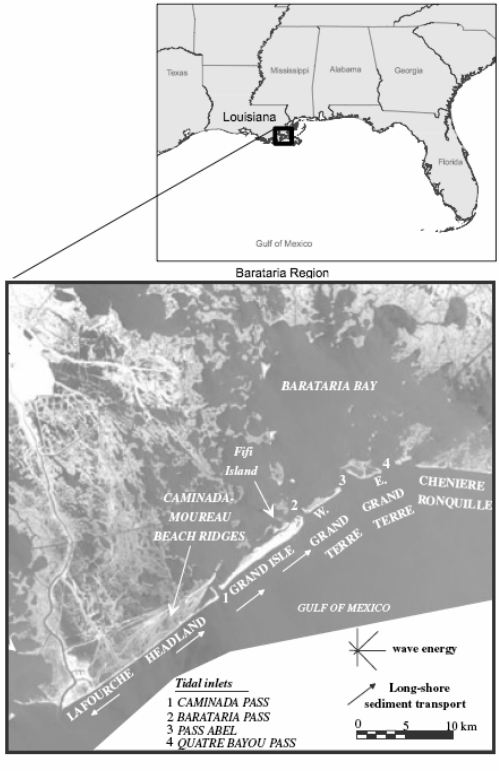

Fig. 1. Location of Barataria Bay and fronting barrier island complex. Tidal exchange between the bay and the Gulf of Mexico occurs through four tidal inlets. This basin has developed between the Lafourche headland to the west and the Plaquemine headland to the east.

Physical Setting

The Barataria barrier island complex is situated between the active Plaquemines delta lobe to the east and the Lafourche delta headland to the west (Fig. 1). The barrier chain that fronts Barataria Bay has formed from sediment shed from these two distributary

headlands, including the beach ridge/chenier systems of Caminada-Moureau beach ridges to the west and Chenier Ronquille to the east. Similar to much of the Gulf of Mexico, the Barataria coast is low-energy with a microtidal range of 0.4 m that increases to about 0.6 m during spring tides. Generally, breaking waves are small along the coast (< 0.4 m). However, during the passage of winter storms nearshore wave heights as high as 3.0 m can prevail for days (Stone and Muller 2003). Infrequent hurricanes (1 every 7 years; Muller and Stone 2001) cause the greatest impact on the shoreline resulting in widespread erosion, washovers, and tidal inlet formation (Boyd and Penland 1981; Stone et al. 2003).

DATA BASE

The areal extent and rate of wetland loss for Barataria Bay were derived from compilations produced by Britsch and Dunbar (1993) and Barras et al. (1994 , 2003). Land loss attributed to Hurricane Katrina was determined by Barras (2006). Documentation of historical changes in tidal inlet cross sectional area and longitudinal transects across the ebb-tidal delta were derived from an Atlas of Sea Floor Changes (List et al. 1994) and additional bathymetric data files (List, pers. comm.). Present-day tidal inlet bathymetry was determined from single beam surveys conducted in August 2006. During that field session, tidal current velocity distributions were recorded across the inlet throat using an Acoustic Doppler Current Profiler (ADCP). Additional current data were measured by Moffat-Nichols (LA DNR, pers. comm.). Approximately, 200 grab samples were collected throughout the inlets to determine the surficial facies characteristics of the inlet channels and ebb-tidal deltas.

RESULTS

Wetland Loss

During the past half-century rapid relative sea-level rise (0.94 cm/yr, Grand Isle tide gage: 1947-2006) and erosional processes within Barataria Bay have led to substantial wetland loss, converting more than 1,100 km^2 of wetlands to open water (16.9 km/yr) since 1935. Conversion of wetlands to intertidal and subtidal environments is a product of several linked processes including subsidence, marsh front erosion, and catastrophic scour during large magnitude hurricanes. Although a temporal plot of wetland loss and relative SLR in Barataria Bay shows similar directions in trend during the past 50 years, a comparison of their slopes indicates no close correspondence (Figure 2). Thus, other forcings must be operative. For example, Morton et al. (2003, 2005) have demonstrated convincingly that accelerated wetland loss in adjacent Terrebone Basin is related to rapid subsidence following peak volume fluid production from nearby oil and gas fields. A large number of oil and gas fields also exists in the Barataria Basin, which have likely contributed to subsidence in this region as well (Morton et al. 2006).

The formation of ponds and bays within wetland regions leads to marsh edge erosion by local wind generated wave attack. As open-water areas grow in size, a positive feedback exists whereby increasing fetch produces larger waves accelerating marsh edge retreat (Schwimmer 2001). In addition to the stratigraphy of the wetlands, which largely controls the resistance of the marsh to wave abrasion and undercutting, erosion rates are

related to fetch length and shore orientation with respect to storm and prevailing wind regimes.

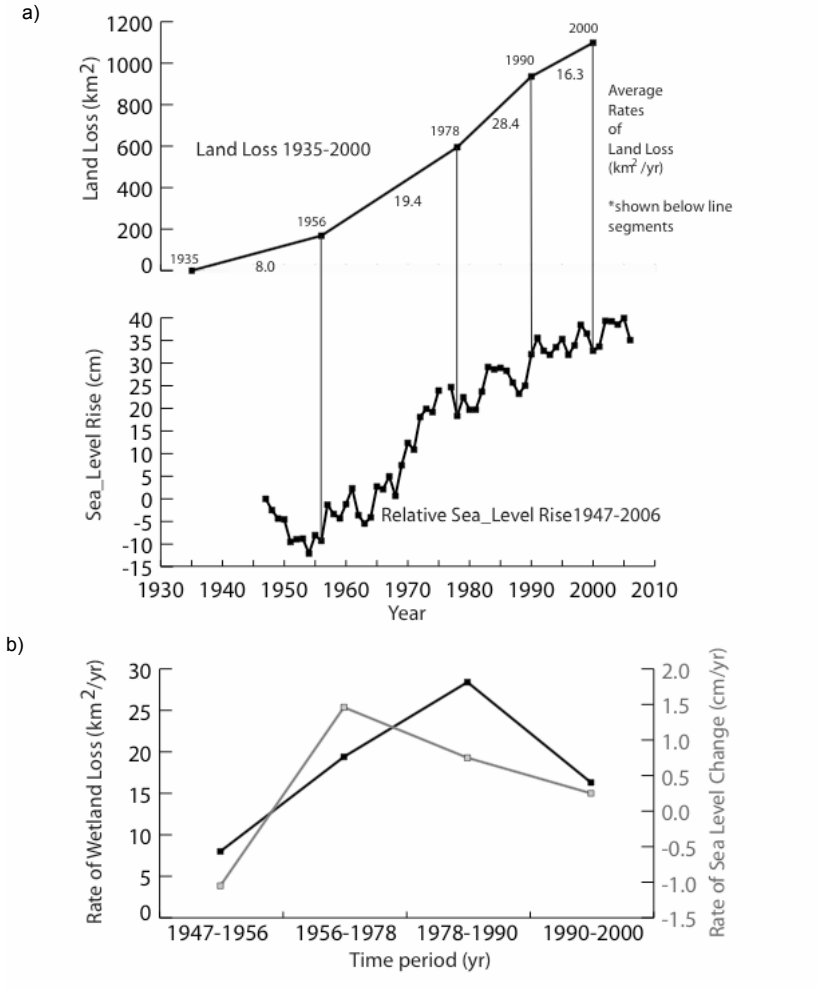

Fig. 2. Temporal plots of a). wetland loss and relative sea level since the mid-1900's and b). rate of wetland loss and sea level rise. Sea level curve from the Grand Isle gage (Miner 2006).

A recent study of marshes in Barataria Bay, Breton Sound, and the Balize Delta showed that wave erosion produces a 50 cm scarp at the marsh edge. This scarp transitions to a steep slope and then flattens with the bay bottom at a depth of 1.0 to 1.5 m (Wilson 2006). The retreating marsh produces a ravinement surface that is eventually covered by a shelly bay mud facies. It is interesting that nearshore transects surveyed off numerous marsh islands in Barataria Bay and Breton Sound show that the erosion processes produce a near same equilibrium profile (Wilson 2006).

In addition to the ongoing processes that are operative in converting wetland to open water, significant losses also occur during single large magnitude events such as 2006 Hurricanes of Rita and Katrina. Barras et al. (2006) showed that the Louisiana marshes lost a total 562 km^2 between 2004 and 2005, which can largely be attributed to Rita and Katrina that produced maximum storm surges of 5.5 and 8.0 m, respectively (IPET 2006; Hsu et al. 2006) and wave heights of 3 to 4 m. As seen in Figure 3, a direct connection exists between the path of the hurricanes and land loss. The greatest amount of wetland loss occurred in Mermentau and Breton Sound, which coincide with areas immediately east of where Rita and Katrina (respectively) made landfall accompanied by their strongest wind velocities.

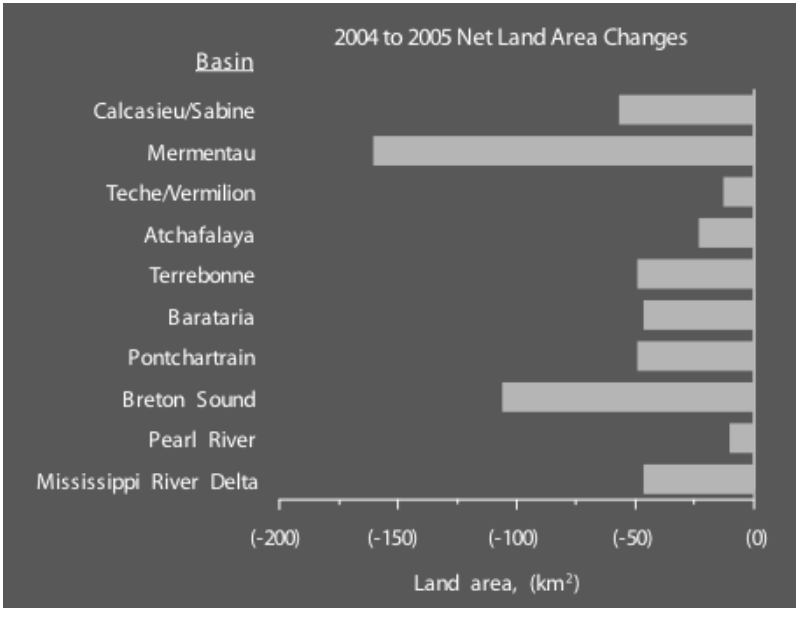

Fig. 3. Land loss resulting from the impact of Hurricanes Rita and Katrina. Note the significant increase in wetland loss immediately east of the hurricane landfalls.

A map of wetland loss in Barataria Bay resulting from the hurricanes of 2005, and primarily the impact of Hurricane Katrina, reveals that the majority of lost marshlands

occurred on the northward facing shorelines of the bays and ponds. This trend is especially apparent in large open water areas such as the shoreline along Little Lake, but is also observed in protected areas such as the terraced wetland regions east of Golden Meadow. There are exceptions, but this pervasive pattern would suggest that the return flow and the northerly winds following the passage of Katrina caused the most damage to the wetlands. Extensive loss of marshlands in the semi-protected region of Point a la Hache indicates a different erosional process. We suggest that return flow from the storm surge cascading over the western levee excavated the wetlands in this region.

Fig. 4. Map of wetland loss in Barataria Bay shown by red colored areas (from Barras 2006).

The pattern of wetland loss attributed to Hurricane Katrina appears to duplicate historical trends as seen in Figure 5. Although the map insets demonstrate that erosion occurs in all sectors between 1985 and 2000, the north and northeastward facing shorelines exhibit a more continuous and greater amount of erosion as compared with other shoreline orientations.

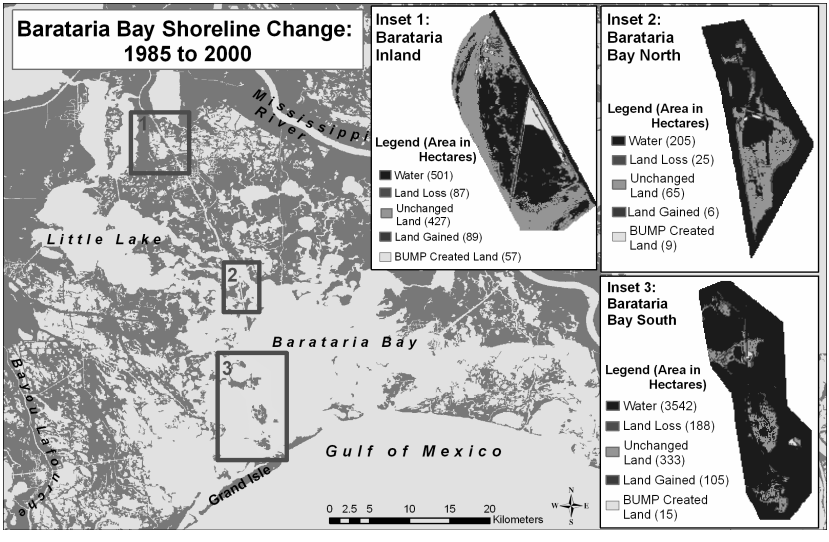

Fig. 5. Representative areas within the Barataria Basin illustrating patterns of marsh loss between 1985 and 2000.

Tidal Discharge And Tidal Prism

Long term conversion of wetlands to open water (> 125 years) has steadily increased tidal exchange between Barataria Bay and the Gulf of Mexico resulting in larger inlet tidal prism. Two direct consequences of the increasing tidal discharge are the enlarging tidal inlet geometry and growth of ebb-tidal delta shoals (List et al. 1997; FitzGerald et al. 2004). Recent data collected during the summer of 2006 allow an updating of hydraulic and morphologic trends previously established for the Barataria Bay barrier system for the period between 1880-1980.

Simultaneous synoptic ADCP surveys were conducted across the inlet throat of Caminada, Barataria Pass, Pass Abel, and Quatre Bayou Pass to obtain discharges through time and calculate tidal prisms for each pass. The surveys could not be conducted at night, hence the peak discharges of the flood tidal cycle were not measured. As a result, the ebb tidal volumes were used in the tidal prism versus cross sectional inlet area plots.

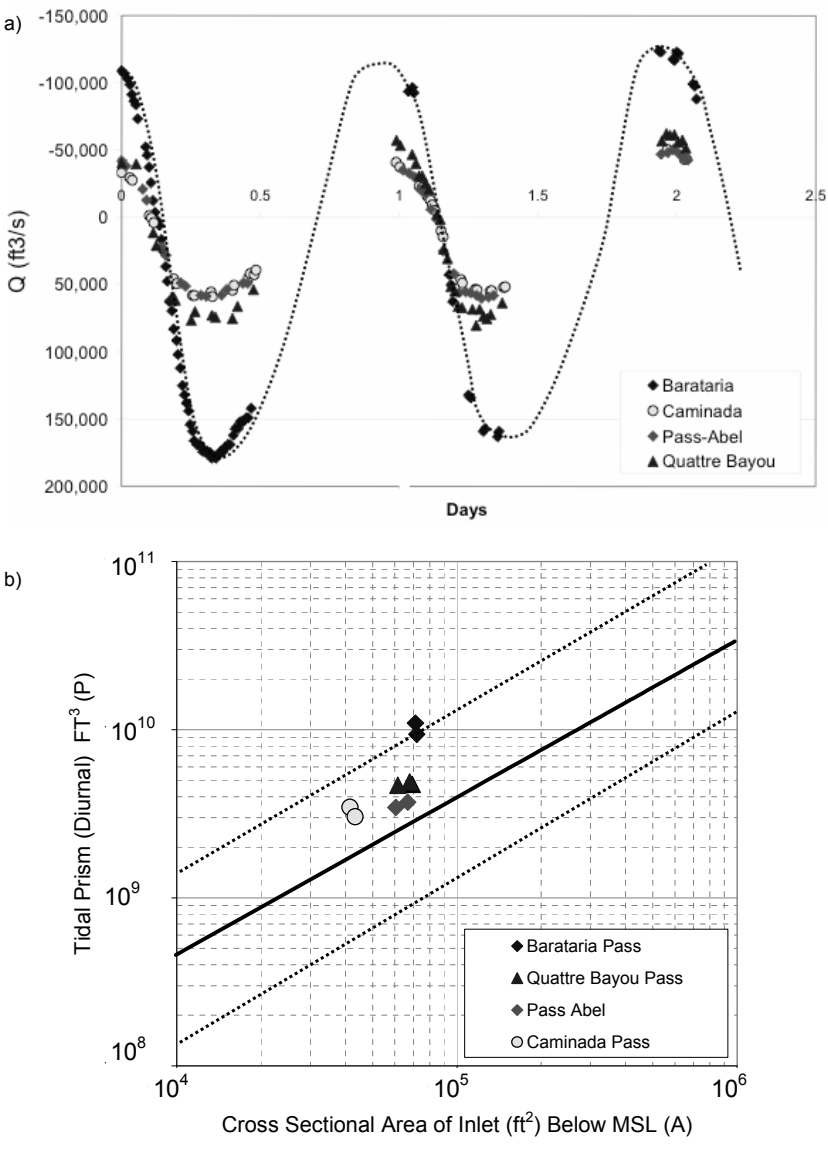

Fig. 6. ADCP data collected across the inlet throats were a) fitted to a sine curve and then used to determine tidal prisms for two ebb cycles for each inlet and then b) plotted against their corresponding maximum cross sectional area for that day. The graph also shows the Jarrett (1976) curve for unjettied Gulf Coast Inlets, as well as the 95% confidence limits.

The missing data to compute the calculation of ebb tidal prism volumes were filled by curve-fitting a distorted sine function. The function distortion lies in the slope of the rising and falling limbs of the tide and hence the discharge through the inlets. The distortion slopes of the sine function were obtained from data during this survey and data collected during the summer of 2006.

Cross sectional areas of the Barataria tidal inlets are plotted against their tidal prism (for two ebb cycles) and shown on Jarrett's (1976) regression curve for unjettied tidal inlets along the U.S Gulf Coast (Fig. 6). As seen in Figure 6, Caminada Pass, Pass Abel, and Quatre Bayou Pass plot well within the 95% confidence limits, but the Barataria Pass data points plot at the edge and outside of this field. As compared to the other Barataria inlets, and Gulf Coast inlets in general, Barataria Pass has a relatively small cross section given its tidal prism. One explanation for its relatively small size maybe related to the stratigraphy of the region, and perhaps the inlet channel is eroded into consolidated clays, which resist erosion.

Table 1. Inlet Cross Sectional Area (m^2)

Year	Abel	Barataria	Caminada	Quatre Bayou	Total X-sect area
1880	0	3996	809	133	4938
1930	395	7079	1353	2590	11417
1980	4193	8712	1532	3777	18214
2006	6669	7541	3372	6726	24308

Tidal Inlet Historic Morphologic Changes

Long-term wetland loss and increasing tidal prism have steadily enlarged the size of the tidal inlets. As seen in Table 1, Pass Abel and Quatre Bayou Pass have shown the greatest increase in area, and Caminada Pass the least, although it quadrupled in size. Interestingly, Barataria Pass doubled in size between 1880 and 1980, but subsequently shoaled by about 1,300 m^2 during the following 26 years. In Figure 7, the total inlet cross sectional areas is plotted for four time periods from 1880 to 2006. The regression analysis indicates a remarkable temporal correlation of increasing total inlet cross-sectional area, however this may be fortuitous. As most of the existing wetland area is now situated some distance from the tidal inlets (Fig. 4), the conversion of marsh area to open water will have an increasingly smaller effect of tidal prism due tidal wave attenuation and frictional factors within Barataria Bay.

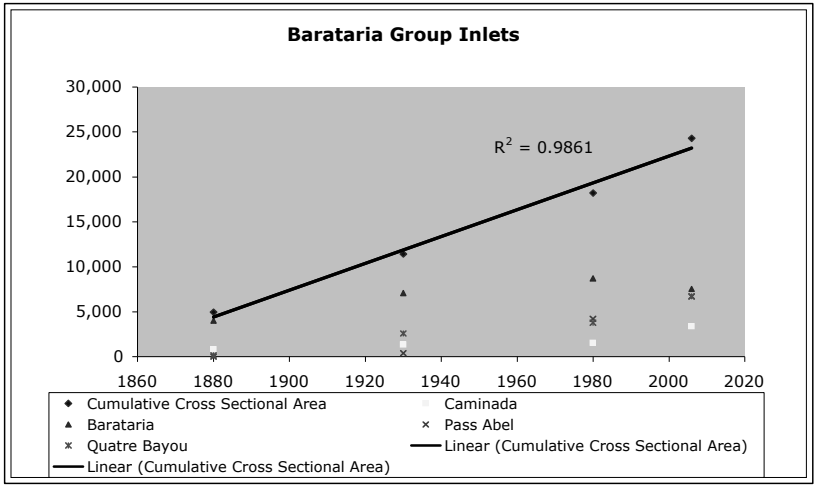

Fig. 7. Barataria tidal inlet cross-sections through time.

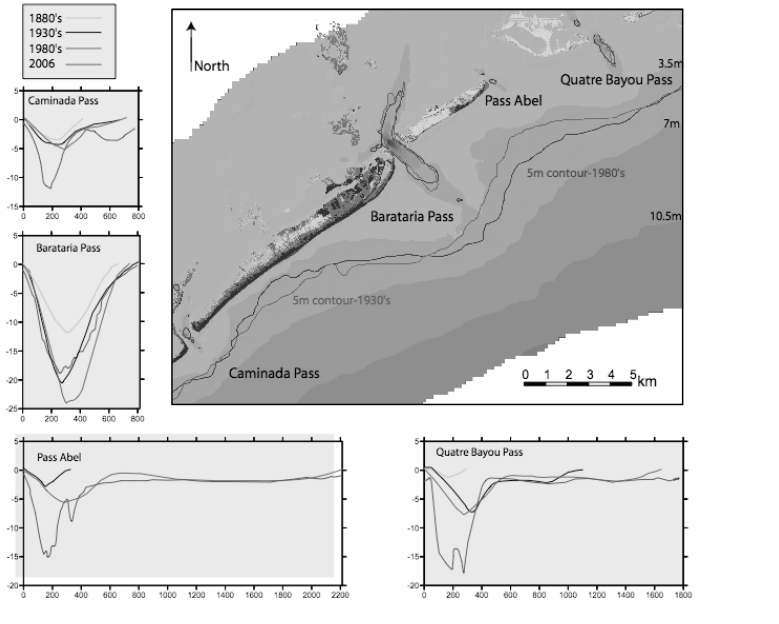

Fig. 8. Historical morphological changes in tidal inlet throat morphology between 1880 and 2006.

Historical changes in the throat geometry of the tidal inlets are illustrated in Figure 8. The most apparent trend at all the inlets is a deepening of the channel thalweg through time, with the exception of Barataria Pass that shoaled between 1980 and 2006. Although the total Barataria inlet cross-sectional areas increased since 1880, the decrease in size of Barataria Pass may be related to a capture of a portion of its former 1980 tidal prism by the adjacent inlets. Both nearby Pass Abel and more distant Quatre Bayou Pass substantially increased in size since 1980, deepening by more than 10 m. In addition, Caminada Pass doubled in size and deepened by 7 m to 12 m in depth.

CONCLUSION

Long-term conversion of wetland areas to open water in Barataria Bay is a product of the high rate of relative SLR and is attributed to both natural and anthropogenic causes. In addition to subsidence, land loss is due to marsh edge erosion and catastrophic scour during major hurricanes. Examination of wetland loss maps covering decadal time scales and after the impact of Katrina indicate that north and northeastward facing shorelines experience preferential erosion. Although the historic loss of wetland area corresponds with rising sea level, there is no direct correspondence in the rate of wetland loss and the rate of sea level rise. Expanding open water area has led to increased tidal exchange and enlarging tidal prisms. In response to this forcing, tidal inlets have grown in size and ebb-tidal deltas have prograded seaward. Total inlet cross sectional area has quadrupled in size since 1880. Although there is a very strong correlation between increasing total inlet throat section and time, the lack or marshlands close to the inlets and frictional attenuation of the tidal wave deep into the bay will reduce the historic rate of increasing tidal prism.

AKNOWLEDGEMENTS

The authors would like to thank Jeff Motti, Phil McCarty, Mike Brown and Dallon Weathers for their help in the field. This project was funded by NOAA's Pontchartrain Restoration Program.

MODELING FUTURE COASTAL WETLAND TRANSITION INDUCED BY RELATIVE SEA-LEVEL RISE

James C. Gibeaut[1]

1. Bureau of Economic Geology, Jackson School of Geosciences, The University of Texas at Austin, University Station Box X, Austin, TX 78713, USA. jim.gibeaut@beg.utexas.edu.

Abstract: Using a 1-m lidar digital elevation model and detailed wetlands mapping, we developed an inundation model that projects future wetland distribution caused by sea-level rise. Vertical accretion, edge erosion, and land-subsidence components are also included in the model. Applying the model to a section of Galveston Island, Texas, and using the actual annual record of ocean level recorded by a nearby tide gauge shows the complicated interplay of decadal-scale water-level variation and topography in determining the future distribution of wetlands. Total wetland coverage declines by 22% in 30 years but recovers to a net loss of just 5% within 90 years. Uplands transitioning to high-marsh wetlands more than offset the effects of inundation, allowing high-marsh wetlands to increase in coverage by 132%. Low-marsh wetlands, however, decrease by 77% at the end of the 90-year model period.

INTRODUCTION

Distribution of barrier-island subenvironments is strongly related to elevation above or below mean sea level. The style of transition of estuarine habitats during rising sea level depends largely on the slope of the upland and sediment supply, Brinson et al. (1995). Fringing wetlands on the barrier islands of the upper Texas coast exist within a narrow elevation range, with shifts from barren tidal flat to marsh to upland vegetation occurring across areas with just a 50- to 60-cm rise in elevation, Gibeaut et al. (2003a). On the bay sides of barrier islands, this amount of topographic change occurs on a small scale and in complicated patterns across relict geomorphic features, such as storm-surge channels, washover and flood-tidal delta deposits, and beach ridges and swales.

For this research, a wetland map derived from manual interpretation of color infrared photography and extensive field checks, White et al. (2004), is combined with a high-resolution (1-m postings and .1- to .15-m vertical accuracy) lidar-derived digital elevation model (DEM), Smyth et al. (2003), to quantify topographic relationships of barrier-island wetland types. The combined data set forms the basis of an inundation model to determine the likely transition of wetlands during expected future sea-level rise. The model is applied to a section of Galveston Island, Texas USA, a sandy barrier island on the upper Texas coast.

MODEL

The DEM is classified using elevation intervals assigned to the following wetland types in order of increasing elevation: (1) low-flat; (2) low-marsh; (3) high-flat; and (4) high-marsh. Elevation is the primary factor in determining these environments, but not the only factor, thus causing some inconsistencies with the photography-mapped classifications. Noise in the elevation data and coarser-scale photographic mapping compared to the DEM also cause differences. Therefore, to arrive at an optimal and realistic classification, the lower boundary of the low flat is determined, and then the upper boundary of the high marsh, which is the wetland/upland boundary, is adjusted until the total area of wetland matches what was actually mapped on the photography. Elevation intervals for other wetland environments are then adjusted so that they have the same area as what was mapped.

In addition to changes caused by inundation, wetlands may erode along the bayward fringes as a result of waves and tidal currents. Therefore, rates of shoreline change computed by comparing historical shorelines from the 1930's, 1950's, 1980's, and 1995/2002 are incorporated into the wetland change model, Gibeaut et al. (2003b). Vertical sediment accretion occurs and partly offsets the inundating effects of relative sea-level rise. A sedimentation model that describes vertical accretion as a function of elevation is also contained in the wetland model. The sedimentation function is based on measured accretion rates in similar settings in the Gulf of Mexico that indicate slower rates at higher elevations, Callaway et al. (1997). The highest vertical accretion rate occurs at the elevation of the lower low-marsh boundary and is set equal to the long-term relative higher high water rise rate, as measured from 1908 through 2002 and adjusted for local land subsidence. Below the low-marsh boundary the rate is zero. Above the boundary, the function decreases the accretion rate according to the expected duration of tidal inundation. At the high marsh/upland boundary, the vertical accretion rate is zero and is zero above that level.

The record of mean annual levels of mean higher high water, as measured at the Pier 21 tide gage on the bayside of Galveston Island from 1908 through 2002, was used to calculate water-level input for the model. Because wetlands are not expected to respond to water-level fluctuations within a year's time, the running average of the previous 3 years of water level was used. The 3-year running average was differenced to provide the amount of water-level change for annual iterations of the model. The pier 21 tide gage measures relative sea-level change at its location, but relative sea-level change varies

along the barrier islands because of varying land subsidence rates. To account for this, various releveling surveys conducted along the main coastal highway from the 1950's to the 1970's were used to estimate subsidence rates relative to the pier 21 tide gage location. A differential subsidence grid was developed from these data using guidance from geologic studies showing the thickness of relatively compactable Holocene sediment beneath the islands.

MODEL RESULTS

The model test area is a 7.5-km-long, undeveloped part of the bay side of Galveston Island (Fig. 1). Relict storm-surge channels create a highly crenulated bay shoreline dominated in low-marsh environments by *Spartina alterniflora* (smooth cordgrass), with high-marsh environments characterized by *Borrichia frutescens* (sea oxeye), *Spartina patens* (saltmeadow cordgrass), and other plants. The diurnal tide range is 30 cm, but the elevation of the wetland/upland boundary is about 1 m above mean sea level. Episodic high wind tides cause a higher encroachment of estuarine wetlands than would be expected from the tide range. Rate of relative mean higher high water rise, as measured from 1908 through 2002, is 6.5 mm/yr; however, considerable interannual and decadal variation has occurred. Estimates of differential local subsidence, as described previously, indicates that long-term relative water-level rise varies from about 6.4 to 7.5 mm/yr in the study area.

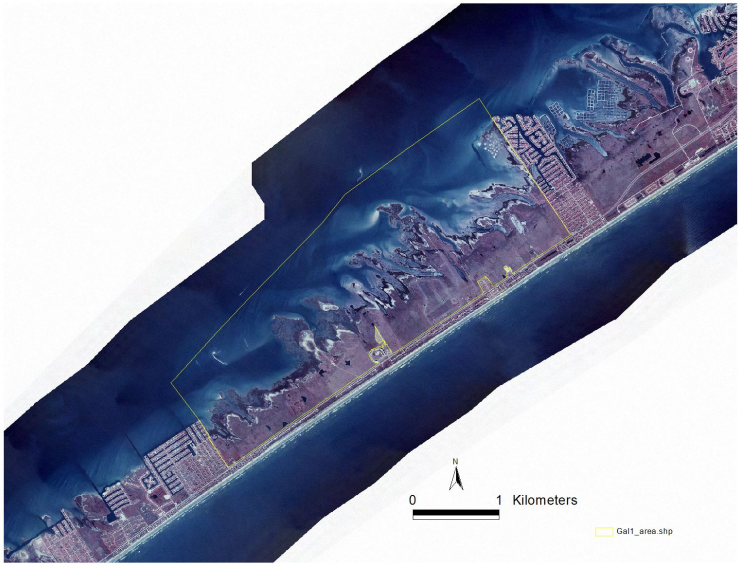

Fig. 1. Color infrared aerial photograph of model test area on Galveston Island, Texas. The Gulf of Mexico is toward the lower right and West Bay toward the upper left. The study area is outlined.

The wetlands model was run 90 years into the future. In 2002, 402 ha of wetland, which included low flat, low marsh, high flat, and high marsh, were mapped with 46% of it being low marsh and 32% high marsh (Fig. 2). After 30 years, the model projects an overall decline in wetland of 22%, but low marsh declines 58% and high marsh increases 47% (Fig. 3). High marsh continues to increase and low marsh decrease until 90 years when the model projects just 5% less total wetland than in 2002. By 90 years, however, low marsh has decreased by 77% and high marsh has increased by 132% (Fig. 4). Shoreline retreat caused the loss of about 30 ha (16%) of the low marsh but did not affect high marsh.

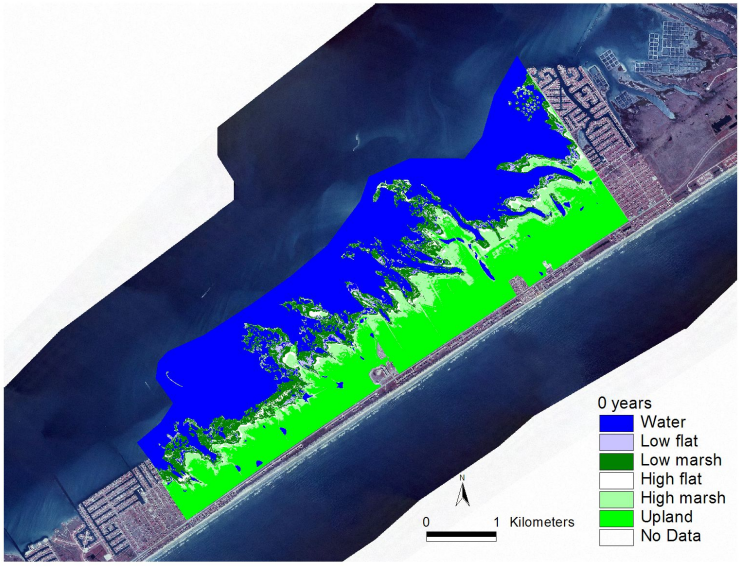

Fig. 2. Classification of wetlands according to elevation. Zero years is the beginning of the model run and represents wetland status in the year 2002.

DISCUSSION

The model shows marsh, particularly high marsh, migrating up the gently sloping back barrier in a complicated pattern dictated by the relict geomorphology but disappearing on the bayward side owing to inundation and shoreline retreat. Similar patterns and rates of change are observed when comparing 1956 and 2002 aerial photography. During that 48-year time period, there was about a 26% loss of marsh area. High- and low-marsh environments were not broken out on the 1956 photography, so comparing marsh types is not possible. However, observed marsh upland migration patterns and an overall similar decrease in marsh area indicate that assumptions in the model, particularly the vertical accretion function, shoreline retreat, and marsh-elevation relationships, are reasonable.

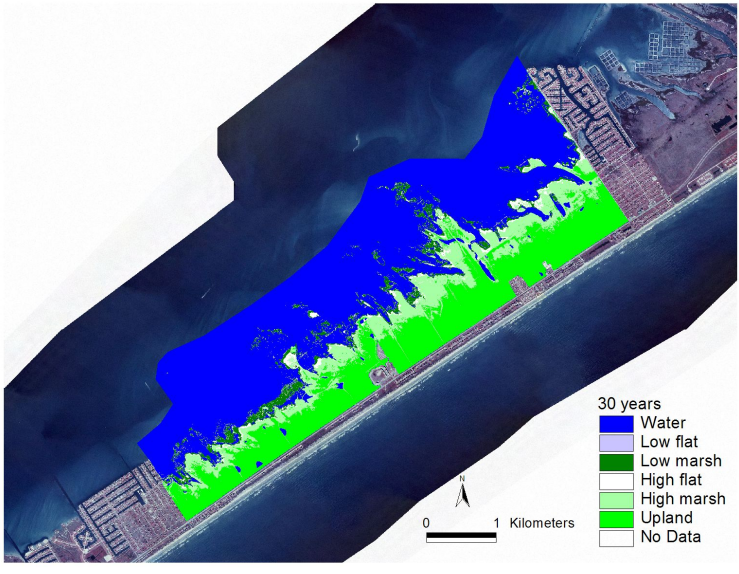

Fig. 3. Projected wetland distribution after a model run of 30 years.

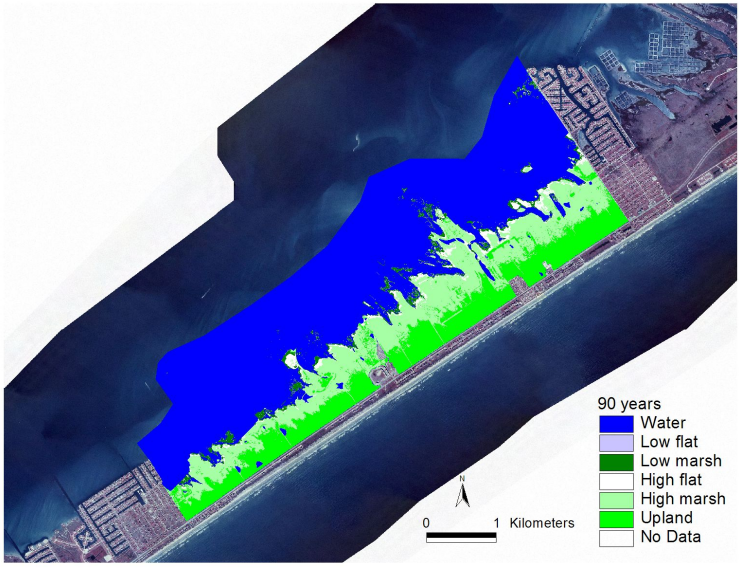

Fig. 4. Projected wetland distribution after a model run of 90 years.

The variability of wetland change over the projected 90-year period is a result of the complicated interplay of topography and decadal variation of mean higher high water level that is superimposed on a long-term rising trend. This variation causes ranges in water-level change rates input to the model to be several times the magnitude of the long-term trend for several years at a time. At the end of 90 years, upland migration allows for little net change in the combined area of the four wetland environments. However, the low marsh environment decreases dramatically. The low marsh is a crucial environment for fishery juveniles. The high rate of low-marsh decline is partly offset by upland migration in this undeveloped setting. Development is now occurring, however, and more is proposed in areas where the model projects an upland transition to wetlands. This development will also curtail the development of future high marsh. Furthermore, no increase in the rate of sea-level rise, as predicted in global warming studies, is included in the model.

We are currently refining and applying the model to other barrier islands where we have developed the necessary data sets. Model projections of wetland distributions could be used to establish buffer zones where development is restricted or to guide the acquisition of uplands for conserving future wetlands. The model will also allow experimentation to determine the relative importance of the various processes that determine the style of transition of barrier island environments during relative sea-level rise.

CONCLUSION

The wetlands inundation model shows the importance in considering annual to decadal variation in sea-level curves and detailed topography when projecting future wetland distributions, particularly in microtidal settings. Results from the 90-year model run presented here are based on a historical sea-level-change record without accounting for any increase in rate of sea-level rise due to climate change. Nonetheless, the important low marsh environment decreases drastically (77%). Some of this decrease is offset by upland migration of wetland, but future development of back barrier areas will eliminate the space needed for wetlands to migrate landward. Results from this study can be used to draw buffer zones for migrating wetlands.

MORPHOLOGICAL INTERACTIONS WITHIN UK ESTUARIES: A PRELIMINARY ANALYSIS OF CRITICAL RATES OF SEA-LEVEL RISE

Kate Rossington[1], Robert J. Nicholls[2], Michiel A.F. Knaapen[3]

Abstract: This paper uses historic bathymetry data for five UK estuaries to examine past morphological changes and to calibrate an equilibrium-based morphological behaviour model of estuarine evolution (ASMITA - Stive *et al*., 1998). After calibration, ASMITA is used to predict the maximum rate of sea-level rise (SLR_{crit}) which each estuary can experience without losing all intertidal areas. SLR_{crit} varies significantly between estuaries suggesting that some are quite vulnerable to sea-level rise (e.g., Southampton Water) and others are more resilient (e.g. the Ribble). Estuary area, sediment supply, sediment transport potential and human interference all appear to influence the sensitivity of an estuary to sea-level rise.

INTRODUCTION

Over 170 estuaries with a variety of physical characteristics, spatial extents and management issues dissect the coastline of the United Kingdom (Pontee and Cooper, 2005). Many have some form of nature protection designation and intertidal areas are particularly important for numerous species, especially migrating birds (Townend, 2002). Intertidal areas may also provide important natural coastal defences,

strengthening the flood protection of the low lying land surround estuaries, by dissipating wave energy (Möller, 2006).

Many estuaries have urbanised shorelines, with towns, cities and other developments around the estuary often being built on low-lying, flood prone land. In less developed areas, the land surrounding estuaries may be fertile farm land. Low-lying developed and agricultural areas are usually protected by embankments and sea walls. Estuaries are also used for recreational activities such as sailing, fishing and walking and are economically important as ports (with associated dredging), fishing grounds and for aggregate extraction (Townend, 2002).

The diverse uses and morphologies of estuaries can lead to complex and sometimes conflicting management demands. In order to manage estuaries effectively it is important to be able to predict how they are likely to change in the future, both due to natural and anthropogenic forcing.

Sea-level rise is predicted to accelerate over the 21st Century, with a global-mean rise of 9 to 88 cm, with the largest relative sea-level rise in the UK in the south (Hulme *et al*., 2002). Hulme *et al.* (2002) predict that by the 2080s the relative rate of sea-level rise around the UK could be between 0.3 and 12 mm/year with the highest rates of rise in the south west. This is likely to be a major driver of change within estuaries, possibly resulting in loss of intertidal areas, erosion of shorelines, and flooding of low lying areas around estuaries. Changes to shoreline management, such as increased use of managed realignment may also influence the morphological behaviour of estuaries (Townend and Pethick, 2002).

This paper has a main focus on the critical rate of sea-level rise when estuaries will lose their intertidal areas. It presents a) historic morphological changes for a sample of five UK estuaries covering a range of behavioural morphological types described in FutureCoast (Dyer, 2002), as shown in Table 1; and b) the use of ASMITA, which is an equilibrium-based morphological behaviour model of estuarine evolution (Stive *et al*., 1998). Previously, ASMITA has mainly been applied in lagoonal environments. This is the first time that it has been applied to and calibrated for estuaries with widely differing morphological characteristics and this research gives valuable insight into the behaviour of different estuaries under rising sea levels.

METHOD

Study Sites

Five estuaries were selected from around the United Kingdom (Fig. 1) to cover a range of morphological types, based on the behavioural characterisation of estuaries given in FutureCoast (Dyer, 2002): Ribble, Dart, Southampton Water, Langstone Harbour and Chichester Harbour. The main characteristics of each estuary are summarized in Table 1.

Fig. 1. Locations of the five study estuaries: 1) Ribble, 2) Dart, 3) Southampton Water, 4) Langstone Harbour and 5) Chichester Harbour. Reproduced from Ordnance Survey map data by permission of the Ordnance Survey © Crown copyright 2001.

Table 1. Summary of the major characteristics of the five study estuaries (Dyer, 2002).

	Estuary	Morphological Type	Area (ha)	Length (km)	Mean Tidal Range (m)	Mean river flow (cumec)	Tidal Asymmetry	Sediment	Human Influences
1	Ribble	Funnel shaped	11920	28.4	7.9	43.87	Flood dominant	Mainly sandy	Extensive reclamation, training walls & dredging
2	Dart	Ria without spits	863	19.8	4	11.07	Ebb dominant	Rocky	Training walls & some dredging in upper estuary
3	Southampton Water	Single spit enclosed estuary	3975	20.2	4	18.1	Ebb dominant	Muddy with some gravel	Extensive reclamation, capital & maintenance dredging
4	Langstone Harbour	Symmetrical tidal inlet	1925	7.7	4.2	0.36	Strongly ebb dominant	Mainly muddy	Reclamation & aggregate extraction from ebb-tidal delta
5	Chichester Harbour	Symmetrical tidal inlet	2946	8.1	4.2	0.71	Weakly ebb dominant	Muddy	Gravel extraction from ebb-tidal delta

Data on the historic morphologies of the Ribble and Dart estuaries, Langstone Harbour and Chichester Harbour were digitised from historic hydrographic charts obtained from the UK Hydrographic Office (UKHO). For Southampton Water, digital point elevation data were supplied by ABP Marine Environmental Research (ABPmer). The dates, types and sources of data used in this study are summarised in Table 2. Additional data and literature relating to the study sites has been reviewed for information such as amounts of dredging, dates of land reclamations and other significant human interventions.

Table 2. Summary of data used for each estuary.

Estuary	Data Type	Dates	Source
Ribble	Admiralty Charts	1904, 1951, 1977, 1990	UKHO
Dart	Admiralty Charts	1853, 1900, 1952, 1972, 1983, 1995	UKHO
Southampton Water	Point elevation data	1783, 1911, 1926, 1951, 1965, 1976, 1996	ABPmer
Langstone Harbour	Admiralty Charts	1955, 1961, 1968, 1974, 1997	UKHO
Chichester Harbour	Admiralty Charts	1955, 1961, 1968, 1974, 1997	UKHO

The data from the hydrographic charts were stored and manipulated using ArcView 9.0 Geographical Information System (GIS). All charts were georeferenced using known control points and transformed to British National Grid for comparison. Spot heights, depths, bathymetric contours and coastline were digitised from the hydrographic charts and converted to metres below ordnance datum (approximately mean sea level).

The point and contour data were interpolated to give a continuous bathymetry surface using ArcView's "Topography to Raster" interpolation method. This method was chosen because it is designed for catchment analysis and should create hydrologically realistic digital elevation models. It is the only interpolation technique available that can accept point elevation and contours as inputs. The area and volume of the tidal flats, channel and ebb-tidal delta (where present) were calculated using the Area/Volume tool in ArcView 9.0. The definitions of the tidal flats, channel and ebb-tidal delta are the same as those used in ASMITA (Fig. 2) and the area and volume data from the GIS analysis are used directly with the model.

Potential error in the volume and area data may come from numerous sources, including survey error, digitising and interpolation error. Survey error was estimated to be +/- 0.5 m for surveys conducted before 1968 and +/- 0.25 m for later surveys (van der Wal and Pye, 2004; Friend *et al*., 2006). Digitising and interpolation errors were calculated to be +/- 5 % of the element volume, in addition to the survey errors. A comprehensive

review of potential error when using historic charts and maps to investigate coastal change is given by Carr (1980).

ASMITA

ASMITA was first presented as a behaviour-based model "describing morphological interaction between a tidal lagoon or basin and its adjacent coastal environment" (Stive *et al*., 1998). The model consists of a schematisation of a tidal inlet system with the major morphological elements being viewed at an aggregated scale (Fig. 2). The major assumption of ASMITA is that, under constant hydrodynamic forcing, each element tends towards a morphological equilibrium which can be defined as a function of hydrodynamic forcing and basin properties (van Goor *et al*., 2003). Empirical relationships are used to define the equilibrium volume of each element (Stive *et al*, 1998).

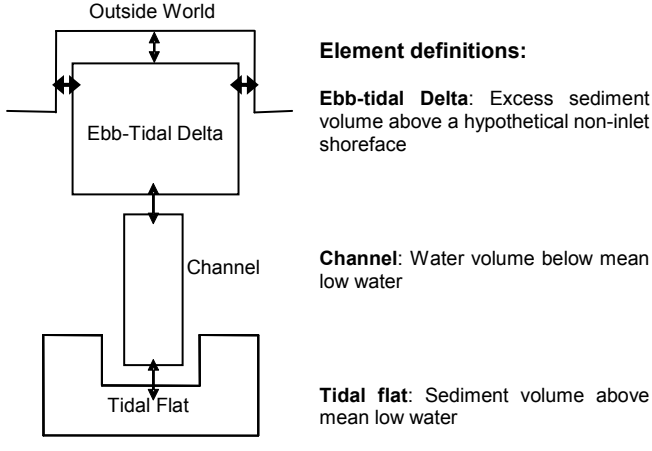

Fig. 2. ASMITA schematisation and element definitions (from van Goor *et al*., 2003).

The morphological elements in ASMITA, intertidal area, channels and ebb-tidal delta, interact through sediment exchange and this interaction plays an important role in the morphological evolution of the whole system, as well as that of the individual elements (van Goor *et al*., 2003). In cases where morphological elements are not present (e.g., ebb tidal delta), reduced element models can be applied. Long-term, residual sediment exchange is assumed to occur between adjacent model elements and it is assumed that development of the tidal inlet does not affect the availability of sediment in the outside world, represented by the global equilibrium concentration (van Goor *et al*., 2003). Volume changes within elements and sediment exchange between adjacent elements are described by equations 1, 2 and 3.

$$\delta_{fc} \cdot (c_f - c_c) = Ws_f \cdot A_f \cdot (c_{fe} - c_f) \quad (1)$$

$$\delta_{fc} \cdot (c_c - c_f) + \delta_{cd} \cdot (c_c - c_d) = Ws_c \cdot A_c \cdot (c_{ce} - c_c) \quad (2)$$

$$\delta_{do} \cdot (c_d - C_E) + \delta_{cd} \cdot (c_d - c_c) = Ws_d \cdot A_d \cdot (c_{de} - c_d) \quad (3)$$

Where δ_{fc}, δ_{cd} and δ_{do} are coefficients for horizontal exchange between the flat and channel, the channel and delta, and the delta and outside world; A_n is the area of element n; Ws_n is the vertical exchange coefficient for element n; c_n is the actual concentration and c_{ne} is the element's local equilibrium concentration, defined in equations 4, 5 and 6. Subscripts, f, c and d, refer to the tidal flat, channel and ebb-tidal delta elements, respectively.

$$c_{fe} = C_E \cdot (V_f / V_{fe})^r \quad (4)$$

$$c_{ce} = C_E \cdot (V_{ce} / V_c)^r \quad (5)$$

$$c_{de} = C_E \cdot (V_d / V_{de})^r \quad (6)$$

Where V_n is elements n's current volume; V_{ne} is elements n's equilibrium volume; C_E is the global equilibrium concentration and r is greater than 1 and is usually taken as 2 in compliance with a third power of sediment transport and a non-linear function of flow velocity (van Goor, 2001).

Model Application

In the current study, ASMITA was used to estimate the critical rate of sea-level rise (SLR_{crit}) for each estuary (van Goor *et al*., 2003). SLR_{crit} is the maximum rate of sea-level rise (SLR_{crit}) an estuary can keep pace with before it can no longer maintain equilibrium morphology and intertidal area is lost, with consequences for the habitat and natural flood defence functions of the estuary. SLR_{crit} is smallest in the tidal flat element, indicating the sensitivity of intertidal areas to sea-level rise. Below SLR_{crit}, intertidal flat volume progressively decreases and the channel volume increases (van Goor *et al*., 2003).

ASMITA was applied to each of the five study estuaries and calibrated to estimate a range of suitable sediment exchange coefficients (vertical exchange (Ws_n) and horizontal exchange (δ_{nm})) for each estuary. These coefficients were assumed to be the same for each element within the estuary. Southampton Water, the Ribble estuary and the Dart estuary do not have identifiable ebb-tidal delta elements and a two-element form of ASMITA comprising just the tidal flat and channel elements was used for these estuaries. The principles and base equations are the same for this two-element

ASMITA, but the channel interacts directly with the outside world. The three element model described above was used for Chichester and Langstone Harbours.

In order to calibrate ASMITA, first the value of C_E was estimated. The estimate was based on the relative availability of sediment at each site and does not represent a real or measurable concentration. The earliest area/volume data set was used to give the initial morphological conditions for each estuary. The ASMITA predictions from these initial conditions were compared with the volume data for later dates and the sediment transport coefficients (Ws_n and δ_{nm}) adjusted so that predictions fell within the error range of the data. Within this range, a least-squares approach was used to select the parameters giving the "best-fit" between the model predictions and the observed volumes.

Table 3. Total estuary area, intertidal area and % intertidal area of the earliest and latest data sets used for each estuary (numbers in brackets give error range).

Estuary	Date	Total Area (x 10^6 m^2)	Intertidal area (x 10^6 m^2)	% intertidal
Ribble	1990	127.9 (117.8 – 138.0)	98.8 (93.9 – 104.1)	77
	1904	131.6 (114.3 – 148.9)	106.8 (97.8 – 115.0)	81
Dart	1995	8.3 (7.0 – 9.6)	1.7 (1.0 – 2.3)	20
	1853	7.3 (6.0 – 8.5)	1.2 (0.6 – 1.9)	17
Southampton	1996	27.2 (25.6 – 27.4)	6.1 (4.6 – 7.6)	22
Water	1783	35.6 (35.2 – 38.3)	16.0 (12.7 – 19.8)	45
Langstone	1997	18.5 (18.1 – 18.8)	12.5 (11.9 – 13.8)	68
Harbour	1955	19.1 (18.8 – 19.4)	12.7 (11.0 – 14.3)	66
Chichester	1997	29.3 (29.0 – 29.6)	17.5 (15.6 – 19.5)	60
Harbour	1955	29.5 (29.2 – 29.7)	17.5 (15.3 – 19.7)	59

RESULTS

The data suggests differing morphological behaviour for each estuary. Southampton Water and the Ribble Estuary have been heavily modified over the last 100 – 200 years, with extensive reclamations and dredging; the influence of these disturbances can be seen in the sudden changes in element volumes, particularly in the flat element (Fig. 3 and Fig. 4). By contrast, the Dart Estuary and Chichester Harbour (Fig. 5) are relatively unaltered by human interference. Langstone Harbour has under gone reclamations in the past, and these may still be affecting the harbour's morphological evolution. Overall changes in estuary area and intertidal area are shown in Table 3.

Once calibrated, ASMITA predictions showed good agreement with observed data for all of the estuaries (Fig. 3, Fig. 4 & Fig. 5). In Southampton Water the volume of the tidal flats has decreased over the study period and the channel volume has increased over the same period. In the Ribble estuary, channel volume is approximately constant, but tidal flat volume has increased over the last century. In Chichester and Langstone Harbours and the Dart estuary, the channel and tidal flat volumes show only small

variations over the study periods, with ASMITA predicting the general behaviour well. The ebb-tidal deltas of Chichester and Langstone Harbours are more variable and have high error estimates. ASMITA represents the general behaviour of the ebb-tidal deltas but does not predict the detailed behaviour due to the nature of the model.

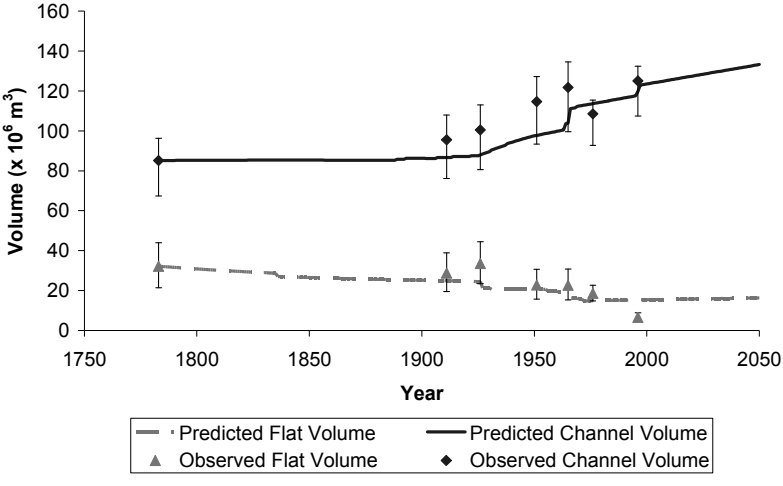

Fig. 3. Observed and predicted tidal flat and channel volumes in Southampton Water, assuming a historical rate of sea-level rise of 1mm/year.

The sediment transport coefficients producing the best fit to the data and the corresponding SLR_{crit} values are presented in Table 4. The Ribble is estimated to have a relatively high sediment availability, and hence $C_E = 0.0005$. The Dart has relatively low sediment availability ($C_E = 0.0001$) and Southampton Water, Chichester Harbour and Langstone Harbour have intermediate sediment availabilities ($C_E = 0.0002$).

Values of the vertical exchange coefficient (Ws_n) giving the best fit to the data varied between estuaries. Ws was smallest in Southampton Water ($Ws_n = 0.000001$). The other estuaries had vertical exchange rates approximately one order of magnitude larger than the Southampton Water value (Table 4) suggesting that sediment dynamics in Southampton Water differ considerably from nearby estuaries.

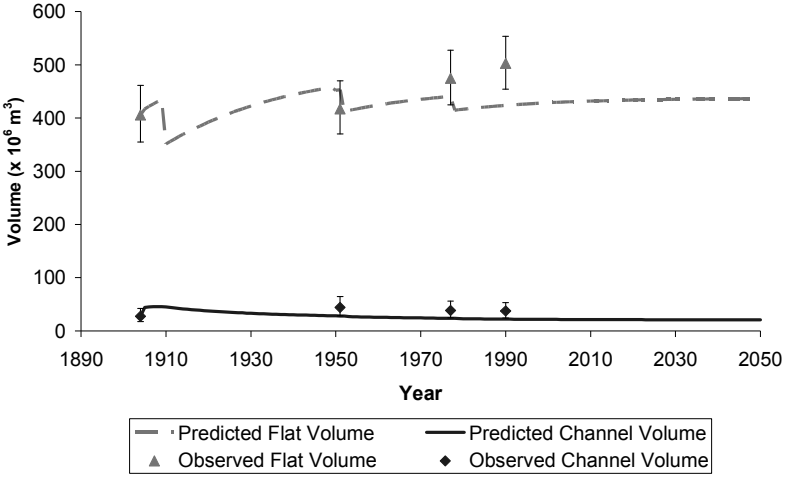

Fig. 4. Observed and predicted volumes for the tidal flats and channels in the Ribble Estuary.

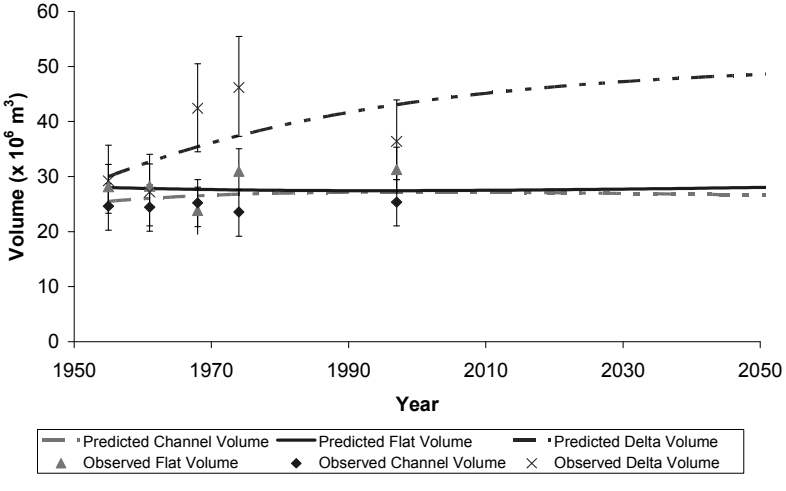

Fig. 5. Observed and predicted volumes for the tidal flats, channels and ebb-tidal delta in Chichester Harbour, assuming a historical rate of sea-level rise of 1mm/year.

Table 4. Values of CE, Ws_n and δ_{nm} giving the best fit for each estuary.

Estuary	C_E	Ws_n	δ_{nm}	SLR_{crit} (mm/year)
Ribble	0.0005	0.00003	1700	90.9
Dart	0.0001	0.00002	1500	56.7
Southampton Water	0.0002	0.000001	400	5.6
Langstone Harbour	0.0002	0.00001	200	17.9
Chichester Harbour	0.0002	0.00001	200	10.9

The value of the horizontal exchange coefficient (δ_{nm}) also varied between estuaries. The best fit value is given in Table 4; however a range of horizontal exchange coefficients gave a good fit for each estuary. In the Ribble, δ_{nm} varied between 1500 and 2500, giving a range of SLR_{crit} values of 82 to 122.5 mm/year. The Dart estuary also had a large range of δ_{nm} (400 to 3000). SLR_{crit} in the Dart appears relatively insensitive to the value of δ_{nm} within this range, with values of 40.3 to 59.7 mm/year.

For Southampton Water, δ_{nm} varied between 100 and 1500 and SLR_{crit} between 4.2 and 6.1 mm/year. In Langstone and Chichester Harbours the range of δ_{nm} and the SLR_{crit} values were similar: in Langstone Harbour, δ_{nm} ranged from 100 to 500 and SLR_{crit} was between 8.1 and 26.8 mm/year; in Chichester Harbour δ_{nm} was between 200 and 500, and SLR_{crit} between 10.9 and 21.7 mm/year. The range of predicted SLR_{crit} values for each estuary are summarised in Fig. 6.

DISCUSSION

The range of SLR_{crit} values varies considerably between the study estuaries, with Southampton Water having the smallest predicted SLR_{crit} and the Ribble estuary having the largest (Fig. 6). Langstone Harbour and Chichester Harbour, located next to each other on the south coast of England, were predicted to have very similar SLR_{crit} ranges. For comparison, van Goor *et al*. (2003) estimated the SLR_{crit} for Amelander zeegat and Eierlandse Gat to be 10.5 mm/year and 18 mm/year respectively. These are similar to the values for Langstone Harbour and Chichester Harbour, which are morphologically most similar to these inlets.

Predictions for the Ribble estuary suggest that sedimentation can keep pace with sea-level rise for rates of between 80 and 120 mm/year. Predicted rates of sea-level rise for the Ribble area in the 2080s are between 0.3 and 10.7 mm/year, suggesting that the intertidal areas of the Ribble estuary are unlikely to be threatened by sea-level rise in the next century. High values of Ws_n and δ_{nm} suggest the sediment transport potential is large. This is supported by the Ribble's large tidal range. The predicted SLR_{crit} values seem large and it is possible that they over estimate the capacity of the Ribble to adapt to sea-level change. The Ribble estuary, however, is flood dominant suggesting a net landward sediment transport into the estuary from the sea. It also has a plentiful supply of sediment from deposits on the floor of the south eastern Irish Sea (van der Wal *et al*., 2002).

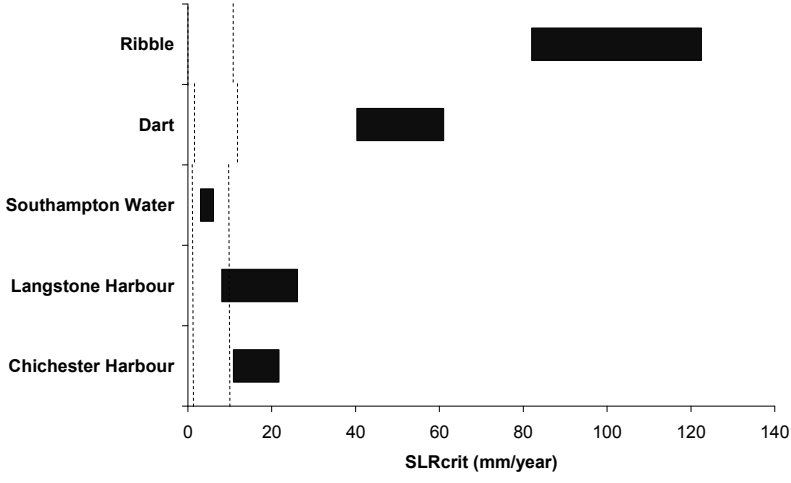

Fig. 6. Ranges of SLR_{crit} predicted for each estuary; the dashed lines represent the range of relative sea-level rise rates predicted for each region for the 2080s (Hulme et al, 2002).

The SLR_{crit} predictions for the Dart estuary suggest a high resilience to sea-level rise, with SLR_{crit} values of 40 to 60 mm/year. Again, this is much greater than the maximum predicted rate of 12 mm/year by 2080 (Hulme *et al*., 2002). These values seem high given the limited sediment supply to the Dart estuary from the coast, however, intertidal area is relatively small ($17x10^5$ m^2), and accounts for just 20 % of the estuarine area, so the volume of sediment needed to keep pace with sea-level rise is much smaller than in estuaries with large intertidal areas. A study of sediment dynamics in the upper Dart estuary suggests there has been recent sedimentation in line with what is observed in the current study (Dart Estuary Environmental Management, 2004).

SLR_{crit} for Southampton Water was predicted to be between 4.2 and 6.1 mm/year, falling within the predicted rates of sea-level rise for the 2080s (1 to 10 mm/year, Hulme *et al*., 2002). Major morphological changes and intertidal loss are likely in Southampton Water, if the model predictions are correct, and are consistent with current significant intertidal losses (Williams, 2006). The low threshold values for Southampton Water reflect the small value of Ws_n used for this estuary. Ws_n affects the rate of erosion and deposition in ASMITA. The low value for Southampton Water suggests that erosion and deposition rates may be extremely low. Bray *et al* (2004) suggest that sediment deposition in the channel is restricted by strong ebb-tidal currents and sediment transport in Southampton water is limited compared to other UK estuaries because it is sheltered from wave action by spits at the mouth and has a relatively small tidal range. Regular dredging in Southampton Water makes deposition in the channel effectively zero and it is possible that the calibrated value of Ws_n is artificially low because of this human influence. It is difficult to separate the effects of dredging and other man-made changes

from the natural behaviour of the estuary. It is also possible that the extensive reclamations and dredging in Southampton Water contribute to the sensitivity of the estuary to sea-level rise.

Langstone Harbour and Chichester Harbour had similar SLR_{crit} ranges, 8.1 – 26.8 mm/year and 10.9 to 21.7 mm/year respectively). In Langstone Harbour the range of SLR_{crit} values overlaps slightly with the maximum predicted sea-level rise for the 2080s. Best fit values of Ws_n and δ_{nm} were the same for the two harbours, but the best fit SLR_{crit} is predicted to be slightly higher in Langstone Harbour. This difference is explained by the differences in intertidal area between the harbours. As in the Dart estuary, the harbour with the smaller intertidal area (Langstone) requires less sediment for intertidal accretion to keep pace with sea-level rise.

There are a number of potential sources of uncertainty in the predictions. Use of the same parameter values for each model element means that all of the model elements have the same sediment transport potential. This is unlikely to be true in reality where current velocities and wave impacts are likely to vary with water depth. Using individual coefficients for each element increases the number of free parameters in the model and increases the uncertainty and complexity of the calibration. Further work is needed to improve this and to link the sediment transport parameters used in ASMITA to physical processes operating in estuaries. For example Ws_n, representing vertical sediment exchange in ASMITA, could be linked to wave climate and sediment type. In the current study these factors are not included; however, there is a trend for larger values of Ws_n in estuaries that are less sheltered from externally generated waves, such as the Ribble.

The estimation of C_E is also a source of uncertainty and needs further work to develop a reliable method of estimating C_E for the UK. It is possible that the value of C_E selected influences the sediment transport parameters to a greater extent than it affects the value of SLR_{crit}. The effect of varying C_E has so far only been investigated in the Ribble estuary. It was found that altering C_E causes the best fit values of the other parameters to shift, whilst the SLR_{crit} range remains approximately the same.

Improving estimates of C_E for UK estuaries is important because it represents sediment availability and affects the values of the sediment transport coefficients, which may influence estuarine management decisions. Cowell *et al*., (2003) found that sediment supply may be more important than sea-level rise rates in determining estuary evolution so improved estimation of C_E is potentially very important for accurately predicting future estuarine evolution. van Goor *et al*., (2003) used $C_E = S/Q$, where S is the bulk sediment transport along the barrier beaches and Q is the longshore wave generated discharge to estimate C_E for inlets in the Dutch Wadden Sea. It is outside of the scope of the current study to collect and analyse the data needed to estimate C_E by this method. It is also possible that the van Goor *et al*., (2003) method is not appropriate for UK estuaries where littoral drift and sediment bypassing at estuary mouths may be small.

Estimates of C_E based on suspended sediment concentration may be more suitable for UK estuaries, but cannot currently be directly related to C_E.

Planned future work includes the addition of extra study sites to better sample the range of UK estuaries, including Portsmouth Harbour and the Blackwater Estuary, investigating links between model parameters and physical processes and linking model predictions to holistic management approaches.

CONCLUSION

The ASMITA approach (Stive *et al*., 1998) has been successfully applied to a number of UK estuaries, indicating the generic value of this approach. The values of SLR_{crit} predicted for the five estuaries in the sample varied considerably. For some estuaries, such as Southampton Water, ASMITA predicts very low tolerance to sea-level rise, and SLR_{crit} could be reached within the next century with major morphological changes and intertidal loss and consequences for wildlife and flood defences. In contrast, ASMITA forecasts that other estuaries (especially the Ribble) are highly resilient to the full range of sea-level rise scenarios expected during the 21st Century.

Estuary area, sediment supply and sediment transport potential all influence the ability of an estuary to adapt to sea-level rise. Human interventions, including dredging, can also have important effects on the ability of estuaries to keep pace with increasing rates of sea-level rise, and this signal cannot always be separated from the natural behaviour, hindering interpretation of the model results.

The next stage of this work is to increase the number of sample estuaries to cover different morphological types and management issues and to examine the linkages between model parameters and physical processes operating in estuaries in more detail.

ACKNOWLEDGEMENTS

The authors would like to thank Marcel Stive & Tjerk Zitman from TU Delft for help and advice on applying and calibrating ASMITA; ABPmer for supplying bathymetry data for Southampton Water and UK Hydrographic Office for their assistance in finding historic data for other estuaries. Funding for this research was provided the Engineering and Physical Sciences Research Council.

Abstract: Researchers and coastal managers are addressing how climate change will affect shorelines (Gornitz 1991; Titus, Richard et al. 1991; Anderson, Rodriques et al. 2001; Field, Boesch et al. 2001; Brown, Few et al. 2004). Important questions include: How far will a sandy shoreline retreat as sea level rise accelerates (Cowell, Roy et al. 1995; Zhang, Douglas et al. 2004)? And, how far landward will the effects of possibly intensified storms reach (Zhang, Douglas et al. 2000)? These questions are most often investigated in a cross-shore profile framework, (Brunn 1962; Cowell, Roy et al. 1995) fostering the implicit assumption that coastline responses will be approximately uniform in the alongshore direction. However, we describe here experiments with a recently developed numerical model of coastline change involving shoreface geology and sediment-transport processes (Ashton, Murray et al. 2001; Valvo, Murray et al. 2006) which suggest that the responses to sea-level rise are likely to be alongshore-heterogeneous. The interactions between accelerating sea-level rise, alongshore sediment transport, and spatially variable underlying material will tend to cause spatially variable retreat rates. We compare these sea-level-rise effects to other climate-change related shoreline impacts suggested by recent modeling work. Slott et al. (2006) have suggested that as storm behaviors and wave climates change, shifts in complex large-scale coastline shapes will cause alongshore variation in shoreline-change rates that could be an order of magnitude greater than sea-level-rise-related shoreline changes.

INTRODUCTION

When addressing the effects of sea-level rise on sandy coastlines, researchers usually consider cross-shore transport processes (Bruun 1962; Cowell, Roy et al. 1995; Zhang, Douglas et al. 2004). Assuming that the cross-shore profile shape of the nearshore seabed (the 'shoreface') and sub-aerial barrier are maintained by wave action and remain constant over time, cross-shore transport will tend to cause landward retreat of the shoreline (Bruun 1962; Cowell, Roy et al. 1995). This cross-shore focus fosters the implicit assumption that sea-level rise will tend to produce alongshore-uniform shoreline retreat. However, considerations involving alongshore-transport processes, and how they interact with shoreface lithology (the 'geologic framework'), call this assumption into question.

Wherever shoreline erosion is sustained, the underlying geology will eventually emerge on the seabed, and will be transformed ('weathered') into mobile sediment. Where the underlying material weathers into grains that are coarse enough to remain in the high-energy nearshore environment (i.e. sand and gravel)—and erosion does not outpace the maximum weathering rate—the conversion into mobile sediment should not directly affect shoreline evolution. However, if some segment of the shoreline is underlain by a greater proportion of fine-grained material (e.g. muddy lagoon deposits) than are adjacent segments in the alongshore direction, these composition variation will affect shoreline change, as Valvo et al. (2006) have recently investigated with a numerical model. Using this model, we show in the third section how composition variations, coupled with alongshore transport, will tend to cause alongshore-heterogeneous shoreline change during a period of accelerating sea-level rise.

In the fourth section we discuss the effects of changes in the angular-distribution of wave influences, including stochastic variations in these 'wave climates' as well as variations associated with changing storm behaviors (e.g. increasing tropical-storm intensity) (Slott, Murray et al. 2006). These wave-climate shifts produce alongshore variations in shoreline change (including localized accretion as well as erosion) that will likely overwhelm sea-level-rise related shoreline changes—suggesting that simple shoreline retreat caused by sea-level rise may not be the most important aspect of shoreline response to climate change.

BACKGROUND AND METHODS

The magnitude of wave-driven alongshore flux can be related to deep-water wave height, and to the wave approach angle in deep water (before nearshore refraction), relative to the shoreline orientation (Fig. 1); the alongshore sediment flux reaches a maximum for relative wave-approach angles of approximately 45° (Ashton, Murray et al. 2001; Ashton and Murray 2006 a). On a sandy coastline, alongshore gradients in this sediment flux, Q_s, tend to cause changes in the shoreline position, η (Fig. 1):

$$\partial \eta / \partial t = -(1/D) \partial Q_s / \partial x, \qquad (1)$$

where D is the seabed depth to which erosion or accumulation extends. Large-scale (> kms) bends in a shoreline cause gradients in alongshore flux that alter the shoreline shape. When deep-water waves approach from nearly straight offshore, gradients in alongshore transport cause the large-scale shoreline shape to become smoother (Fig. 1). However, when waves approach from angles greater than approximately 45° ('high-angle' waves), plan view shoreline undulations grow (Ashton, Murray et al. 2001).

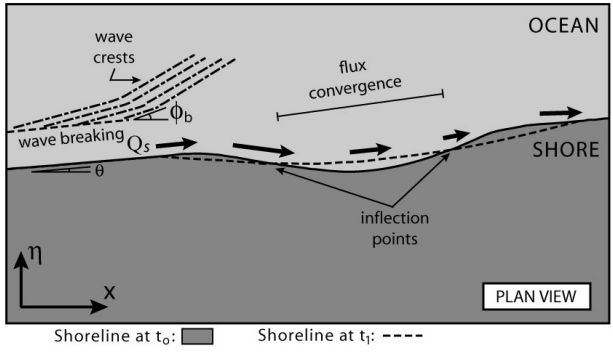

Fig. 1. Schematic illustration of gradients in the magnitude of alongshore sediment flux, caused by changes in shoreline orientation, and the consequent zones of erosion and accretion. The accretion (erosion) where the shoreline has seaward-concave (convex) curvature, shown here, occurs with low-angle waves. (From Valvo et al. 2006.)

Ashton et al. (2001) developed a numerical model to explore what shoreline behaviors might arise as undulations grow and interact with each other along an extended coastline. Using a 'one-line' model extended in a way that allows arbitrarily complex shoreline shapes to develop, they found that different shapes including cuspate capes and spits evolve under different wave distributions (characterized by the proportions of high- and low-angle waves, and by the degree of asymmetry—the proportion of wave influence from the left versus right, looking offshore) (Ashton, Murray et al. 2001). Valvo et al. (2006) incorporated geological-framework effects into this modeling framework, to investigate how they influence coastline evolution. Here we use these models to address shoreline responses to climate change—sea-level rise and changing wave climates (from changing storm behaviors). The model algorithms are described in detail elsewhere (Ashton, Murray et al. 2001; Murray and Ashton 2004; Ashton and Murray 2006 a; Valvo et al. 2006); here we recapitulate the main points.

A new deep-water wave angle is chosen daily from a probability distribution function representing a wave climate (e.g. Fig. 2). Breaking-wave height and angle relative to local shoreline orientations are calculated assuming refraction and shoaling over shore-parallel contours. Alongshore sediment fluxes, Q_s, are based on the commonly used CERC equation (Komar and Inman 1970; Komar 1998):

$$Q_s = KH_b^{5/2}\sin(\phi_b-\theta)\cos(\phi_b-\theta), \qquad (2)$$

where H_b and ϕ_b are breaking-wave height and crest angle, θ is local shoreline orientation (Fig. 1), and K is an empirical constant equal to 6.4 x 10^4 m^3d^{-1}. The model domain is discretized into cells, and shoreline changes are determined by a discretized form of (1).

Where protruding shoreline features block other coastline segments from the current deep-water wave-approach angle, no sediment transport occurs in the 'shadowed' segments.

To explore how these geologic influences interact with alongshore sediment transport processes, Valvo et al. (2006) imposed a landward retreat across the model domain, by removing sediment from each shoreline cell at a uniform rate. Here we interpret this shoreline retreat to be caused by sea-level rise. (The landward retreat rate can be roughly related to the rate of sea-level rise by multiplying the later by 100—a common but crude conversion that involves an assumed average slope to the shoreface profile of 1/100 (Brunn 1962; Dean and Maurmeyer 1983).

To represent the geologic framework, in each model cell the amount of mobile sediment and underlying, unweathered material are separately accounted for. The rate that the underlying material weathers, W, decreases with the thickness of mobile sediment covering it, Th. This basic relationship represents the assumption that as the amount of sediment on a shoreface decreases, the underlying material will be exposed more often to the complex set of physical, chemical and biological processes that transform it to loose sediment. We choose an exponential decrease, $W = ke^{-Th}$, as a simple parameterization roughly consistent with terrestrial bedrock weathering (Heimsath, Chappell et al. 2000; Anderson 2002), in lieu of empirical data on which to base such a relationship for the shoreface. k is a weathering coefficient equal to the assumed maximum rate for bare rock with no sediment cover—k = 20 m/yr in simulations presented here. The exact form of the weathering curve does not affect any of these results, because in these experiments the underlying material weathers at least as fast as alongshore and cross-shore transport processes uncover it.

The proportion of coarse (representing sand and gravel) and fine (representing silt and clay) grains composing the underlying material is defined in each cell at the beginning of a simulation. Then, as that material is weathered, the coarse fraction is transformed into mobile sediment, and the fine fraction disappears from the domain. This volume loss will tend to create an indentation in the shoreline corresponding to the alongshore extent of a fine-grained deposit (Fig. 2). Considering these geologic influences alone, the indentation should deepen landward as long as shoreline retreat—such as that caused by sea-level rise—continues.

However, in most locations alongshore transport will tend to fill in the indentation (Fig. 1). Most local wave climates are dominated by low-angle waves, even in areas such as the Carolina Capes where the regional wave climate is high-angle dominated (because of local shoreline rotation and wave-shadowing effects) (Ashton and Murray 2006 b). In

addressing geologic-framework effects, we therefore assume a local wave climate that tends to smooth the shoreline.

In experiments conducted by Valvo et al. (2006), as composition-related indentation deepens, the shoreline curvature and related alongshore-transport gradients increase; the rate of shoreline smoothing increases. Therefore, the model indentation's amplitude, or 'offset,' approaches a steady state (Fig. 2) in which alongshore transport redistributes sandy material into the indentation as fast as mud volume is lost there. Shoreline retreat rate thus becomes alongshore uniform (Fig. 2), with a rate reflecting the combined influences of sea-level rise and alongshore-averaged fine-sediment loss (Valvo, Murray et al. 2006) (Fig. 3a).

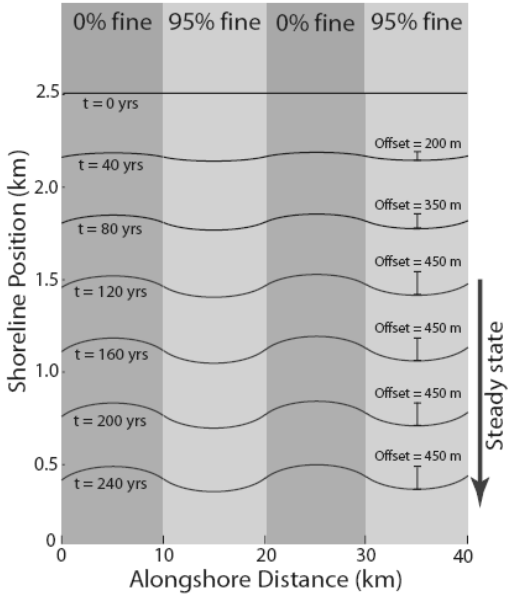

Fig. 2. Model results showing the plan-view evolution of a shoreline with two different lithologies alternating alongshore—one composed of material that weathers into 95% fine sediment (i.e. mud) that is not retained the nearshore system, and one that weathers into coarse sediment (i.e. sand or gravel). An indentation forms where fine-sediment is lost. However, alongshore transport redistributes into the indentation sediment liberated as the coarse lithology weathers. Steady-state indentations result, as shown by the offset values and highlighted by the red shoreline shapes (which are exaggerated in the cross-shore direction). (After Valvo et al. 2006.)

HETEROGENEOUS RESPONSE TO ACCELERATING SEA-LEVEL RISE

The steady-state offset in experiments such as that depicted in Fig. 2 depends on several factors, including the compositional contrast between adjacent shoreline segments, and the alongshore length of those segments (Fig. 3b). In the next section we will examine the consequence of the offset's dependence on wave climate; as the effective shoreline diffusivity (Ashton, List et al. 2003; Falques 2003; Ashton and Murray 2006 a; Ashton and Murray 2006 b) increases (a wave climate weighted more heavily toward low-angle waves), smaller curvatures are required for alongshore transport to redistribute sediment into the finer-grained shoreline segments as fast as fine material is lost there, so that indentations will exhibit smaller offset.

In this section we focus on the offset's dependence on the overall shoreline retreat rate, interpreted here to be driven by sea-level rise (Fig. 3b). As the overall retreat rate increases, the rate that fine sediment is lost in the fine-grained domains increases. Therefore, shoreline curvatures become higher and consequently indentation offset becomes greater before a steady-state evolves. If a steady-state shoreline configuration evolves under one rate of sea-level rise, and then the rate of sea-level rise and overall retreat increases, offsets will increase. Therefore, as the rates of sea-level-rise and coastal retreat accelerate in coming decades and centuries, the subtle indentations in present sandy shorelines (Riggs, Cleary et al. 1995; Honeycutt and Krantz 2003) will likely deepen; during this acceleration, shoreline retreat rates related to sea-level rise will not be alongshore uniform.

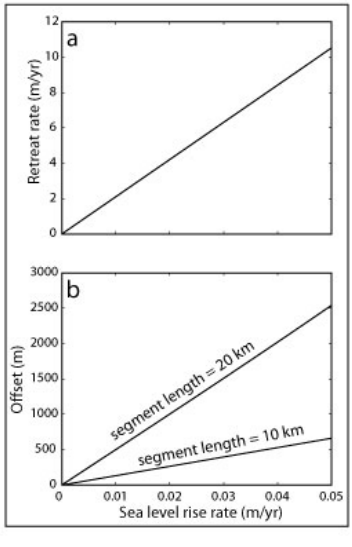

Fig. 3. Summaries of multiple model experiments like that depicted in Fig. 2, showing the variation of **a** retreat rate and **b** indentation offset, as functions of the rate of sea-level rise, for alternating fine and coarse shoreline segments with alongshore lengths of 10 km and 20 km.

The model experiments depicted in Fig. 3 predict that, if the sea-level-rise rate doubles on a time scale of a century (IPCC 2001), from 0.0025 m/yr to 0.05 m/yr, the offset will increase by approximately 300 m for 10-km long fine-grained segments, and by approximately 1200 m for 20-km segments. This amounts to a *difference* between the retreat rates in coarse and fine shoreline segments of approximately 3 m/yr for 10-km segments and 12 m/yr for 20-km segments, during the period of sea-level rise acceleration. Thus, these experiments suggest that the alongshore variation in erosion rate from growing indentations could be comparable to or greater than the alongshore-averaged retreat rate.

Because of poorly constrained model parameters, including shoreface compositions and alongshore length of compositional segments, the results in Fig. 3 should not be considered quantitatively reliable predictions. For example, a smaller alongshore-averaged fine-sediment content will produce slower overall retreat rates. However, this exploratory modeling exercise suggests that because the composition of underlying material commonly varies alongshore (Riggs, Cleary et al. 1995), the qualitative result of alongshore variability in shoreline loss should be widespread as sea-level rise increases.

DISCUSSION: WAVE-CLIMATE VARIATIONS

Two recent modeling studies suggest, however, that shoreline change caused by sea-level rise might be difficult to detect on many shorelines—they suggest that variations in wave climates, either stochastic or systematic, could cause alongshore variations in shoreline change that could swamp sea-level-rise related shoreline change.

Erosion Hot Spots

First, in the Valvo et al. (2006) experiments, indentation offset fluctuated significantly around the long-term, steady-state value. In the model, this behavior arises from stochastic variations in the short-term wave climate, as different mixes of wave-approach angles result from different sequences of daily random draws from the probability density function that represents the long-term wave climate. During periods in which the effective wave climate is less heavily weighted toward low-angle waves than is the long-term wave climate, the effective shoreline diffusivity is decreased. During these periods, offset increases, just as it decreases during periods in which the short-term wave climate more diffusive than the long-term average. Increasing offset corresponds to accentuated shoreline retreat in the finer-grained indentations, while decreasing offset corresponds to accentuated erosion in the coarser domains, which form subtle promontories. Surprisingly, in the Valvo et al. (2006) experiments, the periods in which either the subtle indentations or promontories acted as erosion hot spots lasted from years to decades.

This interaction between alongshore transport, the geologic framework, and shifting short-term wave climates could be responsible for decade-scale erosion hot spots on various coastlines. Recent observations on the northern Outer Banks, North Carolina,

USA, suggest that paleo-river channels (with abundant coarse sediment) outcrop on the shoreface offshore of the major decade-scale hot spots (Schupp, McNinch et al. 2006; Bill Birkemeier, pers. comm.). Examination of the shoreline shows these areas to be subtle promontories (unpublished observations). Ashton et al. (2003) showed that the major erosion and accretion patterns over a 20 year time span result from a smoothing of the coastline—in other words, to accentuated erosion of the promontories and even accretion in the indentations (Fig. 4). Is this erosion hot-spot behavior caused by a shift toward a more diffusive wave climate in recent decades? Further work is needed to investigate this potential explanation. However, Fig. 4 indicates that over decadal time scales, alongshore heterogeneities in shoreline change can overwhelm alongshore-averaged shoreline retreat from sea-level rise.

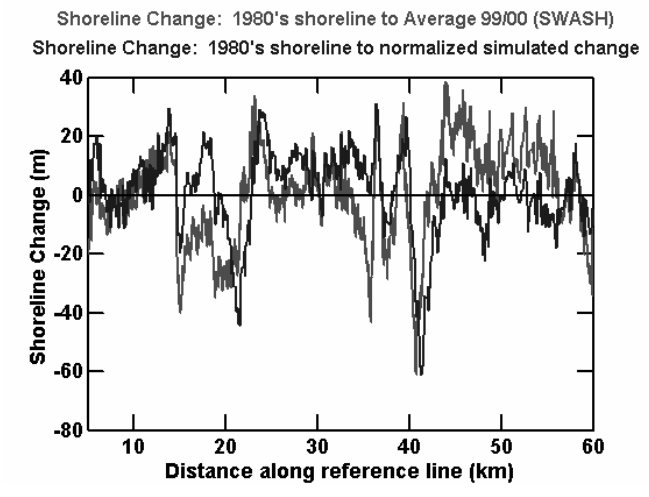

Fig. 4. Modeled and observed shoreline change along the northern Outer Banks of North Carolina, USA. The red line shows observed shoreline change over 20 years, and the blue line shows the results of a model experiment that used the observed coastline shape (1980) as an initial condition, and was forced with a wave climate based on WIS hindcasts in the region (USACE 2005). The magnitude of the model changes were normalized so that the maximum change in the model matched the maximum change in the observations. Because the regional wave climate is weighted toward low-angle waves, the model results represent smoothing of the initial coastline shape. (After Ashton et al. 2003.)

Changing Storm Behaviors

The warming of the atmosphere and oceans expected in coming centuries (IPCC 2001) will likely cause storm behaviors to change. Although how storm distributions will change cannot currently be predicted with confidence, extra-tropical and tropical cyclones may well change in frequency and severity (Emanuel 1987; Lambert 1995; Geng and Sugi 2003; Emanuel 2005; Webster, Holland et al. 2005). Shifts in storm behavior will alter the wave climates felt on coastlines, changing the relative amounts of

wave energy approaching from various directions. Model experiments indicate that sandy coastline shapes can depend sensitively on the angular distribution of approaching wave energy (Ashton, Murray et al. 2001; Ashton and Murray 2006 a), so that changing wave climates could cause significant shoreline change along some coastlines as large-scale shapes adjust.

Slott et al. (2006) recently explored how rapid changes in wave climate would affect a cuspate coastline shape (Fig. 5). The model coastline in Fig. 5b resembles the shape of the Carolina Capes, from Cape Hatteras, NC, to Cape Fear, SC, USA (Fig. 5a). To produce the coastline in Fig. 4b, Slott et al. forced the model with a wave climate based on 20 years of wave hindcast off of the Carolina coast (Wave Information Study station 509 (USACE 2005)). Mid-latitude winter storms off of the US East Coast produce waves that tend to approach from the northeast at high-angles relative to the trend of the Carolina coastline, and Atlantic tropical storms produce high-angle waves from the south. These two storm influences combine to produce a regional wave climate dominated by high-angle waves, as well as a moderate asymmetry (net transport would be to the southwest along a straight coastline with the overall trend of the Carolina Capes, Fig. 5a).

In the model, developing a cuspate pattern with the length scales shown in Fig. 5b requires millennia (starting from an unrealistic, approximately straight initial condition), and the rate of shoreline change slows with time (Ashton and Murray in press a). Fig. 5b shows the changes in the coastline over a further 200 years of evolution under a constant wave climate; the large-scale coastline shape changes relatively little on human timescales under these conditions, although continued southwestward translation of the capes does cause shoreline changes approaching a kilometer/century near the capes, consistent with historical observations (Pilkey, Neal et al. 1998).

Fig. 5c-e shows the results of model experiments that started with the same initial coastline as in Fig. 5b, but then involved 200 years of evolution under altered wave climates. Figure 5c shows how the simulated coastline changes under a wave climate that features a 10% greater proportion of high-angle waves, and a 10% lower asymmetry (an increase in waves from the right), compared to the wave climate that shaped the initial coastline. These changes along the Carolina Capes would correspond to an increase in the relative influence of tropical-storm waves. Figure 5d shows the effects of a 10% increase in the proportion of high-angle waves and a 10% higher asymmetry (increase in waves from the left). For the Carolina coast, this would correspond to an increase in the influence of extra-tropical winter storms. Figure 5e shows how the shoreline shape would change if the proportion of high angle waves decreases by 10%, which would occur along the Carolina Coast if the relative energy from tropical and extra-tropical storms decreased.

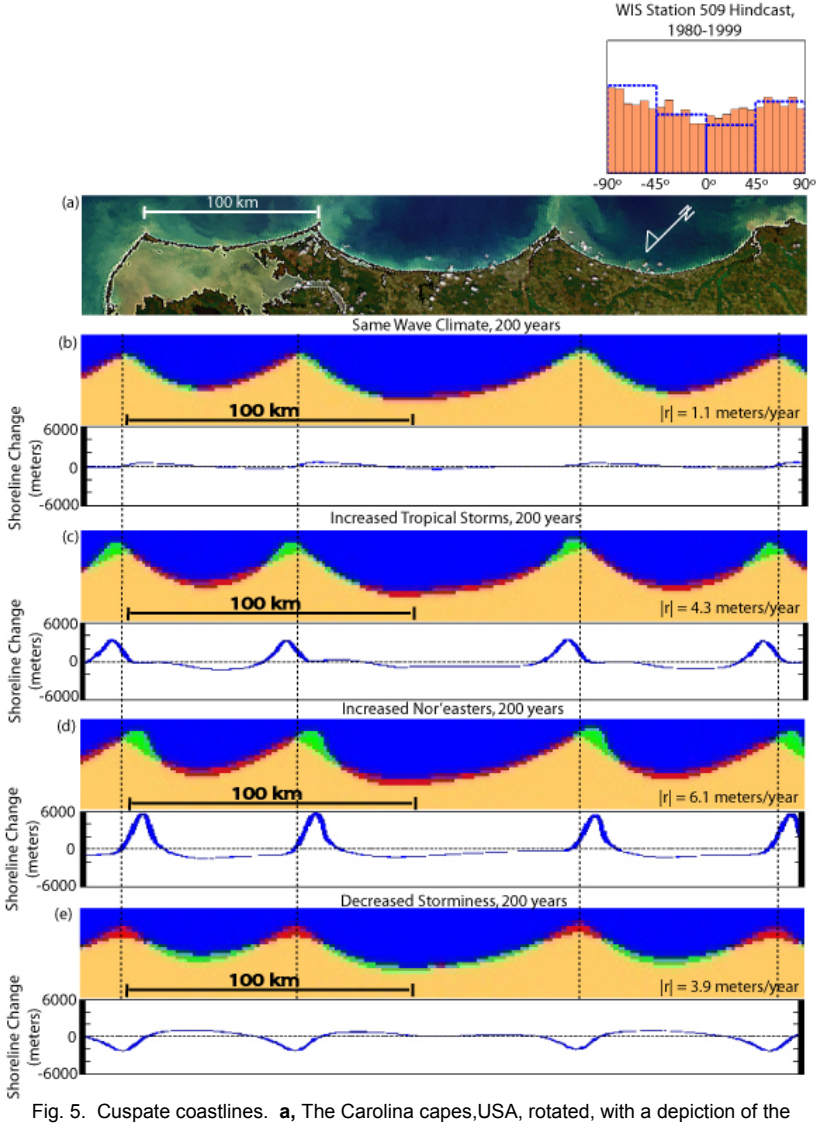

Fig. 5. Cuspate coastlines. **a,** The Carolina capes,USA, rotated, with a depiction of the regional wave climate. **b,** Model shoreline shape produced using a constant wave climate (blue bin outlines in the histogram), and the shoreline changes occurring over 200 years with this same wave climate; red indicates shoreline erosion, and green accretion. The alongshore average of the magnitude of shoreline-change rates is denoted by |r|. **c-e**, coastline changes over 200 years with altered wave climates. Satellite image courtesy of the SeaWiFS Project NASA/GSFC and ORBIMAGE. (From Slott et al. 2006.)

These experiments suggest that changing wave climates will tend to increase the alongshore-averaged shoreline-change rates considerably, relative to the case with a constant wave climate, and that maximum shoreline change rates could approach an order of magnitude higher than the maximum rates with the unchanged climate (Fig. 5). In addition, each changed-climate scenario in Fig. 5 exhibited markedly alongshore-heterogeneous shoreline change, featuring areas of accretion as well as erosion.

The model experiments, which involve several millennia with a constant wave climate followed by an abrupt shift, should not be taken too literally. Climate has shifted on various time scales in recent millennia, and global-warming induced climate change will not occur instantaneously. However, these experiments suggest that if wave climates have changed slowly enough for coastline shapes to maintain quasi-equilibrium, and then shift more rapidly, relatively rapid rearrangement of coastline shape should be expected on complex-shaped coastlines, including parts of the US Southeast and Gulf coastlines and the northwest Alaska coast. On such coastlines, the component of the shoreline change signal related to sea-level rise will be especially difficult to detect.

CONCLUSIONS

Alongshore variations in the composition of the underlying geology will tend to create alongshore variations in shoreline retreat rates during an acceleration in sea-level rise. The magnitude of these alongshore variations in retreat rates could be comparable to the overall retreat rate induced by sea-level rise (and loss of fine-grained material) (Fig. 3). However, shifting wave climates, interacting with the geologic framework, will tend to superimpose alongshore variations in shoreline change that could obscure the sea-level-rise effect. Decade-scale shoreline changes along a well studied coastline suggest that neither the alongshore-uniform nor the alongshore-varying components of sea-level-rise-related changes are currently the most important drivers of shoreline change (Fig. 4). Finally, on complex-shaped coastlines, climate change and associated wave-climate changes could cause rapid and alongshore-varying shoreline changes—shoreline change rates that locally exceed those expected from sea-level rise alone by an order of magnitude (Fig. 5).

If worst-case scenarios for rapid sea-level rise on the order of meters occur on human time scales, the effects on sandy coastlines will undoubted be severe. However, the model explorations described here suggest that coastline responses to sea-level rise are not likely to alongshore homogeneous, and may not be the most important component of climate-related shoreline change in many locations. These initial results suggest that researchers should consider alongshore as well as cross-shore processes when addressing coastline responses to sea-level rise and climate change, and that coastal management strategies should not be based on the assumption of approximately alongshore-uniform shoreline response to climate change.

Abstract: Kaanapali beach is a well-defined littoral cell of carbonate sand extending 2 km south from Black Rock (a basalt headland) to Hanakao'o Point. The beach experiences dynamic seasonal shoreline change forced by longshore transport from two dominant swell regimes. In summer, south swells (H_s = 1-2 m T_p = 14-25 s) drive sand to the north, while in winter, north swells (H_s = 5-8 m T_p = 14-20 s) drive sand to the south where it accumulates on a submerged fossil reef. The Delft3D modeling system accurately predicts directly observed tidal currents and wave heights around West Maui, and is applied to simulate shoreline change. Morphologic simulations qualitatively resolve the observed seasonal behavior.

INTRODUCTION

Numerical modeling allows for simulations of coastal behavior provided that physical processes involved in sediment transport and morphologic development are well

resolved. Thus effort is needed to observe and, through modeling, reproduce wave and current fields with adequate spatial resolution.
The Delft3D modeling system accurately reproduces hydrodynamic behavior at a number of field sites (Elias et al. 2000; Klein et al. 2001; Luijendijk 2001; Walstra et al. 2001, 2003). Delft3D also reproduces observed sediment transport patterns in laboratory tests and morphologic simulations (Lesser 2000; Lesser et. al. 2004; Elias 2006) using the Van Rijn 1993 transport formulations. As an extension of these successes, it is hoped that adequate resolution of water levels, waves, and currents allow the model to reproduce sediment transport patterns in carbonate reef environments.

Kaanapali

Kaanapali Beach, located on the west coast of Maui, Hawaii, lies within a well-defined littoral cell extending 2 km south from Black Rock (a basalt headland) to Hanakao'o Point. Kaanapali Beach is at the center of the Maui Nui complex shown in Figure 1, which consists of the islands of Molokai, Lanai, Maui, and Kahoolawe. Shadowed by these islands, Kaanapali is exposed to direct swell from limited windows: north (350-10^o), south (210-170^o), west (280-260^o), as well as refracted swell from the remaining directions.

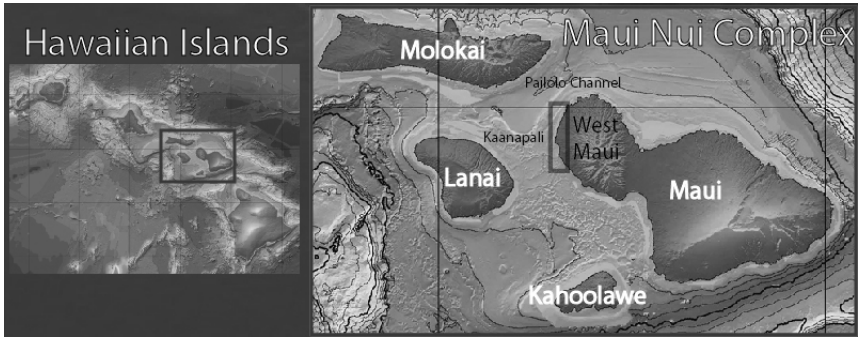

Figure 1 –Hawaiian Islands, Maui Nui, and Kaanapali.

Like the wave field, the Maui Nui current field is also spatially complex due to mean flows through the Pailolo Channel, which have been investigated in (Flament et al. 1996; Sun 1996; Storlazzi et al. 2006). Eversole (2003) characterized Kaanapali as an alongshore system that transports approximately 30,000 m^3 of sand to the north during summer months driven by south swell, which later returns to the south in winter months forced by north swell. This volume of sand can result in dramatic beach width changes of more than 50 m.

Erosion Event

In early July 2003, Kaanapali experienced a rapid-onset erosion event that undermined resort landscaping and infrastructure landward of Hanakao'o Point. This event was likely the result of unusually high sea levels resulting from a series of

mesoscale eddies that arrived over spring and summer months as seasonal sea level increased due to water column warming. Mesoscale eddies, investigated in Firing et al. (2004), can persist for weeks to months and produce sea levels 15-20 cm above normal.

The Kahului tide station on Maui reached its highest recorded hourly water levels during the mesoscale eddy sequence of 2003. While 15-20 cm may seem like a small sea-level signal, in micro-tidal areas such as Hawaii (tide range = 0.6-0.8 m), these eddies represent a significant percentage of the tide range, and a significant increase on sandy shorelines otherwise exposed to nearly constant water levels. It is unlikely that the sea-level signal produced by these events would be able, by themselves, to cause significant erosion. However, when these coincide with spring tides and swell, the conditions for significant erosion exist. Mesoscale eddies are an episodic phenomenon today that represent a future permanent condition in coming decades due to eustatic sea-level rise on the order of 3 mm/year.

South swell associated with the July eddy in 2003 reached a significant wave height of only 0.75 m at 10 m water depth (Tp = 15 s, breaking wave height = 1.3 m), which is considerably lower than the annually recurring deep-water significant wave height of 2 m (Tp = 17 sec, breaking wave height = 2 m). These factors emphasize the importance of sea level as a contributing factor to erosion, and seem to be a clear case of unprecedented water levels in combination with uneventful waves leading to unprecedented erosion.

Seasonal Change

Seasonal profile changes at Kaanapali beach are pronounced. Accretion periods can be idealized as two simple, different systems: accretion updrift of a headland (acting as a barrier to longshore transport, similar to a groin) and accretion on a flat fossil reef. Accretion updrift of a groin has been widely studied and is a common occurrence on coastlines in the US and abroad. The case of sand accretion on a perched beach is much less common, receiving only limited scientific attention.

Beach widening at Hanakao'o Point during winter months is an acute example of accretion on a perched beach, and poses one of the most interesting questions presented by the dynamic cycle of accretion and erosion at Kaanapali. Accretion at Hanakao'o is much more concentrated and dramatic than at Black Rock, even though the north end has an obvious accretion mechanism in place: the physical barrier of Black Rock. It is likely that the shallow, rough reef at Hanakao'o slows southward propagating alongshore currents generated by north swell leading to bed deposition. Hanakao'o also marks the point where swell regimes change from surging breakers in the northern portion of the beach at Black Rock where swash transport may play an important role in beach morphology to offshore dissipative breakers on the reef (characterizing the southern portion of the beach). Because of the difference in offshore depth and wave breaking characteristics, Hanakao'o likely marks the termination of swash zone transport. Improving an understanding of the various

processes governing beach dynamics is critical to defining the role of eddy-generated water-level changes in episodic erosion.

METHODS

Data

An array of instruments shown in Figure 2 (including CTD/OBS and ADCP's) was deployed at the 10 m depth contour along West Maui in 2003 as part of the USGS coral reef project to monitor physical processes affecting formation and lifespan of coral reef systems (Storlazzi et al., 2006). Another instrument (PUV) was deployed at Kaanapali in the summer of 2006 for further monitoring of waves and currents in shallow water.

Modeling

The Delft3D-FLOW module (v. 3.24.03 used here) solves the unsteady shallow-water equations with the hydrostatic and Boussinesq assumptions. In 2D mode the model solves two horizontal momentum equations (see Eq. 1-2), a continuity equation (Eq. 3) and a transport (advection-diffusion) equation (Eq. 4) shown below:

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+g\frac{\partial \eta}{\partial x}-fv+\frac{\tau_{bx}}{\rho_w(h+\eta)}-\frac{F_x}{\rho_w(h+\eta)}-\nu_e\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right)=0 \quad (1)$$

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+g\frac{\partial \eta}{\partial y}-fu+\frac{\tau_{by}}{\rho_w(h+\eta)}-\frac{F_y}{\rho_w(h+\eta)}-\nu_e\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right)=0 \quad (2)$$

$$\frac{\partial \eta}{\partial t}+u\frac{\partial[(h+\eta)u]}{\partial x}+v\frac{\partial[(h+\eta)v]}{\partial y}=0 \quad (3)$$

$$\frac{\partial[hc]}{\partial t}+\frac{\partial[huc]}{\partial x}+\frac{\partial[hvc]}{\partial y}=h\left[\frac{\partial}{\partial x}\left(D_H\frac{\partial c}{\partial x}\right)+\frac{\partial}{\partial y}\left(D_H\frac{\partial c}{\partial y}\right)\right] \quad (4)$$

where u and v = the horizontal velocities in the x and y directions respectively; t = time; g = gravity; η = free surface height; h = water depth; f = coriolis force; ρ_w = density of water; τ_b = bed friction; F = external forces due to wind and waves, ν_e = horizontal eddy viscosity; D_H = horizontal eddy diffusivity; and c = concentration of suspended sediment. The equations are solved on a staggered finite difference grid using the Alternating Direction Implicit (ADI) method after Stelling (1984).

Computational Grids

The computations of Delft3D are performed on orthogonal curvelinear grids shown in Figure 2. Modeling for this project involves two flow grids: a regional model covering the West Maui coast and a local Kaanapali model. These grids are linked either by domain decomposition (DD) or interpolation of boundary conditions from the regional grid to the local grid. The use of DD models is very elegant, although primarily used here to validate the flow field in the smaller models, and justify the use of the local grid by itself. The use of just a local grid for simulations offers an

improvement in computation time over domain decomposition models, especially if the single domain models return results similar to the DD models.

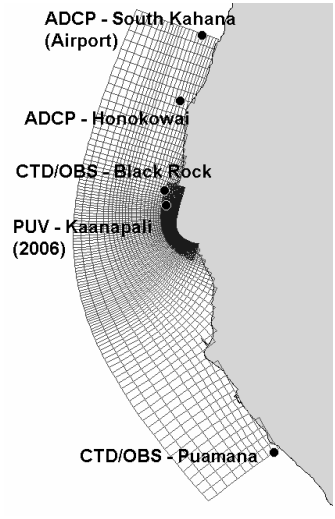

Figure 2 - Instrument locations and grid layout.

Boundary Conditions

West Maui experiences a propagating tide, where gradient phases and amplitudes of tidal constituents exist along the coast, and tidal velocities are directed shore parallel (Storlazzi et al., 2006). Boundary conditions ideal for modeling this particular tidal configuration have been expressed in Roelvink and Walstra (2004), using water-level boundaries at the open (offshore) boundary and water-level gradient (Neumann) boundary conditions at lateral boundaries to solve for alongshore tidal velocities.

The boundaries use a harmonic forcing type, which facilitates use of the harmonic tidal components in water-level boundaries and determining water-level gradients. Water-level gradient boundary conditions can be determined simply from the amplitudes and phases of the tidal constitutes at each lateral boundary using the equations given in Roelvink and Walstra (2004):

	Given tidal constituent	Gradient amplitude:	
Amplitude:	η_i	$\eta_i \left(\frac{\phi_i^{north} - \phi_i^{south}}{d_{ts}} \right)$	(5)
Phase:	ϕ_i	$\phi_i + \pi/2$	(6)

where η_i = amplitude of the tidal constituent (m); ϕ_i = phase of the tidal constituent ($\phi_i^{north}, \phi_i^{south}$ for north and south boundaries respectively (radians)) and d_{ts} = distance between the lateral boundaries (m). With these boundary conditions prescribed, the bed roughness is tuned to match the observed current magnitude. These boundary conditions have been shown to provide accurate simulations of tidal velocities in Roelvink and Walstra's modeling studies (2004) at Egmond (Netherlands). This study provides another example of the excellent performance of boundary conditions developed from this scheme (see Results).

The wave boundary conditions are determined from model hindcasts (WaveWatch III) because there are no recorded buoy observations that include wave direction. These hindcasts adequately resolve observed wave heights and periods at a number of buoy locations in Hawaii. In this study, hindcast values of significant wave height, peak period and direction are applied uniformly at the open boundaries of the largest SWAN model, and a series of nested grids resolve the wave field down to the nearshore scale (10m grid) at West Maui and Kaanapali Beach. The SWAN nesting scheme is shown on Figure 3.

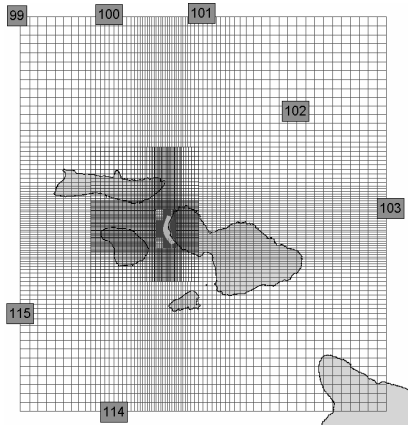

Figure 3 - SWAN nesting scheme. WaveWatch III hindcast locations are shown in boxes.

RESULTS

Model calibration has been carried out with the USGS data set. The model shows good comparison to the observed data set for tidal water levels, wave heights, and currents.

Good comparisons of tidal water levels are readily achieved with the use of a water-level boundary at the open boundary. The modeled and observed tidal components at the instrument location are shown in Table 1.

Agreement between modeled and observed currents is more difficult to achieve because of unresolved current-generating sources including mean flows through the Pailolo channel, internal tides, and the influence of the mesoscale eddy. Nevertheless the model shows good comparison with the observed currents, especially for stations dominated by barotropic flow, shown in Figure 4 and Figure 5.

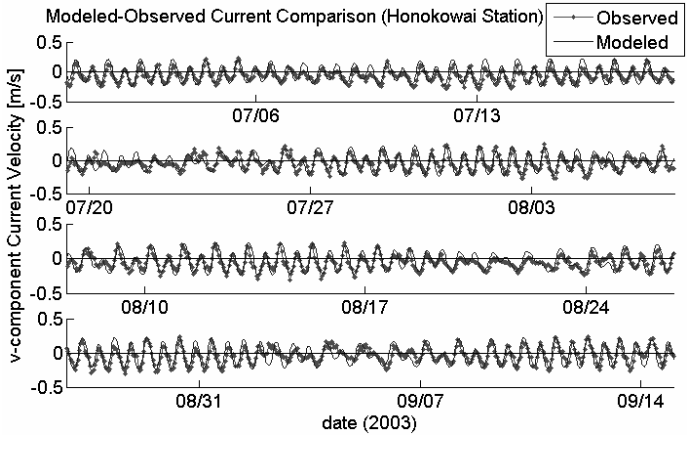

Figure 4 - Modeled vs. observed current comparison for Honokowai station.

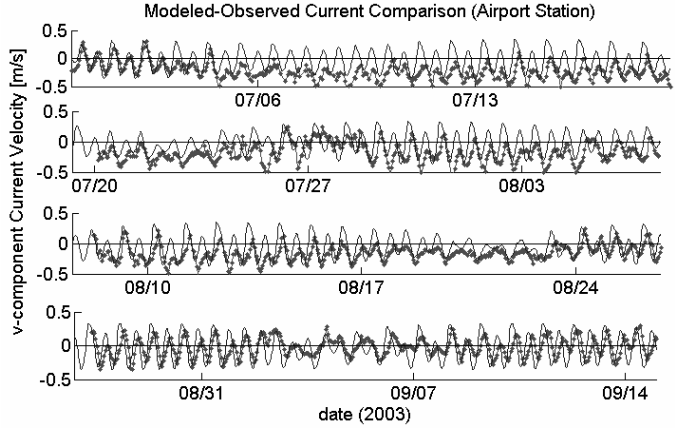

Figure 5 - Modeled vs. observed current comparison for the South Kahana (Airport) station.

Use of the SWAN model appears to resolve spatial variability around and inside of the Maui Nui complex. Modeled wave heights show good comparison with observations at instrument locations shown in Figure 6.

Tidal residuals from two dominant swell regimes are shown in Figure 7, which show significant longshore currents at Kaanapali.

Morphologic simulations under dominant north and south swell conditions are shown in Figure 8 with aerial photographs of the seasonal beach states when these swell regimes dominate.

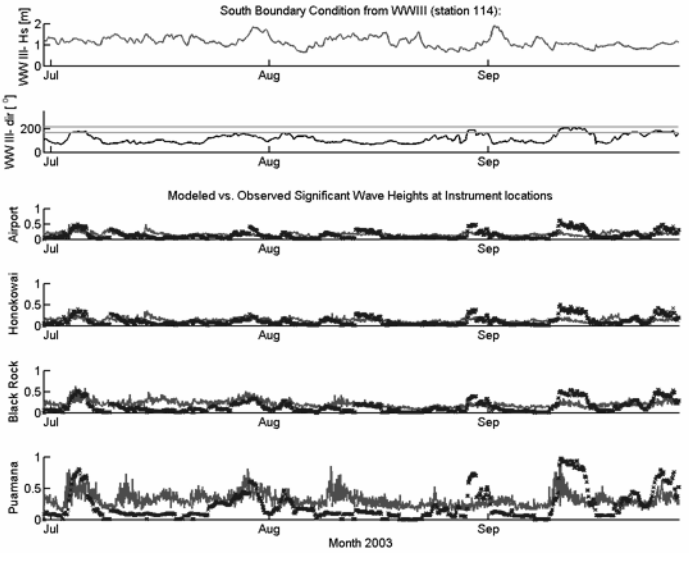

Figure 6 - WaveWatch III boundary conditions and comparisons of modeled (x) and observed (-) wave heights [m] at instrument locations. The lines on the second subplot represent the south swell window (170-210^{o}).

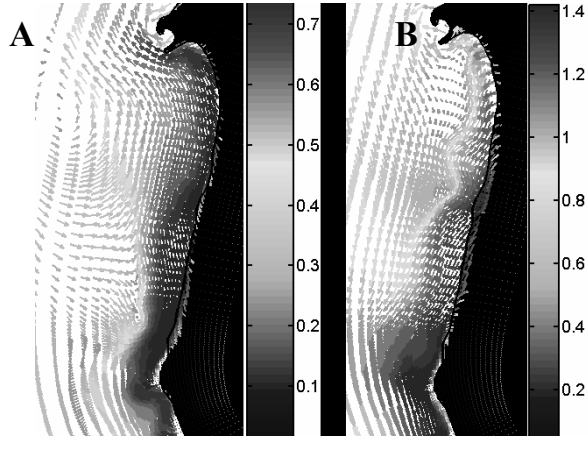

Figure 7 - Tidal residuals [m/s] for South (A) and North (B) swell at Kaanapali Beach

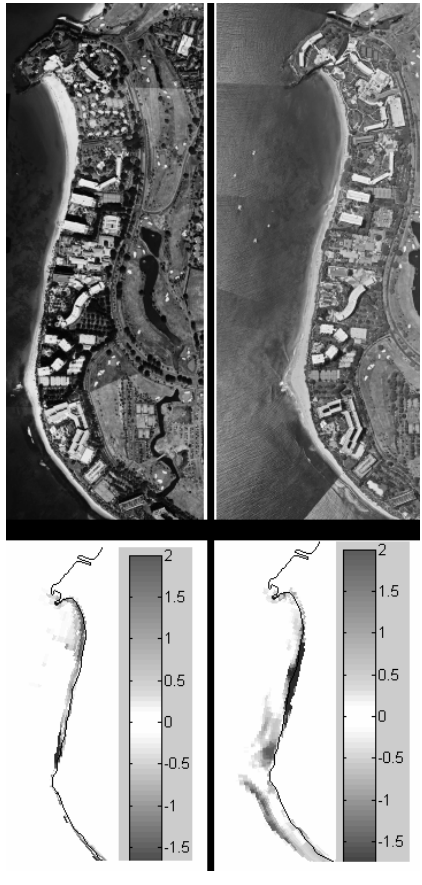

Figure 8 – Observed (above) and simulated (below) beach states (accretion - red; erosion - blue [m]) during summer (left) and winter (right) swell conditions.

DISCUSSION

Using Delft3D with water-level gradient boundary conditions prescribed in Roelvink and Walstra (2004) provide excellent resolution of current velocities in regions dominated by barotropic tidal flow. For regions influenced by mean flows and internal tides, more physical processes need to be accounted for to better resolve observed velocities. It appears the Honokowai station (Figure 4) is well resolved, while the South Kahana (Airport) station (Figure 5) is influenced by the presence of mean flows and internal tides. Despite the influence of unresolved processes, the models show good comparison with the observed flow velocities.

Mean flows observed at the South Kahana (Airport) Station appear to be related to wind direction, and may be related to island-trapped wave events (Merrifield 2002; Storlazzi 2006). Figure 9 shows the time series of wind speed and mean flow and their inter-relationship.

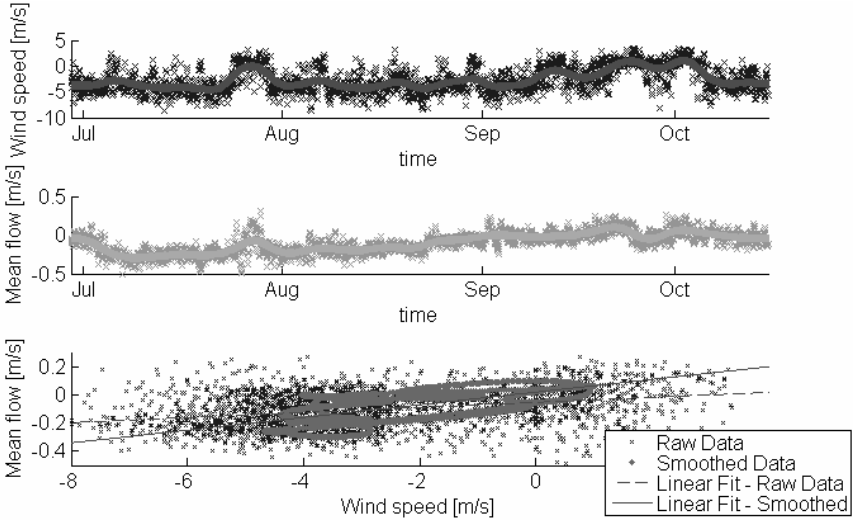

Figure 9 - Relationship between winds and mean flow through the Pailolo Channel.

Wind speed and mean flow seem to mirror each other. A notable event in the time series is the decrease in wind speed in late July which leads to a corresponding decrease in the mean flow through the channel. Although the model accounts for wind forcing, the mean flow is not resolved. If the mean flow is due to wind forcing, the inability to resolve the mean flow is probably due to the limited coverage of the model domain: inability to develop significant wind-generated currents, and/or the topographic influence of West Maui which may cause local acceleration of the wind field.

The mean flow observed at South Kahana seems unlikely, from the two observed time series, to extend past the Honokowai station and potentially affect currents and sand transport at Kaanapali Beach. The major influence in sand transport at Kaanapali seems to be the wave-generated currents that arise from obliquely incident waves from north and south swell breaking on the westward-facing shoreline.

While simulations of shoreline accretion and erosion forced by the dominant swell regimes show a qualitative morphologic behavior, the ultimate goal of modeling is to reproduce or predict transport volumes and resulting changes in the beach profile. Modeling beach profile changes often captures observed changes in mean state, but is

less successful at predicting significant erosion and accretion events. While the model seems to perform adequately for scenarios on timescales of a few days, variability of wave and current conditions on longer timescales make simulations on timescales of months to years more difficult to resolve. Comparisons of observed and modeled profile changes, in Figure 10, show that the model tends to overpredict accretion (indicated by the frequency of records in quadrant 2 and above the perfect fit line) and to miss large erosion and accretion events in the end members of the littoral cell (Black Rock and Hanakao'o). Bias towards accretion is likely due to the persistence of small wave states during the 3-month simulation, and inability to resolve swell events that lead to significant change. The effects of 2D vs. 3D modeling on accretion predictions should also be investigated.

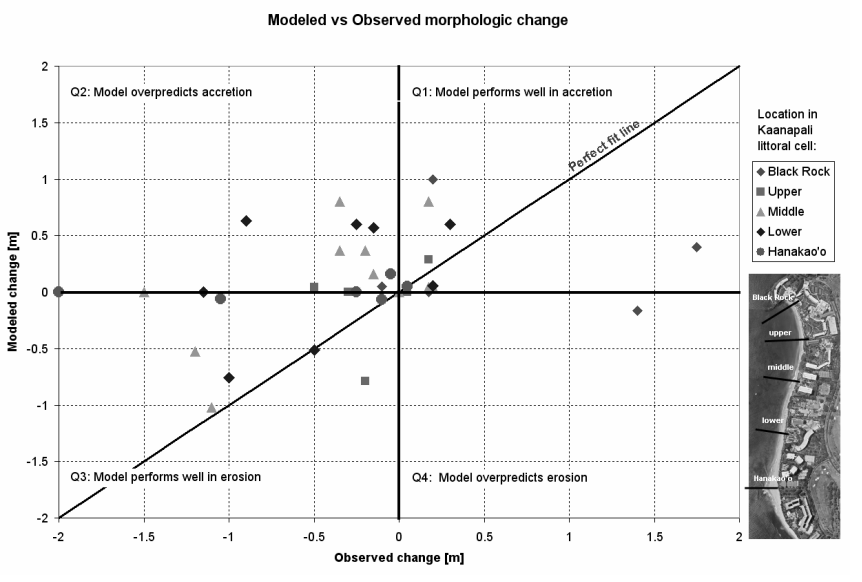

Figure 10 - Observed vs. modeled beach profile changes over 3 months at a number of locations at Kaanapali, Summer 2000.

Additionally, there appears to be no significant difference in modeling the summer 2003 erosion event with and without the presence of the small sea-level signal contributed by mesoscale eddies. This is likely the result of discretization by the model. There is an inherent problem simulating natural processes using discrete numerical simulations, especially when variability of a particular process, in this case sea level in its vertical and horizontal position, exists on a smaller scale than the discrete grid is capable of resolving. Another process we are not effectively resolving in the model is the action of swash transport producing morphologic changes in the beach face. The model does, however, have a scheme to replicate morphologic beach face changes by applying a relative amount of erosion or accretion in wet grid cells to

adjacent dry grid cells. While this scheme is a practical solution to an extremely complex problem, it does leave a potentially important processes unresolved.

We can, however, make interesting conclusions about sand transport from simulations of simple scenarios. Morphologic simulations of transport due to north swell with a uniform bed roughness demonstrate transport of a considerable amount of sand around Hanakao'o Point. Increasing the simulated roughness for the submerged fossil reef offshore from Hanakao'o Point causes the sand to accumulate in this location. This is consistent with field observations.

Inability of the model to resolve the signal of the mesoscale eddy should not cause us to dismiss its influence. Simple Bruunian models assign sea-level position paramount influence, although the presence of reef surfaces may change this simple dynamic. It appears that increased sea level on a normal shoreline profile (not perched) may exist in unstable equilibrium until wave energy initiates transfer to a new position. The duration of mesoscale eddies is sufficient to begin this transition as evidenced by the considerable erosion observed in summer 2003 at Kaanapali. The event also suggests that increased sea-level signals may cause accelerated seasonal response in alongshore systems.

CONCLUSIONS

Robust numerical models allow for realistic shoreline change simulations. Adequate observations are indispensable to ensure realistic performance. Poor modeling performance arises from inadequate tuning, unresolved processes, and spatial discretization of continuous natural processes. Use of water-level gradient boundary conditions given by observations of tidal components and the equations used in Roelvink and Walstra (2004) successfully model tidal velocities. Scenario-based modeling of seasonal shoreline change is qualitatively successful, whereas real-time, long-term simulations often to not capture significant changes in beach profile and shoreline position.

Mesoscale eddies and accretion on perched beaches atop rough reef substrates play a potentially significant role in beach morphology of Hawaiian shorelines, and merit continued investigation.

ABSTRACT

Along many shorelines, the coastal foredune plays a key role in protecting against coastal flooding while providing a unique environment for specialized flora and fauna. Over the past 20 years, researchers with backgrounds in engineering, geography, geology, and geomorphology have expanded our understanding of the coastal aeolian processes that build and shape these landforms. In 2002, the U.S. Army Corps of Engineers (U.S.A.C.E.) replaced its *Shore Protection Manual (SPM*) with the *Coastal Engineering Manual* (*CEM*). The *CEM* is intended to provide "*in a single source the current state-of-the-art in coastal engineering to provide appropriate guidance for application of techniques and methods to the solution of most coastal engineering problems*" (*CEM* 2002, p. I-1.1), thus establishing it as the legal standard for coastal engineering practice in the U.S. Chapter 4 in Part III, "Wind-Blown Sediment Transport" is intended to provide engineers such guidance where wind blown sand is a part of the problem or the solution. This paper reviews Chapter III-4 and compares it to the published research to assess the degree to which this section communicates and codifies "state-of-the-art" understanding of coastal aeolian processes and landforms. Our review suggests that three specific areas require revisiting: (1) the "Transport Rate" section should be revised to direct the user to conservative transport rate estimation methods; (2) the coastal aeolian and dune process descriptions should be expanded to incorporate recent research findings, especially those that encourage and permit the engineer to incorporate more natural processes and landforms in solutions; and (3) an outdated and incorrect recommendation should be removed immediately.

INTRODUCTION

"Engineering is not applied science. Our limited understanding of nature is one constraint, but it is far from the only one, seldom the hardest one, and almost never the limiting constraint for coastal engineering design." (*CEM* 2006, p.V-3.18)

"Engineers, geographers, oceanographers, geologists and other scientists have made significant contributions to our present understanding of the coastal environment. As usual, however, interdisciplinary communication has not been good because each discipline is engrossed in specific problems. Nonetheless, if demands on the coastal system continue to increase, the cooperative efforts of all coastal workers are necessary to avert environmental disaster." (Ritter *et al*. 2002, p. 434)

In 2002, the U.S. Army Corps of Engineers (USACE) published the *Coastal Engineering Manual* (*CEM*) to provide coastal engineers "*the current state-of-the-art in coastal engineering to provide appropriate guidance for application of techniques and methods to the solution of most coastal engineering problems*." (*CEM*, 2002, p I-1.1) In the first section, the *CEM* identifies Ritter's '*engineers, geographers, oceanographers, geologists and other scientists'* as producing a 'coastal science' that it defines as a "*suite of interdisciplinary technologies applied to understanding processes, environments and characteristics of the coastal zone*." (*CEM*, 2002, p I-1.2) It continues: "*Coastal engineers use these understandings to develop physical adaptions to solve problems and enhance the human interface with the coast.*" (*CEM*, 2002, p I-1.2) This introduction admonishes users that proper design and implementation of solutions to coastal problems requires understanding of coastal processes. The *CEM* lays a heavy burden on coastal engineers to incorporate understanding of all processes working on the harbors, navigation channels, shore protection projects, flood control projects, and environmental preservation and restoration efforts that they design. The manual attempts to provide all of the necessary knowledge, an effort that helps explain why the *CEM,* at 2838 pages, is almost three times longer than the *Shore Protection Manual* (1984) it replaces. The U.S.A.C.E. developed the *CEM* to document both the state-of-the-art in coastal engineering designs and procedures and the scientific understanding of coastal processes and landforms.

If Ritter *et al*. (2002) are correct about the communication challenges between coastal engineers and coastal scientists, the question arises: Does the *CEM* reflect and communicate our best understanding of coastal processes? If it does not, what changes move us closer to this goal? This paper addresses these questions as they pertain to Chapter III-4 to assess whether it meets the "state of the art" standard. Through its identification with this standard, the U.S.A.C.E. has elevated the *CEM* to status of preemptive authority for the courts, in political debate and in public discussion. This importance dictates that geomorphologists and ecologists as well as coastal engineers provide critical review of the *CEM* to achieve and maintain this standard. The knowledge codified in the *CEM* finds it way into most designs and construction contracts for coastal work in the United State as the U.S.A.C.E retains project management and engineering responsibilities for the U.S. government. Moreover, U.S.A.C.E.'s translation of the *CEM* into many other languages, including Chinese and Catalonian, and the provision of free internet access only serve to increase its global impact.

This paper involves comparing the *CEM*'s Chapter 4 in Part III, "Wind-Blown Sediment Transport" (hereafter referred to as Chapter III-4) with the recent literature on aeolian processes and coastal dunes. To gauge Chapter III-4's degree of currency as of its publication on 30 April 2002, preference was given to articles published between 1990 and early 2001. To assess Chapter III-4's success, the question was posed: Does it provide the necessary guidance and information to maximize an engineer's chance to develop a sustainable, cost-effective, environmentally acceptable solution when assigned to develop a flood protection "sand dune" or to stop wind-blown coastal sand from encroaching on infrastructure or agricultural lands? For example, could the guidance of Chapter III-4 prevent the inundation of a city with sand from its beach nourishment project, such as occurred at Riells, Spain in 1988 and 1994? (Marques *et al*. 2001). If not, how could the guidance be improved?

ALTERNATIVE PERSPECTIVES

The typical technical code or design manual provides engineers two basic types of standards, (1) a prescriptive standard where the ways and means to attain an end result are fully defined; or (2) a performance-based standard where a specific description of the end result to be attained is defined and the engineers is required to determine how this is to be achieved (American Society of Civil Engineers 2006). Implicit in a prescriptive standard is the code writer's promise that if applied as prescribed, the solution will be conservative enough to not fail because of other (reasonable) factors that were not considered. Professors and textbooks inoculate neophyte engineers against failures by stressing the importance of conservative calculations and design. They emphasize early in the academic training the importance of applying generous safety factors or "factors of ignorance" that help reduce the number of "*sleepless nights wondering if those he has used are sufficient*" (McCormac 1967, p. 4). Similarly, performance-based standards presume the engineer has adequate scientific knowledge to apply to the problem. The C*EM* functions as a technical standard and more, with Part I through IV providing the "scientific foundation on which the engineering-based parts rely." (*CEM* 2002, p. I-4-3). The U.S.A.C.E. intended Chapter III-4 to provide state-of–the–art knowledge of aeolian processes and landforms at work in the coastal zone.

While our analysis to date cannot be considered complete, we feel that as currently constituted, Chapter III-4 does not provide the engineer with adequate, and in some cases correct, information to properly work with, specifically:

> 1) It prescribes (without the prescriptive language defined in American Society of Civil Engineers 2006) a method to calculate aeolian transports rates that is scientifically flawed and that does not produce conservative predictions.
> 2) The discussion of aeolian processes and coastal dunes is not adequate or current enough to meet the "state-of-the-art" standard. As published, Section III-4 provides weak foundation to develop successful performance-based solutions that will be effective and efficient.

3) While some of the text is only "weakly correct" or ignores established best practices, the chapter also includes text that perpetuates a relic recommendation to utilize an invasive plant species to stabilize sand dunes.

Predicting wind-blown sand transport rates

Chapter III-4 prescribes primitive methodologies for obtaining the data needed for predicting aeolian transport rates, prefaced by an out-of place description of "Wind Regimes in the US" (in Section III-4-2). Although generically interesting, this description offers little to assist an engineer facing a local challenge. Except in the rarest of cases, regional climate patterns and data will not produce the level of detail needed for successful estimates. A more appropriate start to Chapter III-4 would be a general introduction to the aeolian boundary layer and sampling methodologies.

Many of the protocols presented assume that the project engineer will not have the necessary resources to gather the appropriate data for transport rate estimates. For example, the discussion begins with a presentation of the "Law of the Wall:"

$$u_z = \frac{u_*}{\kappa} \ln\left(\frac{z}{z_0}\right) \quad (1)$$

where u_z is the wind speed at elevation z above ground, u_* is the shear velocity, z_0 is the roughness length, and κ is von Karman's constant (about 0.4), and d is the mean grain size. Estimation of u_* is the critical step for predicting transport rates as it is the fundamental parameter in most transport models. To determine u_*. estimates or measurements of u_z at height z are required. The standard practice is to use arrays of three to six anemometers to measure the wind speed profile at the location of interest, determine statistical best-fit line, and use the slope, m, and intercept, b, of that line to estimate: (Bauer *et al.* 1992)

$$u_* = m\kappa, \quad (2)$$

$$\text{and } z_0 = e^{-(b/m)} \quad (3)$$

Chapter III-4 describes processes for deriving estimates of roughness length and shear velocity using either one or two anemometers, rather than the preferred statistical analysis of wind profiles measured with three or more anemometers. Before continuing our review of this protocol, it is important to note that, given the normal cost of a three-cup anemometer between US$50 and $400, the recommendation to deploy only one or two anemometers will save the project engineer less than $1000 at a cost of inferior estimates for key transport parameters. Chapter III-4 suggests that roughness length can best be calculated by measuring wind speeds at two different elevations and then solving for z_0. If the relevant profile is perfectly log-linear, then this method will yield results identical to those obtained using the statistical protocol provided above. However, perfect log-linearity is rarely found in empirical wind data and even small departures from this state will lead to large degrees of uncertainty roughness length estimates. More importantly, however is the fact that if you have two (or more) anemometers and a log-linear profile, there is no need to estimate roughness length because estimates of u_* can be obtained directly from Equation 2. However, Chapter III-4 continues, somewhat contradictorily,

to argue that because velocity measurements at two elevations are rarely available, u_* could be determined from the relationship:

$$u_* = 0.044\, U_{2m} \quad (4)$$

where U_{2m} is the average hourly wind velocity measured two meters above the beach. Chapter III-4 also identifies that the constant for surface types other than a smooth beach varies from 0.037 for a tidal flat to 0.093 for the lee side of a dune, while admonishing that this relationship only holds for the grain size and sorting for which they were developed (although these values are not reported).

There are three flaws in this one-anemometer approach. First, there are several methods to estimate roughness lengths if the sand grain size is known or can be approximated (although such methods must, perforce, ignore complicating factors such as the presence of ripples, local topography, vegetation, etc.). For example, from the work of Nikuradse:

$$z_0 = d/30 \quad (5)$$

where d is the diameter of uniform grains. For non-uniform grain-size populations Namikas (2003), suggests the relationship:

$$z_0 = 2d/30 \quad (6)$$

where d is the mean grain diameter. This later relationship should be included because this condition is common to most beach surfaces and it could be used to estimate aeolian interactions with sand from potential beach or dune nourishment sources. Combining Equations 1 and 6 includes more information about a specific site:

$$u_z = \frac{u_*}{\kappa} \ln\left(\frac{15z}{d}\right) \quad (7)$$

The second flaw associated with the use of one (or two) anemometer(s) as described in Chapter III-4 concerns recommended measurement heights. For one anemometer, the recommended height is two meters, for two anemometers it is suggested that they be placed three, four, or more meters apart, vertically. At these elevations, however, there is a chance that the instruments would be above the internal boundary layer developing over a beach. The height, δ, of such a boundary layer increases with distance, X, down wind of a change in surface roughness or orientation – *e.g.*, the transition from wind flow over water to over sand Granger *et al.* (2005) suggest:

$$\delta = 0.18X^{0.62} \quad (8)$$

for relatively smooth conditions such as those over a sand surface. For a site 100 m from the water line, for example, this would put the top of the internal boundary layer at about 3 m. For a distance of 50 m, from the water line, berm crest, or dune crest, the estimate of δ decreases to about 2 m. Wind speeds should be measured conservatively below these elevations in order to best represent the conditions acting on the sand surface.

The third flaw arises from treating the roughness length as a constant. Since the work of Owen (1964), we have known that the presence of saltating grains produces an apparent roughness length, z_0' that is proportional to the shear velocity:

$$z_0' = \frac{Cu_*^2}{2g} \quad (9)$$

where C is a constant and g is gravity acceleration. A similar, but alternative formulation, is that of Raupach (1991):

$$z_0' = \left(\frac{Cu_*^2}{2g} \right)^{1-r} z_0^r \tag{10}$$

where r is the ratio of the threshold shear velocity to shear velocity. Either Equation 9 or 10 can be used with wind speed measured at one elevation to solve Equation 1 iteratively for shear velocity. Again, this approach includes much more environmental information than the approach presented in Chapter III-4. Any one of these three flaws could be enough to distort the critical estimates of shear velocity that would result from their use. Therefore, we conclude that these protocols do not represent best practice.

Section III-4-3 "Transport Rates" presents an incomplete review of transport rate equations that include only the models of Bagnold (1936), O'Brien and Rindlaub (1936), Zingg (1953), and Hsu (1971). At this point, instead of continuing to identify the many other formulas developed by researchers such as Kawamura (1951), Kadib (1964), Lettau and Lettau (1977), Horikawa *et al.* (1984), Sørensen (1991), and Spies et al. (1991), Chapter III-4, justified on the basis of Chapman's (1990) paper, jumps to the designation of **the one best** formula, that of Hsu (1971):

$$q = K \left(\frac{u_*}{\sqrt{gd}} \right)^3 \tag{11}$$

where q equals sand transport rate in gm/cm-s, u_* is shear velocity, d is mean sand grain diameter and K = dimensional aeolian sand transport coefficient, which in turn equals:

$$K = e^{-9.63+4.91d} \tag{12}$$

In selecting this formula as the prescribed transport estimation relationship, Chapter III-4 ignores the analyses of Svasek and Terwindt (1974), Sarre (1988), Bauer *et al*. (1990), Pye and Tsoar (1990), Sherman and Hotta (1990), Arens (1996) and Sherman *et al*. (1998). All of these studies tested the various models in various environments and collectively showed that none of the transport models provide consistent, accurate results. The recommendation to use the Hsu (1971) model even ignored Chapman's summary analysis (1990, p. 752) that of the models reviewed, including Hsu (1971), "*it is clear that there is no unequivocally 'best' method."*

There are many local factors that mitigate against the success of a general transport model that incorporates only wind speed (shear velocity) and grain size as independent variables. However, even without these complications, the different transport models produce a wide range of predicted transport rates. For a constant grain size and an identical range of shear velocities, Sherman *et al*. (2005) showed that the different models produce a set of predictions that vary by more than 700%. Pye and Tsoar (1990) had earlier identified this magnitude of variability. Researchers have not been able to narrow this variability in part because so many other factors (as listed by Arens (1996) and Sherman *et al.* (2005), for example) affect the rate. Beaches are also subject to significant temporal and spatial variations in wind speed over small time and space scales (Arens 1996; Gares *et al*. 1996) that complicates this problem further.

When the general transport models are corrected for moisture, the discrepancies between the predictions may increase depending on the moisture correction model used and the

moisture content for the sediments being evaluated. Many researchers have recognized that moisture content can be the third most important factor affecting transport rates (Sarre 1988; Gares 1988; Pye and Tsoar 1990; Sherman and Hotta 1990; Namikas and Sherman 1995; and Cornelius and Gabriels 2003).

Chapter III-4 contains four flaws in the treatment of sediment moisture content. First, it is presumed that moisture content is important only for days where precipitation exceeds evaporation. This is problematic for four reasons: 1) it requires reliance on data from weather stations that might be remote from the site under consideration; 2) it requires assessment on a daily basis, thereby ignoring the much shorter duration of many transport events; 3) it requires prediction of a daily evaporation total, a complicated process ignored in the chapter; and 4) perhaps most seriously, it presumes that precipitation is the only source of sediment moisture on a beach – this is clearly nonsense.

The second flaw is that only the Hotta *et al*. (1985) model is considered to represent the moisture influence on threshold shear velocity. There is no independent verification of the propriety of this designation (see review by Cornelius and Gabriels, 2003), and the predicted effects of moisture content vary widely depending on the model chosen (Namikas and Sherman, 1995). The third flaw is the assumption, based loosely on the field data of Svasek and Terwindt (1974) that the sand moisture content is either 2.5% or 0%, depending on the balance between precipitation and evaporation. Sand moisture is difficult to measure but readings vary from 1% to 25% with a recommended default value of 4% not recently flood by rain or tides (Sherman *et al.* 2005). Several researchers have developed correction factors for moisture, which Namikas and Sherman (1995) found could produce widely different results.

The fourth flaw associated with the moisture content analysis is that there is no way, according to the protocol spelled out in the chapter, to actually apply the results of a predicted effect because the Hsu (1971) equation does not include a term for threshold shear velocity. Indeed, examination of Tables III-4-4 and III-4-5, illustrating the use of moisture information for transport prediction, indicates that the moisture content effect either prevents transport entirely (nonsense) or has no effect at all (also nonsense).

At this point we can return to our premise that one duty of the engineer is to provide conservative estimates for project planning and design. Clearly, the protocols presented in Chapter III-4 cannot produce such estimates as only one outcome is possible for a particular data set. This ignores the large degree of variability that exists in transport (and related) models. It is more appropriate to provide a selection of approaches that would provide maximum and minimum likely transport rates. Following Sherman *et al*. (2005) we recommend that the engineer concerned about potentially damaging blowing sand (such as occurred on the nourished beach at Riells, Spain (Marques *et al*. 2001) use a model that yields an upper limiting calculation. Kawamura's (1951) model does this:

$$q = C\frac{\rho}{g}(u_* - u_{*_t})(u_* + u_{*_t})^2 \qquad (13)$$

where q is the transport rate, C is an empirical constant (typically 2.78), u_{*_t} is the threshold shear stress and ρ is the density of the sediment. This model could be used with a conservative moisture correction, such as that of Hotta *et al*. (1984):

$$u_{*_{tw}} = u_{*_t} + 7.5w \tag{14}$$

where $u_{*_{tw}}$ is the wet threshold shear velocity, which substitutes in equation 12 for u_{*_t}, combining equations 13 and 14:

$$q_{wet} = C\frac{\rho}{g}(u_* - u_{*_t} - 7.5w)(u_* + u_{*_t} + 7.5w)^2 \tag{15}$$

where q_{wet} is the moisture corrected transport rate.

One the other hand, for the engineer needing to estimate a potentially beneficial impact from blowing sand, (*e.g*. building a dune), a method that consistently gives low estimates should be considered, such as Zingg's (1953) modification of the Bagnold model:

$$q = C(\frac{d}{D})^{3/4}\frac{\rho}{g}u_*^3 \tag{16}$$

where q is the sediment transport rate, C is 0.83, and D is the reference grain size of 0.25mm. In this case, moisture correction should be applied and the method that identifies the largest reduction in rate, the Belly (1964) model, should be applied. It works by calculating the wet threshold shear velocity:

$$u_{*_{tw}} = u_{*_t}(1.8 + 0.6\log_{10} w) \tag{17}$$

Since the Zingg formula does not include a threshold shear velocity term, the moisture correction is made by increasing Bagnold's (1942) reference grain diameter D by solving for d in Equation 18 for the wet threshold velocity. D_{wet}, the moisture compensated equivalent reference grain diameter (Sherman *et al.* 2005) is determined by:

$$D_{wet} = \frac{u_{*_{tw}}^2}{A^2 g(\frac{\rho_s - \rho}{\rho})} = \frac{u_{*_t}^2(1.8 + 0.6 * \log_{10} w)^2}{A^2 g(\frac{\rho_s - \rho}{\rho})} \tag{19}$$

D_{wet} then substitutes for D in Equation 16 to obtain the conservative transport estimate:

$$q_{wet} = C(\frac{d}{D_{wet}})^{3/4}\frac{\rho}{g}u_*^3 \tag{20}$$

An example of the range of transport rates calculated by the two recommended methods, the Chapter III-4 method, and Bagnold's (1936) original model is shown in Figure 1.

The engineer can also compensate for other the factors that affect transport rate estimates for a given site, but it is important to establish the worst case estimates, whether they be low or high.

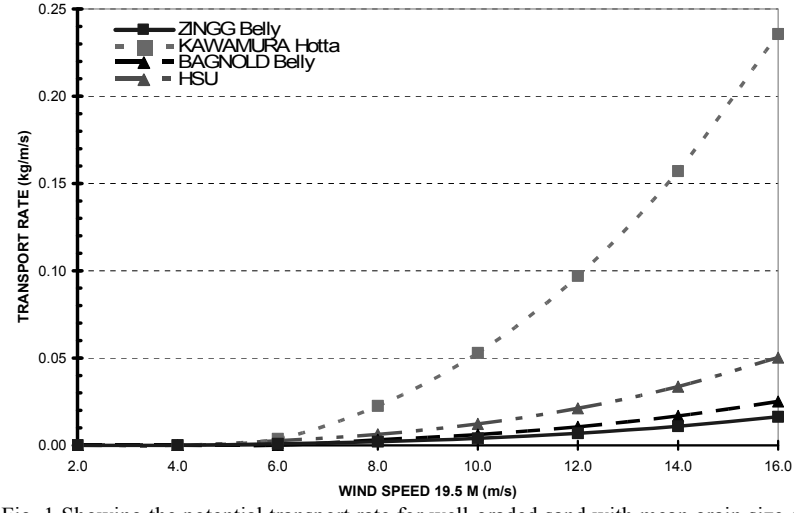

Fig. 1 Showing the potential transport rate for well-graded sand with mean grain size of 0.125mm with moisture content of 3.0% using various models mentioned in text for various measured wind speeds.

Scientific information about dunes and aeolian processes

Chapter III-4's relatively short section "Dunes and dune processes" begins with "*Sand dunes are important coastal features that are created, enlarged, and altered by wind–blown sand…. These dunes often result from the natural accumulation of wind blown sand originating on the beach face: however, they may also be man-made. Whether natural or man-made, they are subject to continued growth, alteration and movement due to natural wind transport processes. When present and if sufficiently large, foredunes can provide protection from coastal flooding, shoreline erosion, and wave damage. Dunes can also shelter the area landward from wind-blown sand*." (*CEM* 2002, p. III-4-47) Unfortunately, this promising introduction is not backed with sufficient information to help an engineer with the assignment of creating a protective dune with a given performance requirement (such as it shall provide a volume of 50 cubic meters/meter length above the 100-year flood level.) A short list of the critical scientific concepts that such an engineer should be aware of include:

1) A dune created by natural aeolian processes, in whole or in part, can be more effective in resisting storm waves and be more aesthetically pleasing than mechanically piled sand (Brunsden and Moore 1999, Psuty and Ofiara 2000, Nordstrom and Lotstein 1989)
2) Stabilization by native vegetation offers many advantages over fencing but there are situations where properly designed sand fencing will be required to create / maintain the dune. (Hotta *et al*. 1987; Nordstrom *et al*. 2000; Miller *et al*. 2001)

3) The foredune provides a niche microenvironment that should be preserved, or mimicked as much as possible. (Nordstrom and Allen 1978; McLachlan 1990)
4) Where they exist, foredunes are a critical element of the dynamic, linked offshore bar-beach-dune system where sediment budgets (natural and augmented) play a key role in the morphology of the elements. (Short and Hesp 1982; Sherman and Bauer 1993; van der Wal 2000; Garcia-Mora *et al.* 2001)
5) Dune blowouts are a natural part of the coastal sediment system and may not require immediate stabilization if the movement of sand is acceptable. (Hesp and Hyde 1996; Arens and Geelen 2006)

The bottom line is that Chapter III-4 does not provide the user with enough information to pursue engineered solutions that incorporate, reflect, or mimic natural aeolian processes and landforms. No other chapter of the *CEM* picks up the slack. Chapter VI is content to explain that "*Dune construction is the piling up of beach quality sand to form protective dune fields to replace those washed away during severe storms*" (VI-2.5). A levee or mechanically piled sand is the default "sand dune" solution. Chapter III-4 leaves the engineer with inadequate information to determine if there is sufficient sand, wind, and space to develop a more self-sustaining and environmentally acceptable dune solution. As noted by Brunsden and Moore, (1999) where the "*scientific knowledge of the coast is poor, the safest practice is to use an engineering solution, …often a 'heavy' solution…" CEM*'s Chapter III-3 acknowledges that "heavy" solutions (seawalls, groins, jetties, artificial reefs are breakwaters) are increasingly challenged, discouraged, and even outlawed because of fairness, cost, and environmental concerns. While a sand "levee" or dune with a sheetpile reinforced heart is not specifically listed as a "hard" solution, it shares issues with those structures on the list.

In one respect, this lack of guidance is disappointing because much relevant research is available. Nordstrom's (2000) book, published two years before the *CEM*, covered many of the same topics as Chapter III-4, but was directed to coastal managers. It refers to 699 research articles, books and papers, of which 613 were published after the *Shore Protection Manual* publication date of 1984, indicating substantial recent research interest in the subject. In contrast, Chapter III-4 cites a mere 36 research articles and books, only nine of which were published since 1984. Numbers alone do not guarantee quality but the disparity raises concerns about comparative currency and completeness. This is more concerning when one notes that Chapter III-4 is missing critical references to works such as Short and Hesp (1982), Bauer *et al.* (1990), Psuty (1990), Pye and Tsoar (1990), Arens (1996), Nordstrom *et al*. (2000), Nordstrom (2000), and van der Wal (2000), to name a few.

Correcting obvious problems

While it is simple error, Chapter III-4's recommendation to plant European beach grass *(Ammophila arenaria)* to stabilize West Coast dunes should be corrected By 2002, European beach grass had indeed stabilized many dunes on the Pacific Coast but it had done so in a manner that damaged the form of the coastal dunes while choking out all native species, causing state and Federal agencies to conduct very expensive and difficult

eradication efforts all along the coast north of San Francisco. (Wiedeman and Pickart, 1994) The recommendation also appears in with similar wording in *CEM* Chapter V-4 (p. 77).

CONCLUSIONS

The U.S.A.C.E. took on a difficult task in creating the *Coastal Engineering Manual*. It intends to provide both a breath of subject matter and the rigorous standard of being "state-of-the-art." This standard implies a close connection of the document to the research program of the larger community of coastal engineers and scientists. Although the *CEM* is not even five years old at this writing, most sections (with the exception of Chapter III-4) have already been revised at least once. While this paper reviews only particular aspects of Chapter III-4, it is clear that (1) the chapter should immediately be revised to prescribe conservative aeolian sediment transport rate estimates; (2) the aeolian process and dune description section needs to be revised to allow engineers the knowledge and tools to at least consider incorporating natural processes in designs and solutions, and (3) outdated references promoting use of invasive plants in designs should be purged from all sections of the *CEM*.

The long-term success of the *CEM* depends on the updating process. Given the scope and status, the review process could serve as a focal point for communication among Ritter's "*engineers, geographers, oceanographers and geologists*" to both share the findings of current research and to help set important areas where additional research needs to be conducted. While this paper identified shortcomings in Chapter III-4's explanations of coastal science's understanding aeolian process and landform science to engineers, as Nordstrom (2000) observed, coastal science is itself currently limited to offering knowledge of natural coastal processes because "*the state of knowledge of human-altered landforms is still primitive, in part, because so few geomorphological investigations have been conducted of these landforms.*" Clearly much work remains.

Abstract: The distribution of the horizontal distance traveled by the sand grains in saltation, which is equal to the distribution of the falling sand grain rate in the region from the end of the sand bed and down wind, is quite similar to the vertical distribution of sand transport rate above the sand surface. This observation is explained by assuming that the height of the trajectories of transported sand grains in the air is different but the trajectories are similar in form. The wind tunnel experiment showed that the equation for the distribution of horizontal distance traveled by the grains converted from the vertical distribution of sand transport rate can be applied.

INTRODUCTION

An important problem for the coastal areas is how to stabilize sandy beaches against wind-blown sand. Wind-blown sand generated on beaches intrudes and disturbs activities in neighboring areas, which may be economically important for farming, industry, transportation, and recreation. In order to control wind-blown sand it is crucial to understand the detailed motion of the sand grains transported by the wind. There is a considerable amount of knowledge about wind-blown sand, but little of this focuses on the detailed motion of the grains. Blown sand grains exhibit characteristic types of motion, known as surface creep, saltation, and suspension.

The great bulk of grains (over 80% of total blown sand) moves by saltation. Only limited knowledge is available concerning saltation motion and no reliable quantitative information exists on the distance traveled by the saltating sand grains. Hotta and Horikawa (1991) reported that the distribution of the horizontal distance traveled by the sand grains in saltation, which is equal to the distribution of the falling sand grain rate in the region from the end of the sand bed downwind, is quite similar to the vertical distribution of sand transport rate above the sand surface that can be described with a theoretical formula derived by Kawamura (1951). This behavior is explained by assuming that the height of the trajectories of transported sand grains in the air is different but the trajectories are similar in form. However, the experiment by Hotta and Horikawa was limited to a sand grain size of 0.3 mm in median diameter and to shear velocities below about 100 cm/s. Thus, to re-examine these results and to establish a reliable predictive formula for the distribution of horizontal distance traveled by saltating sand grains for engineering purposes, a laboratory experiment was carried out using four different kind of grain sizes and a wide range of wind speeds employing a large wind-tunnel. The overall objective of this paper is to report on the experimental data and the associated results obtained through analysis of the collected data.

THEORETICAL BACKGROUND

The equation for the distribution of horizontal distance traveled by the grains converted from the vertical distribution of sand transport rate can be expressed as,

$$q(x) = G_0\left[\lambda\left\{2\sqrt{2}K_0(\zeta) - 2\sqrt{2}\beta\sqrt{\frac{l_0}{g}}\zeta K_1(\zeta)\right\} + \frac{1}{\sqrt{2}}\frac{a\beta\sqrt{0.75l_0}}{g}\zeta^2\{K_0(\zeta) + K_2(\zeta)\}\right] \quad (1)$$

$$\zeta = \sqrt{2x/l_0}, \qquad \lambda = \overline{u_1}/\sqrt{2gl_0}, \qquad \beta = 3\pi\mu d/m, \qquad \int_0^\infty lf(l)dl = l_0$$

where $q(x)$ is the falling sand grain rate at the distance x from the origin (the downwind end of the sand bed), g is the acceleration of gravity, $u(z)=a\sqrt{z}$ is the average horizontal component of transported sand grains when grains are set in motion from the sand surface, μ is the dynamic viscosity, d is the diameter of a sand grain, m is the mass of a sand grain, a is an experimental constant, G_0 is the mass of sand being entrained from a unit area of the sand surface per unit time, K_0, K_1, K_2 are the modified Bessel functions, and l_0 is the average horizontal distance traveled.

EXPERIMENTAL FACILITIES AND PROCEDURES

Facility

The experiment was carried out using a blow-off type wind tunnel with a test section that was 1.1 m high, 1.0 m wide, and 20 m long. A mobile sand bed was formed with a thickness of 10 cm from the upwind end of the tunnel to a distance of 16 m downwind. The mobile bed was retained by a timber board with a thickness of 9 mm and a height of 10 cm that was tapered upwind with a gradient of 45 degrees. Adjacent to the board on the downwind side, a horizontal distribution-type trap was

placed at the center of the tunnel in the transverse direction. Figure 1 shows the horizontal distribution-type trap used that has the same shape as the trap employed by Hotta and Horikawa (1991), but the width and arrangement in the horizontal of the segments were somewhat different.

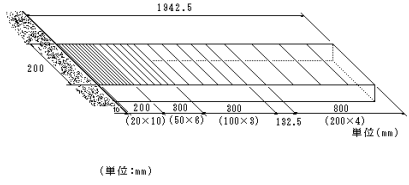

Fig. 1. Horizontal distribution-type trap

Four types of sand taken from a natural beach were used in the experiment. The sand was sieved to yield median diameters of around 0.15, 0.25, 0.48, and 0.68 mm. For convenience, hereafter we refer to the sands with median diameter of 0.15, 0.25, 0.48, and 0.68 mm as D15, D25, D48, and D68, respectively. Figure 2 shows the grain size cumulative curves for the four sand sizes studied.

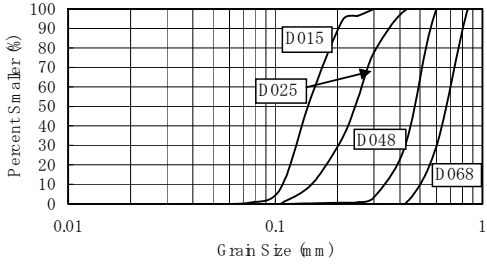

Fig. 2. Grain size cumulative curves.

The vertical distribution of wind speed was measured with a hot-film anemometer array consisting of fifteen anemometers at a location 13 m from the upstream end of the tunnel. The elevations of the measurement points were approximately 2.5, 5.0, 7.5, 10.0, 12.5, 15.0, 17.5, 20.0, 22.5, 25.0, 27.5, 30.0, 40.0, 50.0, and 60.0 cm above the sand surface.

Procedure

The sand was spread over the 15-m long test section in the tunnel and the sand surface was carefully flattened. After that wind was generated, where the time intervals for blowing the wind over the bed varied from two minutes to ten minutes, depending on the wind speed employed. After stopping the wind, the sand volume which passed the downstream end of the test section where the trap was placed was collected from the remaining portion of the wind tunnel (5 m long) and in the sand collection chamber located at the downstream end of the tunnel, and weighed. The sand trapped in the each segment of the vertical distribution-type trap was also

measured. After weighing the sand it was brought back and placed along the test section, the sand surface was flattened again, and additional sand was supplied as necessary. The same procedure was repeated for all experimental cases.

RESULTS AND DISCUSSION

Vertical Distribution of Wind on the Sand Surface

Figure 3 shows a semi-logarithmic plot of the vertical distribution of the wind speed on the sand surface. From Figure 3 it is clear that the distribution obeys the logarithmic law below an elevation of about 30 cm and that the wind speed is approximately constant in the upper region above 30 cm, although some scatter exists in the data. The wind speed may be described by:

$$u_z = 5.75u_* \log_{10}\frac{z}{z'} + u' \tag{2}$$

The vertical profiles of the wind speed measured on the four sand beds yielded the same basic results. It was difficult to detect any difference in the range of elevations where the logarithmic law is satisfied for four sands investigated. This observation implies that the thickness of the boundary layer developed near the surface is almost the same and the variation in sand surface roughness for the sands employed in the experiment did not have any significant influence on the formation of the boundary layer. The shear velocity was calculated from the vertical distribution of wind speed below an elevation of 30 cm. The focal point values (Bagnold, 1973) read form the Figure 3 are (330 cm/s, 0.28 cm) for D15, (320 cm/s, 0.24 cm) for D25, (510 cm/s, 0.75 cm) for D48, and (540 cm/s, 0.90 cm).

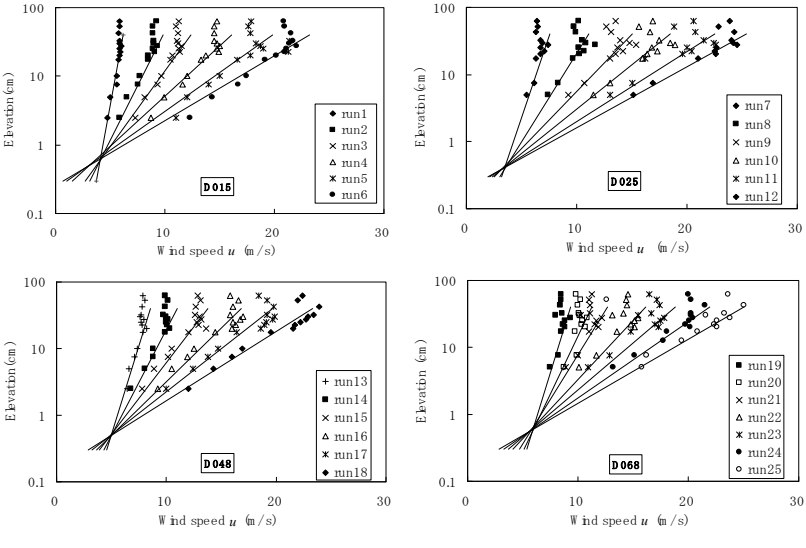

Fig. 3. Vertical distribution of wind speed

Total Sand Transport Rate

Here we define the total sand transport rate as the entire sand mass per unit time that passed the transverse section of the downstream end of the sand bed, where the horizontal distribution-type trap was placed. This quantity is often referred to as "the transport rate", but in this paper we use the word "transport rate" to denote the transport rate per unit height in the vertical direction in agreement with a related paper (Hotta et al., 2006). Therefore, to avoid misunderstanding, we use "the total sand transport rate" for the former quantity. Figure 4 shows a plot of the total transport rate versus the shear velocity on a semi-logarithmic paper. The curves displayed in Figure 4 are obtained by using the predictive formula for the total sand transport rate given by Kawamura (1951), taking the critical shear velocity to be 31.1 cm/s for a diameter of 0.48 mm. Kawamura's formula is,

$$q = K \frac{\rho_a}{g} \left(u_* + u_{*c}\right)^2 \left(u_* - u_{*c}\right) \tag{3}$$

where q is the total sand transport rate, g is the acceleration of gravity, u_{*c} is a threshold shear velocity, and K is an experimental coefficient.

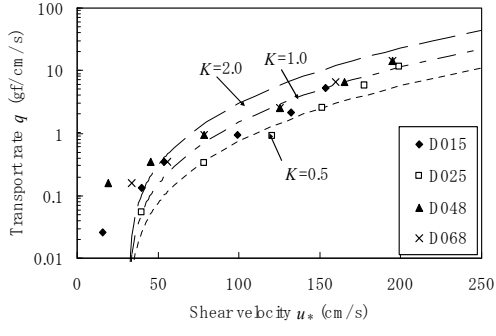

Fig. 4. Total sand transport rate

It is difficult to find a significant difference in the total transport rate between the four types of sand. The total transport rate for the four sands is almost the same and the scatter in the data is within the experimental error. This means that the difference in the median diameter is not significant enough to produce a difference in the transport rate (taking into account the experimental error) for the conditions investigated, although the median diameters determined by the sieving test were indeed quite different. The Kawamura formula can describe the total transport rate with an experimental coefficient of about 0.8. However, the value of 0.8 is somewhat smaller than that obtained in previous studies.

Trapping Efficiency of the Employed Horizontal Distribution-type Tap

Figure 5 shows the trap efficiency for the utilized distribution-type trap. Here the trap efficiency is defined by the ratio of the total amount of sand caught by the trap and one–fifth of the total amount of sand through the tunnel width (the width of the trap is 20 cm and the width of the tunnel is 100 cm). The trap efficiency becomes smaller with an increase in the shear velocity. Careful observation of the trapping conditions during the experiments suggested that this might be caused by the fact that an increase in wind speed leads to an increase in the amount of sand grains that rebound from the trap when the falling sand touched the trap. The trapping efficiency of the original trap used by Hotta and Horikawa (1991) was about 0.59 for a shear velocity between about 25 cm/s and 100 cm/s.

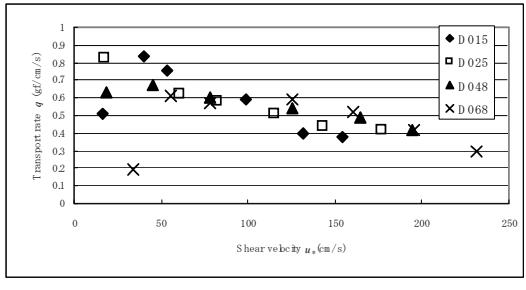

Fig. 5. Trapping efficiency of horizontal distribution-type trap.

Distribution of the Horizontal Distance Traveled by the Sand Grains

Figure 6 shows examples of the measured distribution of the horizontal distance traveled by the grains. Here *q(x)*, the falling sand grain rate at the distance *x,* is corrected by the trapping efficiency obtained. In Figure 6 curves are also drawn corresponding to Eq. 1, where suitable experimental coefficients or parameters were fitted by using trial and error. Figure 6 indicates that Eq. 1 describes the experimental data fairly well, although a discrepancy exists between the predicted curves and the data in the region close to the end of the sand bed and for locations where the dimensions of the segments changed. There is also a discrepancy between the curves and data in a region beyond 1 m downwind for sand sizes D15 and D25. Thus, it may be concluded that Eq. 1 converted from the expression of the vertical distribution of sand transport rate can be applied for the distribution of the horizontal distance traveled by the grains.

Figure 6 shows that a large amount of sand grains will fall within a distance of 20 cm downwind, if a sand bed does not exist. The falling rate becomes one order of magnitude smaller at a location of about 20 cm downwind from the end of the sand bed than that close to the end of the sand bed, and two orders of magnitude smaller at a location about 100 cm downwind.

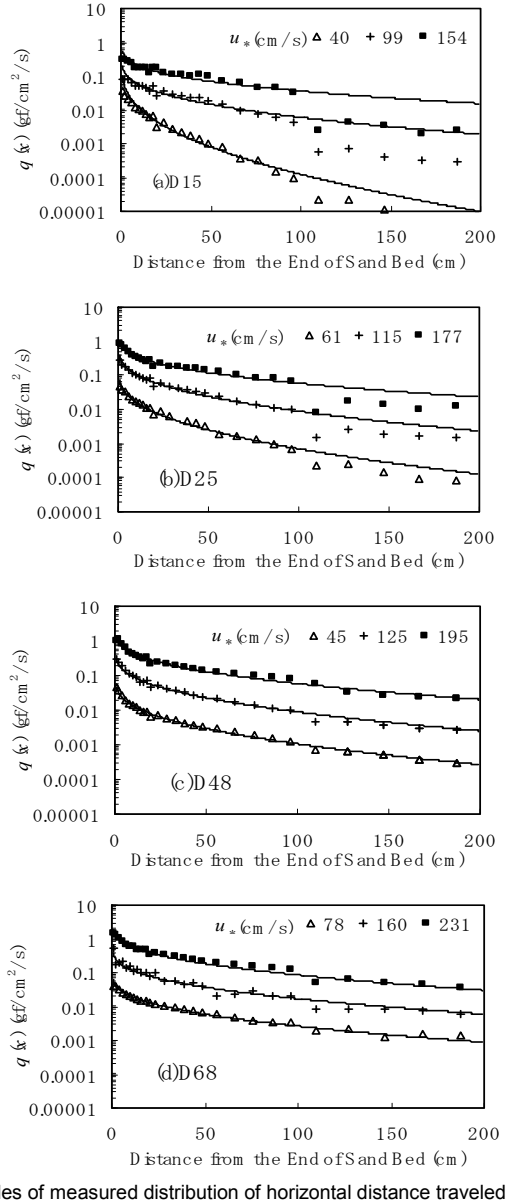

Fig. 6. Examples of measured distribution of horizontal distance traveled by sand grains

ESTIMATION OF EXPERIMENTAL COEFFICIENTS IN PREDICTIVE EQUATION

Estimation of Experimental Coefficient *a*.

In derivation of Eq. 1, the power law with a power of (1/2), $u(z)=a\sqrt{z}$ is assumed for the vertical distribution of wind speed in the moving sand layer near the surface. This assumption was made to facilitate theoretical development and not based on the theoretical background. However, Kawamura (1951) showed that the experimental results could be approximately described in the layer below a level of about 10 cm above the sand surface using a power law with the power of (1/2).

For the analysis in this experiment we used data points on wind speed obtained below 10 cm in elevation where moving sand were highly concentrated. Values of *a* determined under these conditions are plotted against the shear velocity in Figure 7. It is difficult to distinguish any differences in *a* for the studied grain sizes. Thus, it may be concluded that the value on the experimental coefficient *a* is independent of grain size in the present experiment. From Figure 7, the following experimental relationship may be developed:

$$a = 1.33\,u^* + 104.5 \qquad (4)$$

In this formula the dimension of *a* is $\sqrt{\text{cm}}$ /s and of u_* cm/s.

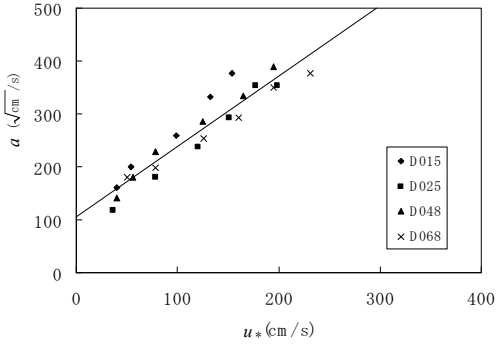

Fig. 7. Relationship between *a* and u_*

Estimation of Experimental Coefficient G_0

Figure 8 shows a plot of G0 versus u* in a log-log diagram. The straight line drawn through the data is the best fitted one by visual judgment. It is difficult to distinguish any differences in the value of G0 with respect to grain size. A general equation for the best-fit line is given by,

$$G_0 = 1.75\times10^{-7}\times u_*^{2.5} \qquad (5)$$

where the value of 1.75×10^{-7} is a dimensional constant with the unit gf/cm^5/s.

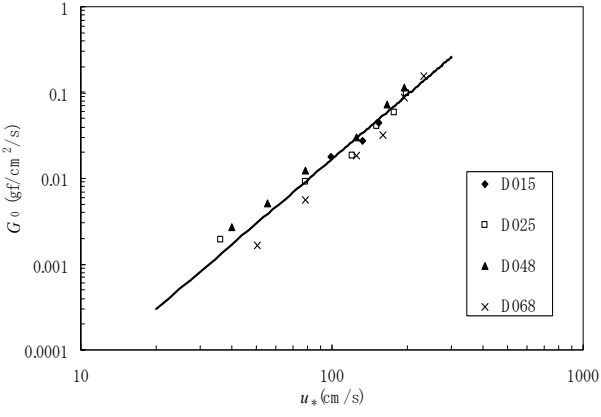

Fig. 8 Relationship between G_0 and u_*

Estimation of Experimental Coefficient l_0

Figure 9 shows the plot of l_0 versus u_* for the collected data. It is clear that l_0 and u_* display a linear relationship for all grain sizes and that the gradient of the straight lines becomes steeper with increase in grain size. Thus, the following general form can be assumed for the lines in Figure 9,

$$l_0 = B' u_* + C' \tag{6}$$

where B' and C 'are constants.

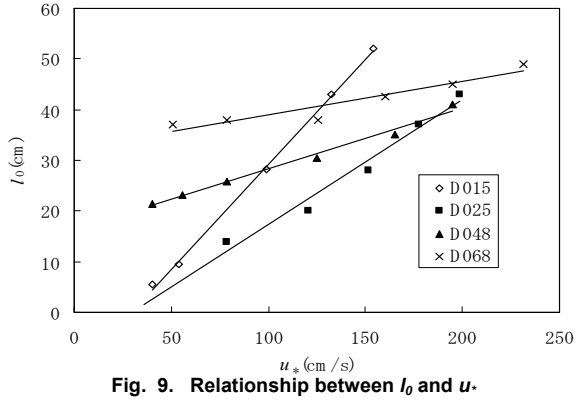

Fig. 9. Relationship between l_0 and u_*

The values of *B* 'and *C* 'can be derived from the straight lines in Figure 9 as the gradient and the intercept on the l_0 –axis, respectively,. Figure 10 shows a plot of *B'* versus the grain size *d*. The variables *B'* and *d* exhibit a linear relationship and from Figure 10 we can obtain the relationship:

$$B' = -6.2\,d + 0.45 \tag{7}$$

Figure 11 shows the plot of *C* versus *d* in a log-log diagram. The variables *C* and *d* display a linear relationship and the following equation may be derived:

$$C' = 873\,d + 26.8 \tag{8}$$

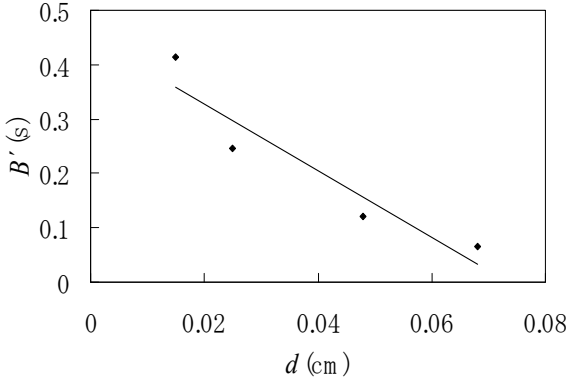

Fig. 10. Relationship between *B*' and *d*

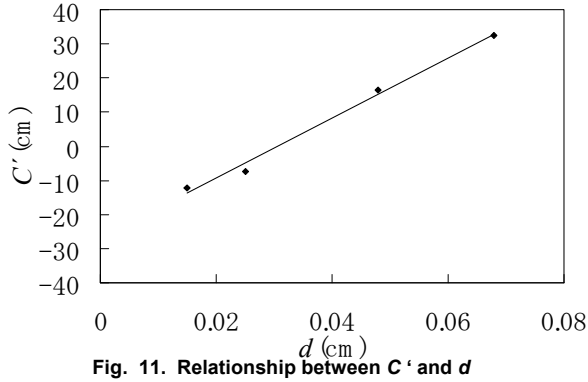

Fig. 11. Relationship between *C* ' and *d*

Substituting Eqs. 7 and 8 into Eq. 6 yields,

$$l_0 = (- 6.2\, d + 0.45\,)\, u_* + (873\, d + 26.8) \qquad (9)$$

where the dimensions of l_0, u_*, and d are (cm), (cm/s), and (cm), respectively.
Thus, the experimental coefficients and parameters a, G_0, and l_0 in Eq. 1 can be determined from Eqs. 4, 5, and 9, respectively.

EXAMINATION OF EQ. 1

In numerical calculations with Eq. 1, it was demonstrated that the second, third, and fourth terms are considerably smaller than the first term. In the following, a comparison is made of the four terms within the square brackets of Eq. 1.

The numbers in parentheses are the order of the parameters, coefficients, and variables that is under consideration ($0 < \zeta < 10.0$). Dividing the first and the second terms by $\lambda\, 2\sqrt{}2$, the order of the first term and the second term are:
$K_0(\zeta)$

Second term
$\lambda(0)^{-1} \cdot \beta(0) \cdot l_o(0)^{1/2} \cdot g\,(-3)^{1/2} \cdot \zeta\,(0) \cdot K_1(\zeta) = (-3) - ^{1/2} \cdot \zeta\,(-1 \text{ or } 0) \cdot K_1(\zeta)$

$= (-2) \text{ or } (-3) - ^{1/2} \cdot K_1(\zeta)$

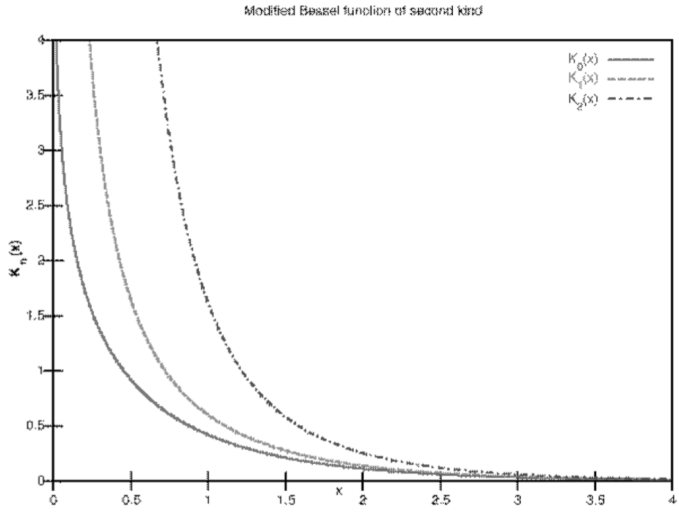
The functions $K_0(\zeta)$ and $K_1(\zeta)$ are almost of the same order. Thus, the second term must be smaller than the first term by two orders, implying that the second term can be neglected.

For the third and fourth terms the order of the constants, coefficients and parameters yields:

$1 \cdot 2^{-1/2} \cdot 0.75\,(0)^{1/2} \cdot a\,(2) \cdot \beta(0) \cdot l_o(0)^{1/2} \cdot g(-3)^{1/2} = (0) \cdot \quad (-1)^{1/2}.$

The functions $K_0(\zeta)$ and $K_2(\zeta)$ increase to infinity when ζ approaches zero from the value of 1.0, and $K_0(\zeta)$ and $K_2(\zeta)$ approach zero when ζ becomes larger than 1.0 (see Figure 12). Therefore, we may estimate that $\zeta^2 \cdot K_0(\zeta)$ and $\zeta^2 \cdot K_2(\zeta)$ become small when ζ takes on small and large values compared to 1.0.

However, $\zeta^2 \cdot K_0(\zeta)$ and $\zeta^2 \cdot K_2(\zeta)$ take on significant values when ζ is around 1.0. The third and fourth terms are considerable smaller than the first term, but it is not possible to know how much smaller they are than the first term and whether the third term and fourth term can be neglected or not. Thus, numerical experiments were carried out using obtained values on coefficients and appropriate values on governing parameters.



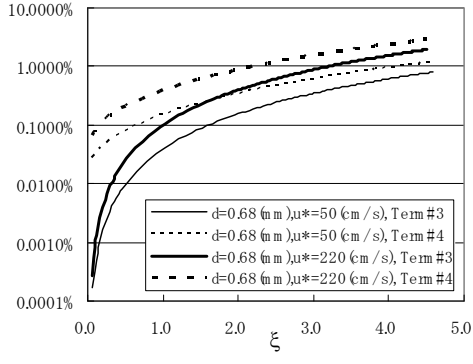


Fig. 12. Behavior of $K_0(\zeta)$, $K_1(\zeta)$, and $K_2(\zeta)$
(From wikipedia)

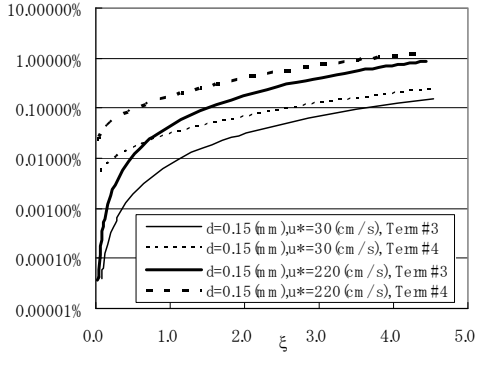

Figure 13 shows examples of the results of the calculations. The third and the fourth terms in $q(\zeta)$ contribute with around 3 or 4 % when ζ exceed 4.0 for cases when the third and the fourth terms attain large values (Fig. 13 (a)). However, the third and the fourth terms in $q(\zeta)$ contribute around 1 or 2 % when ζ exceed 4.0 for cases when the third and the fourth terms attain small values (Fig. 13 (b)). These results depend on the values of a, β, and l_o.

The region of ζ where the third and the fourth terms have large values is far from the region near the sand bed (ζ is small). Therefore we may typically neglect the third and the fourth terms in Eq. 1 and the simplified transport equation becomes:

$$q(x) = 2\sqrt{2}\lambda G_0 K_0(\xi) \tag{12}$$

(a)

(b)

Fig. 13. Examples of calculated results for third and fourth terms in Eq. 1.

CONCLUDING REMARKS

Equation (1), which is converted from the equation for the vertical distribution of sand transport rate derived by Kawamura, described the experimental data fairly well and the experimental coefficients a, G_0, and l_0 in Eq. 1 were determined as empirical functions of the grain diameter d and the shear velocity u_*. Therefore, the distribution of the horizontal distance traveled by the sand grains can be predicted if the grain diameter d and the shear velocity u_* is known.

Equation 1 is converted from the equation originally expressing the vertical distribution of the sand transport rate, assuming that the height of the trajectories of transported sand grains in the air is different but the trajectories are similar in form. Thus, the experimental parameters and coefficients in Eq. 1, except quantities

(experimental parameters and coefficients) related to the vertical direction, must be the same as those of the vertical distribution of transport rate, if both experiments measuring the vertical distribution of transport rate and the falling rate of sand grains are correctly performed. In an experimental study for the vertical distribution of sand transport rate, Hotta et al. (2006) obtained an experimental relationship for a and G_0 according to:

$$a = 1.88u_* + 210.0 \tag{10}$$

$$G_0 = 2\times10^{-9} d^{-2} u_*^{2.5} \tag{11}$$

Equation (11) contains the grain diameter d as a variable but Eq. 5 does not contain the grain diameter. The authors can not explain this difference between the experiments on the vertical and horizontal distribution. Experiments were carried out for the same conditions, except for the traps employed that were of the vertical distribution-type or the horizontal distribution-type. Therefore, G_0 must be the similar if the experiments were correctly carried out at the same condition for both traps (vertical and horizontal), and if both traps collected sand with the same efficiency. Our assessment is that the discrepancy is related to a lower sand trapping efficiency for the upwind part (near sand bed end) of the horizontal trap.
However, we need further well-controlled experiments with a trap that has better efficiency to confirm this assessment.

Abstract: At present, many beaches in Japan are experiencing severe erosion and prevention works to combat this erosion forces changes to the conventional works used to control wind blown sand in the past. Detailed field inspections were carried out of the wind blown sand controlling works and windbreaks at beaches in the central part of the main island of Japan. This study reports precious results obtained by the field inspections.

INTRODUCTION

Reducing damages from strong wind and controlling wind blown sand are important issues in beach stabilization and effective beach utilization. In Japan, a strong wind blows over the country from Northwest to West in the winter. During this season, the wind often causes damage to infrastructure and buildings, as well as to the natural environment (e.g., trees and plants), and significant transport of wind blown sand occurs on the beaches facing the Japan Sea. On some Pacific Ocean beaches wind blown sand is also generated by these winds, but on other Pacific beaches wind damage and wind blown sand occur in the different seasons. The beaches on the Japan Sea side are exposed to rain or snow in the winter, whereas the prevailing

climate on beaches located on the Pacific Ocean side is mostly fine during this period.
Thus, meteorological and topographical conditions are very different from one coast of Japan to the other.

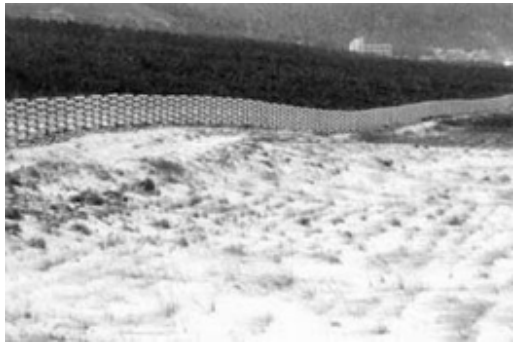
To reduce wind damage and to control wind blown sand many types of prevention works have been employed in Japan. In order to develop effective and suitable systems of prevention works on beaches, the method of trial and error was applied in former times, implying that systems emerged that are specific for each beach. At present, different types of systems are found in different parts of the country depending on the local conditions at the beach, such as climatic, oceanographic, and geographical conditions as well as the economical importance of the region. The main objectives of this study is to introduce characteristic prevention works utilized in Japan, to point out problems faced, and to attempt to find fundamental principles for the successful usage of these prevention works as windbreaks and for controlling wind blown sand. The present paper constitutes a first preliminary report on the main findings.

STUDY AREA AND PROCEDURE

The field areas that were the focus in the present study were located on coastal stretches along the central part of the main island of Japan (Fig. 1). Detailed field inspections were carried out of the prevention works and wind breaks, documenting their design and general characteristics. The history of the works as well as the design procedures employed were also recorded as far as possible and photographic documentation were frequently employed. The effects on the beach morphology in terms of induced topographic change were determined using topographic maps.

Fig. 1. Study field site

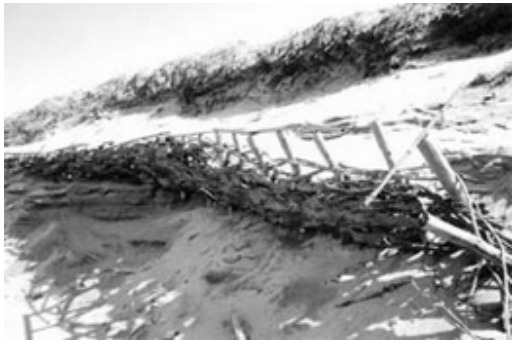
RESULTS



The following results were obtained based on the field surveys and associated analysis.

Fundamental System of the Prevention Works

The fundamental system employed for the prevention works was a combination of vegetation works, sand fences (or wind breaks), foredune, and conservation forests from shore to inland, although variations in this system could be found where certain parts were not included. This system has functioned well with appropriate maintenance at non-eroding beaches. Photo 1 shows typical examples from wide beaches. The foredune in the Photo 1 (a) has been created by repeated emplacement of sand fences on a dune formed by buried old sand fences. In order to keep the foredune, fencing works are still continuously maintained. The beach grass in front of the dune grows naturally. Photo 1 (b) shows vegetation work with beach grass, windbreaks (sand fences) framed by thinned timber logs, and afforestation works by pine trees.



(a) A foredune with sand fences (Kashima Coast)

(b) A system of prevention works (Shounai Coast)

Photo 1. Examples of wind blown sand controlling works

At present, on many beaches, foredunes formed by fencing works have started to erode. Photo 2 shows examples of beaches where erosion has reached the foot of the foredune formed by using repeated emplacement of sand fences.

(a) A beach at Shounai Coast

(b) A beach at Ensyuunada Coast

Photo 2. Foredunes on eroding beaches

Countermeasures to combat beach erosion forces changes to the conventional works used to control wind blown sand in the past. However, there are no technical standards or guidelines how these beaches should be treated at present.

Photo 3 shows examples of eroding beaches where countermeasures have been completed. Photo 3 (a) shows a beach at Ishikawa Coast where detached breakwaters, a seawall, and an artificial embankment were constructed. The crown of the seawall is used as a bicycle road along the shore. This artificial embankment have multiple protective functions, that is, to trap wind blown sand, to stop wave splashing, to reduce the effects of storm surges and tsunamis, and to work as a windbreak for the area behind. Photo 3 (b) shows a beach at Ensyuunada Coast where a seawall and a sea dike located on the landward side as countermeasures against beach erosion have just been constructed. The countermeasures in Photo 3 (b) are chosen as an option to remedy the conditions shown in Photo 2 (b).

(a) A beach protected by multi-defense works (Ishikawa Coast)

(b) A foredune protected by structures (Ensyuunada Coast).

Photo 3. Examples of protected beaches

For the eroding beaches there is no clear indication regarding the kind of countermeasures needed, whether hard coastal structures, such as seawalls or revetments, or soft structures, such as artificial nourishment, would be most appropriate to employ.

However, when employing structures some additional considerations are needed. On protected beaches wind blown sand might be generated by the local disturbance of the wind field due to the coastal structures, as long as a sandy beach exists. In addition, structures often cause violent wave breaking with high and abundant splashing during stormy conditions. Thus, the possibility to induce damage from salt transport by wind in combination with wave splashing increases.

Site-Specific Design of the Prevention Works

Each beach almost always has a site-specific design of the prevention works. There are windbreaks, sand fences, and different kinds of artificial embankments and protection works for sloping surfaces.

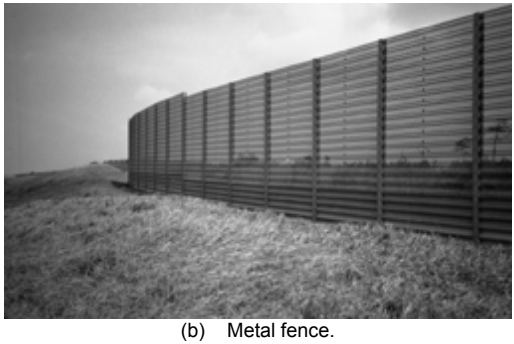
Windbreaks

Photo 4 shows examples of windbreaks (fences) formed by thinned timber logs. The purpose of these windbreaks is different. The type in (a) has been widely used any place where windbreaks were needed. The type (b) has mainly been employed to protect shrubberies, whereas the type (c) was used to protect the front of afforestation works. The windbreak efficiency of these fence types varies greatly and the efficiency becomes lower in the order which they are shown in (a), (b), and (c).

(a) Timber windbreaks at Ishikawa Coast

(a) Timber windbreaks at Ensyuunada Coast

(b) Timber windbreaks at Niigata Coast



(c) Timber windbreaks at Syounai Coast

Photo 4. Windbreaks formed by thinned timber logs

Many other kinds of windbreaks (fences) are employed as well. Fences are ordinarily higher than 1.8 m (about 6 feet). The fence material most commonly employed is bamboo because many kinds of bamboo abundantly grow in Japan and it is economically beneficial to use. Fabric or metal fences are also commonly employed for protecting important facilities and obtaining fences with a long life. Photo 5 shows examples of bamboo and metal fences.

(a) Bamboo fence.

(b) Metal fence.

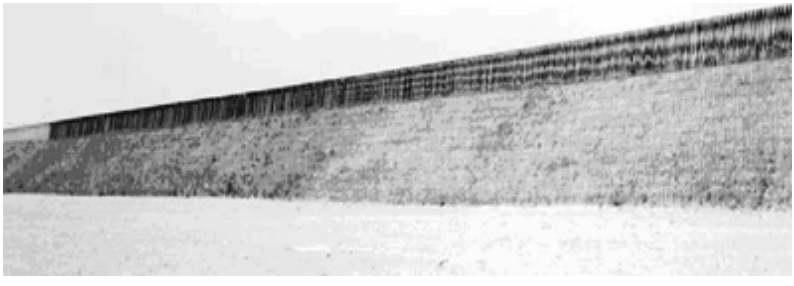
Photo 5. Bamboo and metal fences

Sand Fences

Many kinds of sand fences with regard to type and material are employed for trapping and keeping wind blown sand. Typical fence material used is fern, reed, brush, and bamboo, which all decompose with time. Thus, no long-life fabrics and metals are used. The height of ordinary sand fences is about 1 m (about 3 feet), and the slat-type sand fences that are commonly used in the United States has not yet been utilized in Japan. Photo 6 shows a typical bamboo sand fence. A summary of the

characteristics of windbreaks and sand fences may be found in the Proceedings of Coastal Sediments '87 and '91 (Hotta et al., 1987; Hotta et al., 1991).

Photo 6. Bamboo sand fences (Shounan Coast)



Artificial Embankments

Recently artificial embankments have been frequently employed instead of foredunes formed by fencing works, because construction of the embankment can be rapidly and economically done by using large earth-moving construction machines. Photo 7 (a) and (c) show artificial embankmenst positioned at the upper part of a beach that is relatively wide. The foreslope is vegetated with beach grass and it is not armored by any hard material. In Photo 7 (a) it is also possible to see examples of windbreaks (fences) formed by thinned timber logs from afforestation works on the crown. Other representative examples are displayed in Photo 3 (a) and photo 7 (d) where the embankment is located near the shoreline and its foreslope is armored by hard materials such as stones or precast concrete armor units. This type of embankment has multiple protective functions with respect to wind and wave action, as described before.

The cross-sectional shape of the embankment is typically designed as follows: a foreslope of 1:1 – 1:3, a backslope of 1:1 – 1:2, a crown width of 1–5 m, and a height of 3–10 m. The dimensions adopted have no engineering basis and are employed according to site experience.

Photo 7. Artificial embankment as a substitute of a foredune

Oblique Foredunes

A specific foredune arrangement was found in the eastern part of the Ensyuunada Coast for controlling wind blown sand. This arrangement is based on the idea of "*making the wind turn aside*", as demonstrated in Fig. 2. In the figure, α is the azimuth of the shoreline. When the wind blows from the west, the wind blown sand generated on the beach surface sweeps into the sea if α is smaller than 90 degrees, and the blown sand is transported towards the inland if α is greater than 90 degrees.

The predominant direction of the wind on the Ensyuunada Coast is west in the winter and the azimuth of the shoreline on the eastern part of the Ensyuunada Coast is greater than 90 degrees and smaller than 135 degrees.

Considering conditions described in Fig. 2, formation of foredunes is attempted by using repeated placement of sand fences. Foredunes formed by this method function well. The blown sand from the west direction turns aside and sweeps into the sea. The height of formed foredunes is 5-10 m and the azimuth of the dune crest direction is from 120 degrees to 135 degrees.

Foredunes formed here represent oblique artificial foredunes.

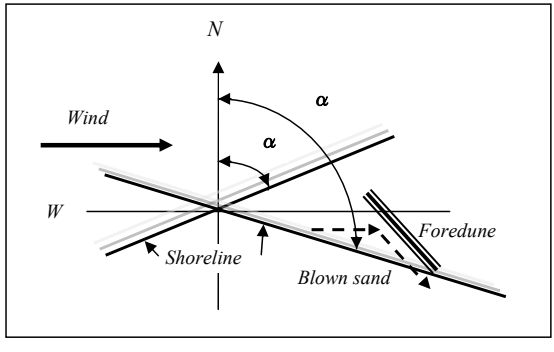

Fig. 2. Schematic illustration of an oblique artificial foredune

Concerning the oblique artificial foredunes, Takezawa et al. (2002) offered a simple model that gives the relationship between the slope gradient, wind incident angle and the crest direction of the embankment.

Design guidelines for artificial embankments

To develop technical standards for designing embankments, Hotta et al. (2000) carried out an experimental study using a wind tunnel which was 1.1 m high, 1.0 m wide, and 20 m long. Two series of embankments were included in the experiments. One series involved trapezoidal-type embankments where the foreslope changed

between 1:0, 1:0.5, 1:1, 1:2, 1:3, and 1:5 keeping the ratio of B/H = 1.0 (where B is the crown width and H is the height of the embankment) and where the backslope was kept at 1:1. The other series encompassed rectangular-type embankments with varying ratios of B/H = 0.05, 0.5, 1.0, and 2.0. Two main types of measurements were carried out, namely a tracer experiment to visualize the flow pattern and measurements of the wind speed field. The experiments produced the following results: In order to obtain a large area where the wind speed decreases on the windward side of the embankment, the foreslope of the embankment should be steeper than 1:1 and the ratio B/H should be smaller than 1.0. An area where the wind accelerated appeared behind the embankment at elevations from H to 5H. The area of acceleration considerably decreased when the foreslope became gentler than 1:1 and the ratio of B/H became larger than 1.0. The wind speed amplification at the upwind edge of the embankment crown was the largest when the foreslope of embankment was 1:1 and the width of the crown did not influence the wind speed amplification.

Considering general practice for construction in the field and the experimental results, Hotta et al. (2000) concluded that the appropriate dimensions are a foreslope of 1:3, a backslope of 1:2, and a crown width of 0 m. It is acceptable that both slopes, the foreslope and the backslope, are made steeper if needed, providing that surface protection of the slopes is carried out.

Problem of access to shore

It was found that the access to the beach is seriously interrupted when the foredunes, artificial embankments, and conservation forests are extended for a considerable distance alongshore. Then illegal access paths were made by residents for daily usage or by people who want to go beach for reasons such as surfing, swimming, fishing, and walking. Photo 8 shows example of the illegal access paths.

Photo 8. An example of illegal access path through artificial embankment

The alongshore distance between illegal access paths varied greatly depending on the local condition of the seashore and coastal area. The distance between these paths is more or less random and it ranges from about 300 – 400 m to more than 2 km. This means that access paths to the beach must be prepared in a suitable distance to avoid illegal paths. This is a difficult problem which concerns the management of the coastal area. At present there are no standards on the suitable distance between access paths.

To create and maintain access paths to the shore result in other problem. There is a possibility that tsunami or storm surge waves may intrude through the path openings, if parts of the embankments or foredunes are cut by access paths.

Concluding remarks

At present, many beaches in Japan are experiencing severe erosion and prevention works to combat this erosion forces changes to the conventional works used to control wind blown sand in the past. Some parts of the beaches protected by hard concrete structures have lost the sandy shore, but some parts of the beaches still have the limited narrow sandy beaches. On protected beaches the wind blown sand will be generated as long as a sandy beach exists. At present, no considerations of wind blown sand and increase in the possibility for salty wind damage are given when countermeasures for beach erosion are designed.

It was found that many artificial embankments have been constructed all over the investigated field sites. The high elevation of the constructed embankments is blocking the view towards the sea as well as disturbing the landscape. This problem is never discussed when embankments are designed.

In addition to the above, in order to develop new systems for protection the following matters must be studied in greater detail:

1) Which is a good selection of countermeasures and whether to employ hard coastal structures or soft structures, such as artificial nourishment, when erosion has reached the foot of the foredune?

2) Is the mechanism of wind blown sand generation on narrow beaches with structures the same as that on the wide flat beaches? Concerning this problem, Ugai et al. (2005, 2006) offered the interesting studies that the local disturbance of the wind field by structures (local currents or wakes, or cell currents around structures) mainly govern the wind blown sand phenomenon.

In conclusion it is possible to state that the trial and error to develop for controlling wind blown sand on erosive beaches begins.

Abstract: This paper analyzes the main characteristics of the aeolian dynamics and dune evolution in the Corralejo coastal dunefield. This is an area with limited sediment supply and subjected to the action of a quasi-unidirectional wind regime. The governing conditions induce a long-term migration of the dune field in the direction of the wind with an expected long-term change in the landscape due to a change in the sediment supply to the dunefield through the upwind end due to natural and human-induced factors.

INTRODUCTION

The Corralejo dunefield is located in the NE coast of Fuerteventura (Canary Islands, Spain, Fig. 1). It has an extension of an approximated surface of 1,900 ha comprising the adjacent beaches and the dunefield itself, which is composed by transverse, barchan and barchanoid dunes. This sedimentary environment is one of the main resources of Fuerteventura island in terms of environmental quality –natural values contributing to its geodiversity and biodiversity- as well as in terms of landscape quality. This last one can be translated to economic values since the landscape is the most distinctive value of the Island for tourism, which is the main economic activity.

Due to its importance, the area is protected under the figure of Natural Park, which regulates the kind of activities to be permitted. In spite of this, the human influence is clearly observed through the presence of urbanized areas in its northern and western limits and by a road crossing the dunefield. These perturbations are products of the tourism development and, due to the dynamic conditions of the area they are behaving as threats to the physical conservation of the area.

The main aim of this paper is to analyze the dune dynamics in the area and to identify the potential effects of the cut in the sediment supply on the long-term behavior of the dunefield.

THE CORRALEJO DUNEFIELD

The study area is located in Corralejo, at the NE coast of Fuerteventura Island, Spain (Fig 1). Fuerteventura is located in front of the Saharian coast in the Atlantic Ocean and it is under the influence of the action of the Trade winds. The Corralejo dune field is located in the NE corner of the island. It occupies a rectangular surface with its larger axis oriented along the N-S direction along 8 km approximately and with an average width of 2 km (Fig. 1).

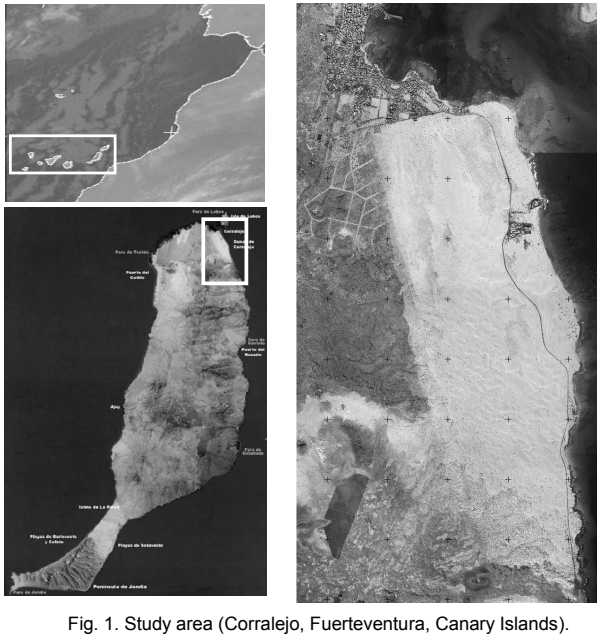

Fig. 1. Study area (Corralejo, Fuerteventura, Canary Islands).
Distance between crosses in the figure at the right is 1 km.

The climate in Fuerteventura is arid, without significant precipitation because, in contrast to the other Canary Islands, due to its very low altitude clouds brought by the action of the Trade winds are not stopped by the island relief. Fig. 2 shows the seasonal distribution of temperature and precipitation in the island.

The islands are subjected to the action of Trade winds which, in practical terms, it means that the area is affected by winds blowing from a quasi-constant direction, N-NNW (Fig. 2). These dominant directions are also the ones with the largest velocities. In general terms, the wind in the area can be characterized by a N wind with a mean velocity of 5.4 m/s with a standard deviation of the velocity of 2.4 m/s and where the 82.5 % of the year the wind velocity is lower than 8 m/s (Fig. 2).

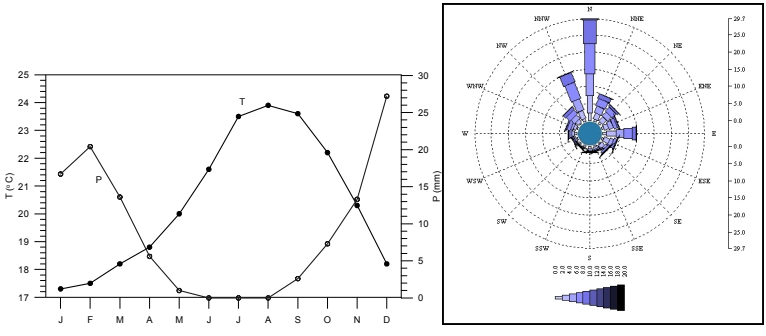

Fig 2. Left: Seasonal distribution of monthly averaged temperature and precipitation recorded in Fuerteventura airport (adapted from Gobierno de Canarias, 2002). Right: wind rose for records in Corralejo meteorological station.

According to Meco *et al.* (1997), sand forming dune fields in Fuerteventura are bioclastics and they come from marine deposits from Messinian containing warm water fauna from late Miocene and early Pliocene and large quantities of calcareous algae. These sands were exposed during the post-Messinian regression to wind action that reworked them forming the original dunes and, in some areas, they were covered by lava deposits from different volcanic eruptions. On these lava accumulations from 0.4 millions of years, new dune deposits were accumulated in a sedimentary activity that is associated to the middle Peistocene, between 0.181 ky and 350 ky ago. In the case of Corralejo dune field, the dunes are limited at the south by Montaña Roja and Apartaderos Malpais (lava flows).

These sand deposits were activated by wind action forming new generations of dunes until arriving to the actual mobile dunes. The alternation of active and inactive periods of aeolian transport was due to the alternation of dry and wet climatic periods. During the dry periods, the aeolian transport was important whereas during the wet ones the alteration of the basaltic substratum was favored (Damnati *et al.,* 1996).

These bioclastic sands are composed by a minimum of 85 % of carbonates (in some cases up to 95 %), with the high magnesium calcite with more than 18% of $MgCO_3$ being dominant (Coudé-Gaussen, 1991). Table 1 shows the mean values of textural parameters of sands in the area. They have been grouped into three main environments: mobile dunes, relict areas and beaches (Fig 3). As it can be seen, mean grain sizes are slightly coarser in beaches than in dune deposits (both active and relict). Thus, we shall find coarse sands of 0.6 mm in beaches whereas sediment mean size in dunes is about 0.4 mm. In the aeolian sub-environments (active dunes and relict areas) whereas the mean grain size is quite similar, they show a very significant difference in sediment sorting that is significantly larger for relict areas due to the presence of large shell fragments together fine sediments.

Table 1. Mean and standard deviation (between brackets) of textural parameters of sediment in each sedimentary environment of the dune field.

environment	mean (Φ)	mean (mm)	sorting	skewness	Kurtosis
mobile dunes	1.563	0.367	0.590	0.071	1.167
	(0.275)	(0.074)	(0.092)	(0.134)	(0.256)
relict areas	1.540	0.416	1.365	-0.264	1.971
	(0.707)	(0.236)	(0.556)	(0.199)	(0.863)
beaches	0.926	0.595	0.624	0.039	1.132
	(0.485)	(0.193)	(0.209)	(0.169)	(0.290)

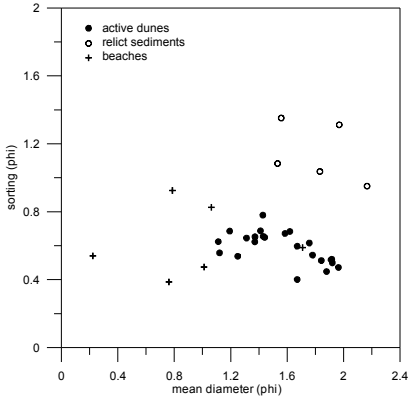

Fig. 3. Sediment characteristics in the sedimentary sub-environments of the dunefield.

These climatic conditions acting on the existing sand deposits have determined the actual evolutionary stage of the area. At present, the dune field can be described as a

sedimentary environment characterized by the presence of different sub-environments in terms of sediment and processes. Thus, the northern part and the westward border are formed by a land strip without dunes with a very narrow sand layer on the top of ancient sediments which area visible as outcrops in many locations. There is an important vegetal cover and it can be assumed that, at present, this area is not playing any significant role in the dynamics of the dune field (Fig. 4). Southward of this area, the thickness of the sand layer increases and, simultaneously, the vegetation decreases and, as a consequence, the sand mobility increases. This area is occupied in its central part by a sand body with a NNW-SSE orientation which is surrounded by stabilized areas. In this part there are no significant dunes and the outcrop of older sediments seems to indicate that active sand stocks are being progressively exhausted in some parts.

Fig. 4. Aspect of different areas of the dune field. Top: stabilized northern area. Middle: active sand without significant dunes in the Northern area. Bottom: example of dune types in the Central-Southern part of the dune field.

From this limit towards the Southern end, the field is covered by a layer of active sands forming dunes migrating in the southward direction. Dunes in the area are not homogeneous and, in fact, different dune trains and with different shapes can be

observed. Among them, barchans, barchanoids and transverse dunes dominate (Fig. 4), which are typical of environments subjected to the action of unidirectional winds (*e.g.* Lancaster, 1995). This area is limited in the southward end by the Malpais (lava flows) and in its eastern boundary by the sea. Within this area there are two artificial elements: (i) a road along the eastern boundary that it is easily crossed by mobile sands and, in consequence, its influence on the dune behavior is limited because it does affect sediment transport and, (ii) two hotels that affect the sediment dynamics in the adjacent area, specially the one located in the middle of the active zone.

Dune heights were determined from a topographic field campaign performed between September 2004 and March 2005 by Hidtma-Iberinsa for the Ministry of Environment. The averaged dune height (measured as the maximum height along the dune front) was about 8.4 m with maximum heights of about 29 m. The dune height distribution across the area was not uniform, with the Northern and Southern ends being the areas with the lowest height. This could be associated to the fact that the N area is behaving as a generation area whereas the S end is a way out area since the dune starts to move on to the lava flows area (malpais).

DUNEFIELD DYNAMICS

In order to characterize the present evolution of the dunefield, the first task was to estimate the changes in the surface occupied by the different dynamic sub-environments. This is shown in Table 2 for dunes, sand and stabilized areas to the East and to the West of the road crossing the area obtained from aerial photographs taken in 1987 and 2002.

The area of dynamic sands but without dunes located at the N area maintains its form with a slight surface increase. This increase is related to a redistribution of sediments under the action of winds which tend to enlarge the area along its southern end. Since there is no new sediment input in the area from the N, it is expected that the sediment thickness will progressively decrease, which is already visible in some parts (outcrops of older materials).

The area with mobile dunes (westwards of the FV-1 road) suffers during the monitored period a change that can be simply described as a southward displacement of the southern end (Fig. 5). This is easily explained by the continuous action of Trade winds on sediment deposits that transport them into the lava flows. In this southern end, the averaged displacement of the front is 80 m (with a maximum displacement of 240 m) which is equivalent to an averaged migration rate of the dune field into the lava flow of 5.3 m/y. This modification of the southern end means that the surface of the dunefield has increased about 42 ha during the 1987-2002 period (Jiménez et al., 2006). However, this increase cannot be understood as a gain of sedimentary material because it is due to a redistribution of the existing sediment volume.

This surface increase without new sediment inputs should imply that the averaged thickness of the sediment cover would decrease in time. Moreover, in the case of

stationary climatic conditions this behavior would tend to force the migration of the entire dunefield towards the south since the sediment transported in such direction from the Northern areas should not be replaced.

The evolution of the vegetated and stabilized areas within the dunefield does not present a systematic behavior. There is an apparent decrease in the stabilized surface probably due to the migration of dunes and burial of areas with isolated vegetation or outcrops in the inter-dune spaces (see Fig. 4) in such a way that changes are detected across the entire field.

Finally, in the area eastwards of the FV-1 road, the most significant change is an increase in the urbanized land due to the expansion of one of the existing hotels (already present in 1987). In addition of this, there was also an increase in the stabilized sands southwards (downwind) of the hotel area. The increase of the stabilized area from 1987 to 2002 was estimated in 3.5 ha.

Table 2. Surface (ha) of the main sedimentary environments of the Corralejo dunefield in years 1987 and 2002. FV-1 is the road along the Eastern coast.

Type	1987	2002
Westward of FV-1		
T1 –sands-	47.5	56.9
T2 –dunes-	636.7	679.1
T3 –stabilized-	97.3	78.8
Eastward of FV-1		
T1 & T2 –sands & dunes-	149.3	145.8
T3 – stabilized	9.8	13.2

Once the change in the sediment-dynamics sub-environments were estimated, the second step consisted in the evaluation of aeolian transport rates and dune migration rates within the mobile dune area. To estimate them, dune fronts were identified in the 1987 and 2002 photographs and the displacement in different sections of the front were measured (Fig. 5). The estimated dune migration rate was 5.8 m/y towards the South with a maximum value of 11.4 m/y (Table 3). It has to be stressed that this averaged value is nearly the same than the averaged rate of displacement of the southern end of the dunefield into the lava flows (5.3 m/y).

This mean value obtained for the period 1987-2002 is of the same order of magnitude than the reported by Hollerman (1982) for earlier stages and, this should be indicating that the actual conditions of sediment availability and mobility under the action of Trade winds have been steady during the last decades.

Finally, if dune migration is spatially analyzed, the lowest migration rates are observed in the N and S strips of the active area (Fig. 5), with the largest gradient in migration rates being located in the N end (difference in spatially averaged rates up to 2.5 m/y).

Table 3. Basic statistics of dune migration from 1987 to 2002. Analyzed dunes are showed in Fig 5.

Parameter	Displacement, m	Migration rate, m y^{-1}
Mean	87	5.8
Stand dev	30	2.0
Maximum	171	11.4
Minimum	29	1.9

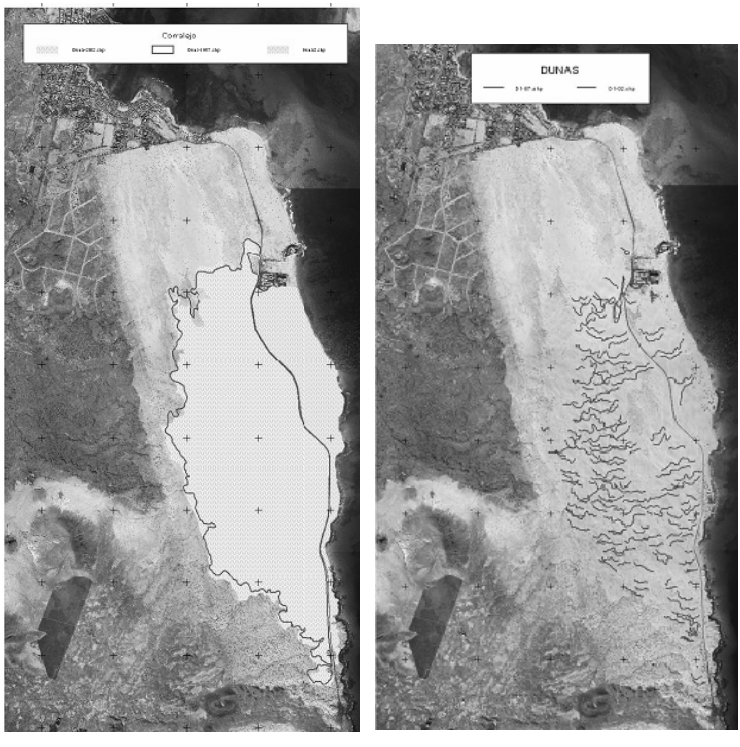

Fig. 5. *Left*: Evolution of the surface occupied by mobile dunes from 1987 (line) to 2002 (colored). *Right*: Dune migration from 1987 (green) to 2002 (red). Distance between crosses is 1 km (adapted from Jiménez et al., 2006).

Taking into account the measured migration rates and the averaged dimensions of dunes measured in 2005 we made an estimation of the aeolian transport in the area. To do this, we assume that actual dunes are migrating without experiencing any change in volume, i.e. they are in equilibrium, and as a consequence, sediment transport producing such

migration is simply the product of the migration rate by the dune height (see e.g. Illenberger and Rust, 1988). With this, net transport rates across the dunefield were estimated to have a mean value of 37 m^3/m/y with a standard deviation of 19 m^3/m/y. This transport rate should be acting in the direction normal to the dune fronts and, according to the distribution of the dunes in the W-E direction (Fig. 5), there will be significant changes in transport rates across the dune field.

Finally, these estimations from the observed dune behavior were compared to theoretical ones obtained by applying s-o-a formulations. Thus, the Bagnold (1941) model was applied to the conditions of the area. First, the probability of exceedence of mobility conditions in the dunefield was calculated by estimating the threshold velocity (impact velocity) associated to the different grain sizes across the area. Once this velocity was calculated, the probability of occurrence was obtained from the long-term wind velocity distribution. Table 4 shows the obtained values for the mean sediment sizes of the different environments. As it can be seen, and as it was expected, the larger mobility (probability of exceedence of transport conditions) is associated to sediments composing mobile dunes, followed by relict areas and finally the beaches. It has to be mentioned that these calculations were done for sediment of density 2710 kg/m^3, which was the value measured in laboratory for the carbonate sands of the area.

Table 4. Mean grain size dor the different sub-environments of the dunefield, impact threshold velocity and probability of exceedence.

environment	d50 (mm)	u_t (m/s)	P ($u \geq u_t$)
dunes	0.367	7.41	0.2132
stabilized-relict	0.416	7.81	0.1753
beach	0.595	9.09	0.0499

Due to the presence of coarse carbonate fragments (such as shells) in the sediment, the presence of sediment showing bimodal distributions was not infrequent. Under these conditions, the use of a mean grain size could be unrealistic and it would not be properly representing the selective action of wind on sediments (see *e.g.* van der Wal, 2000). To take into account this potential effect, computations were also performed by splitting each bimodal distribution –when present- into two sediment classes (Fig. 6). For each sediment type, the threshold velocity was calculated and the final probability was calculated as the weighted sum of the respective probabilities of exceedence. Final results do not differ too much from the ones showed in table 4, although in general, an increase in the mobility was obtained. It has to be stressed that threshold conditions for sediment composing stabilized areas only take into account the sediment size. However, the sediments show a high degree of compaction and, due to this, it is expected that the real mobility should be lower than the calculated one.

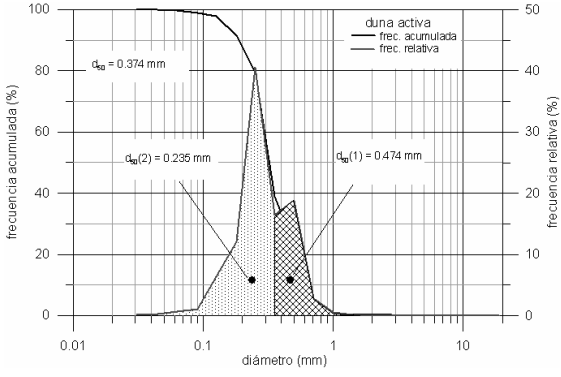

Fig. 6. Schematization of bimodal grain size distribution into two populations.

Once the minimum conditions for aeolian sediment transport were calculated, the following step was to estimate the potential transport rates. There exists a relative large number of transport models, all of them depending on some calibration coefficients in such a way that when applied to a given set of conditions they predict transport rates significantly different (see e.g. Sherman *et al.,* 1998). In this work we have estimated the potential transport rates in the area by using the Bagnold (1941) model that according to the comparative analysis done by Sherman *et al.* (1998) gives predictions in the intermediate range.

Although this model does not explicitly includes threshold conditions, it has been applied only for wind conditions exceeding the calculated threshold conditions for the given sediment environment (see e.g. Craig, 2000). Fig. 7 shows the aeolian sediment transport rose calculated for the area where it can be seen that the directional distribution of Trade winds induce a sediment transport with a resultant direction to the south as it was already observed in the dune migration analysis. This type of distribution is typical for areas with barchans and, transverse dunes in areas of good sediment availability (Lancaster, 1995).

The calculated averaged potential transport rate ranged from 3 m^3/m/y for the sediment composing the dunes to 5 m^3/m/y for the ones in beaches. This difference is only due to differences in sediment grain size and it does not include any possible variation in wind conditions across the dune field.

When comparing with transport rates obtained from dune migration, this rate is 3 times lower. This under-prediction of theoretical models against transport rates estimated from dune migration was also observed by Craig (2000) and Illenberger and Rust (1988), although other authors have found conditions in which they claim the Bagnold's model to over-predict real transport rates (*e.g.* Goldsmith *et al*., 1990).

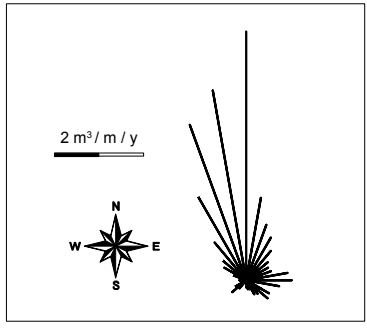

Fig. 7. Aeolian sediment transport wind rose for Corralejo.

CONDITIONS AFFECTING THE SEDIMENT SUPPLY

As it was shown in the previous section, the Corralejo dunefield is experiencing a southward migration with sand going out the former limits through the south towards the lava flows and through the SE towards the sea. Under these conditions, this means that unless new sediment will get into the system towards the N end, the dunefield will progressively migrate towards the S and, at the same time, part of the sediment will be removed and transported to the sea.

Due to this, it is important to know the actual situation of the potential sediment supplies to the system through the Northern limit. Nowadays, sediment sources in the area has nearly disappeared due to two main causes: **(i)** a very long term natural one, which is the progressive exhaustion of the sand sources in the coastal shelf, in such a way that at present it can be assumed that no sediment is susceptible to be transported towards the dune field. This can be detected in the distribution of sediment facies in the coastal shelf, where rocky outcrops are dominant along the shallower part of the area with sediment rich areas being unconnected to beaches (Fig. 8); **(ii)** a medium/long human-induced one –decadal scale-, due to the progressive urbanization of the Northern coast.

This last point is illustrated in Fig. 9 where the evolution of the urbanization in the northern border of the dune field is shown from 1941 to 2002. It can be clearly seen that whereas in 1941 only a small fishing village existed, nowadays (2002), the area is fully urbanized due to the growth of the original village and, specially, due to the construction of tourist resorts (tourism is the main economic activity of Canary Islands in general and this area in particular).

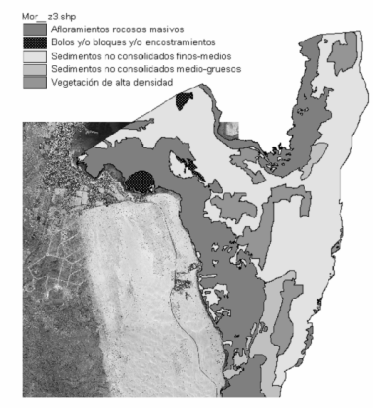

Fig 8. Sedimentary facies in the northern coast (brown: massive rock outcrops; black: cobbles and boulders; yellow: fine and medium sands; orange: medium-coarse sands; green: high density vegetal cover –Cymodocea-, adapted from Jiménez et al., 2006).

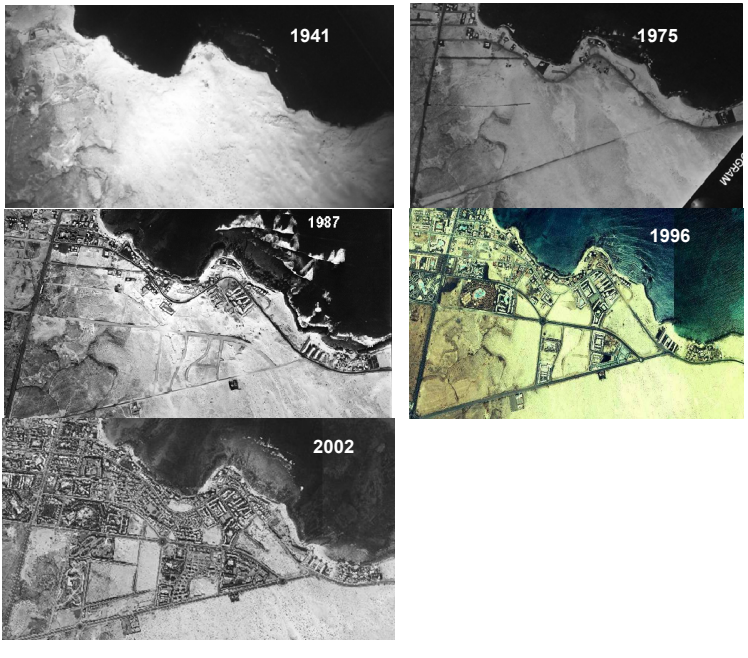

Fig 9. Evolution of the urbanization in the Northern coast of the Corralejo dunefield.

This urban growth acts on the sediment supply to the dune field by two ways: **(i)** as a barrier for the sediment that potentially could be incorporated to the aeolian dynamics of the area and; **(ii)** by eliminating a large volume of sand already existing in the area due to land occupation, preventing its mobilization and transport by wind. Thus, the loss of useful sand surface due to the urbanization of the northern coast has been estimated in 86.73 ha (measured in 2002).

These two effects have generated a gradient in the aeolian transport just southward of the urbanized area (the northern border of the dune field) during the last decades because the sediment transported towards the south is not been replaced by new sediment. This is behaving as the main boundary condition for the evolution of the dunefield and will determine in the long-term (assuming steady climatic conditions in about 6 centuries) a drastic change in the landscape. Thus, it is expected that dunes will progressively disappear from the Northern areas, decreasing the thickness of the sand cover and increasing the areas with vegetation (southwards displacement of the actual stabilized northernmost strip). The active dunes will move on to the lava flows across the actual southern end with also a progressive loss of sediment to the sea across the SE end.

CONCLUSIONS

In this paper, we have shown the main characteristics of the aeolian dynamics and resulting dune evolution in a coastal dunefield subjected to limited sediment supply and subjected to the action of a quasi-unidirectional wind regime. The dune field which is formed by carbonate sediment (bioclastic sands) is experiencing moderate dune migration rates and, in the upwind field limit is beginning to show the exhaustion of sediment. This results in a long-term migration of the dune field in the direction of the wind with an expected long-term change in the landscape due to a change in the boundary conditions at the upwind limit due to natural and human-induced factors. The migration of the overall dunefield at the downwind end which is formed by lava flows has been estimated to be of about 5.3 m/y, which is of the same order of magnitude of dune migration rates in the area (6.8 m/y). These rates together the dunefield dimensions seem to indicate that the change in landscape will occur in a very long-term scale (several centuries). However, although slow, this is continuous process provided climatic conditions remain stable.

Abstract: Numerical model simulations of tidal inlet hydrodynamics, sand transport and topographic change were performed using the Coastal Modeling System (CMS) to investigate the morphological response to time varying forcing, sediment texture, and the influence of rock reef outcrops within the Sebastian Inlet system. The presence or absence of rock within the inlet throat and in the surf zone on the south side of the inlet resulted in distinctive differences in topographic changes to the ebb shoal over a year long simulation. Comparisons between three sand transport formulations over a shorter period (2 months) showed some variation among the formulations, but predicted net topographic changes were well within an order of magnitude. Comparisons between predicted and measured net topographic changes demonstrated agreement in terms of pattern. Agreement in absolute terms improved as the model spatial resolution was refined by decreasing cell sizes.

INTRODUCTION

Inlet/bay systems and their morphologic features exist in dynamic equilibrium, with sand fluxes between shoal sand reservoirs due to complex interactions with the surrounding forcing mechanisms. The accurate modeling of the morphologic evolution of tidal inlet shoals is an important management tool, since they control sediment budgets. Inlet hydrodynamics depend on physical forcing, inlet and bay geometry, bottom topography, and presence of stabilizing structures that influence

sedimentation and flow patterns. Controlling jetties have been constructed at most of the smaller tidal inlet systems of the U.S East and Gulf Coasts to prevent shoaling and safety of navigation channels and stabilize the inlet location. Stabilization may also influence inlet evolution by enhancing the formation of ebb shoal and flood shoal deposits. Net longshore sediment transport and wave forces reshape the ebb shoal through a mechanism in which sediment is bypassed around the inlet, forming a bypass bar and eventually an attachment bar which connects the ebb shoal to the downdrift beach. As the shoal system of a stabilized inlet evolves, variations within the wave climate can abruptly increase or decrease the volume of sediment on the ebb or flood shoals and cause temporary, but large variations in the volume of sand bypassing the inlet (Zarillo et al., 2003).

Regional sand management has become a national issue that requires data collection and monitoring of tidal inlets and surrounding beaches as well as better predictive tools for predicting morphology changes. Computationally efficient numerical models to reproduce and predict sedimentation patterns at inlets such as ebb-shoal growth, scour patterns around structures, cross shore transport between shoals have been developed under the Coastal Inlets Research Program (CIRP) at the Coastal and Hydraulics Laboratory of the U.S. Army Water Ways Experiment Station. Termed the Coastal Modeling System (CMS) the suite of models provides realistic simulations of inlet behavior. However, the remaining limitations of numerical modeling include the computation times, which increase with spatial resolution, limited morphologic constraints to prevent over prediction of topographic change, and the lack of extensive field data to calibrate model results. The model application presented in this paper summarizes the results based on the state of the CMS technology as of the middle of 2006.

OVERVIEW OF THE MODELING APPROACH

The CMS is based on the M2D model, which is a time-dependant, 2-D finite difference circulation and morphology model, which calculates water surface elevations, two components of the current and sediment transport on a rectilinear grid (Militello et al., 2004). Coupling of M2D with the Steady Spectral wave model STWAVE (Smith et al, 2001) was performed through the Surface Modeling System interface (SMS) using the steering process to include the radiation stresses and wave induced currents (Zundel, 2000).

The CMS includes three sediment transport modules: Watanabe formulation (Watanabe. 1987), the Lund-CIRP formulation, and Advection-Diffusion (AD) enhancement of the Lund Formulation ((Buttolph et. al, 2006). The sediment transport formulations are directly coupled to the M2D model along with a continuity-based calculation of morphologic change that considers sediment volume exchanges among computational cells (Buttolph et al., 2006). The Watanabe formulation for total load is a function of an empirical coefficient for wave irregularity, bed shear stress, critical shear stress of incipient motion, the water density, gravitational acceleration and total depth averaged current velocity. The Lund-CIRP formulation is more complex including the added the benefits of writing out bed load and total transport as separate values and calculating the wave energy

dissipation. In the AD formulation diffusivity terms in the horizontal dimensions are added are added to enhance sediment motion. Another important feature included in the model calculations is the representation of non-erodible cells (Hanson and Militello, 2005).that can be used to represent shore protection structures including breakwaters and jetties, as well as natural features.

MODEL APPLICATION AT SEBASTIAN INLET, FL

This paper presents several examples from an ongoing modeling effort at Sebastian Inlet, FL to investigate the sediment transport and morphological evolution. Numerical simulations of the coupled circulation/wave models (M2D/STWAVE) are discussed under the followings topics: 1. preliminary hydrodynamic runs and calibration, 2. hard bottom subroutine testing, 3. shorter term (2 months) model test cases run applying different sediment transport formulations. Computed topographic changes were analyzed and compared with measured data from bathymetric surveys.

Sebastian Inlet is located in the southern part of the Indian River Lagoon (IRL) on the east coast of Central Florida. Rock outcrops of coquina line the bottom of the inlet throat and form a rock reef area exposed in the surf zone on the southern side of the inlet. The inlet is also characterized by a small throat cross section area and a large bay (IRL), which promotes strong currents through the. The present Sebastian Inlet was artificially cut into the coquina of the Late Pleistocene Anastasia Formation in the late 1940's and stabilized by offset jetties from 1950's to 1970's. The present configuration of the inlet (Figure 1a &1b.) includes a 250 meter-long curved north jetty and a shorter straight south jetty of approximately 75 meters.

The main morphologic features include the ebb shoal and bypass bar, which is obliquely oriented to the southern beaches and connects to the attachment bar about 700 m south of the inlet entrance, a large flood shoal, and an excavated sand trap (Figures 1a &1b). The mean tidal range is approximately 1 meter. The east central Florida wave climate is moderate having a mean annual wave height of 0.6 meter (Zarillo *et al*., 2003). However the wave regime is subject to strong seasonal variations in energy and approach, punctuated by the higher wave energy from northeasters and tropical storms and hurricanes. Analysis of the 15 years of surveys of the inlet indicates that the inlet is in state of quasi-equilibrium in terms of shoal volumes, but the dynamic ebb shoal can gain or lose more than 100,000 m^3 of volume in a single year and controls the inlet sediment budget. The net sand budget of about 120,000 to 230,000 cubic m^3/yr is thought to be driven by a few extratropical storms creating southerly drift, whereas tropical systems from the south tend to drive longshore sediment transport toward the north (Zarillo et al., 2003). Figure 2 summarizes the wave climate in terms of the longshore component of wave power. The cumulative plot indicated that the net component is directed south but that reversals and strong variations in magnitude are common.

Model Setup

In the Sebastian Inlet region the model grid was setup on the inner continental shelf and shoreface from approximately 12 km north of the Inlet to 12 km south of the inlet (Figure 2). Data sets for model grid development and model boundaries include

topographic data, wave data from the Wave Information System (WIS) and from local monitoring programs, water level data, and sedimentologic data available from local sand source investigations, and beach condition surveys.

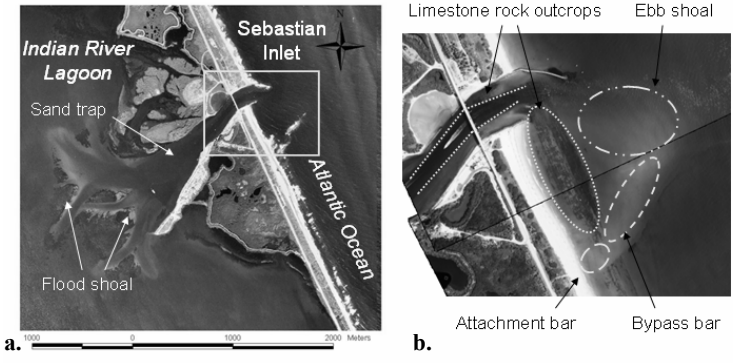

Figure 1. Study area. Note the waves breaking around the southern bypass bar. Hard bottom appears as dark bands on the aerial image.

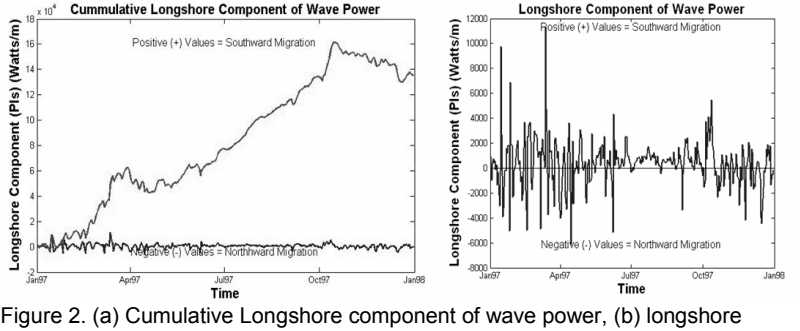

Figure 2. (a) Cumulative Longshore component of wave power, (b) longshore component of wave power.

Topographic data from the National Geodetic Data Center (NGDC) was combined with shoreface data from 1997. The simulation was forced by three measured water surface elevation (WSE) time series applied at the north lagoon, south lagoon, and ocean boundaries of the model grid. Wave inputs into STWAVE consisted of 365

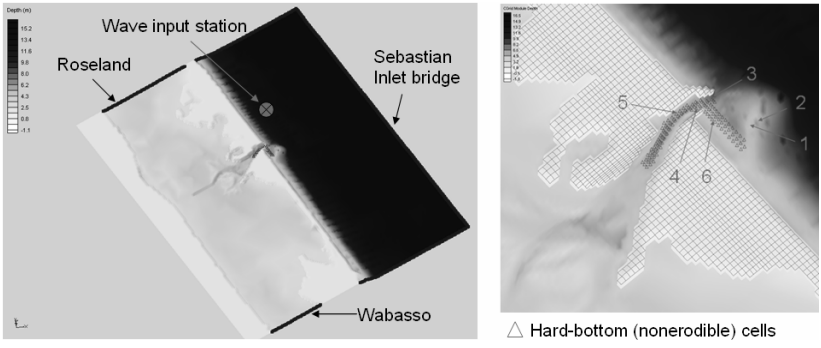

Figure 3. M2D grid and water surface elevation boundaries. The bottom topography contours are in meters.

directional spectra for coupling to M2D through a steering module that updated the wave field every 24 hours. Hind cast wave data from a nearby WIS station were propagated within a regional STWAVE grid to obtain the nearshore wave climate. The wave climate during the simulation time mainly consists of fair weather conditions with some storm events in summer and more frequent storms in fall and winter months. The largest wave heights were approximately 2 meters along with periods ranging from 4 to 15 s. The M2D grid cells corresponding to rock outcrops were selected and tagged as non-erodible (Figure 3). The depth of maximum erosion was set to 20 cm to account for occasional sand layers on the hard substrate. Observation cells were selected at different points of the model domain to extract time series of model outputs for analysis. For the longer term model runs (12 months) and testing the hard bottom routine, the circulation and wave model resolution was set to 50 meters. The two model cases used the Watanabe transport formula, sediment grain size set at 0.2 mm, the Watanabe sediment transport coefficient A set to 0.5, and total simulation time set to one year (8760 hours). For the three model cases comparing sand transport formulations and topographic changes between formulations the offshore cell sizes were set to 50 meters and refined to 25 meters in the inlet vicinity. Sediment grain size was set to 0.2 mm and simulation time was set to 1344 hrs (56 days).

Calibration and Preliminary Hydrodynamic Runs

A first step prior to sediment transport computations consisted of calibrating the hydrodynamic model. Predicted time series of water surface elevations were compared with measured elevations in terms of amplitude and phase. No measured current data were available for the model period. A comparison between computed and measured water surface elevations for Wabasso, FL tide station near the south boundary of the model is shown in Figure 4. Computed and measured elevations were found to match closely in terms of amplitude and phase. An example of computed current magnitude and direction during the ebb stage is displayed in Figure 5. Average computed velocities ranged from near zero behind the flood shoal to around 2 m/s between the two jetties confining the inlet throat. Stronger currents were found

in the inlet channel and throat. The model represents the ebb jet feature in between the jetties, where tidal currents peak and eddies forming on both sides and propagate offshore as current decreases around the ebb shoal. Current velocity was found to be strongly attenuated by the shoals.

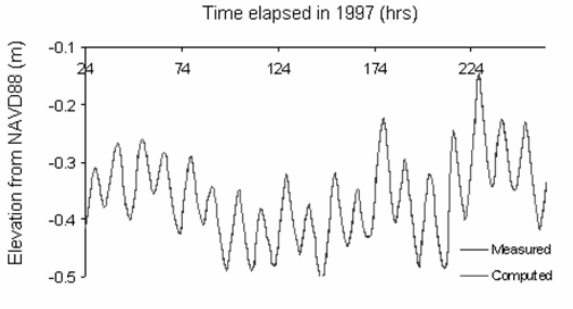

Figure 4. Model calibration: measured versus computed water surface elevations at Wabasso, FL.

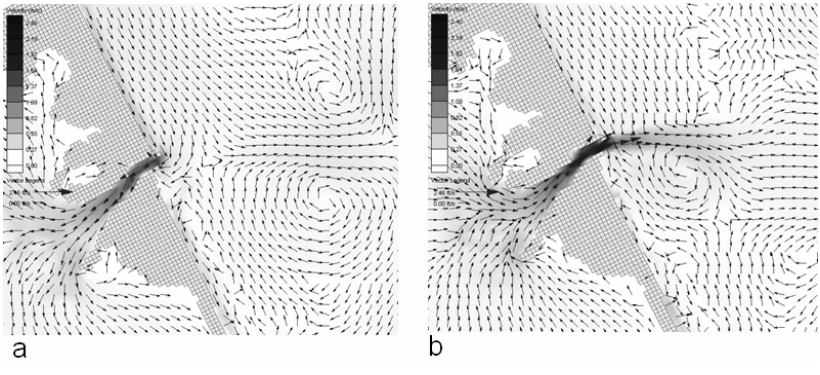

Figure 5. Current magnitude and directions extracted during a) flood stage and b) ebb stage.

During tests of the wave model wave height and direction were extracted for two cases: a northeaster and storm waves approaching from the south (Figure 6). Shoaling over the crest of the ebb shoal and along the bypass bar increased wave heights followed by a decrease and breaking at the shoreline. Strong wave refraction occurred around the ebb shoal/bypass bar area, especially when waves approached from the North East. Wave penetration into the inlet throat was predicted when waves were coming from the South East.

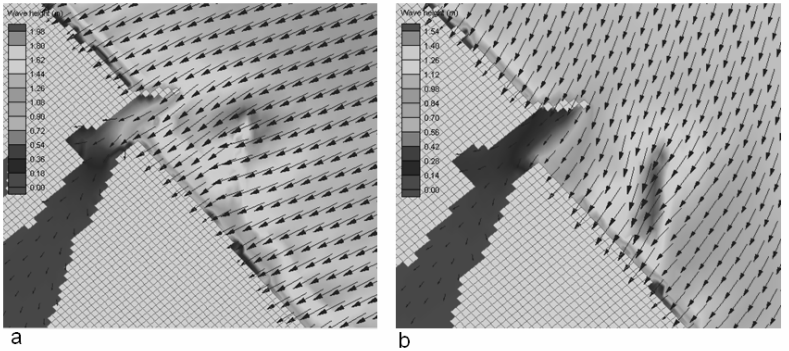

Figure 6. Predicted wave height and direction for a) swell approaching from the south typical of tropical systems b) Extratropical northeaster storm.

Long Term Runs

Model test cases were run with and without selected mode cells tagged as non-erodible to simulate the influence of rock outcrops on inlet dynamics. Computed net topographic change after a one year simulation under the Watanabe sand transport formulation is shown in Figure 7. Erosion areas corresponding to negative values are represented by blue colors and deposition areas (positive values) are represented by red colors. In the two model cases, channel bank erosion was observed, as well as scour at the seaward end of the offset jetties corresponding to areas of maximum current velocities during ebb and flood stages. Patches of erosion alternating with accretion were predicted on north and south shoreface areas, as well as over the flood shoal. For the south beaches and attachment bar, more complex patterns with patches of accretion and erosion alternating on the upper shore-face, probably due to interactions with rock reef.

Transient and permanent sand deposition is also predicted within the inlet throat section and ebb shoal complex and in both cases, a substantial net growth of the ebb shoal is predicted. When model cells were tagged as non-erodible through main inlet conveyance channel bank erosion increased as the inlet adjusted to a larger equilibrium cross-sectional area and the terminus of the ebb shoal extended farther from the inlet throat. Cross-shore transport on the bypass bar was observed for both runs, but deposition and erosion areas were reversed.

The hard bottom influence at specific cells corresponding to rock reef outcrops was investigated by extracting time series of topographic changes at high temporal resolution (Figure 8). Observation points 1, 2 and 3 were cells tagged as non-erodible with an initial layer of sand of 20 cm. At point 1, located on the reef in the outer surf-

zone of the south beaches, slight erosion of about 5 cm was predicted in the run, whereas net erosion to a depth of 0.5 meters was predicted in the run without non-erodible cells. At observation point 2 on the south side of the inlet throat episodic scour and deposition was predicted along with net erosion after about six months. The hard bottom run shows a less variable pattern of scour and deposition but with maximum erosion limited to 20 cm. Point 3 in a channel margin area west of the inlet throat experienced episodic scour and deposition without hard bottom and deposition when tagged as a hard bottom cell.

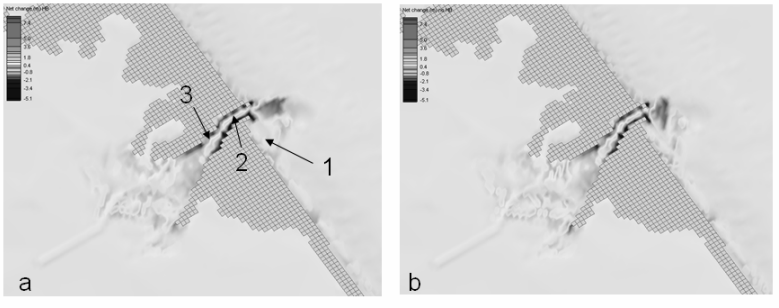

Figure 7. Computed Net topographic change after 1 year run under Watanabe formulation a) hard bottom and b) no hard bottom. Numbers correspond to observation cells for time series extraction.

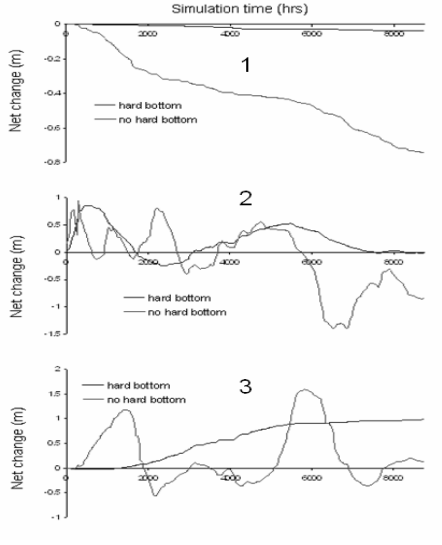

Figure 8. Extracted time series at observation stations for 1 year run (1997) under Watanabe formulation hard bottom versus no hard bottom.

Comparisons Between Sand Transport Formulations

Computed net topographic change after two months of simulation (1344 hours) is compared for the runs applying the Lund-CIRP formulation (Figure 9), Watanabe (Figure 10), and Advection Diffusion formulation (Figure 11). For all runs, the greatest erosion occurred along the margins of the inlet channel, whereas deposition is observed in the inlet channel. The Advection-Diffusion formulation showed more complex patterns, with less sand deposition in the channel, more deposition on the shoreface. All formulations agree in terms of sedimentation pattern including sand transport over the bypass bar with erosion on the outer part and deposition on the inner bar. However, the AD formula is the only one to reproduce natural bypassing and patches of sand accumulation on the attachment bar and shore-face between the south jetty and attachment bar. Under the Lund formulation, a small amount of sand was bypassed, but erosion was the dominant pattern between the beach and the first reef line. Over the flood shoal calculated net topographic changes very are small and mostly concentrated on the margin of the sand trap consistent with reality. Similar to the ocean side of the inlet patchy sand deposition is predicted by the AD calculations.

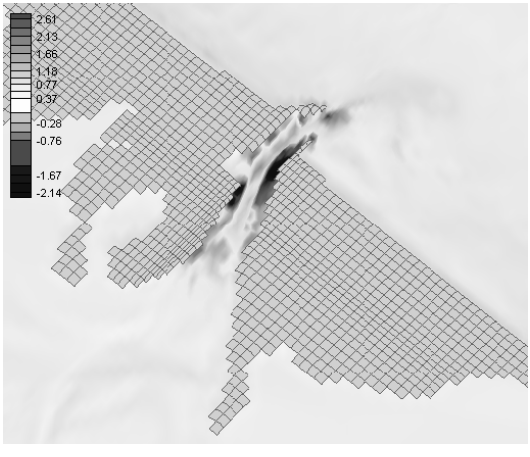

Figure 9. Computed net topographic change after 2 months of simulation under Lund-CIRP formulation.

Time series of bottom topography extracted at five observation cells shown in Figure 3 were used to compare the net predicted bottom change from each formulation. The sedimentation time series shown in Figure 12 agree well with visual observations of net change including erosion on the outer part of the bypass bar (point 2) and

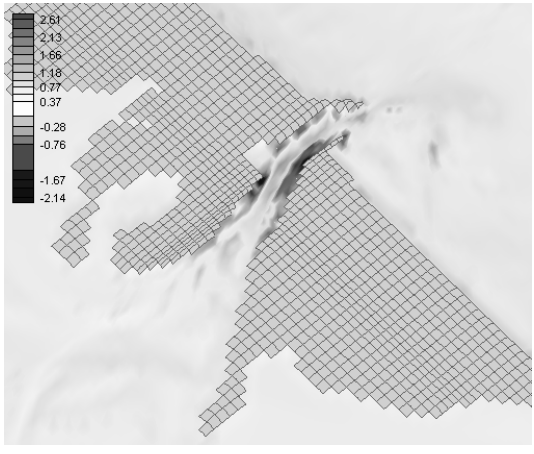

Figure 10. Computed net topographic change after 2 months of simulation under Watanabe formulation.

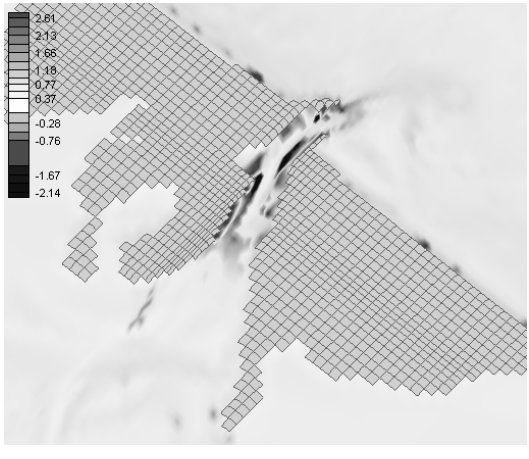

Figure 11. Computed net topographic change after 2 months of simulation under Advection-Diffusion formulation.

accretion on the inner part (point 1). For the three formulations, the overall trend is in accretion. Under Lund and AD formulas, the same trends of scour and deposition were observed, with the main difference in the magnitude of the net change. Computed net erosion at observation cell 2 was predicted by the three formulas. However, the magnitude of the net topographic change under the Watanabe formula was smaller compared to Lund and AD. Observation cell 3 is located off the east tip

of the North jetty. Here accretion was predicted by the three sediment transport formulas. Under the AD formula the predicted time series was more variable, whereas Lund and Watanabe formulas produced a more linear increase in net topographic change. Observation cell 4, 5, and 6 (Figure 2) were tagged as hardbottom cells. At cell 4 located off the tip of the south jetty, between the inlet channel and jetty structure the largest deposition was observed under the AD formula. Results diverge by the end of the run when scour was predicted by Lund. Model results at observation cell 5 on the North Channel margin of the inlet throat are similar for about half the simulation. However during the second half net deposition at this hardbottom cell under the AD formulation decreased while the other formulations continued to predicted a net increase. Model results at cell 6 is located on the rock reef outcrops located on the shoreface south of the inlet entrance indicated near zero net change under all three formulations. Only the AD results showed episodes of slight deposition and erosion.

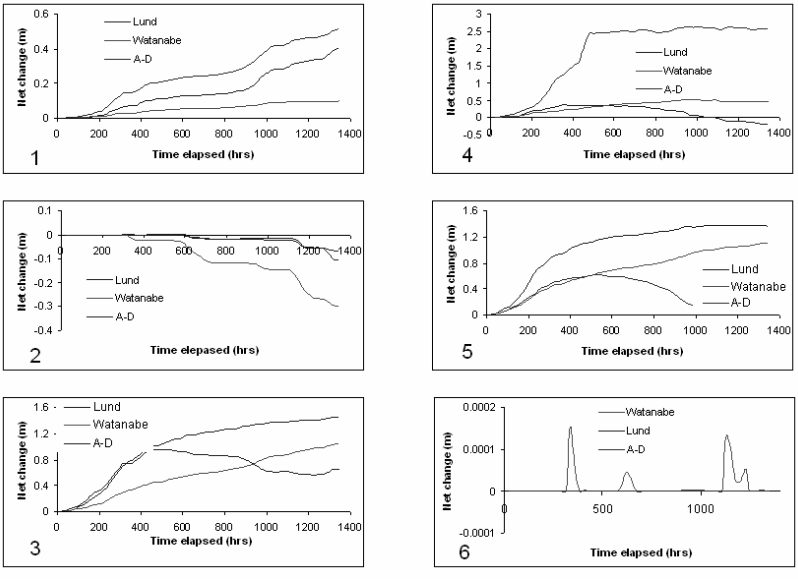

Figure 12. Time series of net bottom change extracted at each observation point.

SUMMARY AND DISCUSSION

Computed tidal currents were well within the range of magnitude determined by field measurements. The circulation model reproduced the expected ebb-jet during ebb stage, as well as the expanding turbulent wake. Through the longer term model runs wave driven currents were predicted on the upper-shoreface cells to the north and south of the inlet entrance, whereas tidal currents controlled sand transport within the inlet entrance. Predictions from the wave model reproduced complex wave refraction

and breaking over the ebb shoal and bypass that influence local sand transport directionality. During extratropical storms wave driven circulation patterns induced northward sand transport on the south side of the inlet between the south jetty and the attachment bar.

The largest computed net topographic changes were related to the hydrodynamic regime within the inlet/bay system. Channel bank erosion occurred, as well as scour at the seaward end of the offset jetties corresponding to areas of maximum current velocities during ebb and flood stages. Transient and permanent sand deposition was predicted within the inlet throat section and ebb shoal complex. The presence or absence of rock within the inlet throat and in the surfzone on the south side of the inlet resulted in distinctive differences in topographic changes to the ebb shoal over a year of real time simulation. When model cells were tagged as non-erodible through main inlet conveyance channel, bank erosion increased as the inlet adjusted to a larger equilibrium cross-sectional area. Episodic scour and deposition patterns across the shoreface were associated with storm conditions frequency and intensity and reversal in longshore transport.

Comparisons between sand transport equations showed some variation among the formulations but net topographic changes predicted from the formulations were well within an order of magnitude. However, the AD formula was the only one to reproduce bypassing and sand accumulation on the attachment bar. Under the Advection-Diffusion formulation, more complex sedimentation patterns were predicted. Less deposition occurred in the channel, which may be due to increased quantity of sediment in suspension in the channel.

Comparisons between predicted and measured topographic changes on an annual basis qualitatively agreed in terms of morphological evolution pattern. Agreement in absolute terms improved as the model spatial resolution was refined by decreasing cell sizes. Figure 13 is a comparison between predicted and modeled topographic changes at the entranced of Sebastian Inlet between March and September of 1997. The model predicted erosion and deposition patterns observed over the ebb shoal and bypass bar area and erosion along the south jetty. However, predicted deposition in a topographically low area off the end of the north jetty was not present in the survey data. Some of this difference could be due to inadequate representation of the north jetty and may require better resolution and further tuning of sand transport calculations. In addition, the sand transport module considered uniform grain sizes over the entire inlet. Material is usually coarser in areas of intense hydrodynamics, such as around the jetty fillets and on the ebb shoal. A more recent version of the M2D model now allows a variable grain size to be specified over the model grid.

CONCLUSIONS

Numerical simulations of coupled circulation, wave and sediment transport models were applied to Sebastian Inlet to calculate the morphology change and determine the influence of limestone rock outcrops on inlet dynamics. Evolution of morphology at Sebastian Inlet was found to be associated with the ebb-jet and wave-induced transport. General patterns of ebb shoal growth, sand bypassing, and scour of the

channel banks and around the jetties were reproduced by the CMS-M2D. The hard-bottom feature of the M2D model was effective in reducing the sediment transport in the channel and on the shoreface to the south of the inlet where natural rock reef outcrops occur. The inclusion of hardbottom cells though the main inlet channel induced erosion of the channel banks as the inlet adjusted to a larger equilibrium cross-sectional area. Adjustments to the ebb shoal topography in the model simulations was controlled by interactions between tidal and wave forces. Specifying non-erodible cells along model inlet channel produced deposition over the seaward portions of the ebb shoal most likely as a result of decreased sediment impoundment and increased regions of channel margin areas. Known patterns of topographic change on the shoreface were reproduced by the model cases, with erosion on the outer part and deposition on the inner part of the bypass bar. Predicted and measured topographic changes at Sebastian Inlet qualitatively agree. Further tuning and refinement of sand transport calculations are required to improve the match between model and real topography.

Abstract: Cape Shoalwater, at the north side of the mouth of Willapa Bay, Washington, has experienced some of the most severe erosion in the United States, exceeding 30 m per year during most of the 20th century. Morphological studies have documented that the rate of shore retreat near the Shoalwater Reservation has slowed to almost zero since the mid- to late-1980's. The reason is the presence of outcropping hard strata, a very dense, brown Pleistocene Terrace unit. This finding was unexpected because previous studies suggested that the shoreline would continue to retreat and that there were unlikely to be any practical engineering solutions to help stabilize the remnants of North Cove. Water diversion structures, such as dikes are impractical because they would need to be massive to have any effect in controlling the ebb- and flood-currents. Wave analysis verified that the waves causing local flooding in the reservation were generated in the fetch of the bay and that Pacific Ocean waves are effectively dampened as they pass over the Willapa ebb shoal.

INTRODUCTION

The Shoalwater Bay Indian Reservation is located on the northern side of Willapa Bay, on the Pacific coast of the state of Washington (Figure 1). Cape Shoalwater, at the north side of the mouth of the bay, has experienced some of the most severe erosion in the United States, exceeding 30 m per year during most of the 20th century (Komar 1998; Terich and Levenseller 1986) (Figure 2). The reservation, deeded in trust to the tribe by

President Andrew Johnson in 1866, formerly consisted of a land area and a protected bay where the tribe harvested shellfish. Because of the severe shore retreat, much of this bay has disappeared and the livelihoods of the tribe's members are threatened. In 2001, Congress directed Seattle District of the U.S. Army Corps of Engineers (NWS) to develop alternatives to arrest erosion and prevent storm and flood damage. NWS coordinated a study among the Coastal and Hydraulics Laboratory (CHL), Washington State Department of Ecology (WA DOE), and U.S. Geological Survey (USGS).

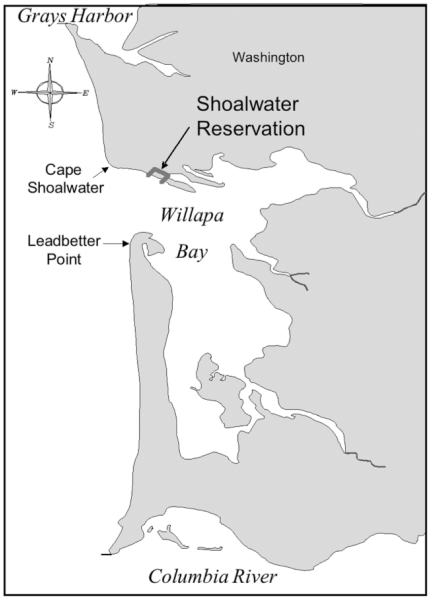

Figure 1. Study area, Willapa Bay, WA

In support of this study, from 2002 to 2004, a team of researchers from CHL conducted research on:

- Historical erosion, morphological changes and conditions, and potential future impacts
- Numerical model simulations of various hydraulic alternatives proposed by the USACE and the tribe
- Simulated flooding and storm overwash.

MORPHOLOGY AND HISTORICAL CHANGES

Bathymetric Data

The NWS has conducted hundreds of hydrographic surveys of portions of Willapa Bay in the last 150 years. Historical bathymetry data were imported into ESRI® ArcView™ v 3.2 software. Data were contoured and grids created with the Spatial Analyst module. Some of the data already existed in project files from the previous Willapa Bay project (Kraus 2000). Once the bathymetry was gridded, the thalwegs were visually traced (Figure 3).

The plot of all the thalwegs reveals some important details. In the east, the Willapa River has barely deviated from its channel over a century. South of the reservation bay, the Willapa River and the main bay channels join at a junction near cross-section line 7. The location of this junction has been surprisingly constant over time. Further west, the thalwegs showed a steady progression to the north, a rotation with the pivot point at the junction. Over 75 years, the thalweg changed from an east-west orientation to a southeast-northwest orientation. But, the rate of change decreased, and after 1996, the thalweg essentially stopped migrating.

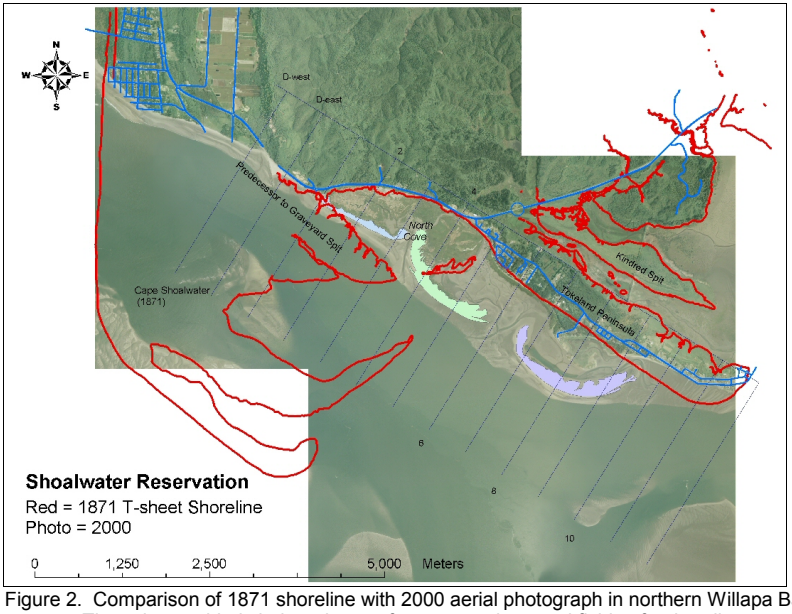

Figure 2. Comparison of 1871 shoreline with 2000 aerial photograph in northern Willapa Bay. The spits provided sheltered water for oyster culture and fishing for the tribe.

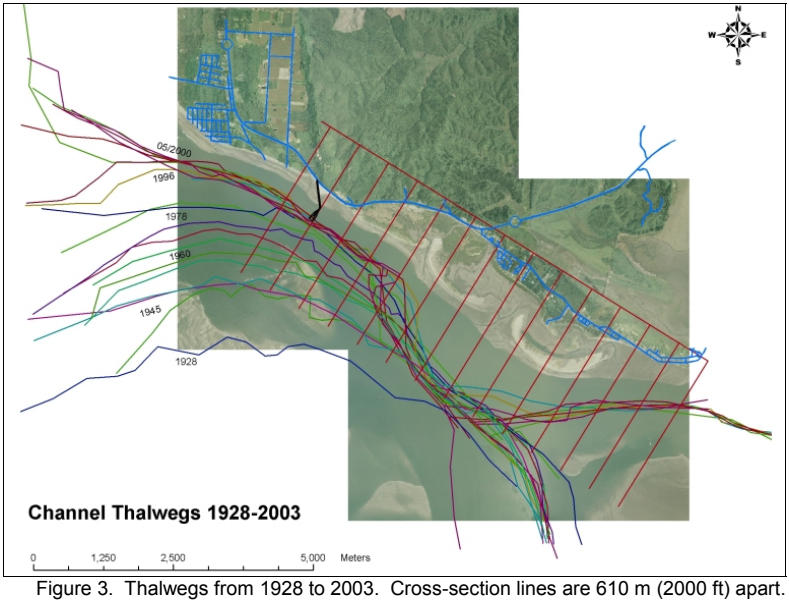

Figure 3. Thalwegs from 1928 to 2003. Cross-section lines are 610 m (2000 ft) apart. Background photo: Oct. 2000

Aerial photography and historical charts

Aerial photographs and U.S. Coast and geodetic Survey T-sheets were an invaluable source of information on changes at Graveyard Spit, the islands, the bay, and the nearby shorelines over the last 130 years. The 1942, 1945, and 1955 photographs came from the archives of the USACE's Beach Erosion Board (Morang 2003). NWS and the WA DOE provided more recent photographs as well as historical shorelines based on T-sheets. To convert the photographs into photomosaics, paper prints had to be scanned and processed in a multi step procedure, with CHL supplying many of the scanned files and WA DOE performing the mosaicing. CHL traced the shorelines and outlines of the spits and islands from the photomosaics by visually interpreting the wet-dry line. Figure 4 is a composite of the changes that have occurred to Graveyard spit and the sand islands.

To determine if the retreat rate has changed over the years, the position of the shoreline versus time were plotted. Plots for cross-section line 2 are shown as an example. Here, as at the other cross-section lines, the retreat of the shoreline and the thalweg paralleled each other (Figure 5). The cross-section curves show that the north flank of the channel was fixed for over a decade, while the south flank was irregular (Figure 6). The same phenomenon could be seen at other locations and was particularly noteworthy at cross-section line 4 (Figure 7).

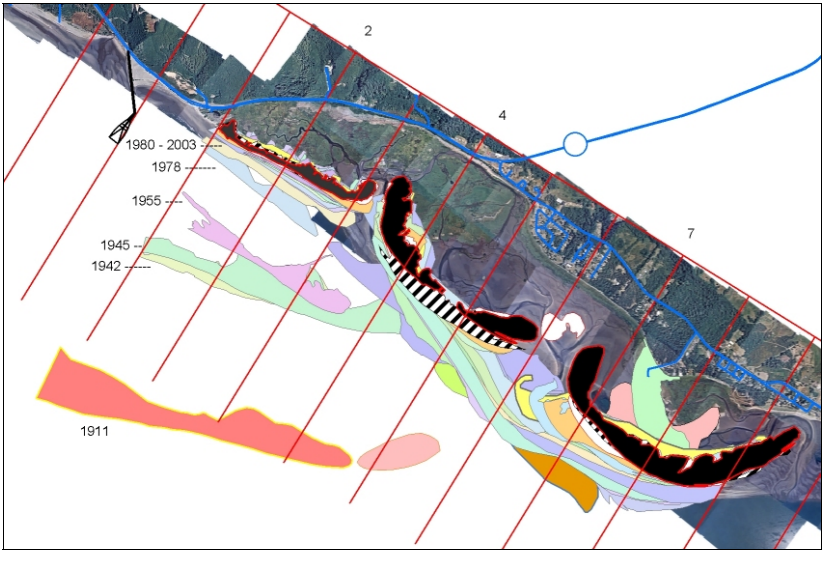

Figure 4. Plan view of Graveyard Spit and sand islands from 1911 to 2003. The spit moved much more rapidly during the first few decades of the 20th century. By 1980, the spit had stabilized in approximately the same position that it occupies today. Background photograph: July 2002. North is to the top

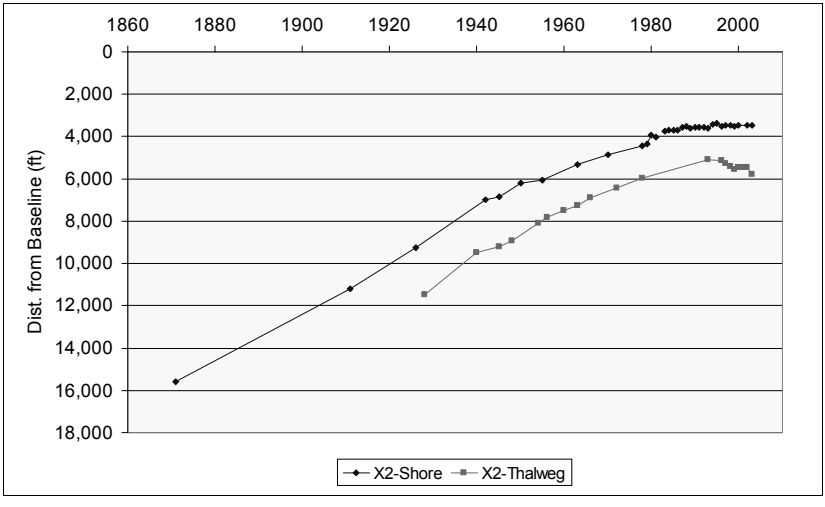

Figure 5. Cross-section line 2: shoreline and thalweg position. The shoreline stabilized in the early 1980's, while the thalweg moved away from shore (to the south) after 1996.

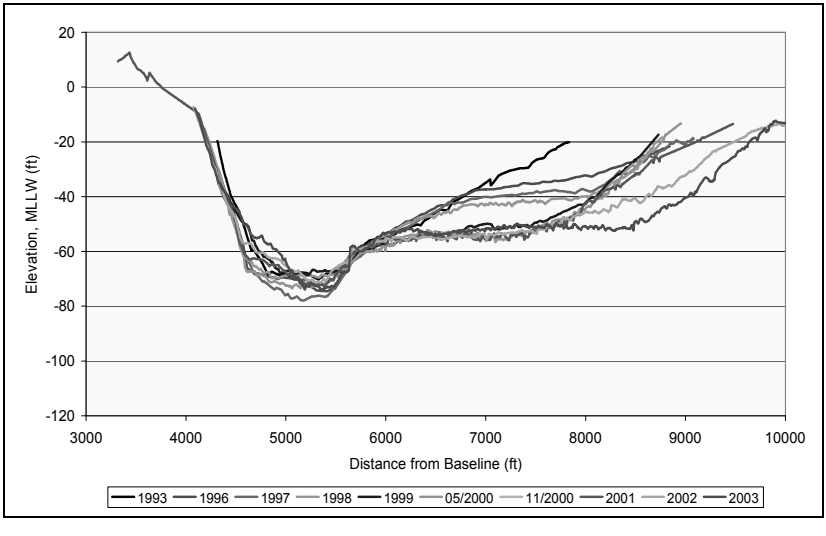

Figure 6. Cross-section line 2: channel sections. North is to the left. After 1993, the south flanks of the channel began to deepen, although the thalweg remained in approximately the same position. Note that the north flank remained fixed for a decade

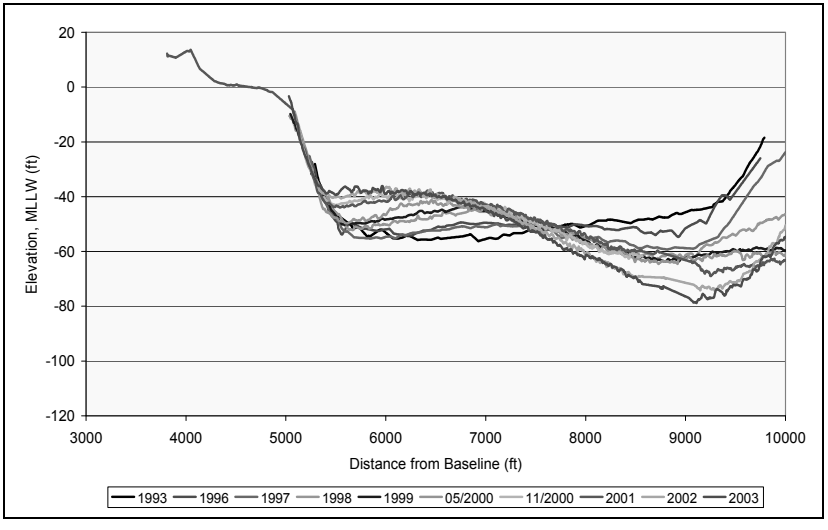

Figure 7. Cross-section line 4: channel sections. Since 1993, the north edge of the channel was fixed. Over time, the thalweg migrated south (to the right) as the area beyond 8,000 ft (2400 m) to the south deepened

Morphological findings

A number of trends emerged from the analyses which indicated that an engineering solution could be developed to protect the reservation from storm flooding and retard continued degradation of the remaining shellfish bay. As stated earlier, the thalweg stopped migrating northward after the mid-1990s. West of cross-line 2, the bottom became deeper as the thalwegs clustered along one path during the 1980s and 1990s. The channel was unable to continue moving northward, and as a result, the bottom became deeper as the flow was concentrated against the shore. From cross-lines 2 to 8, there is no evidence that the bottom is deepening near the spits or islands (i.e., the channel is not progressively moving north). This conclusion is verified by examining the cross-section curves.

Another finding was that the north sides of the channel had not migrated in over a decade and that the slope remained constant. This suggested that some form of harder strata was outcropping along the channel wall which was resistant to erosion. When the Washington State Department of transportation rerouted part of SR-105, they made a number of borings along the proposed highway route. At borings B-1-97, B-2-97, and B-3-97 (not shown in the above figures) they encountered a unit they identified as "very dense, brown Pleistocene Terrace" (Jackson, Allen, and Lowell 1997). We believe this unit extends under the Shoalwater bay and under the present spit and islands. Therefore, the remaining islands and spits are perched on a relatively stable base, although they are still vulnerable to overwash and loss of sand during flood events.

HYDRAULIC ALTERNATIVES

Members of the Shoalwater Bay Indian Tribe proposed investigating training structures, or dikes, as a possible remedy for controlling the extreme erosion along the North Cove shoreline. The purpose for these structures would be to deflect the high current away for the shore or to divert the flow in the North Channel such that it opens and maintains the Middle Channel to the open ocean. Seven locations for dikes were proposed, of which four were evaluated with the ADCIRC model, alternatives 1, 3, 4, and 6 (Figure 8). These four were selected because they are the closest to the tribal lands, thereby having the greatest potential to deflect the current away from the shore compared to the remaining alternatives.

The base or existing-condition grid was adapted for each alternative by adjusting the nodal positions and adding nodes so that each alternative is highly resolved in the grid. In all cases, the structure protrudes above the water surface and no water overtopping of the structure was permitted. Each alternative was tested under spring tide conditions, and no wind forcing was imposed in the simulation. Furthermore, the yearly mean river inflow was specified at the upstream boundary of the Willapa River. Peak spring ebb and flood currents were extracted from each simulation and analyzed as to their effectiveness.

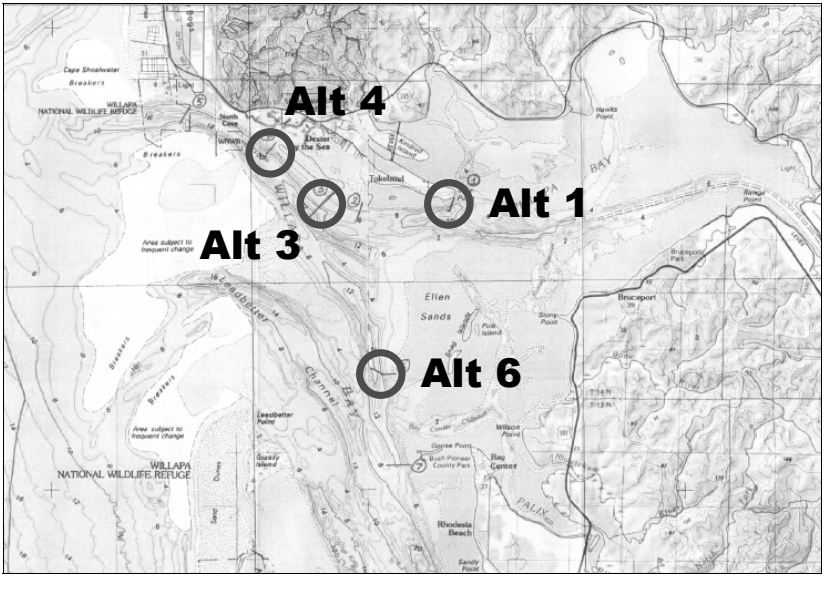

Figure 8. Proposed locations for training dikes

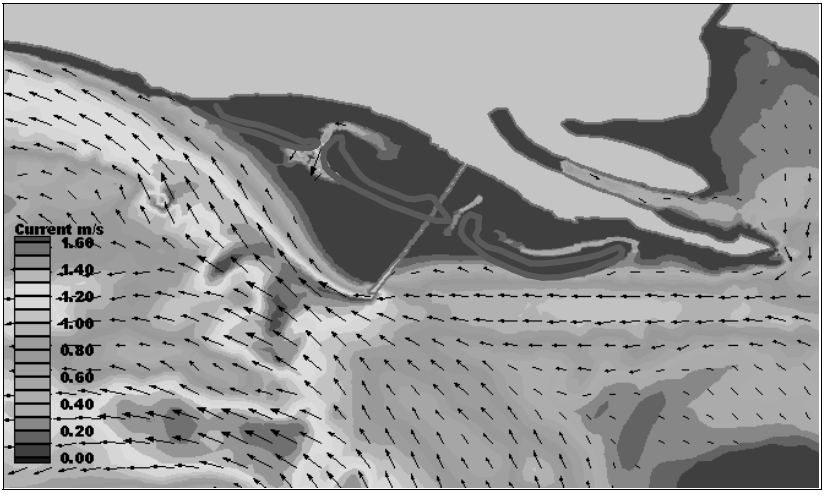

Figure 9. Peak spring ebb current with Alternative 3 in place

Alternative 3 extends directly across the North Cove and into the channel. The structure is 3,900 m long and extends 2,400 m into the channel. Peak spring ebb current in the vicinity of the North Cove for with-alternative condition is presented in Figure 9. The structure reduces the peak ebb current along the western extent of Empire Spit, and, to a lesser extent, at the eastern end of the spit. Current along the eastern end of the Spit is reduced during flood tide, whereas a small reduction in current is found to the west.

Two consequences of training structures is the creation of gyres, a circular or spiraling current, on the lee-side of the structure, and impediment of sediment transported along the shore. Although the gyres are weaker than the main current, the spiraling gyre will still suspend the sediment along the shore, and transport it into deeper water; with the structure preventing movement of sediment along the shore, the area being eroded by the gyre is not replenished, leading to a loss in land.

This investigation found that flow modifications caused by a training structure are localized, and if a structure is constructed, it must be in close proximity to the North Cove to have any impact on the current. Furthermore, the structure must be massive to divert or deflect the strong current away for the shoreline. For example, Alternative 3 measured 3,900 m in length, and extended into the channel to a depth of about 21 m. To have an appreciable impact on current, the remaining structures must block a significant portion of the channel in order to reduce the current speed along the shoreline. Each training structure reduces the conveyance of flow within the channel. As such, the current increases when it flows past the structure. As shown in the numerical experiments, the increase in current will induce the formation of a scour hole at the toe of

the structure. To prevent potential failure of the structure, regular maintenance will be required to prevent toe from sliding into the hole.

FLOODING AND STORM OVERWASH

The long-term erosion of the North Cove shoreline has been driven by the strong tidal currents that hug the shoreline, but waves also play a role in dune erosion during storms. The numerical model STWAVE (Smith et al. 2001) was used to transform waves into Willapa Bay for evaluation of alternatives. Smith and Ebersole (2000) measured and modeled waves in Willapa Bay and concluded:

- The incident wave climate at Willapa Bay is severe, with storm wave heights exceeding 7 m (as measured by the Grays Harbor Buoy, Station 03601).
- The shoals extending north from Leadbetter Point substantially attenuate incident waves. The tide level modulates waves within the bay, with more wave energy penetrating the bay at high water levels and less at low water levels.
- Field measurements validated the wave transformation model STWAVE for wave transformation and attenuation across the shoals and into the bay.
- The STWAVE model demonstrated that wave-current interaction is significant in the outer Willapa entrance channel where currents can exceed 2 m/sec, but is relatively insignificant in the interior channels.

Figure 10 shows incident offshore waves from the Grays Harbor Buoy and the nearshore Cape Shoalwater wave and water level measurements for the period 6-31 December 2002. Note the event with incident waves exceeding 5 m during 13-16 Dec (Julian days 347 through 350). These data illustrate that waves within Willapa Bay are strongly attenuated across the shoals and are modulated by the tide elevation. The relationship between water level and interior bay wave height is almost linear (see Figure 11; simulation results for 1-5 March 1999 storm). During storm events with elevated water levels, more wave energy penetrates into Willapa Bay. The elevated water levels allow waves to attack higher elevations on the dunes and shorelines.

The channel migration and shoreline retreat rates within Willapa Bay have slowed over recent years, but degradation of the barrier dunes protecting the Reservation shoreline indicate continued damage to the dunes and flooding of tribal land during storms with elevated water levels. To investigate protection from wave attack provided by the dunes, STWAVE was used to compare waves at the shoreline with and without the barrier dunes in place.

A grid of the dune and shoreline area was developed with a resolution of 30 m. This grid nested into the larger Willapa Bay grid and focuses on the North Cove area. Two versions of the grid were developed: one with the dunes as they exist based on 2002 bathymetry, and one with the barrier dune elevations above mean high water removed (Figure 12). The existing condition is referred to as the 'with-dune' case and the altered bathymetry as the 'without-dune' case. The offshore boundary conditions for the nested

grid runs are taken directly from the larger-scale STWAVE simulations, including local generation in southern Willapa Bay.

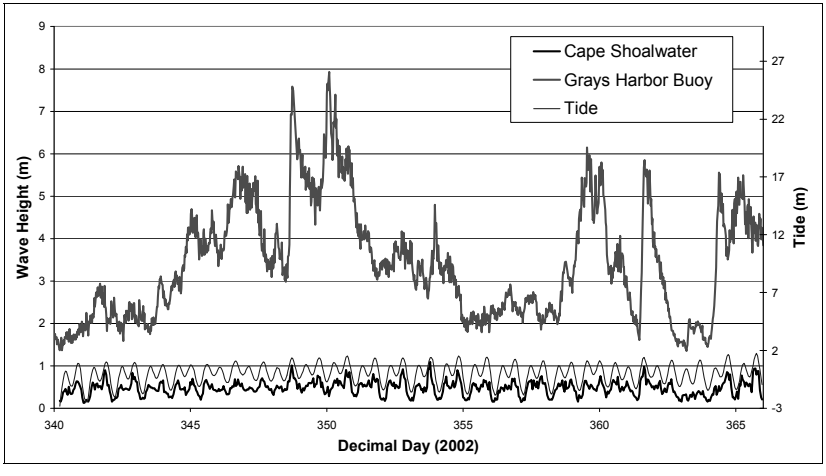

Figure 10. Measured waves and water levels (December 2002)

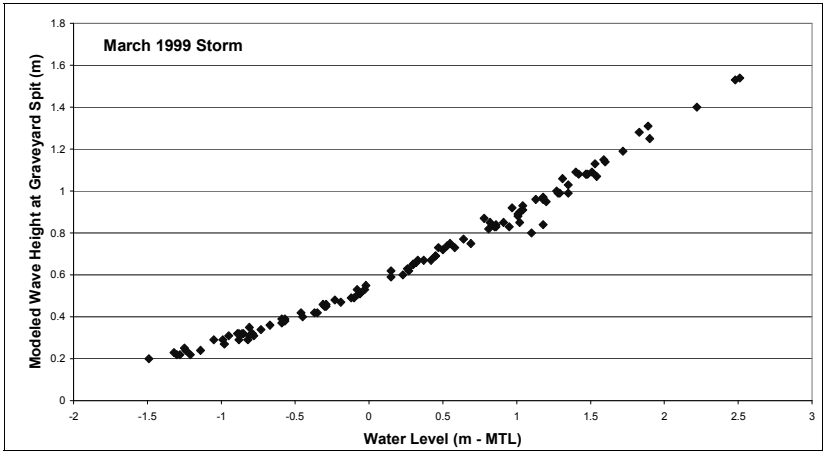

Figure 11. Relationship of modeled wave heights and water levels at Station 1 for March 1999 storm

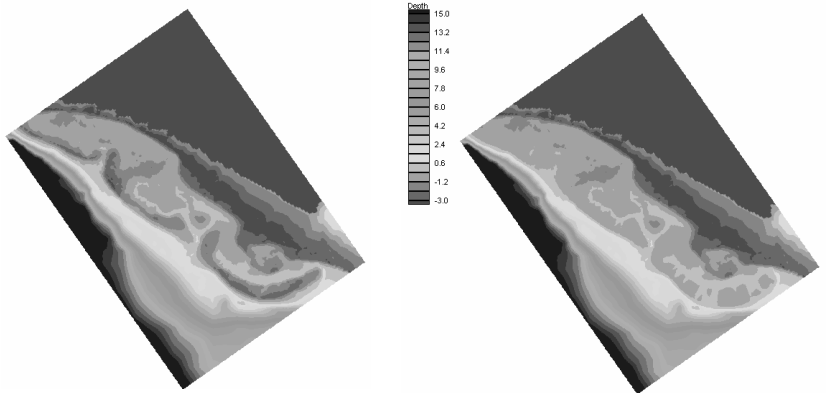

Figure 12. Bathymetry grids for nested grid simulations with and without dunes (with dunes on left and without dunes on right, depths in meters)

The March 1999 storm (the storm of record) was selected to simulate the with- and without-dune cases. The results are shown in a series of figures. Figures 13 and 14 show a snap shot of the wave heights for the with- and without-dune cases, respectively, for 3 March at 0900. The warmer colors (orange to green) indicate larger wave heights and the blues indicate lower heights. These plots are representative of the storm. The orange regions represent where waves shoal and break as they propagate up the slope to the dune. In the with-dune case (Figure 13), waves continue to break up to the crest of the dune. Wave energy also passes through some gaps in the dune line. In the without-dune case (Figure 14), waves exceeding 1 m in height pass over the lowered dunes and strike the shoreline. Eight station locations are indicated in Figures 13 and 14, with Sta 1 being the furthest to the northwest and Sta 8 to the southeast. Figure 15 shows the wave height for the 8 alongshore stations at the peak of the March 1999 storm (same hour as Figures 13 and 14) for the with- and without-dune simulations. The wave height is significantly reduced at the shoreline for the with-dune case for all stations except Sta 6, which is behind a gap in the dune line. Wave heights for these 8 stations are plotted in Figure 16 for the duration of the March 1999 storm. The filled symbols indicate simulations with the dunes and open symbols indicate without the dunes. Wave height is plotted as a function of water level (similar to Figure 11, which showed waves seaward of the dunes). The figure shows quantitatively, the protection provided by the dunes. With the dunes in place (existing condition), wave heights at the shoreline are generally less than 0.6 m, but without the dunes, wave heights are approximately twice as large. In summary, the existing dunes provide significant protection to the shoreline. Loss of the dunes would increase wave heights at the shoreline (increases storm damage) and increase overwash into North Cove.

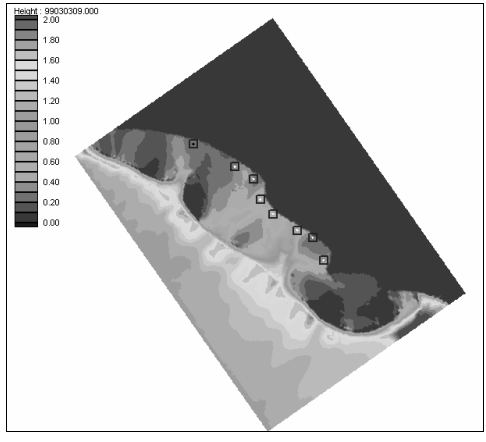

Figure 13. Contour plot of wave height with dunes for 3 March 1999 at 0900 (wave height in meters)

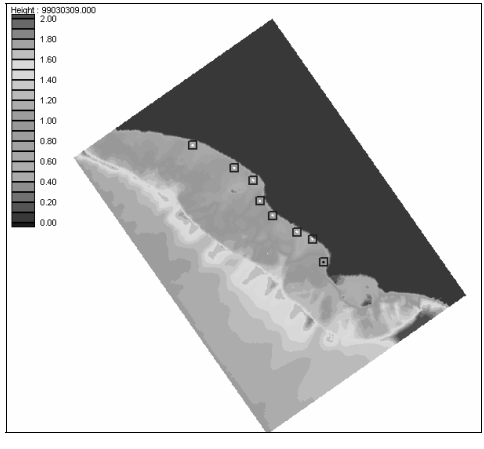

Figure 14. Contour plot of wave height without dunes for 3 March 1999 at 0900 (wave height in meters)

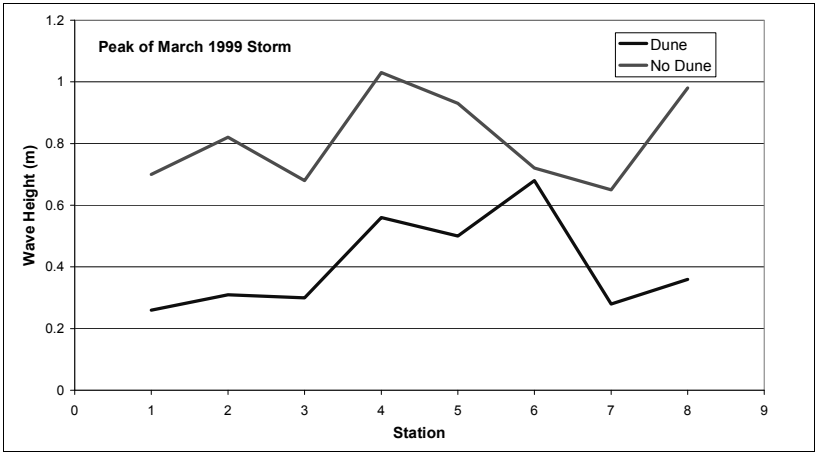

Figure 15. North Cove alongshore distribution of wave heights with (lower curve) and without dunes (upper curve), 3 March 1999 at 0900.

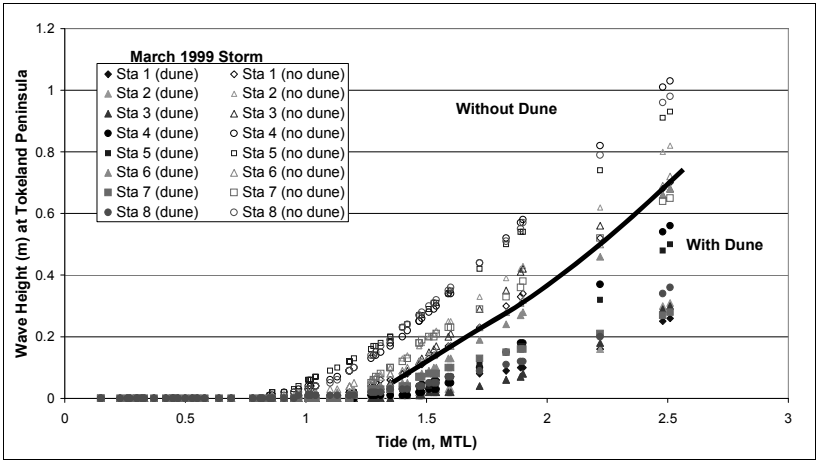

Figure 16. North Cove wave heights with and without dunes for March 1999.

Waves are attenuated across the shoals at the mouth of Willapa Bay, and water level over the shoals is the critical limiting parameter. Offshore-generated waves reaching North Cove are generally in the range of 0.3 to 1.0 m. During storms, water levels are elevated across the shoals and the larger wave heights occur. Also during storms, local winds from the south generate waves in southern Willapa Bay. The total wave heights (offshore plus local generation) at the project site are potentially in the range of 1.5 to 2.0 m. The wave heights simulated for the March 1999 storm peaked at 1.6 m along the

spit. Even as the overall shoreline erosion rate is reduced by reduction in the Willapa channel migration, waves will continue to act on the barrier spit during storm events (surge and southerly winds). This will result in continued flooding, overwash, and loss of dune elevation. Model results showed that the existing dunes provide significant protection to the shoreline, and further loss of dune elevation will exacerbate flooding and storm damage.

CONCLUSIONS

Although Cape Shoalwater was notorious during most of the 20th century for its rapid erosion, the north shoreline inshore (east) of the ebb shoal appears to have largely stopped migrating north. The analysis of historical bathymetry and aerial photographs demonstrates that retreat rates of the thalweg and the shoreline along north Willapa Bay were almost identical during the 20th century. We believe that the thalweg's movement has largely driven or been the forcing factor for the shoreline retreat. Since the mid-1980's, slope of the north bank of the main channel has been constant and has remained in a fixed position. The reason is that the channel encountered hard strata that are resistant to erosion, probably the very dense, brown Pleistocene terrace unit recovered in borings made by the Washington State Dep. of Transportation (Jackson, Allen, and Lowell 1997).

As the thalweg rotated to the north and northeast, the spits and islands that formerly protected the bay also moved north. After 1985, Graveyard Spit stabilized, but the islands to east continued to retreat due to loss of sand supply. Since the mid-1990s, the islands also semi-stabilized in position but become narrower and lower as a result of storm overwash.

The apparent end of gross shoreline retreat and the stabilization off the channel's north flank was an unexpected finding of this study. It meant that a relatively simple construction project could provide protection for the reservation without being washed away within a few months or years. The project will include dune restoration on islands using dredged material. The dunes will need 460,000 m^3 on 10-year maintenance interval. Along the Tokeland shoreline, a low rock flood berm will be extended to an elevation of +5.1 m MLLW. Construction of the flood berm is scheduled for mid-2007 to mid-2008, and dune restoration for 2009 to 2010. Work is dependent on continued Congressional funding, and there is no local cost-sharing at this project beyond provision of lands, easements and rights-of-way by the Shoalwater Bay Indian Tribe.

In Willapa Bay, flow diversion structures were eliminated from further consideration because they did not appear to be either cost effective or environmentally acceptable, or verifiable as to the beneficial effect in reducing the flood and coastal storm damage threat to the Reservation. Because of the volume of tidal flow from Willapa Bay, only massive dikes or jetties on the scale of Dutch control structures would have any hope of modifying the ebb or flood flow. The cost would be vastly greater than would ever be allocated for this setting, which is no longer used for deep-draft navigation.

ACKNOWLEDGEMENTS

We appreciate the cooperation of the Shoalwater Tribe and various collaborators in this rewarding study. We thank Steven Babcock, Eric Nelson, Larry Scudder, and Joyce Rolstad (NWS) and George Kaminsky and Dinah McCandless (WA DOE) for support and for providing valuable historical data from their agencies' archives. Yen-hsi Chu and Edward Hands (both now retired) and Gary Ray (ERDC Environmental Laboratory) participated in the CHL project team. Steven Babcock reviewed this paper. Permission was granted by Headquarters, U.S. Army Corps of Engineers to publish this information.

Abstract: A comprehensive approach was used to evaluate recent changes to the St Lucie Inlet system and was used as the basis for the evaluating future sand transfer and shoreline stabilization projects associated with the region. The analysis relied extensively upon hydraulic, bathymetric, and coastal monitoring conducted over multiple years and dredging cycles to evaluate impacts upon the hydraulics of the St. Lucie Inlet and Estuary. The monitoring data was used to assess the effects of the impoundment basin dredging on tidal prism/circulation patterns, navigation, and shoaling patterns/sediment transport pathways. Analysis of coastal processes through the development of numerical modeling tools in the vicinity of the inlet provided baseline information for management decisions.

INTRODUCTION

St. Lucie Inlet is located along the east coast of Florida in Martin County and links the Atlantic Ocean with the Indian River Lagoon. To the north side of the inlet lies Hutchinson Island, with the residential development of Sailfish Point being located adjacent to the inlet. Jupiter Island is located south of the inlet, where approximately the northern six miles of the island are undeveloped State and Federal property. The estuarine system landward of the Jupiter-Hutchinson Islands barrier complex consists of the Indian River to the north, St. Lucie River to the west, and Great Pocket to the south. The Intracoastal Waterway (ICWW) runs parallel to the barrier beach system along the

landward side. Regionally, the ICWW provides a direct connection between St. Lucie Inlet and nearby inlet/estuarine systems: Ft. Pierce Inlet to the north and Jupiter Inlet/Loxahatchee River to the south.

Similar to many tidal inlets along Florida's east coast, St. Lucie Inlet requires periodic maintenance dredging to ensure navigation safety. To address concerns related to inlet management, Applied Technology and Management, Inc. (ATM) was hired by the Florida Department of Environmental Protection and Martin County to assess inlet sand resource management, as well as safe navigation. The inlet management plan (ATM, 1995) provided the first comprehensive assessment of the relationship between the coastal engineering structures stabilizing the inlet and sediment management. In addition, the management plan recommended the following elements:

- Continued maintenance of the navigation channels, with dredge material placed on Jupiter Island beaches at least 14,000 feet south of the inlet
- Use of beach compatible material from interior shoals for nourishment programs within the Town of Jupiter Island
- Raising a 350 ft section of the north jetty, sand tightening a 250 ft portion at the west end of the north jetty to limit the weir section to 450 ft, and potentially expanding the impoundment basin
- Assess the feasibility of extending the south jetty by 400 ft

The St. Lucie Inlet Technical Advisory Committee (TAC) was initiated in 1996 to provide a link between the various stakeholders and the U.S. Army Corps of Engineers (USACE). The USACE is responsible for maintaining St. Lucie Inlet for navigation purposes. The local sponsor, Martin County, organized the TAC to ensure that various interests affected by inlet management practices were addressed through the USACE planning process. In addition, the TAC provided a mechanism for developing a 'locally preferred plan' that contained additional design elements that could not be funded as part of the Federal navigation project.

Since the development of the 1995 inlet management plan, a series of management strategies have been implemented to reduce maintenance dredging frequency and improve sediment bypassing at the inlet. In addition, the St. Lucie Inlet Design Memorandum (USACE, 2000) recommended a number of inlet improvements that have not been constructed at this time. The Design Memorandum was developed in close coordination with the TAC; therefore, primary concerns of the various stakeholders were reviewed as part of the USACE design process.

As originally proposed, the inlet management plan was designed to be a 'living document' that would require periodic updates. Since this plan was written, the USACE and Martin County have funded and constructed some of the elements described in the plan; however, new information developed by the Corps led to some changes from the Inlet Management Plan. Specifically, The USACE St. Lucie Inlet Design Memorandum addressed several of the elements described in the inlet management plan; however, the

planned placement location for bypassed sediment was altered to reduce potential maintenance costs. The locally preferred alternative includes beach placement of sand dredged from the impoundment basin at least 9,800 feet south of the south jetty along Jupiter Island.

Based on recommendations included in the St. Lucie Inlet Design Memorandum, the impoundment basin was enlarged in 2002-2003. Creation of the larger impoundment basin initially caused modifications to the sediment transport pathways, as tidal currents were influenced by the modified inlet cross-section. These alterations, combined with implementation of different sand management practices within the vicinity of the inlet, required an updated analysis of regional sediment transport processes.

ANALYSIS APPROACH

To update the analysis of the regional sediment transport and the management of sediment, a comprehensive inlet monitoring, numerical modeling, and analysis program was developed. Further data was required to supplement information developed during these previous efforts. Updated inlet surveys, beach profiles, aerial photography, tidal elevation information, and inlet tidal currents studies were performed to evaluate recent changes to sediment transport patterns resulting from the inlet improvements.

This comprehensive approach was used to evaluate recent changes to the inlet system, however it can be used as the basis for the evaluating future sand transfer and shoreline stabilization projects associated with St. Lucie Inlet. The program included components needed to characterize the immediate changes as well as facilitate future planning including:

- identification of shoreline and volumetric changes;
- refining the inlet sediment budget;
- identifying any hydraulic effects of flood shoal dredging and future inlet improvements;
- evaluating the benefits of sand transfer;
- providing advance planning for maintenance of navigation within the inlet by identification of channel depths and the sedimentation rate within the channel; and,
- providing a basis for design of future sand transfer and shoreline stabilization projects.

BATHYMETRIC CHANGE WITHIN ST. LUCIE INLET

Surveys of the inlet were conducted to provide the data necessary to identify shoaling and scouring within the inlet. In this manner, the surveys could be used for advanced planning for maintenance dredging and sand transfer and to update the sediment budget. Annual bank-to-bank hydrographic and topographic surveys were completed to accurately document the bathymetric change within the inlet prior to and following the impoundment basin construction, as well as throughout the subsequent years as the inlet adjusted to its new equilibrium state. Accurate observations of the actual bathymetric

change were necessary to properly parameterize the sediment transport model, to assist in determination of sediment transport pathways, and to evaluate maintenance dredging needs.

Bathymetric change within the inlet throat was computed for the time periods of June 2002 – March 2003 and March 2003 – June 2004. Three regions were selected based on observations of bathymetric change in the inlet, as well as the sediment transport modeling (Applied Coastal 2006). Specifically, the demarcation between Area I and Area II represents the separation between the sediment entering the inlet over/through the north jetty (Area I) and sediment derived from the beaches and or ebb shoal deposits to the south of the navigation channel (Area II). Area III represents the seaward portion of the flood shoal. The limits of the bathymetric change areas are shown in Figure 1.

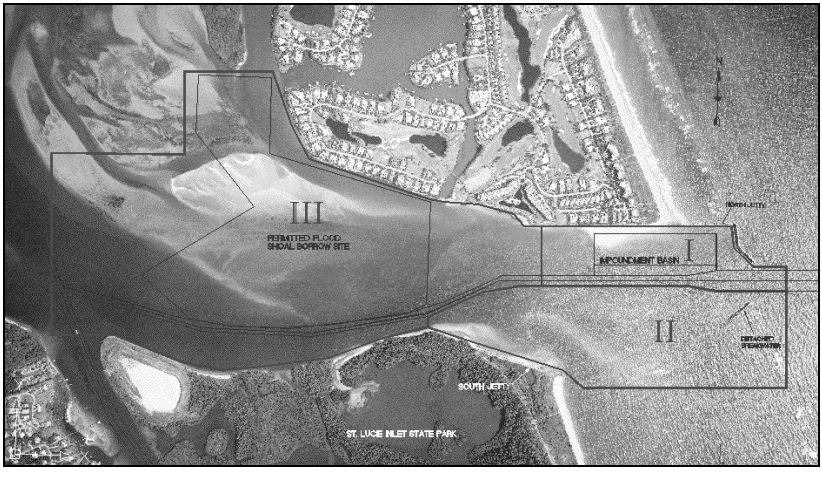

Figure 1. Bathymetric change areas.

A summary of the observed bathymetric change following the impoundment basin improvements is shown in Table 1. Significant accretion is observed for both Areas I and II, and much of this accretion is offset by erosion in Area III. During the latter half of 2003, the inlet was adjusting to its new equilibrium form, where the cross-section of the inlet throat increased significantly as a result of the navigation channel and impoundment basin dredging. Initially, larger flood and ebb tidal currents across the flood shoal caused sediment to migrate both east and west off the shoal. As a first approximation, 50% of the approximately 142,000 cubic yards could be expected to migrate to the east (into Areas I and II) and the remaining material migrated west and north toward the St. Lucie and Indian River Lagoon, respectively. Both the observed bathymetric change and the sediment modeling indicate that the dredged channel is self-scouring and likely prevents significant accumulation of material derived from the flood shoal. Conversely, the more efficient inlet has slightly lowered current velocities across the southern half of the inlet

throat, allowing settling of flood shoal derived material in this region. Figure 2 shows the significant region of accretion associated with Area II. If it is assumed that material eroded from Area III is split 25% to Area I and 75% to Area II, the sediment derived from other sources would be approximately 113,000 cubic yards and 52,000 cubic yards for Areas I and Areas II, respectively. This result indicates that shoaling from the south does not account for more than about 30% of the shoaling within St. Lucie Inlet.

Table 1. Analysis of Bathymetric Change within St. Lucie Inlet for the period March 2003 - June 2004.

Area I	**Volume (cy)**
Erosion	75,202
Accretion	205,622
Net Difference	130,420
Area II	**Volume (cy)**
Erosion	103,052
Accretion	208,597
Net Difference	105,545
Area III	**Volume (cy)**
Erosion	336,254
Accretion	169,126
Net Difference	-167,128
Corrections for Dredging	
Sailfish Point Maintenance (cy)	25,429
Adjusted Net Difference	-141,699
Total Erosion (cy)	514,508
Total Accretion (cy)	583,345
Total Net Change (cy)	68,837
Adjusted Net Change (cy)	**94,266**

COASTAL PROCESSES ANALYSIS

Analysis of coastal processes in the vicinity of the inlet provided baseline information for future management decisions. Specifically, sediment management within the inlet throat has been a chronic problem for navigation safety and has led to extensive shoreline retreat south of the inlet. The proposed improvements to the inlet are designed to reduce maintenance dredging frequency and to encourage placement of dredged material south (downdrift) of the inlet's "zone of influence". To support inlet management strategies, the following quantitative analysis techniques were performed:

- collection of tide and current information as necessary to alterations to inlet circulation resulting from inlet modifications;

- revise and update existing hydrodynamic and sediment transport models for the inlet (utilizing tide and current information previously collected, as well as updated information developed during this project); and,
- update the inlet sediment budget by utilizing bathymetry data, regional shoreline change information, and developing a wave and wave-induced sediment transport model for the coastal region surrounding St. Lucie Inlet.

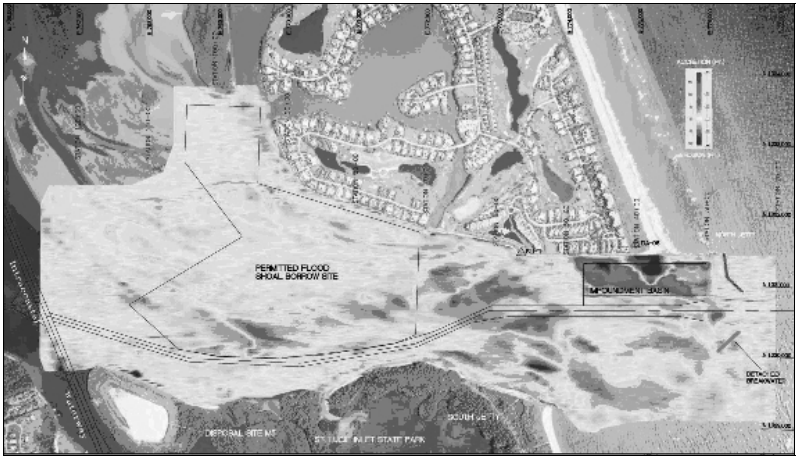

Figure 2. Observed bathymetric change between March 2003 and June 2004. Red areas define regions of accretion and blue areas define regions of erosion.

Modifications to the St. Lucie Inlet jetties and impoundment basin modified both tidal circulation patterns and sediment transport dynamics within the inlet throat. A two-dimensional hydrodynamic and sediment transport model was developed to evaluate the proposed inlet modifications and to provide a predictive tool for determining impacts of future flood shoal dredging events on tidal circulation and/or sediment transport. The sediment transport model was calibrated with available bathymetric change information.

To assess sediment movement within the inlet, it was critical that the volume of material entering the inlet from both Jupiter and Hutchinson Islands is accurately determined. Regional spectral refraction wave modeling and historic shoreline change data were incorporated into the updated calculation of the inlet sediment budget (Applied Coastal 2006). The numerical model results were utilized to alter or "fine-tune" assumptions from previous sediment budget estimates. The analysis was verified with recent bathymetric change information within the St. Lucie Inlet system.

ANALYSIS OF SEDIMENT MOVEMENT

One of the primary goals of the data collection and numerical modeling effort was to update the existing sediment budget for St. Lucie Inlet. The original Inlet Management Plan based the sediment budget on regional beach profile information, inlet dredging

records, and limited bathymetric change data. The present effort relies on much of the same types of information; however, bathymetric change analyses incorporated detailed surveys within the inlet throat and the seaward section of the flood shoal for 2000, 2002, and 2003. In addition, numerical modeling of coastal processes was utilized to determine, as well as verify, different components of the sediment budget.

The initial step in developing an inlet sediment budget is to define the various features comprising the inlet. By evaluating data and modeling/analysis results associated with each of these features, sediment transport pathways and quantities can be constrained within reasonable bounds. St. Lucie Inlet can be defined as a stabilized inlet; however, due to its relatively large size, the inlet exhibits features of an unstabilized inlet. For example, the existing jetty system does not confine the inlet to a narrow self-scouring channel. Instead, the confining cross-section (the smallest inlet cross-section, where tidally-induced velocities typically are highest) exists landward of the north and south jetties. Figure 3 illustrates the features used to define sediment transport pathways within the St. Lucie Inlet system. As shown, a large marginal ebb shoal exists to the south of the navigation channel, extending from approximately 2,000 feet west of the south jetty tip (inclusive of the shoal deposit along the south shore of the inlet immediately seaward of the flood shoal) and terminating seaward of the breakwater. Although the seaward extent of this feature likely is influenced by the existence of the breakwater, this region of sand accumulation is related to ebb shoal formation along the channel margins. For the purposes of this analysis, the flood shoal is defined as the region immediately landward of the most constricted inlet cross-section. Although part of the flood shoal, a region of sediment deposits north of the defined flood shoal in the Indian River lagoon is shown separately. Both the impoundment basin and the outer dredged navigation channel are combined, due primarily to their hydraulic connection and similar water depth.

From a longer-term perspective, sediment management practices have changed since 1993, where material dredged from the inlet is taken out of the local littoral system (either disposed of offshore or deposited in nearshore berms several miles downdrift of the inlet). Therefore, the updated sediment budget analyses does not consider the shoreline south of the inlet to be dominated by significant accretion associated with sand placement, rather the short-term shoreline change rate between 1999 and 2003 indicates a stable or moderately accreting shoreline to the north of where the attachment bar joins the shoreline (Applied Coastal 2006). The coastal management practices have been relatively consistent north of St. Lucie Inlet, the longer-term shoreline change is appropriate to assess beach volume change for the sediment budget analysis. The annual volumes of sediment retained by the beach south of the inlet was determined to be approximately 39,800 cubic yards and the by the beach north of the inlet (fronting Sailfish Point) was 6,200 cubic yards per year.

Numerical modeling of wave induced transport yielded updated gross and net longshore sediment transport rates, as well as ratios between the north and south directed transport which was useful for modifications to the previous assumptions utilized for the previous

sediment budgets (ATM 1995 and Bodge 1999). Results from the spectral wave modeling and longshore sediment transport analysis indicate a reduction in south-directed transport between Bathtub Reef and the north jetty. Protection from offshore waves is afforded by the natural reef system fronting Sailfish Point. South of St. Lucie Inlet, available sediment is controlled by the bypassing efficiency of the inlet; therefore, sediment transport potential only serves as a relative guide to realized longshore sediment transport rates. Since no sediment is available for southerly transport at the south jetty, only north-directed transport is realized at this location. Within the immediate region influenced by the inlet, sediment availability is controlled directly by (a) sediment traveling along the bypass bar and (b) sediment derived from the inlet via the marginal ebb shoal system. In addition, the local wave climate generates significant north-directed sediment transport into the inlet (around the south jetty).

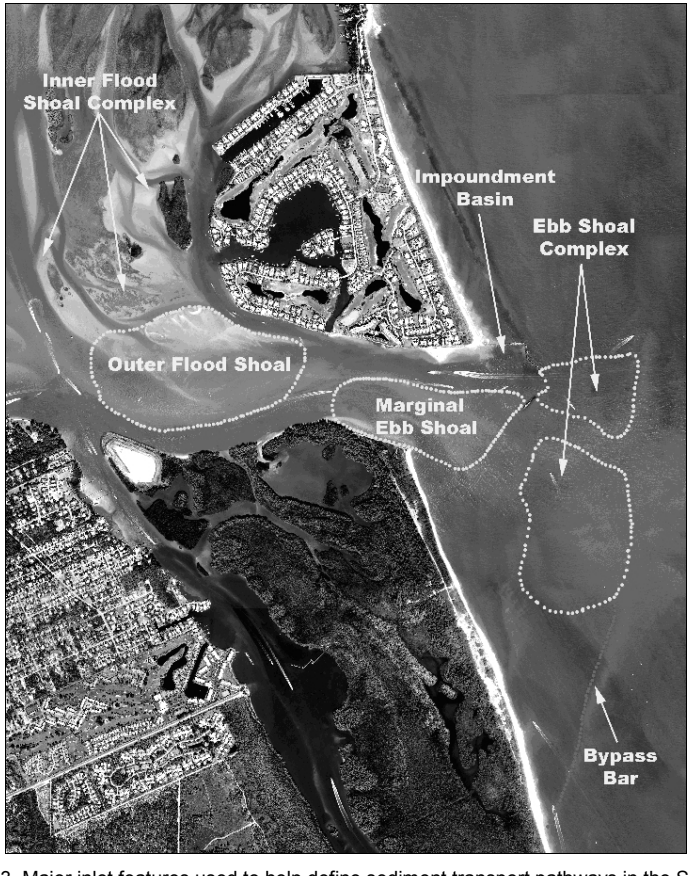

Figure 3. Major inlet features used to help define sediment transport pathways in the St. Lucie Inlet region.

The result of the wave-induced longshore sediment transport analysis is the net south-directed transport at the updrift boundary is approximately 260,000 ± 50,000 cubic yards per year. Modeling also indicated south-directed sediment transport at the north jetty weir section is approximately 150,000 ± 29,000 cubic yards per year (Applied Coastal Research 2006).

Since longshore sediment transport along the south side of St. Lucie Inlet is governed by sediment bypassed across the inlet, likely only the ratios of north and south directed sediment transport are applicable to the sediment budget analysis. At the downdrift boundary the modeled ratio of north-directed to south-directed transport is approximately 1:2. However, it should be noted, the area within the limits of the bypass bar (north of the shore attachment of the bypass bar) is sediment-rich relative to areas further south. This condition is a direct result of the tidal current-induced sediment transport discussed below. Therefore, north-directed transport within this region is more available in the littoral system and the 1:2 ratio of north-directed to south-directed transport likely overestimates the contribution the southerly littoral drift at the downdrift boundary of the sediment budget.

The sediment transport pathways within the St. Lucie Inlet system are strongly influenced by the various structural improvements made since 1929: the north jetty (including the weir section), the breakwater, the impoundment basin, and the south jetty. Based on a review of the inlet bathymetry data and the hydrodynamic modeling results, it is apparent that the controlling inlet cross-section (the smallest cross-section through the inlet throat) is not between the two jetties, but rather about 2,000 feet west of the inlet mouth, near the western limit of the south jetty. Based on the 2004 bathymetric survey, the cross-section between the south jetty tip and the north jetty was approximately 23,340 ft^2 and approximately 22,430 ft^2 at the narrowest section of the inlet. Although this represents only a 4% reduction in inlet cross-section between the two stations, it indicates that sediment accretion is more likely seaward of the restriction during the ebbing portion of the tidal cycle.

In addition to observed changes, the hydrodynamic and sediment transport modeling results provided further insight into sediment transport pathways. The tide elevation signal for the estuary exhibits generally flood-dominant behavior (Applied Coastal 2006), indicating that the estuary tends to be a sediment sink. A more detailed analysis of tidal currents within the main channel and across the marginal ebb shoal reveals overall sediment transport pathways through the throat of the inlet. A simple analogy for typical tidal inlets, similar to St. Lucie Inlet, is that they behave as a “drain” during the flooding portion of the tide cycle and a “jet” during the ebbing portion of the tide cycle. At St. Lucie Inlet, the relatively wide ocean entrance allows water to enter the inlet from a variety of directions including over/through the north jetty, between the breakwater and north jetty, and across the extensive ebb shoals. In general, there is no hydraulically preferred path for water to follow and water velocities across the entire entrance are fairly uniform (similar to a “drain”). After the estuary fills and the tide

begins to ebb, the least restrictive pathway back to the ocean is via the deep navigation channel. This deep channel acts as a "jet", where tidal flow preferentially is directed along this route as indicated by higher velocities in this portion of the inlet during the ebb cycle.

Quantitatively, an analysis of modeled tidal currents through the main navigation channel and across the marginal ebb shoal was used to determine likely sediment transport pathways. Tidal ebb currents through the navigation channel are significantly stronger than flood currents, indicating that the channel tends to export sediment in the direction of the ocean. However, the channel margins exhibit slightly flood-dominant behavior, where the flood velocities are greater than the ebb velocities. For St. Lucie Inlet, currents through the impoundment basin and across the marginal ebb shoal tend to drive sediment into the estuary. A constituent analysis of the tidal currents was used to determine the degree of flood or ebb dominance. Friedrichs and Aubrey (1988) describe this methodology in more detail. The analysis of modeled currents indicated that the navigation channel adjacent to the north jetty weir section is strongly ebb dominant and the marginal ebb shoal exhibits slight flood dominant behavior. Comparison of these results with tidal currents shows excellent agreement, where ebb velocities are higher than flood velocities in the navigation channel and ebb velocities are slightly lower than flood velocities across the ebb shoal. Based on this analysis, general sediment transport pathways were developed between the series of shoals within the inlet throat (shown in Figure 4). Sediment entering the inlet appears to be dominated by material entering the system across the north jetty weir section. Migration of this material along the Sailfish Point shoreline is responsible for annual maintenance dredging requirements for the navigation channels along the northern shoreline. A significant volume of this material also is deposited on the flood shoal, and likely is resuspended, where a portion is deposited within the marginal ebb shoal. In addition, the high ebb currents within the navigation channel transport material from the channel to the ebb shoal. The south-dominated wave-induced transport continually moves ebb shoal deposits to the south and flood dominant currents south of the breakwater drive a portion of this sediment onto the marginal ebb shoal. This analysis of tidal current asymmetries within the outer portion of the inlet indicates a bypassing mechanism across the weir section of the north jetty to the marginal ebb shoal in addition to the traditional bar bypassing driven by the net littoral drift. This significant mode of sediment transport within the inlet throat is unique for inlets along the east coast of Florida, due to the relatively wide entrance that allows formation of significant shoal areas within the inlet constriction.

SEDIMENT BUDGET

The quantitative and qualitative information above was used to develop a comprehensive sediment budget for St. Lucie Inlet. The sediment management practices for the inlet have been modified since assumptions were developed for the previous sediment budget calculations. Primarily, beach compatible sediment dredged from the impoundment basin and channel no longer are placed along the beach immediately south of the south jetty. Sediment basin improvements also altered the sediment transport pathways within the inlet throat. Dredging of the enlarged impoundment basin removed a

significant volume of bedrock along the northern side of the outer inlet navigation channel. This dredging increased tidal exchange along the general route of the navigation channel and caused a slight reduction in the outer flood shoal volume. Although the system continues to equilibrate to this modification in inlet bathymetry, the influence of the new sediment basin geometry represents a long-term shift in sediment transport pathways. The slight increase in tidal exchange and velocities over the existing shoal system likely will cause landward migration of the outer portion of the flood shoal, as well as enhanced accretion of the inner portions of the flood shoal and the marginal ebb shoal.

Figure 4. Generalized sediment transport pathways based upon numerical modeling of tidal currents, southerly-directed littoral drift north of the inlet, and northerly-directed littoral drift south of the inlet. Red arrows represent ebb-dominant transport and green arrows represent either flood-dominant transport or wave-induced sediment transport.

Numerical model results also were utilized to alter or "fine-tune" assumptions from previous sediment budget estimates. Wave modeling provided the driving force for wave-induced sediment transport estimates along the shorelines to the north and south of St. Lucie Inlet. Hydrodynamic and sediment transport modeling within the inlet was performed to quantitatively and qualitatively evaluate sediment transport pathways. By "calibrating" the sediment transport model with available bathymetric change information, as well as evaluating both short- and long-term bathymetric change, a more complete determination of shoaling and erosion rates within the inlet were developed. In addition to the numerical modeling efforts, the full range of bathymetry and shoreline position data sets were reviewed and analyzed for incorporation into the sediment

budget. Improved bathymetric surveys of the flood shoal, marginal ebb shoal, navigation channel, and impoundment basin serve as a baseline for future inlet management decisions.

Figure 5 summarizes the sediment budget analysis results from this study. Along the southern shoreline of Hutchinson Island, sediment transport potential decreases from approximately 260,000 cubic yards per year toward the south at Bathtub Reef to about 150,000 cubic yards per year. It was assumed that littoral drift in this region not accounted for by the reduction in south-directed transport or local beach volume change was bypassed to the ebb shoal system (approximately 129,000 cubic yards per year). Accretion on the ebb shoal east of the north jetty/breakwater system was assumed to be 12,000 cubic yards per year, based on the previous work in the original inlet management plan (ATM, 1995).

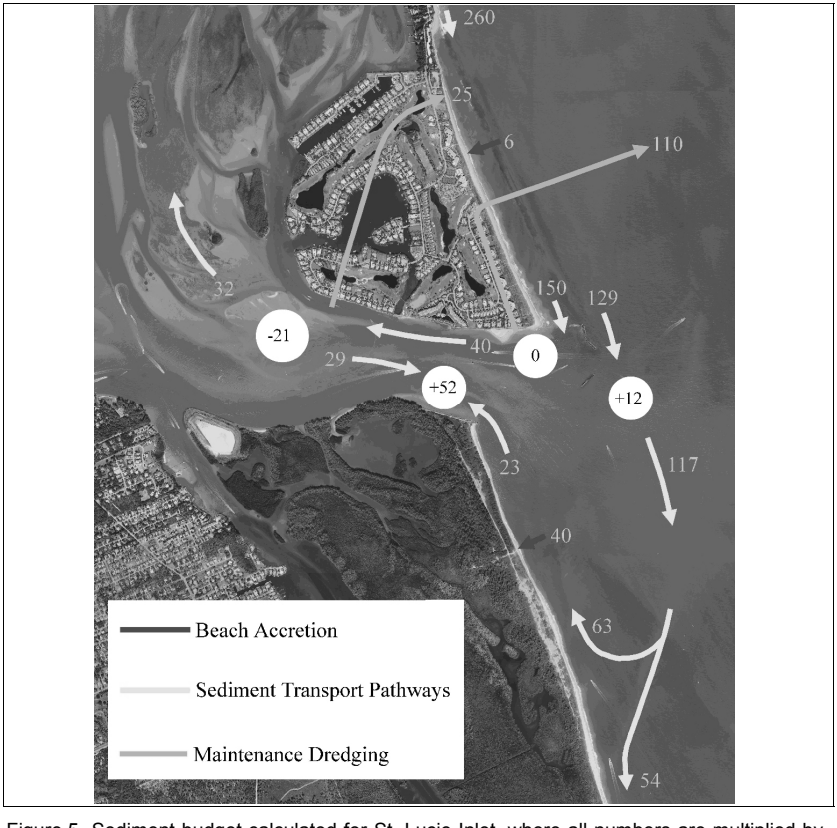

Figure 5. Sediment budget calculated for St. Lucie Inlet, where all numbers are multiplied by 1000 cubic yards per year. White circles represent areas of measure or assumed accretion/erosion.

The remaining 117,000 cubic yards per year was available to the littoral system south of the inlet, including the extensive marginal ebb shoal. As noted previously, the littoral system along the northern portion of Jupiter Island is not sediment-rich; therefore, it likely is inappropriate to use sediment transport potential calculations directly to determine the sediment budget in this region. A more appropriate technique is to utilize ratios of south- to north-directed transport as a guideline. At the shore attachment location of the bypass bar, south-directed sediment transport potential was computed to be 208,700 cubic yards per year. At the south jetty, north-directed transport was computed to be 81,500 cubic yards per year. The computed ratio of north-directed to south-directed transport for this case is 0.39. Since cross-shore transport from the marginal ebb-shoal influences the volume of bypassed material that reaches the beaches in this region, the aforementioned ratio likely is the most defensible. Based on beach accretion and requirements of balancing the sediment budget within the interior portion of the inlet, the south-directed transport at the shore attachment location of the bypass bar was determined to be 54,000 cubic yards per year and north-directed transport at the south jetty was determined to be 23,000 cubic yards per year. The ratio of north-directed to south-directed transport was 0.43, which is nearly identical to the ratio computed from sediment transport potential at these locations.

Within the inlet, the 150,000 cubic yards that enter the impoundment basin and outer navigation channel are distributed between maintenance dredging (recorded to be 110,000 cubic yards annually) and flood shoal accretion (40,000 cubic yards per year). The 110,000 cubic yards of material generated from maintenance dredging historically has been taken outside the region represented by the sediment budget; therefore, Figure 5 represents this “loss” to the system as an offshore directed arrow. The outer flood shoal is eroding at a relatively small rate of approximately 21,000 cubic yards per year, based on surveys between 1996 and 2002. The analysis of sediment transport pathways indicates that much of this eroded material migrates to the marginal ebb shoal region (29,000 cubic yards annually) and the remainder migrates to the inner flood shoal (32,000 cubic yards annually, from ATM, 1995). Only a portion of the recent significant accretion on the marginal ebb shoal can be attributed to the long-term sediment budget. The remainder of the accretion likely was caused directly from the impoundment basin improvements, as described above.

Abstract: The North End Restoration Project uses a regional sediment management approach to address jetty-induced sediment deprivation and accelerated erosion on Assateague Island, Maryland. The biannual sand bypassing project dredges sand from the ebb and flood tidal deltas and places it in the nearshore area of the project site rather than on the upper shoreface, thereby replicating natural sediment transport processes and minimizing adverse impacts to subaerial habitats. Calm weather has prevailed since sand bypassing began, and accretion occurred at all depths within the placement area and at shallow depths to the north and south. Erosion occurred at lower depths and north of the ebb tidal delta attachment bar, which may block sand transport to the northernmost shoreface and where and where wave refraction over the ebb tidal delta and unique tidal circulation patterns contribute to upper shoreface erosion.

INTRODUCTION

Since its construction in 1935, a jetty system at Ocean City Inlet has caused unnatural sediment deprivation on northern Assateague Island, Maryland, thereby accelerating the natural erosion rate and causing associated habitat degradation. Assateague Island was later established as a National Seashore, and because the National Park Service (NPS) is required to reestablish natural functions and processes, NPS partnered with the U.S. Army Corps of Engineers (USACE) to address the ongoing and future effects of the jetties. The North End Restoration Project uses a regional sediment management approach to re-establish an historic, pre-inlet sediment transport to the northern 13.2 km of the island.

The method chosen to restore natural sediment transport processes at Assateague Island is known as sand bypassing, the hydraulic or mechanical movement of sand from an area of accretion to a downdrift area of erosion, across a barrier to natural sand transport such as large-scale jetty structures. Most sand bypassing projects around the world build permanent pumps to move sand across inlets and onto beaches (see Boswood and Murray, 2001 for an extensive list). A less common approach, and the one chosen for Assateague Island, is to use dredge boats to bypass sand to the nearshore or surf zone rather than onto the beach. This method has been successful at several locations including Tweed River, Australia, and Mount Maunganui, New Zealand, where placed sand remained in the nearshore and beach system at least one year later (Foster et al., 1994; Dyson et al., 2002).

The North End Restoration Project at Assateague Island will develop information concerning the effectiveness of restoring natural barrier island processes through the systematic nearshore placement of bypass sand and regular topographic and shoreline surveys over a 25-year period. For the purposes of this study, "surf zone" is defined as the area of breaking waves, and "nearshore" is defined as the subaqueous region extending offshore from the mean high water (MHW) line out to the depths at which waves begin to be significantly altered by the shoaling bathymetry, an area which encompasses the survey depth limit of -10 m (North American Vertical Datum, NAVD88). The biannual sand bypassing project, which began in January 2004, dredges sand from the ebb and flood tidal deltas and places it in the nearshore area of the project site rather than on the upper shoreface, thereby minimizing adverse impacts to subaerial habitats. An additional advantage of this method is a reduction in dredging needed to maintain the inlet navigation channel.

REGIONAL SETTING

Assateague Island is a barrier island that extends 58 km along the coast of Maryland and Virginia (Figure 1). Island width ranges from 300 m to 1200 m, and elevations are generally around 2 m (NAVD88), though dunes may rise up to 10 m high. Its northern end is bounded by Ocean City Inlet, which has an associated flood tidal delta and a large ebb tidal delta that extends both north and south of the inlet, curving to form a 300-meter wide attachment bar that currently meets the shoreline between 650-950 m south of the inlet (Figure 1). The growth of the ebb tidal delta since inlet formation, and its shoreline attachment by 1980, are well documented (Dean and Perlin, 1977; Leatherman, 1984; Underwood and Hiland, 1995; Rosati and Ebersole, 1996; Stauble, 1997; Kraus, 2000). This attachment bar is a significant bathymetric feature in the nearshore, rising 3.5 m above the surrounding seafloor, and steeper on its south flank (1:46 slope) than its north flank (1:180 slope).

The coast is classified as wave-dominated (average height of 1 m) and microtidal (0-2 m tide range) with spring tides fluctuating from -1 m to 3 m relative to mean low water (MLW) (Field 1979). Winter storms and high wave energy create a low, flat beach with sand stored in a nearshore sand bar; summer beach profiles are steeper. Depth of closure, defined as the depth beyond which sediment transport of engineering significance does

not occur (Hallermeier, 1981), is estimated to be -6.2 m NAVD88 (Stauble, 1994) and is typically found about 275 to 400 m from the high tide line. Net alongshore sediment transport is southward due to strong winter northeasters; in the summer, waves from the southeast drive sand transport less vigorously northward. As a result, the net annual alongshore transport is estimated to be between 115,000 and 214,000 m³/yr toward the south (Underwood and Hiland, 1995).

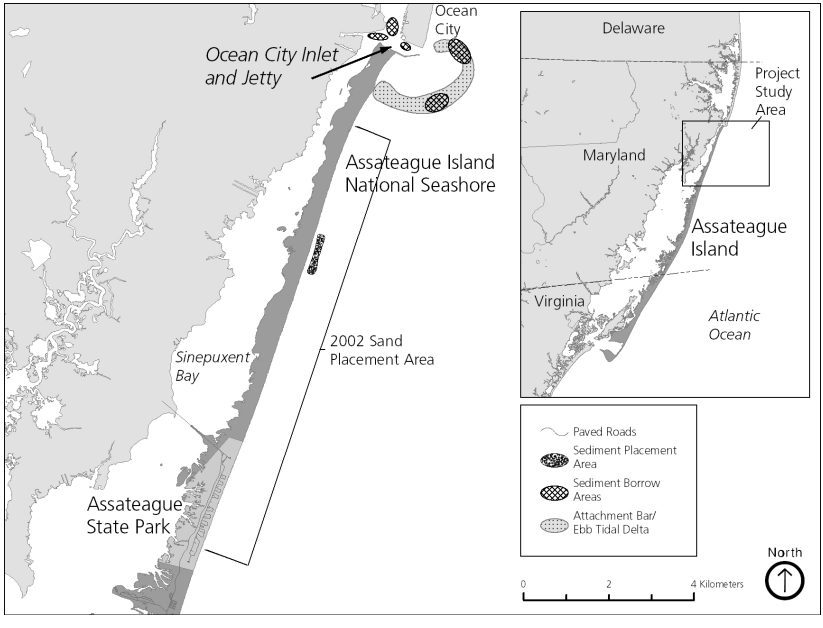

Figure 1. Location of project study area and major sediment features.

The majority of the island is managed as a National Seashore and has little infrastructure along its length, with the exception of the section 10-13.2 km south of the inlet. In that section, a state park constructed high dunes to protect extensive park infrastructure, and maintenance sometimes involves scraping the beach and importing clay to stabilize beach access over the dunes.

North of the state park, most of the northern 10 km of Assateague Island is a dynamic environment composed of a beach and low berm on the ocean side of the island, with a low elevation, sparsely vegetated back barrier flat and a narrow fringing salt marsh with overwash fans along an estuary. This dynamic area is prime habitat for state- and federally-listed endangered species and protects the mainland directly to the west from storm tides and waves.

The northern end of Assateague Island is classified by the U.S. Geological Survey as having 'very high vulnerability' because of its low elevation, frequent overwashing, and high rates of shoreline erosion (Pendleton et al., 2004). This vulnerability is thought to be caused primarily by an interruption in alongshore sediment transport by the jetties built around the Ocean City Inlet in 1935 (Rosati and Ebersole 1996). Along the northern 13.2 km of the island, the shoreline erosion rate more than doubled when the inlet was stabilized, from a pre-inlet rate (1850-1933) of -1.5 m/yr to a post-inlet rate (1942-1997) of -3.70 m/yr.

This increase in shoreline erosion is associated with a volume loss in the active profile (from the beach berm offshore to the depth of closure) that increased after the inlet was stabilized from an estimated 150,000 m^3/yr to 370,000 m^3/yr. Because detailed historical bathymetric data do not exist for this project site, this volumetric loss rate was approximated using a method established by Hanson and Kraus (1989) that integrates the active profile depth, the pre- and post-inlet shoreline change rates, and the assumption that shoreline change is represented as a horizontal and uniform translation of the profile. This assumption and the resulting volume calculations do not include the area north of the attachment bar, where the depth of closure and active berm are quite different from the shoreline directly southward.

North End Restoration Project

USACE predicted that without mitigation, the north end of the island would destabilize and eventually breach during storms in the near future (USACE, 1998). Should this occur, it would have both a significant impact on the values and purpose of Assateague Island National Seashore and serious implications for the adjacent mainland communities, including infrastructure vulnerability, loss of estuarine habitats, and increased maintenance needs for Ocean City Inlet.

To mitigate the loss of natural sand transport processes, local and national government agencies created a comprehensive two-phase restoration plan. The first, short-term phase of the restoration program intended to replace some of the sediment lost since inlet stabilization, estimated to be 9.7 million m^3 in the northernmost 12 km of the island by 1996 (USACE, 1998). During this phase, 1.4 million m^3 of sand was placed just seaward of the mean high water line in September 2002 in an area extending from 2 to 12.5 km south of the inlet (Figure 1).

The second, long-term (25-year) sand management phase is intended to restore sand transport to northern Assateague Island at a pre-inlet rate. The intent of the project is neither to create a fixed-width beach nor to stop erosion, but rather to reduce the erosion rate to the pre-inlet conditions by restoring the sediment transport pathway. Beginning in January 2004, and recurring every early spring and fall, a hopper dredge takes approximately 72,000 m^3 of sand from the ebb and flood tidal deltas (borrow sites delineated in Figure 1) and deposits it just seaward of the surf zone on Assateague Island approximately 2.5 to 5 km south of the inlet (Table 1). Unlike a typical beachfill project in which the material is pumped high on the beach, the bypassed borrow material is

deposited on the crest and just seaward of the nearshore bar, which has an approximate crest elevation of -1.45 m to -1.75 m NAVD88. The loaded hopper dredge, which drafts approximately 2.4 m, enters the placement area perpendicular to the shore until the bow makes contact with the bar. The hopper doors (approximately 30 m long and 7.6 m wide) are then slowly opened. As the material starts to exit the hopper and the load lightens, the vessel attempts to move shoreward to deposit the remaining material as close to shore as possible. The dredge deposits the majority of sand in depths of -1.5 to -5 m (NAVD88) and about 80-250 m from shore (Figure 1). Ideally, because the sediment is placed landward of the depth of closure, waves and alongshore transport processes then move this material onshore, shaping this sand into a natural configuration in the surf zone and on the beach.

Sand is not deposited along the northernmost 2.5 km of the island because USACE hydrodynamic models indicate that within that region, sediment has a localized net northward transport. The net northward transport is apparently caused by wave refraction and wave breaking on the ebb tidal delta and attachment bar (Buttolph et al., 2006).

Table 1. Sources and Volumes of Borrowed Sand Delivered to Assateague Island

Time Period	Borrowed from Inlet and Flood Tidal Delta (m^3)	Borrowed from Northern Ebb Tidal Delta (m^3)	Borrowed from Southern Ebb Tidal Delta (m^3)	Total delivered to Assateague Island (m^3)
Spring 2004 (1/30 – 4/1)	10964	45090	0	56054
Fall 2004 (10/1 – 11/26)	3280	0	66814	70094
Spring 2005 (3/29-4/28)	776	0	24332	25108
Fall 2005 (9/18-11/13)	12374	49386	0	53140*
Total	27394	94476	91146	204396

*8620 m^3 of the total borrowed volume was delivered to Ocean City.

Design studies performed prior to the short-term phase of the restoration project indicated that the native beach sediments in the active profile of the project area had a mean grain size of 0.25 mm and a standard deviation of 0.88 mm (moderately sorted sand), with finer sand seaward of the storm bar (USACE, 2001). Samples collected in 2004 and 2005 from the ebb and flood shoals indicate that the mean diameter of the sediments range from .17 mm to .65 mm, or fine to coarse sand and moderately well to well sorted.

Storm activity during the bypassing phase, from January 2004 through December 2005, was relatively minor, according to observations at the USACE wave and water level

gauge located about 3 km north of the inlet in about 9 meters of water. It is not uncommon for the gauge to record wave heights in excess of 3 meters several times a year, with a maximum wave height of 4.2 meters being recorded during the January 1992 northeaster. In contrast, between January 2004 and December 2005, wave heights exceeded 3 m during only one event. It should be noted, however, that the gauge was inoperable during the first half of 2005.

METHODS

To monitor the effects of the restoration project and the sand permanence, nearshore bathymetric profiles are surveyed annually and shoreline position is mapped quarterly, as described below.

Volume Change

Nearshore bathymetry profiles were surveyed just after the second round of dredging each fall. The profiles extended in an offshore direction from the beach berm out to about -10 m NAVD88. Surveys relied on a towed survey sled and an optical total station and were tied to monuments established along the island. The towed sled surveys have been performed on an irregular time interval since 1986, usually in response to engineering activities or storm events, and have been surveyed annually since 2003 as a part of the North End Restoration Project. The surveys analyzed for this paper were collected November 14-16, 2003, November 7-9, 2004, and November 11-13, 2005. Each survey followed mild frontal passages with minor waves, tides and sediment transport activity, so that the surveys could be performed during the offshore winds and calmer surf zone activity that follow the fronts.

Due to the distance between each of the nearshore profiles, true volume changes cannot be calculated, and were instead approximated using the following method. The change in cross-sectional area at each transect during each year was calculated for four different depth categories:

1. the beach, from 2 m to 0.36 m NAVD88 (MHW);
2. the shallow water, from 0.36 m (MHW) to -3 m NAVD88 (active profile zone);
3. deep water, from -3 m NAVD88 down to the closure depth as observed in graphs of the three surveys at each transect line; and
4. the total area from 2 m NAVD88 down to observed closure depth (varies for each transect).

The observed closure depth varied between transects and did not always extend to the generalized depth of closure for two reasons: not all transect surveys were collected out to the documented depth of closure; and for each transect line, the three surveyed profiles closed (joined at depth with no change in bathymetry on the three survey dates) within the survey area and at a unique depth.

Next, to approximate volume change over the two year period, the average area change of adjacent transects was multiplied by the distance between the two transects to get the approximate volume change between each pair of transects. These approximated

volumes were then summed for a total volume change estimate. This process was used for each depth category.

Shoreline Change

To calculate shoreline change rates, several sources of shoreline positions were used. The seven historic shoreline positions from 1850 to1980 came from various sources, including NOS T-sheets and aerial photographs. Recent high tide shoreline positions, collected from 1994 to the present, were surveyed quarterly at Assateague Island during near-average tidal ranges when the predicted high tides ran close to MHW. The high tide line, as evidenced by the wet/dry line or deposited wrack, was collected with a kinematic differential GPS receiver mounted on an ATV, and was post-processed.

The linear regression rates of shoreline change (LRR) were calculated using DSAS (Thieler et al., 2005), which cast shore-perpendicular transects at 50 m intervals between a user-defined baseline and each shoreline position. It then fit a least-squares regression line to all shoreline points for a particular transect and assigned the slope of the line as the change rate. Negative rates indicate erosion; positive rates indicate accretion. Although this method tends to underestimate the rate of change relative to other statistical methods, such as end point rate (Dolan et al., 1991), it offers the following benefits: all the data are used, regardless of changes in trend or accuracy; the method is purely computational and does not require any other analysis such as error measurements; and it is based on accepted statistical concepts (Thieler et al., 2005).

To examine the patterns in shoreline change related to the restoration project, several eras were selected. The long-term shoreline change rate was calculated for 1850-2005, and the shoreline change related to the long-term restoration phase was calculated from the positions surveyed between February 2004 and December 2005, which was a relatively calm weather period, with recorded wave heights exceeding 3 m (moderate intensity) during only one event. For comparison, shorelines from December 1994 through December 1997 were used to calculate the shoreline change rates for a pre-restoration period with similar weather. During that period, there was relatively little storm activity; wave heights at the gauge reached or just exceeded 3 m on only three occasions.

RESULTS

Nearshore Volume Change

As a whole, the study area experienced net accretion in the first year and erosion in the second year (when less sand was bypassed, Table 1), resulting in a net volume loss (Table 2). In the two-year period, net volume loss occurred at nearly all profile locations, with the exceptions of the attachment bar location, the sand placement location, and the state park (Figure 2A). After two years, the majority (63%) of volume increase lay in two places: within the placement area (96299 m^3) and on the attachment bar (32339 m^3).

Volume changes at each profile and in each depth category varied, with net accretion in the beach and shallow areas and net erosion in deeper areas (Table 2, Figure 2). Despite

the large volume of sand deposited in the nearshore of Assateague Island, and despite a relatively calm period of weather, there was a net volume loss in the active profile of Assateague Island. Most of this loss was at depth.

Table 2. Volume Changes by Depth Category 2003-2005

Depth Category (NAVD88)	2003-2004 (m^3)	2004-2005 (m^3)	2003-2005 (m^3)
Beach (2 to 0.36 m)	135718	-25415	110303
Shallow (0.36 to -3 m)	507596	-127531	380065
Deep (-3 m to deepest)	-628462	-370623	-999085
Total Profile	14852	-523569	-508717

The beach (2 m to 0.36 m NAVD88) accreted some sand the first year and then lost 30% of that volume the second year, resulting in an overall accretion along the 13.2 km study area (Table 2). The majority of this accretion was measured within two sites: the 2.5 km region centered on the sand placement site, and the point at which the attachment bar meets the beach (Figure 2B).

The shallow region (0.36 m to -3 m NAVD88) experienced net accretion over the two years (Table 2, Figure 2C). During the first year of the project, sand accreted at every transect location with one exception: north of the attachment bars (Table 2, Figure 2). During the second year, the shallow region experienced a 30% net loss of this accreted sand along much of the study area. As a result, over two years, the net change at this depth was erosional north of the attachment bar but accretional along most of the shoreline, particularly in and north of the placement area and in the northern section of the state park, where a large bar moved shoreward into shallower water.

At depth (below -3 m NAVD88), sand eroded at every transect location every year, with three exceptions: within the placement area, which gained sand both years; where the attachment bar meets the beach; and at one location within the state park, where a large bar migrated landward, moving into the 'shallow' depth category (Figure 2D). Most (60%) of the sand loss occurred in the first year (Table 2).

The volume of sand bypassed to Assateague during the first year of the project accounts for only 20% of the net volume of sand accreted in the beach and shallow areas that year. Over the two-year study period, the volume gained in the beach and shallow regions accounts for only 41% of the combined volume of bypassed sand and sand lost from the deep water (1.2 million m^3, Tables 1 and 2). The active profile area north of the attachment bar, represented by the northernmost two transects, accounts for a net volume loss of -129891 m^3, or 34% of the net volume loss along the whole study area (11% of the combined bypassed and lost volume).

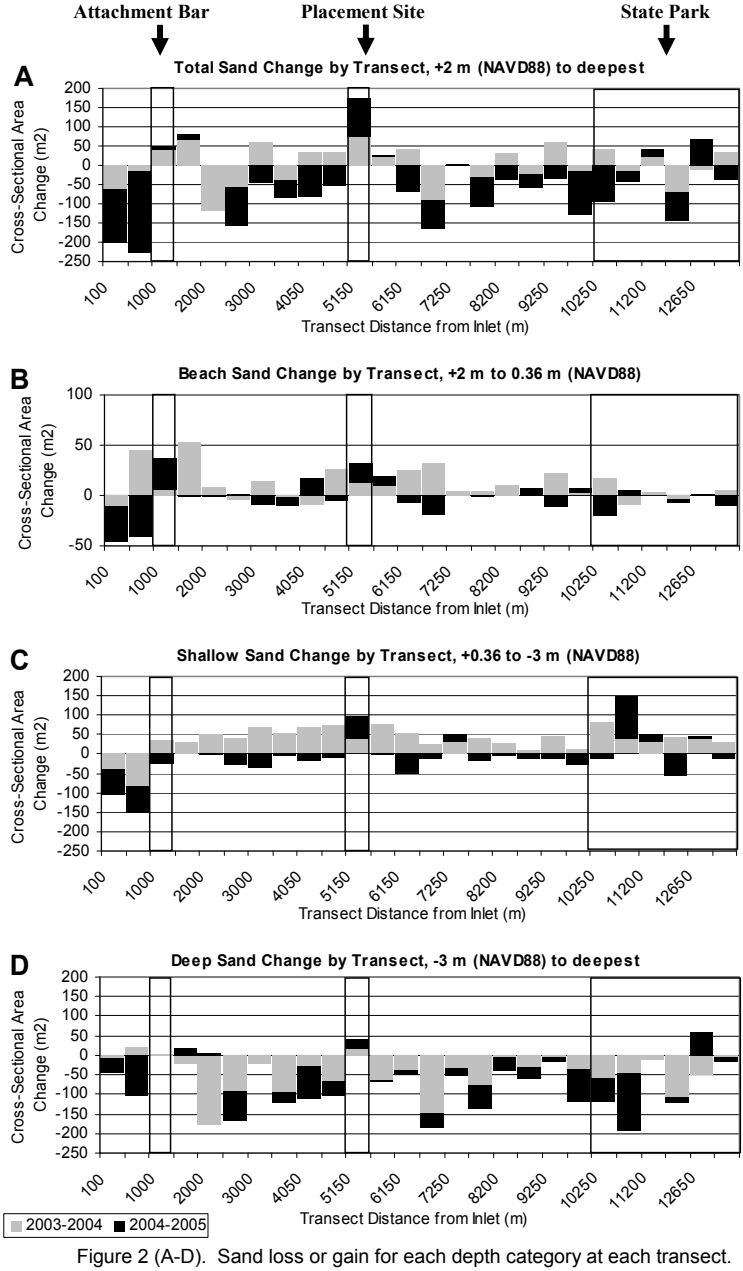

Figure 2 (A-D). Sand loss or gain for each depth category at each transect.

Shoreline Change Rates

The long-term (1850-2005) shoreline change rate in the 13.2 km study area averages -3.25 m/yr (erosion), with a slightly lower erosion rate in the area south of where the attachment bar developed (Table 3, Figure 3). Because the rate is calculated over a longer period of time with fewer shorelines, the standard deviation is lower than for the short-term rates (Table 3).

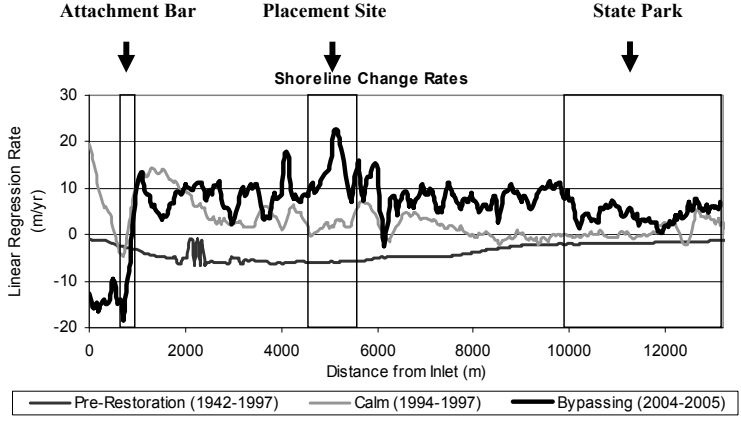

Figure 3. Linear regression rates of shoreline change before and during the long-term restoration project. Positive rates indicate accretion; negative rates indicate erosion.

Table 3. Linear Regression Rates of Shoreline Change by Era

Time Period	LRR (m/yr) in Study Area	Standard Deviation (m/yr)	LRR (m/yr) in Study Area, South of Attachment Bar	Standard Deviation (m/yr)
1850-2005	-3.25	1.96	-3.02	2.01
1994-1997 (calm weather, pre-restoration)	1.87	2.39	1.87	2.39
2004-2005 (calm weather, sand bypassing)	6.22	6.49	7.69	3.82

The tendency of the shoreline to accrete during calm years was evident during a calm-weather period (1994-1997) just before the restoration project began, when the shoreline in the northern 13.2 km study area was stable or accreting along its entire length, with the exception of the area north of the attachment bar, where the shoreline eroded (Figure 3). The two-year study period (February 2004 through December 2005) experienced a similar lack of major storms in addition to sand bypassing, and the accretion rate along the entire 13.2 km study area shoreline was even higher, although erosion quadrupled in

the area north of the attachment bar (Figure 3). In the state park, the shoreline also accreted during the recent period, but at a lower rate (Figure 3).

DISCUSSION

Correlation of Shoreline Change and Volume Change

The alongshore trend of shoreline accretion and erosion over the two-year period reflects the alongshore pattern of sand gain and loss in all depth categories. The volume loss seen north of the attachment bar is reflected in the high shoreline erosion rate there, and the high shoreline accretion rate at the northern end of the placement site is also reflected in the volumetric gain in all depth categories. Appropriately, the shoreline change rate is tied more closely to the alongshore volume changes on the beach than to the changes in other depth categories. The large sand gains in the beach and shallow regions were associated with a high accretion rate along most of the shoreline, particularly in the sand placement area, which had a large net volume increase (96,300 m^3).

Sand Sources and Sinks

Although the processes driving the volumetric changes along Assateague Island are difficult to ascertain based on two years of monitoring data, the likely sources of sand transport are known.

The long-term natural processes of barrier island retreat, which have driven Assateague Island toward the west, likely have continued. These processes include recession of the entire active profile and would account for the continued loss of material seaward of the -3 m contour. The sediment that is lost from the active profiles is being transported in possibly all four directions, along with the bypassed sand that was placed in the nearshore. The lost material probably did not move seaward of what is assumed to be the maximum depth of the active profile. Because the period 2003-2005 lacked major storms, it is assumed that the wave energy was not sufficient to move sand from the beach and shallow areas and into deeper waters; instead, waves would tend to deposit sand onto the beach and shallow areas, a process described by Hoefel and Elgar (2003).

Some of the sand from below the -3 m contour, along with the large amount of sand bypassed to the nearshore, would have been transported onshore by long period waves. This process accounts for the significant gains of sand above the -3 m contour and the associated shoreline accretion. Much (45%) of the sand remained within the nearshore placement area, a tendency documented in a similar project site at Mount Maunganui, New Zealand, where all of the placed sand remained in the placement area one year later (Foster et al., 1994). The retention difference may be attributed in part to the reduced wave energy and larger placement area at the New Zealand site.

Although topographic volume changes were not quantified for this study, it can be assumed that some of the sand carried into the shallow areas may have been carried farther onto the island as overwash fans, which have been measured on Assateague as accreting by 20 to 90 cm in one year (Kochel and Dolan, 1986). Sand may also have blown inland from the lower beach; Leatherman (1976) found that deposition by aeolian

sand transport could dominate even overwash processes, particularly in wide low areas such as the north end of Assateague Island. Likely, some of the bypassed sand was also transported southward from the placement area, along the island and out of the study area, as indicated by the effects in the shallow and beach areas diminishing with distance from the placement site, and by the absence of recognizable effects on the deeper areas (Figure 2). The muted accretion in the state park likely reflects the combination of increased sand supply from the north and the impacts of dune construction and maintenance; beach scraping can result in compaction, altered morphology (slope), and sediment transport (Conaway and Wells, 2005).

Northerly transport toward the inlet and into the ebb shoal complex due to tidal circulation occurs almost continuously and probably in large volumes. The assumption of northward transport is supported by the expectation of northward transport in the absence of storms, the shoreline accretion and volumetric gain on the attachment bar, and the trend of volume loss increasing with distance north of the placement site. The attachment bar appears to have blocked the northward transport of sand, as there was no sand accretion north of the attachment bar. The northward-moving sand likely welded to the bar both within the profile survey area and farther offshore as sand was shunted eastward around the curve and toward the inlet. Some natural accretion at the location where the attachment bar joins the shoreline is typical of tidal inlets (Fenster and Dolan, 1996), but the increased accretion can probably be attributed to the increased sand supply from the south.

The localized tidal circulation pattern contributes to the erosion of the island north of the ebb shoal attachment point. The expansion of the ebb tidal shoal and southward movement of the attachment bar has expanded the reach of erosive tidal currents north of the attachment bar, translating those profiles landward. This erosion was probably exacerbated by jetty tightening in 2002 and 2003, which in reducing jetty permeability also reduced sand transport to the areas adjacent to the jetty and shunts sand further offshore (Buttolph et al., 2006).

Future Work

The two-year period of data used in this paper helps to document sediment transport processes and the evolution of various features of the island. However, the period is far too short to examine long-term or weather-related trends, and is considered anomalously calm compared to typical conditions on Assateague Island. As more storminess occurs, other processes will become evident, such as overall beach erosion throughout the active profile, while other processes will become more pronounced, such as island overwash and both alongshore and cross-shore transport. Continued monitoring of bathymetry and shoreline position over the 25-year project period will shed great insight on the sand bypassing effects, including sand borrow and placement location, the feasibility of restoring natural sediment transport processes, and the effectiveness of restoring natural barrier island processes through nearshore sand placement. A fuller understanding of the project effects will be gained by statistically analyzing the correlation between changes in both shoreline position and sand volume; by including subaerial volumetric changes

driven by wind and overwash; and by comparing the performance of the bypassed sand project to that of the traditional beachfill project at neighboring Ocean City, MD.

CONCLUSION

The reduced erosion of the shoreface in the project site and the increase in shoreline accretion indicate that the sand bypassing project is effective in delivering beach-quality sand to the surf zone and shoreline of the project site. When assessing the effects of nearshore sand bypassing, volumetric changes must be assessed not only along the total depth profile but also within various process-related depths. In the two-year study period, which lacked major storms, the sand spread both north and south of the project area, and accreted only on the beach and at shallow depths. Much of the sand lost at depth is believed to have accreted to the ebb tidal delta and upper shoreface, with significant volume also being transported alongshore and out of the study area.

Abstract: Empirical orthogonal function (EOF) analysis is applied to examine the morphological responses to jetty construction at the first entrance of Lake Saroma, Japan with a 14-year bathymetric survey data set. The result clearly shows that the erosion trend along the channel and the accretions of ebb shoal far offshore appear during and after the jetty construction. Moreover, the volume change around the entrance is investigated, and the result agrees with that from EOF analysis. The entrance was found to be stable in analyzing the relationship between the tidal prism and the cross-sectional area.

INTRODUCTION

There are a few tidal lakes in Japan. Among them, Lake Saroma is famous for the basin size. Lake Saroma has the 3rd largest basin (151.7 km^2) in Japan and is facing the Sea of Okhotsk, located in the northern region. The tidal range at this lake is 1.12

m. The tidal prism is 9.83×10^7 m^3 (Kondo et al. 1988). In the past, an entrance was located at the east end of the lake. The old entrance was opened artificially every spring, and it closed naturally due to the littoral drift during winter. At present, two inlets, which were artificially opened on the eastern side (so-called first entrance) and western side (so-called second entrance), connect the lake to the ocean (Fig. 1). The distance between two entrances is about 13k m. The first entrance was opened in April 1929 and has never closed. And the narrowest width is about 250 m. A jetty began to be constructed at the western side in 1990 and was completed in 1997. The total length of the jetty is 443m. In this study, the morphological characteristics at this entrance are examined. The second entrance was open in 1979and is 50 m wide, which is much smaller than the first entrance. In addition, the bed and sides are protected by concrete and has dual jetties (100 m length). Two large scour holes have subsequently appeared at both the ocean and lake sides; however, the inlet has been stable. Inside the lake, there are many aquacultural work facilities for scallops, oysters and so on, and also serves as a refuge from high waves during stormy weather. Therefore, these inlets are extremely important for fisheries.

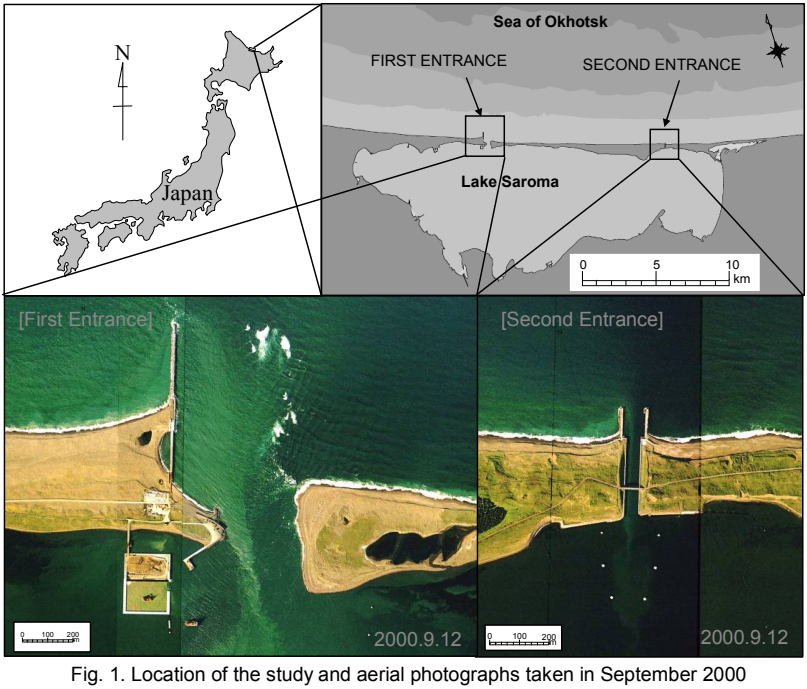

Fig. 1. Location of the study and aerial photographs taken in September 2000

There is one long-term wave observatory in the Sea of Okhotsk; Monbetsuminami. One of the most significant characteristics of this ocean is that the drift ice across the sea stays at the coast from the middle of January to the beginning of April. During

the term, the severe winter waves are prevented from attacking the coast. The observatory is located at about 28 km western from the inlet and the depth is 52.6 m. In this study, the observed result (2001.1.1 through 2004.12.31) is analyzed. From spring to summer, the wave climate is relatively clam and wave incidence toward shore from the east increases. From autumn to winter, the wave energy increases from NE and NNE.

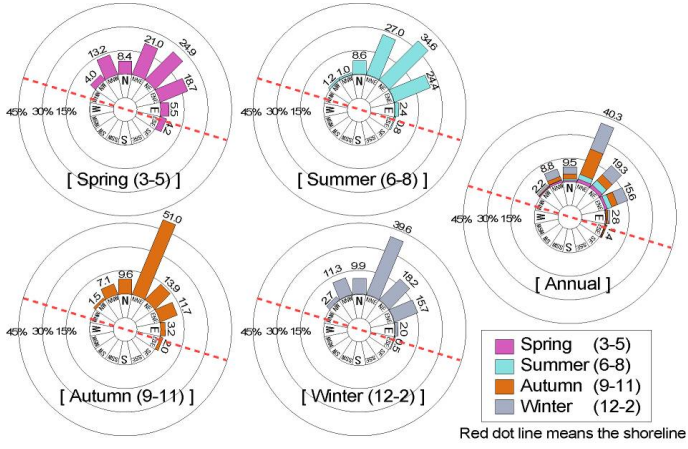

Fig. 2. Wave energy flux ratio for each direction observed at Monbetsuminami

There is no long-term current observatory along the coast. According to Fukushima et al. (1970), the maximum tidal current at the entrance was observed at more than 2.0m/s. A current observation was conducted from September to November in 1999. In this observation, an Acoustic Doppler Current Profiler (ADCP) was used to measure the current velocity at each vertical layer. Fig. 3 shows the measured points and the result at points 2.5 and 8.5m below the surface. The maximum ebb flow was 2.3m/s and the maximum flood flow was 1.7m/s.

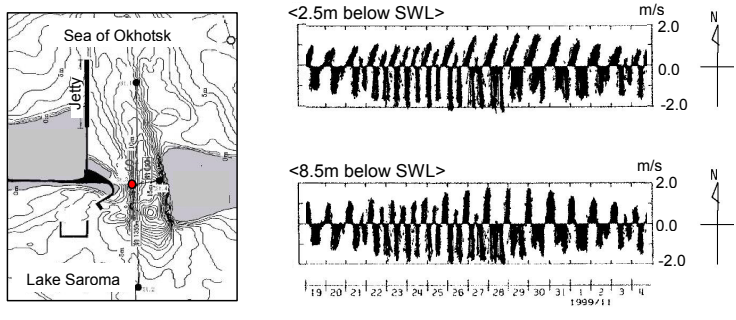

Fig. 3. Location and Result of Current Measurement in 1999

In terms of the longshore sediment transport, some researchers have studied it and made estimates. The predominant direction of longshore sediment transport is reported westward by Kikuchi et al. (1991). On the other hand, Uda et al. (2005) estimated that the longshore sediment transport eastward is dominant, which was investigated from comparison of aerial photographs, which was taken in 1947 and 2001. It is, therefore, difficult to determine the dominant direction and magnitude of longshore sediment transport on this coast.

Kikuchi et al. (1991) summarized the characteristic of grain size around the entrance and the coast. The median grain size at the entrance was very coarse and the maximum grain size was 15.5 mm. On the other hand, sediment around the entrance is comparatively fine. The average median grain size around the shorelines was less than 1.0 mm.

BATHEMETRIC ANALYSIS

Since its opening in 1929, many surveys were conducted at the western inlet. Fig. 4 describes the progress of the bathymetry, influenced by the jetty construction. Before jetty construction, Kikuchi et al. (1991) reported that the characteristic of the morphological changes at the inlet mouth, which is greatly influenced by the tide and wave, was for the channel thalweg to curve to the western offshore. The spit is growing from the east side due to the dominant longshore sediment transport and the tide breaks through the spit and then the channel thalweg made straight toward offshore. After the jetty construction, the channel thalweg has been kept straight toward offshore without curving westward, and the end of the terrace also has moved far offshore.

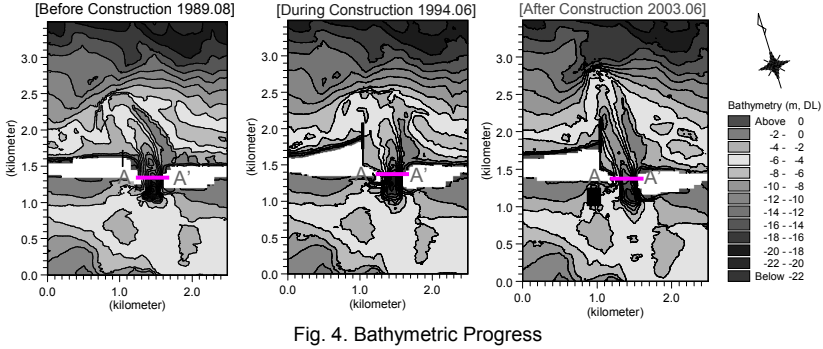

Fig. 4. Bathymetric Progress

When the cross-sectional profiles at A-A' (see Fig. 4) of the inlet-entrance are compared, during the construction of the jetty, the depth increased at the center of the entrance, and the west side has been gradually eroded. After construction was completed, the west side eroded continuously eroded and the depth at the center of the entrance became shallow, because the tidal thalweg have been shifted toward the

west jetty. On the other hand, the spit on the east side has been accumulated. However, the average cross-sectional area has not changed greatly, presumably controlled by the tidal prism of the lake (see Table 1).

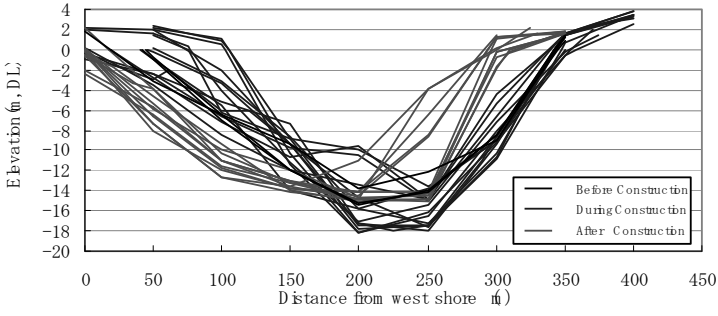

Fig. 5. Cross-sectional profiles at inlet mouth

Table 1. Cross-sectional area at inlet mouth

Time Period	Averaged Cross-sectional Area below DL, m^2
Before Construction (1989-1990)	2700
During Construction (1990-1997)	2720
After Construction (1997-2003)	2800

In consideration of the equilibrium cross-sectional are of this inlet, it is difficult to determine how much area is influenced by each inlet. In this study, the cross-sectional area is supposed to be the same as the sum of the narrowest profiles of both inlets. According to Fig. 6, the total area falls inside at the 95% confidence limits of the trend equation between cross-sectional channel area and the tidal prism (Jarrett 1976). Therefore, the inlet mouth has almost achieved equilibrium.

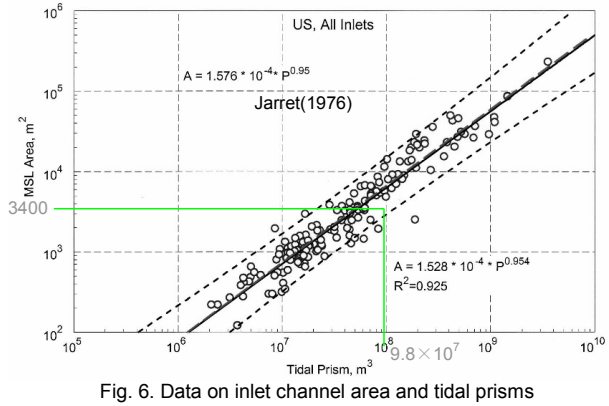

Fig. 6. Data on inlet channel area and tidal prisms

EOF ANALYSIS

Empirical orthogonal function (EOF) analysis, which is also referred to as principal component analysis (PCA), is one of the useful statistic methods to compress complicated variability of three-dimensional bathymetric data either in space and in time into the fewest possible number of modes. This method is widely applied for analyzing the morphologic characteristics (e.g. Katoh et al. 1980; Kuriyama 2002; Uchiyama et al. 2003). This method is basically different from the basic analysis, which includes Fourier analysis, and empirically determine the $e_n\ (x,y)$ and $C_n(t)$ based on the observed three-dimensional data. In this analysis, the observed data is expressed by

$$z(x,y,t) = \sum_n C_n(t) e_n(x,y) \tag{1}$$

where $z(x,y,t)$ = the observed data (m); x = offshore distance (m); y = the alongshore distance (m); $e_n\ (x,y)$ is the variable in space; $C_n(t)$ = the variable in time (m); and the subscript n is the n-th principal components.

In this study, 23 surveys during 14 years are analyzed to investigate the morphological characteristics, because the origin point in the old surveys is not more accurate than those surveyed in recent years. The surveyed area covers a 2.5km alongshore and a 3.5km on-offshore, from the offshore region at the 20m water depth (i.e. D.L.-20.0m) to the lake at about 5m water depth. Here, D.L. is the local datum level and is equivalent to the mean lower low water (MLLW) of the area.
In order to make the influences of jetty construction clear, the observed time period is divided into two intervals; Term A (1990~1997), focused on the construction of the jetty, and Term B (1997~2003), after the construction of the jetty is complete.

Table 2. Variances from EOF analysis

	Term A	Term B
Mode 1	35.3%	53.6%
Mode 2	23.6%	17.0%
Mode 3	10.4%	7.0%

Table 2 shows the variances for each mode. The total sums of the variances are 69.3% in Term A and 77.6 % in Term B. This shows that these three modes seem to mostly describe the morphological change in this area. The results of the first mode are displayed in Fig. 6. In Term A, the C_1 is decreasing constantly for first several years. This means the bathymetric change is constant. In other words, the channel thalweg at the entrance is eroded due to the changed direction of tidal flow straight toward offshore and the ebb shoal is accumulated offshore. After the several years, the constant C_1 means the channel keeps straight toward offshore. Also, the western shore is advanced offshore by the jetty construction. During Term B, the C_1 is decreasing constantly. Regarding to Fig. 7, the jetty construction trains the tidal flow along the jetty and push the sand offshore and right side.

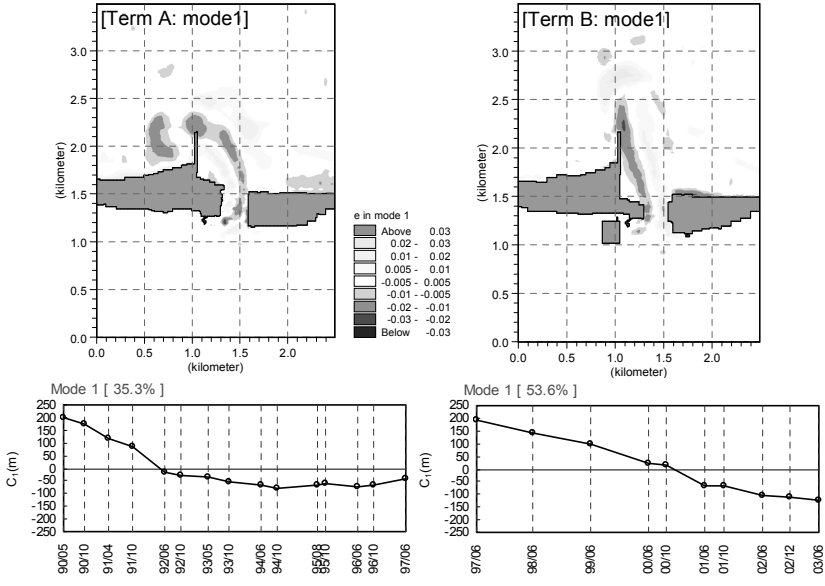

Fig. 7. Result of EOF analysis

VOLUMETRIC ANALYSIS

The surveyed area is divided into 5 sections (A through E) to understand the trend of volume change during and after the jetty construction. Fig. 8 shows the accumulated volume change for each area. The result is summarized by Fig. 9.

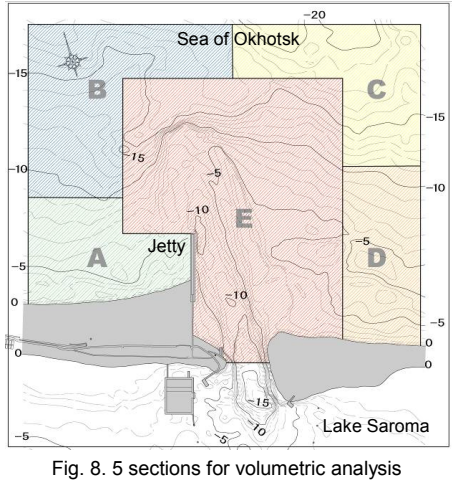

Fig. 8. 5 sections for volumetric analysis

As seen in Fig. 9, during the jetty construction, Section A has an accretion trend gradually and the other sections are almost constant, although they have both erosion and accretion trends. The volumetric change ratio in Section E, however, is greater than the other sections. These trends are clearly shown in the result of EOF analysis. After jetty construction, all sections have an accretionary trend for several years. Especially, Section E accumulates over 1 million m^3. This could be the influence of trapping longshore sediment transport. After several years, Section E starts to be eroded and the other sections seem to be almost stable.

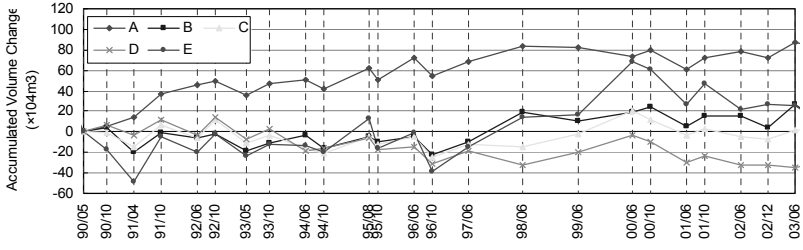

Fig. 9. Accumulated volume change for each section

CONCLUSION

The result of the EOF analysis is in agreement with observed the significant morphological characteristics at the western inlet, Lake Saroma, Japan. The constant erosion in the thalweg and the accretion in the offshore ebb shoal appear to be represented successfully. Also, when the cross-sectional volume is examined, this inlet was found to be stable. Since 2003, at the east side, new jetty construction was also started. In future work, we would like to apply a numerical approach to the morphological change at this site and continue to monitor the morphology influenced by the new jetty.

ACKNOWLEDGEMENTS

We would like to express appreciation to the cooperation and efforts of Abashiri Port and Harbor Office, Hokkaido Regional Development Bureau, Ministry of Land, Infrastructure and Transport, Japan for providing the great number of bathymetric survey data and aerial photographs. We appreciate a critical review of this paper given by Dr. Nicholas C. Kraus, of the U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, and Dr. Hideo Kondo, of Alpha Hydraulic Engineering Consultants Co., Ltd.

Abstract: Different aspects of both the short- and long-term morphological evolution of Texel Inlet, and the underlying processes and mechanisms were studied, ranging from long-term descriptions of historic inlet evolution, 1550 A.D. to present, to detailed analyses of hydrodynamics and morphodynamics on the process scale using the latest state of the art process-based models. It is shown that the morphodynamic evolution of the inlet is governed by human intervention. At present a large sediment import (5-6 Mm^3/year) prevails as a result of a second-stage adaptation process to the effects of Closure of the Zuiderzee in 1932.

INTRODUCTION

Texel inlet, the largest inlet in the Dutch Wadden Sea, has undergone drastic changes in the morphology of its back-barrier basin, ebb-tidal delta and adjacent coastlines after the closure of the Zuiderzee (1926-1932). As a result large sand losses were observed along the adjacent coastlines and still until today the maintenance of this part of the coast is the most intensive of the entire Dutch coast. The processes controlling the sediment exchange between the North-Holland and Texel coasts, the ebb-tidal delta, tidal inlet and back-barrier basin are insufficiently understood despite intensive monitoring and analysis. This paper summarizes the results of a 4-year study aiming to acquire more understanding of this sediment exchange and of the inlet morphodynamics in general. The research covered a wide range of temporal and spatial scales ranging from long-term descriptions of historic inlet evolution, from 1550 A.D. to present, to detailed analyses of hydrodynamics and morphodynamics on a tidal and seasonal process-scale.

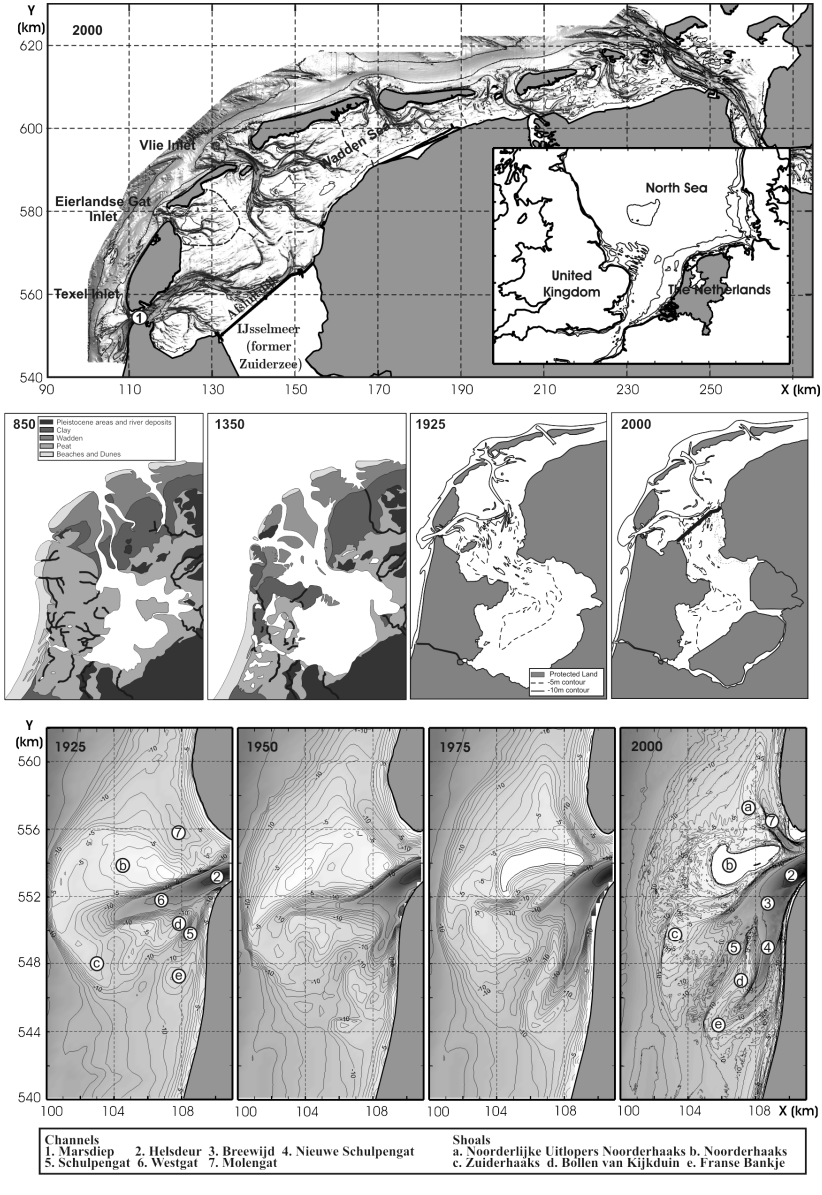

Figure 1: Location map of Texel Inlet in its present form (top panel), development of the inlet and basin through time 850 A.D - 2000 A.D. (middle panels), and evolution of the ebb-tidal delta in detail since closure of the Zuiderzee completed in 1932 (bottom panels).

STUDY AREA

Texel Inlet is the largest tidal inlet of the Dutch Wadden Sea, and is located in the north-western part of The Netherlands between Den Helder and the barrier island of Texel (Fig. 1 top panel). With bathymetric data of the inlet and ebb-tidal delta being available since the 16th century, the inlet is probably the longest regularly monitored inlet worldwide.

Tides and wind-generated waves are the dominant (natural) processes governing the morphological developments. Only a small supply of fresh water through the discharge sluices in the Afsluitdijk is present. Following the classification of Hayes (1979) the inlet qualifies as mixed-energy wave-dominated, even under spring tide conditions. However, the morphology of the inlet shows tide-dominated characteristics such as a large ebb-tidal delta. This is caused by the large tidal prism and the relatively low wave energy.

The inlet gorge is formed by Marsdiep that is about 2.5-km wide with a maximum depth of 53 m. The semi-diurnal tide with a mean tidal range of nearly 1.4 m in Marsdiep produces an average tidal prism through the inlet of $1x10^9$ m^3 with maximum tidal velocities ranging between 1.0 and 2.0 m/s. At present, the ebb-delta shoals protrude approximately 10 km seaward and stretch 25 km alongshore, determining the nearfield bathymetry of the adjacent North-Holland coast in the south and the Texel Island coast in the north (see Fig. 1 bottom panel 2000 for details).

Most of the bed sediment in the basin consists of fine sand with a median grain size around 200 μm. Grain size diameter decreases towards the mainland. Near the inlet sediment diameters over 450 μm are observed locally. On the ebb-tidal delta largest grain diameters (exceeding 450 μm) are observed in the inlet channel and proximal ebb-delta channels. Generally, in seaward direction the grain size decreases towards values between 150 and 200 μm on the shoals and 250 to 350 μm in the distal parts of the channels. The varying bed composition, presence of erosion resistant layers and coastal defence works must have played a role in the present stable state of the ebb-delta (Elias and van der Spek, 2006).

LONGTERM INLET EVOLUTION

To a varying degree of accuracy Texel Inlet's ebb-tidal delta bathymetry has been monitored over the last 400 years forming a globally unique morphodynamic dataset. This series of regular bathymetric observations allows the description of the inlets long-term morphodynamic evolution.

Texel Inlet is believed to have evolved from a small local drainage channel (Fig 1, 850 A.D.) that connected to the inland Zuiderzee around the 12th century A.D. after a series of severe storm events (Fig 1, middle panel 1350 A.D.). The size of the inlet increased with time as a result of subsidence of the surface level due to excavation and drainage of low-lying peat areas bordering the inlet's initial basin for agricultural use. With increasing basin volume the tidal prism through the inlet increased considerably causing the inlet channels to scour and increase in depth and width. Up to c. 1600 A.D. this

natural feedback mechanism of erosion and increasing tidal prisms governed the development of the inlet system. Ever since an increasing impact of major engineering works (e.g. construction of dykes, embankments, coastal protection works in the inlet gorge and recently the damming of the Zuiderzee completed in 1932 (Fig. 1925 and 2000) have governed the morphodynamic behavior and evolution of the system.

The well-monitored changes in ebb-tidal delta morphology, each characterized by specific orientations of the main channels and shoals, clearly show the impact of the inlet modifications and anthropogenic changes in the back-barrier basin (see Elias and van der Spek, 2006 for details). Prior to construction of extensive coastal defense works on the southern shore of the inlet in 1750 A.D. (predecessors of what is now known as Helderse Zeewering) the ebb-tidal delta showed a downdrift asymmetry, while the inlet gorge migrated southward. Periodic shoal breaching and downdrift channel relocation were the dominant mechanisms for sediment bypassing (major shoal bypassing). This period is most representative for the 'natural' behavior. After construction of the coastal defense works, a stable ebb-tidal delta with a westward stretching main ebb-channel developed over a period of c. 60 years. Sediment bypassing took place as minor shoal bypassing; the main channel remained in a westward position and smaller parts of the swash platform (periodically) migrated landward over the ebb-tidal delta to attach to the downdrift Texel coast. See Fig. 1, bottom panel, 1925 for a representative bathymetry for this situation.

The closure of the Zuiderzee (1925-1932) is the largest single intervention ever constructed in the Wadden Sea. Preceding the closure, the Texel and Vlie tidal basins covered the southwestern part of the Wadden Sea and the former Zuiderzee (Fig. 1, middle panel 1925). In total, the basin covered a surface area over 4000 km^2 with a basin length of 130 km. After the closure, the basin area reduced substantially to an area of roughly 712 km^2 (Fig. 1, middle panel 2000) and a length of about 30 km. The closure considerably altered the hydrodynamics and morphodynamics in the remaining active part of the basin (Elias *et al*., 2003 and Elias and Van der Spek 2006). The tidal characteristics changed from predominantly propagating to a more standing tidal wave resulting in an increase of the tidal range and tidal prism through Marsdiep by approximately 26%. With these large changes in hydrodynamics and particularly in basin geometry pronounced changes in the morphology of the inlet have taken place. The closure separated the back part of the basin (Zuiderzee) that contained a relative large portion of shoals. In the remaining active part of the basin the remaining shoals area was too small compared to the channel area, therefore, a morphologic adjustment of the basin was to be expected.

On the ebb-tidal delta a two-stage adaptation is observed. The initial (first-stage) response of the ebb-tidal delta lasted approximately 40 years. In this period the changed tidal characteristics of the basin and increased tidal prisms through the inlet forced an asymmetrical ebb-tidal delta development with updrift (southward) directed main channels (Fig. 1 bottom panels). Over 200 million m^3 of sand was eroded from the ebb-tidal delta and coastlines (due to scouring of channels) and deposited in the basin. The re-orientation of the main channels on the ebb-tidal delta since closure has had large

consequences for the coastal maintenance of the adjacent coasts. Both, the Texel and the North-Holland coastline are still subject to structural erosion and maintenance of these stretches of coast belongs to the most intensive of the entire Dutch coastal system (Mulder, 2000; Roelse, 2002).

The morphodynamic adjustment process is interesting as the observed behaviour of ebb-tidal delta and basin cannot be described by generally accepted empirical relations. For example, an increase in tidal prism through Marsdiep was observed despite the apparent reduction of basin area after closure. This increase is related to the changes in tidal wave characteristics from a propagating to a more standing wave character, and amplification of the tide due to reflection at the closure dam (Elias *et al.* 2003). A second interesting aspect is the decrease in ebb-delta volume. According to the empirical relation of Walton and Adams (1976) the volume of sand confined in the ebb-tidal delta (V_0) relates to the tidal prism magnitude (P) and an empirical constant ($V_O = cP^{1.23}$). With the 26% increase in tidal prism magnitude after closure an increase in ebb-delta volume was expected. In reality large sand losses were observed. One of the main reasons for these discrepancy between observed and based on empirical relations expected behaviour is the dominant effect of the human interventions. The well-monitored large-scale changes on the ebb-tidal delta, which were initiated by the construction of the coastal defence works and closure of the Zuiderzee, show that in-corporation of inlet modifications and back-barrier processes is vital for a correct description of the ebb-tidal delta dynamics and processes of Texel Inlet (Elias and van der Spek, 2006).

SEDIMENT BUDGET SINCE CLOSURE OF THE ZUIDERZEE

The sediment import into the Wadden-Sea was identified as one of the major sources of sand loss in the Dutch coastal sand balance (Stive and Eysink, 1989; Mulder, 2000). Partly, this sediment import is related to relative sea-level rise (Louters and Gerritsen, 1994), and partly import relates to the infilling of closed of channels after the damming of the Zuiderzee (Elias *et al.*, 2003; Elias, 2006). Previous studies agreed on the net sediment influx into the basin since the Zuiderzee damming, but estimates of the present import rates and predictions on future evolution varied between 0 - 3 Mm^3/year.

A major reason for this large variation in import rates is that these studies assumed that the individual inlets in the Wadden Sea can be defined as 'more or less' unconnected sub-systems separated by tidal divides. In principal basin and ebb-delta form a coherent morphological system and the volume change of ebb delta and basin are related; if the ebb-tidal delta erodes a corresponding rate of sedimentation in the basin is expected. Comparing the sediment volume change of Texel and Vlie basin and ebb-tidal delta in detail (upper plots of Fig. 2) we can observe a clear imbalance between ebb-tidal delta and basin changes on individual inlet level; the Texel ebb-tidal delta looses nearly 100 Mm^3 of sediments, while the basin volume remains near constant. A similar but opposite discrepancy is observed in the Vlie inlet system. An important conclusion from the individual sand balances is that we cannot describe the sediment budgets of the inlets separately.

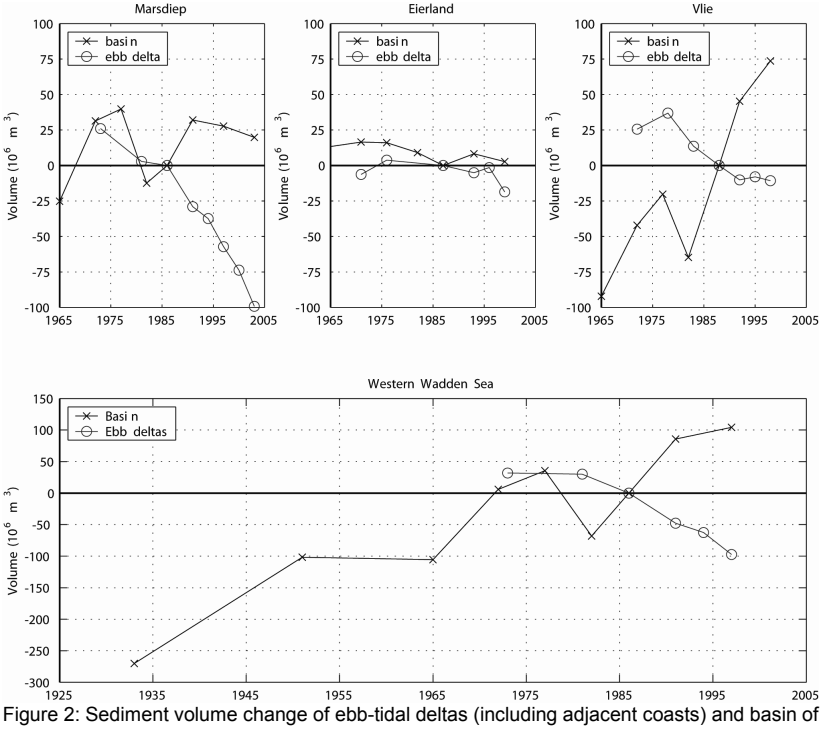

Figure 2: Sediment volume change of ebb-tidal deltas (including adjacent coasts) and basin of the western Wadden Sea. Upper plots: sediment budgets on inlet level over the period 1965 - 2003, lower plot: sediment budget for Texel, Vlie and Eierlandse Gat inlet combined (1927-1997). All plots relative to the 1986 volume.

The sediment budget of the entire western Wadden Sea (Texel, Vlie and Eierlandse Gat inlet combined) shows a near 400 Mm^3 of sediment deposition in the basin over the period 1927 – 1997 (Fig 2). The relative large fluctuations between 1950 and 1986 possibly relate to 18.5 year tidal modulations, or an indication of the measuring accuracy. The recent sediment import (1986 to present) ranges between 9 to 10 Mm^3/year of which most of the sediments, 5-6 Mm^3/year, are supplied by Texel inlet.

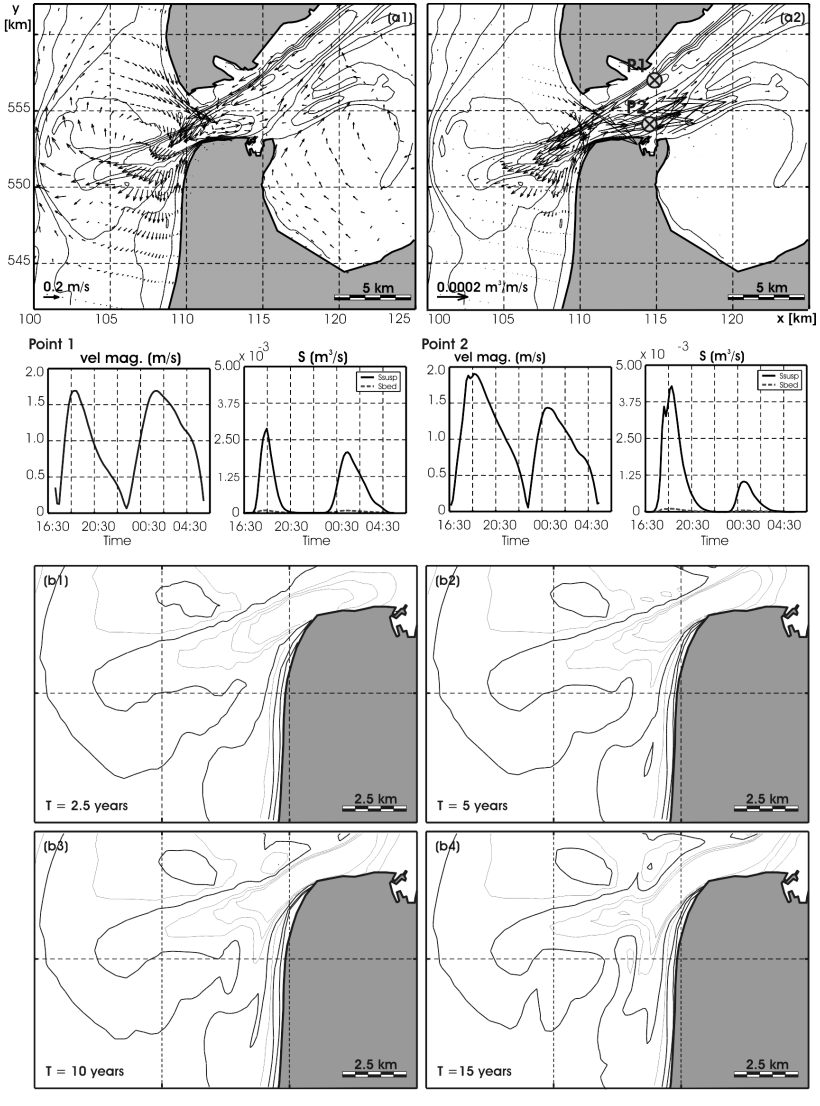

Figure 3 (a1 and a2): Delft3D Online morphology representation of residual flow and transport vector fields for the 1933 situation (directly after closure, before morphodynamic updating), (point 1 and 2) selected time-series for modeled flow and transport magnitude in point 1 and 2 during spring tide conditions, (b1 – b4) modeled development of a two-channel system on the ebb-tidal delta after 2.5, 5, 10 and 20 years of simulation (tidal forcing only).

INITIAL RESPONSE OF TEXEL INLET TO CLOSURE OF THE ZUIDER SEA

Elias and Van der Spek (2006) conclude that during the adaptation stage following the engineering works the large changes in the ebb-delta morphology cannot be described in terms of natural hydrodynamic processes such as the ratio of wave versus tidal energy alone. Moreover, these authors hypothesize that the morphodynamic ebb-tidal delta evolution after closure was triggered by the changed hydrodynamics in the basin. The altered tidal characteristics, the northward displacement of the basin centre, the closing of southward channels and the amplified tidal prism increased the discharges through Texelstroom. Texelstroom determines the ebb outflow into the inlet gorge that re-orientated resulting in a more southward-directed outflow onto the ebb-tidal delta. The expression back-barrier steering was introduced to describe this 'forcing' induced by the basin on the ebb-tidal delta.

Short-term hydrodynamic and morphodynamic process-based simulations (using Delft3D Online Morphology) were used to explore the importance of the main tidal asymmetries for the large sediment influx in the basin (not shown here), and the back-barrier steering mechanism (see Elias et al 2005 and Elias 2006 for details). Back-barrier steering is investigated by running the flow model for a 1-month period under tidal forcing using the buildin Van Rijn 1993 sediment transport solver (Lesser *et al.*, 2004). The tide-averaged flow and sediment transport patterns presented in Fig. 3 summarize the main model results. An interesting characteristic is the imbalance between the location of the largest residual flow and transports, and the position of the main channels (Fig. 3 a1 and a2). The main channel orientation is westward, whereas largest instantaneous and residual flow velocities and transports are directed southwestward towards Schulpengat. Major gradients in residual transport rates are observed at the locations where Molengat and Nieuwe-Schulpengat developed (erosion) and in Westgat (sedimentation). This inequality between flow and bathymetry, directly after closure before morphological updating, is interpreted as a manifestation of the back-barrier steering effect. With ongoing morphological adaptation of the bathymetry, filling in of Westgat and the scouring of Schulpengat and Molengat, the imbalance between transports and bathymetry and the residual transport rates decrease. The sediment influx is dominated by the large flood-dominant transports along the North-Holland coastline (point 2) that exceed the minor ebb transports along the Texel coastline (point 1). The suspended-load component dominates over the bed-load.

A model forced by tides only is capable of reproducing the major developments on the southern part of the ebb-delta (although time scales differ). Nieuwe Schulpengat enlarges and extends along the North-Holland coastline. Similarly to the observations first an ebb-chute develops along the coastline (Fig. 3 b3) that gradually increases in depth and length forming the main ebb channel. After 15 years of simulation (Fig. 3 b4) a two-channel system arises separated by a linear shoal (similar to the 1975 in the observations). The formation of the two-channel system is due to the segregation of ebb and flood flow. Ebb currents dominate the main channel and form a hydrodynamic obstacle for the flood currents. Flood currents are pushed seaward along the ebb-shield front. Already Van Veen (1950) showed the formation of separate ebb and flood channels separated by

shoals due to the evasive action of the ebb and flood flow. Although the scouring of the channels in the southern part of the ebb-delta is predicted, the landward migration and deformation of Noorderhaaks is not reproduced. This deficit indicates that Noorderhaaks developments are dominated by wave-driven processes that are not included in the present model.

SECOND-STAGE EFFECTS ON INLET MORPHODYNAMICS

With ongoing adaptation of the channels on the ebb-tidal delta a decrease in sediment import rates was expected. However no decrease can be observed by looking at the sediment budget (Fig. 2). The ongoing sediment re-deposition from the ebb-tidal delta into the basin is interpreted as a second-stage response to the effects of closure of the Zuiderzee. The majority of the Noorderhaaks deposits originate from the pre-closure ebb-tidal delta configuration wherein the main-ebb channel (Westgat) was westward orientated. Noorderhaaks was formed as an ebb shield balancing seaward supply of sediment by the ebb-tidal currents and landward wave-driven transports (Elias *et al.*, 2003). The closure of the Zuiderzee distorted this balance as the changed tidal characteristics of the basin forced an asymmetrical ebb-tidal delta development with updrift directed main channels (Fig. 1 bottom panels). This initial (first-stage) response lasted approximately 40 years, and the scouring of the large tidal channels eroded over 200 Mm^3 from the ebb-tidal delta. Due to the large tidal prism and corresponding large tidal transports involved, the channels regained an equilibrium state in a faster rate than the shoal areas (e.g. the abandoned ebb-shield Noorderhaaks). The present ebb-tidal delta development is dictated by the ongoing adjustment of these shoal areas.

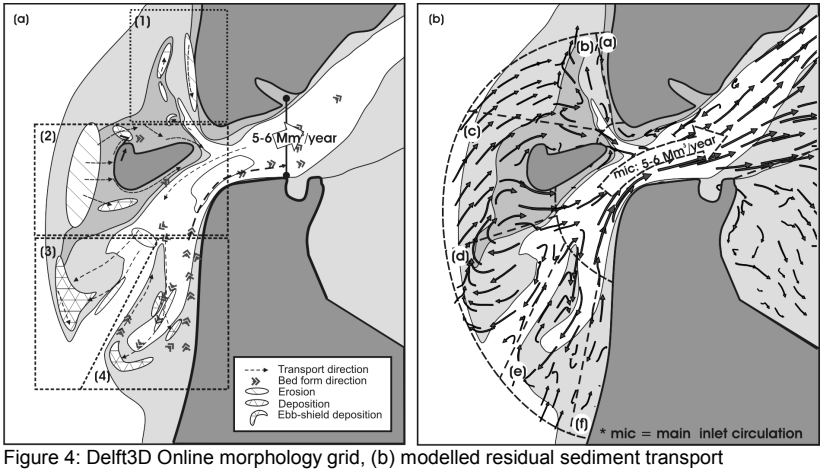

Figure 4: Delft3D Online morphology grid, (b) modelled residual sediment transport

Insight in the present-day behaviour of the Texel inlet system is obtained by focusing the analysis on recent measurements (1986-2003) that were obtained accurately, after stabilization of the channels on the ebb-tidal delta. A schematic depiction of the present-day flow and sediment transport patterns on the ebb-tidal delta based on the analysis of

recent measurements on flow, bedforms, sedimentary structures and sedimentation-erosion patterns is presented in Fig. 4a (based on Elias, 2006).

Despite a relative stability in the shape and form of the main channel and shoal areas on the ebb-tidal delta over the period 1986-2003 there are large morphological changes. Analysis of the sedimentation-erosion patterns shows that sediment redistribution, and local interaction between channels and shoals dictate the present morphological developments. In the north the landward migration of the Noorderlijke Uitlopers of Noorderhaaks and the corresponding displacement of Molengat induce severe erosion of the Texel coastline (Fig. 5, area 1). The central part of the ebb-tidal delta is dominated by landward displacement of sediments; erosion of the western margin of Noorderhaaks and deposition north and south of the supra-tidal part of Noorderhaaks (area 2). The channels Schulpengat and Nieuwe Schulpengat enlarge in depth. In the south we distinguish two areas, separated by Schulpengat, with dissimilar morphological behaviour; Zuiderhaaks (area 3) forms the spill-over lobe of the Nieuwe Lands Diep and Schulpengat channel showing a trend of sedimentation and southward growth. The Nieuwe Schulpengat area (4) is governed by the local interaction of the channel with the adjacent shoals. The Bollen van Kijkduin shoal migrates southward, inducing a small southward displacement and clock-wise rotation of Nieuwe Schulpengat and land-ward migration of the adjacent Franse Bankje shoal. Slip-face asymmetries of the dominant bedforms, derived from analysis of high-resolution multi-beam data, indicate that large flood dominant transports along the North-Holland coast into Marsdiep and towards Texelstroom prevail. The total sedimentation of the ebb-tidal delta is small compared to the erosion volume. As also the adjacent coastlines lose sediment a net sediment transport towards the basin must exist.

Delft3D Online morphology is used to identify the relevance of the governing processes and mechanisms, and to obtain insight in the physics behind the observed morphodynamic changes. The Delft3D Online Morphology model calculates morphologic changes simultaneously with the flow calculations (Fig. 5a shows the model grid). One of the major assets of this type of model is the capability to increase the spatial and temporal resolution of point-oriented field observations. Observations are used to force the model as realistically as possible (quasi real-time by measured time-series of wind, waves and tides) and the model results provide synoptic more or less realistic data of high spatial and temporal resolution over the entire inlet domain. Analysis of this data can provide valuable information on governing flow and sediment transport patterns in the instrumented and the uninstrumented areas. Additionally, such model approach allows for identification of the dominant processes systematically checking mechanisms by varying the forcing conditions. As a first step we modeled tidal transport patterns in order to understand the tidal rectification by interaction of the alongshore, northward, propagating open-sea tidal wave with the cross-shore inlet currents and compound ebb-delta bathymetry (Fig. 5c3). Interaction of tides with ebb-delta topography is known to result in compound flow patterns with local circulation patterns and complex morphodynamic behavior. Next we focused on the morphodynamic behavior by analysis of sediment transport patterns, month-averaged transport magnitudes and governing mechanisms. Here, we present example patterns on ebb-delta scale only.

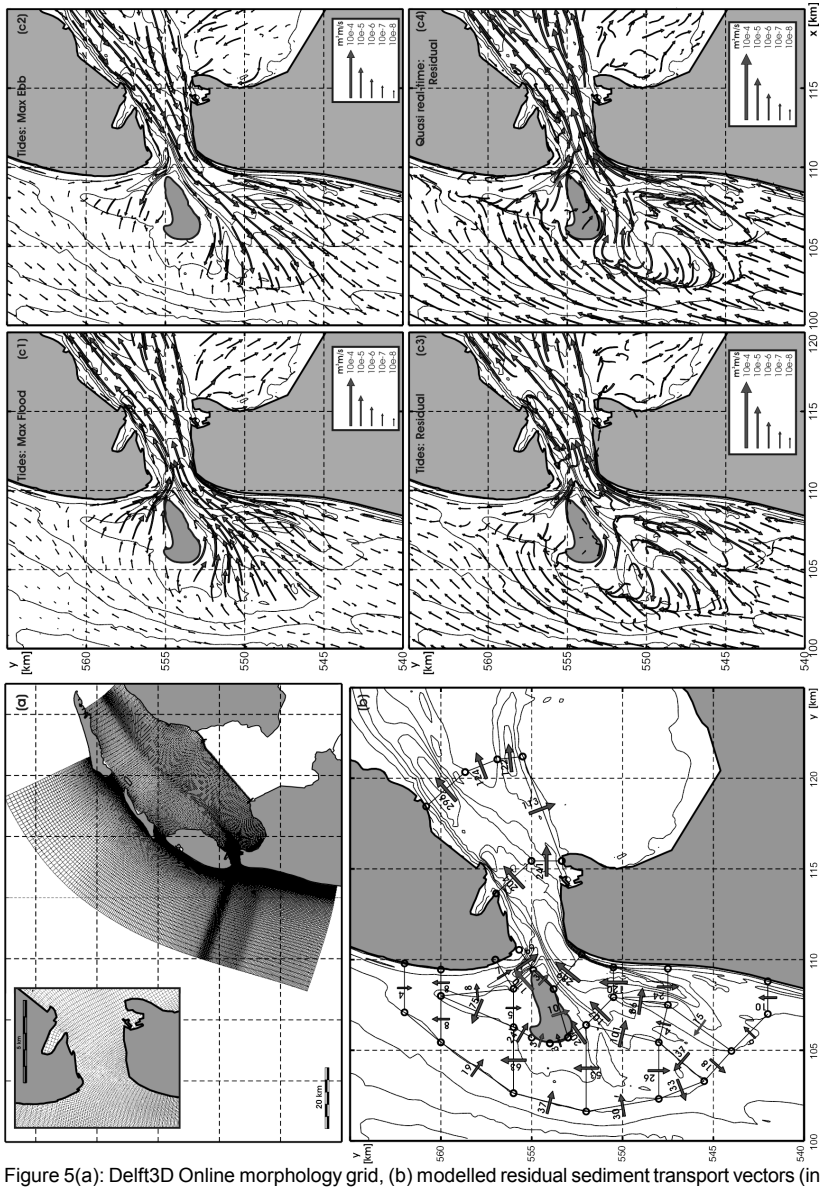

Figure 5(a): Delft3D Online morphology grid, (b) modelled residual sediment transport vectors (in 0.01 Mm3/year) over a 10-month period through a number of selected transects, sediment transport patterns for maximum flood and ebb (c1 and c2), tide-averaged sediment transport patterns for tidal and quasi real-time forcing (c3 and c4).

Figure 5 provides impressions of the modeled sediment transport patterns and transport magnitudes. Outside the ebb-delta domain (roughly bounded by the -15m depth contour) instantaneous and residual sediment transport rates are small compared to the large transports in the inlet channels. The qualitative correspondence in residual transport patterns between tidal and quasi real-time forcing in the southern part of the ebb-delta (Fig. 5c and 5d respectively) illustrates that the interaction of the inlet currents with the compound ebb-delta topography forms the principal mechanism for sediment transports. Due to the non-linearity between flow and transport the major contribution to the residual transport pattern occurs around maximum ebb and flood. During ebb the majority of the transports is flushed seaward onto the southern part of the ebb-delta (Fig. 5c2). Sediment transports through Nieuwe Schulpengat contribute to the accumulation of sand in the Bollen van Kijkduin and Franse Bankje shoals. Transports through Schulpengat and Nieuwe Westgat induce the outbuilding of Zuiderhaaks. Ebb-tidal transports on the western margin of the ebb-delta are minor due to the sheltering effect of Noorderhaaks. Flood transports enter the ebb-delta from the south increasing substantially towards the inlet gorge (Fig. 5c1) due to accelerated velocities. Near Helsdeur transports are further increased due to contraction of flow around the sharp curvature of Helderse Zeewering. As a result in the proximal part of the ebb-delta the flood flow and transports exceed the ebb resulting in a net import of sediment (Fig 5c3). Addition of non-tidal processes (mainly set-up in the inlet gorge) enhances the sediment import rates (Fig 5c4).

Despite relative small residual velocities (compared to the channels) the tidal transports on the western margin of Noorderhaaks show a distinct northward and landward direction. Waves augment these transports. The large shoal complex forms a wide 'surf-zone' area as the location of wave-breaking varies over this domain depending on wave-heigth; large waves lose their energy well ofshore on the ebb-delta front, while smaller waves can propagate relatively undisturbed to the major shoal areas. Similar to normal surfzone processes such as observed along the uninterrupted Holland coast loss of momentum and dissipation of wave energy due to wave-breaking become dominant contributors to the sediment transport The non-tidal mechanisms enhance the landward and northward transport of sediment on the Noorderlijke Uitlopers of Noorderhaaks. Most of the sediments supplied to the northern part of the ebb-delta are transported back into the main inlet circulation along the northern margins of the supra-tidal part of Noorderhaaks, through the Molengat channel, and into Marsdiep. As a result of this circuitous route only little sand actually bypasses the inlet onto the downdrift Texel coastline. Sediment bypassing mechanism at Texel inlet is probably more of an episodic phenomenon; sand accumulates in the downdrift Noorderlijke Uitlopers of the Noorderhaaks spit that eventually will breach and attach to the downdrift shoreline. Figure 4b summarizes the model results (Elias, 2006).

Analysis of monthly-averaged transport rates in Marsdiep indicates that sediment import into the basin is a more-or-less continuous process wherein both tidal and non-tidal contributions play an important role. The non-tidal part consists of near equal but opposite directed wind- and wave-driven contributions, and a larger input by set-up. Most of the sediments are supplied through the southern part of the ebb-delta. Tide and

wave-driven transports along the southern margin of the supra-tidal Noorderhaaks and setup driven contributions through Nieuwe Schulpengat form the major part. A minor part is supplied by the tide-driven sediment transports through Molengat.

CONCLUSIONS

The morphodynamics of Texel Inlet are studied over a wide range of temporal scales, ranging from long-term descriptions of historic inlet evolution, 1550 A.D. to present, to detailed analyses of hydrodynamics and morphodynamics on the tidal and seasonal process scale. A range of methodologies, varying from morphological interpretation of maps to understand long-term morphological developments and behaviour, to numerical process-based modelling and detailed analysis of field measurements to obtain fundamental knowledge of inlet processes was applied.

Over 400 years of regular bathymetric surveys of Texel Inlet and its ebb-tidal delta form a globally unique morphodynamic dataset. During the inlet's recorded history substantial changes in ebb-tidal delta evolution have occurred under the influence of the cumulative effects of human intervention. After construction of the coastal defence works in the inlet gorge (Helderse Zeewering) a stable ebb-tidal delta with a westward stretching main ebb-channel developed over a period of c. 60 years. Damming of the Zuiderzee, completed in 1932 A.D., separated the major part of the back-barrier basin and distorted this stable state; a two-stage adaptation of the ebb-tidal delta is observed. The initial (first-stage) response of the ebb-tidal delta lasted approximately 40 years. In this period the changed tidal characteristics of the basin and increased tidal prisms through the inlet forced an asymmetrical ebb-tidal delta development with updrift (southward) directed main channels. Over 200 million m^3 of sand was eroded from the ebb-tidal delta and coastlines (due to scouring of channels) and deposited in the basin. Tides are identified as the main process for these first-stage developments. Due to the large tidal prism and the corresponding large tidal transports involved, the channels regained equilibrium at a faster rate than the shoal areas (e.g. the abandoned ebb-shield Noorderhaaks).

The present-day ebb-tidal delta development is best described as a second-stage self-organizing process of sediment redistribution, sediment recirculation and sediment exchange to obtain a natural equilibrium state adapted to the changed configuration of the main-ebb channels. Sediment is eroded from the ebb-delta (including adjacent shorelines) and deposited in the basin. Largest erosion prevails on the western margin of Noorderhaaks were tides and waves are important for the landward displacement of sediments. Locally, sedimentation and erosion patterns are governed by channel-shoal interactions; the interaction of the channels Molengat and Noorderlijke Uitlopers of Noorderhaaks induces sediment loss of the Texel coastline, while the Nieuwe Schulpengat-Bollen van Kijkduin channel-shoal-system determines the development of the adjacent North-Holland coast. The presence of large flood-dominant channels along the coast induces a major sediment loss towards the basin. The sediment import in the basin through Marsdiep is estimated to range at 5 to 6 Mm^3/year. A number of aspects contribute to this large influx; (1) sediment deficit in the basin caused by the loss of intertidal shoal areas due to closure of the Zuiderzee and relative sea-level rise, (2)

availability of a vast amount of sediment in the abandoned ebb-delta front Noorderhaaks, and (3) transport capacity due to the large tidal prisms through the inlet.

The large ongoing sediment import into the basin shows that the effects of closure of the Zuiderzee are far from damped out, and it will take many decades before a new equilibrium will be reached.

Abstract: The shoaling rate in Blind Pass entrance channel approximately equals the net southward longshore sediment transport rate. Most of the shoaling occurs along the northern side of the channel. Flow measurements and numerical modeling reveal that the ebb current is approximately twice as strong in the thalweg along the south side as compared to the rest of the channel. In contrast, the flood current is mainly uniform across the inlet and is stronger than the ebb flow over the northern portion. This flow-velocity distribution induced by a nearly 90-deg bend of the channel contributes to the shoaling pattern. Two years after the 2000 dredging, the shoal along the north side became shallow enough to induce wave breaking. Distinctive shoaling patterns influenced by seasonal wave climate were observed. Sediment deposition in the channel is closely related to the passages of cold fronts, which significantly increases the sediment supply by longshore transport.

INTRODUCTION

Tidal inlets are links between the coastal ocean and back-barrier bays, exchanging water, sediments, nutrients, and pollutants between them. Many inlets also serve as navigation channels. Because tidal inlets interrupt the continuity of shore processes, they often influence the sediment budgets and can cause beach erosion. Dean (1988) concluded that more than 80% of the erosion along the Florida coast can be directly linked to tidal inlets. Maintaining stable and deep navigation channels and also allowing for adequate sand bypassing provides a major challenge to coastal engineering. Understanding the processes that control shoaling at inlet channels is, therefore, an important challenge.

Blind Pass, a small stabilized migratory inlet, provides an excellent case for the study of inlet shoaling and interactions with adjacent beaches.

Blind Pass and the adjacent Johns Pass service a portion of Boca Ciega Bay along the west-central Florida coast (Fig. 1). The entire area, from the beach to the inlets to the back-bay, is heavily developed. The origin of Blind Pass is not clear. Before the opening of Johns Pass by a hurricane in 1848, Blind Pass was a major inlet along this stretch of the coast with large flood and ebb shoals. As Johns Pass captured a substantial portion of the tidal prism, Blind Pass became a wave-dominated inlet and started rapid southward migration. It was eventually stabilized with a series of hard structures. Following the stabilization, chronic shoaling of the channel and subsequent dredging occurred, along with a persistent erosion problem at the downdrift Upham Beach.

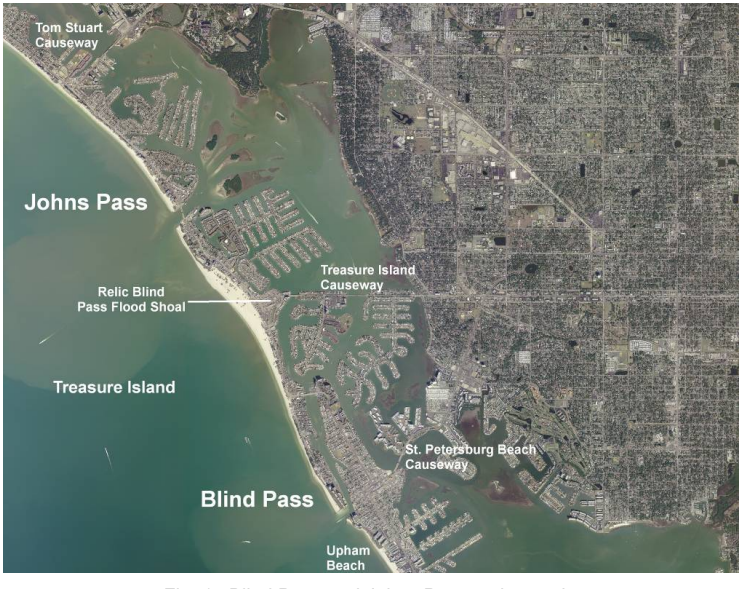

Fig. 1. Blind Pass and Johns Pass to the north.

This study quantifies the channel shoaling and associated processes following the last dredging in 2000. Time-series bathymetry surveys and flow measurements were conducted along with circulation modeling of the Blind Pass and Johns Pass system. The overall goals of this study are to understand the rate and processes of shoaling in the inlet channel and its interaction with adjacent beaches. Specific objectives include: 1) quantifying the shoaling and scouring pattern in the inlet channel, 2) investigating wave conditions and tidal flow velocities, particularly in relation to the inlet morphology change, and 3) determining the relationship between morphology change and the driving forces.

HISTORICAL EVOLUTION AND ENGINEERING AT BLIND PASS

Blind Pass is one of the most artificially modified inlets along the west-central Florida coast (Davis and Barnard 2000). Most of the engineering efforts are aimed at halting lateral inlet migration and reducing shoaling in the inlet entrance channel. The jetties have successfully stopped the longshore migration; however, channel shoaling has continued, and severe and persistent downdrift erosion was induced. The inlet needs to be dredged periodically and the sand used to nourish the adjacent beaches, especially Upham Beach, located directly to the south and downdrift.

Before 1848, Blind Pass was a fairly large inlet and was located directly gulfward of its flood shoal (Fig. 1). The opening of Johns Pass that year started a substantial trend of decreasing tidal prism at Blind Pass. As a result, the inlet began to migrate rapidly to the south so that, by 1926, the inlet had migrated more than 2 km. The year 1937 marks the beginning of direct stabilization with initial dredging and construction of the south jetty and seawall. Continued sediment shoaling in the inlet entrance channel led to extension of south jetty in 1951 and construction of the north jetty in 1962. Also, between 1940s and 1960s, extensive dredge-and-fill construction was conducted in Boca Ciega Bay (Fig. 1). The artificially created land, as well as construction of several causeways, resulted in significant reduction of back-bay area, and thus a further decrease in tidal prism. The south jetty was extended in 1975, and a weir with a 12-m gap was added in 1986. The weir was closed in 2004. The north jetty was extended in 1976 and 1983. These structures along with the significantly decreased tidal prism have made Blind Pass channel a trap of the southward longshore transport allowing little to no bypassing. In order to maintain the channel, the inlet was dredged in 1937, 1964, 1969, 1975, 1979, 1983, 1990, and 2000.

Artificial interferences on the morphodynamics of Blind Pass are illustrated well by time-series aerial photographs (Fig. 2). Blind Pass is characterized by a nearly 90-deg. turn before entering the Gulf of Mexico. We focus on the entrance channel at and gulfward of the turn. In 1926 (Fig. 2A), the inlet was still in pristine condition. A large ebb shoal and southward sand bypassing are apparent. By 1942 (Fig. 2B), the south side had been stabilized. The ebb delta and southward bypassing are still visible, but to a reduced degree. Beach erosion at Treasure Island to the north becomes obvious. By 1957 (Fig. 2C), the ebb shoal and southward bypassing are still visible. At the same time, erosion at the updrift Treasure Island had become severe. By 1969 (Fig. 2D), both sides of the inlet were stabilized. The ebb shoal and southward bypassing diminished substantially. Through a combination of jetty, groin field, and beach nourishment, erosion at the updrift Treasure Island was mitigated. However, severe erosion at downdrift Upham Beach to the south developed. Shoaling of the inlet channel and severe erosion downdrift are the main features of the 1984 photo (Fig. 2E), which was taken a year after the 1983 dredging. The ebb shoal and southward bypassing become indistinguishable. This trend continued and is shown in the 2000 photograph (Fig. 2F) just before the last dredging to date. The present study on shoaling in the channel was commenced after the 2000 dredging.

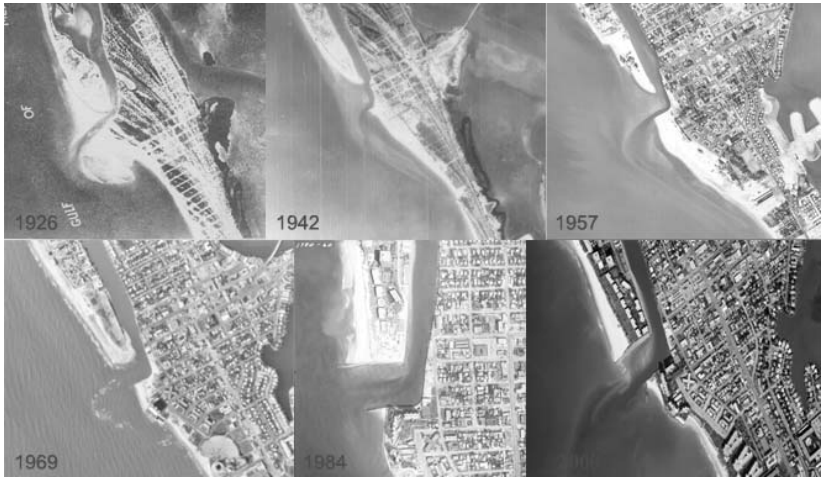

Fig. 2. Time-series aerial photos of Blind Pass.

METHODOLOGY

The present study examines sediment shoaling in the Blind Pass entrance channel via a series of field investigations, through which a numerical model of circulation was established. Time-series bathymetric surveys were conducted, as well as flow measurements. Bathymetric surveys were conducted roughly quarterly from August 2002 to June 2004. The surveys were conducted with a combination of precision echo sounder for depth and a synchronized Real-Time-Kinematic (RTK) Global Positioning System (GPS) for position. Water level variations were measured to cross-check the tidal influence on the floating platform survey. During the study, the northern side of the inlet became too shallow to survey by boat. Level-and-transit surveys using an electronic total station were conducted there monthly from February 2003 to February 2004. The monthly survey of 9 lines over the northern shoal, extending to roughly 1.5 m water depth, was designed to capture the infilling rate and pattern over this active shoaling area (Fig. 3). Surveys are referenced to NGVD29, which is roughly 0.15 m below mean sea level in this area.

Tidal flow patterns through the inlet were measured using an upward-looking acoustic Doppler current profiler (U-ADP) in combination with a side-looking ADP (S-ADP). Therefore, flow patterns both through the water column and across the channel were measured. The flow measurements were conducted at two locations with one near the mouth and one near the bend, each for approximately one month (Fig. 3). In addition, flow velocities were measured simultaneously using two U-ADP placed in the thalwegs near the entrances of Johns Pass and Blind Pass. These data are valuable for examining the interaction of the two inlets and for validating the circulation model.

Fig. 3. The north shoal profiles and locations and times of current meter deployments.

A two-dimensional finite-difference model of depth-averaged circulation, the Coastal Modeling System (CMS)-M2D (Buttolph et al. 2006), was set up to simulate tidal-driven flow patterns at both Johns Pass and Blind Pass. A grid consisting of 15x15 m elements and covering approximately the hydraulic circulation extent of the back-bay was generated based on a 2006 bathymetry survey conducted by this study. The model was driven by water-level measurements obtained in January 2001 at Johns Pass and verified with the flow data as described in the above paragraph. The CMS-M2D model has been applied extensively in tidal inlet modeling (e.g., Kraus and Militello 1999; Militello and Kraus 2003; Bounaiuto and Militello 2004). The CMS is a product of the U.S. Army Corps of Engineers' Coastal Inlets Research Program.

RESULTS AND DISCUSSION

Sediments along the west-central Florida coast are composed of fine quartz sand with various amounts of, typically larger, shell debris. At present, sediment in the Blind Pass channel varies greatly from the channel thalweg to the shoal area. The surface sediment in the channel thalweg is mostly shell lag with grain size ranging from several mm to several cm. The mean grain size of sediment along the slope of the main channel averages about 0.35 mm, with a considerable amount of shell debris. The mean grain size of sediment in the shoal area averages about 0.18 mm, predominantly fine quartz sand. Sediments in the shallow area close to the north jetty tend to be coarser, averaging 1.1 mm, with a large amount of shell debris. This variation in sediment grain size is controlled by selective sediment transport by currents and waves. Stronger currents in the channel thalweg produce the coarse lag; and breaking waves along the north jetty are responsible for the coarse sediment there.

Tidal Flow Patterns

The tide in the study area is mixed diurnal and semi-diurnal. Spring tides, with a range approaching 1 m, tend to be diurnal. A secondary cycle of typically less than 20 cm in range usually occurs on the rising phase of spring tide (Fig. 4). Neap tides ranging to about 0.5 m are mostly semi-diurnal. Therefore, although spring tide has greater overall range, the rate of water level change during the rising phase is not greater than the semi-diurnal neap tide; however, the rate of the falling phase is greater.

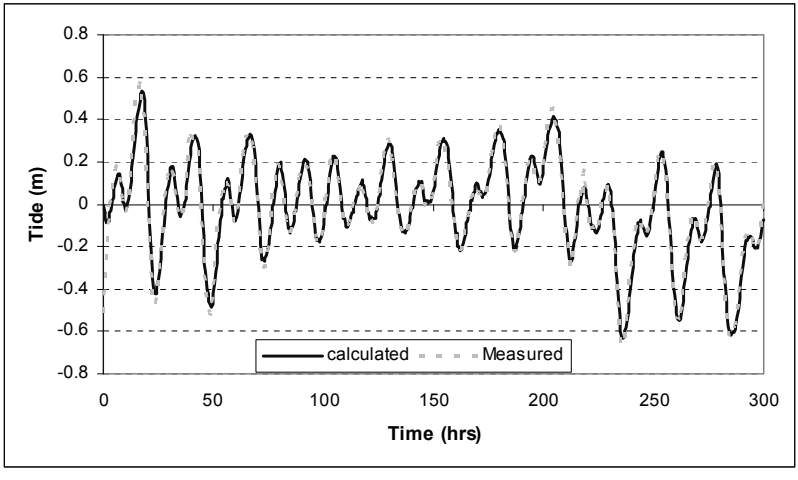

Fig. 4. Measured and calculated tidal water level at Blind Pass, January 12 to 25, 2001.

The measured flow velocity through Blind Pass exhibits the aforementioned tidal water-level characteristics (Fig. 5). The peak flood velocity is fairly uniform through time, with the weaker velocity appearing during the transition from the semi-diurnal neap to the diurnal spring tide. The peak ebb velocity shows large variation. The peak ebb velocity during spring tide is almost twice the magnitude of the peak flood velocity during neap tide in the channel thalweg. As discussed in the following, spatial variation patterns of flood and ebb currents across the channel also influence the peak magnitude.

Vertical velocity profiles are uniform throughout the water column from 1 m above the bed (Fig. 6). Vertical velocity profile measurements were conducted in the channel thalweg. A similar homogeneous trend was demonstrated by nearly all the measurements at the two different channel locations and during the different times (Fig. 3). In addition, overall flow velocity and trends through the channel thalweg, measured in January 2001 shortly after the dredging and in August-November 2002 after significant accumulation on the north shoal, are similar. The similarity indicates that the flow through the channel thalweg along the south side of Blind Pass is not significantly influenced by either the dredging or the shoaling that mainly occur along the north side.

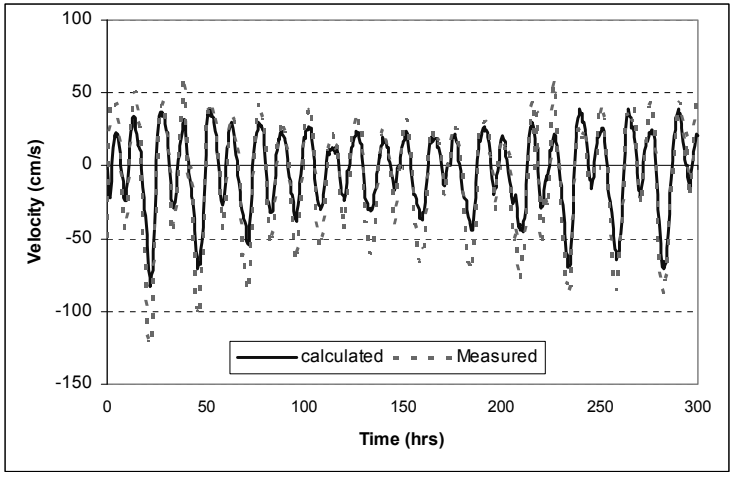

Fig. 5. Measured and calculated tidal flow velocity, January 12 to 25, 2001.

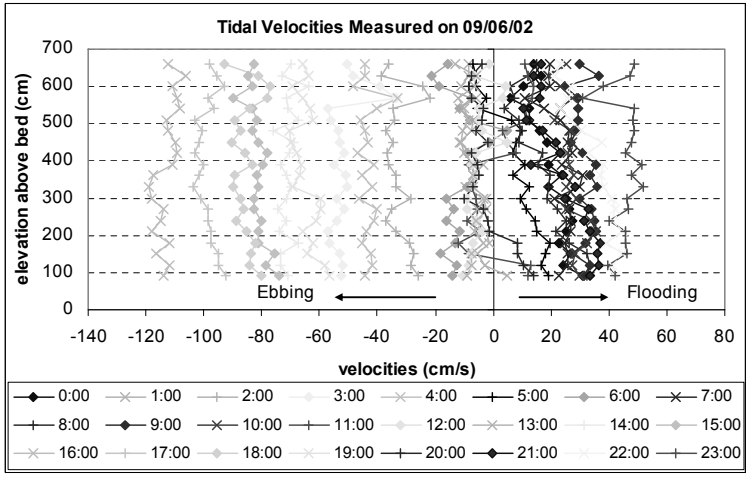

Fig. 6. Typical vertical profiles of current during spring tide.

In contrast to the homogeneous vertical velocity profiles, tidal flow velocity exhibits substantial horizontal spatial variation across Blind Pass channel. In addition, the cross-channel distribution pattern differs between ebb tide and flood tide (Fig. 7). During ebbing tide, flow velocity measured at the channel thalweg is 3 to 4 times greater than that measured over the north shoal. The peak ebb velocity through the channel thalweg approaches 1 m/s, the equilibrium velocity documented at many inlets (Bruun 1978). During flooding tide, flow velocity is primarily uniform across the channel, peaking at

about 0.5 m/s. This distribution of tidal flow velocity across the inlet channel can be attributed to the nearly 90-deg bend. The northern side of the inlet lies in the shadow zone of the ebb current as it turns around the corner. Such a sharp bend is common for migratory inlets, resulting from extension of the updrift barrier island and recession of the downdrift barrier. Therefore, the tidal flow distribution shown in Fig. 7 is likely not unique to the Blind Pass entrance channel.

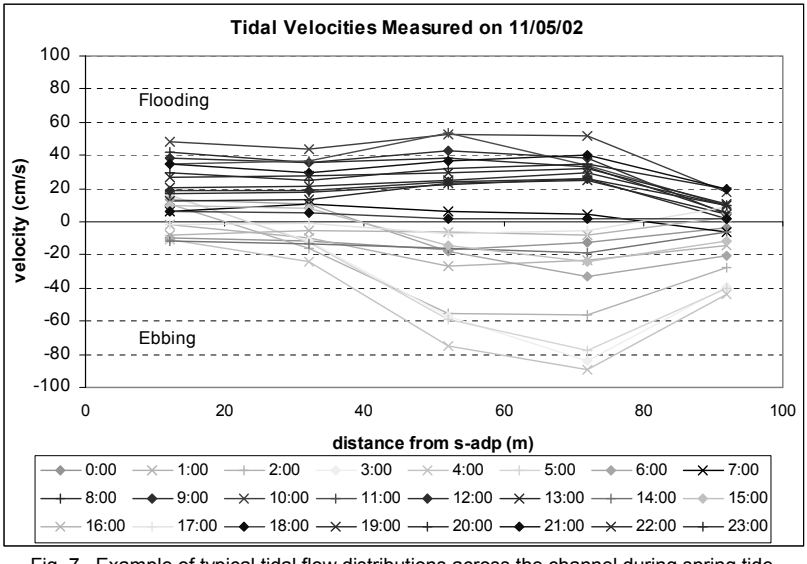

Fig. 7. Example of typical tidal flow distributions across the channel during spring tide.

Given the uniform vertical flow profile and substantial horizontal variation, a depth-averaged circulation model, such as the CMS-M2D, is a suitable and valuable tool to examine the Blind Pass hydrodynamics. The 2-week model run, spanning a spring and neap tide cycle, reproduced the measured water level well (Fig. 4). Measured velocity was also reproduced well, especially during flood (Fig. 5). The under-predicted peak ebb velocity may be related to the fact that a point measurement is compared to an averaged velocity over a 15x15 m grid. The substantial spatial (horizontal) variation of the ebb flow and the exact location of the flow meter may cause a slight inconsistency. Overall, results from the CMS-M2D represented the observations well over the 2-week period.

The predicted horizontal tidal flow patterns across the inlet channel also compare well with the measured pattern (Figs. 7 and 8). The ebb flow tends to hug the south side over the channel thalweg with a peak flow of approximately 1 m/s, whereas flow over the north shoal is much weaker (Fig. 8A). The flood flow tends to be uniform across the channel, peaking at about 0.5 m/s (Fig. 8B). This cross-channel flow pattern is closely related to the shoaling pattern, discussed in the next section.

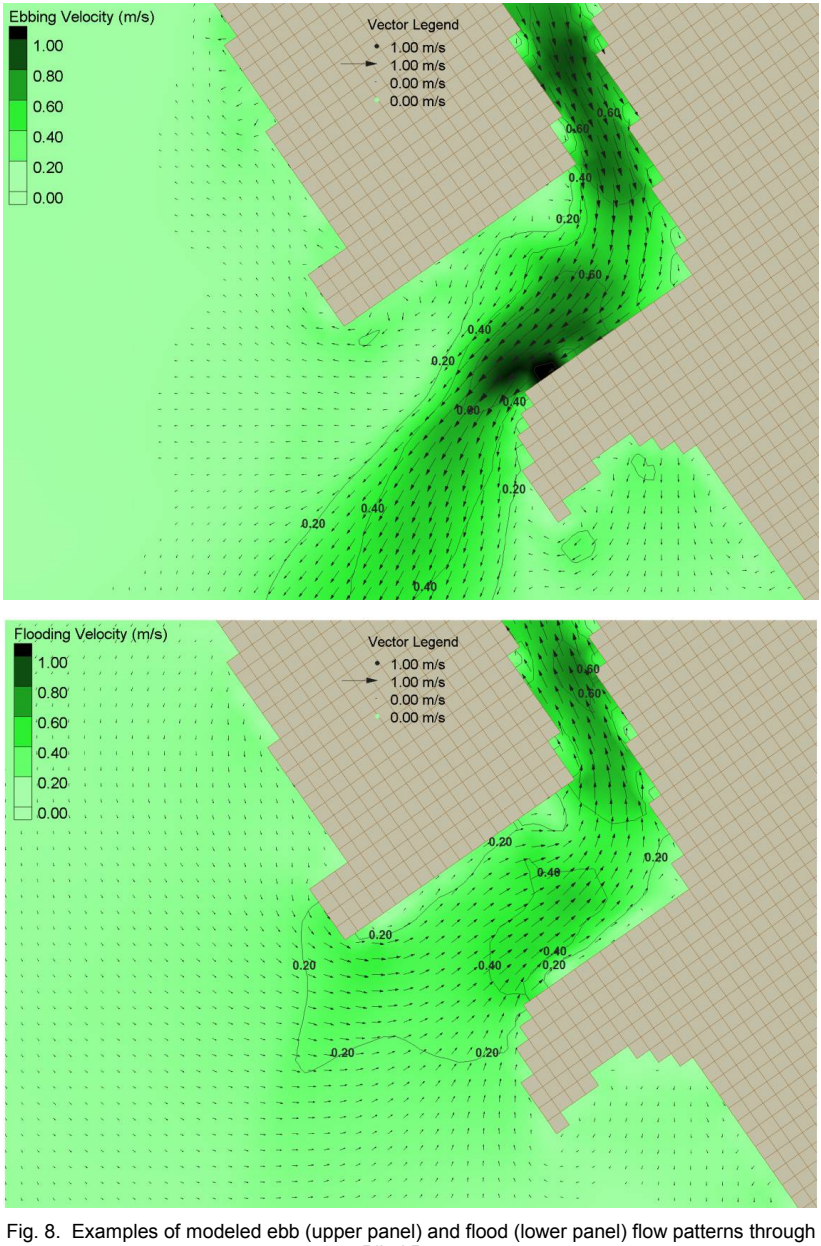

Fig. 8. Examples of modeled ebb (upper panel) and flood (lower panel) flow patterns through Blind Pass.

Shoaling in the Blind Pass Entrance Channel

Six bathymetric surveys were conducted by this study, in addition to one survey by the USACE, Jacksonville District, in July 2000 shortly after the last channel dredging. Significant shoaling is apparent in the time-series surveys (Fig. 9). Active shoaling occurred in three areas: along the north side, at the eastern corner, and along the south weir jetty. By far, most shoaling occurred along the north jetty. Comparing the July 2000 and August 2002 surveys, net sedimentation of 70,000 m^3 occurred during this 2-year period, or 35,000 m^3 per year. This rate roughly equals the net southward longshore sediment transport rate as obtained by Elko and Wang (2007) from measurements of erosion of the down-drift Upham Beach. This result indicates that Blind Pass has served as a total trap to southward longshore transport.

From August 2002 to August 2003, net sedimentation of 17,000 m^3 occurred, as the sum of 25,000 and 2,800 m^3 accumulation from August 2002 to December 2002 and from August 2002 to May 2003, respectively, and 11,000 m^3 of erosion from May 2003 to August 2003. From August 2003 to June 2004, net accumulation of 26,000 m^3 occurred. For both years, net accumulation occurred in the winter months and net erosion in the summer months. This seasonal trend is reflected more clearly in the monthly north-shoal survey, discussed in the following. The reduced amount of sedimentation during 2003 and 2004 is related to sediment backpassing around the corner of the inlet. A beach has developed on the back side of Treasure Island since 2003 and is growing (Fig. 10).

This shoaling pattern relates clearly to the southward net longshore sand transport and tidal flow distribution across the channel. Little shoaling occurs in the channel thalweg due to active flushing by the strong ebb flow. The north side is directly downdrift of the longshore sediment source. The weak ebb flow is not capable of flushing the sand deposited by the longshore transport, whereas the relatively strong flood flow tends to transport the sand deposited near the mouth further into the channel.

Sedimentation on the north shoal was monitored through monthly surveys of nine lines (Fig. 3). Four areas with different patterns of accumulation and erosion in the shoal can be distinguished as the: mouth area (lines 1 and 2), middle area 1 (lines 3 and 4), middle area 2 (lines 5 and 6), and the inner area (lines 7 through 9). From February to August, or the summer of 2003, a considerable amount of scour occurred in the mouth area (Fig. 11A). Little change was observed during the next two months. A tremendous amount of shoaling occurred in the mouth area between October and December of 2003, or at the beginning of the winter season. Scour was measured during the late winter between December 2003 and February 2004. Further into the inlet in middle area 1, little change occurred during the summer (Fig. 11B). A large amount of shoaling occurred at the beginning of winter, followed by further accumulation during late winter. Even further into the inlet at middle area 2, little change was observed during most of 2003 (Fig. 11C). A tremendous amount of shoaling occurred in the late winter. Near the bend of the inlet at line 9, southward progradation of the shoal occurred throughout the year (Fig. 11D). A large amount of shoaling was also observed during late winter.

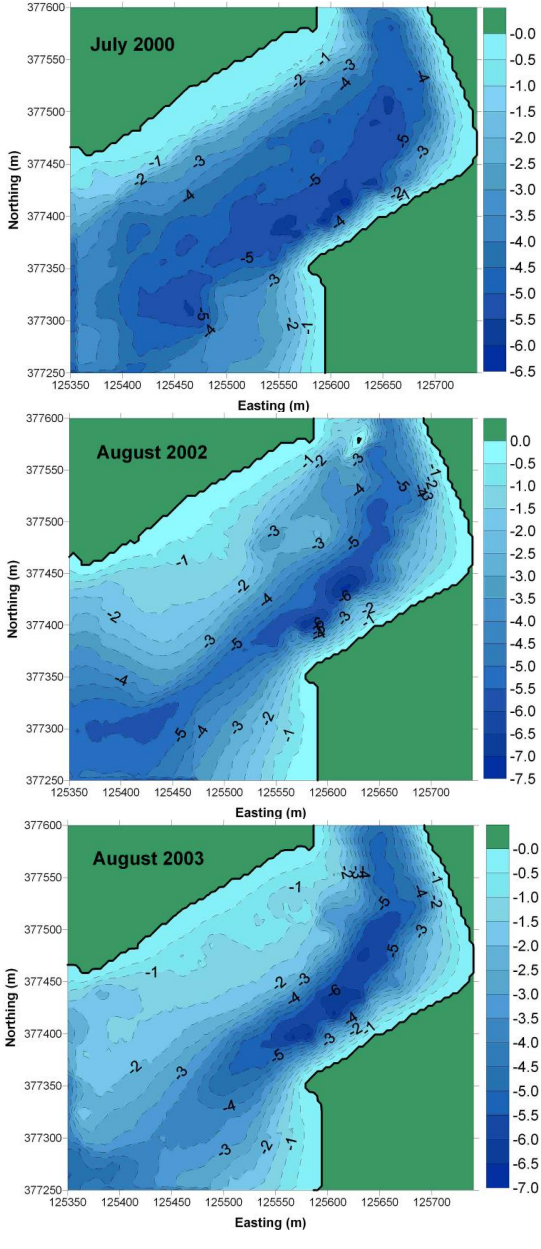

Fig. 9. Shoaling in Blind Pass entrance channel.

Fig. 10. Beach development along the back side of Treasure Island at Blind Pass, looking north.

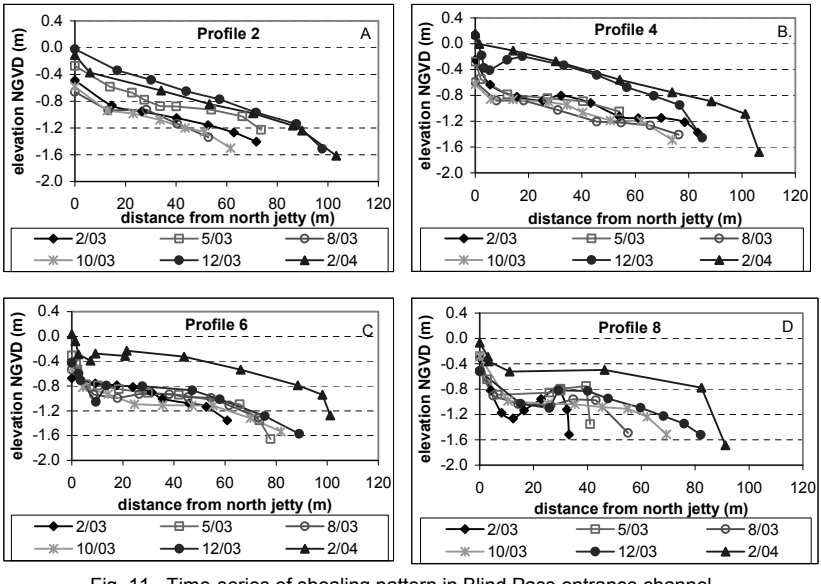

Fig. 11. Time-series of shoaling pattern in Blind Pass entrance channel.

Fig. 11 demonstrates both seasonal and event-driven shoaling and scouring at Blind Pass. During the summer when southwest wind dominates, and little sediment is trapped in the inlet because the sediment supply from the eroding Upham Beach to the south is limited. Furthermore, ebb flushing along the south side is active. As a matter of fact, scour was observed on the north shoal near the inlet entrance, indicating that the sand at the mouth area is being moved further into the inlet, and around the bend. Significant sediment shoaling occurred at the mouth area during the early winter starting in late October,

especially after the passages of the first several cold fronts. The northerly winds and waves are a major mechanism in driving southward longshore sand transport. The longshore moving sand can deposit readily into the space that was created during the summer season at the mouth area. This body of sand migrates further into the inlet during the winter. Therefore, shoaling in the Blind Pass entrance can be summarized as event-driven (particularly by cold fronts) supply of sediment, followed by redistribution during both low- and high-energy conditions.

The relatively strong flood current over the north shoal is a major mechanism transporting sand further into the inlet and around the bend to the back of Treasure Island. This has effectively limited development of an ebb shoal at Blind Pass. In addition to the flood current, wave breaking over the shallow north shoal and the resulting landward moving surf bore should also contribute significantly to landward sand transport, especially during high waves (Fig. 11). The development and significant growth of the beach on the back side of Treasure Island are results of the landward sand redistribution, in contrast to typical seaward sand transport by ebb flow and development of an ebb shoal.

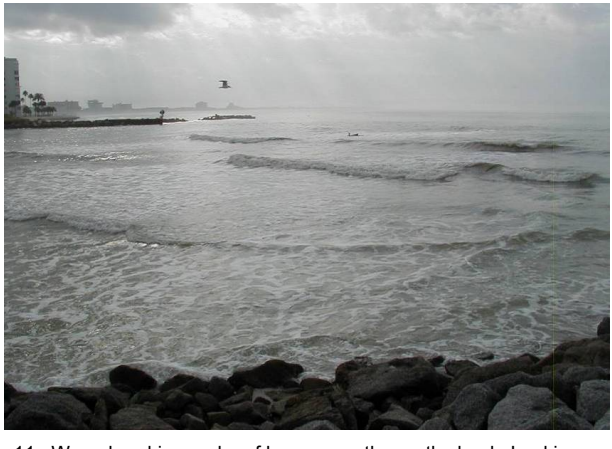

Fig. 11. Wave breaking and surf bores over the north shoal. Looking south.

CONCLUDING DISCUSSION

Blind Pass represents an example of a stabilized migratory inlet. Both in-situ flow measurements and numerical modeling revealed that ebb flow was approximately twice as strong in the channel thalweg along the downdrift side as compared with the rest of the channel. This strong ebb flow maintains the deep channel there. Flood flow, in contrast, was primarily uniform across the entrance and is stronger than the ebb flow over the northern portion of the inlet. This flow-velocity distribution across the inlet channel, which controls the shoaling patterns, relates to the nearly 90-deg. turn at its entrance to the Gulf of Mexico. The CMS-M2D model reproduced the measured tides and currents accurately.

Active sand accumulation occurs in the Blind Pass entrance channel, which is maintained by periodic dredging. The shoaling rate in Blind Pass channel approximately equals the net southward longshore transport rate. The inlet is presently serving as a total trap for southward longshore transport. Most of the active sediment shoaling occurs along the north side of the inlet, corresponding to 1) its proximity to the sand source, 2) weak ebb flushing, and 3) stronger flood current. Wave breaking over the shallow north shoal also contributes to the sand re-distribution further landward into the inlet.

Accumulation and erosion patterns at the Blind Pass entrance north shoal demonstrate distinct trends influenced by seasonal wave climate. High-energy waves, especially those driven by passages of cold fronts, play key roles in transporting littoral sand to the inlet channel. Active shoaling in the Blind Pass entrance channel occurs during the winter. This is followed by redistribution of the sand further into the inlet during the summer. The north side of Blind Pass and the growing beach behind Treasure Island are effectively functioning as an impoundment area for sand that is transported southwestward by the longshore current.

APPROACHES TO UNDERSTANDING MULTIPLE-INLET STABILITY

William C. Seabergh[1]

1. U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA.. William.C.Seabergh@erdc.usace.army.mil.

Abstract: The morphologic response of inlets that are part of a multiple inlet system, defined here as two or more coastal inlets connected to the same bay, is a complex problem. It has been thought that one inlet will eventually dominate, and that other inlets will close. Of course, in nature, there is a full range of situations and physical realities that complicate this situation. As more experience and historical information become available, various approaches can be tested. There may be multiple inlet systems serving a bay region that have naturally developed and coexisted for many years in some cases or there may be newly developed multiple inlet systems whose inlets immediately respond to each other, with the more efficient inlet creating a decline in the size of the other inlet, probably at a varying rate proportional to their efficiencies. An example of this type situation at two inlets on the Guatemalan coast is examined in this paper.

INTRODUCTION

This paper discusses recent understanding of multiple inlet stability and then examines a multiple inlet stability case study that may be considered common in engineering practice. A multiple inlet system is defined here as two or more inlets connecting one bay region to an ocean, sea or lake, i.e., a body of water much larger than the bay, and which typically is tidal and forces currents into and the out of the bay over a flood/ebb tidal cycle.

The inlet stability application concerns adding a flood relief inlet to an existing small navigable inlet system presently used extensively by local charter boats. An iterative process of examining Escoffier stability curves is applied to determine the response of both inlets while making reasonable assumptions for the system's representation. The

major question to be investigated is the relative stability of each inlet on the Escoffier stability curve.

BACKGROUND

Many inlet-bay systems with multiple inlets that connect with one bay respond, over time, in a manner where one inlet becomes predominant over the other inlet (or inlets, if more than two). This is the more commonly accepted concept about multiple inlet response, and is especially obvious when a large storm breaches a barrier at a location that is hydraulically "more efficient". For example, a new inlet cuts a channel through a barrier island that provides a shorter distance between bay and ocean. If this new, efficient inlet is not closed within a reasonable time, it can enlarge, capturing an increasing portion of the tidal prism admitted to the bay, reducing tidal prism of the original inlet. The original inlet may then have a tendency to decrease in size due to reduced velocity and channel shoaling. Also, the newly breached inlet would most likely not be associated with ebb or flood shoals, increasing its initial hydraulic efficiency and flow capturing capacity. If the new breach remains open, the original inlet may start to reduce in size. Also, existing constraints, such as preservation of bridges and roads may require closing the newly formed inlet before significant channel development occurs, requiring expensive changes to the existing infrastructure. Headland et.al. (1999) discuss impacts of breaches and multiple inlet systems.

Inlet Equilibrium Area

The equilibrium-area concept for a tidal inlet has been a useful approach to understand the adjustment of an entrance channel's minimum cross-sectional area to the basic hydraulic and sedimentation characteristics of the coastal inlet and bay it serves. Wave-generated and other currents along the coast move sand into the inlet channel, reducing its cross-sectional area. Inlet flow, produced by tidal, wind-generated, seiche-generated or river inflow currents, will tend to scour any excess deposition and that increases the channel cross section area above its equilibrium value. Using a a concept originated by LeConte (1905), O'Brien (1931, 1969) examined field data from tidal inlets through sandy barriers on the West coast of the United States. O'Brien determined a relationship between the minimum cross-sectional flow area of the entrance channel and the tidal prism (the volume of water flowing into the bay during the flood tidal cycle or conversely, the volume of water flowing out of the bay during the ebb portion of the tidal cycle). The form of this equation was:

$$A_c = CP^n \qquad (1)$$

With A_c the minimum inlet cross-sectional area in the equilibrium condition, C is an empirically determined coefficient (small regional differences may exist), P is the tidal prism (typically for spring tide), and n is an exponent usually slightly less than one unit, determined by best fit to data sets.

Escoffier (1940, 1977) combined the O'Brien relationship (Eq. 1) with an analytic model for the inlet hydraulics. He proposed a diagram for inlet stability analysis in which two curves are plotted (Figure 1). One curve, the "Equilibrium Velocity Curve" in Figure 1 is derived from a form of Equation 1 above. The second curve, the "Inlet Maximum

Velocity" curve, is created by solving an inlet hydraulics model for velocity for various values of inlet area. Figure 1 shows the graphical form of the solution for the Unstable and the Stable equilibrium points. These points will be discussed below. Seabergh and Kraus (1997) discuss the formulation of a PC program to create this plot. If an inlet has jetties, the equilibrium velocity curve would be defined by (in metric units)

$$A_c = 7.489 x 10^{-5} P^{0.86} \quad (2)$$

The necessary information to perform this analysis includes the tide range in the ocean, tidal period (12.42 hr in this study to represent a semi-diurnal tide), the surface area of the tidal basin, the channel length, channel width, a frictional coefficient for the channel, such as Manning's n, and estimates of entrance and exit loss coefficients.

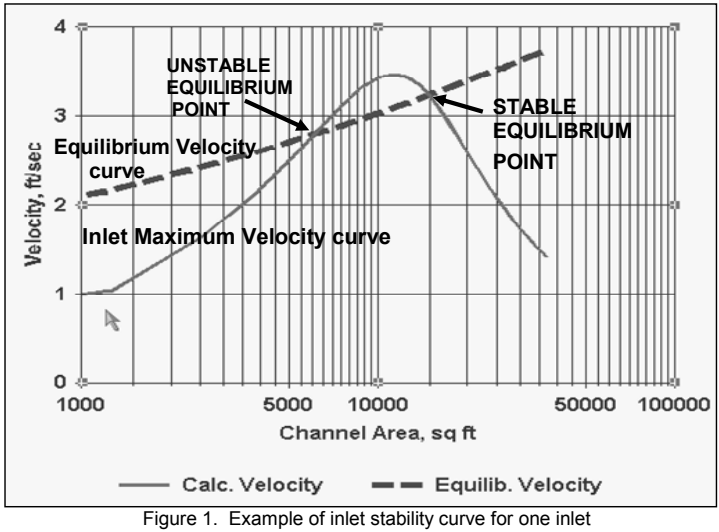

Figure 1. Example of inlet stability curve for one inlet

Referring to Figure 1, the solid line is the inlet's maximum velocity versus the inlet's cross-sectional flow area, A. A single curve represents changing inlet cross-section area conditions if ocean tide parameters and bay and inlet plan geometry remain fixed. As area approaches zero, velocity approaches zero because of increasing frictional forces, which are inversely proportional to channel area. As channel area increases, friction forces are reduced, but on the far right side of the curve, velocity decreases, as tidal prism has reached a maximum (bay fills to same level as ocean, if neglecting inertial term in flow equation), and any increase in channel area decreases velocity, as determined by the continuity equation. This curve can be constructed by calculating the maximum velocity V, resulting by varying channel area A. The maximum velocity V can be determined by an analytical or numerical model. The dashed-line curve is an empirical stability criterion curve such as O'Brien's discussed above (Eqns. 1 or 2). Therefore, as wave action supplies sand to the inlet channel and tends to reduce the cross-sectional area, the inlet flow will scour any depositions which reduce the channel cross section below its equilibrium value.

In Figure 1, the two curves may intersect at two locations, one location (a tangent), or not intersect. In the first case, the right-side intersection is a stable root in that any deviation in area returns movement along the stability curve to its starting point. If channel area increases (moves right on the curve from the stable equilibrium point), velocity will fall and more sediment can fill in the channel to bring it back to equilibrium. If area decreases, velocity will increase, scouring to the equilibrium point. The point of intersection on the left side is an unstable root, where if the area decreases, velocities decrease until the inlet closes. Moving to the right of this point, as velocity increases, area increases until the velocity starts falling and the stable root on the right is reached. If the stability curve is tangent to or below the stability criterion curve, the inlet will close. If the inlet area is to the right of the unstable equilibrium point, and a storm occurs provides a large sediment input to the inlet region, a possibility would exist that it could shift the area to the left of that point and the inlet will close.

Multiple-Inlet Stability

Initially van de Kreeke (1985) took the single inlet Escoffier analysis (1940, 1977) and extended it to multiple inlets. He maintained the simple hydrodynamic approach typically used in the original one-inlet Escoffier analysis. His procedure included the usual simplified assumptions that the bay water surface fluctuated uniformly as the tide entered and exited the bay through multiple inlets and the bay surface area was constant. With these assumptions, van de Kreeke (1990) concluded for multiple inlets connecting the same bay to ocean that for a two-inlet bay system analytical model, there exist no set of equilibrium flow areas, implying that ultimately one or both inlets close.

Van de Kreeke and Borsje (1994) found that if the stringent restraints for natural systems of a uniform bay rise with a constant value bay surface area, discussed above, are removed, and a semi-analytic approach is used with numerical computations, a set of unconditionally stable inlets is possible. Brouwer (2006) supplemented this approach, and found that a uniform water level in basin was too restrictive for shallow, long basins. He connected two bay basins at the topographic high by an interior channel and found three conditions, dependent on the channel's length and area. For small channels, inlets behaved nearly independently, and maintained two stable inlets. For a large connecting channel, one inlet would close, and for intermediate areas, there can be two unconditionally stable inlets in equilibrium.

As more historical information about multiple inlet systems has become available, it is known that some multiple inlet systems have remained as multiple inlets for a long duration compared to human lifetime. This is not to say that the inlets themselves have remained static. An example is the dual inlet system of Pass Cavallo and Matagorda Ship Channel on the Texas coast (Figure 2). Pass Cavallo was a naturally occurring inlet and the ship channel was dredged through the barrier island in the 1960s. Initially this change caused significant reduction in Pass Cavallo's size (Ward 1982) while scour occurred in the newly dredged Ship Channel. Recent analysis by Kraus et.al. (2006) indicated that the width of Pass Cavallo has remained stable since the mid-1990s or even

widened. Therefore this dual inlet system apparently has so far had a continual life of greater than 40 years.

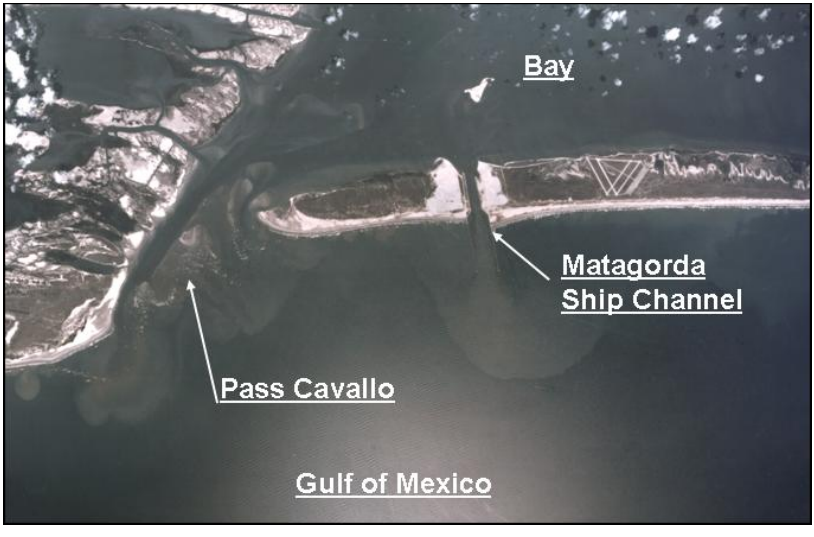

Figure 2. Pass Cavallo-Matagorda Ship Channel multiple inlet system, Texas

Freidrichs et. al. (1993) discussed a cyclical multiple inlet system instability at Chatham Harbor-Pleasant Bay tidal estuary, Cape Cod, Massachusetts. This inlet system has a 150-yr cycle, with a complex variation of inlet change, causing significant change in inlet hydraulics.

Other locations where dual-inlet systems have had one inlet close include Johns Pass (open)/Blind Pass (closed) on the Florida west coast and St Andrews Bay (open)/ East Pass (closed) on Florida's Panhandle, Gulf Coast. The Blind Pass portion of the first pair had reduced tidal prism due to anthropogenic infilling of the bay. For the second pair, East Pass shoaled relatively rapidly due to it's long channel.

In summary, for a bay with two inlets, if the bay is heavily segmented by wetlands, or man-made barriers to flow in the bay, such as causeways, than the bay serving one inlet may not be significantly affected by the other inlet. For this case, inlet interaction may be reduced, and the inlets will operate nearly independent of one another. As the connection in the bay is opened, there is more likely to be stable multiple inlet systems. As the connection between bay segments increases and the bay responds more uniformly to elevation change, one inlet will tend to dominate.

Of possible interest is information for the inlet pairs discussed earlier. Where one inlet closed in this group, the bay for each system was one that filled completely. This situation is also the response of an inlet that has reached equilibrium in Escoffier's

analysis for a single inlet. In contrast, the Pass Cavallo-Matagorda Ship Channel system bay response indicates about fifty percent filling. This is indicative of an inlet system where the inlet areas have a potential to increase in size until the bay fills completely. This might indicate that until the bay reaches a near bay-filling status, an equilibrium situation, one may have change from a stable (but not equilibrium area) two inlet system to a stable (with a true equilibrium area) one inlet system. This would require significant change to the bay planform and/or inlet cross-sectional areas, but could occur as a result of human intervention. It was noted in Seabergh (2003) that the time for a single inlet to evolve to an equilibrium condition can be considerable, if at all, unless there is some man-made change to reduce the energy loss in a system, e.g., entrance channel deepening or greater depth in the bay to reduce friction and create better connectivity between the two inlets. In other words, if the system can evolve to a "simpler" system, one where the bay fills completely and there is good connectivity between the multiple inlets, then one falls back to a single inlet evolution as the final configuration, as Van de Kreeke initially found.

SAN MARINO AND IZTAPA INLETS, GUATEMALA

Background

As part of a reconnaissance trip to the Guatemala coast, the San Marino Inlet and Iztapa Inlet system was examined to understand causes and remediation measures for channel shoaling at San Marino Inlet, an important channel for the local charter boat industry. San Marino and Iztapa Inlets both connect the Pacific Ocean with the same bay or lagoon region. Iztapa Inlet also serves as the closest exit to the sea for the Rio Maria Linda, a small river, but has been associated with flooding at the town of Iztapa. Figure 3 shows the two inlets. Historically there had been periods when only one inlet was open connecting the bay and ocean. Table 1 shows results of an examination of aerial photos. The inlets were consistently located in the region of today's inlets. This is of interest because some non-jettied inlets migrate along the shoreline and can be at very different locations along the coast over their history. Thus these inlets appear to be relatively stable with respect to their location along the shoreline in their pre-structured state, when they were open. The opening and closing of inlets can be associated with large waves, storms and riverine flood conditions. San Marino Inlet was permanently stabilized with two jetties in 1991, and Iztapa Inlet was stabilized in location with two jetties in 2003 (Figures 4 and 5). Apparently the structured inlets were appropriately sited due to their stable location.

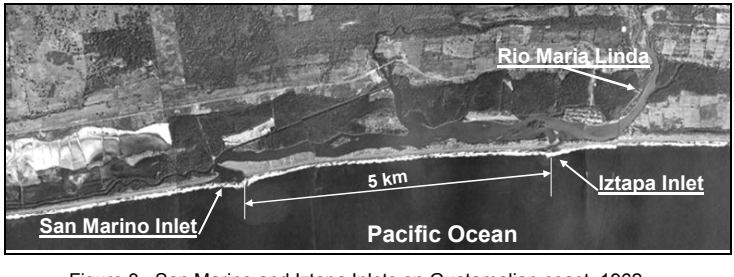

Figure 3. San Marino and Iztapa Inlets on Guatamalian coast, 1962

Figure 4. San Marino Inlet in 1991, just after construction.

Figure 5. Iztapa Inlet under construction in 2003.

However, as seen from Table 1, this dual-inlet system in its entirity does not consistently support two inlets. This instability can occur for a number of reasons. Iztapa Inlet, before being structured, most likely was a function of river inflow, as it is located near the exit of the Rio Maria Linda into the estuary. In the dry season, it would be likely to close, before it became a jettied inlet. The Iztapa Inlet jetties were constructed to relieve flooding of the town of Iztapa, located just adjacent to the river near the coast. Flooding conditions would lead to a breach at pre-jetty Iztapa Inlet once water levels had reached a high level in the lagoon. San Marino Inlet historically served a larger lagoon area than it does now, as the construction of Port Quetzal (in 1983) may have taken in some of the lagoon and blocked a region which previously drained into San Marino Inlet. The Port location would lie in the bottom left corner of Figure 3.

Inlet Cross-Sectional Stability and Tidal Prism

On 23 Jun 04, both San Marino and Iztapa Inlets were visited during a falling ocean tide. Consequently, the currents in the inlet channels were ebbing seaward. Using a tethered current meter, tidal currents were collected in each inlet at a time near peak ebb for that day. These measurements were useful in calibrating the numerical model for the stability analysis. The calibration procedure involved examination of photographs and maps to estimate the surface area of the bay. Because the bays are interconnected, a trial-and-error procedure was performed for each inlet, assuming different splits of the bay surface area until current measurements from the field matched the simple 1-D numerical model. Figures 6 and 7 show tidal elevations and currents for the calibrated models of each inlet. Table 2 shows the values used for model calibration. Also shown are estimated tidal prisms, or volumes of water that flow through the inlet during a flood or ebb tide for the calibration day of 23 June 04.

As noted from the tidal elevations, the bay tide ranges nearly equal the ocean tidal range. No measurements of bay tide range were available; however visual observation of bay tide range appeared to be in accordance with the calculations. If both inlets remain open, this should indicate good flushing of the bay system. Maximum velocities in the channel are in the range of 1.0 m/s, which is a value that indicates the inlet cross-section area is near an equilibrium value for tidal inlets (Bruun 1978). This indicates that both inlet systems appear to co-exist near inlet equilibrium states. This will now be examined by referencing the Escoffier stability plots for each inlet.

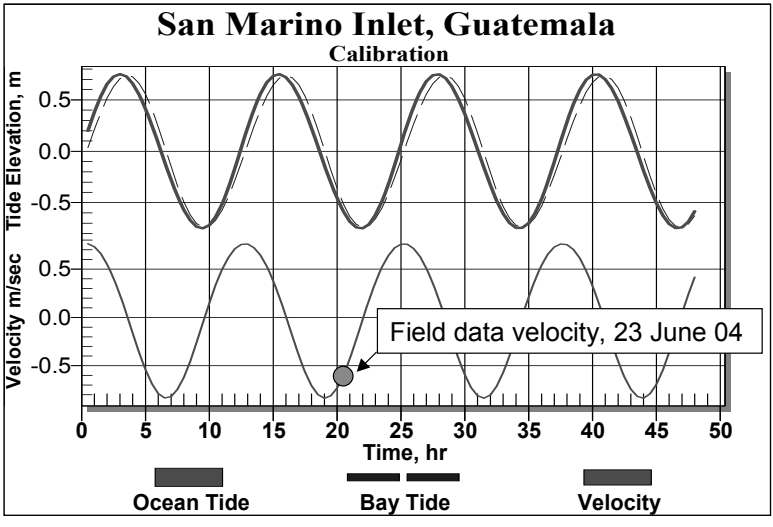

Figure 6. Calibration of San Marino Inlet hydrodynamics

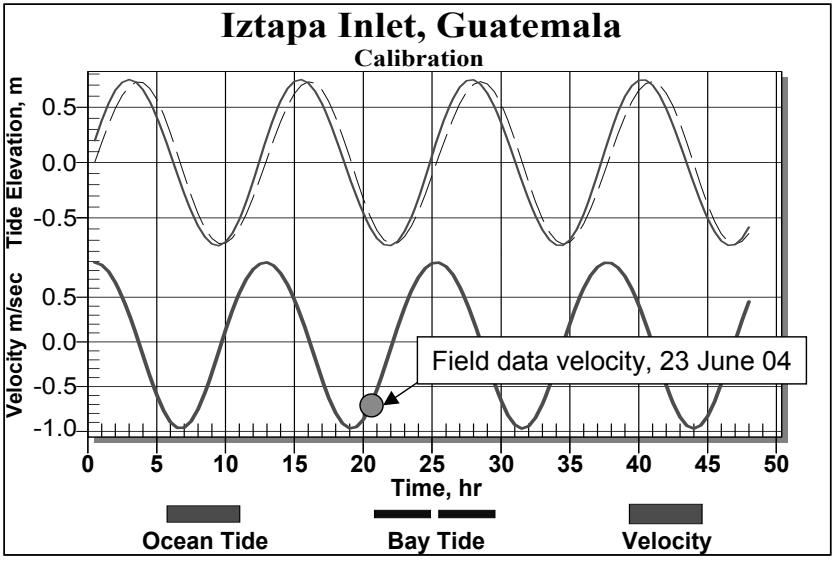

Figure 7. Calibration of Iztapa Inlet hydrodynamics

Table 2. Inlet Parameters and Tidal Prism

Parameter	San Marino Inlet	Iztapa Inlet
Bay surface area (sq meters)	500,000	2,200,000
Hydraulic radius (meters)	1.5	2.0
Channel length (meters)	400	500
Channel width (meters)	42	134
Calibration channel area (sq meters)	65	244
Entrance loss coefficient	1.0	1.0
Exit loss coefficient	0.5	0.5
Manning's n	0.030	0.030
Calibration ocean tide range (meters)	1.5	1.5
Calibration tidal prism (cubic meters)	735,000	3,234,000

Escoffier Analysis of Inlet Stability

The Escoffier plots for both inlets were determined based on the calibration of the hydrodynamics discussed above. Figure 8 shows the San Marino Inlet plot in the form discussed earlier.

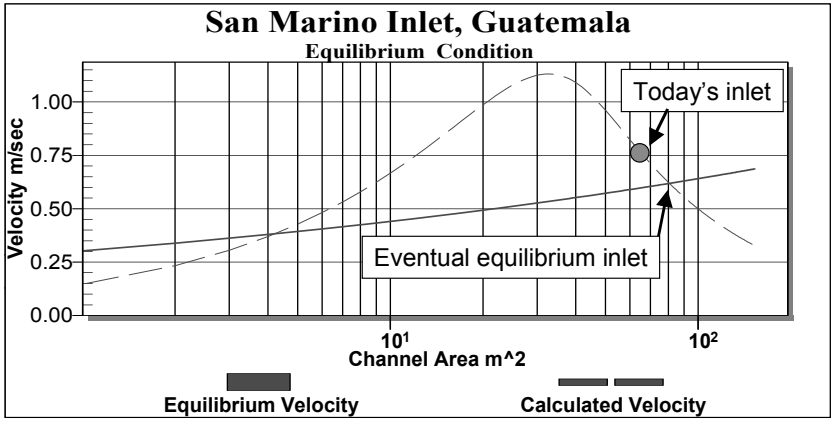

Figure 8. Escoffier plot showing today's inlet area with respect to eventual equilibrium area.

Figure 8 indicates that San Marino Inlet is close to its expected equilibrium value based on existing inlet hydrodynamics and the parameters given in Table 2. Some slight

changes could be expected if dredging were performed and the channel length shortened. At this time the channel into the bay follows a sinuous path. The inlet area is 65 sq m, moving toward an equilibrium value of 80 sq m. This would mean an average depth of about 1.9 m would be expected based on a tide range of 1.5 m. This depth is relative to mid-tide at the inlet and is less than would be expected if Iztapa Inlet was not opened.

Figure 9 shows the stability diagram if only San Marino Inlet was open to the bay and Iztapa Inlet was not present. Figure 9 indicates that the existing inlet area would have strong currents, near 2 m/s, probably similar to those that occurred historically in San Marino Inlet after the jetties were constructed in 1991, but before 2003, when Iztapa Inlet was opened and its jetties constructed. The jetties at San Marino Inlet are relatively short and probably never permitted the inlet to obtain its maximum equilibrium area of 334 sq meter (depth would then be 7.8 m), as sediment could come around the jetties and enter the channel fairly easily. Estimated equilibrium area would be 240 sq m (depth would be 5.6 m) if the prism relationship for an unprotected inlet were applied. This analysis is discussed to illustrate the change that can occur if a bay system is transformed from one primary inlet to a two-inlet system. Thus the creation of a permanent Iztapa Inlet has taken a part of the San Marino Inlet tidal prism and indicates a reduction in channel cross-section area and, therefore, a reduction in depth at San Marino Inlet. The next section examines the state of the Iztapa Inlet.

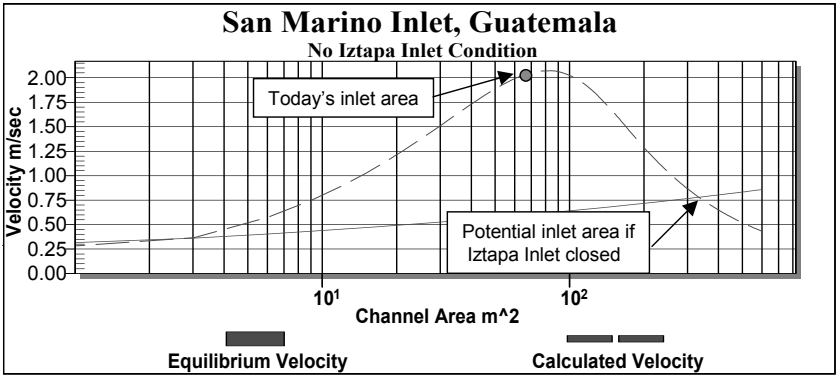

Figure 9. Escoffier plot showing what would occur at San Marino Inlet if Iztapa Inlet were not open (pre-2003)

Iztapa Inlet channel stability is shown in Figure 10. The existing area of 244 sq m is approaching the equilibrium area of 288 sq m. This indicates a potential average depth of 2.4 m. This depth is relative to mid-tide level at the inlet. Possible flooding from the Rio maria Linda could cause, temporally, an increased depth to occur in the channel between the jetties.

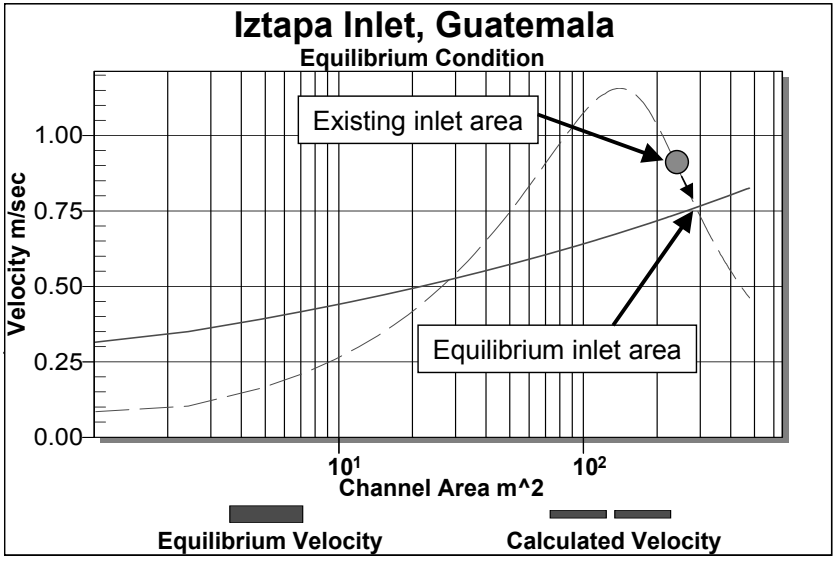

Figure 10. Escoffier plot showing today's inlet location with respect to channel area and eventual equilibrium area.

Historical Note and Summary of Inlet Stability

Important in the examination of inlet cross-sectional area stability are changes that occur in bay size. Anthropogenic changes in bay surface area and flow distribution can alter inlet stability. Most likely the bay size served by the San Marino Inlet was reduced by construction of the Port of Quetzal in the early 1980's. Inlet widths at the natural San Marino Inlet were noted to be as great as 100 m before port construction. Inlet area (and thus width) is proportional to the bay area drained by the inlet. Now, with the addition of a permanent Iztapa Inlet, there is a smaller bay surface area serving San Marino Inlet and, therefore, a smaller equilibrium cross-section area is expected, and thus less depth, for the given width between the jetties. This was seen in the previous analysis in comparing today's San Marino Inlet existing condition with the no Iztapa Inlet condition.

The original San Marino Inlet was stabilized with jetties in 1991. The spacing of the jetties constructed in 1991 at San Marino Inlet was 31 m and relatively narrow for the bay it served and, therefore, strong currents were reported funneling through the entrance channel. The positive aspect of this was that the strong currents would flush sediment from the channel and keep an easily maintained navigable depth. Negative impacts of this type of inlet would include potential navigation problems with respect to vessel control as the currents accelerate towards the inlet, and during ebb, or seaward flowing currents, the interaction of the outgoing current with the approaching waves from the sea can create increased wave height and breaking waves in the channel. Previous maximum currents were probably on the order of 2 m/s at San Marino Inlet, while today's

maximum currents are about 1 m/sec. The weaker currents result in a shallower channel depth and less forcing of the sediments to an ebb shoal seaward of the inlet entrance. Observation at the inlet indicated little evidence of a significant ebb shoal. The ebb shoal typically helps to function as a wave breaker and reduces wave energy entering the channel. Observation showed waves continually breaking at the entrance to the jetties. The depleted alongshore sediment supply due to blockage by Port Quetzal also contributes to a smaller ebb shoal.

Iztapa Inlet in its natural state (pre-2003) would be expected to be influenced by the flow of the Rio Maria Linda. It apparently opened due to floods and probably closed during the dry season when littoral currents on the coast created by waves moved sand into the inlet. Iztapa Inlet was constructed in 2003. This dual-jettied inlet has spacing between the jetties of 122 m. It is relatively shallow and continually had waves breaking at its entrance. It is near its equilibrium area and thus depth of 2.4 m, which is slightly greater than San Marino Inlet depths of 1.9 m. This is due to the greater tidal prism that the inlet serves. The tidal prism of San Marino Inlet was calculated to be 735,000 m^3 and Iztapa Inlet 's prism is 3,234,000 m^3s, about four times greater than San Marino's prism.

Careful observation of the San Marino-Iztapa system must be made to see if this system responds as two independent systems now that both inlets are stabilized with jetties, or to determine if there is still an interaction, since there is a direct channel connection between the inlets.

CONCLUSIONS

Recent work on a multiple inlet-one bay system by Van de Kreeke and others indicates there is a gradation in inlet interaction that can permit three possible outcomes. The multiple inlets can be relatively independent of each other and coexist. They can be interactive and maintain independent stability or if they are too closely interconnected, one will dominate and the other close, as shown in earlier theory.

Inlet channel cross-sectional area is proportional to the surface area of the bay it serves. If an inlet is added to a bay system, the surface area of the bay is apportioned between the two inlets and the original inlet will be reduced in size. In adding a stabilized Iztapa Inlet to the bay system, the San Marino Inlet responded by becoming shallower (since width between the jetties was constant).

The existing depths (2004) at San Marino and Iztapa Inlets are near an equilibrium value (based on limited field data for this analysis). The equilibrium depths at mean tide level are 1.9 m at San Marino Inlet and 2.4 m at Iztapa Inlet. The existing width between the jetties at San Marino Inlet should be appropriate for the present two inlet-system, with reduced maximum velocity for safer navigation.

ENGINEERING GUIDELINES FOR THE SITING OF SAND BYPASSING DISCHARGES

Douglas W. Mann, P.E.[1]

1. Coastal Planning & Engineering, Inc. 2481 N.W. Boca Raton Blvd, Boca Raton Florida 33431, USA dmann@coastalplanning.net

Abstract: This paper summarizes the limited existing guidelines for the establishment of sand bypassing discharges adjacent to tidal inlets. Two recent case studies are presented where discharge siting was analyzed via a review of the littoral transport. Based on these case studies, rational procedures for discharge siting are proposed for any inlet and bypassing system.

INTRODUCTION

The blocking of littoral sediment transport by tidal inlets has been a frequent cause for many coastal engineering projects. One method of maintaining the regional littoral transport and navigation within the inlet has been to mechanically transport the sand to the downdrift beach. Methods to accomplish this include dredging from within the channel or deposition basin, or by dredging sand from the updrift beach and nearshore, bypassing the channel, and discharging the sand on the downdrift beach. Bruun (1978, 1990) and the USACE (1991) provide some design guidance and documentation on the various types of pumping systems used in bypassing sand across tidal inlets or from navigational channels. The design guidance is focused on the pumping operation without much attention to siting discharge operations.

Due to the dearth of specific guidance for siting dedicated discharge pipelines, this paper reports on the results of two discharge pipe siting case studies (Coastal Planning & Engineering, Inc. (CPE), 2004, 2005). The studies identified that the recommended discharge siting should be based on site-specific coastal processes. From these studies, existing engineering guidelines are enhanced for application at any inlet bypassing operation.

LITERATURE REVIEW

While much has been written on the need to bypass sand, only a limited number of papers have focused on the disposal of the sand on the downdrift beach. Among them are the following papers, which provide supportive ideas to the specified subject matter.

Weggel (1981) provides an overview of basic design principles associated with weir jetties. As weir jetties are intricately linked to the bypassing of the littoral drift, one might suppose that discharge location siting may receive some consideration in the report. Nevertheless, Weggel (1981) only briefly summarizes downdrift discharge siting by indicating that it should be located far enough from the jetty to avoid the wave shadow of the jetties.

The USACE (1982) describes the discharge of the Oceanside Harbor sand bypassing system. The sand discharge would be up to 3100 m from the harbor and would include multiple discharge points to permit selective discharge of sand to the beach. No details of the design of the multiple discharge points were presented.

Bruno (1988) performed a feasibility study at Manasquan Inlet, New Jersey, using wave hindcasted transport rates. Bruno (1988) concluded that based on sediment transport properties near the inlet, bypassed sand should be placed at least 490 m north (downdrift) of the north jetty to re-enter the net northerly transport and avoid relatively long "residence time". Bruno stated that within 490 m, the bathymetry was affected by the inlet and would result in southerly net littoral drift.

Clausner (1988) summarizes the Nerang River (Queensland, Australia) sand bypassing system and its early performance. For that system, three discharges are located from 295 m, 440 m, and 520 m from the downdrift jetty. Clausner (1988) notes that during the initial operation, there was some concern that the discharge points were not located sufficiently downdrift of the inlet and that extending the discharge locations may be necessary.

Clausner et al. (1991) provide an overview of the design of the sand bypassing plant at Indian River Inlet, Delaware. They describe the beach disposal pipeline as extending up to 457 m on the downdrift shoreline and that the actual length of the pipeline is flexible. Rambo et al. (1991) state that during the first year of bypassing, the discharge location varied from 122 m to 183 m downdrift of the inlet to produce "an adequate distribution of sand along the beach."

USACE (1991) summarize sand bypassing system selection and briefly describe discharge siting for any bypassing operation. For unidirectional sand transport, a distance from the jetty of 305 m is proposed as a minimum and that the distance should be increased based on the length of the jetties and the size of the ebb shoal. The USACE recommends wave refraction studies to determine a location where inlet dominated processes cease.

If the sediment transport is bidirectional, the USACE (1991) recommends identifying the littoral forces on the downdrift shoreline and identifying any transport reversals. It is recommended that statistical wave data, wave refraction and diffraction diagrams and data on nearshore currents be incorporated. The use of coastal structures to reduce sediment transport (reversals) back to the inlet was also suggested. No specifics were presented on how to apply these prudent suggestions.

In two recent efforts, Bailard (2006) and Applied Technology & Management (2005) utilize the GENESIS shoreline model downdrift of Santa Barbara, California, and Lake Worth Inlet, Florida, respectively. The model was used to simulate the shoreline response downdrift of the harbors under varying sand placement scenarios.

One may conclude from the above literature, that for each inlet, the following guidelines apply to siting a sand discharge point:

a. There may an optimal location to bypass sand to.
b. Flexibility in the discharge location may be important.
c. The optimal location is not immediately against the downdrift jetty.

APPROACH

Given the guidelines above, the most prudent method of determining the optimal location for siting of a sand discharge is the development of a littoral budget for the downdrift shoreline. This should identify gradients in the littoral drift, and any reversals that are occurring. Only after the littoral budget is developed can siting of sand discharges be determined with engineering confidence. In this paper, littoral budget development is discussed and two case studies are presented to provide a range of applications of this approach. From the two case studies, enhanced engineering guidelines on the siting of sand bypassing discharges are presented.

LITTORAL BUDGET THEORETICAL CONSIDERATIONS

The conservation of sand in one dimension along a downdrift shoreline can be expressed as:

$$\frac{dQ}{dx} = \frac{-dV}{dt} + q(x,t) \qquad (1)$$

where Q is the alongshore sediment transport, V is the volume of sand within the beach, q is a source of sediment into the beach cell, and x and t are dimensions in space and time (Figure 1). The volume of sand within the beach, V, or the change in beach volume with time dV/dt, can be determined directly from beach surveys or estimated from shoreline comparisons using an assumption regarding the profile response to a shoreline change such as:

$$\frac{dV}{dt} = \left(b + d_c\right)\frac{dy}{dt} \tag{2}$$

where y(t) is the shoreline position, b is the elevation of the berm and d_c is the depth of closure for the beach profiles (Figure 1).

Solving Eq. 1 for the sediment transport requires some estimation of the sources of sediment. For this paper, the sources are limited to the natural bypassing of sand across an ebb shoal where the re-attachment of the ebb shoal bar is well defined, say at x =xs, or the mechanical bypassing of sand through a pipeline located at a specific location, xp.

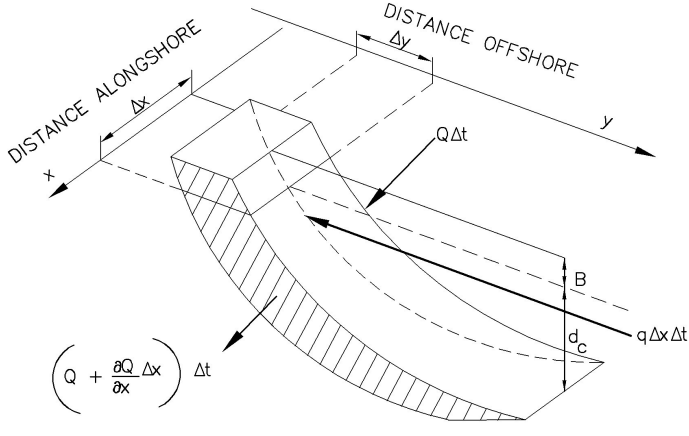

Figure 1. Definition Sketch of a Beach Cell.

Case Study 1: South Lake Worth Inlet, Florida

South Lake Worth Inlet (SLWI) is a manmade tidal inlet constructed in the 1920's to provide flushing of the south end of Lake Worth. While originally designed for flushing, the inlet is also used for small craft navigation. The inlet contains a rock bottom and has a fixed bridge over the inlet, which limit the size of vessels using the inlet. The curved north jetty is approximately 103 m longer than the south jetty and the downdrift beach is significantly offset to the west (Figure 2).

The inlet has an ebb shoal which bypasses a portion of the alongshore sediment transport to the downdrift beach. The ebb shoal bypassing bar attaches itself to the beach between approximately 670 m and 810 m south of the inlet (CPE, 2004). To

counteract the influence of the inlet on the remainder of the alongshore sediment transport, sand has been mechanically bypassed with fixed plants since 1937. Sand is currently discharged to the downdrift (south) beach through a single discharge located 207 m south of the south jetty (Figure 2).

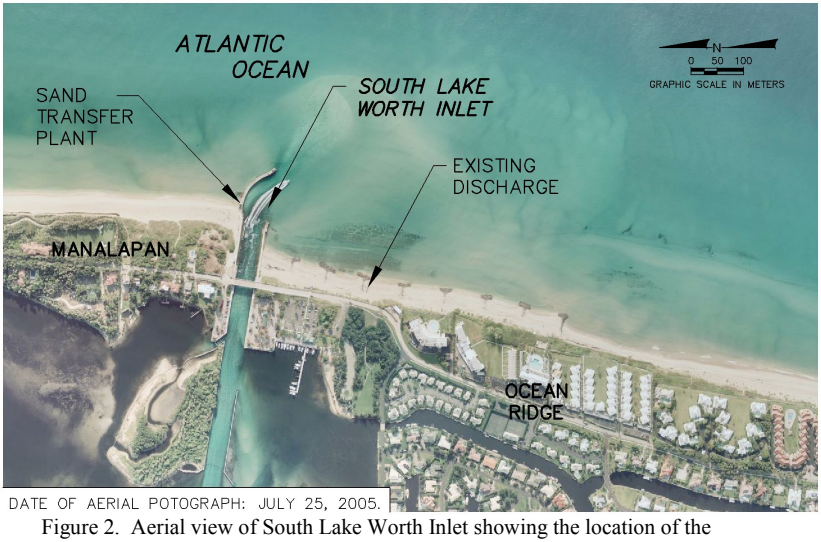

Figure 2. Aerial view of South Lake Worth Inlet showing the location of the bypassing plant, existing discharge and the south adjacent shoreline.

Palm Beach County owns the downdrift beach for the first 240 m. The next 990 m of upland property is privately owned. The first 2285 m of shoreline downdrift of the inlet is part of a Federally authorized shore protection project which includes 8 T-head groin structures and periodic nourishment with sand from offshore borrow areas (Olsen Associates, Inc., 1996).

Palm Beach County currently owns and operates the sand transfer plant at SLWI, which was last relocated in 1967. The current plant has reached the end of its useful life and is scheduled for replacement in 2007. As part of the design for a replacement plant, the County requested recommendations on the siting of the discharge pipe (CPE, 2004).

In this first case study, q (x,t) is expressed as two point sources of sand for the mechanical and natural bypassing. Due to limited data, Eq. 1 was solved on an average annual basis, so $q(x,t) = q(xp)$ for the mechanical bypassing, $q(x,t)= q(xs)$ for the bar bypassing, and $q(x,t)=0$ for all x other than xs, and xp. From Eq. 1, Q(x) was estimated and the littoral transport south of the south jetty is shown in Figure 3.

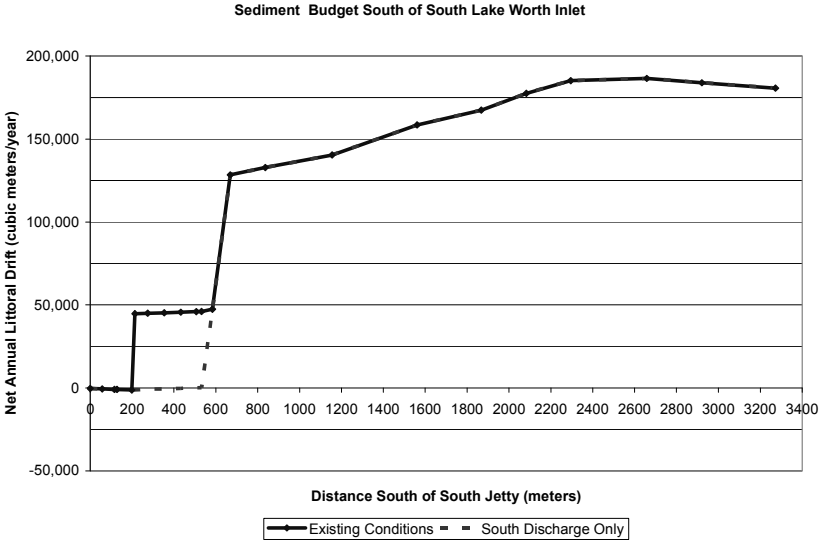

Figure 3. Existing and Proposed Sediment Transport South of South Lake Worth Inlet.

Immediately south of the inlet, the net annual littoral drift is low with an assumed loss back to the inlet of 380 m^3 per year. This value is consistent with the interior shoaling of the flood shoal area. The transport jumps abruptly at the existing discharge pipe (207 m) and at the point of the ebb shoal bar bypassing bar connection to the beach (670 m). South of the bar bypassing connection point, the littoral drift increases abruptly and approaches an asymptotic transport. Figure 3 shows that the wave induced littoral transport is just barely large enough to move the mechanically bypassed sand south along the beach. In fact, the T-head groin field appeared to be over performing. Discharging sand further south where the transport rate is higher appeared to be warranted.

CPE (2004) considered several alternative placements ranging from utilizing just the existing discharge at 207 m, to adding a second discharge at locations ranging from 584 m to as far south as 1130 m. Some of the suggestions were not solely based on technical justification and included upland owner input. A review of the pumping capacity of the proposed sand transfer motor, pump and pipeline system was performed (Four Jays Consulting, Inc., 2003). The review determined that the proposed system could pump a sand slurry to the last T-head groin (584 m) without risking sediment deposition within the discharge pipe.

The littoral drift curve (Figure 3) was adjusted assuming all mechanically bypassed sand was discharged through a second discharge located at the last groin in the T-head groin field (584 m). According to Figure 3, the bypassed sand will be discharged at a location of much greater wave induced sediment transport than at its current location; thus, the effectiveness of the bypassing should increase. From this analysis, support for extending a second discharge to the 584 m was recommended (CPE, 2004). While the use of q(x,t) as point sources is a useful tool, it results in abrupt changes in the wave driven littoral transport, which could be viewed as unrealistic.

The recommendation, for the addition of a second discharge at 584 m, was accepted by Palm Beach County (owner and operator of the plant). Nevertheless, the proposed location fronts private upland property, whose owners are disapproving the placement of the discharge in front of their property. The protection of private property rights is maintained under the State of Florida's beach preservation statute (Chapter 161, F.S.). For the time being, the proposed plant will continue to utilize the existing discharge at 207 m.

Case Study 2: Lake Worth Inlet, Florida

In contrast to the bar bypassing inlet at SLWI, the Lake Worth Inlet (LWI) is a deep draft navigation inlet with no ebb shoal and no natural bypassing of sand (Figure 4). The inlet was dredged in the early 20th century and was deemed a federal navigation project by 1925. The construction of twin jetties impacted the littoral drift significantly. As a result, a sand bypassing plant was constructed in 1958 to bypass a portion of the littoral transport to the downdrift beach. The remainder of the transport is allowed to shoal in the channel where it is dredged. The original discharge was within 25 m of the south jetty.

The plant operated more or less continuously until 1990 when the plant was damaged in a storm and when the steel discharge pipelines were found to be corroded. The plant set idle for several years until two new HDPE pipelines were directionally drilled under the inlet in 1996. Due to the limitations in directional drilling, the discharges were located approximately 64 m south of the south jetty. Since the resumption of bypassing in 1996, the beaches immediately downdrift of the inlet accreted significantly. This implies that only a portion of bypassed sand was being transported to the remainder of the Town of Palm Beach.

Aside from the publicly held lands that contain the south jetty, the upland property along the southern shoreline for several thousand m is privately owned. The Town does hold a beach access parcel at approximately 740 m south of the south jetty. This access parcel is used to deploy heavy equipment on the rare occasion that the existing discharges become landlocked.

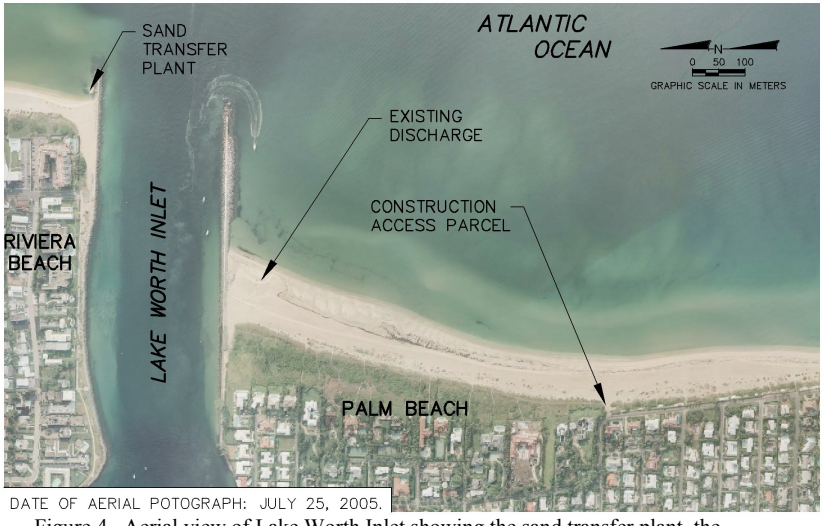

Figure 4. Aerial view of Lake Worth Inlet showing the sand transfer plant, the existing discharge and the south adjacent shoreline.

While the plant continues to operate, there is consensus that the existing sand transfer plant has reached the end of its life cycle and requires a major overhaul or replacement. Prior to initiating engineering of the pump and motors, the Town of Palm Beach requested an analysis of the optimum location of the discharge pipes and to determine if alternative locations would result in less beach accretion and more sand bypassing the immediate downdrift region.

In the second case study (CPE, 2005), the bypassing of sand in Eq. 1 is handled differently. Eqs. 1 and 2 are combined and q(x,t) is set to zero as there is no natural bypassing of sand at Lake Worth Inlet due to the maintained deep draft navigation channel.

The pipeline-bypassed sand is modeled after the diffused sand distribution described by Dean (2002). Dean (2002) states that for an initial narrow planform of sand along a straight beach, that the shoreline position with time, y_d (x,t) is:

$$y_d(x,t) = \frac{N}{\sqrt{4\pi G t}} e - \left(\frac{x^2}{4Gt}\right) \tag{3}$$

where N is the square footage of the initial planform, and G is the shoreline diffusivity (Dean, 2002). N was estimate for each bypassing event by dividing the bypassed volume by the active profile height ($b+d_c$). By doubling the value of N and

taking only half of the solution (positive x), the equation describes the shoreline response downdrift of an impervious jetty subject to a single bypassing event.

The initial diffusion of the narrow area was validated by comparing the resulting shoreline after one month of time for typical average wave conditions. At the end of one month the majority of the area had diffused away. This is consistent with observations of the actual discharge.

To determine the resulting net shoreline from M months of bypassing, the total bypassed induced shoreline change is then the summation of the shoreline responses for the corresponding remaining time intervals,

$$y_{dtotal}(x, M) = \sum_{i=1}^{M} \frac{N_i}{\sqrt{4Gt_i}} e - \left(\frac{x^2}{4Gt_i}\right) \tag{4}$$

where t_i = M-i + 1 in months:

The diffused shoreline response, y_{dtotal} , is then subtracted from the observed shoreline changes dy/dt, and Eqs. 1 and 2 are used to determine the wave induced sediment transport south of the jetty. The resulting net annual littoral drift curve is shown in Figure 5. In contrast to the abrupt changes in the SLWI case study, the littoral drift curve is a smooth transition from zero littoral drift at the inlet to a consensus value 1100 m downdrift of the south jetty.

Figure 5 clearly shows that the bypassing of an annual average of 131,000 m^3 per year to the existing discharge (64 m south of the south jetty) will result in deposition because the location has insufficient wave induced sediment transport to move such a large quantity of sand. Figure 5 also shows that by extending the discharge to approximately 740 m, that the littoral drift is approximately 85 percent of its maximum value and is greater than the volumetric rate of bypassing. The transport rate at 740 m is an order of magnitude greater than at the existing discharge. CPE (2005) recommended construction of a second discharge between 740 m and 1100 m south of the south jetty.

A review of the proposed bypassing pump and motors was undertaken assuming the existing HDPE pipes under the inlet were going to continue to be utilized (Four Jays Consulting, 2005). The proposed pump and motors were found to have the capability to pump a sand slurry to the existing discharge, but not to 740 m south of the jetty. A remotely operated booster pump on the south jetty was recommended if the discharge was to be lengthened.

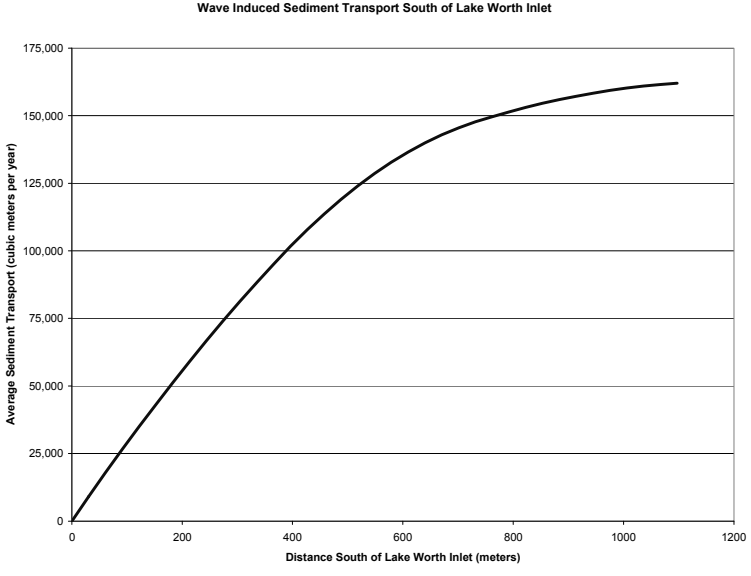

Figure 5. Average Sediment Transport South of Lake Worth Inlet.

The Town of Palm Beach accepted the recommendations and is pursuing the upland owner easements necessary to install a discharge pipe along the beach, and a booster pump at or near the south jetty.

CONCLUSIONS

Based on the previous two case studies and the findings of Bailard (2006), the following guidelines for the siting of sand discharges are offered:

a. Discharges should not be located immediately adjacent to the downdrift jetty. The littoral transport is either too small to transport sand away from the discharge or will transport sand back to the inlet. Neither achieves the objective of sand transport along the downdrift beach.

b. Dedicated sand bypassing systems should utilize two discharges at a minimum. This not only creates an engineering redundancy, but provides flexibility in discharging sand to the instantaneously optimal location as wave climates vary over a year.

1. The first discharge should be located close to the downdrift jetty (<100 m) to reinitialize the net sediment transport. If the inlet is not jettied, the distance should be increased such that reintroduction of sand back into the inlet is minimized. The volume of sand bypassed to this location should be limited to the wave induced sediment transport at this location.

2. The second discharge location should be at or downdrift of any bar bypassing feature, and at a distance from the downdrift jetty such that the wave induced sediment transport is greater than the annual bypassing rate. When the wave induced sediment transport is subject to significant annual fluctuations, additional flexibility in the second discharge location, may be warranted.

c. Discharges must be sited in cooperation with the design of the sand pumping system. Excessively long pumping distances may result in increased capital and operational costs by requiring increased horsepower, larger diameter pumps and pipelines, or thicker pipelines to account for the required increase in pressure in the pipe.

d. All locations should consider appropriate factors of safety (NRC, 1995) and include the effects of variable sediment budgets (Mann, 1999).

ACKNOWLEDGEMENTS

The author would like to thank the Town of Palm Beach and Palm Beach County for authorizing release of this data and for sponsoring the previous studies. The author also acknowledges the contributions of Christin Perkinson and Joseph Chaison, P.E. to the previous studies, and several CPE reviewers of this paper for their constructive comments.

Abstract: Flood-tide deltas are dynamic features that are linked to the morphodynamics of the associated estuarine beaches and shorelines. Flood-tide delta morphodynamics remain largely unknown. Historic aerial photographs from Port Stephens, a ria-like estuary located in NSW (Australia), are analysed using Geographic Information System (GIS) techniques. Port Stephens is used as a case study to define flood-tide delta morphodynamics that will be applicable to similar systems elsewhere. The waterline is chosen to represent the evolution of the estuarine beaches because they are reflective in a microtidal environment. Boundary definition for the flood-tide delta needs further work since it is a submerged feature and the photographs have different quality and correspond to different tidal levels. It is suggested that image processing techniques may help to solve this problem in the future. More studies, both morphologic and hydrodynamic, are needed to establish the sediment paths and magnitudes within the Port Stephens flood-tide delta.

INTRODUCTION

Flood-tide deltas (or shoals) are caused by sediment accumulation at the landward end of inlets. They are often fan- or horseshoe-shaped with a broad ramp that slopes up to the surface in the landward area (Hayes, 1979; 1980; Davis, 1996). This ramp is a shoaling continuation of the inlet channel and delivers sediment to the tidal delta during flooding

tides. Flood-tide deltas are dynamic features that have not been the subject of many investigations; their formation processes are well understood but their morphodynamics remain largely unknown. Flood tide deltas can also be associated with adjacent estuarine beaches whose morphodynamics are linked to the delta. Consequently, the adequate management of these beaches requires in-depth knowledge of the short-, medium- and long-term morphodynamics of delta system.

The objectives of this paper are: (1) to present some of the existing knowledge of flood-tide delta morphodynamics in a micro-tidal estuary at short to medium temporal scales; (2) to identify future directions of research to establish flood-tide delta morphodynamics and their relationship with the associated shorelines; and, (3) to present some preliminary results in the decadal evolution of the flood-tide delta and associated shorelines of a flood-dominated estuary.

STUDY AREA

Port Stephens is located in New South Wales (NSW), SE Australia (Figure 1) 230 km north of Sydney. It is a ria-like drowned river valley estuary (Roy *et al*., 2001) and has an east-west orientation with a total length of 23 km and a surface area of 140 km^2. Two well differentiated basins can be distinguished inside it: the inner and the outer basins, also known as upper and lower ports. The estuary is shallow and that has prevented further development as a commercial/industrial harbour. At present it is the most popular tourist destination on the 1,000 km long NSW coastline.

Tides in the area are semidiurnal and microtidal with mean tidal ranges of 1.6 m and 1.3 m for spring and neap tides respectively (Short, 1985). According to Short and Trenaman (1992), the deepwater wave climate is moderate with mean significant wave heights (H_s) of 1.5 m and 8 s mean wave period (T). The same authors state that the central NSW coast receives few low-energy waves (<1 m, 10%) and a significant amount of high-energy waves (2-3 m, 21%; 3-5 m, 5%). Waves from the NE dominate during summer and E-SE waves are prevalent for the rest of the year; although SE storms may occur at any time of the year, they are more frequent between April and September (Short and Trenaman, 1992).

Rainfall data from the Australian Bureau of Meteorology (BOM, 2006) show that the average yearly rainfall between 1884 and 2004 is 1345 mm; minimum monthly rainfall occurs in October - November (75-80 mm) and increases to reach maximum rainfall in May - June (150-155 mm). Winds in the area are strongly influenced by a daily sea breeze pattern with onshore winds (>30 km/h) occurring in the afternoon from spring to autumn; W-SW winds with speeds over 30 km/h dominate the winter months (BOM, 2006).

Under the framework of Roy *et al*. (2001) classification for SE Australian estuaries, Port Stephens is classified as a tide-dominated estuary because tidal processes dominate the overall estuarine dynamics. Tidal attenuation inside the estuary is negligible because it has a wide mouth (1.24 km); however, it is located on a wave-dominated coast where

ocean waves do not allow ebb-tide delta deposition and propagate into the estuary affecting the flood-tide delta and the associated shorelines.

Port Stephens has a well developed flood-tide delta (Figure 1) that is occasionally affected by swell propagation into the estuary. Several authors (e.g., PWD, 1985; PWDS, 1999) have also emphasised the role of locally generated wind-waves in influencing the flood-tide delta and associated beaches. According to PWDS (1998) the spring tidal prism at the entrance is 168×10^6 m^3 for ebbing and 165×10^6 m^3 for flooding. The same authors provide values for maximum tidal currents at the entrance in excess of 1 m/s.

METHODS

Present Work

The methodology includes an extensive search on Port Stephens to review existing knowledge on the study area. Historic data on Port Stephens include aerial photographs, maps and bathymetric charts of the area; data obtained from technical and scientific publications; and forcing mechanisms records (waves, tides, winds, rainfall). Data is then included in a Geographic Information System (GIS) that is set using ESRI ARC-GIS 9.1. The GIS allows the organisation of the data and the accurate measurement of the evolution of the morphologic features and shorelines. Four photographs from 1963, 1986, 1994 and 2006 have been georectified and used in this study.

Present measurements include: (a) location and evolution of the northern shorelines and Winda Woppa Spit; (b) location and evolution of the shoreline at Shoal Bay; and (c) definition and evolution of the flood tide delta. As a preliminary approach, shorelines are identified as the intersection between the water and the land. The waterline, or instantaneous-shoreline, cannot be always taken as representative of "normal" or "average" conditions (Smith and Zarillo, 1990) because short-term variations can be high. Short-term variability depends mostly on beach slope (tan β), tidal range and wave energy. Estuarine beaches in Port Stephens are reflective: beach measurements in Shoal Bay in October 2006 had an average tan β of 0.12 (i.e. 1 m variation in the water level would imply 8.3 m across-shore displacement of the shoreline). Simultaneously, it is not often that waves propagate into the estuary and they do not seem to be significant in the aerial photographs used for this study. Therefore, taking into consideration the amplitude of mean spring tides (0.8 m) and the average beach slope, the maximum error associated to taking the instantaneous shoreline would be $\pm$7 m across-shore.

Once the shorelines are identified the area of every morphologic feature is calculated using GIS; the evolution of the areas is made by comparing the areas obtained for consecutive years. It should be noted that data presented in this study refer to the extent of the morphologies instead of volumes of sediment.

Future Work

More aerial photographs (1951 to present) and historic maps will be included in the GIS to obtain a more complete evolution of the area over a longer period. More accurate measurements will be made with the possible application of image processing techniques as suggested by Aarninkhof *et al*. (2000), Hoeke *et al*. (2001), Aarninkhof (2003) and Boak and Turner (2005) to identify the shorelines in a more rigorous and accurate way.

Future work will also include the surveying of the flood-tide delta and the associated estuarine beaches in Port Stephens to obtain digital terrain maps (DTM). DTMs will then be included in the GIS and compared with the historic data. The topographic and bathymetric monitoring will be coupled with simultaneous hydrodynamic measurements using acoustic Döppler current profilers (ADCPs) and data from other sources such as wave, tidal and wind data. The combined analysis of the data will allow the

establishment of present and historic flood-tide delta morphodynamics and association with the morphodynamics of estuarine beaches.

PORT STEPHENS: EXISTING KNOWLEDGE

The shorelines on both sides of the estuary have experienced ongoing erosion that threatens public and private property resulting in several engineering interventions being undertaken to manage coastal erosion, namely at Jimmy's Beach, Shoal Bay and Nelson Bay (Figure 1). There has also been scientific interest on the presence of a large sandwave on the Yacaaba Barrier. Therefore, there have been several technical and scientific studies made at the area in order to propose management options and to monitor undertaken engineering interventions. These studies include several reports on Jimmy's Beach erosion (i.e., PWD, 1985; 1992); reports on Nelson Bay (PWD, 1979); a detailed study on the evolution of the sandwave at Yacaaba Barrier (Cholinski, 2004); and more general in-depth geomorphological studies such as Thom *et al*. (1992) and PWDS (1999).

Erosion at Jimmy's Beach and Winda Woppa

Jimmy's Beach and Winda Woppa are part of a sand spit that corresponds to the southern bank of the Myall River mouth (Figure 1). According to Thom *et al*. (1992) the spit was initiated about 1820 and reached its maximum length about 1910; a storm in 1927 caused the breaching of the spit some 1300 m from its end, creating a sand bank that migrated landwards to form a beach on Corrie Island. The same authors point to some westward extension of Winda Woppa occurring before 1992. Figure 2 shows that Winda Woppa spit has been one of the most dynamic features of the estuary; its dynamics seem to be related with the hydrodynamics of the lower Myall River. Thom *et al*. (1992) also stated that the flood-tide delta had undergone a net loss of sand since accurate charts became available (1851) thus facilitating spit breaching during the 1927 storm. The same authors proposed an alternative evolution where the sand spit breaching occurred due to the high energy conditions and extreme flooding that occurred during the 1927 storm, stating that it could be completely independent from the flood-tide delta evolution.

Jimmy's Beach and Winda Woppa have been undergoing erosion for over 40 years (PWD, 1985; 1992; PWDS, 1999). They are narrow reflective estuarine beaches that are backed by a sand scarp of some 2-4 m. The development of the area for residential uses started in the 1960s (Watson, 2000) and at present constitutes expensive beachfront real estate. Recession rates on the beach reach 1.1 m/yr with an average rate of removal of sediment of 8,000 m^3/yr (PWDS, 1999). As a consequence, there have been several studies of Jimmy's Beach and it has been nourished several times (PWD, 1985; 1992; PWDS, 1999). The first nourishment intervention was undertaken in March 1984 and by 1998 a total of 372,000 m^3 had been placed in the area (Watson, 2000)

Some of the studies (i.e., PWDS, 1999) have computed a net eastward direction for the sediment transport along the beach with the application of numerical models. They stated that the main forcing mechanism contributing to the net loss of sediment on

Jimmy's Beach was wind waves generated by westerly winds. They therefore identify the sandwave along Yacaaba Barrier (Figure 1 and 2) as a suitable source of sediment for future nourishment interventions.

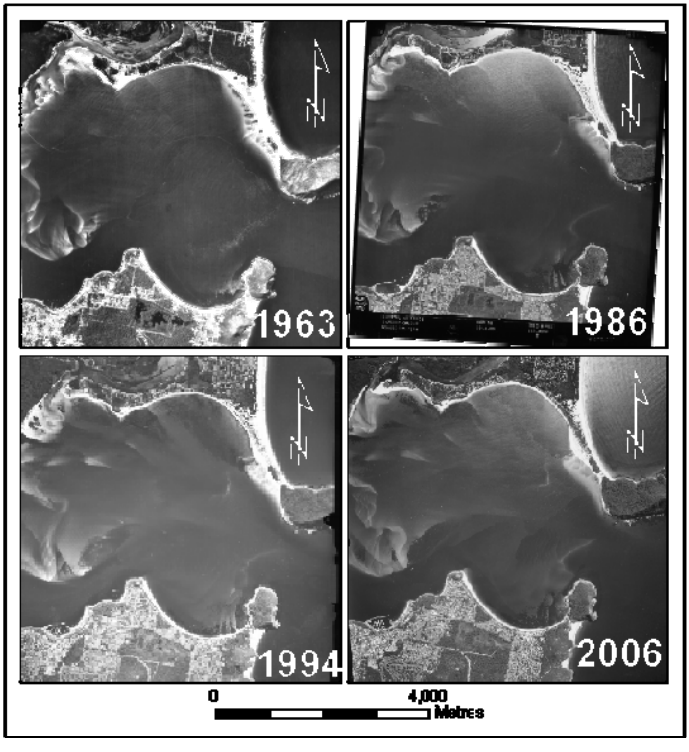

Figure 2. Georectified aerial photos of the study area.

Shoal Bay and Nelson Bay

Shoal Bay is located westward from Tomaree Head (Figure 1 and 2) on the southern shore of Port Stephens; it is an embayed estuarine beach that is aligned to the swash refraction patterns inside the estuary. Its more protected part, next to the headland, is narrow and with mean grain size about 0.25 mm. The most exposed section of the bay is wider with coarser sediments (mean grain size between 0.75 and 1.00 mm). Beach cusps are often present from the middle part of the bay to the westernmost end with typical wavelengths between 20 and 25 m. Westwards longshore transport appears to occur in this beach, evidenced by updrift sediment accumulation on the eastward side of a boat ramp located on the eastern end of the beach

Nelson Bay is the next westward embayment from Shoal Bay. It has been undergoing erosion processes since at least the 1940s, when a concrete slab and revetments were

placed on the beach for protection with limited success (PWD, 1979). A seawall was built in 1940 and it lasted only two years (PWD, 1979). According to the same authors the alignment of the shoreline underwent considerable variation between 1959 and 1977. They state that sediment transport along the beach is eastward directed as a consequence of locally generated wind waves, and attribute some of the erosion problems to the construction of a breakwater at the westernmost end of the beach. They also relate erosion problems to the nearby presence of the main ebb tidal channel (Figures 1 and 2).

Yacaaba Sand Wave Dynamics

Yacaaba Barrier is a sandy isthmus that separates the estuarine area of Port Stephens from Fens Embayment to the North (Figure 1). It is a typical low-energy reflective beach that is located eastwards from Winda Woppa and Jimmy's Beach. It is characterised by a sandwave that forms near the entrance and migrates landwards (Cholinski, 2004). Cholinski (2004) analysed sandwave evolution between 1951 and 2003. The same author identified several sandwaves in the area and concluded the following: (1) the first sandwave was observed in 1981; (2) the average migration rate was 70 m/yr to the west; (3) the sandwaves do not seem to migrate any further than the middle zone of the Yacaaba Barrier; (4) sandwaves increase their size by attaching submerged transverse bars; and, (5) the width of Yacaaba Barrier increased during the study period.

Flood-tide Delta Morphodynamics

The flood-tide delta at Port Stephens occupies most of the outer estuary and is related with the dynamics of Myall's river mouth and Winda Woppa spit (Thom *et al*., 1992) as well as with the adjacent estuarine beaches. It is a shallow delta (Figure 1 and 2) with depths that are mostly less than 5 m. Thom *et al*. (1992) described a net sand loss in the flood-tide delta since 1851 and speculated that Winda Woppa's breaching occurred due to the erosion of the flood-tide delta that caused the deepening of the area.

The morphodynamics of the flood-tide delta are controlled by tidal currents, swell waves that propagate into the estuary and locally generated wind waves. The relative importance of these mechanisms ultimately controls the evolution of the flood-tide delta. Tidal currents in the estuary are not well known. PWDS (1998) measured tidal currents and water levels during two consecutive days in September 1993; the measurements were restricted to the estuary entrance, the mouth of the Lower Myall River, the estuary constriction at Soldiers Point (which separates the outer estuary from the inner estuary, Figure 1) and Karuah River mouth in the north-west of the inner estuary. The estuary has maximum tidal flows occurring during the two hours following mid-tide and minimum tidal flows (slack water) occurring within one hour after high and low tide (PWDS, 1998). The same authors found that the tidal range is amplified along the estuary; they measured 1.13 m at the entrance and 1.31 m at the mouth of the Karuah River on the 29th September 1993.

PRELIMINARY RESULTS ON THE RECENT MORPHOLOGIC EVOLUTION

Figure 2 shows four georectified aerial photos of the study area. These photos are analysed using GIS technology.

Evolution of the Northern Shoreline and Winda Woppa Spit

The area comprising Yacaaba Barrier, Jimmy's Beach and Winda Woppa spit (Figure 3) underwent accumulation of $120x10^3$ m^2. The most significant changes were the accumulation due to Yacaaba's sandwave, mostly in 1994 and 2006; and at the westernmost point of Winda Woppa that showed westwards growth during the study period. The entire area showed no significant variations between 1963 and 1986 (Figure 4). An increase in $60x10^3$ m^2 occurred both for 1986-1994 and 1994-2006 (Figure 4). The westward growth of Winda Woppa Spit was high for 1963-1986, there was some retreat for 1986-1994 and was the greatest for 1994-2006 with approximately 275 m. Jimmy's Beach underwent approximately 50 m of shoreline retreat between 1963 and 2006; retreat between 1994 and 2006 has been between 10 and 20 m.

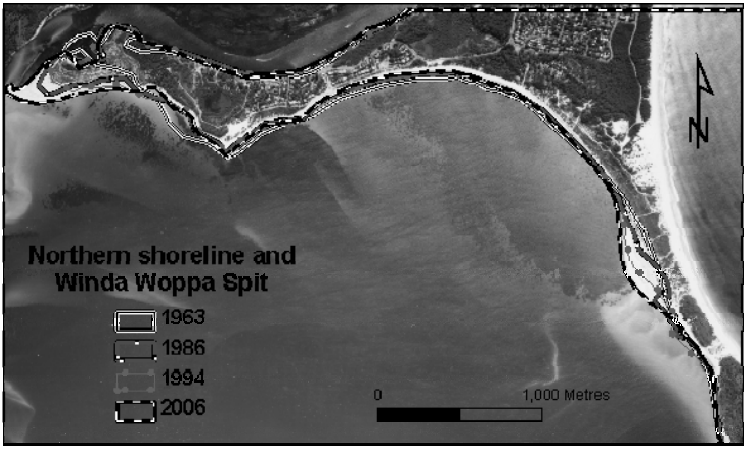

Figure 3.Evolution of northern shoreline/ Winda Woppa 1963-2006. The photo is from 2006.

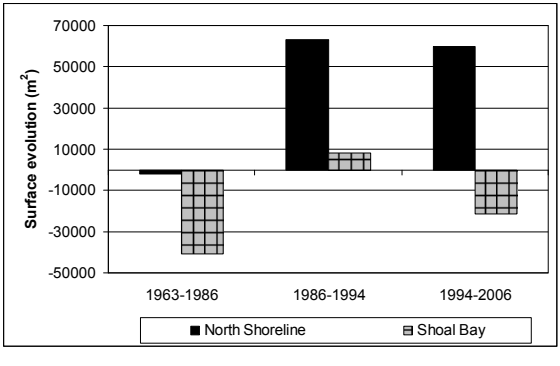

Figure 4.Surface evolution for the Northern Shoreline and Shoal Bay.

Evolution of Shoal Bay

Shoal Bay reduced its surface during most of the study period (Figures 4 and 5). Total erosion implied an area reduction of -55x10^3 m^2. The highest surface reduction occurred on the western part of the beach (Figure 5) with shoreline retreat approximately over 30 m. The largest erosion occurred for 1963-1986 with -40x10^3 m^2.

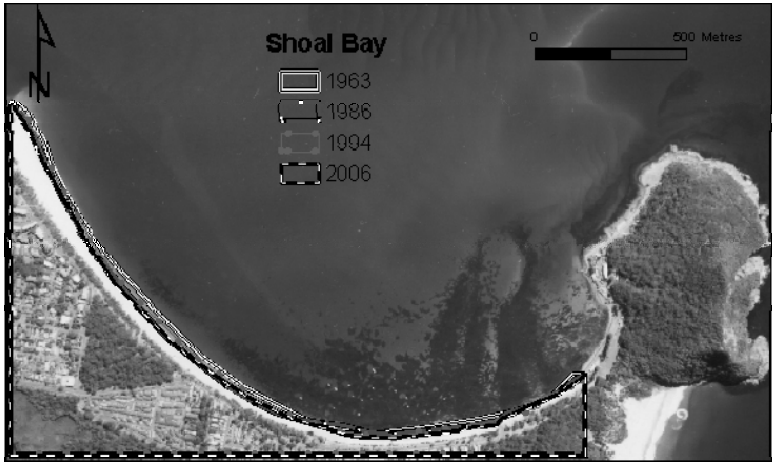

Figure 5.Evolution of the shoreline on Shoal Bay 1963-2006. The photo is from 2006.

Evolution of the Flood-Tide Delta

The definition of the morphological boundaries of the flood-tide delta is not clear and has yet to be defined. However, some approximation was made by enclosing the areas that showed the highest accumulation of sand and the qualitative results are in Figure 6. According to the data, there seems to have occurred a massive accumulation of sediment during the study period. However, it is important to note that the flood-tide delta is a submerged morphology and therefore its visibility highly depends on the tidal level and the quality of the aerial photos. Further work is required to correct the tidal levels, include other data that might help in the analyses and also, to develop a technique that allows the definition of the flood-tide level boundaries that does not require elevation data.

Figure 6 shows the preliminary attempt made to define the boundaries of the flood-tide delta. The western limit is given by the photograph from 1986, and the northern limit was selected to avoid the inclusion of Winda Woppa spit. The southern limit is easier to define because the ebb channel runs along the southern margin of the estuary. The main problem is the eastern limit because it is a continuum, from deeper flood channels next to the mouth, to shallower flood-delta on the westward side. The eastward limit is also heavily dependent on the tidal level.

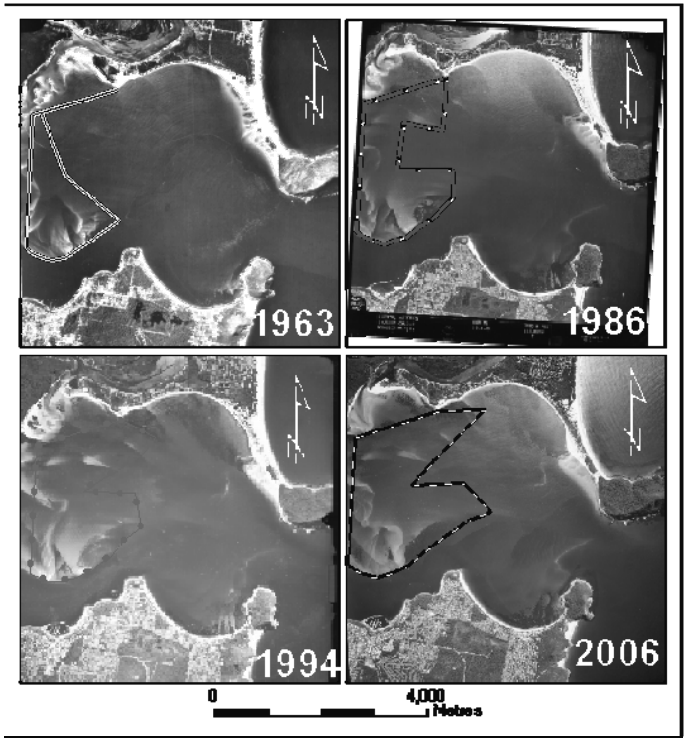

Figure 6. Preliminary attempt to delimit manually the flood-tide delta. Tidal levels are not the same in every photo and the resolution and photo quality also change.

DISCUSSION

Port Stephens is comparable with many ria-type estuaries in NSW and other parts of the world where fluvial processes have relatively less impact today on morphology and hydrology than during periods of low sea-level (Roy *et al*., 1980).

Data presented allows some preliminary analyses on the evolution of the flood-tide delta and associated shorelines in Port Stephens. The basic approach used in this study shows a general accumulative trend along the northern shoreline (Figure 3 and 4) that includes Yacaaba barrier, Jimmy's Beach and Winda Woppa spit (Figure 1). Therefore, when measuring area increase/decrease, the sediment accumulation due to Yacaaba's sandwave and to the westward growth of Winda Woppa spit seems to be of greater magnitude than the erosion occurring at Jimmy's Beach. Between 1984 and 1998 a total of $372x10^3$ m^3 of sand was placed on Jimmy's Beach (Watson, 2000); however, according to the shorelines measured in this work (Figure 3) and *in situ* observations (Figure 7) Jimmy's beach is still undergoing erosion. The westward growth of Winda

Woppa spit had already been described by Thom *et al.* (1992); data between 1994 and 2006 (Figure 3) show an intensification of the westward growth of the spit.

Results from numerical modelling have shown that the effect of wind generated local waves is the dominant control on Jimmy's Beach and therefore there is a net longshore transport from Jimmy's Beach towards Yacaaba Barrier (i.e., PWDS, 1999, Watson, 2000); PWDS (1999) therefore identify Yacaaba's sandwave as an ideal sediment source for future nourishment interventions on Jimmy's Beach. Results from Cholinski (2004) contradict the numerical models stating that the sandwave is rapidly migrating landwards (70 m/year). Further, and according to the same author, the first sandwave observation corresponds to 1981 and the sandwaves do not pass the central part of Yacaaba barrier. Further work is needed to correctly establish the sediment transport paths in this area. Data herein presented also show significant westward accretion of Winda Woppa spit; it is not clear which are the processes involved but spit dynamics seem to be linked not only to the estuary and flood-tide delta dynamics but also to the fluvial dynamics of the Myall River mouth. What appeared as a catastrophic breaching in 1927 might be a cyclic process involving sediment bypassing from the east to the west of the inlet that constitutes the mouth of the Myall River in what would be a typical sediment bypassing mechanism for geographically stable inlets (FitzGerald *et al.*, 2001). Further studies are needed to identify the sediment transport paths and magnitudes involved in the general evolution of the area.

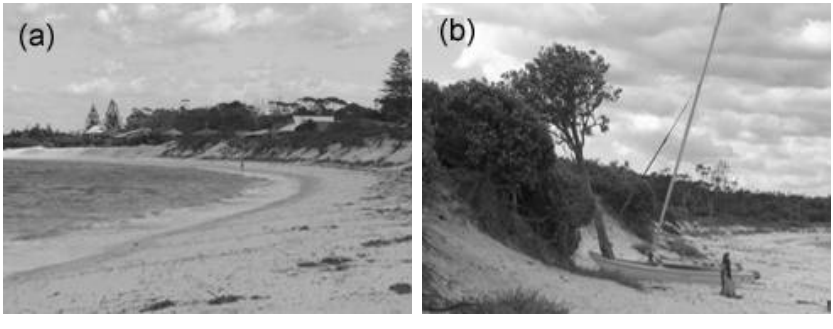

Figure 7. Jimmy's Beach location photos. (a) The beach is narrow with private property behind the scarp; (b) a tree and a tree stump are found in the beach due to strong erosion [Photos by Vila-Concejo, April 2006]

Shoal Bay underwent shoreline retreat during 1963-1986 and 1994-2006 mostly in the central and western part of the beach where shoreline retreat was over 30 m. The southern shoreline westward from Shoal Bay, Nelson Bay (Figure 1), was not analysed in this study but it has been undergoing erosion (PWD, 1979). A more detailed GIS analysis should be made in order to determine the shoreline evolution for the entire south shoreline. Several problems have been encountered when delimiting the flood-tide delta using aerial photos (Figure 6). As it is a submerged feature, the quality of the photograph

and the tidal levels are key factors that should be taken into account. It seems, however, that the flood-tide delta increased its area during the study period.

Roy *et al*. (1980) stated that Port Stephens and similar systems elsewhere are undergoing sand loss processes that are related to: (a) littoral drift; (b) aeolian transport into transgressive dunes; and (c) offshore transport of sand by seaward-flowing bottom currents. It is important to note that the mechanisms controlling sediment exchange through the entrance and outer estuary have not been investigated and therefore are a source of uncertainty for present conceptual models of behaviour that could be applied to Port Stephens and similar estuaries elsewhere.

Future work

The basic approach used in this study allowed the definition of general accretion and erosion/retreat areas. It is not clear however, if the use of the instantaneous shoreline (i.e. the waterline) is a good indicator of the system's variability; data presented in this paper seem to indicate that variations in the system are significantly larger than the associated ±7 m across-shore error. Additionally, Aarninkhof *et al*. (2000) and Aarninkhof (2003) extracted proxy shoreline features from digital coastal images that are not necessarily visible to the human eye. Hoeke *et al*. (2001) also proposed image processing techniques to define the shoreline using GIS. It seems likely that similar techniques will be useful to delimit submerged features taking into account a tidal level correction.

The morphologic evolution of Port Stephens should be coupled with the historic records of wave, tidal, wind and rainfall data to identify which are the processes governing the changes in the system. Present dynamics will be investigated by measuring the morphology and the forcing mechanisms. It is expected that establishing the present morphodynamics of Port Stephens flood-tide delta will help to understand its recent evolution and it will be applicable to other similar estuaries elsewhere.

CONCLUDING REMARKS

Flood-tide deltas are dynamic features that are often linked to estuarine beaches and shorelines. Flood-tide delta morphodynamics need to be established to understand the process-response of the system and to improve future management not only of the flood-tide delta but also of the associated beaches and shorelines.

The flood-tide delta in Port Stephens seems to have increased its extent since 1963. The north shoreline underwent general accumulation with sandwave accretion on the east and spit progradation on the west that has been intensified between 1994 and 2006. The central area of the north shoreline underwent erosion that was managed through sand nourishment but it is still undergoing erosion at present. Shoal Bay (on the southern margin of the estuary) has undergone erosion which, in some parts, has shown over 30 m of shoreline retreat. More studies, both morphologic and hydrodynamic, are needed to establish the sediment paths and magnitudes within the Port Stephens flood-tide delta.

A GIS is a useful tool to analyse the morphologic evolution of estuaries. Using the instantaneous shoreline (waterline) inside an estuary seems to represent shoreline evolution with enough accuracy. The definition of the flood-tide delta needs further development. It is suggested that image processing tools could be applied to determine the boundaries of the flood-tide delta. The extension of the flood-tide delta will have to be further corrected for the tidal levels.

ACKNOWLEDGEMENTS

This work is partially funded by the Australian Research Council (ARC) grant number: LP0668979; Ana Vila-Concejo is also funded by ARC. The authors would like to acknowledge the New South Wales (NSW) Department of Natural Resources (Australia) and the councils of Port Stephens and Great Lakes for financial support.

Dave Hanslow, Doug Lord, Christine Gray and Robert Clout from the Department of Natural Resources (NSW; Australia) kindly helped by providing aerial photos and access to technical reports. Allan Gordon and Des Mitchell from the Department of Commerce (NSW, Australia) provided essential help in finding bathymetries and charts of the study area. We would like to thank Michelle Frolich for her great contribution with the literature search. Also to the UNSW-GEOS3731 students that helped with the measurements on Shoal Bay.

USING SIMPLE SEMI-EMPIRICAL MODELS FOR INTEGRATED ASSESSMENT OF SCENARIOS FOR A NAVIGATION CHANNEL. THE CASE OF THE PORT OF OSTEND, BELGIUM.

Toon Verwaest[1]

1. Flanders Hydraulics Research, Berchemlei 115, B-2140 Antwerp, Belgium, toon.verwaest@mow.vlaanderen.be

Abstract: Scenarios for a new navigation channel to the port of Ostend (Belgium) are to be assessed. Regarding coastal sediments dynamics, two aspects are of importance: first the maintenance dredging of the navigation channel itself (functional aspect), secondly the impact on the surrounding environment. The latter involves primarely the impact on the morphology of the sea bottom and the impact on the turbidity of the coastal waters. Available results of in situ-measurements, numerical modeling and laboratory experiments for the Belgian coastal zone were gathered, as well as general scientific literature. It could be concluded that the state of knowledge on coastal sediment dynamics in the Belgian coastal zone is to limited to be able to completely validate a process-based numerical model. A simple semi-empirical model was built, that is able to represent the essence of the impact on coastal sediment dynamics of a new navigation channel.

INTRODUCTION

The assessment of master plans of coastal ports comprises an assessment of the impact of scenarios regarding coastal sediment dynamics. A functional assessment as well as an environmental assessment are needed. Recent European legislation on environmental impact assessment (EIA) stipulates the use of a cascade approach in two steps : first an assessment of scenarios of masterplans (a strategic EIA) and secondly a more detailed assessment of scenarios of infrastructure works that implement a chosen master plan (a project EIA). This regulation –adding the concept of a strategic EIA- aims at considerations of environmental impact already to be taken into account in the earliest stages of design.

Thuss, for master plan studies a multidisciplinary approach has to be followed. Integration of the different disciplines is very important. Using simple semi-empirical models that can be easily understood by non-experts, but still are able to represent the essence of the impact on coastal sediment dynamics are very usefull in such a framework.

THE CASE OF IMPROVING THE NAVIGATION CHANNEL TO THE PORT OF OSTEND, BELGIUM

For the accessibility of larger ships to the port of Ostend an improved navigation channel is needed, amongst other infrastructure works (e.g. larger breakwaters). The port of Ostend is situated at the Belgian coastline in the southern part of the North Sea. Scenarios for an improved navigation channel have to be assessed, taking into account not only the accessibility for the largest ships but also other functional and environmental issues. Regarding impact on coastal sediments dynamics, two aspects are of importance: first the impact on maintenance dredging of the navigation channel itself (functional aspect), secondly the impact on the surrounding environment. The latter involves primarely the impact on the morphology of the sea bottom (erosion due to dredging nearby) and the impact on the turbidity of the coastal waters. To assess these impacts a.o. a semi-empirical model was elaborated taking into consideration all the available expertise on coastal sediment dynamics in the area that is relevant for the assessment of improved navigation channel scenarios.

STATE OF KNOWLEDGE ON COASTAL SEDIMENT DYNAMICS IN THE AREA

The sea bottom morphology is characterised by the presence of shore parallel sandbanks and swales. This is illustrated on Figure 1. On this figure the present navigation channel and the most probable future navigation channel are indicated.

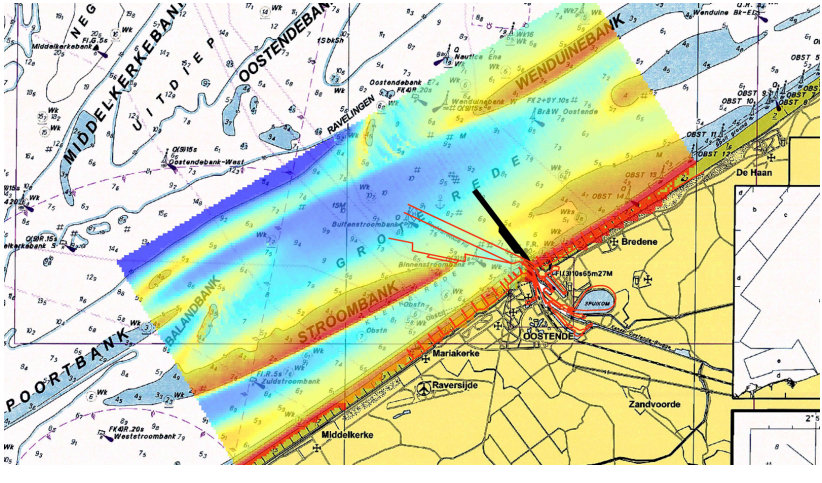

Fig. 1. Sea bottom in front of Ostende, with indication of the most probable future navigation channel (in black) and the present navigation channel (in red)

The sea bottom sediments in the area of the new navigation channel are a mixture of sand and mud particles. From in situ measurements –although limited in number- the relative mass percentages are determined as 50 % sand particles (> 63 μ) and 50 % mud particles (< 63 μ). This composition is based on measurements of surfacial sediment samples. Only a few analyses of drillings are available. Thin layers of soft mud are found in patches on the sea bottom, especially in the lower lying areas after calm weather and neap tides. Waves or spring tide currents remobilises this soft mud.

Prevailing residual tides, winds as well as waves all result on a yearly basis in a net transport from SW to NE. From operational hydrodynamic models, which have been calibrated and validated through many years of oceanographic research around the Belgian Continental Shelf, it follows that a water particle takes on average ca. 4 weeks to cross the Belgian coastal waters (65 km in length, from SW to NE).

The dynamics of mud particles and sand particles are very different. Their dynamics is treated separately, assuming no interaction of mud and sand. Process based models for mud transport as well as sand transport in the Belgian coastal zone are still work in progress. Several decades of research have not yet resulted in completely validated models, indicating the complexity of the coastal sediment dynamics.

Mud dynamics

Regarding mud dynamics the state of knowledge on the large scale is described in Fettweis et al (2005). The major natural transport of mud in the area is a yearly net transport of ca. 15 M TDS (Million Ton Dry Solids) mud per year through the Dover Strait and continuing along the coastline of Belgium (from SW to NE). Mud is advected with the residual water flow. The major antropogene mud transport is by maintenance dredging of the navigation channels and coastal ports in Belgian coastal waters. It amounts to ca. 10 M TDS mud per year. All dredged mud is also dumped in Belgian coastal waters. From several years of remote sensing observations (satelite SeaWIFFS, MODIS Aqua and MODIS images) as well as in situ profile measurements the concentration of mud in suspension is determined as ca. 50 mg/l on average for the more shallow coastal waters (from the coastline to ca. 25 km out the coastline). The resulting amount of mud in suspension is calculated as ca. 2 M TDS mud. The mud on the sea bottom which is readily available for transport, it is the patches of thin layers of mobile soft mud, is roughly estimated to be ca. 20 M TDS on average –although not enough measurements are available for a reliable estimate. The yearly erosion of consolidated mud (in areas where clayey soil outcrops) and the yearly sedimentation+consolidation of mud (in some sheltered areas) are of the magnitude of a few M TDS mud per year, and are more or less compensating each other.

Sand dynamics

Regarding sand dynamics the state of knowledge on the large scale is described in Van Lancker et al (2005). Large scale sand dynamics in the area is determined by a yearly net

alongshore transport in the direction of the prevailing currents and waves (from SW to NE). However, this net sand transport is the result of alternating gross sand transport intensities that are an order of magnitude (factor 10) larger. The momentous sand transport alternates mainly between SW to NE and NE to SW (parallel to the coastline), in accordance with the alternating current direction. The current climate and the wave climate are known accurately, but the resulting net sand transport cannot be determined accurately from this hydrometeo climate because there is no completely validated sediment transport formula available.

From historical nautical maps the morphological response to a navigation channel across the sandbanks can be observed. In the beginning of the 20th century for the first time a navigation channel across the shore-parallel sandbank "Oostendebank" was dredged. During the 20th century this navigation channel, called "Rechtstreekse Kil", has been deepened progressively as the draft of the ships in use became larger and larger. The morphological response caused by the creation, maintenance and deepening of this navigation channel appears to extend much further than the location of the dredging works itself. Relatively accurate historical nautical maps are available every ca. 5 years for this area for the period from the mid 20th century until present. From this time series the area where the influence of the navigation channel is dominant is determined. This influence area is ca. 10 km^2, for a navigation channel of less than 1 km^2. This influence area corresponds to the establishment of a morphological equilibrium slope of ca. 1/200. A clear correlation between the depth of the navigation channel and the sediment volume in the influence area is determined. This correlation is shown in Figure 3.

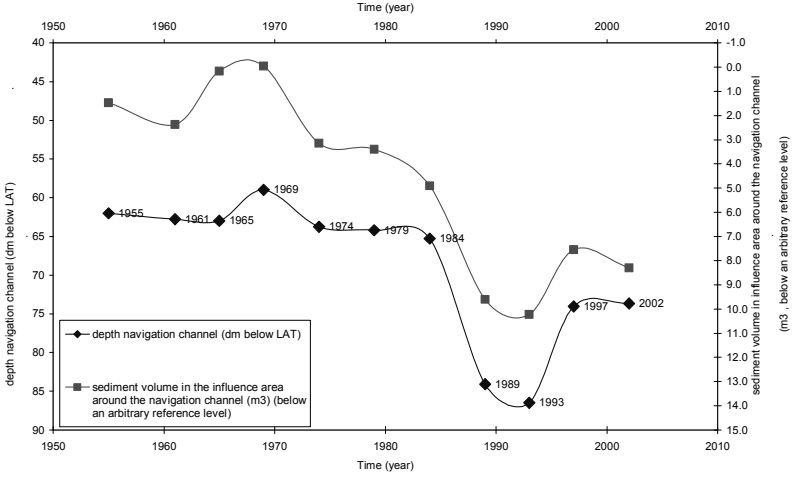

Fig. 3. Correlation between the depth of the navigation channel and the sediment volume in the influence area around the navigation channel

SEMI-EMPIRICAL MODELS FOR MUD AND SAND DYNAMICS

The state of knowledge is incorporated in these semi-empirical models.

Mud dynamics

A distinction is made between an equilibrium, steady state and a state of transition (between successive equilibrium states). The equilibrium state for mud is described in Figure 4.

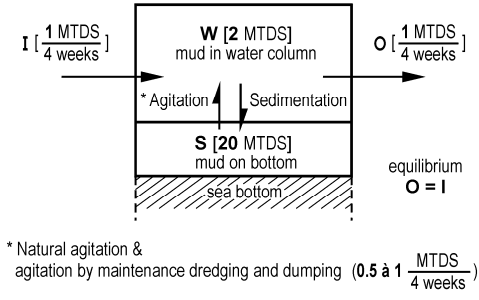

Fig. 4. Concept of equilibrium mud dynamics in the Belgian coastal waters

If one of the boundary conditions changes then the equilibrium state changes. For example, when due to the dredging of an improved navigation channel an additional, permanent source of mud sediment is created, after some time the amounts of mud in the water column, on the bottom and transported per time unit out of Belgian coastal waters will be increased correspondingly. Following a linear approximation the new equilibrium state is then described by the Figure 5.

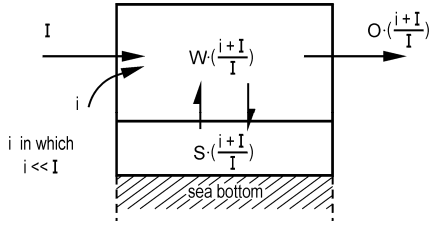

Fig. 5. Effect of an additional, permanent source of mud on the equilibrium steady state

where W = amount of mud in the water column (M TDS); S = amount of mud on the bottom (M TDS); I = transport of mud into Belgian coastal waters (M TDS / 4 weeks); O = transport of mud out of Belgian coastal waters (M TDS / 4 weeks); i = additional source of mud into Belgian coastal waters (M TDS / 4 weeks);

It is convenient to define r as the ratio of the additional source of mud relative to the major transport into Belgian coastal waters (Eq. 1).

$$r = \frac{i}{I} \qquad \text{with } r << 1 \tag{1}$$

The basic assumption is to consider a linear system with two system constants, α and γ (Eq. 2).

$$\alpha = \frac{W}{S} \qquad ; \qquad \gamma = \frac{W}{O} \tag{2}$$

The system constant α is describes the equilibrium between the processes of agitation, natural as well as antropogene, and the processes of sedimentation. The system constant γ is the average resident time in Belgian coastal waters of a mud particle that (by chance) never reaches the bottom.

From conservation of mass for mud and substution of Eq. 2 (Eq. 3) it follows that the transition from one equilibrium state to a new equilibrium state is then described by an exponential decay curve with a half time τ given by Eq. 4 (integration of Eq.3).

$$\frac{dW}{dt} + \frac{dS}{dt} = \frac{dW}{dt} + \frac{dW}{dt}\frac{1}{\alpha} = I + i - O = I + i - W\frac{1}{\gamma} \tag{3}$$

$$\tau = \gamma\left(1 + \frac{1}{\alpha}\right)\ln(2) \tag{4}$$

where τ = the time it takes to reach the mean state between two successive equilibrium states. The transition from the initial equilibrium state (with i=0) to a new equilibrium state (with i=i) is mathematically described by Eq. 5.

$$W(t) = W_1 + (W_2 - W_1)\left(1 - \exp\left(-\frac{t}{\tau}\right)\right) \tag{5}$$

where W_1 = amount of mud in the water column for the initial equilibrium state (M TDS); W_2 = amount of mud in the water column for the new equilibrium state (M TDS);

Sand dynamics

The semi-empirical model for sand states that the sedimentation of sand in a navigation channel is the sum of two processes. First there is sedimentation of a fraction of the sand which is transported along the Belgian coastline. Second there is sedimentation of the sand which is eroded in the "upstream" part of the influence area of the navigation channel. "Upstream" signifies SW from the navigation channel given the net sand transport from SW to NE. The sand which is eroded in the "downstream" part of the influence area is transported away from the navigation channel. This semi-empirical model is schematically described in Figure 6.

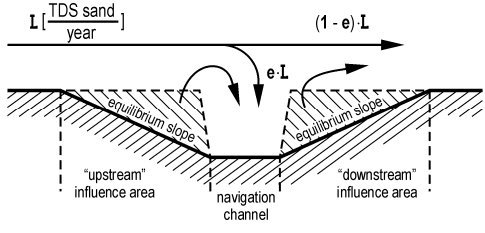

Fig. 6. Concept of sand dynamics in and around a navigation channel

where e = the trapping efficiency factor (-); L = the net sand transport along the Belgian coastline (M TDS / year).

The basic assumption is to consider no interaction between both processes for sedimentation of sand in the navigation channel (Eq. 6).

$$Q_{sum} = Q_1 + Q_2 \tag{5}$$

where Q_{sum} = the sedimentation rate of sand in the navigation channel (M TDS / year); Q_1 = the sedimentation rate of sand transported along the Belgian coastline (M TDS / year); Q_1 = the sedimentation rate of sand that is being eroded in the influence area around the navigation channel, which is caused by the dredging of the naivigation channel itself (M TDS / year).

The first contribution Q_1 is calculated as (Eq. 6)

$$Q_1 = eL \tag{6}$$

in which the trapping efficiency factor e is calculated using the engineering approach given in Van Rijn (2005) which is introduced in Van Rijn (1987).

The second contribution Q_2 is calculated as (Eq. 7)

$$Q_2 = E \tag{6}$$

in which E is the erosion rate of the upstream influence area (M TDS/year).

APPLICATION RESULTS

The described semi-empirical models are applied for different scenarios of improved navigation channels to the port of Ostend. For each scenario this results in a projection of the evolution of the necessary yearly maintenance dredging works –separately for sand and mud-, and in projections of the evolution of the increased turbidity and the extent of the erosion zone surrounding the navigation channel.

The results for one of the scenarios are given here after. Details can be found in Verwaest (2005). However, because the study is still ongoing no quantitative results are given in this paper.

The projection of the evolution of the maintenance dredging works is given in Figure 7. One can note that during the first ca. 3 years after the capital dredging works important quantities of sedimentation are to be expected, which are caused by the erosion in the influence area around the navigation channel where there is a gradual process of slopes flattening towards the equilibrium morphological slope.

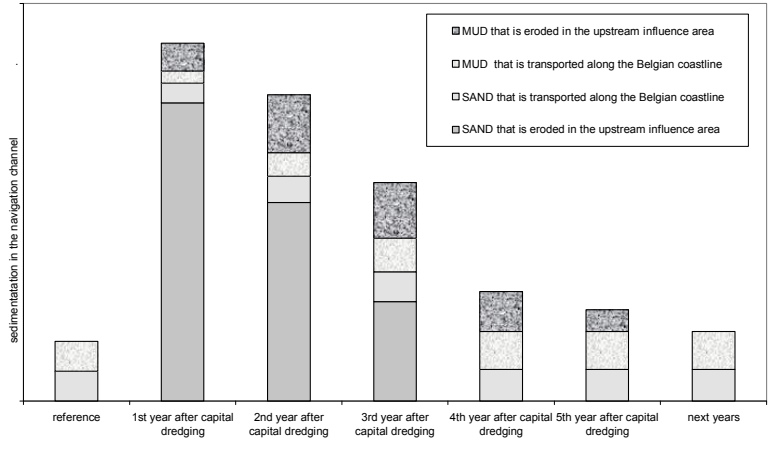

Fig. 7. Necessary maintenance dredging works after the capital dredging for a scenario of a new navigation channel to the port of Ostend.

Projections for increased turbidity in Belgian coastal waters are shown in Figure 8. A maximum increase after ca. 3 years and a half time τ equal to ca. 61 weeks can be seen.

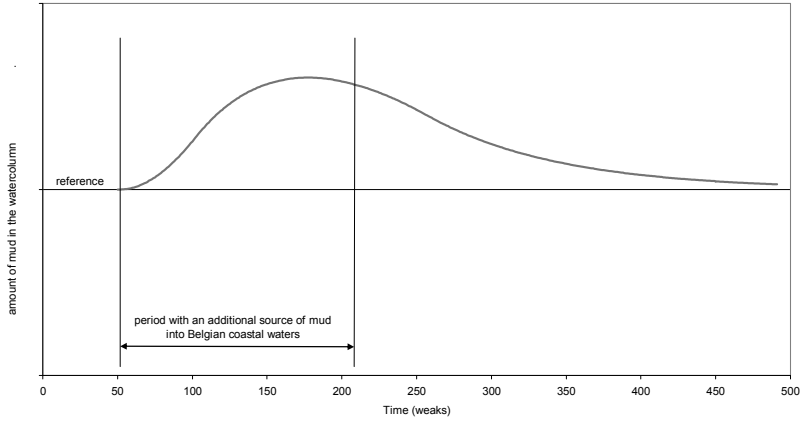

Fig. 8. Impact on turbidity in Belgian coastal waters of an additional source of mud of ca. 1,5 M TDS which is released during a period of 3 years (with a decreasing rate).

Projections of the extent of the erosion zone around the new navigation channel are made in a GIS. Using an average equilibrium slope of ca. 1/200 it is shown that an erosion zone of ca. 5 km^2 is affected, with the surface area of the navigation channel itself only ca. 0,5 km^2.

CONCLUSION

A simple semi-empirical model was built that is able to represent the essence of the impact on coastal sediment dynamics of a new navigation channel in the Belgian coastal zone. The model treats mud dynamics and sand dynamics separately. Using this model projections for maintenance dredging, erosion, and turbidity increase are successfully made for scenarios of a new navigation channel to the port of Ostend.

Abstract: Mangrove-habitat expansion has occurred rapidly over the last 50 years in the 800 km^2 Firth-of-Thames estuary (New Zealand). Mangrove forest now extends 1-km seaward of the 1952 shoreline. The geomorphic development of this muddy coast was reconstructed using dated cores (^{210}Pb, ^{137}Cs, ^{7}Be), historical-aerial photographs and field observations to explore the interaction between sediment processes and mangrove ecology. Catchment deforestation (1850s–1920s) delivered millions of m^3 of mud to the Firth, with the intertidal flats accreting at 20 mm yr^{-1} before mangrove colonization began (mid-1950s) and sedimentation rates increased to ≤ 100 mm yr^{-1}. ^{210}Pb data show that the mangrove forest is a major long-term sink for mud. Seedling recruitment on the mudflat is controlled by wave-driven erosion. Mangrove-habitat expansion has occurred episodically and likely coincides with calm weather. The fate of this mangrove ecosystem will depend on vertical accretion at a rate equal to or exceeding sea level rise.

INTRODUCTION

Enhanced sedimentation is occurring globally in estuaries due to increased catchment sediment yields associated with land-use changes (e.g., Thrush et al., 2004) particularly in the small and mountainous catchments that characterise the active-tectonic margins of the Pacific Rim (Milliman and Syvitski, 1992). Increased soil erosion has accelerated the infilling of estuaries, which have become progressively intertidal. In many temperate and tropical settings these intertidal flats have been colonized by mangroves (Neil, 1998; Ellis et al., 2004). Once established, mangroves influence estuarine sedimentary processes and long-term geomorphic evolution (Thom et al., 1975). Mangroves enhance mud accumulation by dampening currents and attenuating waves so that sediment accumulation rates (SAR) are highest within the fringes of mangrove forests, and decline with distance from the mangrove fringe (Furukawa et al., 1997). While mangroves may

stabilize sediments, provide fish nurseries and enhance water quality, mangrove-habitat expansion is not always desirable. In estuaries that previously had sandy substrates mangrove colonization and/or habitat expansion enhances long-term mud accumulation. This major change in substrate type from sand to mud, results in loss of biodiversity and changes in benthic community structure (Ellis et al., 2004).

In New Zealand (N.Z.), the grey mangrove (*Avicennia marina*), which is a frost-sensitive species, occurs in North Island estuaries above 38°S latitude and can colonize intertidal flats down to mean sea level (MSL), where seedlings are submerged for ≤ 6 hr per tide (Clarke and Myerscough, 1993). Mangrove-habitat expansion has occurred in many estuaries within their range in recent decades (Burns and Ogden 1985; Ellis et al., 2004) as has also occurred for introduced-invasive species such as the Cordgrass, *Spartina anglica*, (Swales et al., 2004). This process has been exacerbated by estuary infilling, forming extensive intertidal flats potentially suitable for colonization. This natural infilling process has accelerated over the last 150 years as sediment loads have increased due to catchment deforestation and SAR of < 0.5 mm yr^{-1} before deforestation have increased by an order of magnitude (Hume and McGlone, 1986, Swales et al., 2002). However, mangrove-habitat expansion observed over the last 50 years has occurred decades after catchment deforestation. Alternative explanations for this relatively recent expansion include climate change and increasing nutrient inputs associated with agricultural activities.

Mangrove-habitat expansion has been particularly rapid in the Firth of Thames, which is a 800 km^2 meso-tidal estuarine embayment on the east-coast of the North Island (37°S 175.4°E) 70-km south-east of Auckland (Fig. 1). Captain James Cook visited the Firth in 1769 and noted the presence of mangrove along the lower Waihou river (Brownell, 2004).

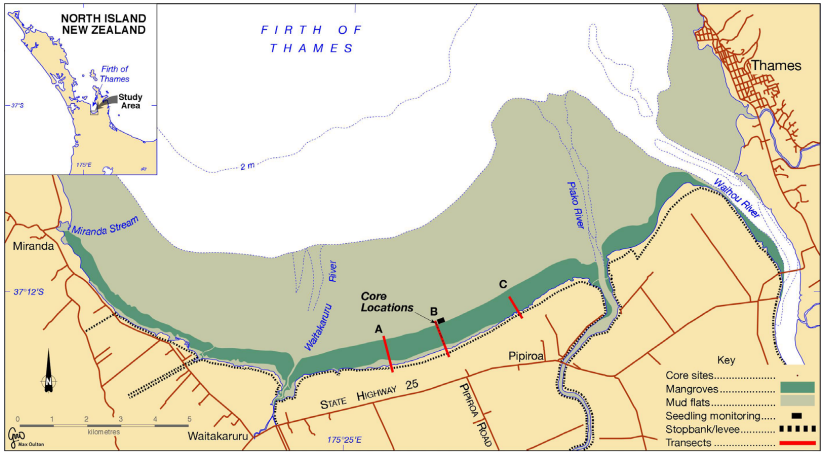

Fig. 1. Location of the study area, southern Firth of Thames, New Zealand.

Aerial photographs show that mangrove-habitat was restricted to delta deposits at river mouths as recently as the early 1950's. Today, mangrove habitat in the southern Firth extends 1-km seaward of the 1952 shoreline and covers 11 km^2 of former intertidal mudflat. The seabed elevation is now 0.1–0.2 m above mean high-water spring (MHWS) tide level so that the mangrove forest is only infrequently inundated.

This rapid mangrove-habitat expansion raises a number of questions that are relevant to the fate of mangrove systems and estuaries: what has triggered mangrove-habitat expansion decades after deforestation; how are mangroves altering estuaries; how does seedling recruitment occur on wave-exposed mudflats; and what is the long-term fate of these mangrove systems given the potential effects of climate change? In this paper we reconstruct the recent geomorphic development of this muddy coast and consider the interaction between sediment processes, geomorphology and mangrove ecology.

STUDY SITE

The Firth of Thames estuarine embayment occupies the Hauraki Depression, which is a structural graben (Healy, 2002) bounded to the east and west by the Coromandel and Hunua Ranges respectively. To the south are the low-lying Hauraki Plains, which are underlain by estuarine sediments (Woodroffe et al., 1983). The Firth receives runoff from a 3600 km^2 catchment and primarily from the Waihou (1966 km^2) and Piako (1476 km^2) Rivers, which deliver an estimated 150,000 t yr^{-1} and 35,000 t yr^{-1} of suspended sediment respectively. The Waihou River has delivered sediment to the Firth for the last 20,000 years. Shoreline-progradation rates have averaged 1.7 m yr^{-1} over the last 6,500 years (Brownell, 2004) and a chenier plain has formed in the last 3,600 years along the western shore of the Firth (Woodroffe et al., 1983).

History

Pre-human catchment landcover consisted of podocarp–hardwood forests on the steeplands while the Hauraki Plains were occupied by freshwater marshes and swamp forests of the podocarp Kahikatea. Maori arrived about 1,000 years ago and forest clearance was restricted to the rivers banks. European settlers arrived in the mid-1800s and large-scale deforestation began shortly after in the Coromandel ranges associated with logging and gold-mining activities (Brownell, 2004). These activities substantially increased sediment loads to the Firth. Hydrographic surveys conducted by the Public Works Department in 1882 and 1918 indicate that *c.* 6.9 x 10^6 m^3 of sediment was deposited within a 16 km^2 area of the lower Waihou River and its tidal delta (Fig. 1) and an estimated 36.7 x 10^6 m^3 was deposited in the 210 km^2 southern Firth. Development of the Hauraki Plains was delayed until drainage works began in 1905 with a stop-bank/levee constructed along the southern shore of the Firth and the tidal reaches of the rivers. By 1920 some 162 km^2 of swamp had been converted to pasture (Brownell, 2004). The 1932 storm flooded the entire Hauraki Plains and consequently the heights of stop-banks were increased. These engineering works constrained floodwaters to the river channels and are likely to have increased sediment delivery to the Firth.

Estuary characteristics

The Firth shoals from a maximum depth of 35 m at its inlet. Tides are semi-diurnal, with average spring- and neap-tidal ranges of 2.8-m and 2-m respectively. Tidal-current speeds are typically ≤ 0.2 m s^{-1} on the intertidal flats. Estuarine circulation and residual-tidal currents trap river-borne suspended sediments within the Firth (Healy, 2002). Northerly winds generate short-period ($T < 6$ s) waves typically < 1 m high (Woodroffe et al., 1983). The historical rate of sea level rise at Auckland (1904–1999) has averaged 1.3 mm yr^{-1}. The large tidal range, shallow bed slope (0.03°) and fine-sediment supply has built some 70 km^2 of intertidal-mudflats along the southern shore of the Firth (Fig. 1). Mudflat morphology is similar to that described for the muddy coast of Surinam, South America (Augustinus, 1980; Wells and Colman, 1981). The lower-intertidal flat is characterized by fluid mud, while a "mud bastion" morphology of isolated consolidated-mud mounds ≤ 20-cm high develops on the middle–upper intertidal flat above 0.7 m MSL. On the Surinam coast, these features have been interpreted as remnants of an eroded mudflat (Augustinus, 1980, Fig. 7). Above 0.8 m MSL, the mud bastions are replaced by a 300-m wide band of large-scale "mud forms" that resemble an irregular ridge-runnel system. These shore-normal, often bifurcating ridges, are ≤0.25 m high with wavelengths ≤2 m and sinuous crests up to 50 m long. These features are not drainage channels as the runnels are isolated from each other. This intertidal morphology is characteristic of a mesotidal, moderately wave-exposed, muddy coast, with large mud supply, high suspended sediment concentrations (SSC) and rapid sedimentation. In similar muddy-coast environments, near-bed SSC in the range 10^3–10^4 mg l^{-1} increase fluid density sufficiently to attenuate shoaling waves (Wells and Coleman, 1981; Mehta, 2002).

METHODS

Mangrove-habitat mapping, forest structure and pore-water salinity

Mangrove-habitat expansion was mapped from vertical aerial photographs of the southern Firth taken between 1952 and 2002. The digitized photographs were geo-referenced and analyzed using ARC-GIS software. Mangrove-forest structure was characterized at *c*. 20-m intervals across-shore using the point-center-quarter method (Cintrón and Schaffer-Novelli, 1984). Pore-water salinity at 30-cm depth was measured using the methods of McKee et al. (1988). A relationship between pore water salinity and forest height was tested using regression analysis.

Intertidal-flat elevation and tides

Intertidal-flat elevations were measured along three transects (A–C) at *c*. 2-km intervals alongshore and up to 1200-m seaward of the stop-bank/levee (Fig. 1) to determine the large-scale shore morphology and relate the sediment-cores to the mean sea level (MSL) datum. Elevations were measured to ±0.5 cm using a Geodimeter Model 464 total station. A sea-level record (1992– present) from Tararu (3 km north of Thames, Fig. 1) was analyzed to determine: (1) the duration of tidal inundation (2004–2006) of the mangrove forest; and (2) exceedance probability (%) for predicted high-tide levels (1900–1999 AD). The inundation time for specified vertical levels was determined for predicted tides (using tidal constituents for 2004-2006); and the measured (storm) tides.

Sediment cores

Replicate sediment cores 7.5-cm-diameter and ≤ 1.9-m long were collected from the mangrove forest along Transect B (February 2005) using a piston corer (Fig. 1, **LC sites** 3–11). A 0.7-m-long push core (site LC-12) was also 50-m seaward of the mangrove seaward edge of vegetation (SEV). Cores were also collected from the mudflats (**T sites,** Feb. 2006) up to 1-km seaward of the mangrove SEV using open-ended, three-sided Perspex trays (0.7 m deep, 2.5 x 19 cm). The trays were pushed into the sediment and then the fourth side inserted to minimize fabric distortion. Core names (e.g., T-50) indicate the seaward distance (m) of the site from the mangrove SEV. Core-compression was < 5% in all cases. The LC cores were logged and sub-sampled at intervals in 2-cm-thick slices for radioisotope, bulk density and particle-size analysis. Particle-size was determined using an Ankersmid CIS-100 "time-of-transition" (TOT) stream-scanning-laser particle sizer. Sediment samples were wet-sieved through a 2-mm sieve to remove vegetation fragments and shell hash and dispersed in an ultra-sonic bath for 10 minutes before and during analysis. Sediment fabric was determined from x-radiographs prior to sub-sampling. The cores were sectioned into 2-cm-thick longitudinal slabs and imaged using a Phillips Model Macrotank 205 X-ray generator with Kodak AA400 film (50 kV, 5 mA, 1.1 min) and digitized using a Nikon D1x digital SLR camera (ISO 125, TIFF). X-radiographs of the T-site cores were obtained using a Thales Flash-scan 35 digital X-ray panel detector, illuminated by a Kramex PX15HF portable X-ray generator (60 kV, 15mA, 3 s). After imaging, these cores were sub-sampled at 1–2 cm intervals for analysis of beryllium-7 (^{7}Be, half life, $t_{1/2}$ 53 days) by gamma spectrometry.

SAR were estimated from lead-210 (^{210}Pb, $t_{1/2}$ 22.3 yr) and caesium-137 (^{137}Cs, $t_{1/2}$ 30 yr). The cosmogenic radioisotope ^{7}Be is particle reactive and tends to be concentrated in aquatic systems, making it a useful sediment tracer in fluvial-marine systems at seasonal timescales. Radioisotope concentrations expressed in S.I. units of Becquerel (disintegration s^{-1}) per kilogram (Bq kg^{-1}) were determined by gamma-spectrometry. Dry samples (50–60 g) were counted for 23 hrs using a Canberra Model BE5030 hyper-pure germanium detector. The unsupported or excess ^{210}Pb concentration ($^{210}Pb_{ex}$) was determined from the ^{226}Ra ($t_{1/2}$ 1622 yr) assay after a 30-day ingrowth period for ^{222}Rn ($t_{1/2}$ 3.8 days) gas in samples embedded in epoxy resin. Gamma spectra of ^{226}Ra, ^{210}Pb and ^{137}Cs were analysed using Genie2000 software. ^{7}Be concentrations in the T-core sediments were also obtained by gamma spectrometry, with10-g dry samples sealed in petri dishes counted for 24 h. The $^{210}Pb_{ex}$ profiles in each core were used to determine: (1) time-averaged SAR from regression analysis of natural log-transformed data; (2) $^{210}Pb_{ex}$ inventory (A, Bq cm^{-2}) and; (3) mean annual supply rate (P, Bq cm^{-2} yr^{-1}) based on the ^{210}Pb decay co-efficient (k, 0.0311 yr^{-1}). These data were compared with the ^{210}Pb atmospheric flux (0.006 Bq cm^{-2} yr^{-1}) measured at Auckland. SAR were estimated from ^{137}Cs profiles based on the maximum depth of ^{137}Cs in each core and included corrections for sediment mixing indicated by ^{7}Be profiles. In NZ, ^{137}Cs deposition from the atmosphere was first detected in 1953 (Swales et al., 2002).

Propagule and seedling establishment and recruitment

The establishment and survival of recently-settled propagules and seedlings on the wave-exposed mudflat was monitored over a 180-day period from January 2006 in an area immediately east of Transect B (Fig. 1). Three replicate sites *c.* 100-m apart alongshore were monitored each with ten 0.16 m^2 quadrats located on the top of the mud forms at. 20 m, 70m and 120 m from the mangrove SEV. Propagule and seedlings numbers and their developmental stage (i.e., # of leaf pairs) were recorded and measurements repeated after 23, 44, 60 and 180 days. Data were pooled for each site by proximity grouping and cumulative survivorship was calculated as the proportion of propagules or seedlings remaining. Survivorship data were log transformed and analysed by repeated measures ANOVA where either site or proximity to the mangrove were fixed effects in the model.

RESULTS

Mangrove-habitat expansion

Historical-aerial photographs show that mangroves colonized the mudflat close to LC-3 between 1952 and 1963 and some 300-m seaward of the 1952 shoreline (Fig. 2a) and by 1963 had formed a 50-m wide stand. Subsequently, the mangrove forest spread seaward and, to a more limited extent, landward. By 1977 the mangrove SEV was located near LC-6 and by 1987 the SEV had extended to LC-8, some 726-m from the 1952 shoreline. By 2002 the mangrove-forest distribution was similar to that we surveyed in 2005.

Large-scale mudflat morphology and tides

The shore profile has a convex-upward shape (Fig. 2a) that is characteristic of stable or prograding muddy-coasts (Mehta, 2002).

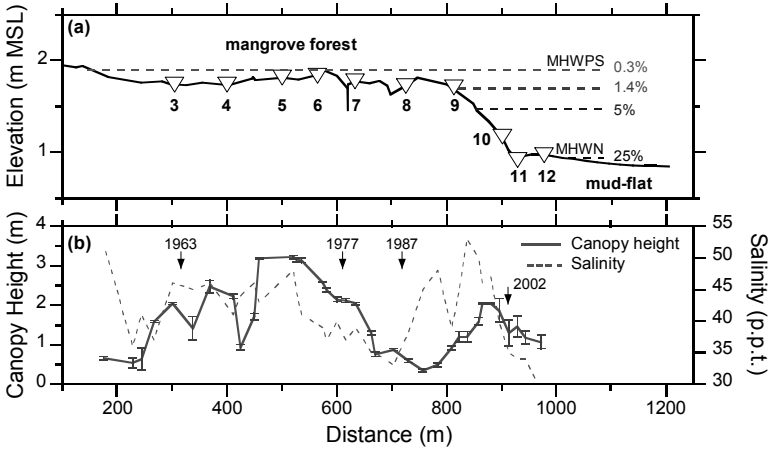

Fig. 2. Transect B: (a) bed elevation, tidal inundation (% of total time) and core locations (3–12); (b) average canopy height (std err = 0.01 – 0.03 m) and sediment pore-water salinity (parts per thousand). The positions of historical mangrove seaward fringes are also shown.

The profile is characterized by a uniformly flat surface within the mangrove forest, with elevations of 1.7–1.89 m above MSL and close to the MHWPS tide at 1.87m MSL, apart from a tidal creek (1.49-m MSL). The elevation maximum occurs near LC-6, which coincides with the tallest trees in the forest. This cross-shore sequence is repeated for the present mangrove SEV at 850–950 m. The prograding beach face (LC-9 to LC-11) slopes seaward at 0.37° and is ten-times steeper than the adjacent mudflat. Mean high water neap tide (MHWN, 0.98m MSL) coincides with the mangrove SEV, so that the present fringe on the beach face is only inundated during fortnightly spring tides (Fig. 2a). Predicted MHWS-tide elevation is 1.60 m above MSL. The length of tidal inundation rapidly decreases with increasing intertidal elevation and reduces from 25% on the mangrove SEV to < 1.4% for much of the mangrove-forest above 1.7 m MSL. The landward boundary of the mangrove forest is close to MHWPS, which is inundated ≤0.3% of the time. Comparison with predicted tides indicates that the measured meteorological or storm tides increase the length of time that the mangrove forest (above 1.7 m MSL) is flooded by *c*. 40%, which is equivalent to an additional 30 hrs per year. The largest storm tide during 2004–2006 (18 Sept. 2005) at 2.33 m MSL was 0.6 m higher than predicted.

Mangrove-forest structure

The mangrove-forest that has developed over the last 50 years displays a wide range of structure. Canopy height varies from < 0.5m to 3.5 m (Fig. 2b). Tree architecture also varies from open, spreading tree forms, which are indicative of trees that have grown in high-light environments without competition on colonizing edges, to trees with very straight trunks that have grown competing for available light. Variation in forest height did not significantly correlate with distance from the 1952 shoreline or porewater salinity. A repeating pattern of taller trees giving way to short, dwarf trees was evident along the cross-shore transect. For example, the current seaward fringe (850-1000 m seaward of the 1952 shoreline) gives way to a dwarf stand, with average canopy heights <0.5 m, between 650–800 m. Landward of these dwarf mangroves, are found the tallest trees (450–600 m), with an average-canopy height of 3 m, where a well developed and clearly older forest occurs. Lichen accumulation on the bark of trees in this tall forest is substantial. The tallest stand gives way to shorter forest again at 560 m, after which forest height increases before declining to be replaced by saltmarsh dominated by glasswort (*Sarcocornia quinqueflora*).

Sediment properties

Sediments deposited since the early-1950's on the mangrove flat (LC-3 to LC-9) are composed of homogenous muds, with median (D_{50}) and mean particle diameters ≤ 20 μm (Figs. 3a–c). Vertical profiles to 1.9-m depth show little variation except near the base of cores LC-8 and LC-9, which show abrupt increases in particle size at about 0.1–0.2 m above MSL. Sediment wet and dry bulk densities are between 1–2.4 g cm^{-3} and 0.4–0.8 g cm^{-3} respectively. Cores LC-10 and LC-11 collected on the mangrove fringe near the base of the actively prograding beach (0.9–1.2 m MSL) sample older deposits down to 0.8 m below MSL. The upper 0.8–1 m of these cores is also composed of homogenous fine-grained mud (D_{50} *c*.15 μm), below which an abrupt increase in particle size occurs (D_{50} > 40 μm) at 0.17 m above MSL (Figs. 3d–e).

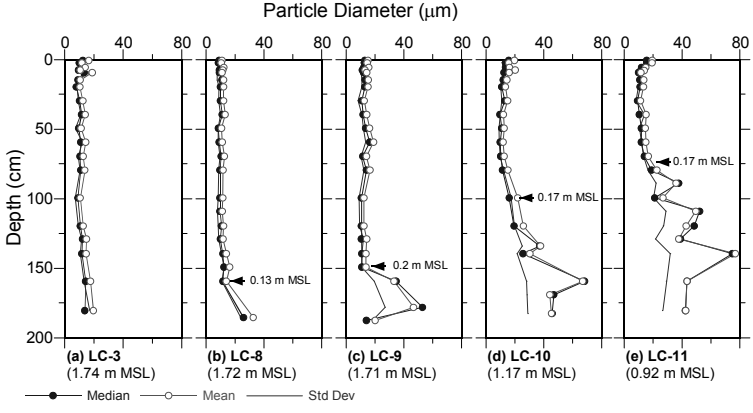

Fig. 3. Particle-size profiles for selected cores from the mangrove-forest (LC-3 to -9), seaward fringe (LC-10) and adjacent mudflat (LC-11). Surface elevation at sites is also shown.

Below this *c*. 1-m-thick mud layer, x-radiographs clearly show laminated clays, silts and fine sands overlaying abundant shell valves and hash of cockle (*Chione stuchburyi*) and estuarine trough shell (*Mactra ovata*), which is a suspension feeder characteristic of estuarine intertidal flats. The thickness of the laminations increase in scale with depth from mm to cm. X-radiographs of the T cores (Fig. 4), collected on the open mudflats, are characterized by two distinct zones of contrasting sedimentary fabric.

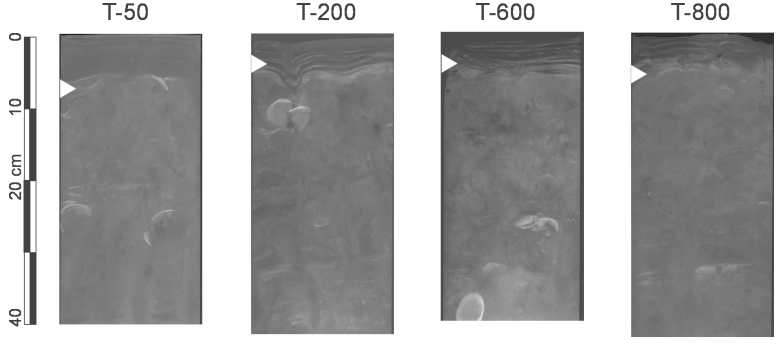

Fig. 4. X-radiograph negatives of the T-series cores from the mudflats. Bright shades indicated high-density or coarser sediment, and dark shades indicate low density or finer sediment. ^{7}Be penetration depth indicated by white triangles. Shell valves are of *M. ovata*.

A surficial layer, 3-7 cm thick, contains prominent laminations and cm-scale beds that display sharp basal contacts, and grade upward from coarser (light gray in X-radiographs) to finer (darker gray) sediments. These sediments have relatively high water content, as indicated by the dark shades in X-radiographs, and are mostly unbioturbated. Below this stratified surface layer, sediments display a range of biogenic

structures, including indistinct mottling and clearly defined burrows (mostly of polychaetes and *M. ovata*). These biogenic structures have overprinted mm-to-cm-scale stratification that is similar to the surface layer, but less clearly preserved, due to post-depositional bioturbation. Grain-size distributions in open-mudflat cores are slightly coarser than those observed in surface sediments of mangrove cores, with mean particle sizes of 25-43 μm, including 0-13% sand (concentrated in coarser beds evident in Fig. 4).

Radioisotope distributions

All profiles of ^{210}Pb in cores display prominent changes in gradients that indicate changes in SAR over time (Fig. 5). The lowermost section of all cores is characterized by a clearly defined region of relatively low SAR (8-25 mm yr^{-1}). The upper boundary of this region ranges from 1.5 to 1.7 m below the sediment surface close to the landward margin, to ~0.25 m below the sediment surface on the open mudflats at LC-12. Above this basal zone, in cores LC-3 to LC 12, SAR increase (to 33-108 mm yr^{-1}). These sub-vertical gradients extend to the sediment surface in cores LC6 to LC-11 (with a prominent discontinuity in LC-6). The surface of core LC-3 is characterized by a less vertical gradient and SAR of 8 mm yr^{-1} from 0.25 m below the sediment surface to the core top. In contrast, the two seaward-most cores (LC-11 and LC-12) have approximately vertical ^{210}Pb profiles in the upper ~0.25m of core, suggesting either: extremely high deposition rates, rapid vertical mixing, or a combination of the two.

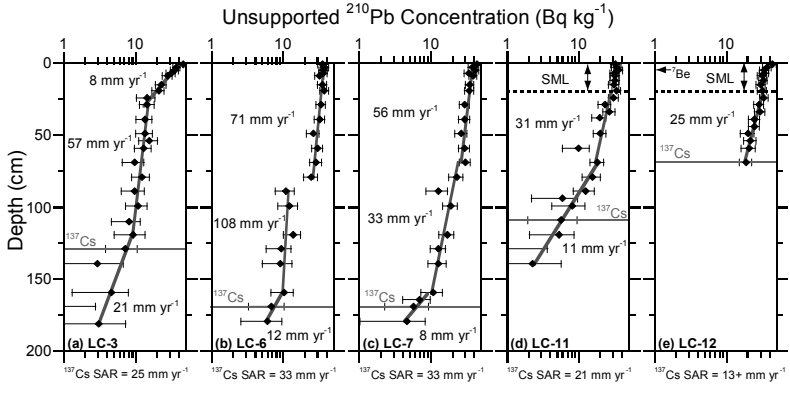

Fig. 5. ^{210}Pb$_{ex}$ concentration profiles and 95% conf. intervals and SAR for long-core sites (LC): mangrove forest (LC-3–LC-7); mangrove seaward fringe (LC-11); and mudflat (LC-12), Maximum ^{137}Cs depth and SAR also shown. SML = surface-mixed layer.

The presence of ^{137}Cs to 169-cm depth in LC-6 and LC-7 shows that these sediments have been deposited since the early 1950s and ^{137}Cs-derived SAR for the mangrove forest were 21–36 mm yr^{-1}. ^{7}Be occurs to 2-cm depth in cores LC-5 to LC-11 (mangrove forest) and to 4-cm depth in LC-12 (mudflat). Maximum SAR coincide with LC-8 and LC-9 located landward of the present-day mangrove fringe. The ^{210}Pb$_{ex}$ inventories (*A*) and mean annual supply rates (*P*) calculated for the long-cores display distinct spatial

patterns (Table 1). Inventories for cores LC-3 to LC-5 taken from the oldest (i.e., pre-1970s) mangrove forest gradually increase seaward.

Table 1. $^{210}Pb_{ex}$ inventories (A) and mean annual supply rates (P) and concentration factors (C) in the long cores.

Core	A (Bq cm^{-2})	P (Bq cm^{-2} yr^{-1})	C
LC-3	1.27	0.039	6.7
LC-4	1.40	0.044	7.4
LC-5	1.59	0.050	8.4
LC-6	3.75	0.117	19.8
LC-7	1.87	0.058	9.9
LC-8	1.73	0.054	9.1
LC-9	1.75	0.055	9.3
LC-10	1.21	0.038	6.4
LC-11	0.15	0.005	0.8

By comparison, A is similar for cores taken from mangrove forest established since the late-1970's (LC-7 to LC-9). At LC-6, A is more than double that measured at any other site. The concentration factor (C) indicates how P scales with the measured ^{210}Pb atmospheric flux (0.006 Bq cm^{-2} yr^{-1}). Table 1 shows that sediments in the mangrove forest are accumulating $^{210}Pb_{ex}$ at rates 6–20 times higher than expected if supplied by direct atmospheric deposition alone (i.e., $C = 1$).

Propagule and seedling establishment

Mangrove propagules settled on the mudflat in January 2006 over a 250-m wide band seaward of the present mangrove fringe. Propagule and seedling density at the first survey (28 January 2006) reached up to 187 m^{-2}, with a mean density of 36.4 ± 3.6 m^{-2} (± std error, n = 90). Propagule and seedling numbers declined rapidly and exponentially over time ($r^2 = 0.99$) so that < 10% of the initial propagules remained after 60 days and only one seedling remained after 180 days. Propagule attrition was not significantly influenced by site or distance from the mangrove fringe ($P > 0.05$). Despite the high-attrition rate of propagules, surviving seedlings were actively growing as shown by the proportion of seedlings that entered the 2–3 leaf pair stage after day 23 (Fig. 6).

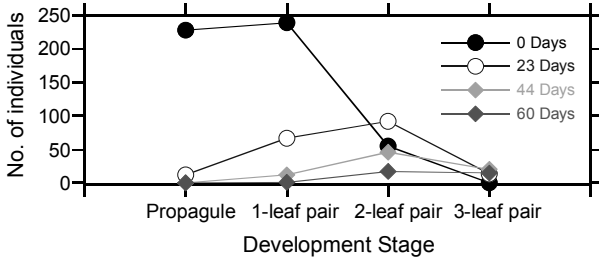

Fig. 6. Number of mangrove propagules and seedling in each development stage during the first 60 days of the monitoring.

DISCUSSION

The recent geomorphic evolution of the Firth is closely linked to historical increases in sediment loads following large-scale catchment deforestation and river-engineering works (1850s–1920s). The estimated 44 x 10^6 m^3 of mud was deposited in the southern Firth over a 36-year period to 1918 is equivalent to *c*. 280 years of present-day sediment loads. Cores record the physical effects of this mud influx on the Firth. Below the base of the 0.8–1.6-m thick homogenous mud layer at 0.2-m MSL are the original laminated silts and sands that are characteristic of energetic mixed-sediment intertidal-flats (Reineck and Singh, 1980). The abrupt transition to a pure-mud substrate indicates a fundamental change in the sediments and geomorphology of the Firth, which has initiated a sequence of large-scale environmental change. These changes include the rapid mangrove-habitat expansion that began in the 1950's, which continues today. Similar environmental changes have occurred in many N.Z. estuaries. However, the magnitude of these changes has been much larger in the Firth.

$^{210}Pb_{ex}$ profiles record the temporal and spatial sequence of initial mangrove colonization and mangrove-habitat expansion over the last 50 years. $^{210}Pb_{ex}$ profiles in cores from the oldest mangrove stand (LC-3 to LC-5) closest to the 1952 shoreline show a characteristic stair-step form (Fig. 5a), which are consistent with the known chronology of mangrove colonization and ^{137}Cs dating. Core LC-3 provides the longest record of sedimentation dating back to the 1920s (Fig. 5a) with SAR averaging 20 mm yr^{-1} that are similar to the present-day mudflat (25 mm yr^{-1}, Fig. 5e). These values are 5–10 times higher than SAR observed in other North-Island estuaries. Mangrove colonization resulted in a three-fold increase in SAR, with one metre of sediment deposited at LC-3 in little more than a decade. As the mangrove-forest expanded seawards so did the locus of maximum SAR. This process is recorded in cores from the oldest mangrove stand by an abrupt reduction in SAR to 8–11 mm yr^{-1} from the late 1960s onwards (Fig. 5a), as the sediment supply from open mudflats was cut off by forest expansion. Core LC-6 displays a discontinuity at 80–85-cm depth (Fig. 5b), with substantially lower $^{210}Pb_{ex}$ concentrations below this layer than above and SAR of 71–108 mm yr^{-1}. Cores LC-7 (Fig. 5c) to LC-9 also show that the mudflat was rapidly accumulating (21–33 mm yr^{-1}) even before mangroves colonised these sites (late 1970s–) and further increasing SAR (53–56 mm yr^{-1}). The present-day mangrove SEV established in last decade is also rapidly accumulating sediment (LC-11, Fig. 5d). X-radiographs and ^{7}Be profiles (≤ 7-cm) from the mudflat (Fig. 4) show that sediment resuspension and/or deposition introduces ^{7}Be into the seabed, rather than bioturbation. $^{210}Pb_{ex}$ inventories in the cores indicate that the mangrove-forest is a major long-term sink for fine sediments.

In many mangrove ecosystems canopy height reduces with distance from the seaward fringe. This reflects a reduction in tidal-water, nutrient and sediment inputs and an increase in salinity as evaporation exceeds tidal recharge (Smith, 1992). In the Firth, the complex variation in forest structure suggests multiple forest building events (Fig. 2b). This system provides an important case study of how mangrove forests develop through time, and a baseline to investigate how the function of mangrove ecosystems change as they undergo succession. Mortality of propagules and seedlings on the mudflat is primarily due to episodic wave-driven erosion of the substrate in which the seedlings are

rooted. In southern Australian, wind and wave conditions are also the most important factors influencing *A.marina* seedling mortality in estuaries (Clarke and Myerscough 1991). The early development of seedlings (Fig. 6) indicates that conditions are suitable for growth in the absence of physical disturbance. The repeating pattern of tall seaward-fringing forest and short/dwarf forest landward and observed high seedling mortality on the mudflats suggests that major phases of mangrove-habitat expansion have occurred infrequently and likely coincide with extended periods of unusually calm weather conditions that are required for successful seedling establishment

Mangrove colonization of the upper-intertidal flat at LC-3 occurred when the bed elevation was ≥ 0.5 m above MSL (Fig. 5a). This is well above the 0-m MSL lower-elevation limit (LEL) for grey mangrove (Clarke and Myerscough, 1993). The intertidal flat was rapidly accreting mud and by the 1950s eventually reached a critical elevation, with mangrove colonising the site during a period of calm weather. In nearby Tauranga Harbour, with its smaller wave fetch, the LEL for mangrove at wave-exposed sites is *c*. 0.3 m above MSL. Tidal range also influences the LEL for mangrove because wave-energy expended across the intertidal flats varies with water depth due to water-column attenuation and bed-friction effects for the short-period waves typical of New Zealand's fetch-limited shallow estuaries (Green et al., 1997; Swales et al., 2004). We normalised LEL for mangrove for both estuaries by the "king tide" amplitude to obtain a non-dimensional LEL of 0.3 for both estuaries. This approach could potentially be useful for predicting future mangrove colonization and habitat expansion in estuaries.

The fate of mangrove-forests primarily depends on the surface elevation increasing at a rate equal to or exceeding sea level rise (SLR). This has previously been assessed by comparing SAR derived from cores with SLR but is complicated by the effects of sediment auto-compaction (Cahoon et al., 1999). Furthermore, the frequency and duration of flooding by tides and freshwater runoff varies with elevation and controls sediment delivery, substrate oxidation and plant growth. Sedimentation-Erosion Tables (SET) have been used to apportion substrate elevation changes due to shallow subsidence and sedimentation. Cahoon et al. (1999) reported that: (1) surface-elevation gains lagged SAR at 50% of the 43 SET sites studied; and (2) surface-elevation change is a more suitable predictor of the future effects of SLR on mangrove/marsh stability. In the Firth, SAR of 8–100 mm yr^{-1} have substantially out paced SLR (1.3 mm yr^{-1}) so that the mangrove forest is now close to the upper limit of the tide and is very infrequently flooded. Surface elevations within the forest vary by < 20-cm despite large spatial variations in SAR. This suggests a complex feedback between the physical and biological processes controlling substrate elevation that has not yet been determined.

CONCLUSION

Rapid mangrove-habitat expansion in the Firth of Thames over the last 50 years is closely linked to historical increases in sediment loads due to catchment deforestation since the mid-1800s. The large quantities of mud deposited in the Firth over the next several decades buried the original laminated silt–sand substrate. Dated cores indicate that the upper-intertidal flats were rapidly accreting mud (20 mm yr^{-1}) for several decades. This initiated a sequence of large-scale environmental change that included

rapid mangrove colonization and habitat expansion since the 1950s. Mangrove-habitat expansion further increased SAR (≤ 100 mm yr^{-1}), rapidly building and elevating vegetated mudflats. The mangrove forest is a major long-term sink for fine sediments. Seedling recruitment is largely controlled by wave-driven erosion of the mudflat to ≤ 7-cm depth. Major periods of mangrove-forest expansion have been infrequent and have likely coincided with extended periods of calm weather. The lower-elevation limit for mangrove colonization at *c*. 0.5 m above MSL was higher than expected due to wave exposure. The mangrove forest is now near the upper limit of the tides and is infrequently flooded. Most sediment is deposited along the seaward fringe of the forest so that sedimentation decreases landward (50 to 8 mm yr^{-1}) due to reduced sediment supply and accommodation space. The long-term fate of this mangrove system depends on the surface elevation increasing at a rate equal to or exceeding SLR. This cannot be evaluated from sediment cores alone, due to the complications arising from shallow subsidence and the feedbacks between physical and biological processes.

ACKNOWLEDGEMENTS

Dr Terry Hume (NIWA) reviewed the paper and Mr Ron Ovenden (NIWA) undertook the elevation surveys and processed the sediment cores. Radioisotope analyses (LC cores) were conducted by the N.Z. National Radiation Laboratory. Dr Brian Sorrell (NIWA) participated in the ecological study. We thank Mr Rick Liefting (Environment Waikato) for supporting the initiation of this study. The study was funded by the NZ Foundation for Research Science and Technology (CO1X0307) and Environment Waikato. Funding to S. Bentley was provided through a NIWA visiting-scientist fellowship, and the US National Science Foundation (CAREER grant OCE-0093204).

Abstract: The inner shelf, shoreface and beach at Cassino, located in the southernmost sector of the Brazilian coastline, are characterized by marked differences in grain size and sediment composition compared to adjacent areas. This lateral heterogeneity in sediment properties controls the geomorphology of the inner continental shelf and shoreface, and influences the shoreline accretion rate and beach morphodynamic behavior along a 25 Km stretch of coast. Short-term effects are associated with episodic events of mud deposition on the beach during heavy storms that often result in strong gradients in hydrodynamic processes. These gradients in turn influence the morphodynamic behaviors on the sectors affected by the mud deposits and can create coastal hazards relating to beach usage. These findings are almost certainly applicable in other regions where significant sediment heterogeneity exists.

INTRODUCTION

The study of coastal regions with significant heterogeneity in sediment properties has been an important research topic within recent years (Holland et al. 2003). Textural maps indicate that heterogeneous bottom types composed of variable amounts of sand, silt, and clay cover some portions of the inner shelf and shoreface in front of Cassino beach, Brazil. Fine sediments provided by the Patos Lagoon are transported mainly toward the south and deposited offshore as fluid mud. Stormy conditions associated with periodic cold front passages, which occur frequently in the area, can rework and transport the fluid mud from the shoreface to the surf-zone and foreshore of Cassino

Beach causing lateral changes in the bottom sediment texture along the shoreface and surf-zone.

Such events have strong influence on the geomorphology of the inner continental shelf, surf-zone processes, beach morphodynamics, shoreline changes, and coastal hazards. The aim of this work is to describe and quantify the long and short-term effects of the mud deposits on the geomorphology of the shoreface and on related beach and surf zone morphodynamics within the different sedimentary regimes.

METHODS

Since 1984 long-term geologic superficial sampling, echosounding and side scan sonar has been used to define the location and type of sediments in the Cassino beach region (Calliari and Abreu, 1984). Approximately fifty piston and gravity cores have been collected within this region to define the historical boundary of the mud deposit (Calliari and Fachin, 1993, Calliari et al., 2001; 2005) and more than 150 beach sediment samples taken at 1 km spacing over a 25 Km interval have been analyzed by sieving (Figueiredo and Calliari, 2006; Calliari et al. 1996). Shoreline change along the same study region was determined using aerial photographs taken between 1947 and 2000 using the methodology based on the studies of Dolan *et al.* (1978, 1980) basically consisting of the superposition of a temporal series of aerial photographs under the same cartographic projection, on the definition of normal profiles taken at regular intervals and on the calculation of the differences between each shoreline over each profile.

Fifteen years of beach profile data combining automatic level and rod and total station surveys has also been obtained. After storms occurred on January 17 and March 10 of 1998 during a 14-month period, two sectors of the beach, one with mud deposits in the surfzone and shoreface and the other sector without, were systematically surveyed to monitor beach response. Additional high-resolution aerial photos using the ADAR system allow small mosaics to be constructed that indicate differences in surf zone morphology and hydrodynamics. In summary, these data represent a significant repository of observations concerning the influence of the fluid mud on coastal processes.

LONG TERM EFFECTS

The first long-term effect of the mud deposition identified adjacent to Cassino beach is on the geomorphology of the inner shelf and shoreface. Figure 1 shows the relief map of the upper 33 m of the continental shelf adjacent to Cassino beach, which includes the inner shelf and the shoreface. It is noticeable in this map the presence of three distinct morphologic regions: From the latitude of the lagoonal mouth down to 50 km to the south, the shoreface and inner shelf is extremely smooth and significant expressive topographic features are absent. This area is distinguished to the north and to the south by two irregular areas characterized by the presence of linear sand ridges with height differences up to 7 m between the crest and the trough.

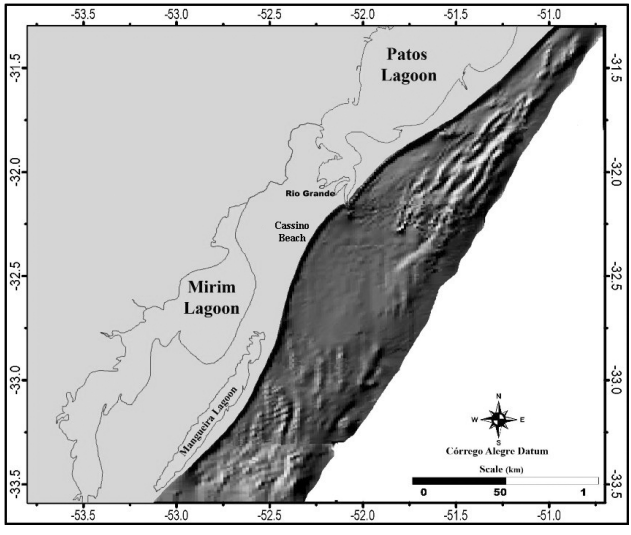

Fig. 1. Morphology of the inner continental shelf adjacent to Patos Lagoon inlet. Modified from Fachin, 1993.

The existence of this smooth area between two regions of irregular bathymetry suggests a different bottom type composed of mixtures of sand and mud. It is well known (Calliari and Fachin, 1993) that the influence of the muddy deposits of the "Patos Facies" (Martins et al. 1967) represented by silty clay, clayey silt, clayey sand and mixed bottoms types surpass the 20 m depth contour in this area. The presence of this homogenous bathymetric area between two irregular sand ridge fields (with all areas subjected to the same wave climate) can be explained in terms of different bottom sediment texture provided by the contribution of fine sediments (silt and clay) from the Patos Lagoon discharge into the ocean. During recent survey done on November of 2006, we were able to confirm the presence of continuous fluid mud and more consolidated mud deposits in the region offshore of the Patos Lagoon Inlet.

Another long term effect caused by the muddier shoreface in front of Cassino beach is the high rate of shoreline accretion on the order of 4.10 m/year found at 10 Km south of the inlet (figure 2). Studies of shoreline change adjacent to the four major inlets along the Rio Grande do Sul coastline (Lélis and Calliari, 2003) indicate that the Cassino beach displays highest accretion rates of all the studied sites. Historical records show that before the inlet stabilization and fixation by two jetties, alternated phases of shoreline accretion/erosion occurred in conjunction with the changeable morphology of

the ebb tide located at the lagoon mouth**.** After the end of the jetties construction, which begun in 1911 and ended in 1915, the shoreline started to accrete at higher rate. The shoreline accretion to the south of the inlet can be explained by the fact that the net littoral drift along the RS coastline is towards the northeast. However the higher rate of deposition coincides with the depocenter of the deposit mapped on basis of thickness of total mud content of the sediment cores (figure 3 from Calliari and Fachin, 1993) as well as the recent fluid mud thickness map (figure 4) of the shoreface obtained by coring and echobathymetric surveys in 2004 (Sperle et al. 2005). The stretch of beach adjacent to this area is also the place where mud deposits on the beach appear more frequently. These data strongly suggest that on a long-term basis there is an association between the shoreface mud deposits and the high shoreline accretion rate found in this area. The higher frequency of mud deposition at the beach and shoreface can substantially reduce the local wave energy and act like a sink for the sediments, which arrive there by littoral drift. Shoreline accretion and stabilization due to the presence of fluid mud on the shoreface has also been reported (Wells and Roberts 1980; Roberts et al 1989; Huh et al 1991) for sectors of the chenier plain coast of southwestern Louisiana.

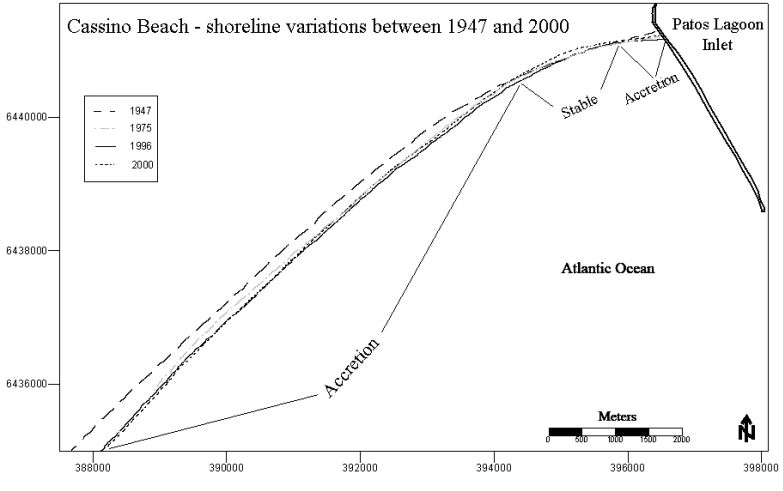

Fig. 2. Shoreline accretion between 1947 and 2000.

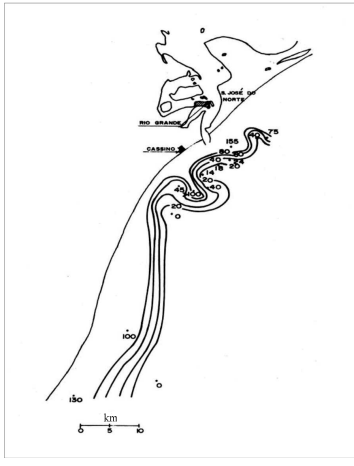

Fig. 3. Isopach map of total mud content (cm) displaying the depocenter of the mud deposit.

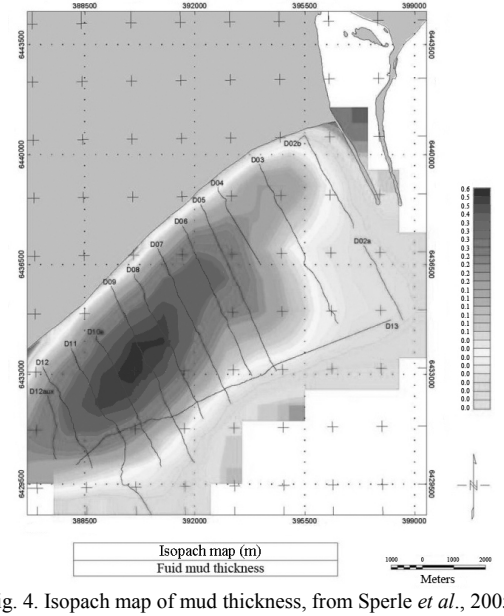

Fig. 4. Isopach map of mud thickness, from Sperle *et al*., 2005.

Alongshore changes in sediment texture also induce long term beach morphodynamic differentiation in the first 25 Km south of the Patos Lagoon inlet. Besides the silt and clay suspension load, Patos Lagoon contributes a substantial amount of very fine sand to the shoreface and adjacent beaches . Based on grain size distribution three main sectors were identified along this stretch of coast (Figueiredo and Calliari, 2006). The first sector called "West Jetty" which comprises the first 6 Km display the finest mean grain size of all RS coastline (2.9 phi units---very fine sand). The next sector the "Central" extends until Km 15 and the sand is slightly fine with a mean grain size of 2.7 phi. Between 15 Km and 25 Km the "Shipwreck" sector exhibit mean grain size of 2.3 phi units. Figure 5 displays the different sediment signatures between the central and shipwreck sectors as well as the long term different morphodynamic behavior between Querência beach located at the boundary of the first two sectors and the Shipwreck beach located at the end of the third sector. Querência beach displays higher beach width, a lower beach face slope and smaller changes in shoreline position and in the thickness of beach profile envelope when compared with the Shipwreck beach. One interpretation is that Querência is a typical dissipative beach and Shipwreck beach behaves more like an intermediate beach (Wright, 1984). Although these differences can be attributed to the fact that the presence of medium sand at Shipwreck beach contributes for its higher beach mobility, one cannot ignore the influence of muddy sediments found at shallower depths at Querência beach in terms of stabilizing the long-term morphodynamics.

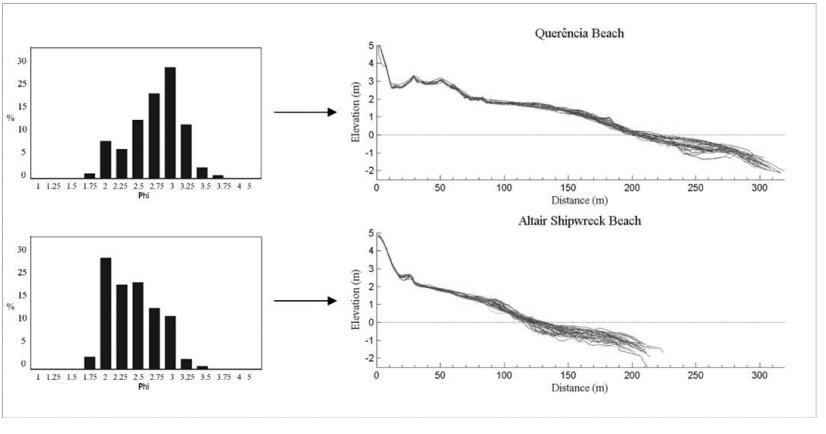

Fig. 5. Textural and morphodynamic long term differentiation between Querência and Shipwreck beach.

SHORT TERM EFFECTS

Short-term effects induced by mud deposition at the shoreface and surf-zone were detected during a mud deposition event which lasted for 14 months. Storms occurring on January 17 and March 10 of 1998 (Calliari et al. 2001**)** suspended and transported fluid mud deposits to the beach forming mud banks, which were exposed at the shoreline and in the surf-zone. The most obvious impact of these deposits over the depositional zone was the absence of surf-zone along vast stretches of beach (figure 6) that dramatically differed from adjacent areas with no shallow water mud deposits. Along these areas of the subaqueous deposits, rapid damping of wave energy could be visualized at distances of up to 6 Km offshore**.** Similar processes have been described by Wells and Coleman (1981) where waves transiting fluid mud bottoms along the coast of Surinam, South America were progressively attenuated nearshore without breaking**.** Similarly, Mathew et al. (1995) analyzed wave data from Kerala coast in India and found that wave height reduction as a result of wave propagation over fluid mud layers can reach 85%. According to these authors during the stage of mud banks formation along the southwest coast of India, the wave energy can be completely damped in a distance corresponding to a few wavelengths. All of these characteristics were obvious at Cassino suggesting that among other factors, the high viscosity of bottom sediments and the strong energy dissipation rate are the main causes of attenuation of the surface waves.

Fig. 6. Lateral variability in wave breaking associated with presence of mud.

A comparative study between two beach profile stations, monitored along Cassino beach, indicated that regions three kilometers apart displayed different behaviors in response to changes in the hydrodynamic conditions. Comparison of repeated beach profiles at the mud-free and muddy locations (Calliari et al. 2001) indicated that the mud-free site (Tourist Terminal) had much more variability compared to the more exposed, but muddier, beach (Rua Bahia) (figure 7). Such anomalous behavior, characterized by an inversion of the normal pattern of beach response, was due to the presence of nearshore and surf zone mud banks, which caused a wave attenuation effect.

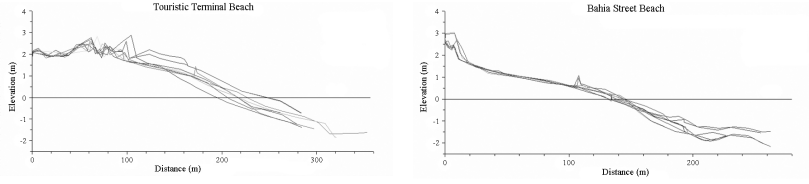

Fig. 7. Profiles showing more variability in the envelope of surveyed depths at the non-muddy site (left).

Micro-deltas, associated with the mouth of washouts that carried sand from the dune field to the beach appeared on the foreshore since the sand was not being remobilized by littoral drift due the complete absence of surf-zone during this period (figure 8). Additional morphodynamic effects relating to the mud deposits occurred with respect to beach protection as process similar to that described by Wells and Roberts (1980) along stretches of the Louisiana coast. During storms, due to the low set up in the area of mud deposits foredunes were protected from erosion. In this way the presence of the mud deposits certainly acted to stabilize the coast over short times and is consistent with the long-term observations previously described.

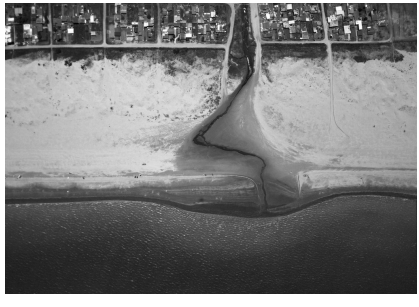

Fig. 8. Micro-delta features associated with the mouth of washouts.

COASTAL HAZARDS

On at least two occasions the presence of fluid mud in the surf-zone during episodes of high wave energy represented a potential hazard for surfers. Due to lateral gradients in wave energy along the surf-zone longshore currents transported surfers to areas where the surf zone was isolated from the beach by fluid mud which had thickness of 1.5 m or even more. Such situation caused surfers to get trapped in the surf zone under risk of life since they suffered hypothermia due to long exposure in autumn temperatures waters. There was some concern that they could be immobilized and buried by the fluid mud

deposits. Fortunately locals used cables and body boards to come across the surf-zone to rescue them.

The presence of mud between the beach face and backshore represents an additional risk for car traffic. The fact that Cassino beach is typically a highly dissipative wide and very fine sandy beach with a high degree of compaction (close-grained) encourages a steady flow of vehicles. Any mud deposited across the beach is rapidly covered by a thin layer of sand as soon as the sea level drops after the storms and acts as a trap for cars which get stuck in the mud sometimes reaching more than 0.3 m thick (figure 9). It becomes impossible to remove the cars without the use of heavy machines (caterpillar type). The accidents become more serious when cars in high velocity get suddenly stuck. Serious bodily injury resulted to tens of drivers during the duration of the mud deposit (14 months).

Fig. 9. Car trapped by mud deposits underneath a thin layer of sand.

CONCLUSIONS

The influence of offshore mud deposits on the otherwise fine sediment sandy beach in the Cassino area of Brazil is often extreme. With respect to regional morphodynamics, the flat shoreface and featureless inner continental shelf adjacent to the Patos Lagoon inlet results from the "Patos" facies composed predominantly by fine sediments from the lagoonal discharge. The high rate of shoreline accretion at 10 Km from the inlet is due to the association of the mud depocenter and the higher frequency of fluid mud deposition on the beach at this sector. The lagoonal source of very fine sand also induces beach morphodynamic differentiation in the proximities of the inlet as beaches located within 15 Km south of the inlet are ultra-dissipative. In contrast, south of this point, beaches are composed of mostly of fine and medium sand, display higher mobility and behave as intermediate.

Changes in sediment properties at the beach, surf zone and shoreface induce beach differentiation up to 25 Km south of the inlet. This lateral variability is identified by

three sectors with distinct morphodynamic behavior. In the first 6 Km (north sector), beach, surf-zone and shoreface are composed of very fine sands (the finest sand along the RS coastline). For the next 9 Km, which characterizes the central portion of Cassino, beach sediments are fine while the shoreface displays muddy sediments mostly composed of clayey silt, silty clay and silty sand. The lateral heterogeneity along the shoreface and surfzone of this beach also causes visible differences in beach morphodynamic behavior which is a response to the hydrodynamic conditions. Due the absence of mud in the shoreface, which can substantially reduce the wave energy, beaches in the first and third sector display more mobility and are subject to higher set-up when compared to the central sector of the region.

Similarly, sporadic mud deposition events during storms create short-term morphodynamic differentiation. Beach sectors under the influence of mud in the sub aerial beach, surf zone and part of the shoreface display low mobility and low hydrodynamics when compared with sectors without mud.
Mud deposition at the surf zone and beach can represent a non permanent potential coastal hazard for bathing, surfers and car traffic.

In short, many coastal sedimentary processes and properties are influenced by the presence of the offshore mud deposit. We expect that other regions with inlets having large sediment discharge rates may behave similarly.

Abstract: On August 29, 2005, Hurricane Katrina sent the largest-ever recorded storm surge into the central Gulf coast. The coastal surge penetrated more than 16 km (10 mi) inland in Jackson County to the east and Hancock County to the west. Wave destruction extended more that 1 km (0.6 mi) inland. Immediately after the storm, URS teams identified and surveyed 312 coastal high water marks (CHWM) in the three coastal counties. The USGS identified an additional 90 CHWM. These were checked, verified and surveyed to within 0.08 m (0.25 ft) vertical and 3.5 m (10 ft) horizontal. In this paper, the Hurricane Katrina storm surge is documented. By considering special features of both the oceanic and overland propagation of the surge it is possible the gain an understanding of why this storm surge was so much higher and spatially extensive than other previous major hurricane events along the coast.

INTRODUCTION

It is well accepted that coastal processes during storms strongly outweigh similar processes during normal weather. When Hurricane Katrina made landfall on the Mississippi coast near 7:30 a.m. (local) on August 29, 2005 it created one of the most devastating storm surges in U.S. history. Modern instruments, including satellites were able to develop a detailed data set on the meteorological properties of the hurricane. Additional insight into the storm surge development and behavior has been gained from post-event field studies and extensive simulations with numerical models. All of this permits us to develop a detailed description of the extreme coastal process that occurred. In this paper we concentrate on easternmost Louisiana and Mississippi because of the availability of our data and modeling.

HURRICANE HISTORY

Hurricane Katrina first made landfall on the southeast Florida coast north of Miami on August 25, 2005. It passed over the state and exited south of Naples early on August 26. It then continued on a westward track until the afternoon of the August 27 when it began a turn to the north. The storm made landfall on the lower Mississippi Delta and tracked across the lower delta in a northward direction. The eye passed between the eastern Louisiana shoreline and the Chandeleur Islands making landfall near the mouth of the Pearl River on the Mississippi/Louisiana border near 7:30 a.m. local time. Figure 1 shows a Doppler Radar Image of this storm just before it made landfall on the Mississippi coast.

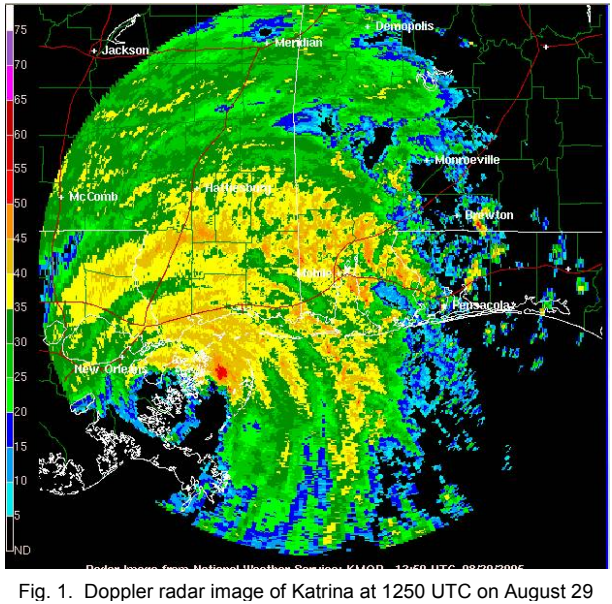

Fig. 1. Doppler radar image of Katrina at 1250 UTC on August 29

Much has been learned in recent years about the structure of hurricane wind fields and how these change in time. These changes are especially interesting to us as the storm centers come within about 150 km of the coast. As shown on Figure 2a, the Hurricane Katrina wind field was skewed to the east with the zone of maximum speed near the 2 o'clock position (i.e. NNE of the storm center) when the storm reached maximum intensity near 1100 hrs (local) on August 28. These winds diminished and the eastward asymmetry increased as the storm passed up the eastern Louisiana coast. Figure 2b shows that winds in excess of 70 meters per second (m/s) extended along the entire Mississippi coast at landfall. The radius to maximum winds at landfall have been variously estimated to be between 42 and 48 km.

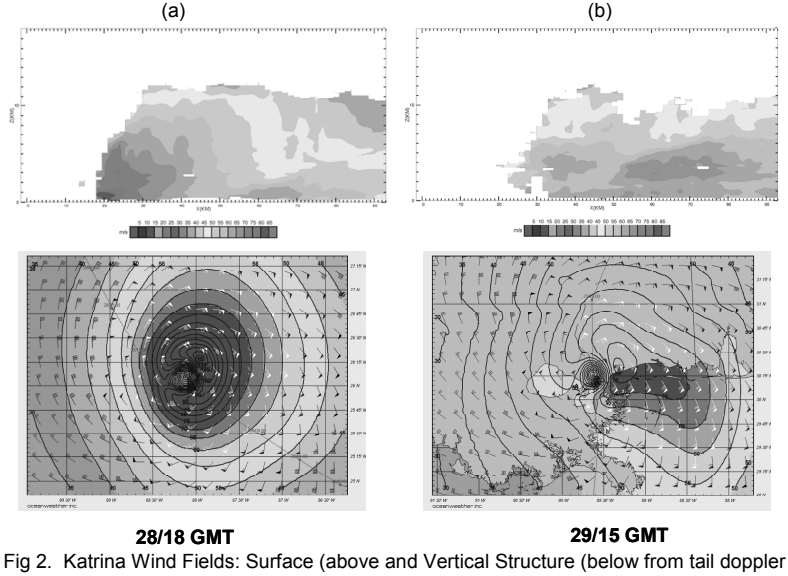

Fig 2. Katrina Wind Fields: Surface (above and Vertical Structure (below from tail doppler – source image from NHC) – (a) August 28, 1800 hrs UTC (b) Aug. 29, 1500 hrs

The details of these variations in the structure and intensity of the storm are very important to both the way that the storm surge developed and the ability of hydrodynamic models to accurately represent the details of the developing surge. For our study an exhaustive review of data sources was conducted to provide a comprehensive time-history of this storm. Hurricane hunter aircraft observations using GPS drops, Stepped Frequency Microwave Radiometer and Tail Radar were taken by NOAA several times a day. These data were combined with ocean data buoy measurements, land station meteorological observations, Doppler radar images, and satellite measurements. With this information the behavior of the OWI Tropical PBL Planetary Boundary Layer Model was adjusted to most closely match the best available interpretation of the wind field. This model was used to represent

conditions from the time that the storm entered the Gulf of Mexico to after landfall on the Mississippi coast.

SURVEY OF COASTAL HIGH WATER MARKS

When major storms make landfall the Federal Emergency Management Agency (FEMA) and other government agencies carry out surveys to describe the extent and maximum water levels over the areas that were flooded. The destruction of Hurricane Katrina was so great and widespread that this response was delayed for several days to avoid interfering with emergency crews. Coastal high water mark (CHWM) surveys were carried out by our crews working for FEMA and personnel from the U.S. Geological Survey (USGS).

CHWM surveys were carried out by personnel trained to identify evidence of the flood level and what each data point represents. A total of 402 points were located and surveyed in coastal Mississippi (312 URS/FEMA points and 90 USGS points). These points are deliberately divided between those reflecting the highest still water level, the highest level reached by the crests of waves propagating on the surge and the greatest wave run-up elevations on natural and constructed embankments.

Although still-water CHWMs are carefully selected from places where direct wave effects have been blocked (i.e. flood marks in interior rooms) it has been found that local spatial variability is unavoidable. In an extremely violent storm such as Katrina there must be large and rapid changes in the local wind and surge. In some rooms in damaged buildings we found evidence of turbulent conditions as waves crashed about and these can distort the watermarks, even in close adjoining closets. The amount and size of debris being piled up and tossed about is almost unimaginable. Locally this can temporarily dam up flow paths and amplify the maximum surges. Many other complicating factors can be envisioned.

With these difficulties in mind we have selected a total of 193 coastal high water marks as being the most reliable measurements of the maximum surge levels. Although, in actuality, as these measurements were first being reported by our field crew we were incredulous. The maximum CHWM elevations were 10.6 m (NAVD 88 datum) which were found near Pass Christian. Figure 3 shows some representative measurements along the shoreline and inland. This figure also has an outline of the inland extent of the surge as mapped by field parties.

We have conducted no mapping of the offshore barrier islands. The Coastal Services Group of the U.S. Geological Survey carried out Lidar elevation measurements a few days after the storm and showed that all of the islands were overtopped by the Katrina surge. They also report extensive erosion.

NUMERICAL MODELING

To better understand the extreme coastal conditions over the duration of the storm surge we have conducted a series of analyses with numerical models. The Ocean Weather PBL model, with the tailoring and adjustments noted above, provided a detailed and accurate time series of wind and atmospheric pressure fields that were

inputs to the other models. Waves were modeled with both WAM and SWAN. The (Parallel) ADvanced CIRCulation Model for Oceanic, Coastal and Estuarine Waters (ADCIRC) model was used to represent the hydrodynamics of the coastal surge.

Storm Waves

The wind and atmospheric pressure data provide by Ocean Weather were used as input to a Gulf-wide WAM model of ocean waves. These storm and wave conditions were then used as input to more detailed regional and local SWAN model grids covering the eastern Louisiana and entire Mississippi areas.

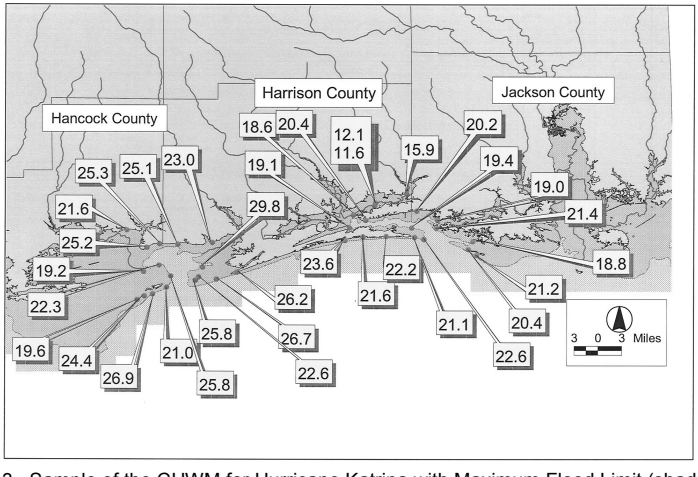

Fig. 3. Sample of the CHWM for Hurricane Katrina with Maximum Flood Limit (shaded)

The primary reason for the modeling of wave conditions during this event was to provide detailed representations of the breaking wave conditions so that the wave set-up component of the coastal surge could be determined.

Figures 4 and 5 show results from the regional SWAN model for August 29, 2005 conditions at 2130 hrs (local) on August 28 and 0730 hrs on August 29, respectfully. At 2130 hrs the barrier islands and shallow depths of both Chandelier Sound and the Mississippi Sound clearly protect the mainland coast. Within these sounds the wave periods are four seconds or less indicating that they are dominantly locally generated. The significant wave heights at this time are less than 2.5 m inshore of the barrier island. Figure 5, representing conditions at 0730 hrs on August 29 indicates this is where the coastal surge has overtopped the barrier islands. The corresponding extent of inland flooding also appears on this figure. Note that in spite of an increase in local water depths due to the developing storm surge on the order of 6 m., the wave periods indicate that the wave energy at the mainland coast is still largely dominated by wind-generated seas. The shoreface of the barrier islands absorbs the greatest share of the hurricane-generated waves from the open Gulf. Only a fraction of the open-Gulf

wave energy passes between the barrier islands. The shallow overtopping of the barrier islands allows them to maintain their important role in protecting the mainland shore.

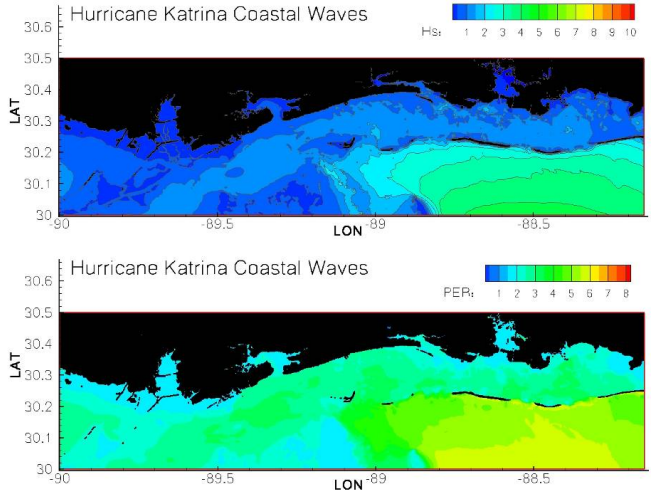

Fig. 4. Significant Wave Height (upper) and Period (lower) for 0430 hrs (UTC) Aug. 29.

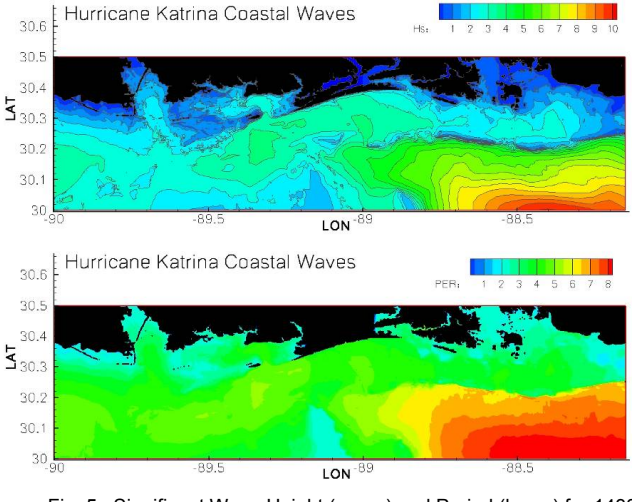

Fig. 5. Significant Wave Height (upper) and Period (lower) for 1430 hrs (UTC) Aug. 29.

This morphology of shallow sounds and low offshore barrier islands serves to restrict the maximum wave conditions and results in also restricting the contribution of wave set-up to the coastal storm surge at the mainland. Our calculations indicate that this component was generally less than 1 m.

Development of the Coastal Storm Surge

The time-history of the Hurricane Katrina coastal storm surge has been mapped out with the ADCIRC modeling. This model was calibrated using CHWM data from Hurricanes Camille, Betsy and Katina. Most of the work in these calibrations involved local adjustments in the way that topographic features were represented in the model grid. However, in the case of Camille and Betsy it was necessary to adjust the details of the wind fields in the OWI Tropical PBL Model. These adjustments were limited by the available data. That is the available data permitted a certain amount of judgment so long as measured behavior was not violated.

As Hurricane Katrina tracked northward on August 28 it strengthened alarmingly. A low barotropic wave propagated ahead of the storm and arrived at the Mississippi coast about a day ahead of landfall on the mainland. As the storm neared landfall on the Louisiana Delta coast just west of the river mouth, the coastal surge east of the river levees began to develop rapidly. The hydrodynamic model results clearly show a bulge of water about 5 m high that developed against the eastern levee system and was forced northward.

As this moved northward it became constrained by the levees protecting the areas around New Orleans. At this time the maximum winds were onshore with hurricane wind speeds extending over the entire coast of Mississippi and well into Alabama. Several factors combined to cause significant gradients in the height of the surge along the open Mississippi shore. The marked turn in coastline orientation from east-west in Mississippi to nearly north-south in eastern Louisiana certainly funneled and trapped the surge. The shallow depths and gentle bottom slopes of the Chandelier and Mississippi Sounds added to this effect. The surge attributable to these direct effects was certainly enhanced by the forced wave traveling up the eastern Louisiana levee systems.

Along the open coast the maximum surge elevations closely corresponded to the place where the strongest onshore winds occurred. The timing of the maximum wind and maximum surge closely correspond. Comparison of the maximum surge elevations shown on Figure 3 with the spatial distribution of the maximum onshore winds shown on Figure 2 is a good indicator of the role that the coastline geometry and offshore bathymetry played in amplifying the surge. The greatest surge developed in the Waveland-Pass Christian area. This surge remained high along the central Mississippi coast as far as Biloxi. Here the surge was held against the rapidly rising land level that parallels the shoreline. Further east, the winds were still strong, but the surge levels became lower.

The combined effects of gravity and wind stress also served to make the pattern of storm surge development irregular as it moved inland. Near the coast the pattern of

inland flooding is dominated by differences in the level of the surge along the entire coastline.

Comparison of how the surge propagated in eastern Louisiana compared to Mississippi show major differences due to local topographic relief. In the wide basins of the Pearl and Pascagoula Rivers the surge moves on a broad front up the drainage way in a manner similar to a progressive wave. However, much of the Mississippi coast has coastal streams in distinct valleys. The surge propagates up these and then spreads into adjacent low-lying areas. In the areas surrounding St. Louis Bay the sequence of wind stress had a strong controlling effect with considerably more flooding along the lowlands adjoining the Jourdan River which enters the bay from the west than in equivalent areas along the Wolf River which enters from the east. This effect was caused by the relative timing of the surge and the direction of the wind stress. The highest surges on the coast occurred around St. Louis Bay and were even higher in the bay itself. As the hurricane eye passed the strong west wind drove a pulse of water up Wolf River which enters the bay from the east. At this time the surge propagated against the wind up the Jordan River which enters the bay from the west. In the lowlands surrounding this river the maximum flood level was lower and its occurrence later than in the Wolf River because of this effect.

From the modeling results it is clear that the time of maximum storm surge levels and the times of maximum winds differed considerably in the different coastal areas. In St. Tammany Parish in eastern-most Louisiana places along the western side of the extensive wetland in the Pearl River floodplain had the storm surge maximum more than three hours later than the time of maximum winds. Inland flooding maximums for points several kilometers from the bays had a lag between one and three hours between maximum winds and maximum water levels. Many place in Harrison and Jackson Counties located between two and five kilometers inland had maximum surges lagging maximum winds by one half to one hour. Along the open coasts these time differences were small or absent.

CONCLUSIONS

This study clearly demonstrates how modern data collection programs combined with detailed numerical models can provide very detailed representations of the time history of a storm surge from a major hurricane and certainly points the way for developments in the near future where such analyses become feasible in a prognostic mode.

The study also shows the beneficial effect of barrier islands, even when they are severely overtopped. The whole mass of the barrier island platform, which extends across the shoreface to the inner shelf serves to cause the large waves to break, starting more than 10 km offshore. As a consequence wave conditions on the mainland coast are substantially less than what would be encountered on an unprotected shore.

The special role of the levees along the east bank of the Mississippi River and protecting the areas around New Orleans is noted. These appear to have served to enhance the surge along the western portion of the Mississippi coast.

The results also demonstrate that the inland propagation of a storm surge from a major storm such as Hurricane Katrina can be complex. The timing of maximum surge and maximum winds is not well correlated.

COASTAL INLETS OF TEXAS, USA

Nicholas C. Kraus[1]

1. U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA. Nicholas.C.Kraus@erdc.usace.army.mil.

Abstract: Presently, 16 permanent inlets connect the inland coastal waterways and rivers to the Gulf of Mexico on the 560-km long coast of Texas. Processes controlling inlet stability in Texas are typically more complex than those acting on the Atlantic and Pacific Ocean coasts of the United States, where the astronomical tide dominates. The tide on the Texas coast is predominantly or fully diurnal and with small range; however, the large surface areas of most Texas bays produce large tidal prisms. Wind is strong throughout the year, either from the southeast in summer or as episodic northeasterly fronts in autumn and winter. Non-astronomical seasonal variations in water level are comparable to the tidal range of Texas bays. Creation of inlets on the Texas coast is ongoing for environmental, commercial, and recreational reasons, and this paper discusses the status and challenges posed to inlet creation, stability, and maintenance.

INTRODUCTION

The coast of Texas is approximately 540 km long and is fronted by sandy barrier islands or barrier spits (Fig. 1) with the exceptions of about 50 km each of mainland near Sabine Pass and Freeport. Texas inlets to the Gulf of Mexico originate as natural river mouths, relocated river mouths, natural entrances to bays, and artificial cuts through the barriers. There are eight federal channels: Sabine Pass, Galveston Pass, Freeport Ship Chanel, Mouth of Colorado River Navigation Channel, Matagorda Ship Channel, Aransas Pass, Mansfield Pass, and the Brazos-Santiago Pass. The Mouth of Colorado River and Mansfield Pass are shallow draft (at about 4-m depth), and the other six are deep draft at 13-m depth or greater. Permanent inlets of Texas are listed in Table 1, according to origin. Many inlets in Texas are named either as “passes” or as “cuts,” signifying the action of a hurricane or of human intervention in opening them. At the time of this writing, January 2007, 16 inlets along the Texas coast were open to the Gulf of Mexico.

Many inlets of Texas are described by U.S. Army Corps of Engineers ((USACE) 1992), and Morton (1977) studied morphologic response to seven federal Texas inlets with jetties (Mouth of Colorado River had not yet been opened).

Fig. 1. Location map for Texas coast with presently open and other inlets

The need for additional inlets along the Texas coast, in particular, for small inlets to allow exchange of water with the Gulf of Mexico and inland bays and lagoons, locally called "fish passes," was documented by Carothers and Innis (1960). In the mid 20th Century, two major inlets with jetties were constructed, Mansfield Pass (Hansen 1960; Kieslich 1977) and the Matagorda Ship Channel (Kraus et al. 2006). Some fish passes have been successful such as Rollover Pass opened to upper Galveston Bay opened in 1959 (Bales and Holley 1989) and Mitchells Cut opened to East Matagorda Bay in 1989 as a flood-relief channel (USACE 1992). Other inlets such as Yarbrough Pass to Baffin

Bay (Lockwood & Andrews 1952), most recently cut in 1952, and the Mustang Island Fish Pass opened in 1972 (Behrens 1979) have been unsuccessful by rapidly shoaling and closing. In contrast, Rollover Pass expanded greatly from its planned dimensions (because of a large phase difference between the Gulf and upper Galveston Bay) and had to be controlled be revetments and a channel weir. Other inlets located close to the Gulf have been considered for opening, including re-opening Parkers Cut to connect Matagorda Bay to the Colorado River Navigation Channel, and opening of a "Southwest Corner Cut" to connect East Matagorda Bay to the Colorado River Navigation Channel (Kraus and Militello 1999). Environmental and legal issues have reduced agency enthusiasm for opening fish passes, but inlet creation continues, as demonstrated by opening of Packery Channel in 2005 (Kraus and Heilman 1997; Williams et al. 2007) and interest in maintaining the long-lived ephemeral inlet Cedar Bayou Pass connecting the Gulf to Mesquite Bay (Simmons and Hoese 1959; Shepsis and Carter 2007). Concern has also been expressed by local interests in maintaining the San Bernard River Mouth (Lin et al. 2003).

Table 1. Coastal Inlets of Texas to Gulf of Mexico

Origin	Name	Comments
Inlets Open as of January 2007		
River Mouths	Sabine, Brazos, San Bernard, Colorado, Rio Grande	The modern Colorado River Mouth diverted into Matagorda Bay in 1992 Brazos River mouth relocated south of Freeport Ship Channel (original mouth) in 1929.
Natural Exchange Passes	Galveston, San Luis, Pass Cavallo, Cedar Bayou, Aransas, Brazos Santiago	Cedar Bayou is a long-lived ephemeral inlet to San Antonio Bay & Aransas Bay.
Artificial Inlets (Engineered Cuts)	Rollover Pass, Freeport Ship Channel, Mitchell's Cut, Matagorda Ship Channel, Packery Channel, Mansfield Pass	
Selected Ephemeral Inlets and Hurricane Passes		
Connecting to Gulf	Brown Cedar Cut & Greens Bayou; Corpus Christi Pass and Newport Pass	Likely will not open again because other inlets present
Proposed Passes to Rivers	SW Corner Cut to connect East Matagorda Bay and Colorado River Navigation Channel	Active discussion on opening this inlet
Attempted, but Failed Artificial Inlets		
Artificial Inlets	Mustang Island Fish Pass to Corpus Christi Bay; Yarbrough Pass to Baffin Bay	Both closed or became inefficient in short time.

Although Carothers and Innes (1960) provide design guidance for constructing fish passes along the Texas coast, it appears that an update based on more recent experiences and knowledge of Texas inlet processes would be beneficial to the coastal engineering and science communities. Creation of inlets can cause morphologic change on widely

varying space and time scales (Kraus 2006). It is the intent here to document recent observations and experiences with inlets along the Texas coast, updating the literature.

STABILITY OF TEXAS COASTAL INLETS

Many natural processes control the creation, stability, and navigability of coastal inlets. Main factors are:

1. Longshore sediment transport, including wind-blown transport.
2. Astronomical tide.
3. Wind tide.
4. Seasonal change in water level.
5. Regional precipitation and watershed characteristics.
6. River discharges for those inlets connected to rivers.
7. Sediment grain size and geological environment.
8. Human interventions, principally dredging, but also constriction of inlet width by jetties and reduction of longshore sediment transport reaching the inlet.
9. Hurricanes and tropical storms.
10. Relative sea-level rise.
11. Width to depth ratio of inlet channel with jetties, with smaller ratio providing a more hydraulically efficient channel (e.g., Kraus and Heilman 1997).

In this paper, the wind tide is examined, as its action is more regular and much more pronounced than along other coasts of the United States and dominates extreme water levels and currents at Texas coastal inlets. Relative sea-level rise (RSLR) on the Texas coast and varies from about 3 mm/year at the Port Isabel (Brownsville) tide gauge to greater than 10 mm/year at Freeport and Galveston. RSLR may increase bay and lagoon surface area, hence tidal prism, and promote inlet stability. On the other hand, protective jetties will become lower with respect to the water surface, allowing more littoral sediment to enter the entrance channels they protect. The sediment along the Texas coast is predominantly fine quartz sand with median grain size of 0.16-0.18 mm.

Because of the concave curvature of the Texas coast to the southeast, regional longshore sand transport is directed from north to south from Sabine Pass and from south to north from the Rio Grande to converge along central Padre Island (Carothers and Innis 1960; Watson 1971). Of course, there are local reversals, especially at inlets (e.g., Heilman and Edge 1996). Owing to the coastal curvature, widely varying magnitudes of net and gross longshore sand transport rates are expected. Volumes of sand dredged from inlet entrance channels indicate average rates of 100,000-300,000 m^3/year, but can reach 500,000 m^3/year.

Wind blowing from the Gulf of Mexico and surge by tropical storms elevate water at the shore, promoting longshore transport in the swash zone. Swash zone transport can cause spit growth into inlets without structures and sand back-passing (sand moving around landward side of a jetty) with spit growth for inlets with low jetties (Fig. 2). The longshore component of wind can also be strong, moving sand over portions of jetties located on the dry beach and contributing to shoal growth and channel infilling (Fig. 3).

Intrusion of channels by wind-blown sand can figure prominently in the closure of small inlets along the Texas coast (Kraus and Heilman 1997).

Hurricanes open many short-term and sometimes long-term ephemeral inlets in the Texas barrier islands (Hayes 1965). Examples of longer term ephemeral inlets are Cedar Bayou opening to Aransas Bay and San Antonio Bay through Mesquite Bay (Simmons and Hoese 1959; Shepsis and Carter 2007), and the presently closed Brown Cedar Cut at the eastern end of East Matagorda Bay (Mason and Sorenson 1971). Brown Cedar Cut will likely remain closed owing to artificial opening of nearby Mitchells Cut in 1989.

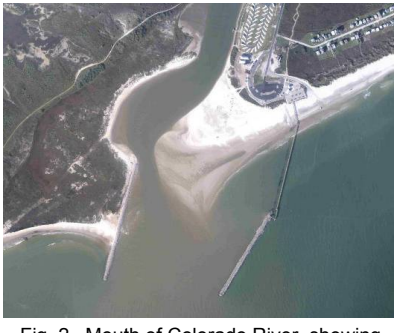

Fig. 2. Mouth of Colorado River, showing sand spit growing into channel from east (right) by transport landward of weir jetty, Jul 06

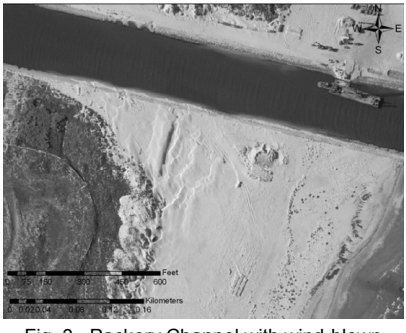

Fig. 3. Packery Channel with wind-blown sand covering the south (lower) jetty, Aug 06

Astronomical tide along the Texas coast is predominantly diurnal from Galveston to Sabine and fully diurnal from about Matagorda Bay to the Rio Grande. Gulf of Mexico tide range on this coast is on order of 0.6 m. Astronomical tide in the bays and lagoons is diurnal, and its range is considerably less than that of the open coast. Some large water bodies, such as Baffin Bay, are considered non-tidal by the National Ocean Service (tide range less than about 0.05 m), and others such as at Port Mansfield are marginally tidal.

In the bays and Texas along the coast, water level extremes and currents through inlets are controlled more by wind and seasonal variations than by astronomical tide. For example, Kraus and Militello (1999) report water level at two stations at the eastern (EMAT) and southwestern (SWEMAT) ends of the major axis of East Matagorda Bay from 7 Sep 1995 to 8 Feb1996 relative to Mean Lower Low Water (MLLW) (Fig. 4). The astronomical tide range in this bay is 0.1 m. The measurements show an almost 0.6-m tilt in water level over the 32 km between gauges during one strong northeast front with wind speed of 12 m/s, with a 0.2 to 0.3-m tilt being common during frontal passages. The bay is 37 km long, and typical depths are in the range of 0.6 to 1.2 m.

On the Texas coast, seasonal highs occur around May and October, and seasonal lows occur around August and December-January (Fig. 5). The seasonal range is about 0.2-0.3 m, which is comparable to or exceeds the tide range in many Texas bays and lagoons.

Figure 5 plots monthly water level for open coast tide gauges (Galveston, Bob Hall Pier at Corpus Christi; and bay gauges (Rawlings at Mouth of Colorado River; Lavaca, and Port Isabel in the lower Laguna Madre) for year 1999. Barge operators and others involved with inlet and coastal waterway navigation are aware of the seasonal highs and lows, and their possible benefit or impediment, respectively, to vessel transit.

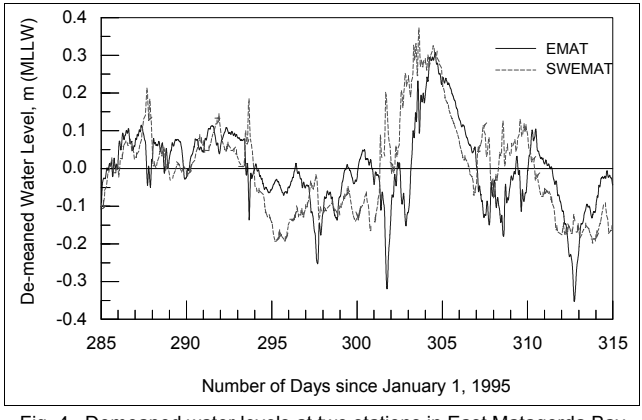

Fig. 4. Demeaned water levels at two stations in East Matagorda Bay

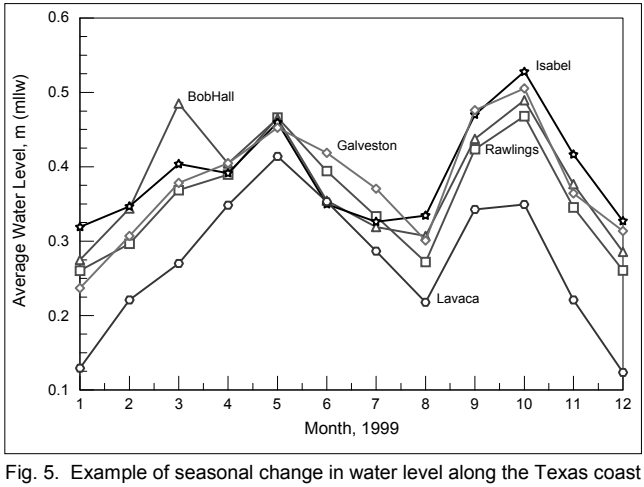

Fig. 5. Example of seasonal change in water level along the Texas coast

Strong wind from the north or northeast can overcome the astronomical tide in forcing water through Texas inlets, as shown in Fig. 6, based on measurements of the current, water level, and sustained wind from north at Packery Channel (Williams et al. 2007). Behrens (1979) explains how the strong wind from the southeast can enhance the flood current through inlets and strong wind from the north or northeast can enhance the ebb

current. For such reasons, Price (1952) noted that funnel-shaped inlets in the southwest corners of bays on the upper Texas coast or in the southeast corners of bays on the lower Texas coast tend to be the natural and stable inlets to the bays. Pass Cavallo in Matagorda Bay is such a southwest corner inlet, remaining open despite capture of much of the tidal prism by cutting of the Matagorda Ship Channel in 1966 (Kraus et al. 2006; Batten et al. 2007). Because wind tide and seasonal lows can dominate astronomical tide, the USACE Galveston District has defined a navigation datum called Mean Low Tide that is specific to location and lies below MLLW (Kraus et al. 1997). Seasonal lows in water level make marginally stable small inlets prone to closure.

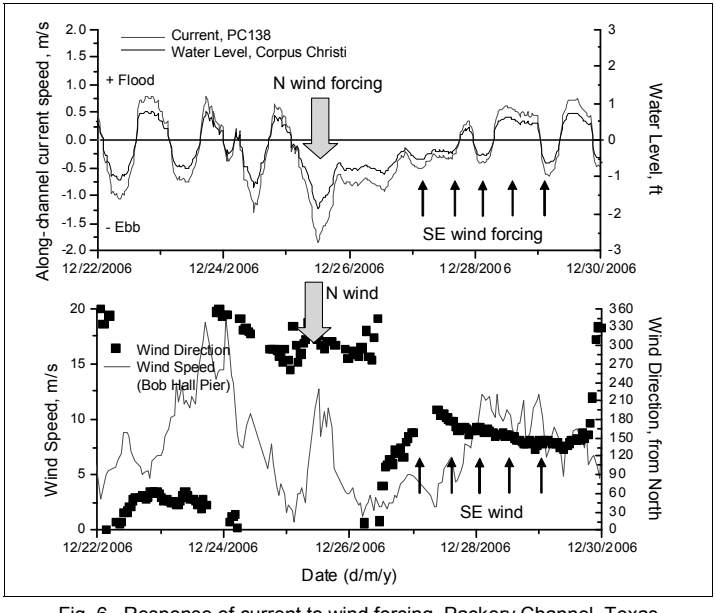

Fig. 6. Response of current to wind forcing, Packery Channel, Texas (from Williams et al. 2007)

TEXAS INLET STABILITY

Implications of Diurnal Tide

It is empirically known that a cross-sectionally stable inlet located on a sandy coast tends to have a mean-maximum velocity through it of approximately 1 m/s (Escoffier 1940; Bruun 1968). By "mean-maximum velocity" is meant the average of a regularly occurring maximum velocity, such as would occur on spring tide. If it is assumed that the discharge is solely related to the tidal prism and that there is a sinusoidal tide with one component, the maximum discharge D_m and tidal prism P can be related as:

$$P = \int_0^{T/2} D_m \sin\left(\frac{2\pi}{T} t\right) dt \tag{1}$$

where T is the tidal period, and t is time. The integration yields:

$$D_m = \frac{\pi}{T} P \tag{2}$$

Tidal prism is defined as the volume of water exchanged between an estuary or lagoon and the open sea during one tidal period (between high to low tide in the bay, giving an ebb-tidal prism, or between low to high tide in the bay, giving a flood-tidal prism). Therefore, the integration limit in Eq. 1 is taken to be $T/2$. Tidal prism can also be calculated as the product of the effective bay surface area served by the subject inlet times the tidal range, or from a computation of water discharge, as through a numerical model. By definition of a discharge, the mean-maximum velocity V_{mm} is:

$$V_{mm} = \frac{D_m}{A_C} \tag{3}$$

in which A_C is the minimum inlet channel cross-sectional area at mean sea level (msl).

Although refinements have been made in empirical predictive equations relating A_C and P, it is convenient for present discussion to consider the linear relation found by O'Brien (1969), based in part on analysis of inlets without jetties:

$$A_C = C\,P \tag{4}$$

where A_C is expressed in m^2, P is expressed in m^3, and $C = 6.6 \times 10^{-5}$ with units m^{-1}. The original units of this equation in feet were converted to metric units for the present work. Kraus (1998) derived a form of Eq. 4 by consideration of a balance of sand transport by the inlet channel-clearing current and the channel infilling by the longshore transport. This equation was also expressed directly in terms of water discharge through the inlet, in addition to tidal prism.

Substitution of Eq. 2 and Eq. 4 into Eq. 3 gives (O'Brien 1969):

$$V_{mm} = \frac{\pi}{CT} \tag{5}$$

For a semi-diurnal inlet, T = 12 hr, 25 min = 44,712 s. Then, Eq. 5 yields V_{mm} = 1.06 m/s, in agreement with empirical observations. For a tide that is primarily diurnal, the tidal period is 89,424 s, giving V_{mm} = 0.53 m/s. The conclusion is that an inlet in a diurnal tidal setting may require a smaller mean-maximum tidal velocity to maintain channel cross-sectional area stability as compared to inlets in a semi-diurnal setting, the more common type of inlet. The Texas coast is an ideal site to explore such a possibility, although the wind tide is expected to take as much a role as the astronomical tide in controlling stability of inlets on the Texas coast.

Implications of Wind Tide – Simple Model for Multiple Tidal Inlets

In this section, the consequence to the current of a wind tide is explored with a simple mathematical model of a bay with two inlets, and model parameters correspond to a bay similar to East Matagorda Bay. The model is a slight extension of a Keulegan bay

approach as discussed in Chapter 13 of Dean and Dalrymple (2002). Following their notation, we define:

$$F = K_{en} + K_{ex} + \frac{f\,L}{4R_H} \tag{6}$$

where K_{en} and K_{ex} = inlet entrance and exit loss coefficients (typically specified as 0.3 and 1.0, respectively), f = Darcy-Weisbach friction coefficient, L = effective length of inlet, and R_H = hydraulic radius of a rectangular cross-section inlet of depth h. Then, the equations of motion are, for two inlets serving the same bay:

$$\frac{dU_i}{dt} = -\frac{g}{L_i}\left(\eta_B - \eta_O \pm \delta\right) - \frac{F_i}{2\,L_i}\left|U_i\right|U_i \tag{7}$$

and

$$\frac{d\eta_B}{dt} = \frac{1}{A_B}\left(A_{C1}U_1 + A_{C2}U_2\right) + \frac{D}{A_B} \tag{8}$$

where U_i = velocity of inlet i = 1 or 2, t = time, g = acceleration of gravity (9.8 m/s^2), η_B = water-surface elevation of bay, η_O = water surface elevation of ocean (Gulf of Mexico in this paper), δ = tilt in water surface elevation across a bay as caused by wind, A_C = inlet cross-sectional area below mean sea level, A_B = surface area of bay, and D = discharge into the bay, as from a river. D was set to zero in this paper. The inlets are assumed to be located at the opposite ends of the bay, and the water level in the entire bay responds to each inlet. Other assumptions of a Keulegan bay apply.

The model formulation is similar to that of Seelig and Sorensen (1978), who included advective acceleration, omitted here, but did not include wind forcing. In a process-based model, the change in elevation by wind and associated current can be calculated by applying wind shear to the water surface, such as done for East Matagorda Bay by Kraus and Militello (1999) and described analytically by Kraus and Militello (2001), demonstrating that the tilt in water surface by wind blowing on a shallow bay is almost linear. The water surface responds rapidly to wind shear, and Kraus and Militello (1999) found it necessary to force the hydrodynamic model with 6-min averages of wind speed rather than 1-hr averages to obtain best agreement of the calculated water level and current with measurements. Here, the quantity δ describes the tilt directly and must be specified. A Matlab program was written to solve Eq. 7 and Eq. 8 in time-marching manner, and the results were checked against the Keulegan (1967) solution that neglects the acceleration term in Eq. 7 and water surface tilt.

The above simple model for a dual-inlet bay system was operated to explore the action of strong wind on a dual inlet. The example here pertains to a bay with surface area of $2\text{x}10^8$ m^2; primary inlet (denoted by subscript 1) of depth 3 m, width 300 m, and length 1,600 m; secondary inlet (denoted by subscript 2) on other side of bay of depth 1 m, width 50 m, and length 1,000 m; ocean forcing amplitude of 0.3 m (corresponding to a tidal range of 0.6 m) and sinusoidal diurnal tidal period of 89,424 s; and friction

coefficient $f = 0.06$. This arrangement roughly describes East Matagorda Bay, with the primary inlet being Mitchells Cut and the secondary inlet being the proposed SW Corner Cut as a narrow, shallow channel through marsh. The cross-sectional area of Inlet 1 is 18 times larger than that of Inlet 2, so the discharge is correspondingly larger.

The situation calculated with only tidal amplitude forcing is shown in Figs. 7 and 8. The figures are plotted for a time interval past the ramp of the solution and cover one diurnal tidal period starting with phase 0 for the Gulf water level forcing. Due to relatively strong friction in long and shallow inlets, the water level in the bay lags the Gulf of Mexico water level substantially and is greatly reduced in range. The current velocity is greater in Inlet 1, as expected, because of its greater depth. Although the tidal forcing is sinusoidal, the non-linear friction terms in Eq. 7 distorts the inlet current velocity. Positive directed current denotes flood, and negative denotes ebb.

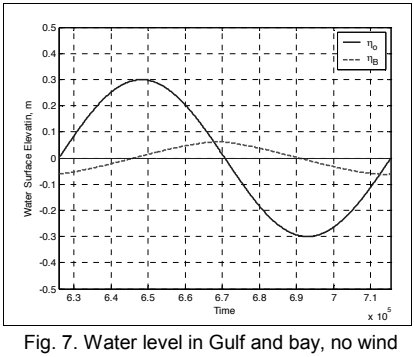

Fig. 7. Water level in Gulf and bay, no wind

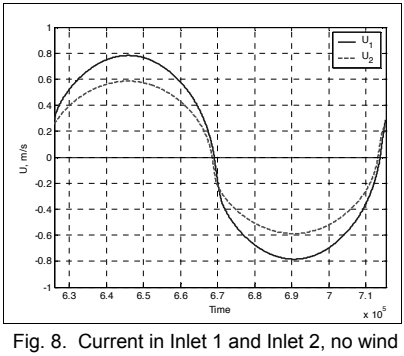

Fig. 8. Current in Inlet 1 and Inlet 2, no wind

The solution for a strong wind blowing such that the water surface is tilted upward 0.2 m toward Inlet 2 and downward 0.2 m at Inlet 1 is summarized in Figs. 9 and 10. In this situation, water can flow from the Gulf through the more efficient Inlet 1 of larger cross-sectional channel area, raising water level in the bay. The current through Inlet 2 increases greatly toward ebb, with the tidal flood current shown in Fig. 8 overcome by the wind tide to cause variable, but complete ebb flow through the tidal period (Fig. 10). The ebb current through the larger Inlet 1 is slightly reduced. The current through Inlet 2 is more distorted, with a longer duration during the latter portion of the tidal cycle.

The solution for a strong wind blowing such that the water surface is tilted upward 0.2 m toward Inlet 1 and downward 0.2 m at Inlet 2 is summarized in Figs. 11 and 12. In this situation, water can flow out of the bay and into the Gulf through the more efficient Inlet 1, lowering water level in the bay. The current through Inlet 2 increases greatly toward flood, with the tidal flood current shown in Fig. 8 overcome by the wind tide to cause variable, but complete flood flow through the tidal period (Fig. 12). The flood current through larger Inlet 1 is slightly reduced. The current through Inlet 2 is more distorted, with a longer duration during the initial portion of the tidal cycle.

CONCLUDING DISCUSSION

As is known to coastal engineers and scientists working along the Texas coast, as well as to ship pilots, barge operators, and fishing boat operators who transit its inlets and inland coastal waters, the water level in bays and current velocity through Texas coastal inlets are strongly influenced by wind and seasonal change in Gulf of Mexico water level. Both wind tide and seasonal change in water level can exceed astronomical tide range in Texas bays and lagoons. As a result, stability of Texas inlets is strongly controlled by wind. Because the wind tide can control the magnitude of the ebb (or flood) current, inlet area-tidal prism relations alone should be applied with caution. In a future paper, the author plans to introduce a formalism that accounts for wind tide in inlet stability analysis.

Intrusion of wind-blown sand into inlet channels is another and significant factor controlling stability of smaller inlets in Texas. The situation of the Colorado River Mouth (Fig. 2) demonstrates that longshore sand transport in the swash zone and wind-blown sand can greatly constrict an inlet channel.

Finally, the diurnal tide experienced on the Texas coast suggests that a smaller maximum current may be sufficient to maintain stability as compared to the more common semi-diurnal inlet. This potential behavior, together with wind tide, acts in favor of inlet stability on the Texas coast. At present, numerical modeling technology allows accurate representation of inlet hydrodynamics involving all water forcing, multiple inlets to the bays, rivers, and inter-bay connecting waterways, as has been demonstrated for the Texas coast (Brown et al. 2003). The challenge remaining is to reliably estimate sediment transport and morphology change at coastal inlets.

ACKNOWLEDGEMENTS

This paper was generated as an activity of the U.S. Army Corps of Engineers (USACE), Coastal Inlets Research Program. Support of inlet studies along the Texas coast over the years by the U.S. Army Engineer District, Galveston, is gratefully acknowledged. Discussions with Ms. Deidre Williams at TAMU-Corpus Christ are appreciated. Dr. Magnus Larson and Julie Dean Rosati provided helpful reviews of the first draft of this paper. Permission was granted by Headquarters, USACE, to publish this information.

ABSTRACT

The paper presents results of a study conducted to identify the feasibility of restoring Cedar Bayou Inlet – a natural fish passage in the Texas Coastal Bend – to its historical, open conditions. The study included historical and new field data collection, empirical analysis, and numerical modeling as well as development and analysis of engineering alternatives. Through analysis and modeling, the connection between Cedar Bayou and Vinson Slough (an adjacent 22,000 acre wetland) was found to be a critical element in maintaining both inlets in an open condition. The primary element of the proposed engineering solution is the reconstruction of the historical connection between Vinson Slough and Cedar Bayou by opening the main channel through dredging. In addition, the dredged material is proposed be used beneficially to re-construction a submerged ebb shoal offshore of the mouth of the Cedar Bayou inlet, which promotes sediment bypassing of the inlet mouth and reduces channel sedimentation.

INTRODUCTION

Cedar Bayou is a natural inlet approximately 3 miles in length that provides a connection between the Gulf of Mexico and several bays in the Texas Coastal Bend Bay System, including Mesquite Bay, San Antonio Bay, Aransas Bay, and others. Figure 1 shows the Cedar Bayou vicinity based on a 1995 DOQQ aerial photo.

The Gulf of Mexico shoreline at the Cedar Bayou outlet is oriented from NE (45º) to SW (225º) and is composed of uniform, well sorted medium to fine sand, with a medium grain size diameter of 0.13 to 0.17mm. The bayward (northern) 2 miles of the Bayou are historically stable, with an average width of 590 ft and an average depth of 6.5 ft below Mean Sea Level (MSL). The seaward (southern) 1 mile of the

Bayou is much more dynamic. The widths and depths of this part of the Bayou vary at present from 570 ft to 30 ft wide, and from 8 ft to just inches deep.

Cedar Bayou, when open, provides a life cycle tidal route for biological resources of the Texas Coastal Bend bay system. During the last several decades, due to natural processes and various engineering activities, the flow through Cedar Bayou has diminished to a level that has affected the biological resources of the Texas Coastal Bend Bay system. A study has been initiated by the Texas General Land Office Coastal Erosion Planning and Response Act Program and Save Cedar Bayou, Inc. to determine the feasibility of restoring Cedar Bayou to its historical, open conditions. The study included historical and new field data collection, analysis and numerical modeling, and development and analysis of engineering alternatives for restoration of the Bayou.

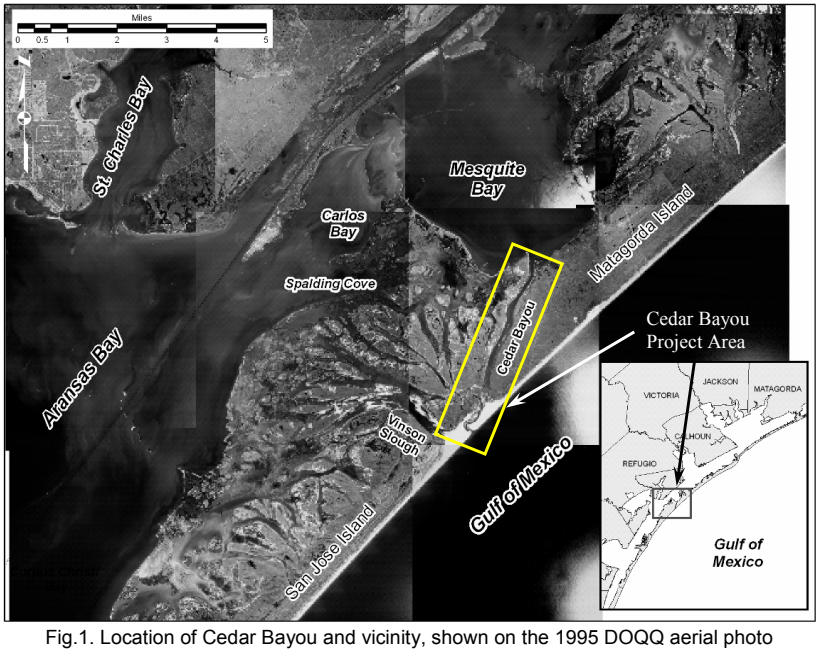

Fig.1. Location of Cedar Bayou and vicinity, shown on the 1995 DOQQ aerial photo

HISTORICAL INLET DYNAMICS

Limited literature exists that discusses the hydraulics of Cedar Bayou; references identified include Lockwood and Andrews (1953) and Simmons and Hoese (1959). This section discusses the inlet dynamics described in the existing literature and through analysis of available historical data.

Throughout the recorded history of Cedar Bayou from the mid 1800's to present time, Cedar Bayou's connection to the Gulf of Mexico has been described as "open" or

"closed". Historical maps as early as 1836 to 1927 show Cedar Bayou to be open, wide, and very shallow (Simmons and Hoese 1959). Figure 2 examines the time history of the opening and closing of Cedar Bayou based on available historical information, along with dredging events and major hurricanes that likely impacted the Bayou. Based on available maps, charts, and photos, Cedar Bayou has also maintained a connection to Vinson Slough, an adjacent 22,000 acre marsh system, and delivers Gulf water to an extensive marsh system and wetlands in Mesquite Bay.

Cedar Bayou has been dredged four times: 1939 (est. 200,000 cy), 1959 (est. 1 million cy), 1987 (est. 300,000 cy), and 1995 (est. 300,000 cy) with varying levels of success in regard to long-term stability of Cedar Bayou. During the most recent dredging in 1995, the dredged material from Cedar Bayou was placed across the mouth of Vinson Slough. The slough has been plugged and no direct connection between Vinson Slough and Cedar Bayou or Vinson Slough and the Gulf of Mexico have existed since.

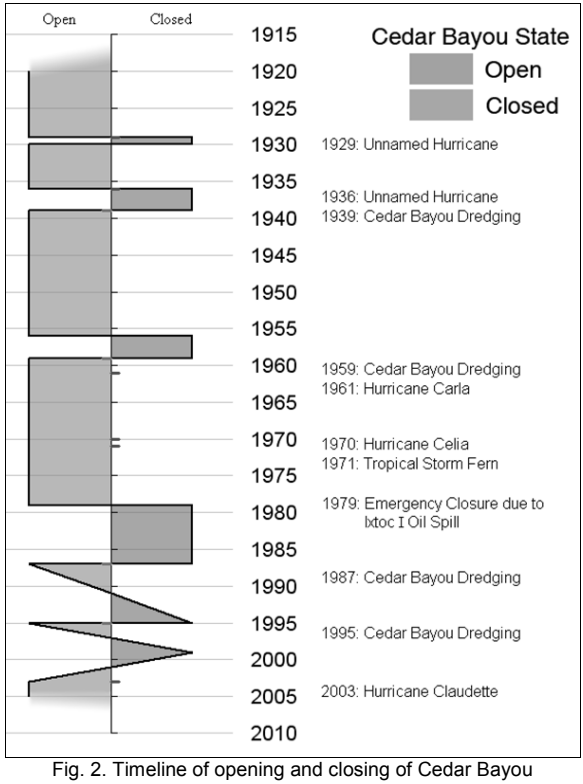

Fig. 2. Timeline of opening and closing of Cedar Bayou

The geomorphology of Cedar Bayou was investigated through a comparison of historical aerial photographs for the period from 1950 to 2003. Figure 3 is an example of the dataset of aerial photographs; it shows six aerial photos of the Cedar Bayou migration zone (the migration zone is the zone through which the Gulf mouth of Cedar Bayou has historically migrated) from 1953, 1973, 1984, 1987, 2001, and 2003. Analysis of photographs revealed that Cedar Bayou migrates from northeast to southwest, with the southwest boundary of migration at Vinson Slough. The Cedar Bayou – Vinson Slough connection typically occurs just upstream from flowing to the Gulf, although the point of connection migrates. Based on a review of aerial photographs, it appears that the Cedar Bayou – Vinson Slough hydraulic system is most stable when there is a substantial connection between the two channels. In addition, the inlet is maintained open for a longer period of time when Cedar Bayou and Vinson Slough are connected with a hydraulic connection with an area on the order of magnitude of the connection between Cedar Bayou and the Gulf of Mexico.

A potential explanation of this phenomenon relies on the hydraulic characteristics of the Cedar Bayou system. When connected to Cedar Bayou, Vinson Slough increases the total volume of flow through Cedar Bayou, which stimulates a higher flow gradient, and respectively, the flow velocities at the mouth of Cedar Bayou. It is likely that disconnecting Cedar Bayou from Vinson Slough (as occurred during the 1987 and 1995 dredging) has resulted in a reduction of the total volumetric flow at the mouth of Cedar Bayou. Consequently, flow velocities have diminished, and the ability of Cedar Bayou to maintain an open condition has decreased.

The ability of Vinson Slough to enhance the flow velocities in Cedar Bayou and increase self-maintaining capability was used as one of the major hypotheses of the project. Based on this hypothesis, the primary component of the engineering solution to restore Cedar Bay was developed to include reconnecting Cedar Bayou and Vinson Slough. Through testing with numerical modeling (as described below), the hypothesis still requires verification with field data because of the project's unique conditions. Therefore, the results of the engineering study and design include a recommendation for monitoring and adaptive management of the project after construction occurs.

The second hypothesis used for the study is that a construction of an ebb shoal offshore of the inlet mouth will promote sediment bypassing and reduce sedimentation in the Cedar Bayou inlet mouth. This hypothesis assisted with development of an engineering solution for disposal of the dredged material. This beneficial use solves the problem of sediment disposal and also adds benefit to the project's performance. The shoal will cause increased wave breaking on its seaward slope, and redirect longshore sediment transport along its seaward side. This would result in the bypassing of longshore sediment transport seaward of the mouth of Cedar Bayou, which would lead to a reduction of the sedimentation effect at Cedar Bayou and increase its longevity. Though not shown on historical hydrographic survey data, the existence of the ebb shoal in front of Cedar Bayou in the past (in the 1960s and 70s) was indicated by local residents and fishermen (Edwards 2006).

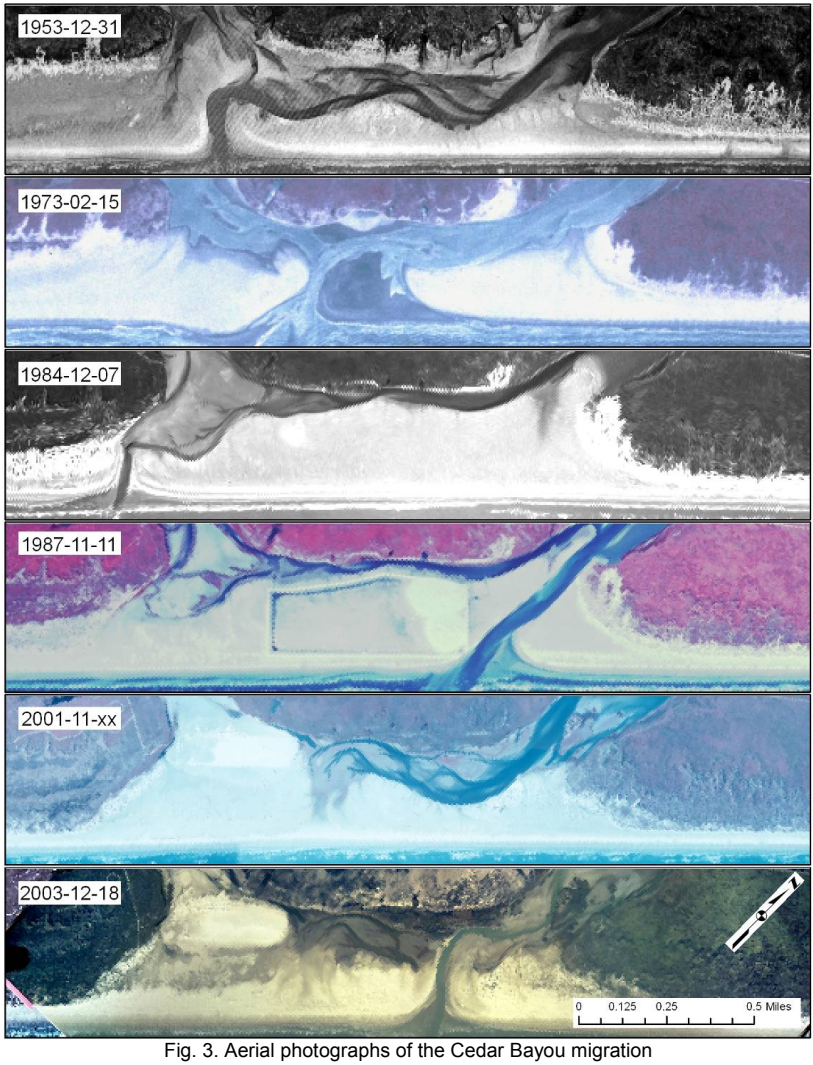

Fig. 3. Aerial photographs of the Cedar Bayou migration zone at the Gulf mouth of Cedar Bayou and Vinson Slough

ALTERNATIVES DEVELOPMENT AND ANALYSIS

The essential components of the Cedar Bayou Restoration Project solution were developed based on the two hypotheses described above. This included beneficial use of dredged material from Cedar Bayou and Vinson Slough for restoration of historical submerged ebb shoal. The restoration of the ebb shoal was proposed by creating a

source of sediment in the littoral zone in anticipation that this sediment will naturally form a submerged shoal in front of Cedar Bayou. The ebb shoal hypothesis was tested and supported through numerical modeling. Further, both of these hypotheses will be verified with field data during the post-construction monitoring program.

A set of various alternatives were developed to restore the Cedar Bayou hydraulic conditions and provide long-term opening of the inlet. These alternatives included various configurations of dredging channels between Cedar Bayou, Vinson Slough, and the Gulf of Mexico in conjunction with restoration of the submerged ebb shoal offshore of the mouth of Cedar Bayou. The most promising alternative, shown in Figure 4, was selected for detailed analysis and engineering. The alternative included dredging a straight Cedar Bayou connection to the Gulf, connection to Vinson Slough, and reconstruction of the submerged ebb shoal with dredged material. The alternative is plotted on the 2004 aerial photograph, and bathymetry is based on 2005 survey data.

Existing (pre-project conditions) are shown in Figure 5 using the same aerial photograph and bathymetric survey data. Note the large mound (red color) on the figure, which depicts the plug in Vinson Slough constructed from dredged material disposal during the 1995 dredging event.

Fig. 4. Layout of the mouth of Cedar Bayou for Alternative 1b, overlaid on the 2004 aerial photo

The evaluation of the proposed solution including testing the hypotheses and engineering design were based on two approaches: hydrodynamic numerical modeling and fitting to morphological analysis criterion. The numerical modeling was conducted to determine the flow discharge through the inlet for existing conditions and for the post-project conditions for various dredging cuts and ebb shoal dimensions. The numerical modeling was fit to the morphologic criterion in order to determine the stability of the inlet and ebb shoal for existing and post-project conditions.

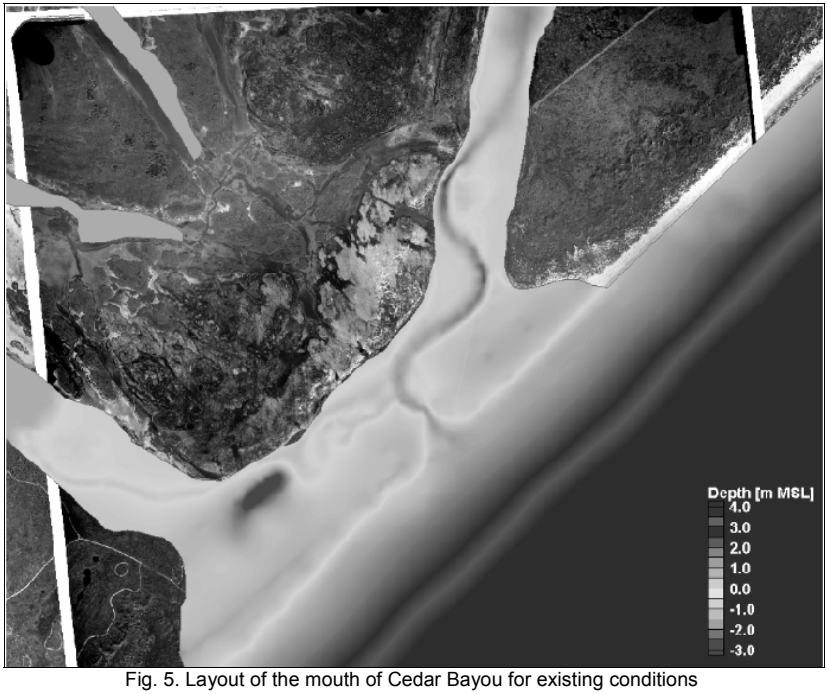

Fig. 5. Layout of the mouth of Cedar Bayou for existing conditions

The numerical modeling included tidal flow circulation and wave transformation modeling. Tidal flow circulation modeling was used to evaluate inlet channel dimensions and effectiveness. Wave modeling was performed to evaluate wave interaction with the inlet mouth. The input parameters were developed for the modeling, tidal range, wind, waves, and modeling grid, and are briefly discussed below.

The tidal range on the Bay side and Gulf side in the Cedar Bayou vicinity was determined by performing a harmonic analysis on the available long-term measuring stations, Bob Hall Pier and Rockport stations (TCOON 2006). The analysis results indicated that the average tidal range on both the Bay side and Gulf side of Cedar

Bayou is approximately 1.5ft. However, during extreme events this tidal range can be as much as 3-3.5ft.

The hindcast deepwater waves from Wave Information Study (WIS) were used for statistical analysis and to develop return periods of deepwater wave heights (WIS, 2006). An example of the extremal return period analysis is shown in Table 1.

Table 1. Extremal analysis of wave heights and corresponding periods for WIS Station 46

Return Period [years]	Significant Wave Height [ft]	Significant Wave Height [m]	Wave Period [sec]
2	14.0	4.3	11.2
5	16.3	5.0	12.3
10	17.5	5.3	13.0
20	18.9	5.8	13.7
50	20.6	6.3	14.6

Tidal flow modeling was performed using the two-dimensional Advanced Circulation Model ADCIRC (Luettich et al. 1992). ADCIRC simulates depth-averaged current velocities and water level fluctuations forced by tidal fluctuations at the boundaries of the modeling domain, and wind inputs over the entire modeling domain. The model domain was constructed extending 100 miles offshore (to the south), approximately 60 miles northeast, and 80 miles to the southwest (far from the project site to avoid boundary effects on the modeling results). The finite element mesh modeling domain is shown in Figure 6 for the entire domain (a) and in the project vicinity (b).

Tidal flow circulation modeling results were used to determine the change of the velocity and flow in Cedar Bayou. Figure 7 shows the velocity vectors at maximum ebb flow for both the existing and post-project (Alternative 1b) conditions. The maximum discharge velocities are increased from about 0.8 m/sec to more than 1.2 m/sec for post-project conditions.

Figure 8 shows the flow discharge across a cross-section in upper Cedar Bayou,near the discharge point from Cedar Bayou into Mesquite Bay. The figure shows the volumetric flow rate over 7 days of modeling with and without project conditions. Results indicate that construction of the project would increase flow by about a factor of 3, and greatly enhance the ebb flow rate through the pass. This increase in ebb flow is critical to the success of the project, as the ebb flow helps flush sediments out of the mouth and maintain a sufficient depth.

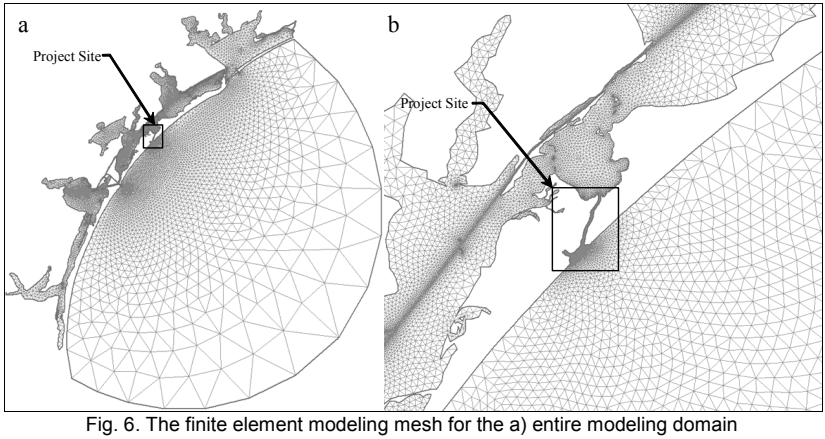

Fig. 6. The finite element modeling mesh for the a) entire modeling domain and b) near the project site

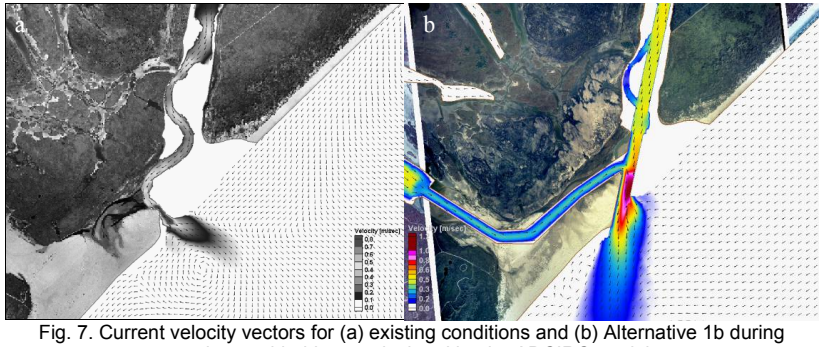

Fig. 7. Current velocity vectors for (a) existing conditions and (b) Alternative 1b during maximum ebb tide as calculated by the ADCIRC model.

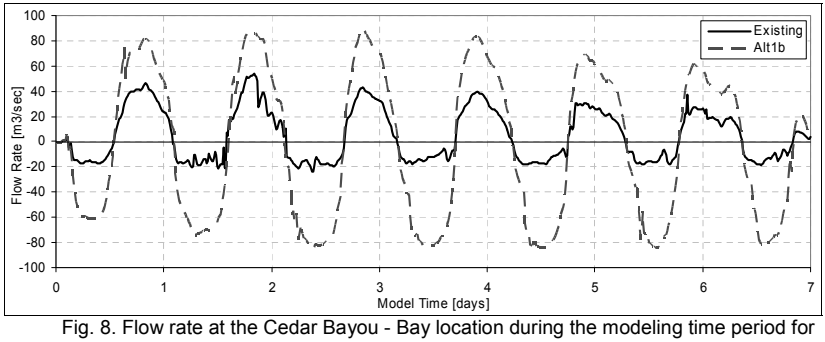

Fig. 8. Flow rate at the Cedar Bayou - Bay location during the modeling time period for the existing conditions and alternative 1b. Positive values are flood flow and negative values are ebb flow.

Wave transformation modeling was conducted to determine the effects from the ebb shoal on wave attenuation in the vicinity of the project. Wave transformation modeling was conducted using the two-dimensional model SWAN (Holthuijsen et al. 1993) and the two-dimensional model Bouss-2D (Nwogu 2001). The results of the wave modeling for a storm event with a 2-year return period showed that the wave heights at the shoreline were reduced 60% to 70% as a result of the ebb shoal construction. Details of the wave modeling analysis of the ebb shoal are available in Coast & Harbor Engineering (2007).

Fitting the project to morphologic criteria included determining inlet stability criterion and balancing the volume of the ebb shoal to the tidal flow rate through the new Cedar Bayou inlet. Final dimensions of the ebb shoal have not been determined at this time; for more details on the shoal dimensions, the reader is directed to Coast & Harbor Engineering (2007).

Fitting the inlet stability criterion was conducted using the Escoffier method. The Escoffier analysis relates tidal basin communication through an inlet to the maximum velocity possible through the inlet for a range of cross-sectional areas (Coastal Engineering Manual 2003). The Escoffier method was calibrated to the Cedar Bayou conditions using the ADCIRC circulation model. The Escoffier method was used to optimize the dimensions of the Cedar Bayou and Vinson Slough dredging cuts. The following is an example of Escoffier application methods to validate the channel dimensions.

An Escoffier curve is shown in Figure 9 for a Cedar Bayou channel dredged to a width of 80 m. The maximum velocity through the inlet was plotted with increasing depth for various inlet widths, along with the equilibrium velocity. The maximum velocity represents the velocity that is expected to occur through the channel for the given bay tidal prism and channel dimensions, while the equilibrium velocity is the velocity required to maintain a stable channel for a given channel area. The intersection of these two curves indicates the channel behavior as the channel dimensions (here, depth) vary. The first point where the maximum velocity and the equilibrium velocity intersect represents the critical unstable depth, and the second intersection represents the stable depth. These two points represent the lower and upper bounds of the depth for a given width of a channel. Based on the two methods - numerical modeling and the Escoffier analysis - the optimal dimensions of Cedar Bayou and Vinson Slough were determined to be:

- Cedar Bayou Channel: 100 m wide and 2.2 m (7 ft) deep
- Vinson Slough Channel: 100m wide and 2 m (6.5 ft) deep
- Mouth: 100 m wide and 2.2 m (7 ft) deep

To verify the hypothesis that the Vinson Slough (VS) connection to Cedar Bayou (CB) is critical for long-term stability of the channel, flow rates were extracted from the tidal circulation model at the inlet mouth, in CB upstream of the CB-VS connection, and in VS upstream of the CB-VS connection. Flow rates were calculated at these cross-sections for the case where CB only is connected to the Gulf

of Mexico, where VS only is connected to the Gulf of Mexico, and where CB and VS were connected together, then connected to the Gulf of Mexico. This allows for the evaluation of the addition of the VS flow to Cedar Bayou.

Results of this analysis are summarized in Figure 10, which shows the total flow rate during a seven day period averaged to the total daily flow rate for ebb and flood flows separately. Flow rates in VS are increased by a factor of 4 when CB is connected to VS. In upper Cedar Bayou, the addition of the connection with VS does not modify the flow rate substantially. However, at the inlet mouth, the addition of VS to CB increases the flow rate into and out of the mouth by nearly 70% - a substantial increase. Therefore, the hypothesis was proven to be correct based on numerical modeling. However, field verification is required to adequately prove or disprove the hypothesis. Therefore, a monitoring program has been built into the Construction phase to verify these results and allow for effective adaptive management.

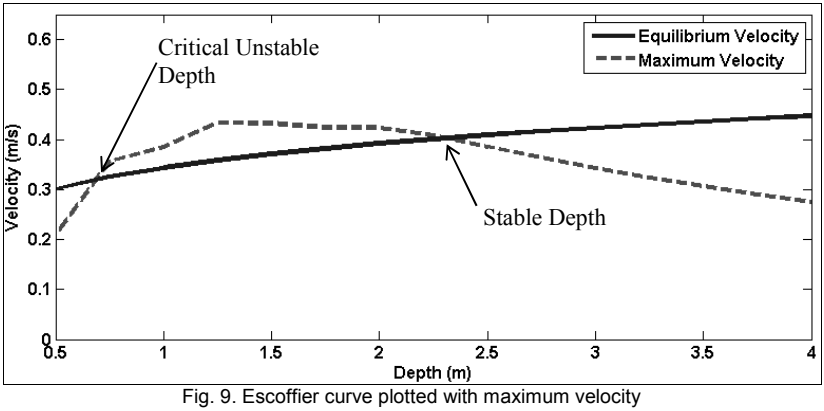

Fig. 9. Escoffier curve plotted with maximum velocity for a channel cross-section width of 80 meters

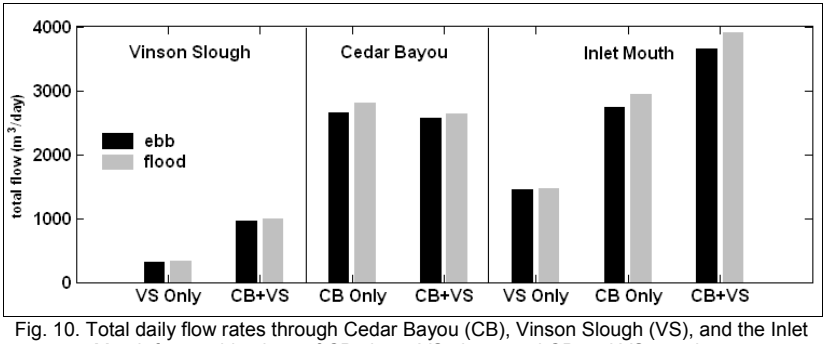

Fig. 10. Total daily flow rates through Cedar Bayou (CB), Vinson Slough (VS), and the Inlet Mouth for combinations of CB alone, VS along, and CB and VS together.

CONCLUSIONS AND RECOMMENDATIONS

Analysis of historical geomorphologic and hydrodynamic conditions at Cedar Bayou was the basis for developing two major hypotheses controlling Cedar Bayou inlet dynamics. These hypotheses are that the additional connection of Vinson Slough to Cedar Bayou is critical to the stability of Cedar Bayou, and that the restoration of an offshore ebb shoal allows for longshore sediment transport to bypass the inlet and therefore reduce the shoaling of the inlet itself. The hypotheses were tested and supported with numerical modeling.

An engineering solution for the restoration of Cedar Bayou was developed, and included deepening the existing Cedar Bayou Channel to the Gulf of Mexico, restoring the historical connection between Cedar Bayou and Vinson Slough, and beneficial use of the dredged material to construct a submerged offshore ebb shoal. Dimensions of the proposed solution were determined with numerical modeling, and were tested by through morphologic criteria including an inlet stability criterion and ebb shoal volume versus inlet flow volume.

The proposed solution was designed and is scheduled for construction in 2007-2008. A detailed monitoring program was recommended for the post-project conditions.

Abstract: This paper describes an ongoing analysis of coastal and inlet processes at the mouth of the Colorado River Navigation Channel, Texas. A weir jetty system with impoundment basin down drift of the weir was constructed at the mouth of the Colorado River in 1985 to reduce the expected rate of dredging of the shallow-draft entrance navigation channel. The required rate of dredging has been about double the design estimate, however, due in part to diversion of the Colorado River away from its entrance to the Gulf of Mexico. A study is underway to better understand the processes involved, design a more efficient entrance, and provide the reduced dredging interval and volume originally desired, while placing the inlet processes within a regional sediment transport framework.

INTRODUCTION

The mouth of the Colorado River (MCR) is located on the Texas Gulf of Mexico coast approximately midway between Galveston and Corpus Christi (Fig. 1). It is a federally authorized shallow-draft navigation channel that experiences relatively weak water exchange between the Gulf of Mexico and East Matagorda Bay, connected through the 10.5-km (6.5 mile) long Colorado River Navigation Channel (CRNC) and the eastward section of the Gulf Intracoastal Waterway (GIWW). The flow system associated with the mouth of the Colorado River is separated from the Colorado River itself and (West)

Matagorda Bay through diversion of the river into the bay in 1992 as an environmental enhancement. Dual rubble mound jetties constructed in 1985 protect the entrance to the CRNC. The west jetty extends 333 m from the shoreline. The east jetty has a 333-m (1,090 ft) long weir section on its landward side with a sediment impoundment basin located westward of the weir. The entrance channel, 5 m deep by 65 m wide (17 ft by 200 ft), connects to the GIWW through a 4-m deep by 33-m wide (15 ft by 100 ft) channel.

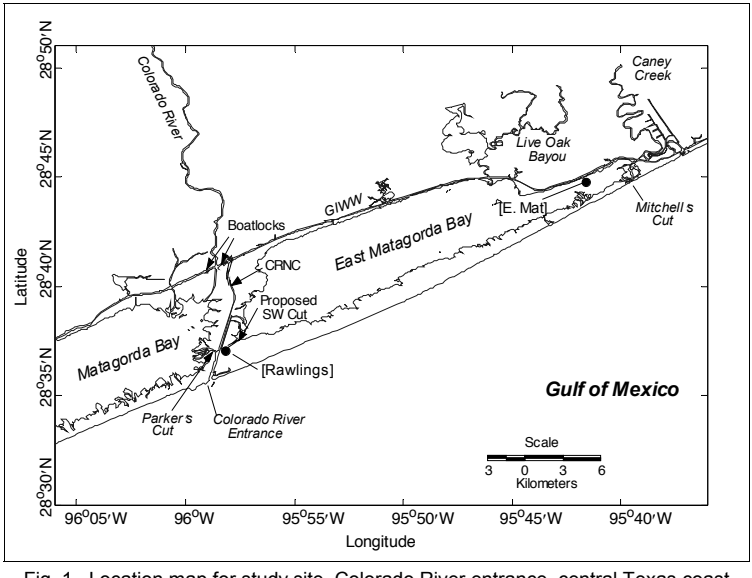

Fig. 1. Location map for study site, Colorado River entrance, central Texas coast

The coastal and inlet processes at the MCR, including circulation, waves, and longshore transport were numerically simulated by Lin et al. (2001). Local-scale modeling of sediment transport of the existing condition has recently been undertaken to analyze potential alternatives to the existing design for enhancing control of sedimentation of the navigation channel. This paper discusses the ongoing study at the MCR, the history, present study efforts, and what might be done in the future.

BACKGROUND

Before 1930, East Matagorda Bay and Matagorda Bay comprised a single Matagorda Bay. The bay was divided in 1935, when a large river delta was formed and moved across the bay after a logjam was freed in the river between 1925 and 1929 (US Army Corps of Engineers (USACE) 1992). The Colorado River began discharging into the Gulf of Mexico in 1935. Dual rubble mound jetties were constructed in 1985 to protect the entrance to the CRNC. Several designs to modify the entrance channel were considered, with the weir jetty and impoundment basin design being judged the most cost

effective for construction and subsequent dredging and bypassing of the sand dredged from the deposition basin and channel. At the time of design (in the 1960s), review (1970s), and construction (1980s), the Colorado River discharged to the Gulf of Mexico. The overall hydraulic system of the MCR is complex because of tide and wind forcing, connection of the CRNC to East Matagorda Bay, possibility of opening the SW Corner Cut to East Matagorda Bay (Kraus and Militello 1999), and possibility of opening the presently closed Parkers Cut to Matagorda Bay (Fig. 1).

Fig. 2. Entrance of Colorado River Navigation Channel, TX

As originally designed, the sediment impoundment basin was located between the weir section and the entrance channel (Fig. 2). The impoundment basin accommodated sand bypassing to the down-drift beaches by means of a pipeline dredge, with discharge in the surf zone on the west side of the MCR. The basin was designed to hold a 2-year supply of sediment estimated at 460,000 m^3 (600,000 cy) (USACE 1977). The jetties had to be placed at relatively large distance from each other to accommodate the deposition basin. The distance between the gulfward ends of the jetties is approximately 400 m (1,300 ft).

The Colorado River was rerouted in 1992 to discharge into Matagorda Bay through a diversion channel as part of an environmental enhancement project. A pair of locks was added to the GIWW at the junction of the Colorado River to mitigate the cross current at

the intersection of the river and GIWW. As a result, the Colorado River was diverted into Matagorda Bay, eliminating the river discharge as a means of scouring sediment from the entrance channel to the Gulf. The CRNC was thereby separated from the main river, but it is connected to the eastward section of the GIWW.

Initial dredging of the impoundment basin was completed in 1990. Since then, the basin has filled more rapidly than designed. The entrance mouth has experienced excessive sediment shoaling, and spits form on both the east and west sides of the landward ends of the jetties, encroaching on the navigation channel. Figure 3 plots volume of sediment dredged in the basin and CRNC from 1990 to 2002 and indicates that the total volume of dredging annually is about 425,000 m^3 (556,000 cy), approximately double the design estimate (in part due to contributions from the northern CRNC bottom and GIWW).

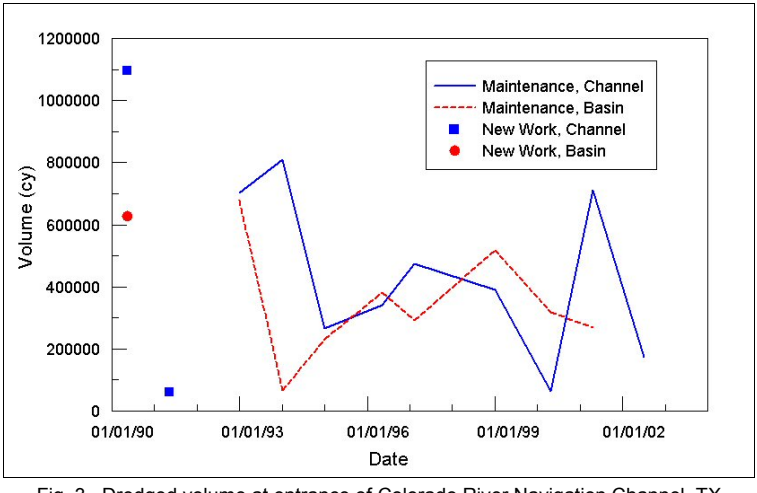

Fig. 3. Dredged volume at entrance of Colorado River Navigation Channel, TX

A 152-m (500 ft) long rock dike was constructed in September 2003 to function as a training structure for the deposition and reduce dredging requirements, as recommended by Kraus et al. (2003). Considered to be economically justified if it eliminated the need for one dredging cycle at annual frequency, it eliminated the need for almost two dredging cycles before being overwhelmed by wind-blow sand transport and swash-zone transport that occurred landward of the deposition basin during times of high water in the Gulf of Mexico. The sediment training structure was constructed shortly before the USACE was required to lower priority of maintaining shallow-draft channels, thereby greatly reducing dredging at the MCR. The beach accreted past the seaward end of the sediment training structure, and it is now almost buried (Fig. 4). Plans to raise the structure an additional 1.2 m (4 ft) to intercept wind-blown sand and swash-zone transport, as well as other incremental measures such as raising the weir jetty, have been considered (Kraus et al. 2003; Lin et al. 2003).

Fig. 4. Sediment training structure south, present west jetty in upper left corner, 6 Aug 06

COASTAL AND INLET PROCESSES EVALUATION

The tide on the central Texas coast is mixed, but mainly diurnal, having a period of approximately one tidal day (24.84 hr). The National Ocean Service (NOS) maintains a long-term tidal station at the Galveston Pleasure Pier, TX. The diurnal tide range calculated from the record for the 5-year period 1990-1994 was 0.65 m. Strong wind along the Texas coast can often dominate the water level in the river, and seasonal lows in water level in the Gulf of Mexico can be a concern for navigation (see Kraus 2007).

Nearshore wave data are available from gauges that were deployed at the 10-m depth contour 3.2 km offshore of the MCR, located 65 km south of the San Bernard River (King and Prickett 1998). The mean significant wave height was 0.6 m and the mean peak period was 5.9 sec over a 17-month period of data collected in 1991-1993. This dataset tends to under-represent the wave conditions during winter months. These waves can generate a strong nearshore current to transport the littoral sediment into the impoundment basin or along the shore in the swash zone to the entrance channel.

Samples taken in the entrance channel and impoundment basin between February 1994 and September 1995 indicate that sediments are primarily sand in the entrance channel, with some silt and clay in the basin. The sediment in the entrance channel has a median grain size of 0.12 mm and silt and clay fractions of 35 percent at some locations. The sediment in the impoundment basin has a mean grain size of 0.03 mm and contains 87 percent silt and clay fractions (Lin et al. 2003). Sediment samples taken in the CRNC show mean grain size of 0.04 mm and contained 60 to 80 percent silt and clay. The fine materials in the basin and CRNC, silt- and clay-sized particles, are consistent with the sediment found in the GIWW and from the river. The samples suggest that riverine sediments are reaching the MCR and likely settling into the impoundment basin.

Both the peak ebb and flood currents are weak, as indicate by data collected in January-February 2002 at Channel Maker 4 of the CRNC. The ebb-tidal current dominates the flow in the CRNC. The mean velocity was 0.013 m/sec (0.042 ft/sec) ebb dominant, and the average maximum current was 0.38 m/sec (1.25 ft/sec) at the throat of the entrance

channel, in a primarily tidal condition (weak wind). The mean velocity and the average maximum current become slightly greater, equal to 0.057 (0.19 ft/sec) and 0.40 m/sec (1.30 ft/sec), respectively, in a combined tide and strong wind condition. Because of weak tidal flow and the active littoral process in the nearshore, there is no appreciable ebb tidal shoal at the MCR.

Longshore Transport

The MCR General Design Memorandum (USACE 1977) estimated a net longshore transport rate of 229,000 m^3/year (300,000 cy/year) to the west and negligible transport to the east, based in part on observed impoundment at the Matagorda Ship Channel east jetty located to the 40 km (25 miles) southwest of the MCR. Heilman and Edge (1996) discussed sediment pathways and compiled estimates of longshore sediment transport on the Gulf of Mexico coast at the mouth of the Colorado River obtained from several sources and by different means of measurement or inference. They concluded that an average annual amount of 230,000 m^3 (301,000 cy/year) is necessary for sediment bypassing to the west beach at the entrance. King and Prickett (1998) estimated the net rate of transport at MCR to be 510,000 m^3/year (668,000 cy/year) to the west, with a gross rate of 670,000 m^3/year (877,000 cy/year), based on the SPM (1984) CERC equation and intermittent wave measurements at the 10-m contour at the site. These estimates (with K=0.35 for significant wave height) are greater than the average annual volume removal of 425,000 m^3, and so are questionable or can be considered an extreme upper limit.

Dredging volumes analyzed here for the 12-year interval 1990 to 2002 indicate the average annual volume removal was 425,000 m^3/year (556,000 cy/year). Of this amount, about 280,000 m^3/year (367,000 cy/year) is estimated to originate from longshore transport, in approximate agreement with the conclusion of Heilman and Edge (1996), and the remainder, 145,000 m^3/year (189,000 cy/year), is supplied by the river and GIWW as finer grained sediment. In the present study, transport rates were estimated with K=0.27 to achieve best agreement with the dredging data and shoreline position data interpreted by GIS analysis from rectified aerial photographs. These calculations gave a net transport rate of 212,000 m^3/year (278,000 cy/year) to the west was with a gross rate of 414,000 m^3/year (542,000 cy/year).

Regional Modeling

Tidal circulation, including influence of wind, at the MCR was examined with a finite-element circulation model ADCIRC (Lin et al. 2001). The model grid (Fig. 5) encompasses the MCR, East Matagorda Bay, Matagorda Bay, and surrounding GIWW based on the work of Kraus and Militello (1999). This grid was constructed as a regional model for the Texas regional coastal modeling study (Brown et al. 2003). The results of such modeling efforts have been used in the present study to force a local model of the circulation (current and water surface elevation) and sediment transport at the MCR, performed at high resolution.

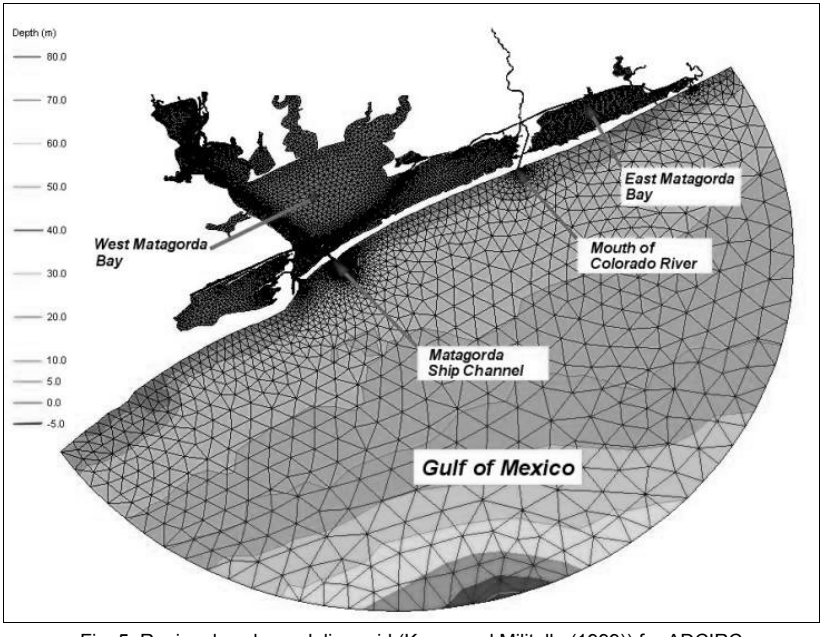

Fig. 5. Regional scale modeling grid (Kraus and Militello (1999)) for ADCIRC

Local-Scale Inlet Processes Modeling

For local-scale circulation modeling, M2D (Militello et al. 2004) was applied with wave forcing from WABED (Lin et al. 2006) to calculate tide, wind, river, and wave-forced currents and water level at the study site. Figure 6 shows the M2D and WABED grid coverage. The circulation and transport models are being run to evaluate the existing condition and construction of a new east jetty located approximately 153 m (500 ft) from the west jetty. Table 1 lists the alternatives being considered, as evaluated with this inlet-processes numerically modeling technology.

Table 1. Alternatives under Evaluation for Improvement of MCR

Alt	Description
-0-	Existing condition
1	150-ft channel with new jetty
2	200-ft channel with new jetty
3	150-ft channel with new jetty, open SW Cut
4	200-ft channel with new jetty, open SW Cut
5	150-ft channel with new jetty, open Parkers Cut
6	200-ft channel with new jetty, open Parkers Cut

This modeling technology and results are the culmination of several studies of the MCR as referenced in this paper. A new east jetty without weir that would be located approximately 153 m center to center from the existing west jetty will provide a much reduced channel width to depth ratio than the existing condition and, therefore, a more hydraulically efficient channel.

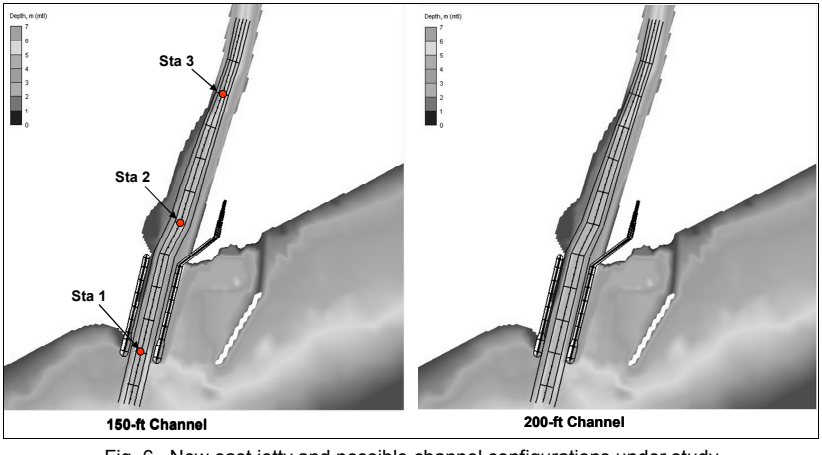

Fig. 6. New east jetty and possible channel configurations under study

Figures 7 and 8 show the calculated currents with the proposed new east jetty in place at maximum ebb (and including wind forcing and wave-induced current) for the situations without and with the presence of the SW Corner Cut. The current in the navigation channel can achieve almost double that measured and calculated for the existing condition, with the wind-dominated current in the SW Corner Cut (especially during winter) (Kraus and Militello 1999) increasing the ebb current hence scouring action at the entrance.

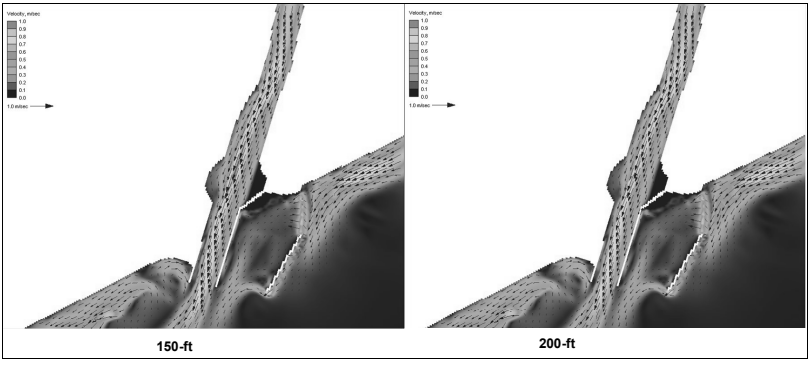

Fig. 8. Calculated maximum ebb tide, wave and wind forcing included, SW Corner Cut open

Shoreline Response to New East Jetty

The shoreline change rate was modeled to determine the existing condition and to predict the effect of proposed changes to the inlet. GENESIS (Hanson and Kraus 1989) was applied with WIS wave hindcast information (Tracy 2004), which gives hourly information on wave height, period, and direction. Based on model calibration using historical shoreline change and maintenance dredging records, a sediment transport factor of $K = 0.27$ in the CERC formula was determined. For the case without sand bypassing, the model predicts significant erosion on the western side of the jetties and accretion on the east side. Figures 9 and 10 plot the predicted shoreline change on the east and west sides of the jetties respectively after simulations from 5 to 20 years.

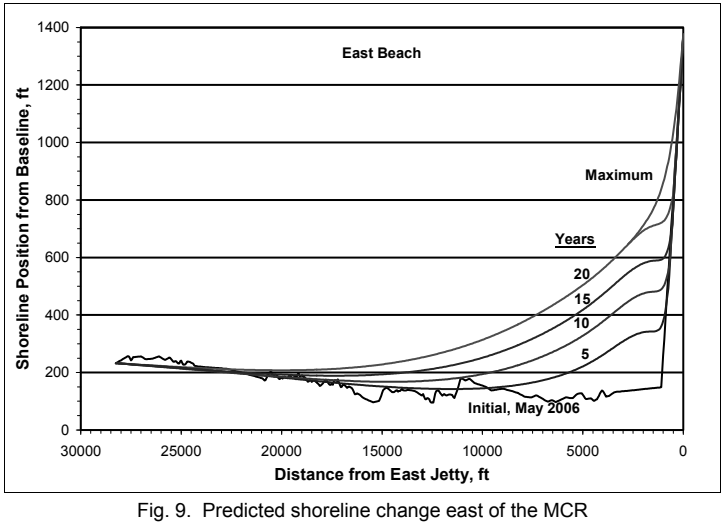

Fig. 9. Predicted shoreline change east of the MCR

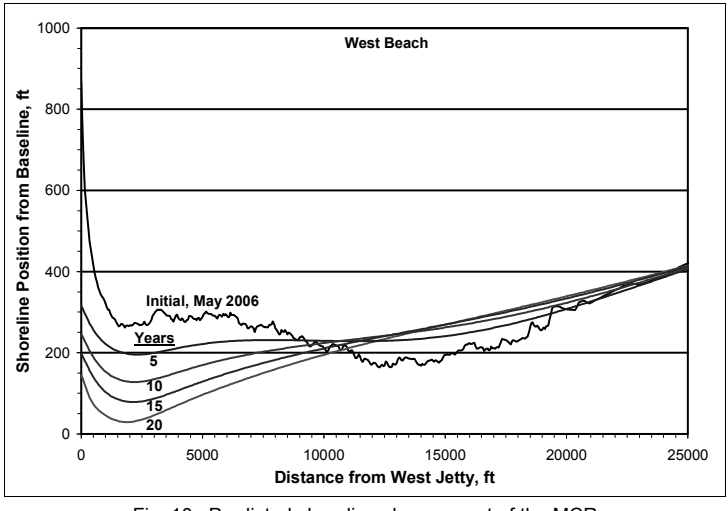

Fig. 10. Predicted shoreline change west of the MCR

Shoreline change also was also simulated including mechanical bypassing (dredging) of the up-drift accretion fillet at the east jetty. A volume of 306,000 m^3 (400,000 cy) was bypassed every 2 years and placed on the down-drift beach. Figure 11 indicates that bypassing is essential to maintain the beach to the west, continuing Galveston District practice, and not allowing a large fillet to form on the east, which would more readily allow littoral material to shoal in the entrance channel from the east beach.

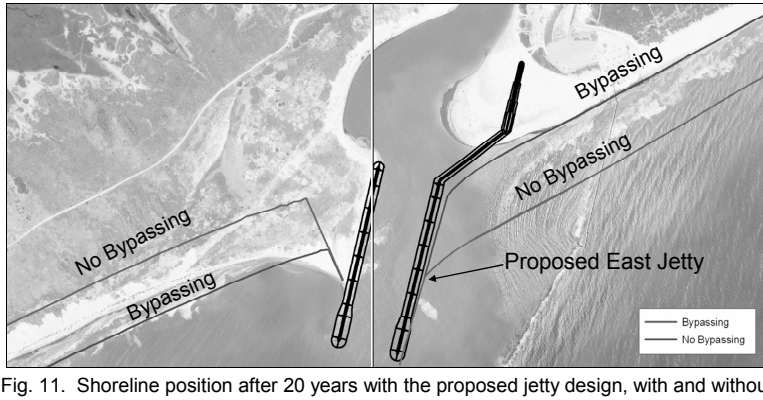

Fig. 11. Shoreline position after 20 years with the proposed jetty design, with and without sediment bypassing from up-drift to down-drift beaches (photograph May 2006)

Review of New East Jetty Concept

Inlet process modeling and shoreline change and sediment transport simulations indicate that the most feasible option for decreasing maintenance dredging requirements is construction of a new east jetty. The new east jetty would be similar to the existing west jetty. The primary difference in design is the proposed crest elevation of the landward section of the new jetty. Elevating the landward section of the jetty would reduce sediment infilling of the navigation channel due to wind-blown transport, swash zone transport, and washover during storms. Observation of the sediment training structure (Fig. 4) reveals the extent to which transport over the dry beach can occur.

The local-scale circulation and transport models are being applied to compare various designs for the new jetty and navigation channel. They indicate where and to what extent erosion and accretion are likely to occur. Shoreline change modeling indicates it essential that bypassing of sediment around the entrance be continued.

Lessons Learned at Other Jetties on the Texas Coast

Jetty design and construction technique can reduce initial construction cost of the proposed east jetty and reduce channel maintenance cost as well. There are nine jettied inlets on the Texas Gulf Coast, the earliest of which were constructed in the late 19th century. A review of these jetties by Sargent and Bottin (1989) provides insight on potential construction pitfalls to avoid in consideration of possible jetty modification or construction at the MCR. Most of the jetties were constructed with block-shaped granite cover stone. The shape of the cover stone increases hydraulic stability, but it makes placement difficult for side slopes steeper than about 3H:1V, especially in shallow water, therefore increasing construction cost for steep sides.

For land-based construction, jetty crest width should be at least 4.7 m (16 ft) to provide adequate room for maneuvering and operation of construction equipment. Although narrower cross sections are possible, they generally increase construction time and cost. Another consideration for land-based construction is the scour hole that tends to form as the jetty construction progresses offshore. The scour hole migrates with the end of the jetty as it is built seaward. Bedding stone is used to fill the scour hole, often resulting in rock overruns and increasing cost. A potential method to reduce such overruns is to use stone filled mattresses (Hughes 2006) instead of loose bedding stone. Finally, providing adequate elevation on the landward side of the jetty will reduce or eliminate bypassing of its landward side by wind-blown and swash zone sediment transport.

CONCLUDING DISCUSSION

A long-term plan for reducing maintenance dredging cost and increasing navigation channel reliability at the MCR is under development. The study entails examination of inlet processes and coastal processes, and modification of existing and construction of new structures. Numerical analysis has shown that a new east jetty without a weir and located closer to the original west jetty than the existing design should reduce the dredging interval by increasing channel hydraulic efficiency. A long-term bypassing plan

will ensure that the MCR navigation project will not cause erosion of the down-drift beach.

Abstract: Matagorda Bay, Texas, is connected to the Gulf of Mexico by two inlets, Pass Cavallo and the Matagorda Ship Channel (MSC). Pass Cavallo is a natural inlet located at the southwest terminus of Matagorda Peninsula, and the MSC is an artificially cut, deep-draft federally maintained navigation channel approximately 7.2 km northeast. Pass Cavallo was historically stable until the 20th century, when the tidal prism was first reduced in 1935 by division of Matagorda Bay due to deltaic progradation of the Colorado River, and later in 1966 as a result of the construction of the Matagorda Ship Channel. In response to these reductions in tidal prism, the entrance width at Pass Cavallo reached historical minimums as Matagorda Peninsula and Matagorda Island prograded into the inlet. Long-term stability and potential of possible closure of Pass Cavallo are evaluated through theoretical and empirical relationships, and long-term analysis of morphologic change.

INTRODUCTION

Pass Cavallo, located on the south-central Texas coast (Figure 1), is the natural, permanent inlet between Matagorda Bay and the Gulf of Mexico. The inlet has existed for at least 2,600 years, being in approximately the same location for the past 200 years (Harwood 1973). The tidal prism through Pass Cavallo has been decreasing over the last century in response to natural processes and anthropogenic activities.

The first cause of this decrease was separation of the historic Matagorda Bay into East Matagorda Bay and the present Matagorda Bay, by growth of the Colorado River Delta across the bay from 1929 to 1935 (Wadsworth 1966; Bouma and Bryant 1969). This initial decrease in tidal prism resulted in shoaling (Harwood 1973) and difficulty in maintaining the commercial navigation channel through the inlet. These issues led to the construction of the Matagorda Ship Channel (MSC), the second and more dominant reason for decrease in the tidal prism at Pass Cavallo. The MSC entrance was cut through Matagorda Peninsula in 1963 approximately 5.5 km updrift of Pass Cavallo at that time. Construction of the jetties and dredging of the inner channel were completed in 1966 (U.S. Army Corps of Engineers (USACE1992)).

The deep-draft MSC enters the bay 7.2 km (as of December 2006) to the north of Pass Cavallo and is a more efficient tidal channel by joining with a deeper and more central portion of the bay. Due to this, the MSC has captured much of the tidal prism forming flowing through Pass Cavallo, resulting in a decrease in inlet width over the last half-century. Figure 2 shows the configuration of the inlet at the time of the opening of the MSC in 1965 and in December 2006.

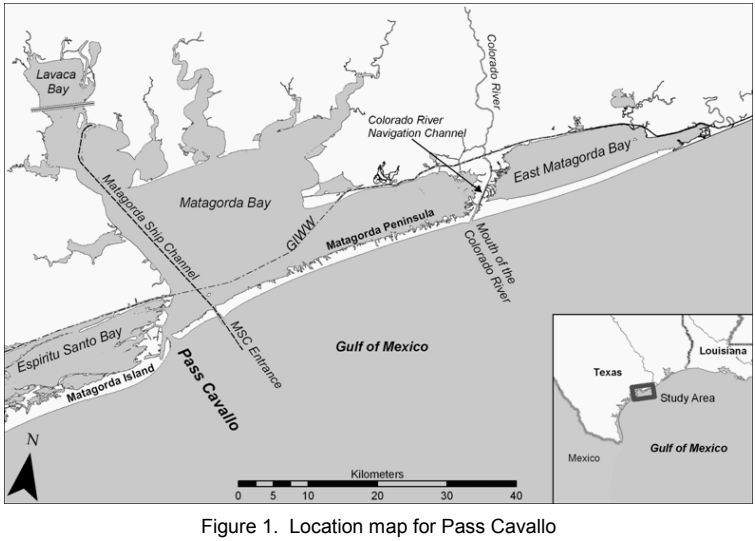

Figure 1. Location map for Pass Cavallo

Previous studies have not been unanimous about the long-term stability of Pass Cavallo. Ward (1982) concluded that the inlet was "shoal unstable," and van de Kreeke (1985) stated that Pass Cavallo would ultimately close because of the presence of the MSC entrance. Van de Kreeke (1990a, 1990b) concluded that multiple inlets to the same bay system cannot exist and that, eventually, at most one would remain. On the other hand, Price (1952) noted that northerly wind fronts, common along the Texas coast from October through May, force water into the southwest corners of Texas bays, promoting

existence and stability of channels in those corners (See Kraus 2007, this volume). Wind setup of water against the southwest shore of Matagorda Bay produces an ebb discharge (wind tide) that adds to that of the astronomical tide. Price (1952) also found that Texas bays from Matagorda Bay and to the south tend to have one inlet per bay, located in the southwest or southeast corners. Harwood (1973) concluded that Pass Cavallo would remain open based on geomorphic analysis and consideration of wind tides.

Therefore, there is uncertainty and concern that the existing MSC and possible enlargement of its entrance being considered might accelerate closure of Pass Cavallo. If Pass Cavallo were to close, the discharge at the MSC entrance would become greater, promoting scour and potentially compromising navigation reliability. The natural water exchange and path through Pass Cavallo for organisms and nutrients would also be lost.

This study proceeded by conducting four separate activities as (a) a tidal inlet morphologic analysis based on existing predictive equations, (b) survey of the entrance to Pass Cavallo, (c) numerical modeling of hydrodynamics, and (d) an analysis of inlet width and spit growth shoreline change.

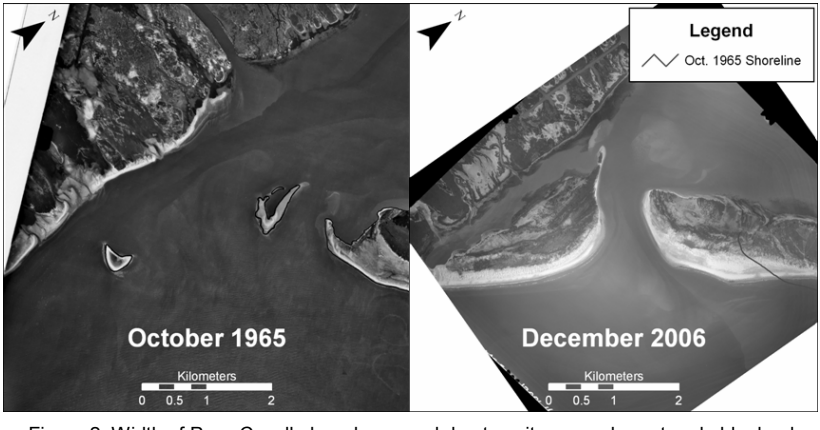

Figure 2. Width of Pass Cavallo has decreased due to spit encroachment and ebb shoal collapse since construction of the MSC.

ANALYSIS AND RESULTS

Empirical evaluation of inlet cross-sectional stability

It is empirically known that a stable inlet located on a sandy coast will have a mean-maximum velocity through it of approximately 1 m/sec (Escoffier 1940; Bruun 1968). By "mean-maximum velocity" is meant the average of a regularly occurring maximum velocity, such as would be generated during spring tide. The mean-maximum velocity V_{mm} can be obtained as:

$$V_{mm} = \frac{\pi}{CT} \quad (1)$$

where T is tidal period, and $C = 6.6 \times 10^{-5}$ is an empirical coefficient with units m^{-1}. For a semidiurnal inlet, T = 12 hr, 25 min = 44,712 sec. Then, Eq. 1 yields V_{mm} = 1.06 m/sec, in agreement with empirical observations for, at least, many semi-diurnal inlets. For a tide that is predominantly diurnal, the tidal period is 89,424 sec, giving V_{mm} = 0.53 m/sec (Kraus 2007). There are relatively few inlets worldwide in a diurnal tidal setting, making empirical validation of this result difficult.

The conclusion is that an inlet in a diurnal tidal setting may require a smaller mean-maximum tidal velocity to maintain channel cross-sectional area stability as compared to inlets in a semi-diurnal setting, the more common type of inlet. For Pass Cavallo, this smaller required value of V_{mm} by astronomical forcing may be an overestimate, because the contribution to the ebb discharge by wind setup in the bay was neglected. A smaller value of V_{mm} works in favor of the preservation of Pass Cavallo.

Tidal Prism

Harwood (1973) and Ward (1982) examined tidal prism at Pass Cavallo over the last century. Figure 3 plots data compiled from those two sources as well as a point for year 2004, in addition to data for a possible deepening and widening of the MSC, based on calculations with the ADCIRC model reported in Kraus et al. (2006). Harwood (1973) studied the Pass Cavallo flood shoal and computed the tidal prism through estimation of effective bay surface area, including a portion of Espiritu Santo Bay, multiplied by the estimated tidal range. Ward (1982) estimated tidal prisms based on measurements of the current and bathymetry in 1959 (prior to opening of the MSC) and in the 1970s. He found that, by the mid-1970s, the tidal prism at Pass Cavallo had decreased by half, similar to results of Harwood (1973).

In addition, Ward (1982) reports maximum values of the current ("during the race of tide") through Pass Cavallo to be on order of 1 m/sec in 1959 and of half that value in the 1970s. Ward (1982) notes that the tidal prisms for Pass Cavallo and the MSC in the 1970s were approximately the same, as can be seen in Figure 3. Our calculation for 2004, based on a calibrated two-dimensional model (Kraus et al. 2006), indicates that the present tidal prism at the MSC is approximately three times that at Pass Cavallo. The tidal prisms for Pass Cavallo and the MSC are large and comparable to the larger Pacific coast inlets, because the surface area of Texas bays is typically several times larger than the Pacific coast inlets, compensating for the relatively small tidal range as compared to the Pacific coast.

A bathymetric survey (Figure 4) was conducted by Frontier Surveying, Inc., Corpus Christi, TX, for the present study to determine the minimum cross-sectional area of Pass Cavallo. Depth across eight transects is shown in Figure 5. Maximum depth in the channel reaches 9 m MSL, and the cross-sectional area, calculated by integrating the curves to MSL, ranged from 3,470 m^2 along Transect 1 to a minimum of 2,060 m^2 along Transect 8. The latter transect was the limit of being able to navigate the survey boat abeam to incident waves in

the Gulf of Mexico that day. Transects 5-8 were interrupted to the south by a large shoal that approaches the channel from Matagorda Island.

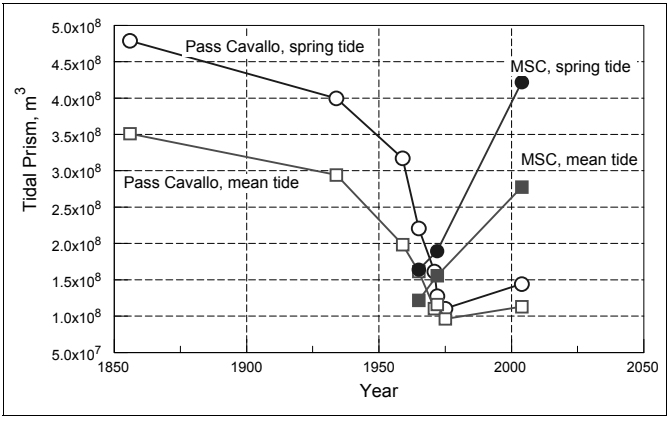

Figure 3. Estimated tidal prisms for Pass Cavallo and the MSC. Lines indicate trends and are not to be interpreted as representing intermediate values.

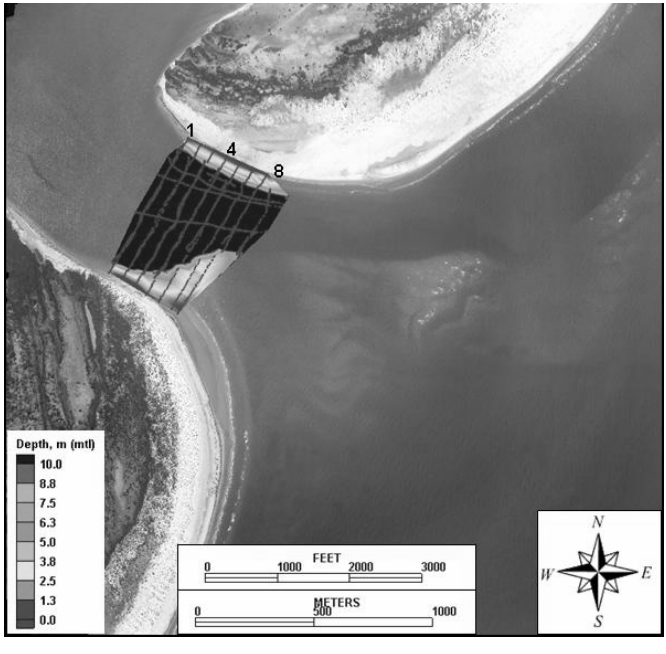

Figure 4. Pass Cavallo cross-sectional survey area of 23 May 2006, superimposed on photograph of 16 May 2006.

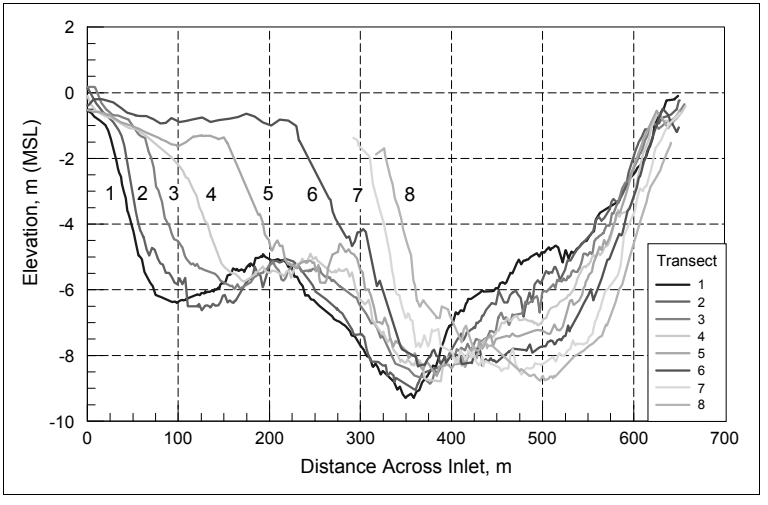

Figure 5. Surveys along eight transects in Pass Cavallo, 23 May 2006. Transect locations are numbered from 1 to 8, starting in Matagorda Bay and progressing seaward.

Accepted empirical relations are available that relate minimum inlet channel cross-sectional area below MSL for a stable inlet and tidal prism. Nishi et al. (2007) have shown that such considerations hold for tidal inlets world wide. Data compiled from six countries were consistent with the relation $A_C = 1.75\times10^{-04} P^{0.952}$ (A_C in m^2, P in m^3), which may be considered a global relation that can be applied if no data are available for a given inlet.

Jarrett (1976) analyzed 108 inlets (yielding 162 data points) along the Atlantic Ocean, Gulf of Mexico, and Pacific Ocean coasts of the United States. His objectives were to determine if inlets on the three coasts follow the same inlet cross-sectional area – tidal prism relation, and if inlet stabilization altered that relation. With relatively high correlation coefficients, all predictive relations were found to fit the form:

$$A_C = C P^n \tag{2}$$

in which C (similar to that in Eq. 1) and n are empirically determined. Jarrett (1976) found the exponent n to vary between 0.86 and 1.10 for inlets with no jetty or with a single jetty and between 0.85 and 0.95 for inlets with two jetties. .

For analysis of the stability of Pass Cavallo, the Jarrett (1976) relation describing unjettied and single inlets for the Gulf Coast, developed from 30 data points, was selected as most appropriate. This relation is $A_C = 6.992\times10^{-04} P^{0.86}$ (units of meters). With the 2004 value of tidal prism (1.44×10^8 m^3) from Figure 3, the result is A_C = 7,300 m^2. This predicted value of A_C is two to three times larger than those measured

from the recent channel cross-sections. This result indicates that Pass Cavallo is presently experiencing a surplus of sediment, and possible sources for this surplus are identified and discussed below.

Morphology change analysis

Aerial photographs were available for this study in both digital and 9' x 9' print format, sourced primarily from USACE archives. Print photographs were scanned on an UMAX 2100XL flatbed scanner at a resolution of 600 dpi and saved in tif format. Selected photographs were then rectified to 1995 1-m resolution digital orthophoto quarter quadrangles (DOQQ) available from the Texas Natural Resources Information System (TNRIS 1995). This photoset provided a high-accuracy (National Map Accuracy Standards, see Anders and Byrnes 1991), high-resolution (1 m pixel) base for rectification.

Few high-quality control points were available in the study area; therefore, control points were improvised from geomorphologic features and vegetation. Rectification quality was evaluated by the goodness-of-fit of the output image to the TNRIS DOQQs. Uncertainty of ground positions from the rectified imagery is estimated at 6-18 m. Images having apparent gross positioning errors were excluded from the study. Shorelines were digitized in the ArcGIS environment from the aerial base using standard techniques (Kraus et al. 2006). The study shoreline was identified as high-water line as defined by National Oceanographic and Atmospheric Administration (2000) and Leatherman (2003). Additional vector shorelines were retrieved from the National Ocean Service (NOS 2005), Texas Bureau of Economic Geology (BEG 2004), and the United States Geologic Survey (USGS) (Morton et al. 2004). In total, 28 shorelines were available from 28 unique dates between 1856 and 2006.

Spit growth was evaluated by establishing two baselines fronting the Gulf of Mexico shorelines of Matagorda Peninsula and Matagorda Island. For Matagorda Peninsula, the baseline originated at the west jetty of Matagorda Ship Channel. The origin of the Matagorda Island baseline was placed at the observed origin of the Matagorda Island spit. Spit growth along each baseline was measured in ArcView 3.2 using BeachTools (Hoeke et al. 2001). Analysis transects were generated along the baseline at 3-m intervals, and the distance of the last transect to intersect the spit shoreline was recorded.

The width of Pass Cavallo was measured from the limited shoreline data that extended into the channel from both sides of the inlet. Inlet width was evaluated in ArcMap from the westernmost extent of Matagorda Peninsula to the easternmost extent of Matagorda Island. Each measurement was recorded along a reference line aligned to the axial orientation of Matagorda Peninsula. This line was positioned at the narrowest section of Pass Cavallo, and then the distance across the inlet was recorded.

Inlet width and Spit Growth

Analysis of available shoreline data showed that the evolution of Pass Cavallo can be generalized into three eras of morphologic behavior (Figures 6 and 7): (1) relative

stability prior to 1963, (2) instability and rapid closure from 1963 to the mid-1980s, and (3) relative stability subsequent to 1990.

The initial decrease of tidal prism at Pass Cavallo due to subdivision of Matagorda Bay by the Colorado River caused significant shoaling within the inlet and a navigation concern (Harwood 1973; USACE 1992). Despite this, island morphology was stable, and minimal spit growth is observed during this time. Pass Cavallo maintained a width greater than 3 km between 1856 and 1965. Shoreline change during these years typically shows one or more (inter- or supra-tidal) islands in or around the entrance. The only emergent feature was a small island (called Pelican Island) between Matagorda Peninsula and Island, which first appeared in 1952. Hurricane Carla made landfall at Pass Cavallo in 1961 with an estimated maximum surge elevation of 3.7 m. Extreme conditions associated with this hurricane created 32 washovers along Matagorda Peninsula (Morton et al. 1976) and presumably forced sediment out of Pass Cavallo to create the maximum width of 3.5 km observed in 1965. Overall, Matagorda Peninsula receded approximately 90 m during Era I, while Matagorda Island remained unchanged.

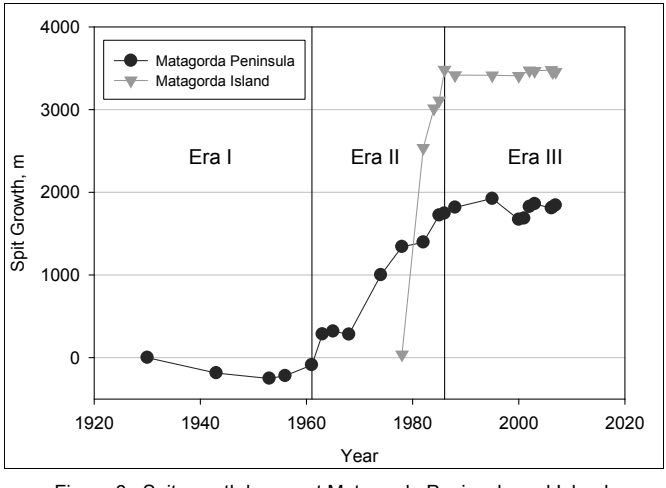

Figure 6. Spit growth by era at Matagorda Peninsula and Island.

The additional loss of tidal prism through Pass Cavallo due to the opening of the MSC (completed in 1966) resulted in significant morphologic change at the inlet, ushering in Era II. This timeframe is characterized by southwestward growth of Matagorda Peninsula that occurred in a rapid, step-wise fashion. Periods of rapid growth are followed by retarded growth and relative inactivity. Net progradation of Matagorda Peninsula between 1963 and 1988 was 1.53 km. In conjunction with this rapid growth on the east side of the inlet, a spit emerged from Matagorda Island in 1978 and rapidly prograded at a high rate to the north-northeast, recurving into Pass Cavallo by 1982. During this 4-year time span, the spit grew approximately 2.5 km. This high rate of

growth continued through 1986; when total spit length reached 3.49 km from the point of origin. Inlet width decreased by approximately 2.67 km, at a rate of 127 m/year over this 21-year period. Potential sources for this material are discussed in the following section.

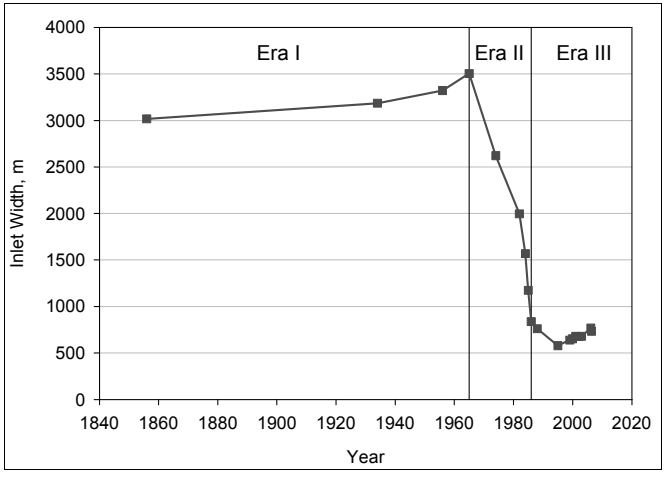

Figure 7. Width of Pass Cavallo, 1856 to 2006.

An apparent maturation of the system occurred in the mid-1980s, as Pass Cavallo achieved equilibrium with tidal forcing in the mid-1980s (Era III). Between 1986 and 2006, spit growth rates of Matagorda Peninsula and Matagorda Island decreased. Matagorda Peninsula prograded 95 m (~5 m/year), whereas the Matagorda Island spit receded west by 24 m (~ 1 m/year). Inlet width decreased by 160 m (9.5 m/year) over this time period.

In summary, Matagorda Peninsula prograded by 1.56 km from 1963 to 2003 and Matagorda Island prograded 3.45 km between 1974 and 2003. Overall, inlet width at Pass Cavallo decreased by 2.76 km. Shoreline change from 1965 through 2006 is shown in Figure 8. Note that although lateral growth of the spits decreased in the 1990s, the planforms began to extend seaward as more sediment was deposited within the inlet complex (1988-2006).

Sediment Sources

Tidal prism calculations indicated that Pass Cavallo was experiencing a surplus of sediment. Morphology change at the inlet subsequent to the opening of the MSC has confirmed that Pass Cavallo has been functioning as a sink within the local sediment budget. This section discusses potential sources for the large amount of material that has accumulated within the inlet complex over the last 40 years.

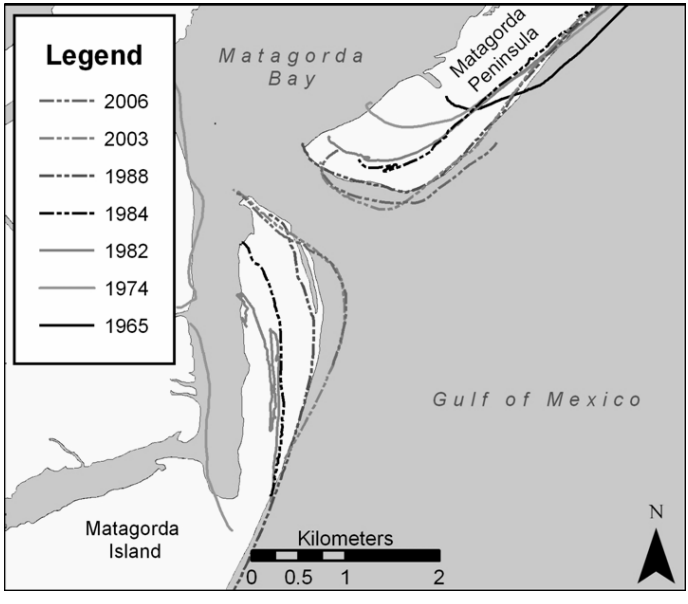

Figure 8. Shoreline time series showing spit progradation into Pass Cavallo.

Ebb-tidal shoals form as a balance between the transporting capacity of the ebb current at an inlet and the capacity of waves to transport material to and away from the inlet. Harwood (1973) studied the flood shoal at Pass Cavallo, which is an extensive sandy platform that protrudes into Espiritu Santo Bay. Flood shoals do not directly depend on wave action for their formation and consist of sediment entering the channel that is transported toward the bay by the flood current. Ebb shoals and flood shoals greatly differ in that, if the inlet reduces in size, migrates, or closes, the ebb shoal will be acted upon by waves and partially or completely disperse, whereas the flood shoal will remain intact. An entire ebb shoal or just a portion of it can become abandoned if an inlet is relocated, if jetties are constructed to confine the ebb current, or if the tidal prism, hence ebb current, decreases. Pope (1991) documents inlets on the southeast coast of the United States for which jetty construction restricted the width of the ebb jet and caused abandonment of lateral portions of the ebb shoal, which then migrated on shore. Kraus (2006) gives a more general discussion of ebb–shoal abandonment and cites other references to the literature. The abandoned portions of ebb shoals will migrate onshore, called "ebb-shoal collapse," if those portions are within the littoral zone.

Ebb shoal volume has been well correlated with tidal prism by Walton and Adams (1976), who concluded that ebb shoal volumes can be larger on coasts receiving less wave exposure, because there would be less transporting capacity to remove the sediment deposited by the ebb current. The following empirical formula was presented by Walton and Adams (1976) to compute the ebb shoal volume V_E for inlets in equilibrium on

mildly exposed (to waves) coasts. The Galveston Entrance, TX, and Aransas Pass, TX, were among the 16 inlets analyzed to obtain this correlation:

$$V_E = 8.458 \times 10^{-3} \; P^{1.23} \tag{3}$$

in which V_E and P are expressed in m^3, a conversion from units of cubic yards and ft^3, respectively, from the original formula.

For 1856, Harwood (1973) estimated the tidal prism of Pass Cavallo to be 4.79×10^8 m^3, and for year 2004, we estimate it at 1.84×10^8 m^3 (includes wind tide). By Eq. 3, these tidal prisms give V_E-values of about 400 million m^3 and 124 million m^3, respectively, assuming the ebb shoal achieved equilibrium volume for each of the tidal prisms. If these estimates are approximately correct, they indicate that since about 1966, when the MSC was cut, the excess volume (400 – 124 = 276 million m^3) has been abandoned by the gradually declining tidal prism at Pass Cavallo. Most of the abandoned sand-sized material in the ebb shoal will migrate down coast and on shore and be partially responsible for growth and volume increase of the spits to either side of the inlet.

The hypothesis for abandonment and collapse of a portion of the ebb shoal at Pass Cavallo is qualitatively supported by the analysis of Morton (1977), who noted that spit progradation and shoreline advance at Decros Point (western end of Matagorda Peninsula) did not appear compatible with recession of the shoreline downdrift of the MSC. Morton (1977) found excess material in the downdrift compartment, described the source as "problematic," and suggested bank and channel erosion as potential sources. These sources are considered by the authors to be inadequate to account for the observed long-term spit growth.

It is hypothesized here that sediment from offshore deposits are also contributing to growth at the end of Matagorda Peninsula and Matagorda Island. The likely source is partial abandonment and collapse of the ebb shoal at Pass Cavallo. This theory is supported by the limited bathymetric data available for the inlet (modern data are not available for comparison). Figure 9 shows a 1934 NOS hydrographic survey (NOS 1934) of Pass Cavallo, overlaid with the 1995 shoreline (BEG 2004). At the time of the survey, the inlet channel was located at the western side of the inlet, and a large ebb shoal is apparent offshore of the terminus of Matagorda Island. Shoreline recession along the eastern extent of Matagorda Island, in addition to the volume of material contained within this shoal, support the deposit as being the source of material for spit progradation into the inlet complex.

Most of the abandonment has occurred gradually over the 43 years since opening of the MSC. After the material in the abandoned shoal is depleted, a significant source of sand tending to close Pass Cavallo will be eliminated, and it is feasible that the inlet will grow (but not return to its historic maximum because of the reduction in tidal prism). The trend in Pass Cavallo for a new equilibrium or possible growth is consistent with the shoreline change analysis of inlet width.

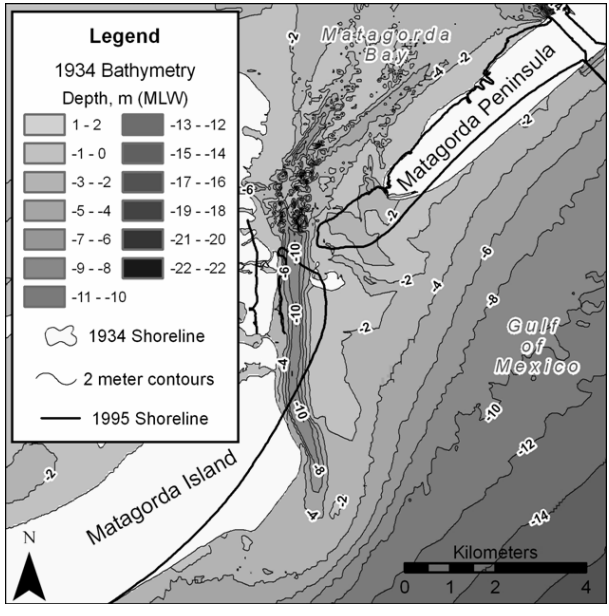

Figure 9. Pass Cavallo channel and ebb shoal in 1934.

Spit progradation on the west side of Pass Cavallo probably also occurs as part of the down-drift inlet offset process (Hayes et al. 1970). The predominant direction of littoral drift is from the northeast to the southwest along Matagorda Peninsula. There are reversals in transport during southerly winds and some storms. Under these conditions, a spit emerged from Matagorda Island and prograded 3.5 km northeast into the inlet. The southwest tip of Matagorda Island shoreline experienced recession (Paine and Morton 1989), and this eroded material could also contribute to support growth of the spit.

CONCLUDING DISCUSSION

Measurements and modeling indicate that the flow through Pass Cavallo is approaching a dynamic equilibrium. This natural inlet has withstood the ebb shoal collapse associated with reduced tidal prism and deposition within the inlet geomorphic complex. The evidence present herein demonstrates that it is not likely that Pass Cavallo will close in the near future. Simple theory indicates that tidal inlets on diurnal tide coasts require a weaker mean-maximum current for cross-sectional channel area stability (Kraus 2007), and the location of Pass Cavallo in the southwest corner of Matagorda Bay works to its favor in having an increased ebb flow due to wind prevalent from the north and northeast in the autumn and winter.

Abstract: In Jul 2005, Packery Channel was opened by Hurricane Emily during the second year of its construction. This inlet connects Corpus Christi Bay and Upper Laguna Madre to the Gulf of Mexico, and it is the first artificially cut inlet in Texas in 17 years. The inlet has remained open and navigable for shallow-draft recreational boats despite construction delays, and its parallel dual jetties were completed in Sep 2006. A physical process monitoring program was initiated prior to construction in 2003 to track the evolution of the channel, surrounding nearshore, and adjacent beaches. Maximum ebb current in the inlet often exceeds 1 m/s, and an ebb shoal has not yet formed. The shorelines adjacent to the jetties, as well as the seaward longshore bars, respond to seasonal changes in wind direction, hence direction of longshore sand transport. Shoreline change varies seasonally, but adjacent to the inlet the shoreline is nearly symmetrical.

INTRODUCTION

Environmental interests as well as the commercial and recreational fishing and boating communities in Texas have long been proponents for opening small inlets to connect its bays and lagoons to the Gulf of Mexico (Lockwood and Andrews 1952; Carothers and Innis 1960). Such inlets modulate salinity in the bays and lagoons, and provide a path for migration of juvenile marine organisms. In the early 1970s, such a “Fish Pass” was cut

across Mustang Island and into Corpus Christi Bay, but it gradually shoaled and closed (Behrens1979). The Texas experience with new small inlets is varied, with examples of inlets expanding and deepening too rapidly (Rollover Pass – Bales and Holley 1989), inlets closing too quickly (Yarbrough Cut – Lockwood and Andrews 1952), and yet other inlets being relatively stable (Mitchells Cut – U.S. Army Corps of Engineers (USACE) 1992). There is a general need for improved inlet design for the Texas coast (see Kraus, this issue, for related discussion). Newly created inlets will alter the surrounding coastal morphology at several space and time scales (Kraus 2006).

Historically, Corpus Christi Bay, Texas, was served by two natural inlets (Price 1952) or "passes" in local terminology, Aransas Pass (shared with Aransas Bay to the north) on the north side and Corpus Christi Pass on the south side, in the SSE corner (Fig. 1 and Fig. 2). Dredging of Aransas Pass started in 1912, and its re-direction into Corpus Christi Bay in 1924 caused Corpus Christi Pass to slowly shoal and become a flat ephemeral pass that was overwashed during more severe tropical storms and hurricanes (Price 1952). For many years, local interests have wanted to reopen the old Corpus Christi Pass through an existing dead-end channel called Packery Channel for water exchange. An additional navigational amenity is that access to the Gulf of Mexico from the Upper Laguna Madre and Corpus Christi Bay system would be about 3 miles (5 km) rather than the 23-mile (37 km) transit to Aransas Pass.

The North Padre Island (Packery Channel), Nueces County, Texas, Storm Damage Reduction and Environmental Restoration Project was authorized in the Water Resources Development Act 1999 as a Federal project with Nueces County, Texas, as the original local sponsor. The City of Corpus Christi assumed local sponsorship in 2000. Construction began in Oct 2003, and the inlet officially opened in Oct 2006. It is stabilized by two parallel jetties oriented 12 deg north of shore normal. The jetties are spaced 300 ft (91 m) apart extending 1,430 ft (427 m) into the Gulf of Mexico. The channel is to be maintained to a depth of 14 ft (4.3 m) MLLW. The original design study estimated that, after equilibrium, a dredging cycle of 1-3 years would be required (Kraus and Heilman 1997). Sand dredged from the channel as new work and maintenance material will be placed on adjacent beaches as a shore-protection element.

In Jul 2005, Packery Channel was opened by Hurricane Emily during construction of the jetties. The inlet connects Corpus Christi Bay and Laguna Madre to the Gulf of Mexico, the first new artificially created inlet in Texas in 17 years (Figs. 1 and 2), and now effectively defines the boundary between Padre Island and Mustang Island to the north. Inlet construction was in its second year when the storm surge eliminated the approximately 350-ft (107 m) wide sand plug that separated the channel from the Gulf and served as a land bridge for construction. The inlet has remained open since then.

This paper presents selected results of the 3 years of physical process monitoring of the channel, shoreline, nearshore bathymetry, and current. In addition to its general benefit for improving knowledge of coastal inlets, monitoring supports adaptive management of Packery Channel and adjacent beaches as a sediment-sharing system.

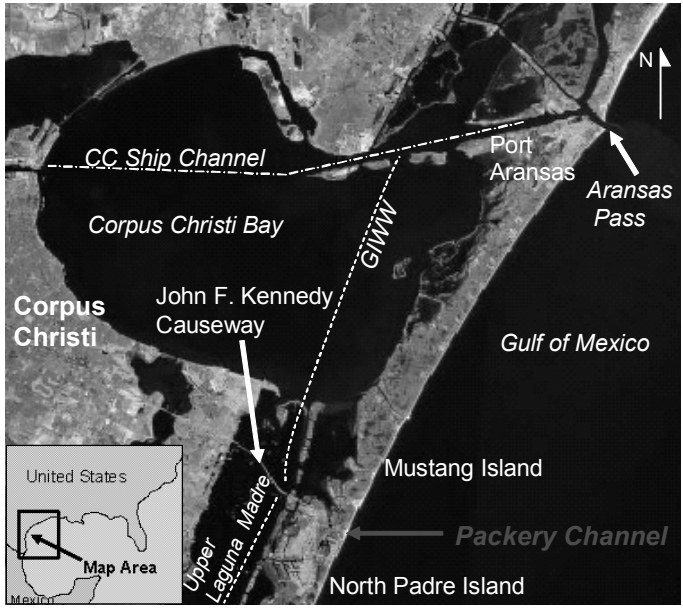

Fig. 1. Location map for region of Packery Channel, Texas.

MONITORING PROGRAM

In anticipation of construction, in Aug 2003 the USACE Galveston District initiated baseline and construction monitoring of morphology change at Packery Channel and the adjacent beaches through a contract with Texas A&M University-Corpus Christi (TAMU-CC). The functional design of Packery Channel identified probable responses in morphology (Kraus and Heilman 1997) and hydrodynamics (Brown and Militello 1997). The monitoring program includes surveys of the beach profile, ebb shoal, and channel; sediment sampling; measurement of channel current; aerial photography; shoreline and upper beach surveys; and development of a combined wave, circulation, and morphology change numerical model. Survey data are recorded relative to NAVD88, and depths are referenced to MSL (MSL = NAVD88 + 0.48 ft). The monitoring area encompasses 2.4 miles (3.8 km) of the Packery Channel inland waterway from the Gulf Intracoastal Waterway (GIWW) intersection to State Highway (SH) 361, the 1 mile (1.6 km) entrance channel west of SH361, and 8 miles (13.2 km) of adjacent beach from south of Bob Hall Pier on Padre Island to north of Mustang Island State Park.

Access to data, aerial photography, and real-time current measurements is available at the Texas Inlets Online website (http://goliath.cbi.tamucc.edu/TexasInletsOnline/). The physical processes monitoring program was described by Williams et al. (2005). An independent environmental monitoring program is also being conducted (HDR/Shiner Moseley 2006). Past monitoring was accomplished in part by coordination with construction milestones listed in Table 1.

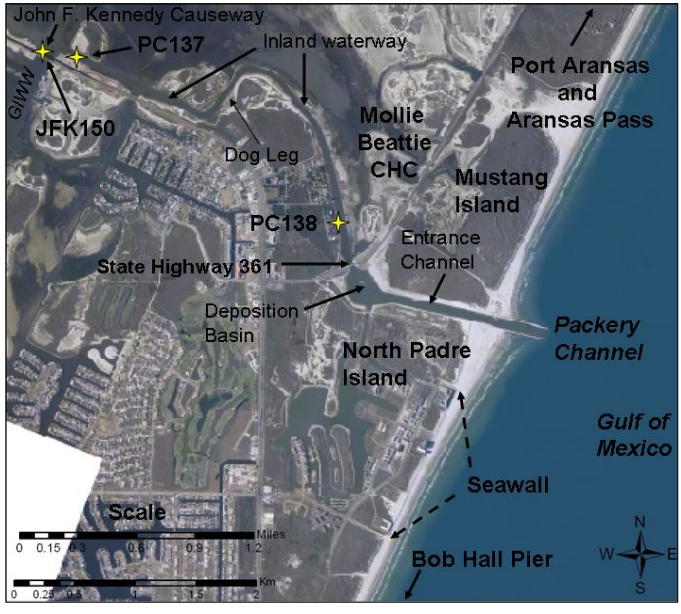

Fig. 2. Packery vicinity map, 16 Aug 2006 (Tobin Aerial Photography).

RESULTS

Water Level, Wind, and Channel Current

Packery Channel is located near two long-term tide gauges, a National Ocean Service (NOS) gauge in the Gulf of Mexico at Bob Hall Pier called "Corpus Christi," and the other on the bay side and along the original Packery Channel inland waterway (Fig. 2). Water level along the Texas coast is controlled by the astronomical tide, local wind, and seasonal change in Gulf water level. A seasonal or low-frequency fluctuation occurs with highs around May and October, and lows in August and December through January. The tide at the Corpus Christi gauge and Packery Channel is diurnal with diurnal range of 1.63 ft (0.50 m) and 0.38 ft (0.12 m) respectively.

The wind along the Texas Coast is strongly bimodal with persistent southeasterly wind from March or April to August or September. Northerly episodic winds accompany frontal passage from September or October to February or March. Southerly winds increase as fronts approach, with rapid reversal in direction as the systems move off the coast. With the opening of Packery Channel, the strong wind enhances water exchange between Corpus Christi Bay and the Gulf of Mexico. Persistent southeasterly and onshore directed easterly wind force water from the Gulf into the bay system, whereas northerly, particularly northwesterly wind, forces water toward the Gulf. Prior to opening of Packery Channel, northwesterly winds set up water in the SE corner of Corpus Christi Bay causing water to rise along the flats adjacent to SH361, now known

as the Mollie Beattie Coastal Habitat Community (CHC). With a pathway to the Gulf through Packery Channel, water exits this portion of the bay during frontal passages, greatly enhancing the ebb current flow in the inlet.

Table 1. Packery Channel Construction Timeline

Activity	Date	Comment
Construction begins	Oct 03	---
Dredge inner channel	Dec 03 - Apr 04	---
Land dredged to form channel; material placed on south beach	Apr – Jul 05	136,077 cy (104,038 m^3) bypassed
Channel opens (Hurricane Emily)	19 Jul 05	Removed sand plug
Narrow channel remains open	Jul - Dec 05	---
Channel dredged; material placed on beach south of inlet	Jan - Feb 06	679,089 cy (519,200 m^3) bypassed
S jetty completed to 1,430 ft (427 m)	Mar 06	---
N jetty completed to 1,430 ft (427 m)	Jun 06	Landward end incomplete
Scour hole at S Jetty filled with rock and concrete slabs	Aug 06	---
Landward end of N jetty completed	Sep 06	---
Official opening. Transfer to local sponsor in progress	Oct 06	---

Three current monitoring stations were deployed to measure the current in Packery Channel and in the GIWW near the Packery Channel intersection (Fig 2). The magnitude of the current is either enhanced or suppressed during periods of strong wind (Fig. 3). The primary Packery Channel current station, PC138, is located 0.25 mile (0.4 km) north of the SH361 Bridge (http://lighthouse.tamucc.edu/qc/138/). The current follows the phase of the tidal signal measured at the Corpus Christi gauge in the Gulf of Mexico. A second station, PC137, is located near the Packery water level station. The Packery stations were deployed during Sep 2005, each equipped with a side looking SonTek Argonaut mounted on existing structures at mid-depth. Data are collected remotely and posted in real time. The current speed at PC138 is an order of magnitude greater than at PC137. The difference in speed is related to distance from the inlet and change in channel orientation (dog leg). In the inland waterway of Packery Channel, the dog leg effectively separates the western section of the channel from the eastern channel. The entrance channel begins at the SH361 bridge and deposition basin.

Since deployment in Sep 2005, the average ebb and flood current speeds have been 0.44 and 0.38 m/s, respectively, and a maximum ebb current of 1.85 m/s and maximum flood current of 1.56 m/s have been measured during strong wind. Flood flow is enhanced by strong E-SE wind forcing water against the Gulf shoreline and into the bay/lagoon system through the channel (Fig. 4). Strong E-SE wind typically precedes frontal passage. Ebb flow is enhanced during frontal passage as water set-up along the northern

shore of the bay/lagoon system by E-SE wind is released, in part, through Packery Channel. Northerly winds can initiate abrupt reversal in current direction. Ebb flow will often continue for several days as the bay system returns to equilibrium level.

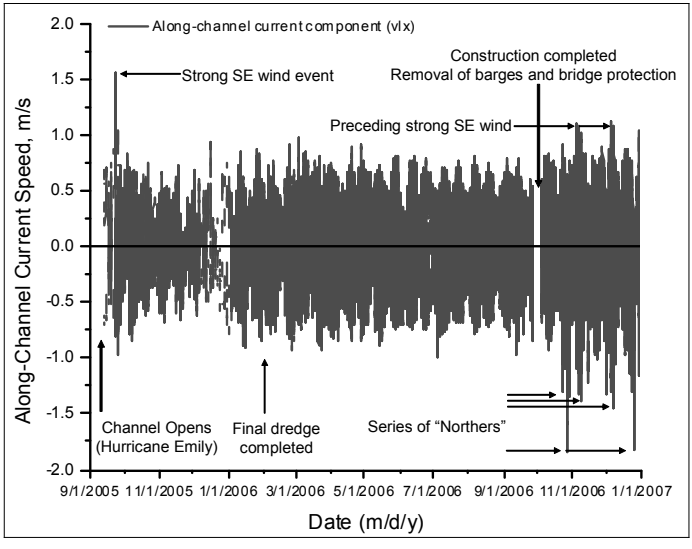

Fig. 3. Current record for PC138 showing key events.

The GIWW current meter (JFK150) is bottom mounted at a depth of 26 ft (8 m) in the center of the channel under the John F. Kennedy Causeway Bridge. Current in the GIWW is strongly influenced by the southeasterly wind that dominates the signal during the spring and summer (Fig 5). Although the signal follows the Gulf tide, flood flow pushing southward may be subdued or reversed during persistent SE wind. The current flows northward under solar diurnal SE forcing with reversals during frontal passage. The average current speed toward Corpus Christi Bay to the north is 0.23 m/s, and to the south it is 0.20 m/s. The maximum current speed toward the north recorded since Jun 2006 was 0.79 m/s and toward the south 0.78 m/s.

Sediment

Sediment in the study area is supplied by two sources. The bay and lagoon supply silt and shell hash introduced through erosion of flats and shoreline. North Padre and Mustang Island beaches supply fine sand. Finer grain size material with a component of shell hash is found in the inland waterway nearest to the GIWW where weaker currents allow deposition of sediment originating in the adjacent bay and lagoon. The deposition basin includes the influence sedimentation with fine material found around the periphery and deeper central sections. The entrance channel bottom is composed of fine sand with a median grain size of 0.15 mm. Sediment grain size increases moving toward the barrier islands where the median grain size of North Padre and Mustang Island sand is, on average, 0.16 mm.

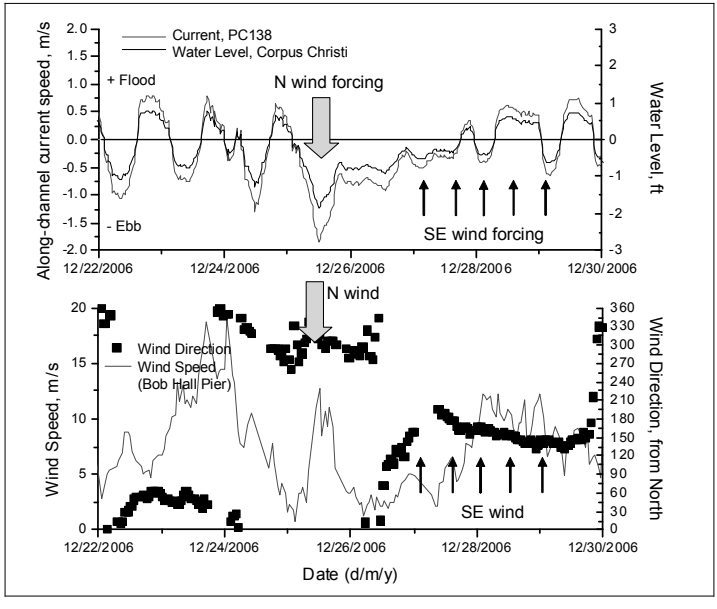

Fig. 4. Response of current to wind forcing at PC138.

Long-Term Shoreline Change and Longshore Sand Transport Rate

Along this coast, long-term shoreline change is recession of about 5 ft/yr (1.5 m/yr) (Morton and Pieper 1977). The design study for the project (Kraus and Heilman 1997) indicated that Packery Channel is located near a divergent nodal point in longshore sand transport. They estimated that the net direction of transport is to the south, with a gross rate of 150,000 to 250,000 cu yd/yr and net rate of 45,000 to 70,000 cu yd/yr.

Nearshore and Channel Morphology

In the early stages of jetty construction from Aug 2004 to Jul 2005, sand accreted between the short jetties. The sand plug that functioned as a land bridge for construction activities began to slowly advance seaward as did the adjacent shoreline to the north. Once the storm surge associated with Hurricane Emily removed this limiting feature, changes in morphology both within and adjacent to the inlet accelerated. In addition to Emily, Hurricanes Katrina and Rita increased flow in the new inlet during autumn of 2005. The narrow entrance channel remained open and navigable by small craft. In Jan 2006, with the channel still open, the entrance was dredged to facilitate barge operation associated with construction, as well as to replace sand eroded at the south end of the seawall during the active storm season. The incomplete north jetty limited the extent of dredging into the Gulf of Mexico.

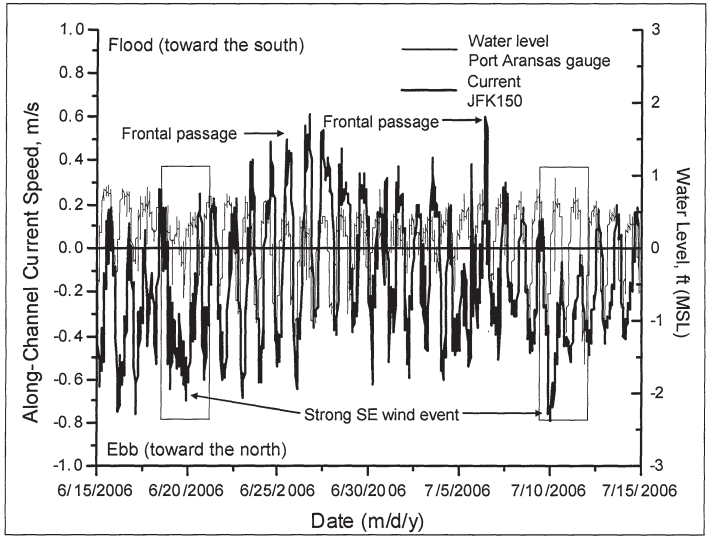

Fig. 5. Wind influence on GIWW current direction.

After the channel opened during Hurricane Emily, shoaling occurred at the existing mouth as observed on 29 Jul 2005 (Fig. 6). Depth in the channel where the sand plug had been was on the order of 2 to7.5 ft (0.6 to 2.3 m) with deepest areas in the center channel. The depth at the planned gulfward end of the jetties was 7 to 13 ft (2 to 4 m).

A survey was conducted on 6 Mar 2006 after completion of dredging in Feb 2006. The mouth of the channel had scoured, with shoaling evident adjacent to the jetties west of the mouth. Scour developed at the ends of the uncompleted north jetty and completed south jetty with depths of 20 to 22 ft (6 to 7 m) and 20 to 26 ft (6 to 8 m), respectively, where the pre-construction depths had been 10 to 13 ft (3 to 4 m) (Fig. 7). This broad region of scour extended beyond the jetties offshore of the mouth with depths of 17 to 20 ft (5 to 6 m). Seven months after Emily forced the channel open, no offshore bar or ebb shoal had formed.

The response of the channel to spring waves from the E-SE was captured in the 17 May 2006 survey (Fig. 8). A well-defined sand bar with crest at a depth of 7 ft (2 m) intersected the south jetty approximately 450 ft (137 m) from its seaward end. The south jetty was completed in Mar 2006, while construction of the northern jetty continued. No longshore bar adjacent to the north jetty appears in this survey. In the entrance channel, deposition occurred along the north jetty and erosion along the south jetty. A probable source for the sediment along the north jetty was a gap that existed between the channel revetment and the incomplete north jetty. This gap allowed transport of sand into the channel during storm surges prior to its closure in Aug 2006. Channel center depth varied from 9 to15 ft (3 to 5 m). Scour at the seaward ends of the north and south jetties decreased to 15 to 19 ft (4.5 to 5.8 m) and 18 to 20 ft (5.5 to 6 m), respectively.

Reduction in scour at the south jetty was related, in part, to placement of the final stone at the offshore extent. The two regions of jetty tip scour on the north and south merged and extended with depths of 15 to 20 ft (4.5 to 6 m) radiating offshore from the mouth and no ebb shoal was present.

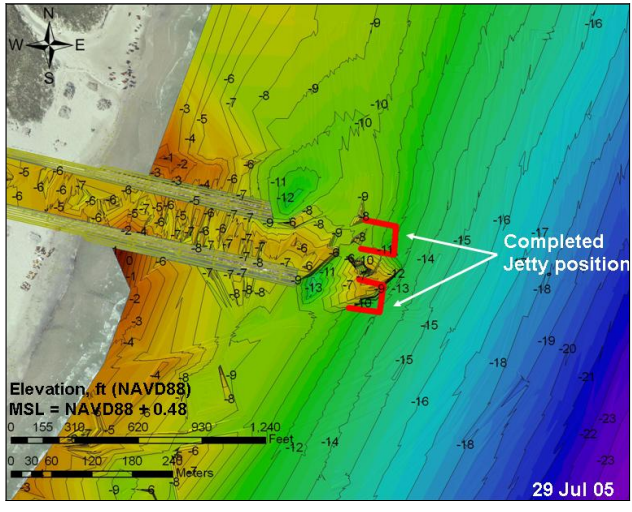

Fig. 6. Channel and nearshore morphology after Hurricane Emily (29 Jul 2005).

By Aug 2006, the offshore extents of both jetties were complete and onshore construction including the landward end of the north jetty was approaching completion. The south bar had become more defined under SE wind waves transporting sediment toward the north. This bar migrated 450 ft (137 m) offshore and was now in line with the end of the south jetty (Fig. 9). A possible jetty tip shoal developed to the north. In the channel, depth increased along the north jetty by 1 to 4 ft (0.3 to 1.2 m), while central channel depth remained variable with an average decrease of 1 to 2 ft (0.3 to 0.6 m). The offshore region of scour expanded, although a narrow, 40-ft (12-m) wide ridge developed between the jetty tip scour and offshore region of scour. Depth of the ridge was on the order of 16 ft (4.8 m). No ebb shoal or bypass bar was present.

The most recent (16 Dec 2006) survey was conducted after a transition period in weather patterns with numerous frontal systems moving off the coast. These abrupt, strong reversals in wind from SE to out of the NE-NW caused a reversal in sediment transport toward the south, changing the nearshore morphology adjacent to the inlet. In addition, prior to this time, the current had been astronomically dominated and only enhanced or subdued by SE wind forcing water from the Gulf into the bay-lagoon system. Two striking changes occurred as the nearshore responded to the reversal in the sediment transport system: 1) the south bar deflated and became less defined with a small shoal protruding offshore at northern end, and 2) a well defined bar developed north of the inlet (Fig. 10). Scour became more pronounced at the seaward end of the north jetty

where depths offshore of the mouth ranged from 14 to 25 ft (4 to 7.6 m) with the deeper region directly adjacent to the jetty. The narrow ridge identified 3.5 months prior widened to 190 ft (58 m), effectively separating the offshore scour from the jetty scour. The depth along the ridge decreased approximately 2 ft (0.6 m) to an average of 14 ft (4.3 m). No ebb shoal was present 1.5 years after the channel opened.

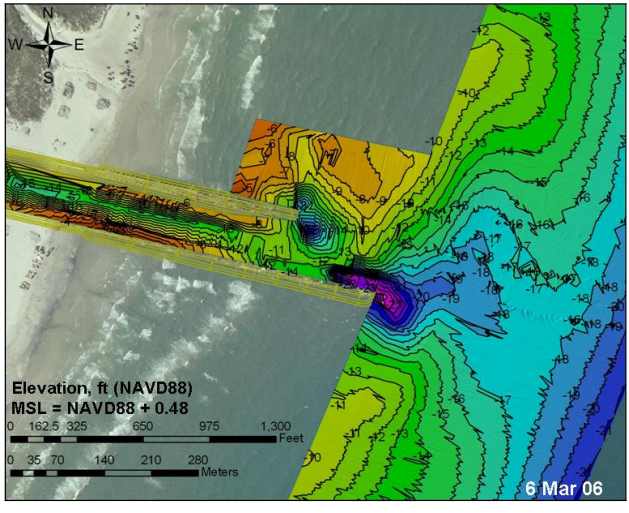

Fig. 7. Scour at channel mouth after final dredging (6 Mar 2006).

By 16 Dec 2006, the majority of the inner entrance channel had deepened, with transport of the scoured sediment toward the inlet mouth. Contours indicate forcing toward the Gulf (Fig. 10). No shoaling occurred at the channel mouth, with depths of 11 to 18 ft (3.4 to 5.5 m) across the entrance. The existence of this deep region at the mouth indicates that the source of the sand shoaling in the inner channel is from redistribution of existing channel sand. Scour along the jetties, particularly the northern jetty, is the likely source.

A strong ebb current exceeding 1.0 m/s with a maximum of 1.85 m/s was measured at PC138 from Oct 2006 through 16 Dec 2006. Over that period, ebb flow occurred more frequently and was sustained longer than flood flow due to strong forcing by N-NW wind during frontal passage. The persistent ebb flow is an effective forcing mechanism capable of redistributing channel sediment eastward toward the channel mouth and ultimately offshore into the Gulf of Mexico. The current in the entrance (between the jetties) will be stronger than that measured at PC138, because of the friction created by channel length and SH361 bridge piers between the entrance and PC138.

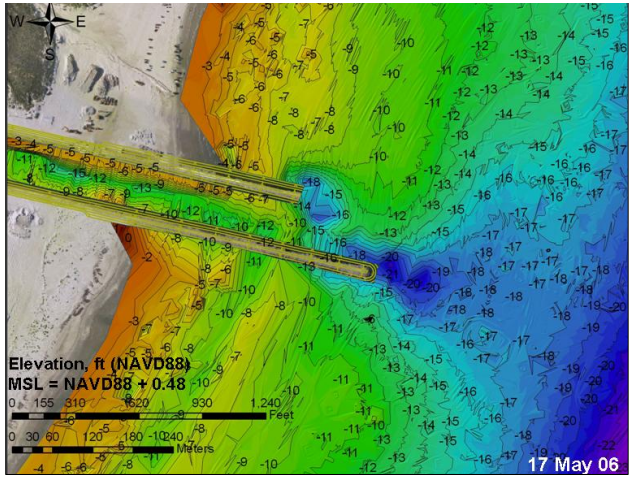

Fig. 8. Scour offshore of channel mouth (17 May 2006).

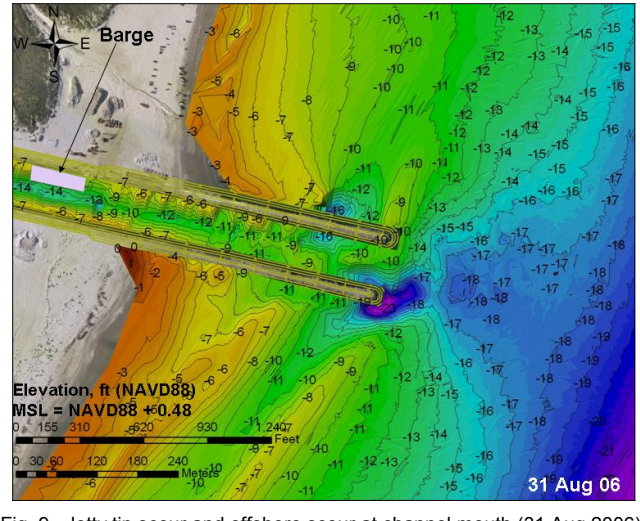

Fig. 9. Jetty tip scour and offshore scour at channel mouth (31 Aug 2006).

Shoreline Change and Beach Profile Response

Shoreline change beyond that attributable to seasonal and annual responses has so far been restricted to the region directly adjacent to the inlet and moderates within 1.5 miles (2.4 km) to the south and 1 mile (1.6 km) to the north. Surveys extended from south of Bob Hall Pier northward beyond Mustang Island State Park, a distance of 8.2 miles (13.2 km). The 1.5 to 2- ft (NAVD88) contour corresponds to the location of the berm crest and was selected for comparison to the Aug 2003 pre-construction baseline.

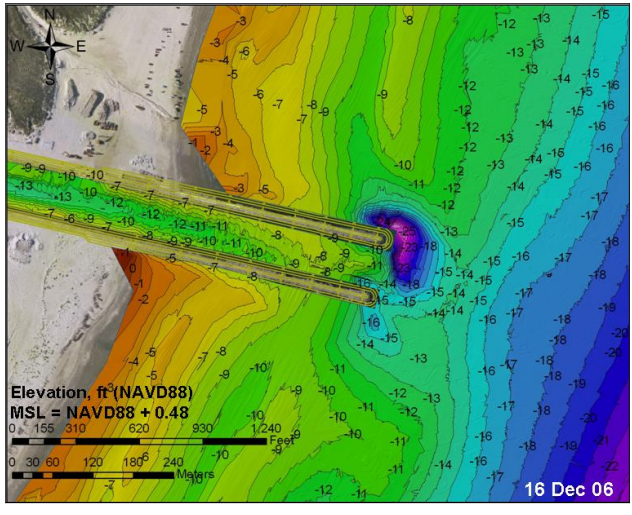

Fig. 10. Ridge between regions of scour offshore of channel mouth (16 Dec 2006).

The shoreline consistently advanced from the inlet to the south end of the seawall from Aug 2003 to Jul 2006. Near to the south jetty, the shoreline advanced a maximum of 400 ft (122 m). Advance in front of the seawall, ranging from a maximum of 200 ft (61 m) on the north end to a post-bypassing maximum of 155 ft (47 m) at the more variable south end, owes to mechanical bypassing (Fig. 11). After the active 2005 tropical storm season, the shoreline at the south end of the seawall receded some 100 ft (31 m), while the northern end remained stable. The shoreline maintained a net seaward position of on the order of 200 ft (61 m) nearest the north end of the seawall and a minimum of 80 ft (24 m) at the south end. Variability in shoreline position at the south end is likely related to distance from the sheltering by the jetties and may be exacerbated by the interaction of the terminus of the seawall and intersection of a paved access road that creates an unrestricted pathway for overwash during storm surge.

Shoreline change adjacent to the north jetty was more erratic, but moderated within 1 mile (1.6 km) of the inlet. During initial construction, shoreline advance near the north jetty was greater than that observed on the south side (Jul 2004 to Oct 2004). Shoreline recession to the 2003 baseline position from Oct 2004 to Jan 2006 was primarily due to sand lost around the incomplete landward end of the jetty during storm surge and may have been compounded by bypassing to the south around the incomplete seaward end of the northern jetty. Once the north jetty neared completion, the adjacent shoreline shifted to a maximum seaward position of 380 ft (116 m). As of Jul 2006, the northern shoreline advance was such that the north and south shoreline adjacent to the inlet were nearly symmetrical. The advance of the northern shoreline indicates at least intermittent transport to the south with impoundment at the jetty.

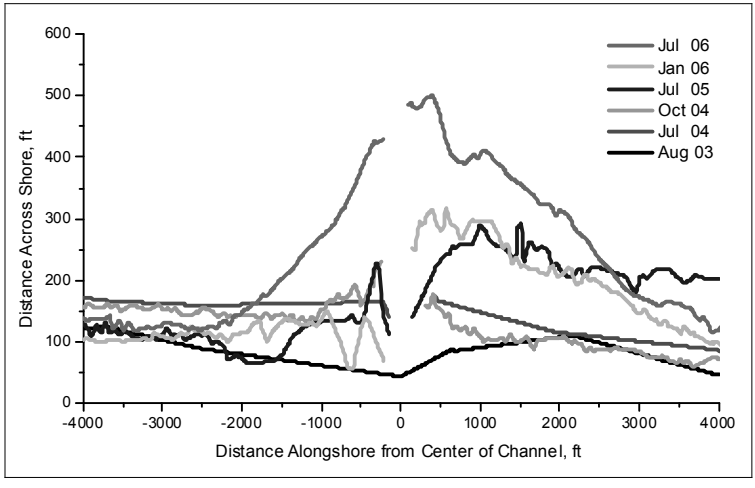

Fig. 11. Shoreline position change adjacent to the new inlet from Aug 2003 to Jul 2006.

CONCLUDING DISCUSSION

Over the 1.5 years since Packery Channel opened in Jul 2005, the channel has remained open primarily by scour induced by consistent, astronomically forced currents enhanced by seasonal wind tide. East-southeasterly directed frontal systems force flow and sediment toward the Gulf of Mexico. Current speed at PC138 is close to that, but as much as 0.35 m/s greater during wind events, than that predicted for the SH361 Bridge in the original design study of hydrodynamics by Brown and Millitello (1997). Therefore, it follows that current speeds on the order in excess of 1-1.35 m/s occur in the entrance channel. The greater observed speed is likely related to shallower channel water and higher than average wind speeds during the monitoring period. As a result of such strong sustained currents in the entrance channel, depth in the entrance channel has mainly increased with redistributed sand transported toward the channel mouth, forming a shoal to the west. The strong ebb flow not only forced the progradation of the shoal toward the Gulf, but, also, in combination with the longshore current, has induced scour at the mouth and contributed to the large region of scour offshore of the mouth. The speed of the ebb current has increased since the channel opened. No ebb shoal formation has been yet been detected.

Southerly directed longshore sediment transport dominates during the spring and summer induced by E-SE winds. The northerly directed transport during the spring and summer of 2006 induced migration of the seaward bars offshore to intersect with the south jetty tip. Autumn is typified by frontal passage and reversal in direction of longshore transport. The southerly directed transport caused rapid development of an offshore bar perpendicular to the north jetty during autumn 2006.

The southern shoreline adjacent to the inlet steadily advanced since 2003, but the northern shoreline position was erratic due to sediment loss around the incomplete north jetty. Once the jetties were completed, the northern shoreline advanced significantly and by Jul 2006 the shoreline was symmetrical with respect to the inlet. Northerly directed sediment transport is generally considered to occur during the summer, but the data indicates an intermittent southerly directed component. Development and dissipation of sand bars supports a strong seasonal bias in sediment transport in the nearshore. The rapid advance of the northern shoreline indicates that southerly directed sediment transport does occur during summer months and is related to the location of the channel at a divergent nodal area in the local longshore sediment transport system.

EVOLUTION OF A RELOCATED TIDAL INLET: MASON INLET, NC

John M. Welsh[1] and William J. Cleary[2]

1. Gahagan & Bryant Associates, Inc., 295-A N. Green Meadows Drive, Wilmington, NC 28405-3933, USA. jmwelsh@gba-inc.com.

Abstract: Mason Inlet, situated between Figure Eight Island and Wrightsville Beach, N.C. was artificially relocated 850 m updrift of its former position at the southern terminus of a migrating barrier spit. Relocation that occurred in early 2002 was chosen from several management options due to the increased backbarrier infilling and southerly migration of the inlet that imminently threatened a resort complex and infrastructure on northern Wrightsville Beach. The relocated Mason Inlet provides an exemplary site to study the evolution and impacts of a recently relocated system from its inception while simultaneously assessing the relative success of the project. Jarrett's (1976) theoretical equation relating tidal prism (T_P) and cross-sectional area (A_C) appears to be a useful tool for estimation of the relocated Mason Inlet's T_P. However, ebb-tidal delta volume after 4.5 years remains well below the equilibrium volume predicted by Walton and Adams' (1976) model.

INTRODUCTION

Most of North Carolina's 19 inlets have been modified to some extent as a result of improved navigation via channel maintenance and removal of sand for beach nourishment. Hard stabilization techniques (engineering solution) by way of jetties or groins are traditionally used in the United States; however, North Carolina implemented a general statute, in 1984, that prohibits the use of hardened erosion-control structures along its coastline. As a result, soft protection techniques (e.g. dredging, beach nourishment, and sandbag installations) have become the mainstays of North Carolina's engineering solutions to these coastal hazard scenarios. Large-scale modification of inlets, associated with relocation or jetty emplacement, commonly alters the parameters (e.g. cross-sectional area, tidal prism, etc.) of an inlet and can result in substantial erosion of neighboring shorelines (Cleary *et al*., 1989;

Cleary and Marden, 1999). Concern over management issues (e.g. artificial inlet relocation) related to these modifications has increased due to severe impacts associated with these alterations and future modifications (e.g. dredging) slated for most of North Carolina's inlets.

Knowledge of how large-scale modification alters the physical parameters, current dominance, basin filling characteristics, as well as the impact on the offshore portion of specific inlet systems in southeastern North Carolina is generally lacking. A key element in evaluating the performance of an inlet where significant artificial changes have occurred is the application of the linear regression relationships derived by Jarrett (1976) and Walton and Adams (1976) for equilibrated inlets.

Mason Inlet, situated along the southeastern North Carolina coast, is characterized as a migratory system (Fig. 1). During the past 20 years the inlet has experienced considerable shoaling due to sand deposition in backbarrier feeder channels and a decrease in tidal prism (Cleary and FitzGerald, 2003). Since the early 1900's, the inlet has exhibited a net migration pattern to the southwest stretching along a 1.6-km corridor. Migration south caused erosion of the downdrift shoreline and eventually threatened to undermine a $22 million resort complex by 1997. Artificial relocation in March 2002 moved the inlet approximately 850 m northeast of its 2001 position and closed the former inlet. Over the past 4.5 years the new inlet has been adjusting to a larger tidal prism and retaining sand within an evolving ebb-tidal delta.

The intent of this paper is to provide a management framework from which the impacts of inlet relocation on tidal prism and inlet-related sand bodies can be better understood. The relocated Mason Inlet provides an ideal site to study the evolution and impacts of a recently relocated system from its inception by comparing the actual measured and derived values to predicted values obtained from regression equations associated with key inlet parameters.

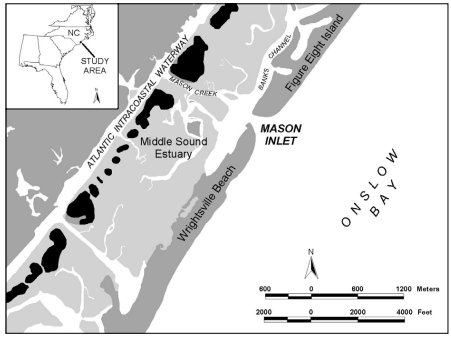

Figure 1. Location map of the study area. Dark features are dredge material islands.

PREVIOUS WORK

Inlet relocation, as a viable management option, has been made available to coastal managers under site-specific conditions. Relocation efforts have exclusively dealt with migrating inlets that have posed some degree of threat to the surrounding coastal zone (usually near field infrastructure) that borders an inlet.

Mason Inlet is not the first inlet along the North Carolina coast to be relocated. Tubbs Inlet, located 75 km to the southwest in adjacent Brunswick County, was relocated in January of 1970. After a period of adjustment the inlet began to migrate opposite its historic migration direction and the regional net littoral drift direction. Although Budde and Cleary (in press) have described morphologic changes in the inlet and their impact on the adjacent oceanfronts no published information exist that deals with the hydrodynamic evolution of the inlet.

Published studies documenting the effects of relocated tidal inlets along U.S. and foreign coastlines are uncommon. Studies of the 1983 relocation of Captain Sam's Inlet (mesotidal setting) near Charleston, South Carolina, include Kana and Mason's (1988) study that monitored the evolution and growth of the ebb-tidal delta, and the Kana *et al*. (1987) study that determined a sediment budget for the system. However, the inlet managed to migrate back to its approximate 1982 position twelve years after relocation (Kana and Mckee, 2003). Consequently, another artificial relocation of the inlet occurred in 1996. Both inlet relocation efforts are summarized in Kana and Mckee (2003). The study of Ancão Inlet's 1997 relocation, along the mesotidal, Ria Formosa barrier island system, in Portugal by Vila *et al*. (1999) determined that dramatic volumetric changes occurred during the first year of evolution, with the enlargement of the inlet and formation of well-developed flood and ebb deltas. Studies such as these are extremely important because they serve as case-studies for future inlet modifications elsewhere. Cleary and FitzGerald (2003) documented tidal prism changes intially induced by the relocation of Mason Inlet. Whereas, Erickson *et al*. (2003) also reviewed the relocation of Mason Inlet and the first year of observations of morphology and hydrodynamics in the system.

Certain fundamental parameters of an inlet system must be monitored as a new inlet system evolves to understand how relocation affects hydrodynamic and morphologic changes. Regression analyses of related morphologic and hydraulic characteristics of tidal inlets have been relatively successful in modeling inlet systems. These relationships between inlet parameters and processes have aided in the research of inlets worldwide (Kana *et al*., 1999). Jarrett (1976) refined Leconte's (1905) and O'Brien's (1931 and 1969) relationship between tidal prism and inlet cross-sectional area. Walton and Adams (1976) derived an empirical relationship between ebb-tidal delta volume and tidal prism.

STUDY AREA

Mason Inlet, situated in southwestern Onslow Bay along North Carolina's southeastern coastline, separates Figure Eight Island to the northeast from Wrightsville Beach to the southwest (Fig. 1). This region is characterized as a

microtidal and wave-dominated setting with mixed semi-diurnal tides (Hayes, 1994). The backbarrier region between the AIWW and Mason Inlet is the Middle Sound Estuary, which consists mostly of marsh incised by tidal creeks. Mason Creek and Banks Channel, two primary tidal channels within the estuary, provide the only navigable connection between the inlet and the AIWW.

Mean wave height and period in this region are 0.79 m and 7.9 seconds, respectively (Jarrett, 1977). The measured tidal range of this system has a mean range of 1.00 m, which increases to 1.20 m under spring tide conditions and decreases to 0.81 m under neap tide conditions. Mean sea level was determined to exist at an elevation of 0.20 m (National Geodetic Vertical Datum 1929 (NGVD 29)). The dominant direction of wave propagation is from the east-northeast and comprises 64% of the total wave energy that affects this area. Net longshore sediment transport is in the southerly direction and occurs at a rate of approximately 587,943 m^3/yr (USACE, 1982).

METHODS

This investigation utilized a relatively robust data set consisting of detailed photogrammetric, topo-bathymetric, hydrographic, and tidal survey information. All tidal and topo-bathymetric data were referenced horizontally to North Carolina State Plane 1983 and vertically to NGVD 29.

Flow Dynamics

A vessel-mounted RD Instruments® (RDI) Workhorse Monitor™ 1200 kHz Acoustic Doppler Current Profiler (ADCP) was used in collection of all flow data within the inlet throat. The ADCP was utilized during short-term deployments (e.g. 7–14 hr periods) for measuring flow velocities and direction, cross-sectional area, water levels, and calculating discharge and flow volume. The inlet throat was perceived as an extremely important location for data collection because a majority of inlet parameter relationships rely on throat measurements. Thus, ADCP surveys concentrated on determining variations in tidal prism and cross-sectional area at the inlet throat. These variations are important for characterizing the inlet's hydrographic nature. Typical surveys included traversing the throat profile a minimum of four times every half hour from the onset of the survey until completion of the tidal stage of concern.

An emphasis was placed on measuring the flood duration of the tide in order to determine tidal prism for a particular survey. Seven of eight surveys included data collection during a flood tide. That resulted in seven tidal prism values calculated from flow data collected by the ADCP between March 2002 and October 2003. No ADCP data were collected following October 2003.

Tidal prism (T_P), for the purposes of this study, is defined as the volume of water that enters an inlet on a spring flood tide (USACE, 2003). Cross-sectional area (A_C) is the channel section below mean tide level (MTL).

Ebb-Tidal Delta and Inlet Throat Analyses

Topo-bathymetric data collected by Gahagan & Bryant Associates, Inc. were used in measurements of throat parameters and sand volumetric analyses of the system. A total of eleven topo-bathymetric data sets spanning March 2002 to October 2006 allowed for the generation of digital terrain models (DTM).

Measurements of these DTM surfaces focused on two main regions. These included the newly evolving ebb-tidal delta and inlet throat for purposes of determining sand volume and A_C. A_C was measured below MSL (0.20 m NGVD) at the inlet throat.

Several studies describe a methodology for calculating the ebb-tidal delta volume by reference to idealized no-inlet bathymetry (Dean and Walton, 1975; Walton and Adams, 1976; Marino, 1986; Stauble, 1998). Hicks and Hume (1997) developed the residual method for analyses of ebb shoal shapes and volumes. In order to perform calculations on the ebb-tidal delta's volume, it was critical to define the boundary of the ebb shoal. Unfortunately, standardized techniques to determine these boundaries do not exist (Stauble, 1998). Volume of the evolving ebb shoal was determined using a variation of the method described by Dean and Walton (1975) for estimating quantities of sand stored in outer shoals of inlets on sandy coasts. Ultimately, the method used for this study followed closely after Stauble's (1998) Residual Method.

RESULTS

Inlet Throat and Tidal Prism

All pertinent ADCP flow data pertaining to the inlet throat are presented in Table 1. Discharge measurements collected during a flood tidal flow were manipulated for the purpose of calculating T_P during the course of the study. A large degree of variation

Table 1. ADCP and tide range data for each of the eight throat surveys.

between these individual T_P values exists from one survey to the next. The first ADCP survey was conducted three weeks following inlet opening during a Spring tide with a flood range of 1.70 m. A relatively large T_P of 7.34 x 10^6 m^3 was calculated at that time. A 64% decrease in the T_P value occurred between the March 28, 2002 and July 1, 2002 surveys. Within the same month (July 1 to July 31, 2002) T_P increased by 52% to 4.03 x 10^6 m^3. The June 27, 2003 ADCP-derived T_P, an 18% increase from the previous survey almost a year earlier, was 4.76 x 10^6 m^3. Eleven days later the T_P decreased by 13%. A relatively large T_P volume of 6.25 x 10^6 m^3 was determined from the September 5, 2003 survey. A large Neap flood range of

1.31 m was measured for this survey and resulted in a 396 m^2 measured channel section. The final survey occurred on October 6, 2003 with calculations yielding a volume of 4.71 x 10^6 m^3. The mean calculated T_P value for the seven surveys was 4.84 x 10^6 m^3.

Correlation between T_P and flood tidal range was determined from acquired field data. As expected, a positive correlation (r = 0.87, significant at the 95% confidence level) was found to exist between these two inlet parameters. The correlation indicates that as tidal range rises or falls the T_P volume will respond in a like manner. Similarly, a positive correlation (r = 0.95, significant at the 99% confidence level) between ADCP-calculated T_P and ADCP-measured A_C was determined. This positive correlation indicates that larger A_C values result in greater T_P values or vice versa with diminished A_C values.

Ebb-Tidal Delta Development

Over the course of the past 4.5 years the ebb-tidal delta has experienced marked changes in morphology and volume. Between March and July 2002 the newly formed shoal had impounded 137,000 m^3 of material. A steady growth continued over the next 2.2 years and by October 2004 the shoal volume increased to 322,000 m^3. Between October 2004 and April 2005 a marked change occurred due to retention of an additional 96,000 m^3 yielding a total volume of 418,000 m^3. Continued growth occurred until October 2005 when the shoal reached its maximum volume of 440,421 m^3. Since October 2005 volumetric loss has characterized the ebb-tidal delta. In April 2006, shoal volume was 338,000 m^3 and by October 2006 the volume had decreased to 288,000 m^3.

Theoretical Relationships and Comparisons

The widely recognized relationship between T_P and inlet throat A_C was initially described by Leconte (1905) and later refined by O'Brien (1931, 1969) who elaborated upon the relationship's potential for estimating T_P. Jarrett (1976) furthered understanding of the relationship by grouping inlets into separate classes based on wave energy setting and on the presence or absence of jetties. Segregating the inlets allowed Jarrett to formulate unique linear regression equations for each class. Byrne *et al*. (1980) determined that relatively small tidal inlets situated within protected coastlines fail to apply to the predicted relationship of Jarrett (1976). Although Mason Inlet is not within a protected coastline, it is a relatively small inlet and consideration of that fact should be noted when utilizing this relationship. Utilizing the throat A_C and T_P derived values from data collected with the ADCP and topo-bathymetric surveys, it is possible to make comparisons between the new inlet channel and the predicted equilibrium cross-sections derived from these regression equations. For the purposes of this study, the frequently used regression equation derived by Jarrett (1976) for the Atlantic Coast was used in order to compare the values for the mean measured T_P and the calculated T_P (Equation 1):

$$A_C = 7.75 \times 10^{-6} T_P^{1.05} \quad (1)$$

where: A_C = throat cross-sectional area (ft^2) and T_P = tidal prism (ft^3). The cross-sectional area values used in Jarrett's equation represent the mean of the cross-sectional area values (A_C = 296 m^2) measured during each of the seven throat surveys conducted during flood tide conditions with the ADCP and the mean of the values (A_C = 291 m^2) measured across the six DTM surfaces. Based on Equation 1 and the A_C measured by the ADCP, the resulting calculated T_P was 4.53 x 10^6 m^3. The difference between this predicted T_P (4.53 x 10^6 m^3) and the mean ADCP-calculated T_P (4.84 x 10^6 m^3) was approximately 7%. The resulting predicted T_P, based on Equation 1 and the DTM-measured A_C, was 4.45 x 10^6 m^3; an 8% difference from the mean ADCP-calculated T_P (4.84 x 10^6 m^3). A t-test (t = 1.41) determined that the difference between the mean predicted values and the mean ADCP-calculated values were not significant (p-value = 0.21). The relatively small difference (7% and 8%) and statistical insignificance between these predicted T_P values and the mean ADCP-calculated T_P values suggest that Equation 1 was a comparable method and fairly useful tool for estimating T_P (Fig. 3).

Inserting A_C values derived from ADCP throat surveys into Equation 1, predicted T_P values were generated that ranged from 2.98 x 10^6 m^3 to 5.98 x 10^6 m^3. Extreme differences between these predicted T_P values and calculated T_P values ranged from <1% to 21%. It should be noted that the greatest difference of 21% occurred during the March 28, 2002 survey when the channel cross-section still maintained an artificial shape considered to be far from equilibrium. The next greatest difference was 13% and occurred in July 2002. Over time the difference between calculated and predicted values decreased as the channel section evolved. Individual ADCP-calculated T_P values were regressed against the corresponding predicted T_P values. A positive correlation was determined to exist (r = 0.97, significant with 99% confidence). This relationship was indicative of the comparativeness of these two different methodologies for estimating tidal prism. Both the ADCP and Equation 1 were useful for T_P estimation and appeared to compare more closely as the channel evolved over the study period.

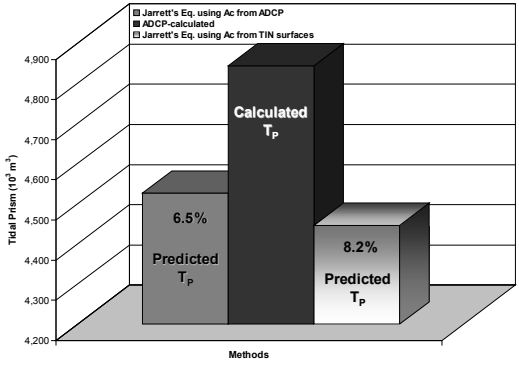

Figure 3. Bar graph illustrating differences in derived tidal prism values.

Based on the strong correlation found between ADCP-calculated and predicted T_P values over the first portion (March 2002 – October 2003) of the study period, Equation 1 was used as a tool to estimate T_P over the remainder of the study period (April 2004 – October 2006). No ADCP data existed for the inlet following October 2003. Utilizing the limited ADCP data acquired in the field, a mean T_P of 4.84 x 10^6 m^3 was calculated to exist between March 2002 and October 2003. Following this period, and based on six DTM-measured throat A_C values used with Equation 1, the inlet's T_P reduced over the second half of the study period to a mean value of 3.65 x 10^6 m^3. That mean value of 3.65 x 10^6 m^3 represents a reduction of T_P ranging 17 – 25% lower than values obtained during the first portion of the study.

A_C varied greatly over the entire length of the study. Initially, 1.6 years following relocation, changes in A_C varied considerably and averaged 46 m^2. However, over the latter portion of the study A_C changes diminished greatly and averaged 8 m^2.

Ebb-Tidal Delta Volume and Tidal Prism

Previous work by Walton and Adams (1976) described a strong correlation, by way of linear regression analyses, between the volume of sand stored in the ebb-tidal delta of an inlet and its T_P. According to their coastal energy classification scheme the inlets along the east coast of the U.S. (except in South Carolina), and Panhandle of Florida (Gulf Coast) fall within the moderately exposed coast range. T_P measurements used in their study were based on measurements from current data obtained at the throat of an inlet or by the "cubature method". The inlets analyzed in their study were considered equilibrated with respect to their surroundings. This study sought to compare ebb-tidal delta volumes derived from DTM surfaces to volumes ascertained from the empirical model of Walton and Adams' (1976). In order to accomplish this task, the mean ADCP-calculated T_P value was inserted in Walton and Adams' (1976) theoretical equation for moderately exposed coasts (Equation 2):

$$V_{ETD} = 10.5 \times 10^{-5} T_P^{1.23} \quad (2)$$

where: V_{ETD} = ebb-tidal delta volume (yd^3) and T_P = tidal prism (ft^3). The T_P value used in Equation 2 represents the mean of the T_P values (T_P = 4.43 x 10^6 m^3) calculated during each of the six ADCP throat surveys between July 2002 and October 2003. The March 2002 T_P value was not used in this analysis due to the artificial shape of the channel and the lack of an ebb shoal located offshore at that time. Using Equation 2 and the mean ADCP-calculated T_P, the resulting ebb shoal volume was predicted to be 963,000 m^3. The difference between this mean predicted V_{ETD} (963,000 m^3) and the final measured V_{ETD} (288,063 m^3) in October 2006 was approximately 70% (Fig. 4).

Ebb-Tidal Delta Volume and Cross-Sectional Area

As inlet throat A_C exhibits a direct correlation with T_P and is considered an easier inlet parameter to measure than T_P, Walton and Adams (1976) derived a correlation between volume of the ebb-tidal delta and A_C of the channel. In order to compare the

volume of material estimated in the ebb-tidal delta from DTM surfaces with the predictions of their empirical model, the mean DTM-measured A_C value was used in conjunction with Walton and Adams' (1976) theoretical equation for moderately exposed coasts (Equation 3):

$$V_{ETD} = 40.7\, A_C^{1.28} \quad (3)$$

where: V_{ETD} = ebb-tidal delta volume (yd^3) and A_C = cross-sectional area (ft^2). The A_C value used in Equation 3 represents the mean of the A_C values (A_C = 245 m^2) measured across the generated DTM surfaces between July 2002 and October 2006. The March 2002 A_C value was not used in this analysis due to the artificial shape of the channel and the lack of an ebb shoal located offshore at that time. Based on Equation 3 and the mean A_C measured across the DTM surfaces, the resulting predicted ebb shoal volume was 745,000 m^3. Comparisons of the individual measured V_{ETD} values with this predicted V_{ETD} (745,000 m^3) revealed that the initial July 2002 V_{ETD} (136,752 m^3) comprised only 18% of the predicted volume. By the end of the study, the shoal increased in size with an (October 2006) V_{ETD} measuring 288,063 m^3 and comprising only 39% of the predicted volume.

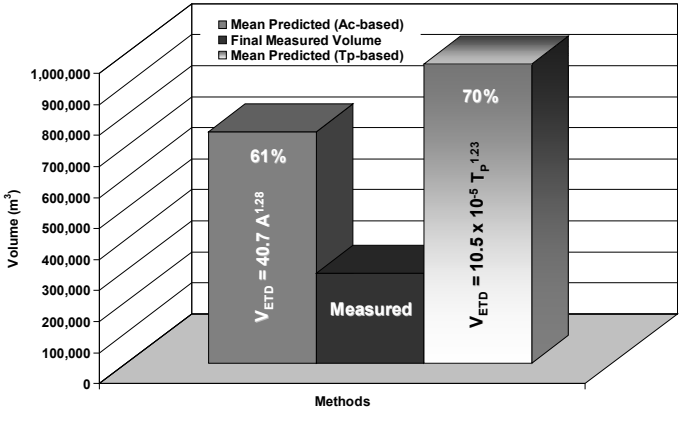

Figure 4. Bar graph illustrating differences in derived ebb-tidal delta values.

DISCUSSION

The regression equations of Jarrett (1976) and Walton and Adams (1976) have been used in this study to predict parameters for inlet conditions. Applicability of these equations to the newly developing system were assessed and provided a "measuring stick" of where the inlet and the parts that comprise it rank with regard to stability/equilibrium. These relationships provided insight into the performance of inlet.

Upon consideration of Jarrett's (1976) A_C and T_P relationship, a high correlation (r = 0.97) between predicted T_P, based on Equation 1 and A_C measured by the ADCP, and individual ADCP-observed T_P values shows a relationship indicative of the comparativeness of these two different methodologies for estimating tidal prism. The percentage differences (7% and 8%) between the ADCP-calculated T_P and Equation 1-derived T_P values are most likely related to extraneous factors such as wind and waves (Fig. 3). From a management perspective, the importance of using this tool is evident when considering that it approximates the potential T_P of the inlet. An adequate T_P is required to flush water through the inlet and reduce the tendency of inlet closure due to clogging of the backbarrier. The 2D hydrodynamic model used in the design phase of the relocation predicted that the relocated inlet would assume an equilibrium T_P of approximately 5.2 x 10^6 m^3 (Erickson *et al*., 2003). The current study revealed that this value has not been assumed. In fact, the latter half of the study indicated that T_P has apparently diminished from 4.84 x 10^6 m^3 to 3.65 x 10^6 m^3 (30% less than predicted by the 2D model). Infilling and shoaling of the backbarrier are believed responsible for T_P reduction and will impede the inlet from attaining the predicted T_P it was originally designed to sustain.

Another implication worthy of consideration is the issue of A_C equilibrium. Jarrett's (1976) empirical relationship was based on inlet A_C's equilibrated to their unique surrounding conditions. Obviously, this becomes an issue of concern for the current study. Unfortunately, there is no established definition for the determination of channel A_C equilibrium. Kana and Mason (1988) determined that the relocated Captain Sam's Inlet achieved channel A_C equilibrium within 250 days after opening with a measured equilibrium value within 5% of the area predicted by the empirical models of O'Brien (1969) and Jarrett (1976). Interestingly, the predicted values of A_C for Mason Inlet began closely approximating the measured A_C values (0.5% difference) 477 days after inlet opening and continued to remain at <8% difference for the remainder of the ADCP-portion of the study. Due to the high correlation (r = 0.97) between the individual ADCP-measured A_C values and the calculated A_C values, equilibration of the channel A_C was plausible. Considering Jarrett's (1976) equation was based on equilibrated A_C values supports this assumption. Based on findings by Kana and Mason (1988) for a relocated inlet with similar physical parameters and considering the high correlation (r = 0.97) between predicted and measured A_C's, it seems Mason Inlet assumed an equilibrated cross-section early in its post-relocation development. Unfortunately, with the lack of ADCP data after October 2003, continued monitoring of whether the actual measured throat section continued to remain close to predicted values proved impossible. Consequently, whether or not an equilibrated cross-section remained after October 2003 could not be determined.

Analyzing development of the ebb-tidal delta can further determine whether or not the inlet has achieved equilibrium within the period of study. Development of the ebb-tidal delta can be grouped into a period of initial accretion followed by volumetric loss. Although varying in its rate of accretion the shoal continually experienced growth volumetrically during the 3.5 years after relocation. Relatively

large-scale losses occurred over the final year of the study with the shoal losing 152,000 m^3. Initial gains were expected; however, losses in the ebb shoal were not projected to occur until after an equilibrated state had been assumed. Erickson *et al*. (2003) predicted that within five years, the ebb shoal would be at 90% equilibrium volume, and natural sand bypassing would be nearly established. Maintenance dredging of the inlet during February 2005, within the backbarrier region, is believed to have led to many of the changes on the ebb shoal. Removal of 140,000 m^3 of material from the flood shoal and inlet throat during the maintenance event first phase directly affected the A_C by deepening and widening the throat. Removing material from the sedimentation basin, situated landward of the throat, created a potential "sink" for sediment deposition. Material excavated from interior areas was used to nourish the oceanfront beach along the southern extent of Figure "8" Island. It is believed that the large gain measured in April 2005 on the ebb shoal was directly related to erosion and subsequent transport of fill material placed along the oceanfront in early 2005. The current trend of shoal volumetric loss is believed related to the latent effects of material removal from the backbarrier as a part of the maintenance event. Wave attack and most likely an increase in T_P has resulted in sand from the ebb shoal being relocated into the inlet's interior. Until the interior shoals adequately gain material the ebb shoal will likely continue to deflate. Induced changes (e.g. maintenance event) serve to disrupt the natural, established flow regime and limit the use of Walton and Adams' (1976) model (based on equilibrated systems) for this inlet.

Equations 2 and 3, used in the prediction of V_{ETD}, were based on data from equilibrated inlet systems. The ebb delta volume in October 2006 remained well below the predicted volume at 288,063 m^3 (between 30–39% of the predicted volume depending on the regression equation used). Even the largest measured ebb delta volume of 440,421 m^3 (October 2005) did not approximate the equilibrium volume predicted. Thus, Walton and Adams' equations did not adequately approximate the V_{ETD} for this inlet. When comparing the predicted V_{ETD} values (963,000 m^3 and 745,000 m^3) derived from Equations 2 and 3 with the actual delta size 4.5 years after opening, it is obvious that the inlet either had not reached equilibrium or did not necessarily conform to Walton and Adams' (1976) model (Fig. 4).

Inlet equilibration alone is not the only factor that possibly accounts for this large discrepancy between actual measured and predicted V_{ETD} values. Inlet size must also be considered since Walton and Adams' (1976) regression analysis included a majority of inlets considerably larger than Mason Inlet. Kana and Mason (1988) discussed this issue at length in their study of Captain Sam's Inlet's ebb-tidal delta evolution. The aforementioned study mentioned several additional factors besides equilibration that may be responsible for the observed difference in V_{ETD} values. One of these variables was that many of the inlets used in Walton and Adams' (1976) study were larger Florida and Texas microtidal inlets that were positioned along "mildly exposed" coasts and therefore were expected to exhibit little movement (Kana and Mason, 1988). Captain Sam's Inlet is quite similar to Mason Inlet in that it is a relocated, small-migrating inlet whose ebb-tidal delta only attained 35% of the

predicted volume 2.2 years after opening. The effectiveness of Walton and Adams' equation, for Mason Inlet, is brought into question due to its small size and poor comparison between measured and predicted V_{ETD} values. However, with regard to Mason Inlet, it is concluded that the size/volume of the ebb-tidal delta is most likely less than that predicted due to a decreased T_P and modifications within the inlet interior leading to a non-equilibrated system. Induced changes within the inlet interior are assumed to affect sediment storage capacity of the ebb shoal as evidenced by the maintenance event.

Based on the findings and time frame of this study, Mason Inlet may have failed to attain an equilibrated state with the surrounding forcing parameters. Several implications associated with the impacts of a non-equilibrated system should be considered, as the inlet will continue to adjust to its surroundings. As the ebb-tidal delta continues to adjust volumetrically and the lagoon infills with sediment the updrift shoreline of Figure "8" Island will likely continue to erode as sand will be transported to the ebb shoal and/or into the backbarrier channels. In addition to sand impounded on the ebb shoal, material is permanently lost from the littoral system when transported into the backbarrier (Cleary and FitzGerald, 2003). Cleary and FitzGerald (2003) concluded in their study of relocated Mason Inlet that the continued tendency of sediment transport into the backbarrier is indicated by flood dominance of the inlet (stronger flood than ebb tidal currents), residual flood flow, and deposition of material within the inlet interior after relocation. If left to its own devices lagoonal infilling will continue and T_P will be reduced over time perhaps leading to inlet closure.

Some degree of inlet equilibrium must be attained. The system continues to exhibit flood dominance and infills with sediment creating an unstable situation. As a result, the inlet's T_P is decreased. Stipulations of the relocation agreement require the inlet to remain within a 305-m corridor and allow dredging for this purpose. Dredging the inlet's feeder channels will aid in keeping the inlet channel in place by providing a larger T_P and flushing through the inlet throat. However, if that material is placed on the updrift shoreline of Figure "8" Island it will likely be transported back into the inlet or to the ebb shoal. Excessive dredging could adversely compromise Figure "8" Island enlarging T_P enough to cause the ebb-tidal delta to require more sand from the updrift shoreline. For this system, finding an equilibration state that works well for the entire system will be challenging.

CONCLUSIONS

Several broad based conclusions are drawn from the study of Mason Inlet over 4.5 years following the artificial relocation of the system in Marc 2002. T_P has been variable in this evolving system and is highly correlated to changes in A_C of the throat ($r = 0.95$) and fluctuations in tidal range ($r = 0.87$). Jarrett's (1976) theoretical equation relating T_P and A_C appears to be a useful tool for estimation of the T_P. From a management perspective, the empirical equation of Jarrett (1976) is important and can be useful in showing that the potential T_P is decreasing. Whether or not the inlet A_C equilibrated remains in question.

The volume of sand in the new ebb-tidal delta after 4.5 years remained well below (61–70% below) the equilibrium volume predicted by Walton and Adams' (1976) empirical relationship. This discrepancy may be related to the inlet's failure to attain equilibrium and/or its inability to conform to Walton and Adams' (1976) empirical relationship due to its relatively small size. Volumetric losses measured on the shoal are believed linked to the maintenance event. Induced changes to the system, that serve to disrupt any degree of equilibrium the T_P and ebb shoal may share, eliminate the usefulness of Walton and Adams' (1976) equations here.

ACKNOWLEDGEMENTS

This research would not have been possible without the aid of countless individuals at the UNCW's Center for Marine Science. A genuine debt of gratitude is extended to the students in the Coastal Geology Lab particularly Ben McGinnis, Chester Jackson, Adam Knierim, Kenny Willson, David Doughty, and Leighann Budde. Special thanks are also extended to Chris Gibson of Gahagan & Bryant Associates, Inc. for graciously providing detailed bathymetric data and aerial photographs.

Abstract: Ancão Inlet (Southern Portugal) was relocated in 1997 and almost 10 years after its opening has the morphodynamic characteristics and migration pattern predicted by several authors. Its eastwards migration is mostly caused by high W-SW storm events, where the downdrift migration of the channel is accompanied by updrift spit growth and both deltas migrate asymmetrically. The inlet migration rates were computed between three new surveys and several inlet parameters measured, revealing the highest migration rates since inlet opening, an a relative stable inlet cross-section area, width and maximum depth at inlet throat through time. Inlet migration rate was compared with storm events and results showed a relation of this rate with the diminishing of E-SE storm events and an increase of magnitude of W-SW storms. Also, during an unusually powerful ex-tropical storm which affected the study area, an ephemeral inlet breached updrift from Ancão Inlet. The new inlet was competing for dominance of the tidal prism with Ancão Inlet, however it closed after three weeks, showing the hydraulic efficiency of Ancão Inlet nine years after its relocation.

INTRODUCTION

Tidal inlets are one of the most dynamic coastal features. The complex temporal and spatial interaction of waves, tides, and currents create and constantly modify the morphology and the sedimentary structure of tidal inlets. Despite being complex coastal systems and difficult to model, inlets are of extreme importance as navigation routes, as sediment suppliers to adjacent beaches, and as conduits that allow exchange of nutrients between backbarrier systems and the coastal zone (FitzGerald 1996).

Several engineering activities can be adopted in order to maintain an open inlet and avoid locational and/or geometrical instability and the subsequent coastal changes. Inlet relocation is a soft coastal management technique that, when applied to migrating inlets, involves the artificial opening of a new tidal inlet along the historic migration path of the inlet. This engineering technique was used to relocate Ancão Inlet (Ria Formosa barrier island system, Algarve, Southern Portugal).

In 1996 Ancão Inlet was in its limiting position (Vila-Concejo et al., 2004) showing severe infilling and meandering of the channel. Following a soft protection programme (Dias et al. 2003), the Portuguese Institute of Nature Conservation (ICN) decided to relocate the inlet 3,500 m to the west of its position in 1996. The new inlet was opened on 23rd July 1997. Since its opening, the new Ancão Inlet has been monitored and it was found to resemble the old inlet both in terms of its hydrodynamic characteristics and its morphology (Williams et al. 2003). According to Vila-Concejo et al. (2003; 2004), Ancão Inlet reached dynamic equilibrium one year after its opening (i.e. in July 1998) and has behaved like a natural inlet since that time.

Vila-Concejo et al. (2003) presented a four stage conceptual model for the natural evolution of artificially opened inlets (stage 1 is the artificially opened inlet; stage 2 corresponds to the developed inlet after reaching dynamic equilibrium; stage 3 represents the situation of a "natural" inlet after migration induced by normal longshore drift; and, stage PS "post-storm" represents the inlet morphological features after high-energy conditions). Williams et al. (2003) defined three morphological states based on three hydrodynamic regimes of Ancão Inlet which are synthesised in Table 1. H represents the wave conditions: H1 – non-storm conditions (prevailing fair-weather conditions), H2 – storm conditions for W-SW waves and H3 – storm conditions for E-SE waves.

Table 1. Three morphological states based on the three hydrodynamic regimes of Ancão Inlet (adapted from Williams et al., 2003)

Morphological state and frequency	Wave conditions
MOR 1 Ebb-tidally dominated period	$H1_A$: 90º<θ<180º, H_s <1 m, 4s <T_p <10 s
	$H1_L$: 180º<θ<270º, H_s <1 m, 4s <T_p <10 s
MOR 2 Post-storm wave-produced period	H2 245º<θ<275º, H_s > 3 m, 8s <T_p <18 s
	H3 120º<θ<140º, H_s > 3m, 6s <T_p <14 s
MOR 3 Transitional period	Establishment of $H1_A$ conditions

- H_s and T_p represent wave significant height and peak period, respectively
- $_A$ and $_L$ refer to mean Atlantic, W-SW and "Levante", E-SE, wave approach, respectively)

Morris et al. (2001) describes different morphological responses of Ancão Inlet and adjacent areas to the different hydrodynamic conditions, considering the status of the inlet as a tide- or wave dominated system, encompassing relationships between inlet morphology and the present and/or antecedent hydrodynamic conditions. The proposed model was supported by different numerical models and field evidence including the morphological conceptual model latter developed by Vila-Concejo et al. (2003). Using

video techniques, Morris et al. (2004) proposed a conceptual morphological model for inlet seasonal behaviour with three model stages (post-storm, transitional and extended calm morphological stage) that are closely related with the incident waves.

The present paper is focused on analysing the morphodynamics of Ancão Inlet 10 years after its relocation and comparing them with the estimates of several authors for its evolution (i.e. migration trend, morphological behaviour, response to oceanographic conditions). In order to achieve this objective, three new topo-bathymetric surveys were performed and several inlet parameters analysed (cross-sectional area, channel orientation, migration trend, and morphological features). Additionally, on the 11th October 2005 the remains of a tropical storm named Vince impacted the study area. It caused the breaching of Ancão Peninsula, near the location where Ancão Inlet was relocated in 1997 and a new inlet (Vince Inlet) was formed. Data presented in this study will show how Ancão Inlet responded to Vince Inlet.

STUDY AREA

Ancão Inlet is located in the Ria Formosa that is a multi-inlet barrier island system located in Southern Portugal (Figure 1). The system consists of five islands and two peninsulas separated by six tidal inlets: two relocated inlets (Ancão and Fuseta inlets), two artificially opened and stabilised inlets (Faro-Olhão and Tavira inlets) and two natural inlets (Armona and Lacém inlets). The backbarrier is characterised by large salt marshes, sand flats and a complex network of natural and partially dredged channels, covering 8.4×10^7 m^2 (Andrade 1990).

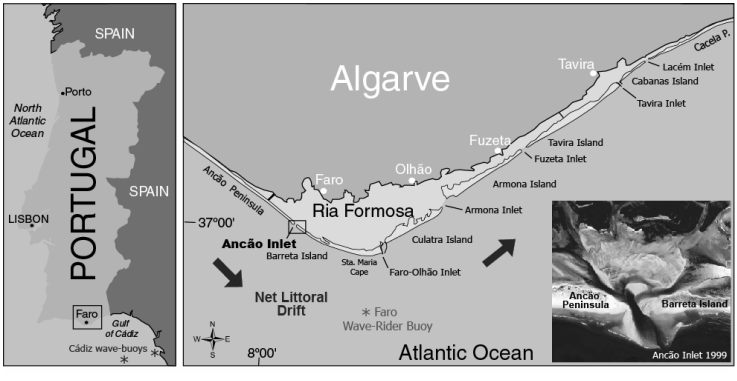

Fig. 1. Ria Formosa barrier island system (Algarve, Southern Portugal). In detail is a vertical aerial photo showing Ancão Inlet in 1999

Tides in the area are semi-diurnal, average ranges are 2.8 m for spring tides and 1.3 m during neap tides but maximum ranges of 3.5 m can be reached. Wave climate in the area is moderate to high (Ciavola et al. 1997). Predominant wave directions are from the W-SW, approximately 76%, while waves coming from the E-SE only account for 24%

of the observations (Costa et al. 2001). The dominant moderate sea state that prevails most of the time is sometimes disturbed by the occurrence of two types of storms: W-SW and E-SE storms. W-SW storms are associated with atmospheric low pressure centres in the south-eastern region of the North Atlantic Ocean, and occur mainly in winter, while E-SE storms occur when "Levante" (strong Mediterranean easterly wind) blows in the Gibraltar strait. "Levante" events may occur in all seasons and are of shorter duration (Pires 1998). The cuspate shape of the Ria Formosa system produces two areas differentiated in terms of exposure to wave action (Figure 1). The west flank is more energetic, being under the direct influence of dominant wave conditions (SW), while the east flank is only directly exposed to SE conditions.

Ancão Inlet is a small migrating inlet that has an average width of 300 m (Vila et al., 1999). The inlet undergoes a cyclic eastward migration (Weinholtz 1964; Esaguy 1986; Dias 1988; Pilkey et al. 1989). Vila-Concejo et al. (2002) analysed the historical development of Ancão Peninsula inlets from 1947 until 1996 and found that Ancão Inlet underwent two eastward migration cycles during this period. The eastward migration trends were very similar for both cycles, with the inlet showing an initial stage of readjustment (characterised by low migration rates), followed by a stage of high eastward migration rates, until reaching a limiting position; while migrating, Ancão Inlet maintains a stable cross-sectional area. This was distinguished as a high-energy migration pattern (HEMP) by Vila-Concejo et al. (2002; 2004).

METHODS

Inlet parameters

Since the relocation of Ancão Inlet a monitoring program has been carried out to study its evolution. Topo-bathymetric surveys were made from the opening (June 1997) until December 2002. The methodology and results of the monitoring program are presented by Vila-Concejo et al. (2003, 2004, 2006b) and included morphological, migration and channel evolution data (inlet width, depth and cross-sectional area).

Three new surveys were made at Ancão Inlet: June 2004, February 2005 and May 2006. These surveys included detailed topography of the adjacent barriers, ebb and flood shoals, as well as detailed bathymetry of the inlet and the adjacent channels (except February 2005 where detailed bathymetry was not possible for the entire area due to wave conditions). The topography was measured with a total station and a Real Time Kinematic DGPS (RTK-DGPS). Bathymetry was obtained by using an echo-sounder and the RTK-DGPS connected to a laptop, by using the HYPACK® 4.3a Gold software for data assimilation and navigation. The RTK-DGPS and echo-sounder were synchronised and measurements were taken at a frequency of 1 Hz. Using this system the recorded depth was immediately corrected for water level variations (i.e. tides and waves). Topographic and bathymetric data were then merged using SURFER® 8. A local metric co-ordinate system known as the Portuguese Melriça Grid (PMG) was used for the maps and the elevation is referenced to mean sea level (msl). Due to lack of bathymetric data, it was not possible to create a detailed topo-bathymetric map for the February 2005survey.

Key morphological parameters such as cross-sectional area (A_c), maximum depth (h_{max}), inlet width (I_w) and migration (M) were determined. This study followed the methodology proposed by Vila-Concejo et al. (2003) to allow comparison with previous studies.

Vila-Concejo et al. (2003) studied the inlet channel evolution in two different ways: (1) the inlet throat was defined for each map in order to analyse I_w, h_{max} and A_c below msl; and, (2) a longshore profile (profile 0 in Figure 2) was defined in order to analyse M by defining the changes of the location of the channel deepest point along the channel. All the gathered data, including those from by Vila-Concejo et al. (2003, 2004. 2006b) was stored and processed using GIS software (Arc View 8.3, ESRI software). The topo-bathymetric survey of 07/2001 was chosen as representative of the initial conditions to analyse the relation between inlet migration trend and the hydrodynamic conditions (measured between June 2001 and May 2006) for the present study.

Three periods were defined to compute M rate: June 2001-December 2002, January 2003-June 2004 and July 2004-May 2006. The last period was subdivided into two sub-periods (June 2004-February 2005 and March 2005-May 2006), in order to include the three new surveys performed and to study the particular effect of a W-SW Storm, the Vince storm. The M rate measurements, for each period and sub-periods, will be compared with the hydrodynamic conditions, in order to evaluate the impact of the most significant storm events.

Two RTK-DGPS topographic surveys were made to analyse the evolution of Vince Inlet that opened on 11/10/2005: these were undertaken on 26/10/05 and 04/11/05. The relative position of Vince Inlet and Ancão Inlet was measured using the maximum high water line (mhwl). The inlet width of both inlets was determined, as well as the distance between them. Additionally, several oblique photographs were obtained to analyse the morphologic evolution of Ancão Peninsula. Post-storm conditions were compared with those described by Morris (2001; 2004) and Vila-Concejo et al. (2003).

Hydrodynamic conditions

Tidal and wave data from the directional wave-rider buoy offshore of S^{ta}. Maria Cape (location 36º54.3'N, 07º53.9'W at 93 m depth, Figure 1) provided by the Portuguese Hydrographic Institute (IH) were used for this study. The buoy records values of significant wave height (H_s), peak period (T_p) and wave direction (θ) for 20 min each 3 h, except during storm periods when data were recorded every half hour. Matias (2006) individualised the storms from June 2001 to June 2004 (defined as $H_s > 3$ m by Pessanha and Pires 1981). The data from Matias (2006) allowed identifying the major storm events for the two first periods of analysis (June 2001-December 2002, January 2003-July 2004), which will be compared with the measured M rates. The same author also characterised the wave climate by applying linear wave theory to estimate deep-water wave power (P). Due to the orientation of the southern coast of Portugal θ is always between 90º and 270º. P was then partitioned according to θ: W-SW ($\theta > 180$º) and E-SE, "Levante" ($\theta < 180$º).

Detailed wave data between July 2004 and May 2006, in order to characterise the storm events for the third period, were not available. However, it was possible to individualise storm events (from W-SW and E-SE) by analysing on-line IH graphs (http://www.hidrografico.pt). It should be noted that there were some gaps in the wave data records. Data from two Spanish wave buoys located offshore of Cádiz (Figure 1) were used to analyse storm occurrence during the IH gaps in the data: a wave-rider buoy (36º28.8'N, 6º57.6' W at 450 m depth) and a triaxys buoy (36º30.0' N, 6º20.0'W at 21 m depth). WAM (Wave Analysis Model) data provided by the Spanish Port Authority (http://www.puertos.es) which generates wave climate using a wind atmospheric/hydrostatic model, were also used. The WAM network node has a point located offshore of Ria Formosa system (approximate location 36º45.0'N, 08º00.00'W), thus allowing a double check of the storm data provided by the Cádiz wave-buoys. This methodology did not allowed to compute neither P value and storm duration.

RESULTS

Inlet parameters evolution

In June 2004 (Figure 2a) the inlet had a narrow updrift spit extending offshore and NW-SE oriented channel. In May 2006 (Figure 2b) the inlet's updrift margin was characterised by strong sediment accumulation. The channel is SSW-NNE oriented. In both maps the inlet presents all the features of a well developed inlet: well defined main and adjacent channel, ebb and flood-tidal shoals.

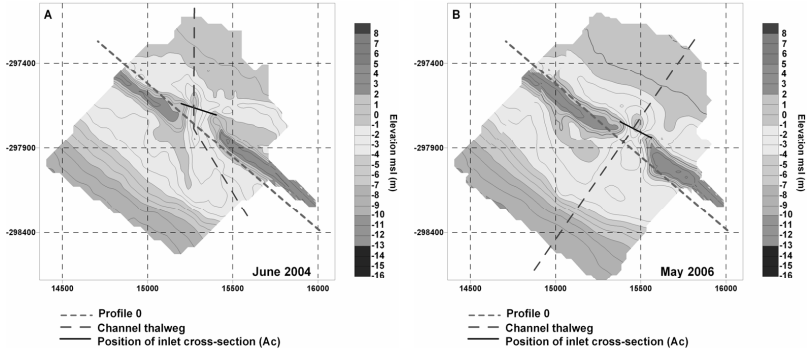

Fig. 2. Topo-bathymetric maps obtained for Ancão Inlet in June 2004 (a) and May 2006 (b). Metric co-ordinates refer to the Portuguese Melriça Grid. Elevation, in meters, is relative to msl.

Recent data show stable A_c values in accordance with previous data obtained by Vila-Concejo et al. (2003; 2004; 2006b, Figure 3). I_w also present small variations, with a minimum in April 2001, after which the inlet recovers to its normal width by May 2006. The survey performed in November 2001 presents the highest h_{max} and has been decreasing towards previous values since then. The A_c and h_{max} parameters, measured for the surveys performed in June 2004 and May 2006 (Figure 3), do not show

significant variations, although the occurrence of the ex-tropical storm Vince (11th October 2005). However, some increasing of I_w is observed.

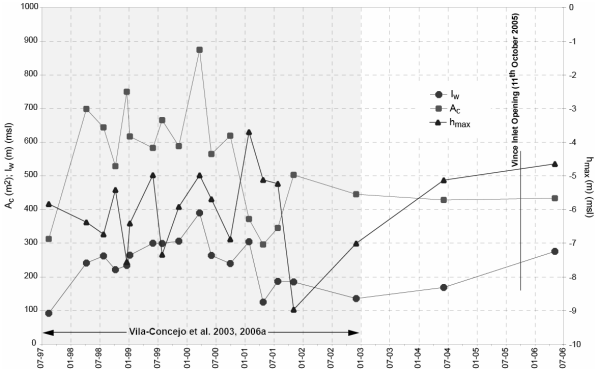

Fig. 3. Evolution of inlet cross-section (A_c), inlet width (I_w) and maximum depth at inlet throat (h_{max}) between August 1997 and May 2006

Inlet channel positions for the three recent surveys were plotted together with data from Vila-Concejo et al. (2003, 2004, 2006b) in relation to the Inlet Opening Position (IOP), and M rates obtained (Figure 4). The I_w, measured between the mhwl, was 50 m for Vince Inlet (shadow area, Figure 4) and 180 m for Ancão Inlet, showing that Ancão I_w did not significantly changed because of the storm (if compared with June 2004, Figure 3).

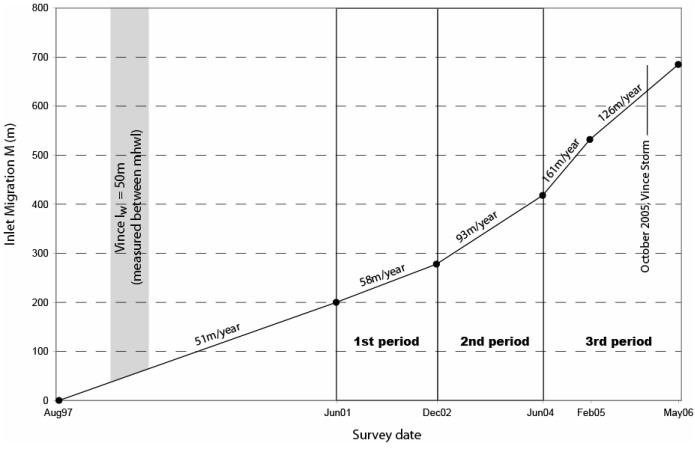

Fig. 4. Inlet migration from its opening position (IOP) until May 2006. The shadow area represents the relative Vince Inlet position and I_w in 26th October 2005

The inlet channel migrated approximately 685 m eastwards from its opening position (IOP) up until May 2006, which implies an 80 m/year migration rate. During the first period of this study (June 2001-December 2002), the inlet migrated ≅ 60 m/year, approximately the same rate measured between IOP and May 2001 (Figure 4). From January 2003 until June 2004 (2nd period), is observed an increase on M rate (≅ 95 m/year, Figure 4). The third period, divided into two sub-periods, present the highest M rate (≅ 140 m/year). The 3rd period M rate is higher between July 2004 and February 2005 (≅ 160 m/year, Figure 4), decreasing to ≅ 125 m/year between March 2005 and May 2006.

Hydrodynamic conditions

The number of storms from each sector (E-SE and W-SW) is shown in Table 2. Data for the two first periods (Jun01/Dec02 and Jan03/Jun04) were obtained from Matias (2006), and include total storm duration and P for all data. The most energetic storm from each sector is also in Table 2 taking into account maximum H_s and maximum storm duration. The H_s and storm duration can or cannot be coincident, i.e., a storm with higher H_s can have a lower duration and vice-versa. Storm data for the third period (Jul04/May06) were obtained from IH and Spanish port authority online graphs and the WAM model. Although it was possible to individualise storm events using maximum H_s, it was not possible to identify its duration and obtain P.

Table 2. Number of storm events from E-SE and W-SW for the three studied periods

Periods	E-SE Storms				W-SW Storms			
	Nº	Hours	Highest H_s (m)	Highest Duration (hh:mm)	Nº	Hours	Highest H_s (m)	Highest Duration (hh:mm)
Jun01/Dec02†	7	≅139	4.9 (17/12/01)	42:00 (19/10/02)	7	≅103	4.8 (17/12/02)	34:44 (17/12/02)
Jan03/Jun04†	3	≅30	5.7 (16/03/03)	25:43 (16/03/03)	11	≅103	4.2 (13/04/03)	39:45 (27/10/03)
Jul04/May06‡	8	*	4.0 (09/10/04)	* (09/10/04)	9	*	5.5 (11/10/05)	*

†adapted from Matias (2006)
‡obtained from IH and Spanish Port Authority online graphs and WAM model
*not possible to identify storm duration

During the first period (Jun01/Dec02), data obtained by Matias (2006) allowed the identification of seven storms from E-SE and seven from W-SW. The total duration was higher for storm events from E-SE than from W-SW. The maximum H_s recorded was 4.9 m for an E-SE storm event on 17th December 2001, however the maximum P was obtained for a W-SW event on the 17th December 2002 (≅150,000 $Jm^{-1}s^{-1}$, Matias 2006).

A small number of E-SE storms occurred during the second period (Jan03/Jun04), both in terms of events and duration (three storm events for a total duration of ≅30 hours). However, maximum H_s and P were recorded for an E-SE event occurring on 16th March 2003 (H_s=5.7 m and absolute P value >240,000 $Jm^{-1}s^{-1}$). The total duration of storm events from W-SW was the same as for the previous period (Table 2), although with higher number of storms. It should, however, be noticed that the maximum H_s of W-SW storm events was lower.

Data obtained using IH on-line graphs and the wave buoys of Cádiz allowed the identification of 17 storms between July 2004 and May 2006 (eight from E-SE and nine from W-SW). In general, W-SW had higher H_s and data allowed to individualise five storms with $H_s \geq 4$ m. The biggest storm, in terms of H_s, corresponds to ex-tropical storm Vince (11th October 2005). The storm, from W-SW, had an approximate duration of 16 hours and H_s of 5.5 m.

Plotted M rate values with maximum H_s for storms from E-SE and W-SW, allows to observe a M rate increase from the first to the second period, join with the decrease on number of E-SE and increase of W-SW storms (Figure5). The M rate increases significantly from the second to the third period, however in this case there is more equilibrium between events from both directions, although maximum H_s for the E-SE events are significantly lower. On the contrary, W-SW presents higher H_s and an extreme event, Vince storm (Figure 5).

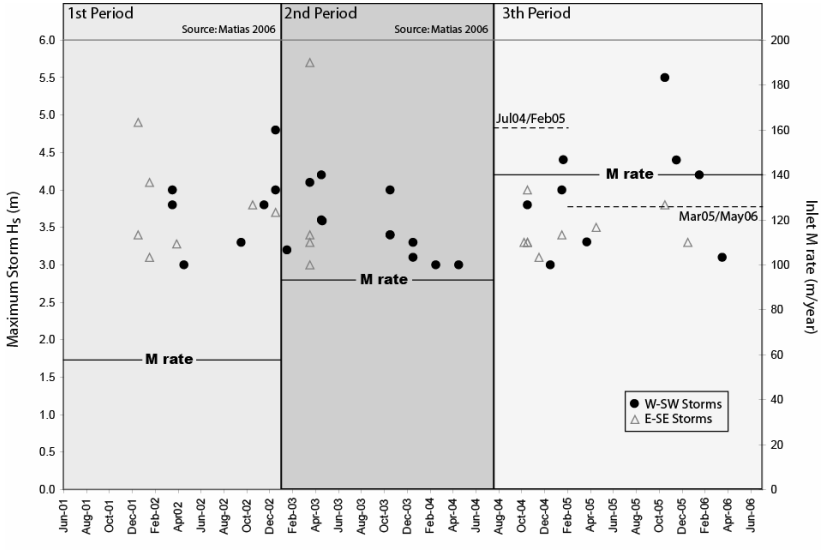

Fig. 5. Storm events between June 2001 and May 2006 plotted with M. The dashed lines marks the differences of M rate measured in the 3rd period.

DISCUSSION

The topo-bathymetric maps and the inlet parameters (Figure 2 and 3) show that despite the increase in M (Figure 4), the inlet has stable A_c, I_w and h_{max}. This is in agreement with Vila-Concejo et al. (2003, 2004, 2006b). The maintenance of a similar A_c represents that the overall inlet hydrodynamic behaviour was not affected by the migration, having a relatively stable tidal prism. Although the main channel presents different thalweg orientation (Figure 2), and some differences in I_w and h_{max} (Figure 3),

the inlet has a hydrodynamically efficient connection between the sea and the lagoon area, not being significantly affected by the wave-conditions and/or inlet migration.

Several storms occurred with different impact on M rates during the study period (June 2001 to May 2006). Morris et al. (2001) found that the combination of high tidal levels and storm events was a key factor for explaining the evolution of Ancão Inlet. The authors observed that a combination of large waves during spring high tide resulted in the most dramatic erosion of the vegetated areas on the downdrift margin. Once these areas erode, the inlet migrates rapidly. For the present paper more emphasis was given to the number of storms, storm duration and maximum H_s. It should be noted that a more detailed wave climate characterisation is needed in order to clearly individualise which storm events have impacted inlet behaviour, especially M.

During the 1st period (Jun01/Dec02) M rate was ≅60 m/year increasing to ≅95 m/year in the 2nd period (Jan03/Jun04). The duration of W-SW storms for both 1st and 2nd periods was about the same (≅103 hours); on the contrary, a decrease was observed in the number of E-SE storms (Figure 5). Since the fair-weather conditions were the same for both periods, the decrease of E-SE events could be related to the increase in M rates.

Within the 1st and 2nd periods, two extreme E-SE events occurred (17/12/2001 and 16/03/2003), with high values of P. The magnitude of these storms has a return period greater than 25 and 100 years, respectively (Pires 1998). Although it is recognised that E-SE events do not have an impact as severe as the W-SW storms at Ancão Inlet (Morris et al. 2001), historical data show that the inlet can widen significantly in a westerly direction (Vila et al., 1999; Williams et al. 2003). Vila-Concejo et al. (2003) recorded 80 m westward inlet migration between July 1997 and April 1998, with an I_w increase of ≅150 m. Thus, it seems plausible that even if westward migration did not occur, the extreme E-SE events can be responsible by episodes of reverse longshore drift (from east to west), attenuating the high eastward migration rates.

Assuming that fair-weather conditions for each period remain approximately the same, and considering that 80% of inlet migration occurs during storms (Williams et al. 2003), regulated by duration, magnitude and tidal level (Morris et al. 2001; Vila-Concejo et al. 2004), it seems likely that the high frequency and magnitude of E-SE events could have been responsible by the lower M rate found in the first period.

In the 3rd period (Jul04/May06) equilibrium in the number of occurrence between E-SE and W-SW events is observed (Table 2). The methodology used to individualise maximum H_s did not allow storm duration to be accurately obtained. It should be noted that the maximum H_s for E-SE storms was 4.0 m (Table 2). W-SW storms had higher magnitude and M was ≅140 m/year, showing a rapid eastward inlet migration that seems to be caused not only by ex-tropical storm Vince but also by the occurrence of four other storms with H_s ranging between 4-4.5 m (Figure 5). In fact, the highest M rate was recorded before the occurrence of the Vince storm (between Jul04/Feb05, M ≅160 m/year, Figure 4), raising the possibility of the occurrence of a W-SW storm

with higher duration and P, possibly during spring-tides (as suggested by Morris et al. 2001), which could have been responsible for the significant increase of the M rate. Thus, the Vince storm, although responsible for the opening of an ephemeral inlet updrift from Ancão Inlet, does not seem to be directly responsible for the high increase of the M rate found during the 3rd period. Possibly it effect could have been greater if the storm impacted the coast during spring-tides instead of the observed neap-tides (tidal amplitude of 1.2 m).

The Ancão Peninsula is a prograding feature owing to the net easterly sediment transport (Williams et al. 2003). Inlet migration is directly related to this fact. As occurs in other tidal inlet systems, the underlying, first order driving mechanism of the evolution of Ancão Inlet is related to storm events. A storm forces morphological changes so that the inlet moves from an essentially ebb-tide dominated condition to a wave-dominated condition (Morris et al. 2001, MOR1 under $H1_A$ Table 1). Following the passage of the storm, the inlet must then adjust its morphology back to a configuration determined by fair-weather conditions. The topo-bathymetric map of May 2006 (Figure 2) shows the inlet developing a fair-weather morphology, presenting the typical morphologies described by Williams et al. (2003) and Morris et al. (2004).

Morris et al. (2004) identified several post-storm morphodynamic features that can be also observed in Figure 6, an oblique photo taken after Vince storm: a down-drift orientation of the inlet channel, an inner sand spit developing in the backbarrier intertidal area of Barreta Island and a narrow across-shore ebb delta. After a series of winter storms, the inlet takes approximately three months to adjust back to its preferred fair weather condition configuration determined by fair-weather conditions (MOR 1, Table 1, Williams et al. 2003).

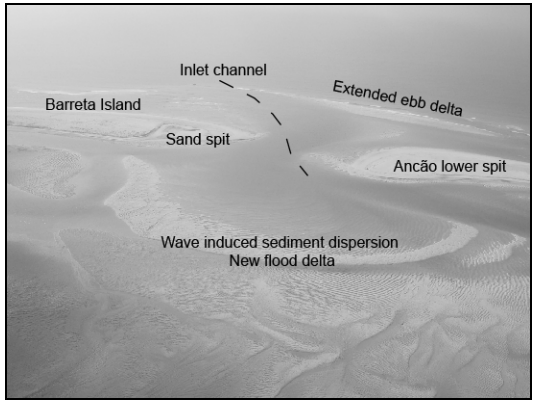

Fig. 6. Ancão Inlet at the end of November 2005, after the Vince storm, exhibiting the typical morphology of the post-storm morphodynamic conditions described by Morris et al. (2004).

Ancão Inlet exhibits a HEMP migration pattern (Vila-Concejo et al. 2002; 2006a). Figure 7 shows two aerial photographs of Ancão Inlet separated by eight years: Figure 7a shows Ancão Inlet one month after the relocation (08/1997) and Figure 7b one month after the Vince storm (11/2005). In the first the initial formation of the channel and a well developed dune field on Barreta Island can be observed. In the second the high eastward migration of Ancão Inlet and the development of a low-elevation spit on Ancão Peninsula can be observed. The dune field on Barreta Island has disappeared completely. The downdrift inlet area, due to its morphology, also has a high susceptibility to non-storm overwash events (Matias 2006). Vila-Concejo et al. (2006a) included the entire length of Ancão migration path inside the Inlet Hazard Area for the Ria Formosa.

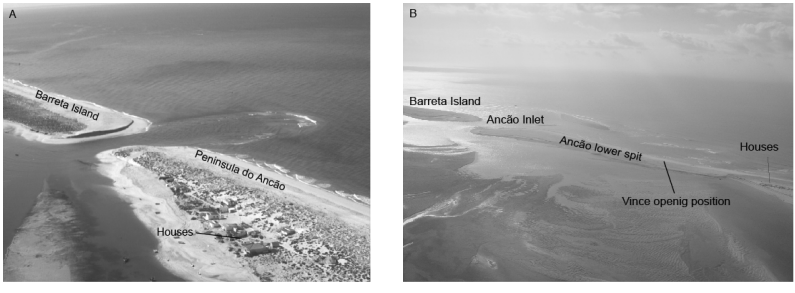

Fig. 7. Photos of Ancão Inlet at two times during its eastward migration cycle: A was taken one month after inlet opening (08/1997). B one month after the Vince storm (11/2005)

CONCLUSIONS

About 10 years after relocation, Ancão Inlet evolution and hydrodynamics were studied by using three new surveys. The obtained data was compared with previous data obtained by other authors. According to the morphological model proposed by Vila-Concejo et al. (2003), the Ancão Inlet is now in Stage 3, i.e., a "mature" migrating inlet, where the downdrift migration of the channel is accompanied by updrift spit growth and both deltas migrate asymmetrically. This stage is characterised by high eastward migration rates, as seems to be the case of the present inlet evolution without any significant changes in inlet parameters. During the study period an extreme event on 11th October 2005 was responsible for the opening of a small inlet in approximately the same place where the Ancão Inlet had been relocated in 1997. This ephemeral inlet remained open for three weeks before closing, showing the high hydraulic efficiency of Ancão Inlet. Migration rates obtained for Ancão Inlet with the three new surveys were the highest recorded since inlet opening. Although data presented within this study did not allow the direct relation of the inlet migration rate with the hydrodynamic data, some considerations can be made on the effect of storms in inlet behaviour: (1) a decrease on the number of E-SE storms seems to cause an increase of the inlet migration rates; and, (2) the Vince storm, although impacting on the M rate, did not seemed to be the major cause of the increase of this parameter, being probably related with a higher frequency of W-SW storms with $H_s > 4$ m.

ACKNOWLEDGEMENTS

This work is a contribution to the IDEM project – Inlet Dynamics Evolution and Management at the Ria Formosa, under contract POCI/MAR/56533/2004. Wave data from 2001 to 2004 was kindly provided by the Instituto Hidrográfico. The Ancão Inlet data corresponding to December 2002 was kindly supplied by the Instituto Portuário dos Transportes Marítimos de Portugal. The authors would like to thank Ana Matias for supplying the wave data treatment and also to Luis Pedro Almeida, Juan Severino Ibanhez and Piet Haerens, as well as to all CIACOMAR team, for helping during fieldwork. Thanks also to Brad Morris for his useful suggestions.

THE INFLUENCE OF TIDAL PRISM AND VEGETATION ON TIDAL CHANNEL MORPHOLOGY: IMPLICATIONS FOR MARSH STABILITY

Abstract: A peculiar feature of tidal channel networks is that their geometry (e.g. channel length, width, density) scales better with watershed area than tidal prism. Platform elevation has little control on network morphology, suggesting that relative platform deepening following sea level acceleration or sediment supply reduction will not cause significant changes to the channel network, despite field observations to the contrary. We explain this paradox with a numerical model of platform and channel network evolution that incorporates feedbacks between vegetation and physical sediment transport processes. In the model, platform deepening stimulates vegetation growth, leading to more stable channel edges. In this situation, channels deepen rather than widen, leading to channel morphologies that do not reflect tidal prism. In an environment where sea level or sediment supply changes have significantly altered the platform elevation, vegetation disturbance will lead to rapid network expansion as channels return to a form determined by tidal prism.

INTRODUCTION

Networks of sinuous tidal creeks and channels typically dissect broad intertidal marshes. Channel networks carry water, sediment, and nutrients into and out of estuaries and on and off of vegetated marsh platforms (Rinaldo et al. 2004). Tidal creeks host many commercially and ecologically important fish and shell fish, and export organic material to estuarine and marine ecosystems (Turner 1977; Lynn et al. 1981; Costanza et al. 1989). In addition to ecological and economic interests, tidal networks often display beautiful morphologic patterns that are intellectually interesting. The evolution of

channel networks and the marsh platform that surround them are thoroughly coupled- the marsh elevation relative to sea level determines the volume of water flowing through the network, and the network distributes the sediment necessary for marsh accretion. Dense vegetation on the marsh platform and channel edges strongly influences the morphology of marsh systems by slowing water velocities, aiding platform accretion, and stabilizing creek banks (Fagherazzi et al. 2004).

Like terrestrial river channels, the shape and distribution of tidal creeks is largely controlled by the discharge of water passing through them. For example, tidal channel width and cross sectional area typically follow well established relationships with discharge (e.g. Rinaldo et al. 1999a). Tidal prism volume is defined as the volume of water passing through a single channel cross section during a tidal cycle. Drainage density, defined as the total channel length divided by the watershed area, increases as a function of tidal prism (Steel and Pye 1997; Marani et al. 2003; Novakowski et al. 2004). These types of relationships have contributed to the development of several morphologic models of channel network development and behavior (Allen 1997; Fagherazzi and Furbish 2001; D'Alpaos et al. 2007).

Recent analyses of remotely sensed channel networks have led to several insights regarding the processes that determine their morphology. One particularly interesting feature is that morphologic characteristics of tidal channels scale better with drainage area than tidal prism volume. For example, total network length increases linearly with drainage area at a rate consistent between several subbasins of the Venice Lagoon characterized by different elevations, vegetation, and tidal amplitude (Marani et al. 2003). On the other hand, network length increases linearly with tidal prism, but at a rate inconsistent among the different basins (Marani et al. 2003). Since tidal prism is determined by both the contributing watershed area, and the inundation height of water above the bed surface at all points within the watershed (e.g. Rinaldo et al. 1999a), Marani et al.'s (2003) measurements suggest that the relative elevation of the marsh platform is not an important influence on channel network morphology. Consistent with this interpretation, Hood (2007) analyzed the drainage density of 37 marsh islands, and found significant correlation with island area, but not island elevation. Moreover, Hood (2007) detected no significant relationship between island elevation and any channel metric, including channelized surface area, mainstem length, number of channels, or the outlet width of the largest channel.

Marani et al. (2003) and Rinaldo et al. (2004) hypothesize that the lack of influence of tidal prism volume on channel morphology reflects the ability for vegetation to "freeze" network morphology. Channel networks in marshes are thought to inherit much of their pattern from unvegetated mudflat or terrestrial sources (e.g. Friedrichs and Perry 2001). While mudflat channel networks are highly dynamic, channel networks bounded by a vegetated marsh surface tend to be highly stable. Indeed, channel migration is often nearly imperceptible in historical photographs (Marani et al. 2003 *and references therein*). However, we note that there have been several recent observations of channel expansion. Channel networks in New York (Hartig et al. 2002) and southeastern

England (Van der Wal and Pye 2004) have widened and lengthened dramatically, perhaps in response to local relative sea level acceleration.

The relationship between tidal prism volume and channel network morphology has significant implication for the response of channels to sea level and sediment supply change. Several numerical models predict that the elevation of the marsh platform, relative to sea level, will decrease in response to sea level acceleration or sediment supply reduction (Morris et al. 2002; Kirwan and Murray 2006; D'Alpaos et al. 2007). Platform deepening expands the tidal prism volume even as the drainage area remains constant (Kirwan and Murray 2006; Kirwan and Murray *submitted*). If changes in tidal prism volume cause changes in channel morphology, then channel networks should expand in response to sea level acceleration or sediment supply reduction. If, however, channel morphology does not respond to changes in tidal prism volume, then channel networks may be relatively stable to sea level and sediment supply change.

In this contribution, we present simple model experiments in which vegetation growth causes tidal channels to be unresponsive to tidal prism changes. In an environment undergoing relative sea level acceleration or sediment supply reduction, channel network morphologies will not reflect tidal prism volumes. In the model, this lack of response occurs because of stabilization of channel edges by vegetation that is more productive when the platform is deep in the tidal frame. Disturbance to vegetation, however, will tend to cause channels to return to a form determined by the tidal prism. In an environment where sea level or sediment supply changes have significantly altered the platform elevation, disturbance will lead to rapid expansion of the channel network and erosion of the marsh platform.

METHODS

To explore relationships between tidal prism volume and channel network morphology, we utilize a numerical model of tidal marsh evolution described in Kirwan and Murray (2006; *submitted*). The model simultaneously treats vegetation-influenced platform accretion and channel erosion processes, and is applicable over large spatial (km) and temporal (decades-millennia) scales. We have previously used the model to describe the response of platform morphology and accretion rates to changes in sea level rise rates.

Our basic approach is to model local elevation change calculated from erosion rates determined by simplified flow routing, and deposition rates determined as a function of water depth and the amount of vegetation growing in each cell. A model iteration begins with the marsh platform flooded to high tide level. We route water across the vegetated marsh platform and into the channel network according to a parametrically represented water surface. Flow directions on the platform are calculated according to the gradient of a constant curvature Poisson surface (Rinaldo et al. 1999b). In essence, the parametric water surface places watershed divides halfway between adjacent channels, and encourages platform flow perpendicular to the channel network. Within the channel network, flow is limited to cells with progressively decreasing along-channel distances to the outlet.

After all the water on the platform drains, local velocities are calculated by dividing the cumulative volume of water passing through each cell by cell width, depth at high tide, and a characteristic time period of high flow (see Kirwan and Murray *submitted* for details). We use $\tau_b = (\rho f_c v^2)/8$ to estimate bed shear stress (Dean and Dalrymple 1991). Erosion occurs when bed shear stress (τ_b) exceeds a critical value (τ_c=*0.4* N/m^2),

$$Erosion\ rate = m * \frac{\tau_b - \tau_c}{\tau_c} \quad (1)$$

where m is a constant equal to 0.0014 kg m^{-2} s^{-1} (Fagherazzi and Furbish 2001). Following Morris et al. (2002), the deposition rate in each cell is proportional to the vegetation biomass, B, and high tide water depth, d, of each cell. The deposition rate is additionally proportional to the concentration of suspended sediment, C_{ss}:

$$Deposition\ rate = (k_1 * C_{ss} + k_2 * B) * d \quad (2)$$

where k_1 (0.1848) and k_2 (0.000015) are proportionality constants adapted from Morris et al. (2002), and k_2 accounts for both the effect of sediment trapping by vegetation and the input of organic sediment.

We account for gravity driven processes such as creek bank slump by invoking a bed smoothing routine where sediment flux, $q_{s,g}$, is proportional to the slope, S, between neighboring cells:

$$q_{s,g} = (\alpha - \beta B) * S \quad (3)$$

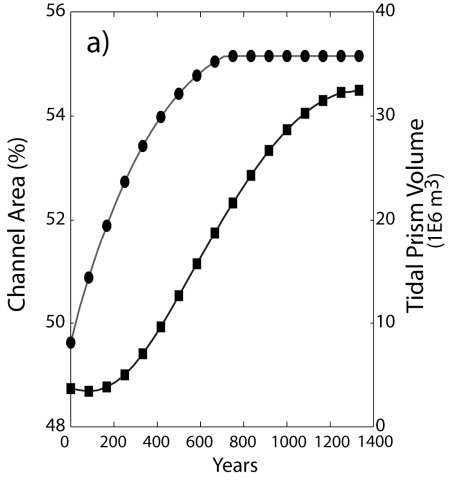
The term $(\alpha - \beta B)$ is a topographic diffusivity that depends on the biomass, B, in the higher elevation neighbor, representing the stabilizing character of plant roots. We use α = 3.65 m^2 yr^{-1} and β = 0.0019 m^4 g^{-1} so that the slope driven transport is reduced by approximately two orders of magnitude for the maximum biomass densities, conservatively consistent with field experiments on terrestrial river banks (Murray and Paola 2003; Kirwan and Murray *submitted*).

In the model, we use biomass productivity as a proxy for total above ground biomass (Morris et al. 2002). We calculate biomass productivity as a function of high tide water depth:

$$Biomass\ productivity = aD + bD^2 + c \quad (4)$$

where a=28.2236, b=-0.0927661, and c=-272.847, which have been adapted from Morris et al. (2002) to fit a 4m tidal range using the methods of McKee and Patrick (1998).

This relationship yields highest productivity rates at some optimum water depth. In nature, salinity appears to limit growth at suboptimum depths and anoxia appears to limit growth at supraoptimal depths (Morris et al. 2002). When water depths are suboptimal, this relationship leads to relative stability of tidal marsh elevation relative to sea level (Morris et al. 2002). An increase in water depth would promote greater productivity, and more rapid deposition rates. However, water depths nearing or exceeding the optimal depth may promote instability of tidal marsh elevation (Morris et al. 2002). In this situation, a small increase in depth would cause a decline in vegetation productivity, and a reduction in deposition rates, causing further lowering of the marsh platform relative to high-tide level.



We calculate deposition and erosion per tidal cycle at the end of each model iteration and multiply by a time step to calculate bed elevation change. A model iteration, explicitly representing a single ebb tide, is multiplied by 120 to achieve a time step of 2 months, assuming 2 tidal cycles per day. Under a constant rate of sea level rise, an equilibrium platform and channel network morphology develops where the net rate of accretion (deposition minus erosion) everywhere equals the rate of sea level rise, and water depths remain constant through time (Kirwan and Murray 2006; Kirwan and Murray *submitted*).

In this contribution, we conduct several model experiments on a 9 km^2 marsh system, discretized into 25 m^2 cells. Each experiment begins with an equilibrium morphology created under a constant, 1 mm/yr rate of sea level rise. We subject the equilibrium morphology to an abrupt 10 mm/yr rate of sea level rise, and examine changes in tidal prism volume and the morphology of the channel network. We exclude vegetation from one experiment, and include it in the other. Model experiments end when a new equilibrium morphology has developed.

RESULTS

As reported elsewhere, an abrupt increase in the rate of sea level rise leads to marsh platform deepening and an increase in biomass productivity in the model (Kirwan and Murray, 2006 Kirwan and Murray *submitted*). This deepening continues until deposition rates, a function of biomass and water depth, increase to the new rate of sea level rise. At this point the marsh platform reaches equilibrium with the rate of sea level rise, and water depths, accretion rates, and biomass productivity remain temporally constant (Kirwan and Murray 2006). An increase in the rate of sea level rise from 1mm/yr to 10 mm/yr leads to about a 30cm depth increase when vegetation is present, and a 300cm depth change when vegetation is absent (Kirwan and Murray *submitted*). This platform deepening, together with channel expansion, converts a basin characterized by channels bounded by intertidal surfaces into a completely subtidal basin. Throughout the experiments, we define the channel network, even in a subtidal environment, as cells that are connected to the outlet by other channel cells and are at least 20mm lower in elevation than the highest platform cells.

In all model experiments, platform deepening leads to expansion of the tidal prism volume (Figure 1). Following a change in sea level rise rate from 1 mm/yr to 10 mm/yr, the prism in the unvegetated scenario approximately quadruples (Figure 1a). This causes water velocities in the channel network to increase and the channel beds to deepen. Slope driven transport, representing processes such as creek bank slump, actively widens channels as they deepen. We observe that the channelized portion of the marsh system slightly increases from about 50% to 55% in response to the 10 fold increase in sea level rise rate (Figure 1a). In this model experiment, channel widening dominates the total increase in channel area, although formation of new channels or the elongation of existing channels could also increase channelized area.

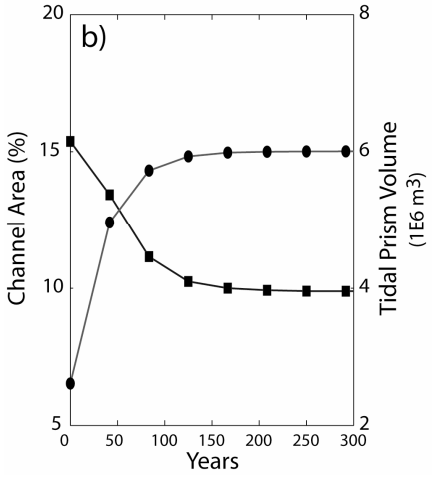


Fig. 1. Response of channel extent (squares, blue line) and tidal prism (circles, green line) to an abrupt increase in sea level rise rate. Vegetation is absent in a) and present in b). Platform deepening causes the tidal prism (green line) to increase in both scenarios, but stimulates biomass growth and resistance to creek bank slump in b). While an increase in tidal prism tends to enlarge channels (a), vegetation stabilization can exceed this effect (b).

Following a change in sea level rise rate from 1 mm/yr to 10 mm/yr, the prism volume in the fully vegetated scenario more than doubles in about 100 years (Figure 1b). While prism enlargement should tend to cause the channel network to erode and expand, we observe that the channelized portion of the marsh system decreases from about 15% to 10% over the same time interval (Figure 1b). We attribute this behavior to vegetation and its inhibition of channel widening processes. Increased platform depths cause increased biomass productivity and a decrease in gravity driven transport. Gravity driven transport processes determine channel width in our model, and in this experiment channels narrow in response to platform deepening.

Rather than eroding into the edges of a stable, vegetated platform, the modeled channel network accommodates the increased channel flow by eroding its bed and becoming deeper (Figure 2). In the vegetated scenario, the depth below high tide of channel cells increases about three-fold until a new equilibrium morphology develops. Therefore, the primary channel network response to sea level acceleration or sediment supply reduction is a decline in channel width-to-depth ratio.

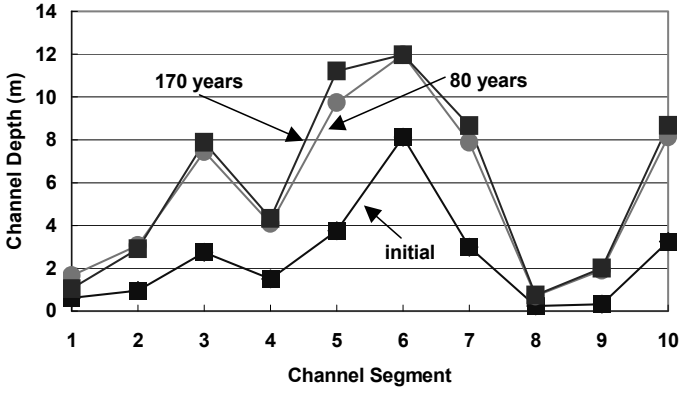

Fig. 2. Response of channel depth to an abrupt increase in sea level rise rate. Channel depths at representative points throughout the network measured as the difference between bed elevation and high tide.

DISCUSSION

Our model experiments suggest that tidal channels are responsive to tidal prism changes in the absence of vegetation, but unresponsive when vegetation is present. These experiments suggest that channel networks responding to increased rates of sea level rise, or decreased sediment supply, will have morphologic properties that do not reflect the current elevation of the marsh platform or tidal prism volume. The diversion of rivers flowing into Venice Lagoon, and the construction of dykes on the Skagit River Delta have resulted in decreased sediment delivery to marshes in these estuaries, and substantial lowering of marsh elevations relative to sea level (Marani et al. 2003; Hood 2007). A change in vegetation productivity in response to deepening could explain the disparities between tidal prism and drainage density in the Venice Lagoon (Marani et al. 2003) or the lack of correlation between platform elevation and any channel metric on the Skagit River Delta (Hood 2007). If true, these channel networks may be considered to be out of equilibrium with their present forcing conditions.

If enhanced vegetation growth leads to channels that are both narrower and deeper than their tidal prism would predict, then disturbance to vegetation may lead to significant morphologic change as channels adjust back to a form determined by prism volume. To address this possibility, we subjected the vegetated marsh surface at equilibrium with a 10 mm/yr rate of sea level rise to random vegetation disturbance. The disturbance consisted of removing all biomass in randomly selected platform cells (totaling 50% of all platform cells) and allowing it to grow back in disturbed cells after 10 years. As in previous simulations, the experiment ended when the platform and channel network morphology reached a new equilibrium.

Immediately following the initiation of disturbances, both the tidal prism and the channel network expanded (Figure 3). Unvegetated cells accreted more slowly than the

rate of sea level rise, leading to platform deepening and expansion of the tidal prism, even though the rate of sea level rise did not change. In this experiment, the tidal prism expanded only slightly, while the channelized area of the marsh system expanded from about 10% to about 60% in less than a hundred years. This suggests that channels expanded in response to increased gravity driven transport in disturbed cells, rather than in response to disturbance-generated tidal prism change. While additional model experiments should be conducted, a channel network out of equilibrium with platform morphology (i.e. network deeper and narrower than the platform elevation and tidal prism would determine) likely enlarges more than a channel network already at equilibrium with platform conditions. If true, disturbance to vegetation represents a process that can cause the channel network to regain a morphology that scales with platform elevation and tidal prism volume.

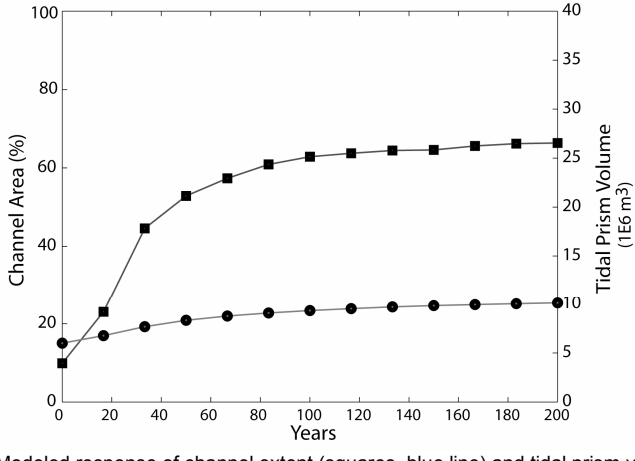

Fig. 3. Modeled response of channel extent (squares, blue line) and tidal prism volume (circles, green line), in a marsh at equilibrium with a 10 mm/yr rate of sea level rise, subjected to random vegetation disturbance (starting at time 0). While changes in the rate of sea level rise cause channel networks in fully vegetated marshes to abandon a plan view morphology determined by the tidal prism volume (e.g. figure 1), vegetation disturbance causes the network to return to a morphology determined by prism volume. In this case, vegetation disturbance leads to slight tidal prism enlargement, but large and rapid channel network expansion.

The disturbance experiment demonstrates that large and rapid changes in channel network morphology can occur after the marsh platform and channel network have stabilized in response to prior changes in sea level rise rates. This behavior is at least consistent with observed channel widening and elongation in New York (Hartig et al. 2002) and Southeastern England (Van der Wal and Pye 2004). In these regions, channels have expanded significantly over the last 50 years, despite accretion rates that mimic or exceed sea level rise rates.

Increased productivity of vegetation at greater water depths, and the ability of vegetation to resist channel widening processes, may have prevented network expansion in some marshes that have recently experienced increased sea level rise rates or decreased sediment delivery. If vegetation remains nearly intact, our model experiments suggest that drainage density will not reflect tidal prism volume. The resulting deep and narrow channels, however, may be particularly prone to vegetation disturbance. If disturbance to vegetation becomes more prevalent, our model experiments suggest that channels that have shown little response to sea level or sediment supply change in the past may widen dramatically in the future. Therefore, changes to channel depth may represent an initial stage of a channel network's response to accelerated sea level rise or sediment reduction. In this case, measurements of channel depth, or width-to-depth ratio, may forecast future change.

CONCLUSION

Our model experiments suggest that channel network morphologies will not reflect tidal prism volumes in an environment that has experienced accelerated sea level rise or sediment supply reduction. In these situations, vegetation productivity increases and channel edges become more stable as platform elevations become deeper in the tidal frame. In the continued presence of vegetation, channels respond to sea level acceleration or sediment supply reduction by deepening rather than widening. The resulting network geometry is metastable, prone to rapid change following vegetation disturbance. If relative platform elevations have changed significantly, vegetation disturbance can trigger widespread channel widening and elongation, as the network returns to a form determined by tidal prism.

NATURAL AND ANTHROPOGENIC INFLUENCES ON THE MORPHODYNAMICS OF BIG SARASOTA PASS, FLORIDA

Abstract: Both natural and anthropogenic factors have played a role in producing the present morphodynamic conditions at Big Sarasota Pass. This inlet, of unknown origin and age, is located between Lido Key, a recently nourished barrier island, and Siesta Key, a classic drumstick barrier island. Stabilization of the south channel margin in the 1960s has resulted in an increase in the southerly shifting of the ebb-tidal delta which has produced a narrow and shallow outer channel. This has caused inlet bypassing of sediment to move beyond the updrift end of the island as is typical of natural offset inlets. The nourishment of Lido Key on the updrift side of the inlet has further exacerbated this condition with the result being erosion on the north end of Siesta Key and considerable accretion several hundred meters to the south.

INTRODUCTION

The west-central Gulf Coast of the Florida peninsula contains a wide range of barrier-inlet morphologies and is arguably the most complicated such system in the world (Davis 1987). This is the consequence of the low tidal range and wave climate coupled with a range of three orders of magnitude in tidal prism, the combination of which produces both stable and unstable inlets along with wave-dominated and mixed-energy barrier islands. The barrier inlet complex displays a generally north-to-south longshore transport of sediment except for a few local reversals (Davis, 1999).

The development of the barrier islands for residential and commercial purposes began after World War II (Fig. 1) with streets, infrastructure and residential construction

becoming widespread within a decade. At Lido Key significant anthropogenic impact began in the early 20th century when John Ringling filled a series of shoals and mangrove islands to make Lido Key and St. Armands Key just landward of it. This focused a geographically dispersed tidal prism into both New Pass on the north and Big Sarasota Pass on the south of Lido Key. Siesta Key, a classic drumstick barrier island, had its north or updrift end protruding well beyond Lido Key in the typical downdrift offset morphology of mixed-energy barrier/inlet systems (Fig. 1).

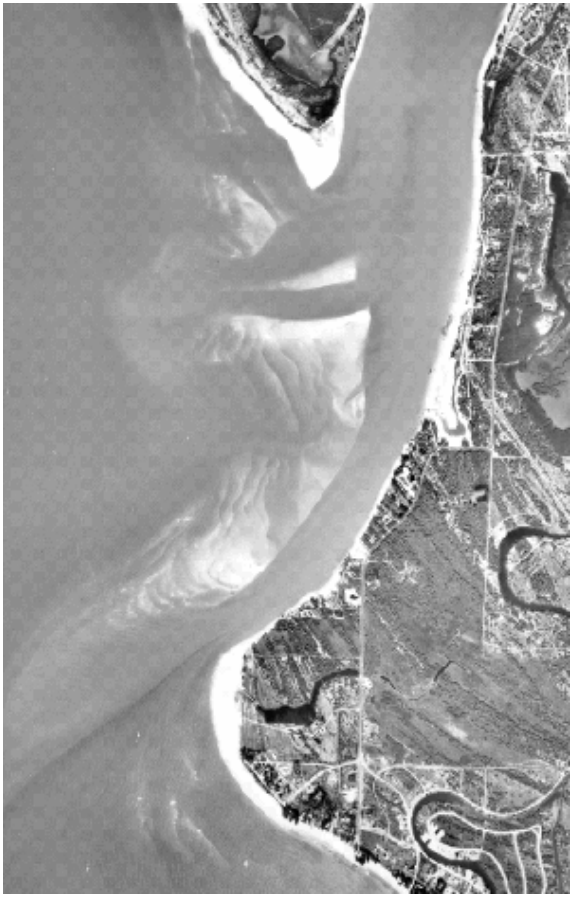

Fig. 1 – Aerial photograph of Siesta Key taken in 1948 showing the beginnings of development on the island overprinting the beach/dune ridges. Note also the flood channels cutting the ebb delta and the accretion at the north (right) end of Siesta Key.

The resulting inlet morphology was one of a strongly asymmetrical ebb-tidal delta (Fig. 1) and a southerly migrating tidal inlet (Big Sarasota Pass). The general process-response systems at such an inlet include the downdrift transport of sediment along the updrift barrier with significant sediment transported around the ebb-tidal delta thereby bypassing the tidal inlet with the remainder of the sediment carried across the ebb delta and into the main channel. Waves from the dominant northerly direction are refracted around the ebb delta causing a local reversal of longshore currents and resulting in a sediment sink at the end of the downdrift adjacent barrier island (Hayes 1974), in this case Siesta Key. This set of conditions produces prograding beach/dune ridges on the downdrift island as seen in Fig. 1.

HISTORICAL CHANGES

This discussion will consider both the natural and anthropogenic changes and consequences for Big Sarasota Pass and its associated barrier islands beginning with the first well-documented chart of 1883.

Predevelopment

The age and origin of Big Sarasota Pass are unknown although the age of adjacent Siesta Key has been documented at about 3000 BP by Stapor et al (1988). The prograding beach/dune ridges are at least 2000 years old implying that the inlet is at least that old. The first accurate chart is from 1883 and shows that Big Sarasota Pass is a maximum of 7 m deep with the shallowest part of the main channel being 2.3 m deep at the Gulfward end. The main channel deepened by the time of the 1953 survey to a maximum of 8 m deep and a minimum of 3.7 m. The first aerial photos available were from 1943 and show the pristine barriers on either side of the curved inlet. It is obvious from the early charts and this photo that the inlet channel is asymmetrical with the thalweg on the south or downdrift side. A plot of the inlet thalweg position shows a southerly migration over the period of record to that time (Fig. 2).

Development Stage

Road construction and other infrastructure installation began shortly after World War II. By the late 1950s there were many residences and commercial buildings present (Fig. 3). Landowners along the north end of Siesta Key along Big Sarasota Pass began to stabilize the shoreline using a combination of seawall, riprap, and groin field to prevent migration of the inlet channel into their property. This private and non-integrated effort did stop migration of the Big Sarasota Pass channel (Fig. 2) and the structures have remained in place to the present time.

Coupled with the stabilization of the south channel margin was the growth of the ebb-tidal delta at Big Sarasota Pass. Initially there were well-developed flood channels that crossed the large asymmetrical ebb-tidal delta (Fig. 1). These channels transported tidal prism and sediments into the main channel.

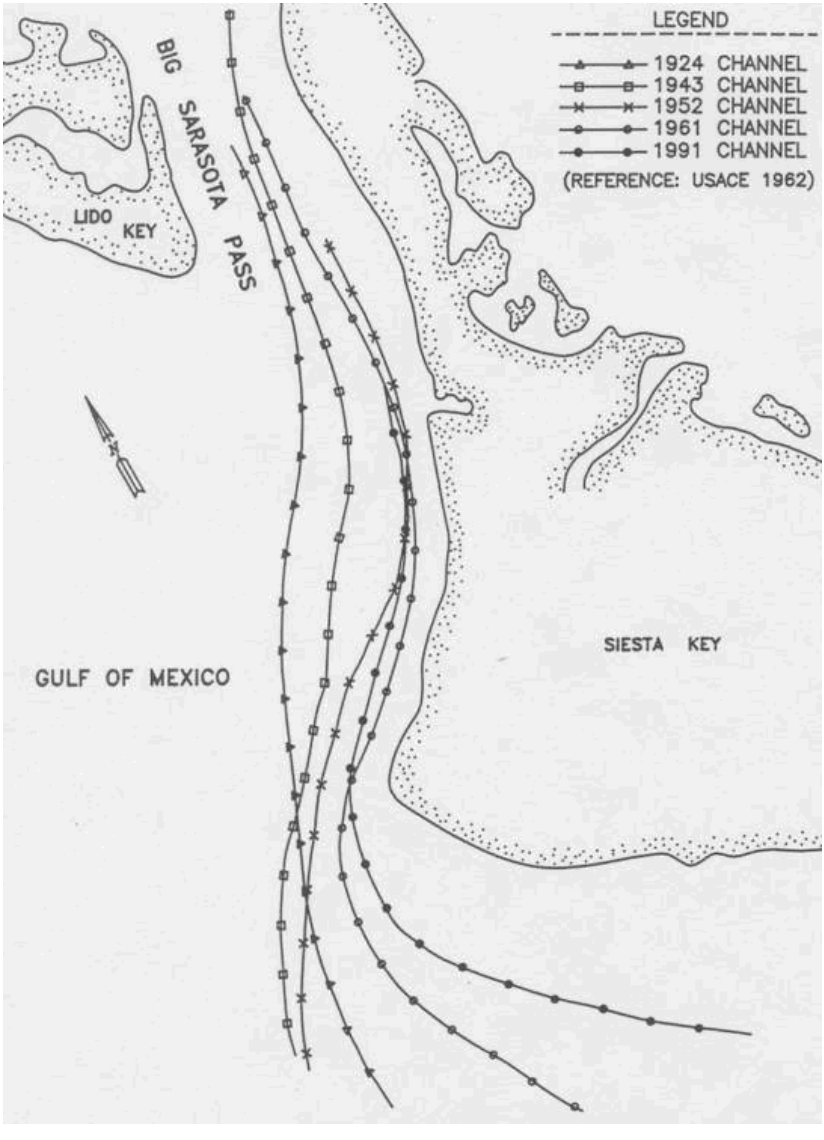

Figure 2 – Migration of the thalweg of Big Sarasota Pass through 1991.

Fig. 3 – Ebb-tidal delta at Big Sarasota Pass as it appeared in 1957 showing the asymmetrical nature of the ebb delta and the increase in development over the previous decade. Compare with Fig. 1.

As development of both Lido Key and Siesta Key proceeded there was need for nourishment on Lido which was not receiving substantial sediment from Longboat Key to the north. New Pass at the north end of Lido Key is tide-dominated with a pronounced channel margin linear bar to inhibit southward bypassing of sediment. As nourishment on Lido took place the ebb tidal delta at Big Sarasota Pass kept increasing in size due to the southward longshore sediment transport (Fig. 4). Bypassing of sediment at this inlet was facilitated by the pronounced offset of the adjacent barrier islands, the growth of the ebb delta and the shallow nature of the distal portion of the main channel. The most recent survey in 2006 showed a maximum depth of 9.3 m and a minimum at the channel mouth of 2.3 m.

As the ebb delta grew and the inlet channel tried to migrate south against Siesta Key, there was removal of sediment on the north end of that island without a means of replacing it. The result was substantial erosion causing residents to place riprap and various structures to protect their property (Fig. 5).

As this condition developed, the growth and extension of the ebb delta at Big Sarasota Pass, coupled with the very shallow distal portion of the channel has facilitated sediment bypassing. This bypassing is now focused several hundred meters from the north or updrift end of Siesta Key (Fig. 5) and has been for the past decade. This condition will continue in the future under the present conditions.

Fig. 4 - Oblique aerial photograph showing huge ebb-tidal delta and the asymmetric nature of Big Sarasota Pass as it appeared in 1994.

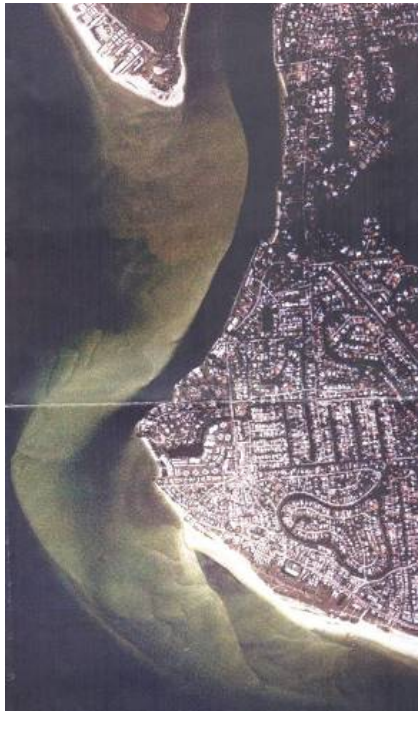

Fig. 5 - Vertical aerial photograph of Big Sarasota Pass in 2004 showing the absence of well-developed flood channels across the ebb delta, erosion on the north end of Siesta Key and considerable beach accretion where bypassed sand has migrated onto the shore area. Compare the north end of Siesta Key with the photos of 1948 and 1957; Figs. 1 and 3).

SUMMARY

Over the past century Big Sarasota Pass had experienced subtle but important modificants as the result of a combination of natural and human modified conditions. These can be listed chronologically to show their relative roles:

1 – Filling of mangrove islands and shoals to form Lido Key in the 1920s. This led to a more channelized tidal prism for both New Pass and Big Sarasota Pass.

2 – As a result of this channelization, Big Sarasota Pass carried an increased prism and migrated to the south (downdrift).

3 – Development of Siesta Key increased rapidly after World War II with residences being constructed along the south side of the Big Sarasota Pass channel. Non-integrated structures and rip-rap were placed along this channel in order to stop erosion. These efforts did halt channel migration.

4 – Because there were no structures on the updrift side of Big Sarasota Pass, the ebb-tidal delta was extended to the south thereby constricting the distal end of its channel. Sediment bypassing was being carried toward the south.

5 – Nourishment of Lido Key in the 1990s provided additional sediment that was transported to the south and caused the ebb delta at Big Sarasota Pass to grow and extend further to the south. This condition resulted in bypassed sediment being accreted to Siesta Key several hundred meters south of the north end and erosion to take place on the north end of the barrier.

Abstract: This paper documents the seasonal opening/closure features of tidal inlets and river mouths in a wave-dominated, micro-tidal environment along the central coast of Vietnam and discusses their formation, temporal morphological changes under typical conditions that are dominant in the dry and the wet season respectively. The interpretations are based on aerial photography, historical maps, satellite images and field observations. In addition a conceptual model of seasonal opening/closure features of tidal inlets in a wave dominated; micro-tidal environment under the influence of episodic river discharges is introduced and examined by numerical modeling.

INTRODUCTION

Seasonal closure and migration of tidal inlets and estuaries usually occur in micro-tidal, wave-dominated coastal environments where strong seasonal variations of river flow and wave climate are experienced. These inlets and estuaries close every year for a number of months due to the formation of a sand bar across the entrance or due to the growth of a sand-spit from updrift to downdrift. (Ranasinghe and Pattiaratchi, 2003). The phenomenon of seasonal closure of inlets or estuaries can be found at many coasts such as at the southern coasts of Australia, the southern coast of South Africa, the south-eastern coast of Brazil, and the south-western coasts of India and Sri Lanka.

The central coast of Vietnam has more than sixty inlets and river mouths connected to the South China Sea. They play a vital role in social-economic activities in the region. The closure of a tidal inlet or the shoaling of a river mouth cause significant negative impacts on the flood discharge capacity, coastal environment, ecological system, navigation and fishery sector, harming the socio-economical development in the region. Therefore, community interest in finding methods to keep these inlets permanently open has always been high. However, in order to find sustainable engineering solutions to keep these inlets perennially open, it is necessary to gain more insight into the morphodynamic processes governing seasonal opening/closure of those inlets and estuaries.

STUDY AREA

Situated on the south-west (SW) sector of the Gulf of Tonkin and the South China Sea, the central coast of Vietnam with a concave coastal plain (see Figure 1) stretches from 18°45' to 10°45' North latitude and from 105°06' to 109°28' East longitude. It consists of 12 provinces with a total area of 88,820 km^2 and population of 13.76 million.

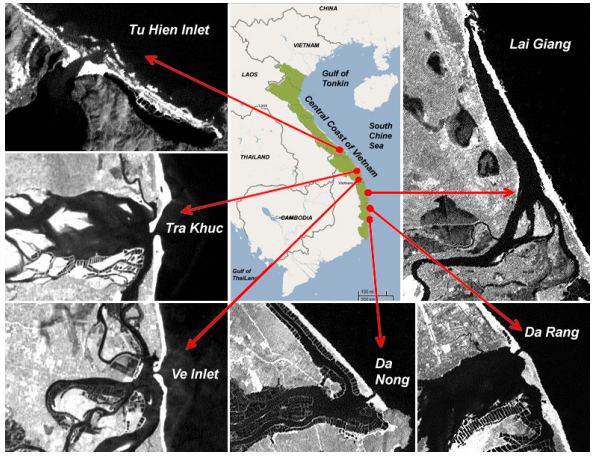

Fig. 1 Map of Central coast of Vietnam showing tidal inlets and estuaries

Vietnam is situated in a tropical region, where many atmospheric phenomena originating from the continent and the Equator Ocean meet. Consequently, climate in the region deeply suffers from the Asia monsoon regime, which originates from continental China in the period October till February and drives winds across the ocean from the north-east (NE). This is called the "winter monsoon" or "NE monsoon", with winds normally about 4 to 8 knots and with occasional strong winds up to 25 knots. In the period from May till August, when the continental high diminishes, the "summer monsoon" or "south-west monsoon" sets in and causes winds from the SW. Wind speeds are normally lower than in the winter months, up to 15 knots.

The long-stretching and narrow coastal plain in the central coast is frequently subjected to floods and storms. Every year, the central coast suffers directly from 3-5 storms and tropical depressions (50% of all SE Asian storms and tropical depressions hit Vietnam every year) causing heavy rain and subsequent flooding. The annual rainfall in the region ranges from 1500 mm to 4000 mm, mainly in the flood season (about 70% of the total yearly rainfall), between September and December. River flooding is a common annual phenomenon in the region as a result of this high rainfall intensity and uneven spatial rainfall distribution.

During extreme river floods the greatest effect is produced on tidal inlet and estuary morphology. The steep hinterland causes high peak discharges as well as high velocities as runoff is transported rapidly to the coast. Historical floodings have occurred 3 times in the past 70 years: 1953, 1983 and 1999. In November 1999, six provinces in the central coast experienced the heaviest rainfall due to effects of the tropical storm Eve. The entire hinterland was subjected to between 200 and 2000 mm of rainfall on a 6-day period. For example at Hue, the rainfall in a 12-hour period was approximately 770 mm. It caused severe flooding in the entire river basin with an estimated peak discharge of about 14,000 m^3/s. Such flooding events have a significant impact on an inlet configuration (closed inlets re-open and river channels widen, deepen and re-align).

Waves and sea level variations

Wave action is the dominant driving force in the morphological development of inlets/estuaries in the central coast of Vietnam. Along the coast waves, currents and sea level variations are defined mainly by the monsoon and storm regime. As a consequence, the wave regime in the central coast is NE dominated in wintertime and SW dominated in summertime. The offshore wave climates along the central coast have been determined from observations in Danang bay and off the Kyha Cape in the central coast from April 1997 to February 1998 and on the basis of a 36-year series of wave hindcast calculations from 1961 till 1997 (Nagai et al.,1998). The analysis showed that relative low waves are present from April till August; high waves may occur from September until February due to typhoons, tropical depressions and the NE monsoon. Waves from the NE are dominant resulting in a net southward littoral drift along the central coast.

Tides along the central coast of Vietnam are semi-diurnal with amplitudes varying from 0.5 m to 1.5 m. Spring tides seldomly exceed 2 m. The coast is therefore micro-tidal according to the classification of Davis (1964).

Coastal Morphology and Inlets Classification

The central coast is characterised by an abundance of small and medium size inlets/ estuaries formed at the mouth of rivers that discharge the rainfall of the steep hinterland. More than 60 rivers meet the South China Sea along 1500 km of coastline. Rivers usually are short and steep with gradients generally steeper than 1:100. The steep rivers with abundant natural but unevenly distributed flows during a year make the small and narrow coastal plains in the Central coast prone to flooding in the wet season, while the river is shallow and almost dry during the rest of the year. Specific topographical

features and the hydrological characteristics of the study area produce a particular highly seasonal variation of tidal inlet and river estuary configurations (from narrowing, shoaling or entirely closing during the dry season to widening and breaching in flood periods).

The coast is predominantly sandy as a result of high fluvial sediment input during flood periods, which nourish the mainland beaches and sandy barriers that form across estuary mouths and tidal inlets. Mainland beaches and barriers are typically steep and narrow and are dominated by cross-shore sediment transports. The sediment of the beaches and barriers is rather coarse. Based on morphological features, inlets and estuaries at the central coast can be classified into three major categories as follows:

1.Seasonal mixed tide-river-wave dominated inlets, connected to a lagoon or series of lagoons in the hinterland. The lagoons may receive water from a river, several rivers or might only receive natural surface run-off from the surrounding area. Tidal currents are the main driving forces maintaining an inlet open most of the time in a year. Meanwhile riverflood-generated currents are the driving force that widen and deepen the inlets in the wet season. Due to the fact that nearly all tidal inlets in the central coast of Vietnam are subject to a micro-tidal regime and wave dominated conditions, they are unstable and tend to narrow (or close) when tidal currents are much smaller than wave-induced currents.

2. Seasonal mixed river-wave dominated inlets are defined as those in which an inlet is maintained by river discharge and in which the tidal prism is too small to generate currents adequate to overcome wave-induced sediment transport in the nearshore that act to close the inlet. They are usually shallow in the dry season or closed for several years and re-open only during major river flood events. In the dry season, river discharges are usually too small or negligible in some cases. It causes estuary entrances to shoal easily and to close gradually due to longshore sediment transport or due to landward migration of offshore sand bars.

3. River-dominated estuaries with large river catchments are maintained by relatively higher river discharges during the whole year, thus the river entrances are kept open permanently. However, these estuaries often shoal, migrate or change their main channel due to the formation of sand-spits at the estuary entrance. These estuaries are not discussed here.

Hereafter, the formation, development and waning of the Tu Hien tidal inlet, which is representative for seasonal mixed tide-river-wave dominated inlets in central coast of Vietnam will be discussed based on historical maps, satellite images and field observations.

HISTORICAL EVOLUTION OF TU HIEN INLET

Located in the Thua Thien Hue Province, the Tu Hien inlet is one of two major inlets, which connect the Tam Giang - Cau Hai lagoon to the sea (see Fig.2A). The water body

of the Tam Giang - Cau Hai lagoon spreads over an area of 216 km^2 with a length of 68 km and an average wet volume of 300 million m^3.
The opening/closure cycle of the Tu Hien inlet starts with a breakthrough of the sand-spit across the closed inlet and forms a new inlet during an extreme river flood event. The inlet at this initial phase has its main channel in the orientation of NE-SW (see Fig.2B). Due to the dominant wave-induced currents in the SE direction the northern bank of the inlet is accreting and extending as a sand-spit in the SE direction. The inlet channel is then gradually lengthened and rotates to SE. When the sand-spit reaches the rocky headlands at the Vinh Phong Mountain, the inlet is then terminated and its morphological cycle is finished. The last entire morphological cycle of the Tu Hien inlet lasted for 9 years. In which the open period was 4 years (from 1990 till 1994) and the closed period was 5 years (from 1994 till 1999).

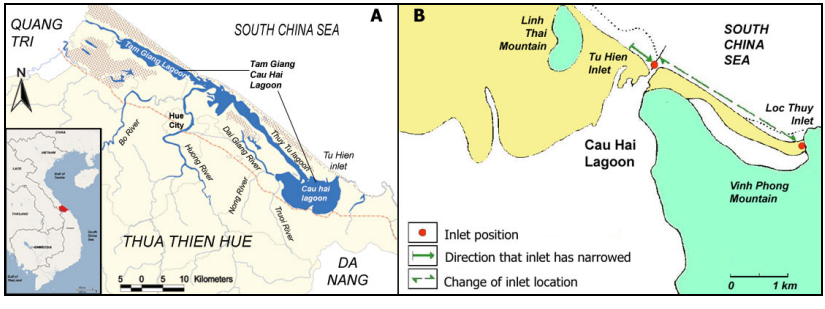

Fig. 2 Map of Hue and lagoon system (A)- Historical development of the Tu Hien inlet (B)

Figure 3 shows a series of the Landsat satellite images of the Tu Hien inlet from September 1999 till May 2005. In September 1999, just 2 months before the occurrence of the severe historical flooding in the region, a long sand-spit extending in SE direction blocked the Tu Hien inlet. A narrow inlet channel formed along the sand-spit connected to the sea through a small inlet namely the Loc Thuy. The inlet channel was flanked by the rocky headlands at the Vinh Phong Mountain and then turned to NE direction. During the historical flood in November 1999, flood-generated currents caused a breakthrough on the sand barrier at 5 places along 50 km of coastline and the Tu Hien inlet was re-opened. The re-opened inlet providing a short route for tidal exchange and flood discharge normally remains open while the less efficient inlets gradually close. Sediment accumulation on the southern bank of the new open inlet completely blocked the old channel formed along the sand-spit and isolated the old inlet from the lagoon. The historical development of an opening/closure cycle of the Tu Hien inlet is found similar to the model of inlet migration and spit breaching introduced by FitzGerald (1988).

In the classification of Hayes (1979), Tu Hien inlet is a micro-tidal inlet, in the wave-dominated region. Such a situation is characterised by long straight barriers, few inlets, well developed flood-tidal deltas and poorly developed ebb-tidal deltas. It means that the

offshore bars which are emergent at the inlet entrance during low tide and visible from the breaking wave patterns on the satellite image observed on March 2003, were not formed by ebb-tidal currents. They were formed as a consequence of river floods, when material which eroded from the flood-tidal delta and from the sand-spit during inlet widening, is pushed through the inlet and then deposited on the foreshore outside the inlet entrance. The satellite images also indicated that the ebb-shoals were elongated oblique to the shore over a distance of 200-300 m. Those were reworked further landward and finally incorporated into the sand-spit and into adjacent beaches in the form of a welded beach ridge. That is our explanation of how the sand-spits are forming on both sides of the inlet and why these are shaped like a triangle.

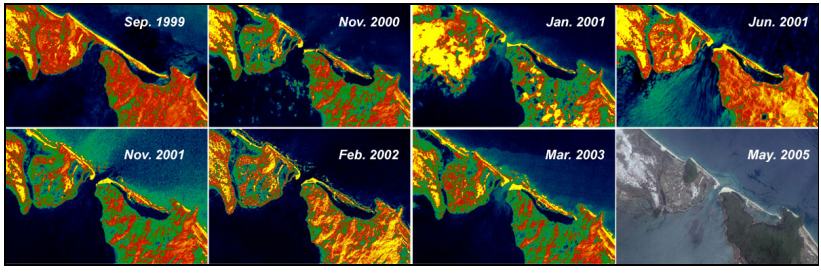

Fig. 3 The LandSat ETM+ satellite images of the Tu Hien inlet (Sep. 1999 till May 2005)

CONCEPTUAL MODEL OF SEASONAL OPENING/CLOSURE OF TIDAL INLETS

Based on the historical development of Tu Hien inlet, a general conceptual model of seasonal opening/closure for tidal inlets in the central coast Vietnam is proposed. The conceptual model is outlined below and in Fig.4. Three main stages are to be considered:

Formation stage

The opening/closure cycle of an inlet or estuary usually starts with a breach of the sand-spit across the inlet entrance during an extreme river flood event. Hence, the inlet formation stage is often occurring during the flood season (from August till December). The inlet or river mouth comprises of a narrow sandy channel with a sinuous course across the floodplain and changes its course along the barrier before the channel discharges to the sea (Fig. 4A and 4E). Long coastal barriers assume plan-form equilibrium with approaching waves.

During extreme flood events (Fig. 4B) floodplains are inundated and broad, while flood channels are produced by lateral scour of the floodplain. Large parts of the long barrier, opposite to the main flood channels are eroded. Also over-bank flow paths contribute to barrier erosion. Increasing flood discharge may breach the long barrier and formation of a new inlet or enlargement of the existing inlet. The breaching of the sand barrier or sand-spit across the inlet entrance removes the accumulated sediment from the estuaries and from the barrier. Sand from the barrier, together with additional sand from upstream of the river flood-plain is deposited as submerged sand bars offshore of the inlet

entrance. Those offshore sand bars are unstable in high wave energy environments and are not persistent for long time.

Development stage

The evolution of inlets/estuaries in this stage falls into two different categories, each discussed in the following two sections.

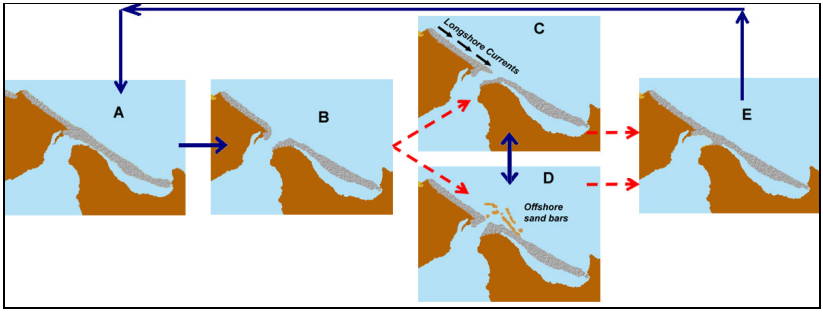

Fig.4 Conceptual model of opening/closure inlet/estuary

a. The development of sand-spits

The accumulation and expansion of sand-spits at an inlet entrance happened at many inlets/estuaries in the central coast such as Tu Hien inlet, Lai Giang inlet, and Da Nong inlet (see Fig.1). Those inlets are characterised by a long-narrow sand-spit forming parallel to the coast. The inlet entrance is usually located at the end of the sand-spit. The updrift bank of the inlet is accreting and extending as a sand-spit in the dominated littoral drift direction. The inlet channel is then gradually lengthened and changes its direction parallel to the coast. When the sand-spit reaches the rocky headlands or when it reaches its equilibrium condition the inlet is then gradually closed (Fig. 4C).

The accumulation and expansion of sand-spits at an inlet/estuary entrance is varying with time. Inlets/estuaries with large tidal prisms or strong river flood-generated currents will show slow expansion rates of sand-spits. Observations at the Tu Hien inlet indicated that the development of a sand-spit at the Tu Hien inlet was 4 years (from 1990 till 1994). Meanwhile, site investigations at the Lai Giang inlet in 2004 indicated that the sand-spit was fully developed in only 4 months, during the period of the NE monsoon.

b. The development of offshore sand bars in landward direction

After river floods decline the offshore sand bars are exposed to wave attack. The initially submerged sand bars rapidly become emergent and migrate landward into shallow water due to wave action. This causes shortening and widening of the bars, which gradually changes into an underdeveloped of a wave-dominated ebb-tidal delta (Oertel, 1975). Offshore sand bars become incorporated into the sand-spit by initially welding onto the beach, usually on the updrift side (Fig.4D). The subsequent landward migration under wave attack changes the bar into sand bodies elongated parallel to the coast (Cooper, 1990). Such mechanism was observed from series of satellite images and air-photos at Tu Hien inlet, Tra Khuc inlet, Ve inlet and Da Rang inlet.

Declining stage

The declining stage of a tidal inlet or estuary usually takes place when the inlet or estuary is much narrower and shallower compared to the initial situation at the formation stage. In the declining stage, wave energy continues to drive offshore sand bars landward onto the remaining breach. Overwash of the bar crest and transport of the forebeach sediment to the back-beach also contribute to this process (Cooper, 1990). Before final closure, the inlet may maintain a small bar similar to ebb-tidal deltas normally produced at small inlets and elongated in the downdrift direction, as in the longshore current-dominated model of Oertel (1975). The inlet may fully close at the beginning of the dry season, when river flows drop down significantly and inlets/estuaries suffer from severe NE monsoon events with high energetic wave conditions and a persistent wave direction for several days.

SIMULATION THE DEVELOPMENT OF AN IDEALIZED TIDAL INLET

An idealized inlet was developed and a process-based morphodynamic model, Delft-3D, was employed to examine flow, wave and sediment transport processes at the inlet area. The simulation purposes are to identify the morphological behaviour of an inlet under different tidal ranges and the variations of wave direction and to test two hypotheses on evolution of inlet closure.

Delft-3D, developed by WL| Delft Hydraulics, is a model system that consists of a number of modules for flow, waves, sediment transport and bottom changes, which are activated by a steering module. The hydrodynamic module is based on the depth-averaged shallow water equations, which are solved on a curvilinear staggered finite differences grid using an ADI scheme. The wave model in Delft-3D may employ the second-generation wave-model HISWA or the fully spectral third generation wave model SWAN (Holthuijsen et al., 1993). The transport model is based on the depth integrated advection diffusion equation for suspended-sediment transport and separately computes bed load transports (Lesser et al. 2004). All modules may operate on different computational grids, but the FLOW grid is used as the basis for data exchange between the modules.

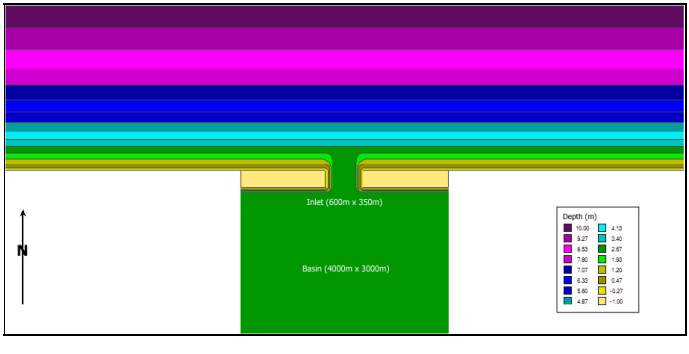

Fig.5 Grid and bathymetry of idealized inlet

Simulation setup and grid specifications

An idealized inlet and a computation grid (Fig.5) was setup for simulation in Delft-3D such that it has high resolution at the inlet entrance and in the surf-zone as the areas of interest and low resolution near the open boundaries which are of less interest. The cell size dimensions varied from 40 meters at the shoreline to 200 meters at the seaward boundary in cross-shore direction and from 60 meters at the inlet entrance to 200 meters at two lateral boundaries in longshore direction. The grid has a total of 110 grid cells in M-direction (in west-east direction) and 58 grid cells in N-direction (in north-south direction). The grid dimensions at sea are 13 km alongshore and 3 km in cross-shore direction. The seaward boundary is defined at the 10 meters depth contour line. The basin dimensions are 4 km by 3 km, with a uniform depth of 2 m. The inlet is located in the middle of the computation grid with dimensions of 700 meters by 400 meters.

Tide forcing for the FLOW model was represented as a harmonic wave having amplitudes varied from 0.1 m to 0.75 m and a period of 12.00 hr (semi-diurnal tide). The WAVE model is forced with offshore wave conditions which are defined at the seaward boundary. Wave height and period are representative of normal-wave conditions with a significant wave height of 1.5 m and a wave period of 7 seconds. The wave direction was varied from 315 degrees to 355 degrees relative to the North. A time step of 15 s was applied for FLOW simulations. The waves were updated every 20 minutes to accurately represent the changing flows due to tide and morphological development. Two sets of model simulation were run, one set which varied the tidal amplitudes (η) and other set which varied the wave directions (Table 1). In both cases, the same bathymetry and grid was used and the same representative tide and wave were employed. These simulations used the 2DH (online) mode of the Delft-3D model system and transport formulations by Van Rijn (1993). Both simulations were run for a period of 20 days. In dealing with the difference in time-scales between hydrodynamic and morphological developments, a morphological acceleration factor of 10 was used.

Table 1. Simulation scenarios with varying of tidal amplitudes and wave directions

RUN-ID	Tidal Amp. (cm)	Wave characteristics			RUN-ID	Tidal Amp. (cm)	Wave characteristics		
		Direction	H_s (m)	T (s)			Direction	H_s (m)	T (s)
W-315	25	**315**	1.5	7.0	**H-10**	**10**	325	1.5	7.0
W-335	25	**335**	1.5	7.0	**H-25**	**25**	325	1.5	7.0
W-345	25	**345**	1.5	7.0	**H-50**	**50**	325	1.5	7.0
W-355	25	**355**	1.5	7.0	**H-75**	**75**	325	1.5	7.0

Simulation results

Case 1- Variation of wave directions

Patterns of bed changes at the inlet entrance under varying wave directions are shown in Figure 6. All patterns of bed changes indicate the growing of a sand-spit from updrift to downdrift and development of ebb shoals at the inlet entrance. A flood delta is also observed inside the basin in all simulations. After 15 days, the inlet reduces 50% of its initial width for run W-355 and up to 75% for run W-315.

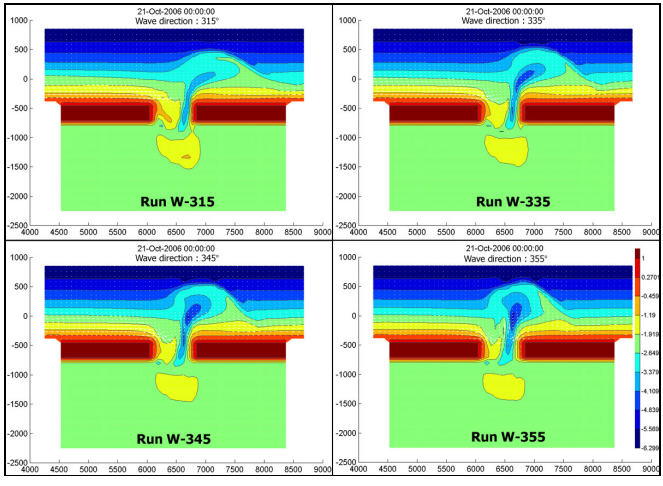

Fig.6 Inlet evolution with wave direction varied

The variations in wave direction causes different patterns of inlet channels and ebb-shoals in each simulation. In run W-345 and run W-355, when waves approach to the inlet at a small angle the inlet channels are formed in a drumstick shape and align perpendicular to the shoreline. In run W-315 and run W-335, the inlet channels section outside the inlet entrance seems to bend to downdrift because of the large wave angles. These channels tend to rotate perpendicular to the direction of the wave approach. The patterns of bed-changes in all four simulations show the seaward extension of the downdrift beach in a triangle shape. There might be a relationship between the enlargements of downdrift beach with the by-passing rate of ebb-shoals. The computed by-passing parameters (r) of 4 simulations, with a tidal prism (P) of 6M m^3, and the total littoral drift per year (M_{tot}) varied from 1.1×10^5 m^3 to 0.8×10^5 m^3 respectively, ranges from 54 to 75. According to Bruun and Gerritsen (1960), if the by-passing parameter ranges from 50 to 150, then the entrance bars are still pronounced and the by-passing at the inlet is a combination of bar-bypassing and flow-by-passing which is also observed from simulation results.

Case 2- Vaiation of tidal amplitudes

Patterns of bed changes at the inlet entrance with different tidal amplitudes are shown in Figure 7. The differences in tidal ranges cause distinct patterns of bed changes in four simulations. In the first simulation (H-10), the computed by-passing parameter (r) is 20. According to Bruun and Gerritsen (1960), the inlet is an unstable, non-permanent overflow channel. The inlet closed after 10 days and an equilibrium condition was reached after 15 days. In other simulations, the computed by-passing parameters are less than 150. It means that in those inlets ebb shoals at the inlet entrance are prominent and the by-passing type is a combination of both bar-by-passing and flow-by-passing. The patterns of bed changes in H-50 and H-75 simulations demonstrate the development of

ebb channels at the inlet entrance. The inlet channels are shifted to the right bank, deepen and extend further to the sea. Outside the inlet entrance, the inlet channel is exposed to the wave action thus it is bended to the downdrift beach. The by-passing mechanism through the ebb shoals is well illustrated in a series of patterns of bed changes which are observed in H-75 simulation (see Figure8).

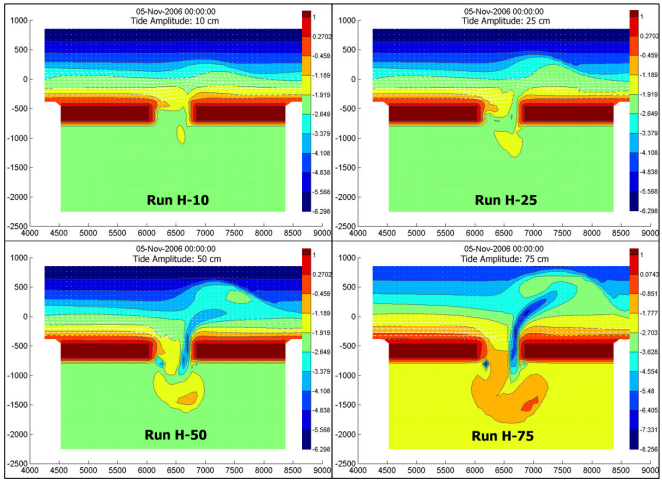

Fig.7 Inlet evolution with tidal amplitude varied

CONCLUSION

At most tidal inlets or estuaries, the existence and persistence of an entrance is dependent on the relative strength of inlet currents (tidal currents and river flood-generated currents) maintaining the entrance and wave-induced currents in the nearshore zone closing to entrance by depositing marine sediment. The balance between these processes determines the nature and the persistence of an inlet or a river mouth.

The morphological features of tidal inlets/estuaries at the central coast of Vietnam were investigated based on historical maps, satellite images and field observations. The historical development of an opening/closure cycle of the Tu Hien inlet was found

similar to the model of inlet migration and spit breaching introduced by FitzGerald (1988). Based on that, the formation, development and declination of an inlet is then generalised into a conceptual model for seasonal opening/closure. Two main mechanisms of inlet evolution were put forward in the conceptual model. The first mechanism is related to the narrowing of an inlet entrance due to the growing of a sand-spit. The second mechanism is controlled by nearshore wave-induced currents and landward movement of the offshore sand bars.

In order to identify the morphological behaviour of the seasonal closure of tidal inlets and to examine the hypotheses on inlet evolution, which were introduced in the conceptual model, a process-based morphological model was employed. The morphological model could successfully simulate the first hypothesis of inlet closure as well as the evolution of ebb-shoals due to the by-passing system. Further research on the second mechanism will be carried out in the future.

ACKNOWLEDGEMENTS

This research is supported by the Project Upgrading of the training capacity in coastal engineering in Hanoi Water Resources University, Phase 2; under the co-operation between Delft University of Technology, the Netherlands and Hanoi Water Resources University, Vietnam.

Abstract: Like ocean beaches, sheltered coastal areas experience land loss from erosion and sea level rise. In response, property owners often install structures that harden the shoreline as a way to prevent further erosion, but these structures cause changes in the coastal environment that alter landscapes, reduce public access and recreational opportunities, diminish natural habitats, and harm species that depend on these habitats for shelter and food. The National Research Council Committee on Mitigating Shore Erosion along Sheltered Coasts concluded that a regional management approach is needed to assess the costs, benefits, and cumulative impacts of structural approaches and to encourage erosion control alternatives that help retain the natural features of coastal shorelines.

INTRODUCTION

Throughout the coastal regions of the world there are a significant number of areas that are partially or fully protected from the high-energy regimes associated with open coastlines, such as ocean-facing beaches. These sheltered coastlines include environments such as estuaries, bays, lagoons, mud flats, and deltaic coasts and may be generally characterized as lower energy coastlines, but there is no quantitative formula that covers the diversity of conditions encountered on these more protected shorelines. Sheltered shorelines, though often contiguous with the open coast, border smaller, contained, bodies of water separated from the open ocean by islands, peninsulas, reefs, or other geomorphic features. Many of the processes that govern erosion and deposition on the open coast also apply to sheltered coasts, but generally the scale at which these processes function is significantly reduced within sheltered coastal areas. Also, unlike the typically long linear features associated with open coasts, sheltered coasts exhibit characteristics that are distinctively more compartmentalized with discrete areas of the coast encompassing a variety of

geomorphic and biological resources. Typical physical conditions associated with sheltered coasts include relatively low velocity tidal currents and mid-to-low energy wave climates associated with a limited fetch (distance from shore to shore). These conditions promote the formation of ecological complexes (i.e., mangroves, marshes, and mudflats) that often characterize habitats on sheltered coasts and are generally not found along open coasts.

Landowners frequently respond to the threat of erosion by armoring the shoreline with bulkheads, revetments, or other structures. Although the armoring of a few properties has little impact, the proliferation of structures along a shoreline can inadvertently change coastal environments and ecosystems. Managers and decision makers have been challenged to balance the trade-offs between protection of property and potential loss of landscapes, public access, recreational opportunities, natural habitats, and reduced populations of fish and other marine species that depend on these habitats.

At the request of the U.S. Environmental Protection Agency (EPA), the U.S. Army Corps of Engineers (USACE), and the Cooperative Institute for Coastal and Estuarine Environmental Technology, the National Research Council (NRC) conducted a study examining the impacts of shoreline management on sheltered coastal environments and evaluating strategies to minimize potential negative impacts to adjacent or nearby coastal resources. The report (NRC, 2007), released in October 2006, is summarized in this paper.

STUDY ORGANIZATION

The NRC committee met three times during the course of the study. The first meeting, held in Washington, DC, in June 2005, provided the committee with an opportunity to discuss the background and study expectations with the sponsors. In addition, the committee developed plans for a workshop that was subsequently held in Seattle, WA, in October 2005. The purpose of the workshop was to provide the committee with additional background information, largely focused on an analysis of options available to mitigate erosion of sheltered coasts. In planning this activity, the committee decided not to limit the discussion to marine or estuarine areas, but to include experts from the Great Lakes. The workshop explored the geomorphic settings of sheltered coasts as well as how various erosion measures affect those settings. The workshop brought together approximately 32 professionals with such diverse expertise as: state and federal regulatory matters, science, engineering, land use planning, and legal issues. The participants came from around the continental U.S. and provided expertise on the range of erosion problems in various coastal regions.

The committee's report identifies four broad categories of options to address erosion on sheltered coasts:

1) Land use regulation and management;
2) Vegetative stabilization;
3) Hardened structures (armoring the shoreline); and

4) Trapping or adding sediment.

These options are described in the context of the physical environment, ecosystem services and values, and the various regulatory, engineering, esthetic, and financial considerations that contribute to the decision-making process for mitigating erosion.

SHELTERED COASTS AND EROSION

Sheltered coasts are shorelines that face smaller bodies of water as compared to open ocean beaches. The water bodies are typically smaller, shallower, and have more varied shore morphologies, in part due to lower ambient wave energy. Lower energy conditions foster habitats and ecological communities, such as marshes and mud flats, typically not found on open coasts. Common shoreline profiles on sheltered coasts are illustrated in Figure 1. The unique characteristics of sheltered coasts affect the potential technological approaches and the consequences of actions taken to stem erosion and land loss from sea level rise.

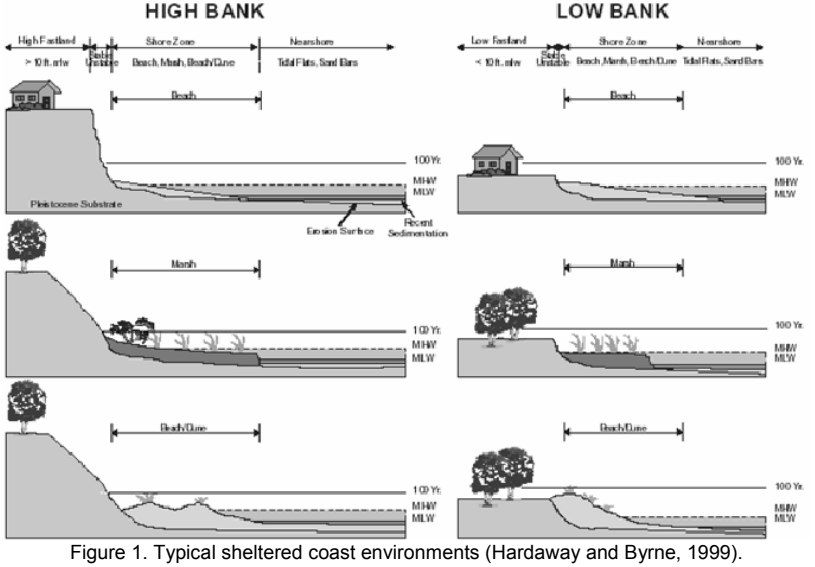

Figure 1. Typical sheltered coast environments (Hardaway and Byrne, 1999).

Erosion is caused by (1) winds; (2) waves, currents, and tides that transport shoreline sediments; and (3) weathering processes that destabilize landforms such as bluffs and cliffs. Although natural processes contribute to erosion, the rate may be accelerated by human activities such as construction of dams upstream of estuaries or installation of groins and seawalls that alter the magnitude and direction of sediment transport. Inundation can also increase because the ground sinks when sediments settle and compact or subsurface resources, such as groundwater and petroleum, are withdrawn. Other human activities that increase erosion include dredge and fill operations, wetland drainage, boat traffic, and channel dredging. Sea level rise will exacerbate

the loss of waterfront property and increase vulnerability to inundation hazards. It changes the location of the coast line, moving it landward and exposing new areas and landforms to erosion. Additionally, sea level rise is chronic and progressive, requiring a response that is correspondingly progressive (Figure 2).

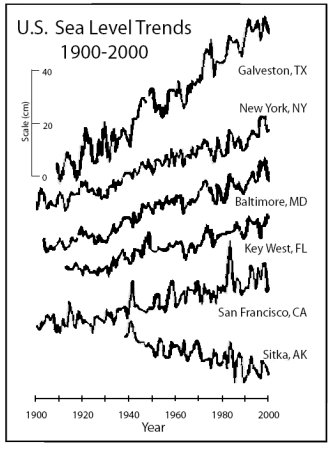

Figure 2. Relative sea–level trends in centimeters, for selected U.S. cities from 1900 to 2000. (Data from National Oceanic and Atmospheric Administration; graph available through the EPA [2000]).

CURRENT APPROACHES TO PROTECTING AGAINST EROSION

The pressure to develop and stabilize shorelines in sheltered coastal areas is increasing because coastal populations are growing. More people desire waterfront homes and coastal property values have risen. There are several types of strategies taken to stabilize shorelines. The most common response is a "hold the line" approach that hardens the shoreline with structures such as bulkheads and revetments. The following example illustrates the escalating rate of shore hardening and the consequent loss of natural coastal habitats.

Mobile Bay, Alabama

Mobile Bay is a shallow body of water (average depth about 3 meters) that empties into the Gulf of Mexico. The bay is approximately 51 kilometers long, 37 kilometers across at its widest point, and the overall length of the shoreline is approximately 160 kilometers. The bay area experiences extratropical storms and is subject to hurricanes from the Gulf of Mexico. With an average flow of 1,800 cubic meters per second, the Mobile Bay estuary has the fourth largest freshwater flow in the continental United States (Mobile Bay National Estuary Program, 2002). In 1997, a study was conducted that investigated the effects of bulkheads on the bay shoreline (Douglass and Pickel, 1999). The authors examined aerial photographs from 1955, 1974, 1985 to document the extent of

> bulkheads around the bay. Aerial video and site visits were used in 1997 to document the "present conditions." Results of the study reveal that the amount of armoring of the shoreline increased dramatically from 8 percent in 1955 to 30 percent in 1997. The study also documented that the rate of armoring from 1955 to 1997 corresponded to the rate of population growth in the area. This is a strong, but not surprising indication, that development trends increase the human impacts on sheltered coastlines. Of greater concern than the amount or rate of armoring was the associated loss of intertidal habitat, roughly estimated at 4 to 8 hectares (approx. 10 to 20 acres) corresponding to about 10 kilometers of intertidal beach shoreline.

There are alternatives to bulkheads, such as constructed marsh fringes, that are designed to preserve more natural shorelines while still reducing erosion (Figure 3). The selection of the type of response to prevent or offset land loss depends on understanding local causes of erosion or inundation. A shift away from the hold the line approach has been slow, in part because there is a greater familiarity with these methods than with alternative approaches such as constructing a marsh fringe or using vegetation to stabilize a bluff. Contractors are more likely to recommend structures such as bulkheads because they have experience with the technology and know the design specifications and expected performance. Landowners often assume that a hard, barrier-type structure will be required to prevent loss of property and protect buildings. In many regions, government regulations may unintentionally encourage shoreline armoring because it is simpler and faster to obtain the required permit(s). However, there are indirect costs associated with mitigation options that armor the shoreline. Many of these costs are borne by the public rather than the landowner. For example, installation of a groin to trap sand can affect neighboring beaches, while a bulkhead built on an eroding beach will eventually become the shore edge, replacing the beach that provided public access and scenic amenities. Construction on a marshy shoreline can lead to the loss of this highly diverse and productive plant and animal communities and their attendant ecosystem services—nursery areas for important fish stocks, removal of excess nutrients from land runoff, feeding areas for migratory birds, and sediment stabilization.

A NEW SHORELINE MANAGEMENT FRAMEWORK

Changing the current practice of armoring sheltered coasts will require a change in the shoreline management framework. Decision makers should appreciate the costs and benefits of the spectrum of potential solutions to shoreline erosion problems, including potential cumulative impacts on shoreline features, habitats, and other amenities. The management framework should encourage approaches that minimize habitat loss and enhance natural habitats in environments where such methods offer effective stabilization. Overcoming the obstacles associated with the current regulatory environment will require a number of societal and institutional changes in the following areas:

- **Improving Knowledge of Sheltered Shoreline Processes and Ecological Services**

Overall, less is known about physical process of sheltered coastal systems than of open coasts. In most areas, the scope and accessibility of information regarding the

causes of erosion at specific sites and the overall patterns of erosion, accretion, and inundation in the broader region (estuary, lagoon, littoral cell) is insufficient to

Figure 3. Planting vegetation offers an alternative for reducing erosion at some sites. Top photo shows a pre-project shoreline on Wye Island in Queen Anne's County, Maryland. Marsh grass was planted on sand fill and short, stone groins were placed. Middle photo is 3 months after installation. Bottom photo is six years after installation. Source: Hardaway and Byrne (1999).

support the development of an integrated plan for managing shore erosion. The report recommends that federal agencies (e.g., USACE, EPA, U.S. Geological Survey [USGS], and the National Oceanic and Atmospheric Administration [NOAA]), state agencies, and coastal counties and communities support targeted studies of sheltered coast dynamics to provide an informed basis for selecting erosion mitigation options that consider the characteristics of the broader coastal system rather than simply addressing immediate problems at individual sites.

- **Improving Awareness of the Choices Available for Erosion Mitigation**

Many decision-makers, particularly homeowners but also some state and federal regulators, are not sufficiently informed about the mitigation options available to them or the short and long term impacts of their choices. Decision makers need assessments of new techniques and materials designed to mitigate shore erosion. The report recommends that major federal agencies involved in permitting activities (EPA, USACE, and NOAA) initiate a national policy dialogue that can be used to develop guidelines for mitigating erosion on sheltered coasts. As part of this dialogue, the agencies should develop publications that contain objective information about erosion mitigation techniques, including descriptions of the conditions under which each option would be effective.

- **Considering Cumulative Consequences of Erosion Mitigation Approaches**

Cumulative impacts refer to the combined effects on legal, social, ecological, and physical systems. From a legal or regulatory standpoint, issuing permits may set a precedent, potentially facilitating the approval process for future requests for similarly situated structures. From an ecological standpoint, the cumulative impact of the loss of many small parcels will at some point alter the properties, composition, and values of the ecosystem. In addition, the economic, recreational, and esthetic properties of the shoreline will be altered, with potential loss of public use, access and scenic values. These cumulative effects are rarely assessed and hence are generally unknown, but an understanding of them is necessary to prevent an underestimation of the impacts of individual projects. The report recommends that cumulative effects be assessed in shoreline management plans, and that a precautionary approach be taken if there is insufficient information to determine cumulative effects.

- **Revising the Permitting System**

The current permitting system fosters a reactive response to the problem of erosion on sheltered coasts. Decision-making is usually parcel-by-parcel and based on relatively little environmental information. The path of least resistance drives choices through a rigid decision-making process, with inadequate attention to the cumulative effects of individual decisions. The decision-making process used for issuing permits for erosion mitigation structures should be revised for sheltered coasts and include consideration of potential cumulative impacts. This could be accomplished by a working group convened by state and federal agencies (EPA, USACE, and NOAA) to evaluate the criteria for sheltered coasts. The report recommends removing the often unintentional regulatory barriers for employing alternative erosion control approaches that have been proven to reduce erosion while preserving natural habitat.

- **Improving Shoreline Management Planning**

Creating a more proactive regional approach to shoreline management could address some of the unintended consequences of reactive permit decisions. The term "regional" is used in this report to reflect an area of shoreline that is defined by functional physical or ecological parameters such as littoral cells, or the scale of processes that affect sediment transport. Several examples of regional planning already exist for shorelines: the USACE Regional Sediment Management (RSM) program, EPA's National Estuary Program, and some special area management plans approved by state coastal management programs.

CONCLUSIONS

Until the government regulatory framework addresses the regional scale of the processes controlling sediment transport, stabilization of individual sites will often include structures that damage adjacent areas and create a domino effect of coastal armoring. The dimensions of the regulatory framework should match the scale of the processes that contribute to shore erosion. Currently there is no national mandate to document erosion processes on sheltered coasts or develop regional scale plans. No federal agency has been assigned to provide that scale of planning, although some states have become more proactive in shoreline management. Hence, implementation of a regional plan will require a new commitment for coordination among local, state, and federal programs, including a regional general permit. Overcoming the obstacles associated with the existing management framework will require a number of societal and institutional changes. The report recommends development of a new shoreline management framework to help decision makers evaluate the spectrum of available approaches to shoreline erosion problems in the context of the environmental setting. The new framework would include assessment of the physical and ecological properties of the shoreline and the potential cumulative impacts.

Abstract: Field observations and model simulations are presented of the tidal flow over a scour hole at the mouth of the Dyfi Estuary, mid-Wales, U.K. This scour hole is maintained by locally high flow speeds resulting from convergence, and then divergence, of the flow over the hole. Fixed features of the local bathymetry may also have served to stabilise its location (over decades). Model simulations of steady flow over a variety of schematised pits of different elliptical shape on an otherwise flat bed are presented to show that shallow elongated pits can (almost) preserve the upstream flow speed at their centre point, making them potentially self-maintaining. Deeper pits reduce the flow speed and so will infill.

INTRODUCTION

A feature of many estuaries and channels is the occurrence of natural pits and scour holes. These fixed features often persist for decades in the erodible seabed sediment. The present paper highlights the dynamics one such scour hole in the mouth of the Dyfi Estuary in the middle of Cardigan Bay, mid-Wales, U.K. Here field observations were made as part of a model validation exercise aimed at demonstrating the ebb-dominant nature of the tidal flow in the Dyfi Estuary. This ebb dominance arises from the extensive areas of drying banks at low tide, together with the discrete channels, that characterise the interior of this predominantly sandy Estuary. The field observations are complemented by modelling work both of the tidal flow in the estuary, here with main emphasis on the area of the scour hole, and also of the flow above an idealized pit that is used to highlight the processes affecting scour-hole dynamics.

The behaviour of offshore sand pits was studied during the EU SandPit Project (2002-5) (Van Rijn et al., 2005). Here numerical models were intercompared in order to simulate both the infill rate and also the migration rate of pits and trenches, and comparisons were made with data from a variety of field and laboratory experiments involving combined waves and currents. Based on scenario model tests for a variety of offshore sand pits, coastal zone management issues were addressed relating to both the near- and far-field effects of these pits. For example, at the centre of the pits investigated it was found that both current velocities and sediment transport rates decreased quite markedly (by up to about 25% and 80%, respectively) compared with the situation without a pit. Work in SandPit was carried out at the University of Wales (Bangor) (UWB) using the Telemac Modelling System in which refinements were implemented relating to the bed roughness, the advection-diffusion scheme for suspended sediment and also the sand transport formulation (Davies and Villaret, 2003; Davies et al., 2005).

In the present study of the Dyfi Estuary the spring-neap tidal cycle has been modelled, and then combined with a schematized representation of the observed offshore annual wave climate. Even at high tide, waves are predicted, and also observed, to penetrate the estuary from offshore only to a limited extent; thus we focus here on the tidal flow over the scour hole at the estuary mouth without regard to waves. The main sections of the paper highlight the field observations made above the scour hole, the modelling of these flows using the Telemac System (Hervouet and Bates, 2000), and some consideration of the dynamics of pits aimed at addressing the question of whether natural scour holes can be self-maintaining and, if so, what shape of hole best serves this purpose.

FIELD STUDY IN THE DYFI ESTUARY

Validation data was obtained in a field campaign carried out in the Dyfi Estuary in January-February 2006 in order to confirm the model's hydrodynamic predictions at the estuary mouth, including the ebb dominance of the system. Figure 1 highlights the scour hole in the estuary mouth; the entire model domain is shown later in Figure 11.

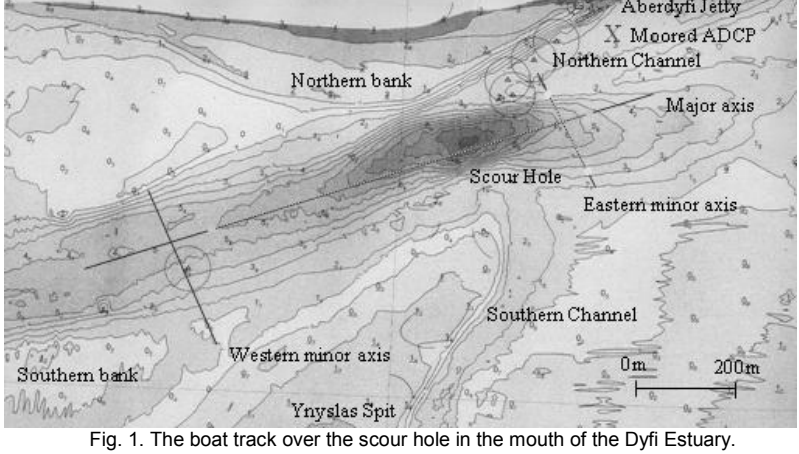

Fig. 1. The boat track over the scour hole in the mouth of the Dyfi Estuary.

The scour hole, which has been present as a fixed feature for decades, is approximately 800 m long, 150 m wide and 12 m deep, forming an asymmetrical elliptic shape. Data were obtained for both neap (24-25/01/06) and spring tides (31/01/01- 01/02/06), though here we highlight only the spring tide. Current data was obtained using a boat-mounted ADCP (the ADCP bin height was 0.25 m with a contaminated near-bed layer as shown). The boat tracked over the hole, following the double-cross shown in Figure 1, every 40 minutes during the tidal cycle. The flow was unstratified for the full spring tidal cycle and there was negligible wind and wave activity. The data presented here was collected along the major axis of the scour hole between the orange circles (Figure 3 and 7) and over the eastern minor axis between the yellow circles (Figures 4, 5, 8 and 9). The state of the tide corresponding to the data presented is indicated in Figure 2 by a red cross for peak flow on the flood tide and a blue cross for peak on the ebb. The water depth in Figure 2 was obtained by a bottom mounted ADCP moored in the main northern channel offshore from Aberdyfi jetty at the position indicated by the red cross in Figure 1.

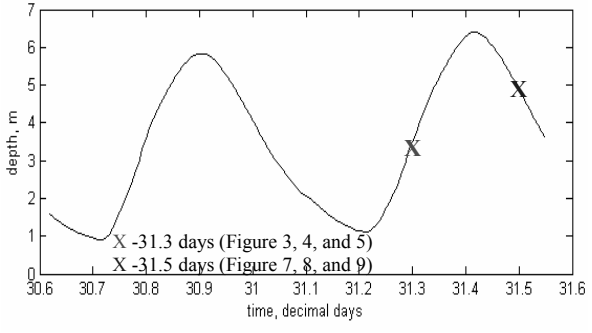

Fig. 2. The tidal curve off Aberdyfi jetty 31/01/06 -1/02/06 (spring tide).

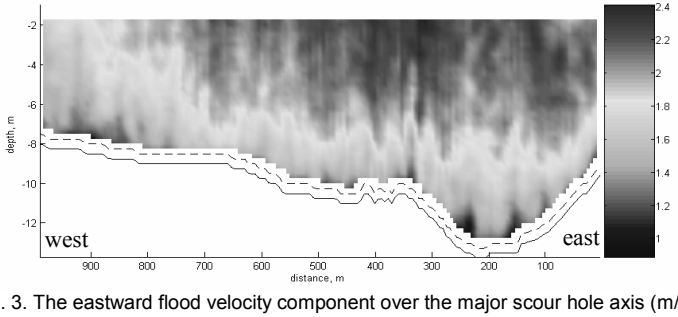

Fig. 3. The eastward flood velocity component over the major scour hole axis (m/s).

During peak flood flow the eastward (positive) velocity component over the hole was 2.4 m/s with maximum flow speeds occurring over the deepest parts of the hole. Figure 3 shows the flow along the main axis of the hole, while Figure 4 shows the flow through the eastern minor axis of the hole. The peak velocity occurred in a surface layer, just off

centre to the southern side of the hole. The change of sign of the northward velocity component (Figure 5) illustrates that the flow diverged as it left the hole on both sides of the eastern minor axis. The north-velocity component was weaker than the east-velocity component only reaching peak values of 0.5 m/s.

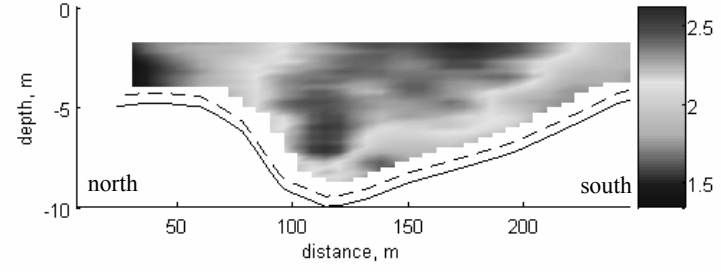

Fig. 4. The eastward flood velocity component over the eastern minor scour hole axis (m/s).

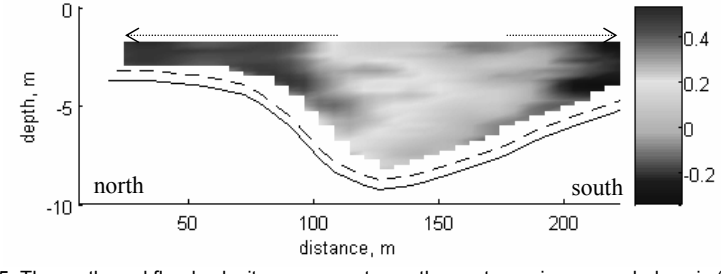

Fig. 5. The northward flood velocity component over the eastern minor scour hole axis (m/s).

It was found also that the flood tide along the north of the channel was deflected off the northern bank before entering the hole, directing the current in a more easterly direction (Figure 6). This also led to convergence over the deepest point of the hole, resulting in the large velocities seen in Figures 3 and 4.

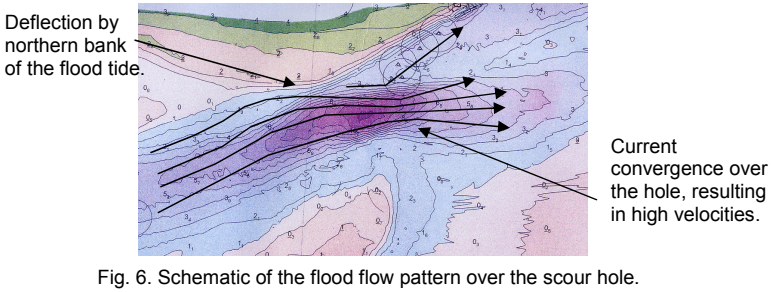

Fig. 6. Schematic of the flood flow pattern over the scour hole.

During peak ebb flow the eastward velocity component achieves maximum (negative) velocity of 2 m/s down stream of the hole (Figure 7). The flow was most pronounced

along the northern side of the hole (Figure 8) due to the main current stream entering the hole from the northern channel, which is ebb tide dominated. The northern channel passes Aberdyfi jetty (Figure 1) and is the main tidal channel in the estuary system. The change of sign of the northward velocity component (Figure 9) demonstrates that flow convergence occurred at the upstream end of the hole, the flow entering the hole over both sides of the eastern minor axis. This convergence may also be due to the northern and southern channels feeding the flow, a consequence of the falling water levels (Figure 2) restricting the flow to the estuary channels. Again the north-velocity component was weaker than the east-velocity component, achieving a peak magnitude of 0.7 m/s.

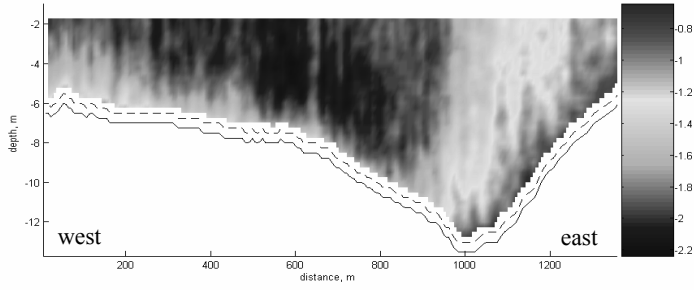

Fig. 7. The eastward ebb velocity component over the major scour hole axis (m/s).

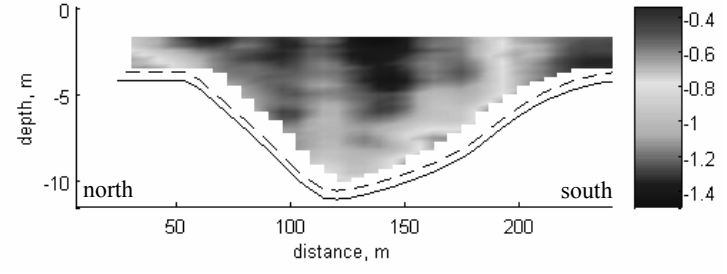

Fig. 8. The eastward ebb velocity component over the eastern minor scour hole axis (m/s).

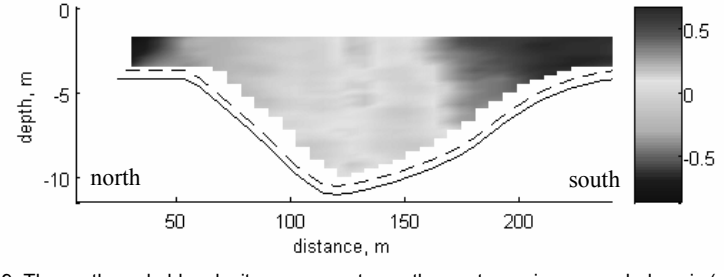

Fig. 9. The northward ebb velocity component over the eastern minor scour hole axis (m/s).

As the flow from the estuary channels met over the deep part of the hole (Figure 10) the flow increased and this process continued offshore giving rise to the peak velocity magnitude, seen to the west of the deepest point of the hole in Figure 7.

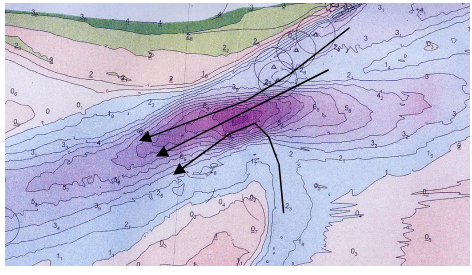

Fig. 10. Schematic of the ebb flow pattern over the scour hole.

In summary, the field data illustrate that over an elliptic hole, with the flow parallel to the major axis, converge/divergence occurs as the flow enters/leaves the pit. The question that then arises is whether this behaviour can cause an increase in velocity that is sufficient for the pit to be self-scouring. Van Rijn et al. (2005) noted the paucity of data of the kind presented here.

MODEL OF THE TIDAL FLOW IN THE DYFI ESTUARY

A complete description of the model of the Dyfi Estuary developed at UWB using the Telemac System is beyond the scope of this paper. Here we present only the details relevant to the present application. The model domain and bathymetry are shown in Figure 11. The offshore north-south boundary, where the water depth is typically 15 m, is 14 km long. The scour hole (marked with a blue cross) is located in the main channel seen entering the estuary. Within the sandy estuary itself large areas of drying banks dominate the bathymetry.

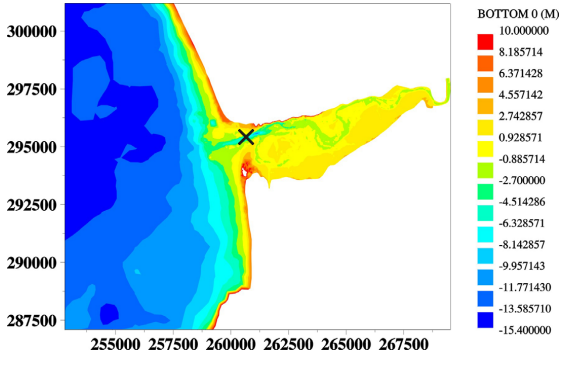

Fig. 11. Telemac model domain and bathymetry of the Dyfi Estuary

Telemac2D has been utilized with a mesh size of 500 m offshore reducing successively to 10 m over the area of the scour hole, thus allowing high resolution of the flow here. The tidal boundary conditions have been have been obtained from the operational POLCOMS model of the Irish Sea, but have here been simplified here by the retention of only the M2 and S2 constituents. A full spring-neap tidal cycle has been simulated with a model time step of 10 s. The field data have been used to undertake a limited amount of model tuning and the description of bottom friction has been matched with the known seabed type (sand with D_{50}= 0.24 mm). Following a spin-up period, the model cycle starts with the spring tide. In the offshore domain both the elevation and velocity fields are essentially symmetrical. This is not the case however in the estuary mouth, near to the region of the scour hole. Here Figure 12 shows that, while the tidal elevation is symmetrical, the velocity field is highly asymmetrical with a short (positive) flood flow into the estuary being followed by a much longer (negative) ebb flow out of the estuary. The reason for this ebb dominance, which has been confirmed by the field measurements, is attributable to the large areas of drying banks within the estuary.

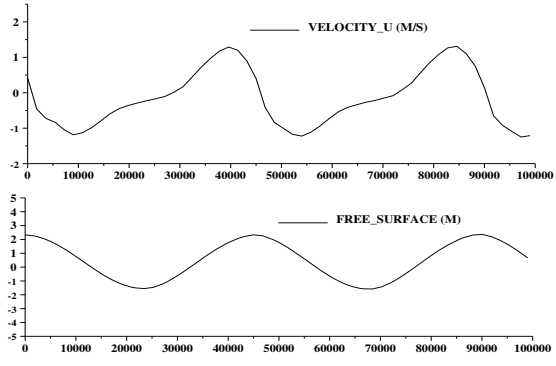

Fig. 12. East-west component of velocity (top), and free-surface elevation (bottom) in the mouth of the estuary.

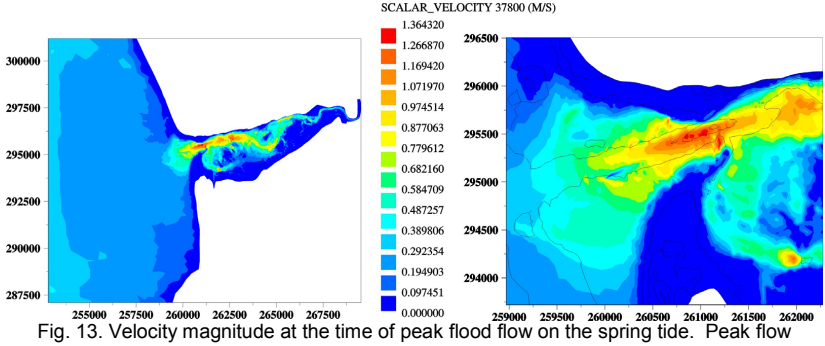

Fig. 13. Velocity magnitude at the time of peak flood flow on the spring tide. Peak flow speeds in the entire domain (left) occur over the scour hole (right, with bathymetry shown).

Figure 13 shows the velocity magnitude at about the time of peak flood flow into the estuary on the spring tide. Offshore the velocities are weak, but in the estuary mouth they are strong, attaining their largest values directly over the scour hole. On the ebb tide (Figure 14) the situation is analogous, though here the offshore directed velocities are maximum somewhat downstream of the point of maximum depth within the scour hole, consistent with the field results shown earlier in Figure 7.

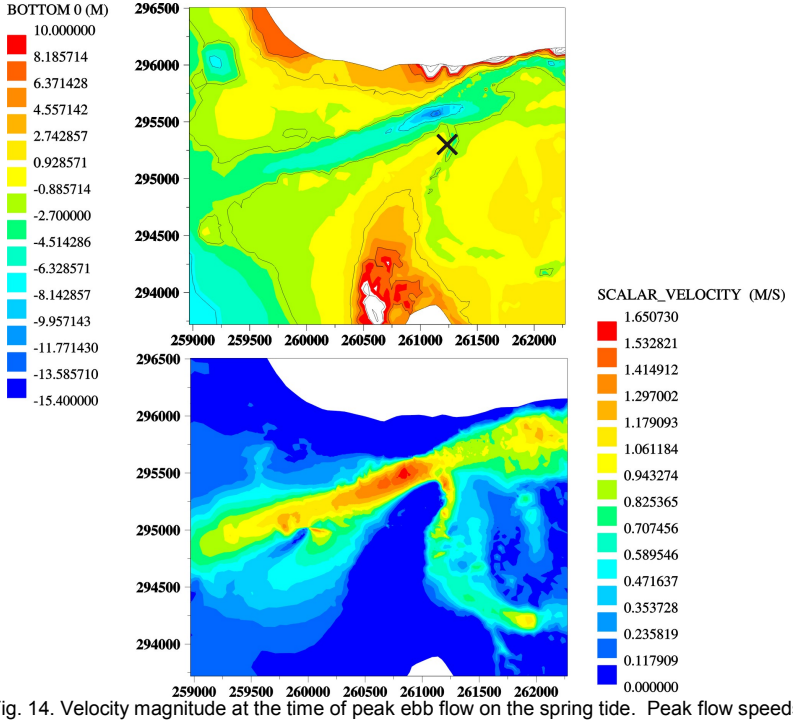

Fig. 14. Velocity magnitude at the time of peak ebb flow on the spring tide. Peak flow speeds again occur near the scour hole (bottom). The bathymetry of the pit is as shown (top).

Evidently both model and experiment show peak flows occurring in the vicinity of the scour hole. In the natural setting of the Dyfi Estuary, this velocity enhancement is caused partly by the funnelling effect of the sides of the estuary at its mouth and, possibly also, by topographic 'anchor points'. The area marked by the blue cross in Figure 14 is actually the site of ballast (rocky material) dumped by cargo vessels during the late 19th century. Although the underlying sediment is erodible, this ballast may have helped to stabilize the scour hole in its location nearby. What is clear is that the scour hole is a stable, persistent feature in the mouth of the Dyfi Estuary. What is less clear is whether its location and elongated geometry is simply forced by the nearby (fixed) topographic features, or whether its elongated shape results from a more fundamental interaction between the flow and the seabed topography.

A MODEL OF CHANNEL FLOW OVER A SCHEMATISED PIT

In order to address the question posed above, we consider next the results of Telemac2D simulations carried out for simple, steady, channel flows above idealized pits of elliptical plan area. The channel is 2000 m long and 1000 m wide, with an undisturbed depth h of 10 m. The nominal grid size is 50 m which reduces to 10 m in the region around the centre point of the channel where the pits are located. An upstream volume flux of $10^4 m^3/s$ imposed in all runs, and 'sliding' boundary conditions are imposed at the sides of the channel. At the downstream end the nominal depth of 10 m is imposed, and so here the (mean) velocity is 1 m/s exactly. To ensure convergence the duration of each run has been taken as 10^4 s with a model time step of 10 s (run time 12 min).

As the model spins up to convergence the surface elevation, which is 'free' at the upstream end of the channel, adjusts to its final value. For example, with a bed roughness of k_s = 0.05 m the perturbation (ζ) to the undisturbed depth h is $\zeta_{upstream}$= 0.058 m. It turns out that the surface slope along the channel is almost exactly uniform, corresponding in this case to -2.9×10^{-5}. Since the converged flow is horizontally non-uniform it is necessary to correct for this in obtaining the local bed shear stress τ_0, which may be obtained quite simply from the equation of motion as:

$$\tau_0 = \rho\left(g\left(h+\zeta\right)-U^2\right)\times\left\{-\,surface\;\;slope\right\}$$

where U is the local depth-averaged velocity along the channel, ρ is the water density, and g is the acceleration due to gravity. In the simple case of a flat bed the flow properties depend only upon one non-dimensional parameter, namely k_s/h. The behavior of the drag coefficient C_D defined in the usual way by $\tau_0 = \rho C_D U^2$ (and obtained in Telemac2D via the Chezy coefficient) is illustrated in Figure 15. This graph shows, for example, that doubling the depth decreases C_D by about 20%.

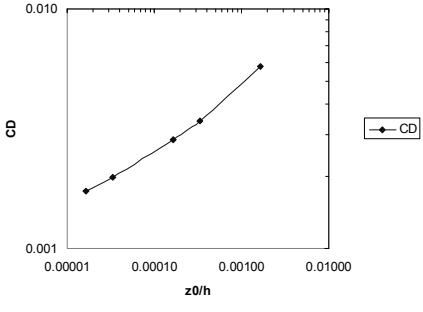

Fig. 15. Drag coefficient for steady flow in a channel (roughness length $z_0=k_s/30$)

Suppose next that we add a circular pit at the centre point of the domain, the pit being taken as an inverted cosine bell. If the depth of the pit below the undisturbed bed level is H and the radius of the pit (to the edge of the bell) is R, the properties of the flow now depend upon the three non-dimensional parameters: $\frac{k_s}{h}, \frac{H}{h}$ *and* $\frac{R}{h}$.

The effect of varying the two new parameters, while keeping k_s (and hence k_s/h) fixed (with k_s= 0.05 m) is shown in Figure 16. At the centre of the pit, the flux $U(h+H)$ increases significantly as H/h departs from its undisturbed value H/h= 0 indicating that fluid is being entrained into the pit from the surrounding area. However, the depth-averaged velocity U decreases as H/h increases, suggesting that such a pit shape is likely to promote infill. The results shown in Figure 16 for both the velocity and also the flux are strongly dependent upon H/h, but only very weakly dependent on R/h.

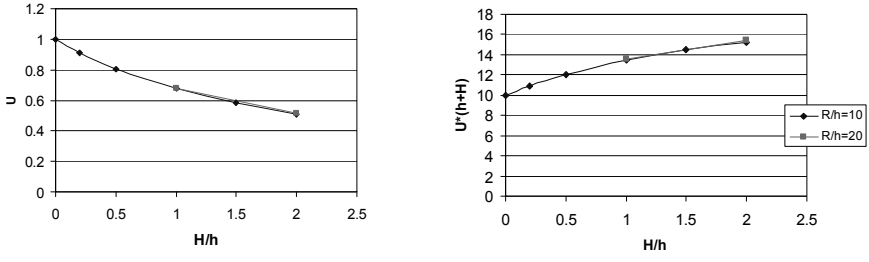

Fig. 16. Velocity (U m/s) (left) and flux ($U(h+H)$ m^3/s/m) (right) at the centre of the circular pit as H/h and R/h are varied with k_s/h fixed.

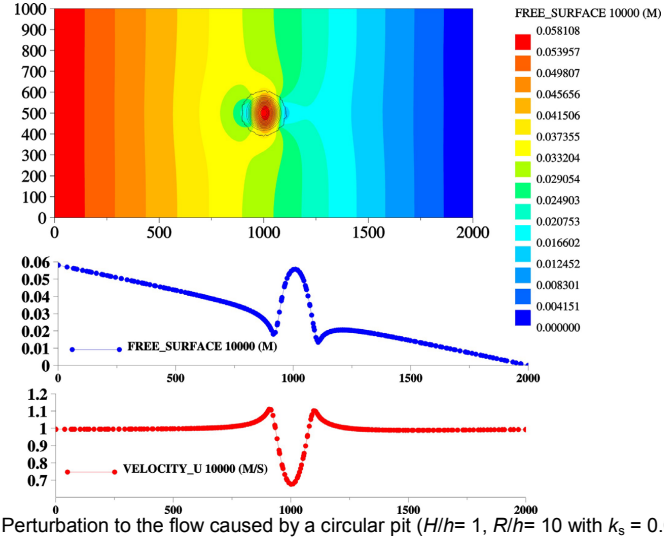

Fig. 17. Perturbation to the flow caused by a circular pit (H/h= 1, R/h= 10 with k_s = 0.05 m).

Some key results in a specific case are shown in Figure 17 in which the location of the pit is shown by the black contour lines. The colour map shows that the converged flow is down-slope from the left to the right of the domain, the surface slope being -2.9×10^{-5} as stated earlier. The pit perturbs the flow to a distance around it that scales on its radius R. The remaining graphs in Figure 17 show the free-surface and the streamwise

component of the depth-mean velocity, along the centre-line of the domain. On approaching the pit the flow accelerates causing the surface elevation to drop while, on entering the pit, the flow decelerates causing the surface elevation to rise. After passing the deepest point at the centre of the pit this pattern is reversed. Evidently the flow is sucked into the pit by the pressure field that is induced in the area surrounding it and Figure 16 shows that, as expected, increasing the depth of the pit reinforces this effect.

It may be inferred from the results above that a circular pit is likely to infill since U decreases as H/h increases. For a self-scouring pit we require the velocity to remain roughly constant (or ideally to increase) as H/h increases. The question that then arises is whether by changing the shape of the pit such an effect can be produced. In order to increase the domain of influence of the pit laterally (i.e. across the flow), it is necessary to increase the streamwise dimension of the pit. Next therefore we replace the circular pit (radius R) by an elliptical one (with streamwise semi-axis a, and transverse semi-axis b), doing this in such a way that the plan area of the pit remains unchanged (i.e. $\pi R^2 = \pi ab$ such that R is the 'effective' pit radius). The flow properties now depend upon four parameters: $\frac{k_s}{h}, \frac{H}{h}, \frac{R}{h}$ *and* $\frac{a}{R}$.

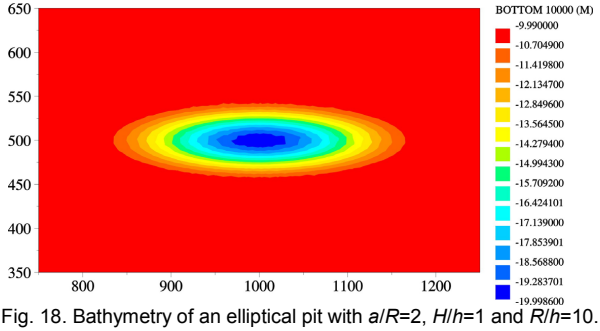

Fig. 18. Bathymetry of an elliptical pit with a/R=2, H/h=1 and R/h=10. Only the central area of the domain (500 × 250 m) is shown.

A typical elliptical pit, corresponding to a stretched cosine bell, is shown in Figure 18. The perturbation to the surface elevation caused by this pit can be seen in Figure 19 and the associated streamwise and transverse velocity components are shown in Figure 20. The effect of stretching the pit from a circle to an ellipse with its major axis in the streamwise direction is to suck more fluid into the pit from both of its now-longer sides. The results in Figure 20 show that the flow converges as it enters the pit and diverges as it leaves it, but the streamwise flow within the pit is now more intense than in the case of the equivalent circular pit. The depth mean velocity at the centre of the pit is 0.852 m/s, while at the upstream and downstream edges of the pit the velocity attains values of 1.068 and 1.083 m/s, respectively. The centre-point value may be compared with the much lower value for an equivalent circular pit of 0.676 m/s, and also with the undisturbed flat-bed value of 0.997 m/s, i.e. in the absence of a pit.

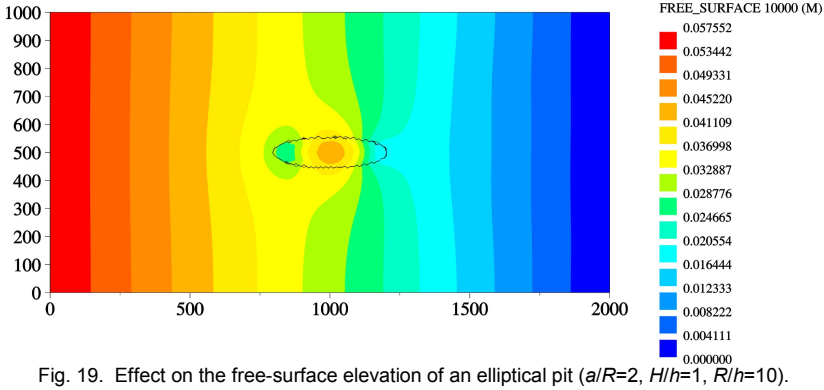

Fig. 19. Effect on the free-surface elevation of an elliptical pit (a/R=2, H/h=1, R/h=10). The perimeter of the pit is shown by the black line.

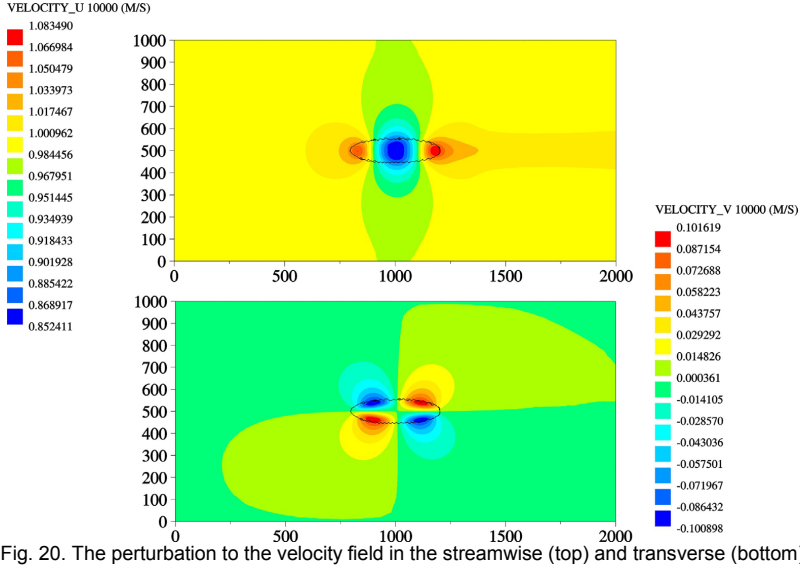

Fig. 20. The perturbation to the velocity field in the streamwise (top) and transverse (bottom) directions as a result of the pit shown in Figure 19 (a/R = 2, H/h = 1, R/h = 10).

The depth-mean velocity at the centre of a variety of elliptical pits is shown in Figure 21. With regard to the shape of the pit, the value a/R = 1 indicates a circular pit. In the limits $a/R \to 0$ and $a/R \to \infty$, the pit becomes, respectively, a trench and a longitudinal furrow. Shallow pits correspond to small values of H/h, while deep pits correspond to large values of H/h. Maximum longitudinal bed slopes only exceeded 10º in two of the cases considered, and were generally much smaller than this (< 5º). Thus flow separation within the pit would not be expected, and the use of a 2DH model is not unreasonable for an assessment of the dynamics.

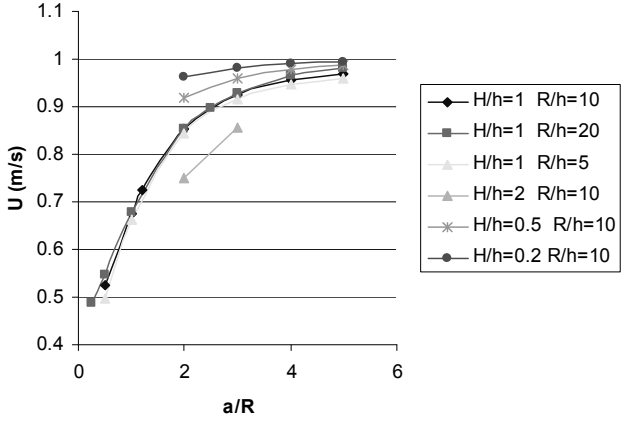

Fig. 21. Depth-mean velocity at the centre of elliptical pits defined by the parameters a/R, H/h and R/h, as indicated by the various symbols.

It is evident from Figure 21 that, if the major axis of the ellipse is across the flow in the transverse direction ($a/R < 1$), then the flow slows down considerably in the pit compared with its undisturbed value of 0.997 m/s (i.e. flat bed case with $k_s = 0.05$ m). However, if the major axis is in the longitudinal direction ($a/R > 1$), then the flow speed at the centre-point takes much larger values ($U > 0.9$ m/s for $a/R > 2$ for all but the deepest pits). The velocity at the centre of the longest shallow pit considered here ($a/R = 5$, $H/h = 0.2$, $R/h = 10$) is 0.993 m/s, virtually the same as the velocity in the undisturbed flow. The results in Figure 21 demonstrate the strong dependence of the maximum velocity upon a/R and H/h; the results are again very weakly dependent upon R/h, as found for circular pits.

DISCUSSION

The results in Figure 21 suggest that the flow at the centre of an elliptical pit may be unable to exceed the undisturbed value of 0.997 m/s. These results were obtained using a spatially constant value of the bed roughness k_s. If a spatially variable bed roughness is employed, the apparent constraint is relaxed. For example, taking $k_s = 0.05$m outside the pit and $k_s = 0.005$ m within it, the velocity at the centre-point increases to a value of 1.023 m/s which is somewhat larger than the undisturbed flat-bed value. However, whether or not this represents a physically relevant scenario when bed form dynamics are taken into account introduces factors other than those considered here.

Although it has been suggested that flow separation will not have occurred in any of the pits considered in Figure 21, three-dimensional helical flow effects are quite likely to play a role in the overall dynamics of sand pits. Such helical secondary flows (with their axes lying in the main flow direction) may be induced by the topography itself or by transverse variations in the bed roughness (McLean, 1981). For example, if the bottom of an elliptical pit is rougher than the seabed generally, then both the shape of the bed

and the roughness effect will complement one another to induce an up-slope secondary flow close to the bed that will help to stabilize the pit. In contrast, a relatively smooth pit interior will give rise to competing (positive 'topography' and negative 'roughness' driven) secondary helical flows that may have little net effect.

CONCLUSIONS

The field data from the Dyfi Estuary indicates velocity enhancement in the scour pit at the estuary mouth, and a tidal simulation of the Dyfi using Telemac2D has confirmed this velocity enhancement. In order to derive some generic results concerning scour hole dynamics, model tests have been carried out using schematized pits in steady flow. These tests have shown that :

- pits entrain additional fluid by perturbing the pressure field in the surrounding area.
- the depth-mean velocity decreases in circular pits, which are therefore likely to infill.
- for elliptical pits, the velocity at the pit centre depends strongly upon a/R and H/h, but only weakly on R/h and k_s/h (H = depth of the pit, h = undisturbed water depth, k_s = bed roughness, R = "effective" pit radius, a = semi-axis of ellipse in streamwise direction) .
- shallow, elliptical pits with major-axes in the streamwise direction may be self maintaining. However, if such a pit deepens, this process will not continue indefinitely.

In reality, apparently self scouring pits may rely on fixed bathymetric features (e.g. the presence of lateral channel banks or, in the Dyfi Estuary, dumped ballast in the estuary mouth). These issues require further study with regard to the sediment dynamics.

ACKNOWLEDGEMENTS

The authors thank the Aberdyfi Partnership for making funds available, through Martin Wright Associates, to support the field campaign reported here. Ben Powell of the School of Ocean Sciences, UWB, and Mark Roberts of Civil Engineering Solutions, Dolgellau, mid-Wales, are thanked for their valuable contributions to the field work.

Abstract: A numerical model for estimating the terrace topography changes caused by floods is introduced, by considering grain size of sediment discharged from a river. Applying this model to Fuji river-mouth, the sediment discharged during floods can be estimated with an aspect of quantity and quality. As the result, it was obvious that the major part of sediment discharged from Fuji river-mouth at floods is flushed out offshore in deeper than 20m depth, which can not contribute as the longshore sediment transport that nourish the neighborhood of the river-mouth.

INTRODUCTION

Fuji coast located at Suruga Bay in Japan (Fig.1) is formed by gravel and sand sediment supplied from Fuji River, which is 128km-long with 3,990km^2 basin (Fig.2). Since the sand-bar is developed from the east side of the river, the small river-mouth comparing with the river width is opened in the west side. In front of Fuji river-mouth the terrace topography is developed (Fig.3). The slope of river bed is very steep, so the river-flow discharge is a little in the usual condition. However during the rainy season, from June to July, and also in typhoon season, from August to October, the flow discharge increases rapidly in accordance with the precipitation. Much of the sediment movement along the river occurs during floods. During a flood,

a part of the sediment discharged from the river is deposited on the terrace; other is flushed out offshore, which can not contributed as longshore sediment transport that nourish the coastal area adjacent to the river-mouth. Since the offshore bottom slope is very steep, 1/3 (Fig.3), the sediment which transported to the deep area, deeper than 20m, will not come back to the shore again.

At Fuji coast, which located 10 km east from the mouth of Fuji River, has suffered from erosion since 1980. Cause of the erosion is decreasing volume of the longshore sediment due to obstruction of the sand flow by the breakwaters. The countermeasure, the sand and gravel fill, 105m^3 per year, has been carried out since 1996, and it has been shown the good results (Takagi et al., 2000). The material of sand and gravel fill is transported by tracks and ships from outside of the Fuji basin. However, it is difficult to obtain the large volume every year, because of the environmental damage in the borrow area and the cost for the transportation. Instead of bringing sediment from outside, discharged materials from Fuji River is reconsidered as useful for the nourishment material since it is a local in nature and the borrow area is closed to the site. A question was that how much amount of the sediment will remain on the terrace, without disappearing offshore.

Fig. 1. Location map

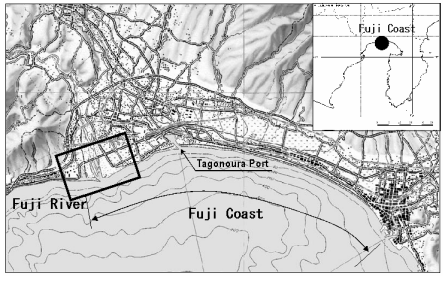

Fig. 2. Fuji River-mouth and Fuji Coast

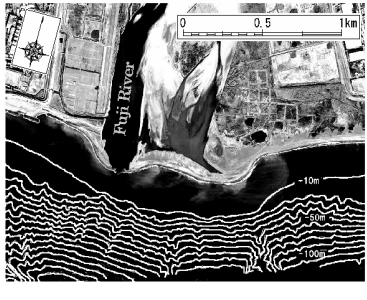

Fig. 3. Topography of Fuji River-mouth

In order to prevent losing the sediment to offshore bottom, a numerical model for estimating the terrace topography change caused by a flood is built. The numerical model is based on a horizontal 2-dimensional shallow water model, in which the sediment grain size is taken into account. The model is verified by depth-soundings and sediment surveys during several floods.

OBSERVATION FOR VERIFICATION

The observation for verification of a numerical model was carried out during several floods. From July to December 2004, 8 typhoons approached to Japan brought floods in Fuji River (Fig.4).

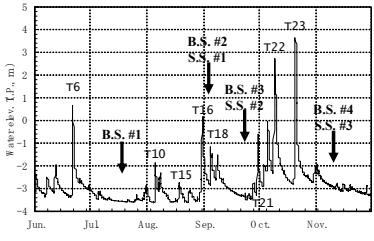

Fig. 4. Flood history and observation schedule

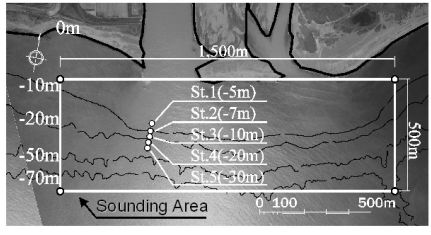

Fig. 5. Observation layout

In particular, Typhoon No.23 (T0423) caused a large flood. The peak discharge reached to 8,338m^3/sec., corresponding to a return period of 13 years in Fuji river. Bottom soundings (B.S.#1-#4) and sediment surveys (S.S.#1-#3) were carried out before and after floods respectively as shown in Fig.4 and 5.

The largest bottom change during the observation was found in the period from the 3rd to the 4th bottom soundings including floods caused by Typhoon No.22 and 23. The distribution of depth change, the comparison of cross section in the center of the river channel and the change volume of sediment in some blocks separated by depth and longshore distance are shown in Fig.6, 7 and Table 1 respectively. The largest depth change reached to about 15m deposition at about 30m depth offshore from almost center of the river channel. The sediment volume of deposition amounted to 366,000m^3 in the sounding area.

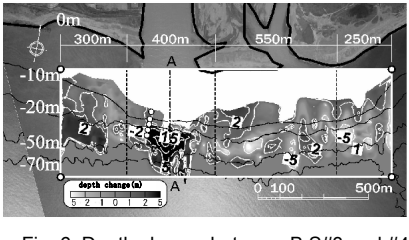

Fig. 6. Depth change between B.S#3 and #4

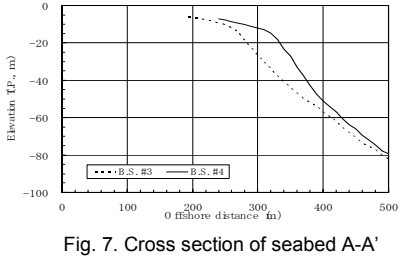

Fig. 7. Cross section of seabed A-A'

According to the depth change analysis, the critical water depth for sediment movement caused by waves was about 14-20m. If the sediment deposit below 20m depth did not come back to the shore by wave action, the amount of sediment about 240,000m^3 was assumed to be lost to offshore area.

Table 1. Change volume of sediment between B.S.#3 and #4

Contour depth	0-300 m	300-700m	700-1250m	1250-1500m	Total (10^3m^3)
≤T.P.-10m	1	13	34	15	100
T.P.-10 to T.P-20m	26	17	1	-7	
T.P.-20 to T.P-50m	63	158	-12	-29	236
≥T.P.-50m	5	66	-6	-9	
Total (10^3m^3)	95	254	17	-30	336

In the 3rd sediment survey after Typhoon No.23, the sediments at every station were mainly composed of gravel and sand on the surface of the bottom. But the sediment at St.3, 4 and 5 deeper than 10m depth included a little silt (Fig.8).

NUMERICAL MODEL FOR TERRACE TOPOGRAPYH CHANGE

A numerical model is presented below; a horizontal 2-D model, treatment of bed load and suspended load, with consideration for sediment grain size. The governing equation for river and sea flow is the shallow water equations using depth-averaged velocity, neglecting the influence of mixture with salinity because the fresh water motion is dominant in the sea nearby the river-mouth during flood. The governing equation for bottom changes is yields from the conservation of sediment volume as follows:

$$\frac{\partial z_b}{\partial t} + \frac{1}{1-\lambda}\left\{\frac{\partial}{\partial x}\sum_l q_{bxl} + \frac{\partial}{\partial y}\sum_l q_{byl} + \sum_l (q_{sul} - w_{fl} c_{bl})\right\} = 0 \qquad (1)$$

where z_b is the bottom elevation, q_{bxl}, q_{byl} are components of bed load transport rates corresponding to grain size l, q_{sul} is the up-lift sediment transport rate from the bottom, w_{fl} is the settling velocity, c_{bl} is the suspended sediment concentration in the vicinity of the bottom, and λ is the sediment porosity. The bed load transport rate in each grain size is estimated by Ashida-Michiue Formula, as follows:

$$q_{bxl} = \sqrt{(\rho/\rho_s - 1) g d_l^3} \times 17 \times \alpha \times \tau_{*l}^{3/2} \left(1 - \frac{\tau_{*cl}}{\tau_{*l}}\right)\left(1 - \sqrt{\frac{\tau_{*cl}}{\tau_{*l}}}\right) P_l \frac{u}{\sqrt{u^2 + v^2}} \tag{2}$$

$$q_{byl} = \sqrt{(\rho/\rho_s - 1) g d_l^3} \times 17 \times \alpha \times \tau_{*l}^{3/2} \left(1 - \frac{\tau_{*cl}}{\tau_{*l}}\right)\left(1 - \sqrt{\frac{\tau_{*cl}}{\tau_{*l}}}\right) P_l \frac{v}{\sqrt{u^2 + v^2}} \tag{3}$$

in which:

$$\tau_{*l} = \frac{u_*^2}{\left(\sqrt{\rho/\rho_s - 1}\right) g d_1} \tag{4}$$

$$\tau_{*cl} = c_t \times \tau_{*cM} \tag{5}$$

$$c_t = \begin{Bmatrix} \dfrac{\log_{10} 19}{\log_{10}(19 d_1 / d_M)}, & (d_1/d_M \geq 0.4) \\ 0.85 \dfrac{d_M}{d_M} & (d_1/d_M < 0.4) \end{Bmatrix} \tag{6}$$

$$c_t = \begin{Bmatrix} 0.05, & R_* \geq 671.0 \\ 0.00849 \times R_*^{3/11}, & 671.0 > R_* \geq 162.7 \\ 0.034, & 162.7 > R_* \geq 54.2 \\ 0.195 \times R_*^{-7/16}, & 54.2 > R_* \geq 2.14 \\ 0.14, & R_* < 2.14 \end{Bmatrix} \tag{7}$$

$$R_* = \sqrt{(\rho/\rho_s - 1) g d_M^3} / v, \qquad d_M = \sum_l d_l P_l \tag{8}$$

where ρ is the water density, ρ_s is sand density, g is gravitational acceleration, d_l is the grain size, P_l is the percentage rate of the grain size, u_* is bottom friction velocity, $v = 1.14 \times 10^{-6}\,\mathrm{m^2/s}$, and α is the coefficient of sediment transport rate.

The suspended load is solved using the following equation:

$$\frac{\partial \overline{c_l}}{\partial t}+\frac{\partial(\overline{c_l}u)}{\partial x}+\frac{\partial(\overline{c_l}v)}{\partial y}=\left(q_{sul}-w_{fl}c_{bl}\right)/h \tag{9}$$

The up-lift sediment transport rate from the bottom is assumed as:

$$q_{sul}=\beta\times P_l\times \mathrm{K}\times\left(\alpha_*\frac{1}{\tau_{*l}}\frac{\rho}{\rho_s}u_*\Omega_l^*-w_{fl}\right) \tag{10}$$

$$\Omega_l^*=14\tau_{*l}^*-0.9 \tag{11}$$

The settling velocity is given by:

$$w_{fl}=\sqrt{\frac{2}{3}\left(\rho/\rho_s-1\right)gd_1+\frac{36\nu^2}{d_1^2}}-\frac{6\nu}{d_1} \tag{12}$$

The concentration of suspended load in the vicinity of the bed is expressed as follows:

$$c_{bl}=\frac{\phi_l\overline{c_l}}{1-\exp(-\phi_l)},\qquad \phi_l=\frac{6w_{fl}}{\kappa u_*} \tag{13}$$

where $\overline{c_l}$ is the concentration of depth-averaged suspended load, β is the coefficient of up-lift rate, K=0.008, α_*=0.14, κ=0.4. The up-wind boundary condition of concentration is given by:

$$\overline{c_l}=B\frac{q_{sul}}{w_{fl}\phi_l}\left[1-\exp(-\phi_l)\right] \tag{14}$$

in which B is an coefficient.

The equation of grain size change introduced the bottom change and exchange layer is:

$$\delta\frac{\partial P_l}{\partial t}+P_l^*\frac{\partial z_b}{\partial t}+\frac{1}{1-\lambda}\left\{\frac{\partial q_{bxl}}{\partial x}+\frac{\partial q_{byl}}{\partial y}+q_{sul}-w_{fl}c_{bl}\right\}=0 \tag{15}$$

$$P_l^*=\begin{Bmatrix}P_l & \left(\partial z_b/\partial t>0\right)\\ P_{l0} & \left(\partial z_b/\partial t<0\right)\end{Bmatrix} \tag{16}$$

where δ is the depth of exchange layer, and P_l is the rate of the grain size, P_{l0} is the rate of grain size in the origin bed. The governing equations are discritized by the Finite Element Method in space and by the selective lumping method (Kawahara et al., 1982) in time.

VERIFICATION OF NUMERICAL MODEL

The present model is verified by the observation data. The verification is carried out in the domain of the river channel and the sea as shown in Fig.9, which is discritized by triangular elements, as illustrated in Fig.10. The boundary conditions of the computation are set under the flow discharge, tidal elevation during the flood caused by Typhoon No.23 as shown in Fig.11. The initial rate of sediment grain size in the bottom is set as four kinds of grain sizes according to the field data as shown in Fig.12.

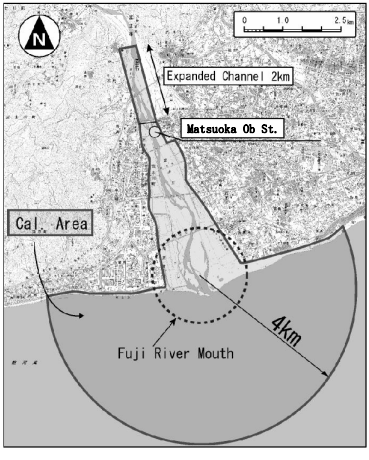

Fig. 9. Calculation area

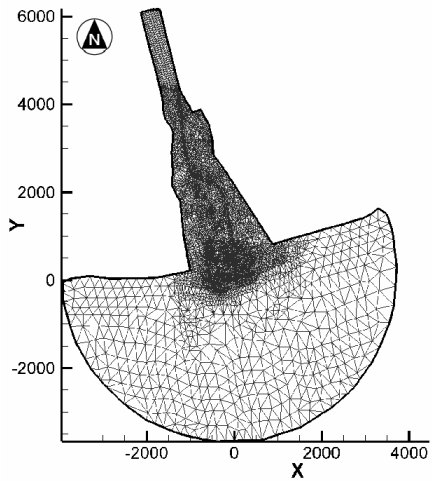

Fig. 10. Finite element mesh

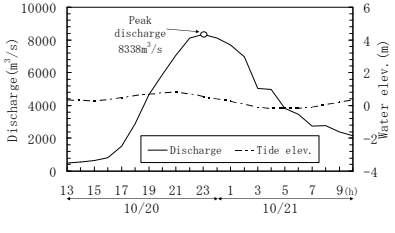

Fig. 11. Flow discharge and Tide level

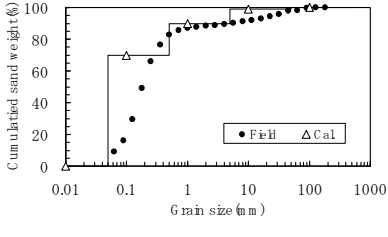

Fig. 12. Initial distribution of grain size

Fig.13, 14 and Table 2, 3, 4 show the horizontal distribution of depth change, the bottom topography in the cross-shore section, and the sediment volume after the flood, respectively.

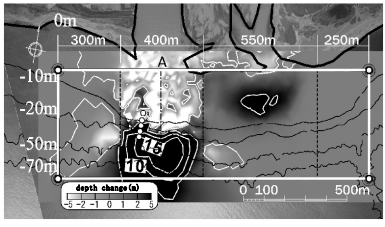

Fig. 13. Calculated depth changes

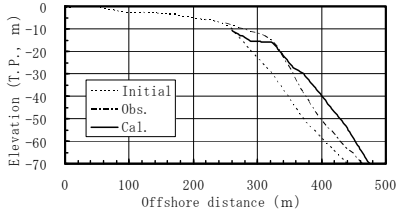

Fig. 14. Depth change in cross shore (A-A')

The sediment from the river deposits in deeper than 10m in front of the river channel is similar to observed data (Fig.5). In particular, the at most deposit area is located at about 30m depth, and it reaches to 15m depth change point, which is in almost agreed with the observed cross section. Moreover, the volume of deposition in the division from 0-700 m alongshore, 10-20m depth is about 45,000m^3, which is almost as same as the observed volume 51,000m^3 (Table 3). However, the sediment volume deeper than 20m depth in calculation exceeds 1,000,000m^3, which is about 3 times as compared to that of the observations. The grain size distribution at each station (St.1-5) is shown in Fig.15. In all stations, the grain size in calculation is rather finer than that of the observations. Also the grain size calculated in 4 hours after the peak discharge at St.1 and 2 relatively, are close to the observation data. Fig.16 shows the flow velocity and grain distribution of St.2 in three instances, one at peak discharge, the other at 4 hours after a peak discharge and at the final. At the time of a peak discharge, the water level is rising over the sand-bar, which was flushed offshore gradually, caused by the flood velocity is beyond 6.0m/sec., and the width of the river-mouth was expanded. At that time the distribution of sediment diameter in calculation is proximate to that of the survey. In 8 hours after a peak, the velocity is decreased, only the finer sediment is moving by then. As the result, the fine sediment is dominant at river-mouth. Above results are different from the sediment survey because of waves. In fact, the large waves which exceeded 5m in height attacked during the flood, the wave motion on the bottom caused fine sand to move toward offshore. Moreover, in this calculation, the sediment supplied from upstream on the boundary is determined by the velocity on the boundary, not considering the condition of the upstream region (Fig.17).

Table 2. Comparison of change volume (from T.P.-10m to T.P.-20m)

Contour depth	0-300 m	300-700m	700-1250m	Total
Observed (10^3m^3)	32	19	17	68
Calculated (10^3m^3)	0	45	10	55

ESTIMATION OF ANNUAL SEDIMENT DISCHARGE

It is very important to estimate the annual sediment discharge from Fuji River in order to understand the suitability of material as beach fill. The annual sediment discharge can be estimated as the expectation volume derived from the analysis using the results obtained by this return period model. Fig.18 shows the each volume of sediment remained on the terrace and lost to offshore be separated at 20m depth in the case of four kinds of floods. The total volume of discharged sediment increased together with amount of flow. However, the volume of sediment remained on the terrace does not correspond with the sediment volume lost into the offshore area. According the analysis using these results, the annual sediment volume which remained on the terrace is 240,000m^3 and the lost amount is 390,000m^3, approximately.

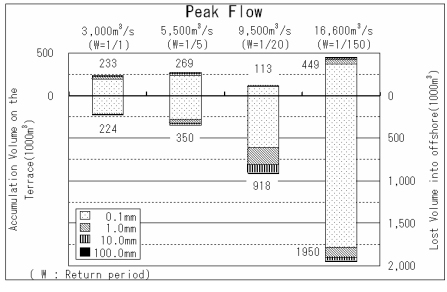

Fig. 18. Volume of sediment deposited on terrace and lost into offshore area at peak low

CONCLUSIONS

The numerical model for an estimation of a terrace topography change, considering sediment grain size, is presented. This model could be verified by the observation data obtained in Fuji river-mouth. In the case like the Fuji river-mouth, which faces the coast with the steep slope, it is obvious that almost 60% of the annual sediment discharged from the river is lost to offshore area. Therefore, the sediment contributed as the longshore sediment transport is well overestimated.

Furthermore, the volume of sediment remained on the terrace is not enough for the beach nourishment for Fuji coast. Since it is expected that the amount of sand discharge from Fuji River will not increase in near future, keeping the remained sediment at the beach is almost important. The present model can be a powerful tool to solve this problem.

ACKNOWLEDGMENT

This work was a part of the project of the countermeasure for erosion in Fuji coast, managed by Numazu Office, Ministry of Land, Infrastructure and Transport.

Abstract: We investigate the near-bed sediment dynamics, that occurs in the oscillating boundary layer, observed during the SandyDuck '97 field experiment, through use of the k-ε turbulence module GOTM (1-D General Ocean Turbulence Model, *Burchard*, 1999). For most of the time, the value of the near-bed Richardson number of the high-energy events under examination exceeds the critical value of 0.25, suggesting suppression of turbulence by sediment-induced stratification. GOTM is used to simulate the onshore sandbar migration observed over a 5-day period during Duck'94 field experiment. Bar migration is predicted with a skill of 0.72 when including stratification effects. The accretion/erosion rates predicted using the same free parameters but neglecting stratification effects are approximately twice as large.

INTRODUCTION

Observations of near-bed sediment dynamics such as those collected by FOBS (Fiber Optical Backscatter Sensor) have highlighted the, at times dominant, role played by high-energy events, close to the bed where the sediment is mobilized and redeposited on time scales smaller than half a wave period (e.g. *Conley and Beach*, 2003). It has been proposed (e.g. *Conley*, 2005) that sediment stratification in this thin granular-fluid layer near the bed may have a strong role in such observed phenomena as the reversal of net cross-shore transport direction with height above the bed. It has been proposed that the stratification due to strong upwardly diminishing sediment concentration gradients can

enhance the role of near-bed dynamics by limiting the dispersion of sediment further into the water column. The result is a reduction in the contribution of the mean sediment transport from suspended sediments higher in the water column and an increase in the coherent transport that is biased to the high-velocity peaks under wave crests.

Turbulence damping by stratification is, typically, identified through the inspection of the gradient Richardson number (the non-dimensional ratio between the square of the buoyancy frequency and the square of the vertical gradient of the horizontal velocity which represents the ratio of flow-stabilizing-to-destabilizing forces):

$$Ri = N^2 \Big/ \left(\frac{du}{dz}\right)^2 = -g\frac{\partial\rho}{\partial z}\Big/\rho\left(\frac{du}{dz}\right)^2 = -gs\frac{dc}{dz}\Big/(1+cs)\left(\frac{du}{dz}\right)^2 \qquad (1)$$

where N = buoyancy frequency (1/s); u = velocity module (m/s); ρ = suspension density (kg/m^3); g = gravity acceleration (m/s^2); s = submerged specific gravity of the sediment (non-dimensional); c = sediment concentration (non-dimensional).

The effects of stratification are negligible until $Ri > 0.03$, and mixing is completely suppressed when $Ri >= 0.25$. While traditional applications of this parameter typically involve mean quantities on time scales of minutes or greater, we examine this parameter for very short periods of time (less than half a wave period) and observe that critical stratification is commonly achieved and that it has dramatic affects on the net sediment transport.

In this paper, we test the ability of the two-equations k-ε turbulence module GOTM (1-D General Ocean Turbulence Model, *Burchard*, 1999) to reproduce such stratification effects. Moreover we investigate the role that the above-mentioned increase in the coherent transport component close to the bed occurring during the analyzed events, can have as an additional cause for onshore sandbar migration.

The field data used for this aim belong to the Duck'94 field experiment (North Carolina), in which a 25-m onshore sandbar migration, observed over a 5-day period, has already been subject of study by many authors (*Thornton et al.,* [1996]; *Gallagher et al.,* [1998]; *Trowbridge and Young,* [1989]; *Hoefel and Elgar*, [2003]; *Henderson et al.,* [2004]; *Hsu et al.,* [2006]). Two different approaches to examine this issue can be found in the literature. The first assumes an energetics approach for the sediment transport model. Originally developed by *Bagnold* [1966], who relates the sediment transport rate for steady flows to the rate of work on the bed by the flowing fluid, it has been subsequently extended by *Bailard and Inman* [1981] to combined (oscillatory and steady) flows. The most recent significant modification to this model has been made by *Hoefel and Elgar* [2003], who showed that the addition of acceleration-skewness-dependent transport to the model of Bailard, leads to successful predictions of both the shoreward and the seaward bar migrations observed during the Duck94 experiment.

The other approach followed in literature, belongs to the wave-resolving eddy-diffusive model, the most recent version being proposed by *Henderson* [2004] and later by *Hsu et al.* [2006]. The common issue to their work is the inclusion of the nonlinear wave boundary layer processes in the determination of the shoreward sediment motion.

THE MATHEMATICAL/NUMERICAL METHOD

To gain insight in up-scaling realistic turbulence closure models under energetic sediment transport conditions, we have run numerical model simulations of sediment-stratified bottom boundary layers using the 1-D General Ocean Turbulence Model (GOTM). GOTM is an open source, two-equations (k-ε) turbulence closure model based on the hydrodynamic equations of motion and which makes use of the Boussinesq approximation (density only considered variable when multiplied with gravitational acceleration), the hydrostatic approximation and the eddy viscosity approximation. Since the time scale required to analyze the suspension events is shorter than one second, the model code used for this exercise has been slightly modified to account for sub-second processes.

A key parameter to model the flow velocity within a sheet flow is the bed roughness length, which depends on the viscosity of the water, the flow speed and the size of the physical roughness of the bed. Assuming hydrodynamically-rough flows, the bottom roughness reduces to:

$$z_0^b = 0.03 h_0^b + z_a \tag{2}$$

where z_0^b = bottom roughness (m); h_0^b = Nikuradse roughness (m); z_a = sediment transport component (m). The Nikuradse roughness is taken as 2.5 times the grain diameter; while for the sediment transport component, which arises from the momentum used by the flow to move the sand grains during intense sheet flows, standard GOTM implements the relation proposed by *Smith and McLean* [1977]:

$$z_a = \alpha_0 \left(u_{*b}^2 - u_{*c}^2\right) / \left[g\left(\rho_s - \rho_0\right) / \rho_0\right] \tag{3}$$

where α_0 = constant equal to 26.3; u_{*b} = actual bed shear stress (m/s); u_{*c} = critical bed shear stress (m/s); ρ_s = sediment density (kg/m^3); ρ_0 = water density (kg/m^3).

With the data at hand we found that the Smith and McLean's relationship over predicts the sediment transport component and that a better formula to quantify the total roughness length, comes from the relation proposed by *Nielsen* [1992]:

$$z_a = 5.67\left(\theta_{\omega s} - 0.05\right)^{0.5} d_{50} \tag{4}$$

where $\theta_{\omega s}$ = skin-friction Shields parameter (non-dimensional); d_{50} = representative sediment size (m). The increase of the roughness height over the corresponding values pertaining only to a clear fluid, due to the inter-granular and fluid-granular interactions in particle-laden flow over a mobile bed, is accounted for also by *Hsu et al.* [2006] to predict the onshore and offshore bar migration. They found that the best fit roughness height to the data available depends on the turbulence closure scheme; in particular for the k-ε closure scheme they suggest a modified Nikuradse roughness equal to 25 times the sediment diameter.

The conservation equation for suspended sediment mass, assuming a pure diffusion process (zero convective flux) reads:

$$\frac{\partial C}{\partial t}+\frac{\partial(\omega_s C)}{\partial z}=\frac{\partial}{\partial z}\left(\varepsilon_s \frac{\partial C}{\partial z}\right) \tag{6}$$

where C = sediment concentration (non-dimensional); ω_s = sediment fall velocity, a constant calculated from the grain diameter using the formula of *Soulsby* [1997] (m/s); ε_s sediment diffusivity (m^2/s). The equation is solved in two steps using a splitting technique by which the advective part is solved first:

$$\frac{\partial C}{\partial t}=-\frac{\partial F}{\partial z}; \qquad F=\omega_s C \tag{7}$$

The surface boundary condition is of zero mass flux F, while at the lowest interface the flux F is calculated with a one-sided first-order upstream discretization.
Instead for the diffusive part:

$$\frac{\partial C}{\partial t}=\frac{\partial}{\partial z}\left(\varepsilon_s \frac{\partial C}{\partial z}\right) \tag{8}$$

at the surface we impose a Dirichelet condition (zero flux), while at the lowest interface a Neumann condition is imposed:

$$C_{dw}=C_a\left[\frac{0.5z}{z_0^b}\frac{h-z_0^b}{h-0.5z}\right]^{-b}; b=\frac{\omega_s}{\kappa u_*^b} \tag{9}$$

where C_{dw} = sediment concentration at the lowest interface (non-dimensional); C_a = bottom reference concentration (non-dimensional); h = water depth (m); z = height of the lowest interface (m); b = Rouse number (non-dimensional); κ Von Karman constant.
A Lickian entrainment relation expresses the bottom reference concentration:

$$C_a=g_1\left[\left(u_*^b/u_*^c\right)^2-1\right] \tag{10}$$

where g_1 = non-dimensional parameter. If the value of z_0^b is computed by means of the α_0-dependent Smith and McLean formulation (3), g_1 is found to be equal to 1.56 E-03. On the contrary, if the formulation (4) proposed by Nielsen is used, a calibration of the sediment transport model is needed by determining g_1, through a least square fit of the available data.

As for the turbulent mixing of sediment ε_s has been parameterized using the reduced eddy diffusivity for passive tracers given by:

$$\varepsilon_s = \beta \frac{\nu_t}{\mathrm{Pr}_t}; \nu_t = C_\mu \frac{k^2}{\varepsilon} \tag{11}$$

where β = constant; ν_t = eddy viscosity (m^2/s); Pr_t = Prandtl number (non-dimensional); C_μ stability function (non-dimensional); k = turbulent kinetic energy (m^2/s^2); ε = dissipation rate (m^2/s^3). In the literature many different sets of stability functions can be found; they have the role to increase mixing in the case of unstable stratifications and decrease it for stable stratifications. We start with a simple choice of stability functions for the momentum equation, i.e. such that which, C_μ is a constant. Instead the stability function for tracers is related to the Richardson number through the Prandtl number as described in *Munk and Anderson* [1948]:

$$\mathrm{Pr} = \begin{cases} \mathrm{Pr}^0 \dfrac{(1+3.33Ri)^{3/2}}{(1+10Ri)^{1/2}}, \text{ for } Ri \geq 0, \\ \mathrm{Pr}^0 \qquad\qquad\qquad \text{for } Ri < 0 \end{cases} \tag{12}$$

where Pr^0 = constant Prandtl number for neutral stratification (non-dimensional); Ri = gradient Richardson number (non-dimensional). The buoyancy frequency used to compute the Richardson number takes into account the contribution due to the sediment concentration gradient. The reductive β parameter of equation (11) is used as a calibration parameter.

PREDICTING ONSHORE BAR MIGRATION

The numerical solution

We compare the onshore sandbar migration predictions given by the model with the erosive/accretive patterns observed during the Duck field experiment of 1994. The model is initialized with the 2-Hz time series of horizontal water velocity measured by near-bottom-mounted current meters extending from the shore to a location of about 4.5m depth. During the chosen period the current meter height above the bed remained of about 0.5m, i.e. sufficiently close to the bottom boundary layer. The seabed elevations used to initialize the model came from the measurements of the sonar altimeters deployed in conjunction with the majority of the current meters. The in-situ mean sediment grain sizes ranged from 0.30mm at the shoreline to 0.15mm at water depths of about 5m. For the numerical simulations we used a constant value of 0.2mm. The sensitivity to the cross-shore variations in grain diameter has been already tested by *Henderson et al.* [2004]. Indeed it is not clear the importance of neglecting the real distribution of sediment size, as for one of the offshore migration events they tested, the solution with constant sediment diameter (1-5 September) provided better results than that obtained with variable diameters, while for the other event (2-4 October) the contrary occurred. Moreover for the event characterized by an onshore sandbar migration, the model using a constant diameter provided a scarce prediction of the observed bathymetry, but not that bad to invalidate the assumption of constant sediment diameter.

The model described in the previous section was run repeatedly for each three-hour run

and for each current meter location. The transport rate signal of each instrument has been partitioned into wave, infragravity, mean and net contribution, the last one being the sum of the other three components. The wave and infragravity components are calculated from the raw co-spectrum of concentration and cross-shore velocity, choosing a cutoff frequency of 0.05Hz (*Conley,* 2003). The total, time-averaged and vertically-integrated transport values are estimated by simple integration of the flux values from the bed to the surface.

If it is assumed that the longshore sediment flux and the density of the sediment packing is constant, the mass conservation along the cross-shore direction yields (*Thornton et al.*, 1996):

$$\frac{dh}{dt} = \mu \frac{dQ_x}{dx} \tag{13}$$

where h = bed elevation (m); μ = packing factor (0.7); Q_x = cross-shore, time-averaged transport (m^2/s). The vertical morphological change appearing in equation (13) is estimated by fitting a continuous cross-shore profile of the sediment flux estimated at each current meter location (non-uniformly spaced in the cross-shore direction). The waves in the period tested were moderately energetic; with the significant wave height measured at 4 m depth slowly diminishing from a peak of 1.3 m to a minimum of 0.1 m mid-day on the 25th and then increasing briefly to a peak of 1.20 m (figure 1a). The mean wave period was approximately 7-8 s until mid-day on the 26th and then increased to a peak of 10 s towards the end of the period analyzed (figure 1a).

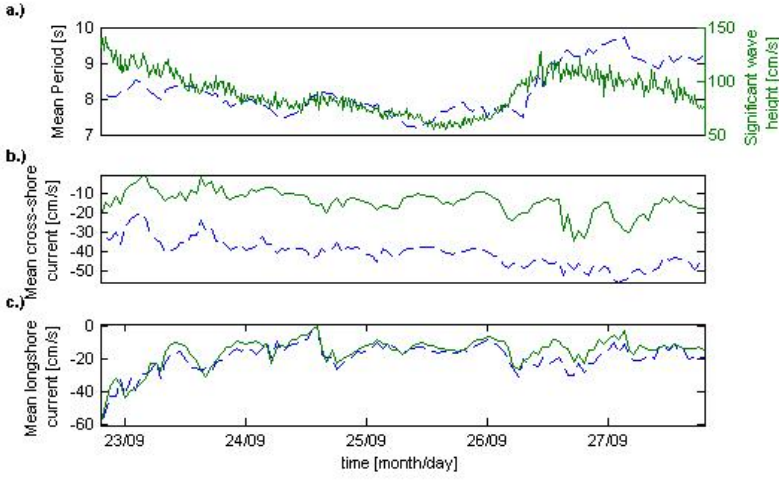

Figure 1 Plot of significant wave height (solid line) and mean period (dashed line) (a), mean cross-shore current near the bar crest (solid line) and trough (dashed line) (b), longshore current at the same locations (c).

Model results suggest that when mean-current-induced transport is small, wave-induced transport leads to the observed onshore bar migration (*Trowbridge and Young,* [1989]; *Hoefel and Elgar*, [2003]; *Henderson et al.,* [2004]; *Hsu et al.,* [2006]). Figure (1b) shows that, at last near the bar crest, the value of the cross-shore mean current for this period was generally low magnitude. As seen in figure (1c) the longshore current remained weak following the initial decrease from the post storm maximum at the beginning of the period.

To assess also the order of magnitude of the wave component to the sediment transport, figure (2) is used to show vertical profiles of one run-averaged (three hours) wave, infragravity, mean and net fluxes near the bar crest. The wave component, directed onshore, clearly exceeds the mean component directed offshore, causing a net sediment transport flux directed onshore. Note that the infragravity component does not affect significantly the net transport rate, its order of magnitude being 10 times lower than that of the wave component.

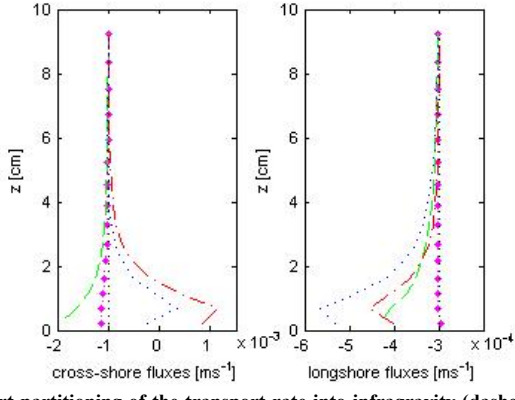

Figure 2 Transport partitioning of the transport rate into infragravity (dashed lines with solid circles), mean (dashed line), wave (dashed-dotted line) and net (dotted line) transport near the bar crest for the cross-shore flux (left panel) and long-shore flux (right panel) for a three-hour run.

Predicted beach profile

Observed and predicted beach profile evolutions are compared in Figure 3 and 4. To quantify the model skill at reproducing the observed morphological changes, we use the same approach proposed by *Gallagher et al.* [1998] and modified later by *Henderson et al.* [2004], who evaluates the model skill through the parameter:

$$S = 1 - \frac{\int_a^b (h_p - h_0)^2 \, dx}{\int_a^b (h_i - h_0)^2 \, dx} \qquad (14)$$

where S = model skill (non-dimensional); h_p= final predicted height (m) ; h_0 = final observed height (m); h_i = initial observed height (m); *a (b)* = most seaward(landward) location at which the current meter observations are available (m). If the model prediction was perfect, the model skill would be equal to 1. If the model prediction was more (less) accurate that the no-change assumption (S = 0), then the skill would be positive (negative).

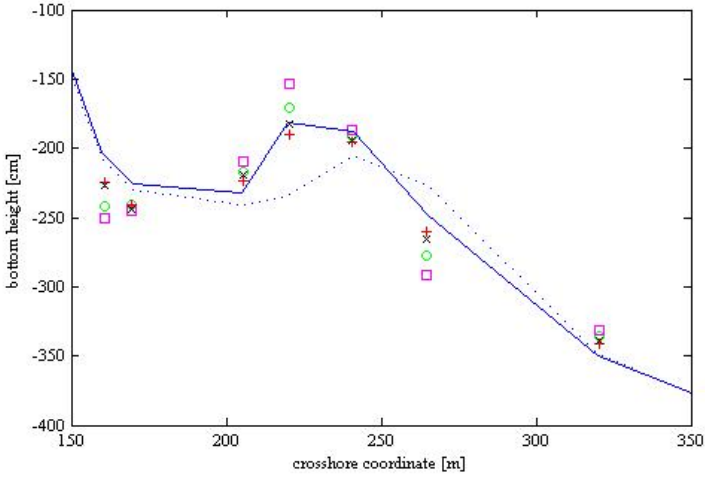

Figure 3 Onshore bar migration. Observations from 22 September 19:00 (dashed line) to 27 September 19:00 (solid line) are compared the numerical solution. Circles and squares represent the prediction with no stratification and , respectively, with g_1=1.80E-03, β=0.4 (S=0.17) and with g_1=2.30E-03, β=0.4 (S=-0.75). Pluses and crosses represent the prediction with stratification respectively for g_1=1.80E-03, β=0.4 (S=0.72) and g_1=2.30E-03, β=0.4 (S=0.58).

As seen in Figure (3), the model with sediment-induced stratification included (hereinafter, stratification included solution SIS), successfully predicts the shoreward bar migration (S=0.72) even if erosion onshore of 180 m is predicted against an observed slight accretion. Figure (3) also shows the sensitivity of the model to the reference concentration parameter: for the SIS, with β constant (0.4), and changing the value of g_1 from 1.80E-03 to 2.30E-03, the model skill decreases from 0.72 to 0.58. The effect of neglecting the sediment-induced stratification in the model predictions (hereinafter, no-stratification solution NSS), using the same calibration parameter, gives an accretion/erosion rate about twice that obtained with SIS. In particular the NSS becomes less accurate than the no-change assumption in the conditions characterized by a large concentration parameter (S = -0.75).

Figure (4) shows also the comparison of the predicted SIS profiles with different sets of the model calibration parameters. For g_1=1.80E-03 the highest skill (S = 0.72) is obtained, while changing the value of β from 0.4 to 1.0, leads to a prediction less

accurate that the no-change assumption (S = -1.29). The figure also reports the result obtained using the value of g_1 proposed by *Smith and McLean* [1977] and a sediment diffusivity equals to that used for the passive tracers. This latter case is characterized, again, by a negative skill, suggesting that the best choice for the model calibration parameter is β = 0.4 and g_1 = 1.80E-03 (giving S = 0.72).

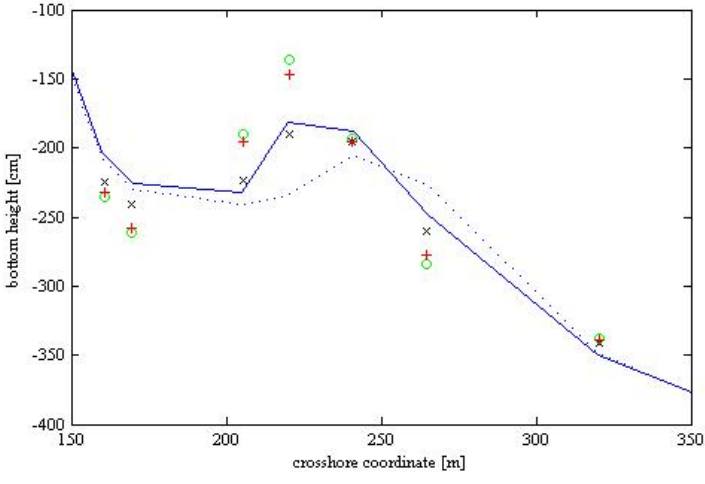

Figure 4 Onshore bar migration. Observations from 22 September 19:00 (dashed line) to 27 September 19:00 (solid line) are compared with the SIS. Circles represent the solution for (g_1, β) = (1.80E-03, 1.0), giving S = -1.29; crosses the solution for (g_1, β) = (1.80E-03, 0.4) giving, S = 0.72; pluses the solution for (g_1, β) = (1.56E-03, 1.0), giving S = -0.66.

Figure (5) shows the separate contributions to the sandbar migration caused by the various transport components. It is clear that the transport occurred around the bar-through location is almost entirely due to the wave component and that the mean and infragravity component have a reduced influence. Only seaward of the bar crest the mean and infragravity induced components of transport significantly affect the bed morphology, causing a large accretion. These model results are consistent with the previous studies (e.g.. *Thornton et al*. [1996]; *Gallagher et al*. [1998]; *Hsu et al*. [2006]) that suggest wave-induced component of transport being the cause of the observed net onshore sandbar migration.

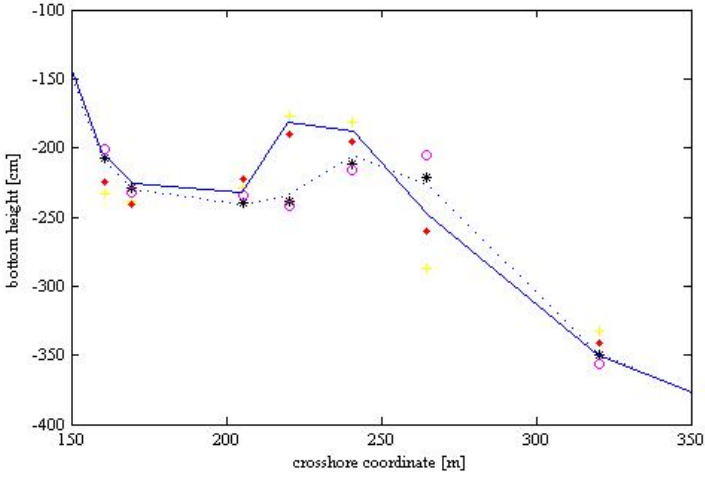

Figure 5 Onshore bar migration. Observations from 22 September 19:00 (dashed line) to 27 September 19:00 (solid line) are compared with the SIS obtained with (g_1, β) = (1.80E-03, 0.4) and the transport contributions highlighted as: infragravity-induced (stars), mean-induced (circles), wave-induced (pluses) and net-induced (dots).

DISCUSSION

The onshore bar migration is fairly well predicted with the calibrated SIS model ($\beta = 0.4$ and $g1$ = 1.80E-03), even if the accretion near the bar crest is slightly underestimated. This result and the small landward erosion predicted onshore of 180m instead of the observed accretion, are findings similar to those reached by *Hsu et al.* [2006] and *Henderson et al.* [2004]. The results obtained have highlighted and clarified the importance of the inclusion of the sediment-induced stratification in a model that reproduces the near-bed sediment dynamics (occurs in the oscillating bottom boundary layer). Neglecting sediment stratification would lead, with the same calibration parameters, to an approximate doubling in accretion/erosion rates. Hence, although in principle it could be attempted to reproduce the appropriate accretion/erosion rates through a specifically-calibrated NSS, we think this approach would obscure the overall physics of the phenomenon. The limited range of flow conditions tested (moderate wave forcing) suggests that extension of the above findings to a wider parameter space be made with care. In particular more tests are needed for strong wave conditions forcing offshore sandbar migration events.

We have attempted to compare our solutions to those provided by various wave-averaged and wave-resolving circulation models available in the literature. However, the different solution strategies and assumptions which are at the core of the various techniques makes such a comparison difficult and preclude a clear understanding of the fundamental phenomena influencing beach morphology evolution. For example, the model proposed by *Henderson et al.* [2004] differs from our SIS solver, because it

includes a second-order non-linear advective flux as well as a diffusive sediment flux in the suspended sediment mass conservation equation. Moreover the highest skill (S = 0.81) in reproducing the same sandbar migration event is achieved with a variable grain size in the cross-shore profile, against our constant value, and a greater value for the reference concentration parameter of 2.9E-03 with respect to the SIS model. However, the model, using the same parameters, fails to reproduce the offshore migration event of the 2-4 October; on the contrary a better results is obtained by means of a non-advective calibrated sediment transport model which makes use of a lower reference concentration parameter. The comparison with the model of *Hsu et al*. [2006], which uses a Meyer-Peter Mueller law for the dimensionless transport rate and a large roughness height (up to 25 times the grain size), to compensate for neglecting intergranular stresses and fluid-granular interactions is also difficult.

CONCLUSION

The onshore sandbar migration event, observed over a 5-day period during the Duck'94 field experiment, has been simulated through use of the k-ε turbulence module GOTM. On the basis of previous studies, which suggest the important role played by the sediment-induced stratification near the bed (*Conley,* [2005]), we investigated the main differences in predicting the observed beach profile change caused by the inclusion/neglection of sediment stratification effects.

The sediment transport model here in use, based on a Lickian entrainment relation for the bottom reference concentration and the relation proposed by *Nielsen* [1992] for the sediment transport roughness, predicts fairly well the onshore migration events under analysis. The result found when neglecting the stratification, show an almost-doubled accretion/erosion rates with respect to the solution which includes the near-bed sediment stratification. It seems possible, though physically undesirable, to obtain the same sediment transport rates and erosion/accretion patterns by means of a NSS obtained with specifically-calibrated model parameters.

ACKNOWLEDGEMENTS

We would like to express our gratitude to Dr. Steve Elgar for furnishing the Duck94 SPUVT data. We would also like to acknowledge the NATO Undersea Research Centre and the D.I.Am. of Genova University, for co-sponsoring the doctoral fellowship of the first author.

Abstract: The Berau delta and barrier reef system, East Kalimantan, Indonesia are subject of an integrated and multidisciplinary research programme that studies the transfer of water and sediment from upland river catchments towards estuaries and offshore located coral reef systems. Estuaries in the Berau delta have a certain trapping efficiency but a significant part of the suspended matter is still able to reach the marine environment. Seismic profiles, isotope analysis for deposition rates, estuarine and offshore measurements of salinity and turbidity patterns and ecological evidence, collected during a pilot study, provide clear evidence for this.

INTRODUCTION: ROLE OF TROPICAL RIVERS

Coastal sediment input by tropical rivers appears to be one of the main driving factors for changes in coastal morphology in tropical regions. Remarkably more than 70 % of the sediment load entering shelf seas and oceans is delivered by rivers in Southeast Asia and Oceania. For a variety of reasons such as the presence of a humid tropical climate,

high topographic relief, the degree of deforestation and the presence of erodible rocks and soils, in particular the Indonesian Archipelago is characterized by a huge input of sediment into the coastal zone (Hoekstra, 1989 and Milliman et al., 1999). The most recent estimates even suggest that 20-25 % of the global sediment transfer is delivered by tropical rivers in the East Indies (or Indonesian Archipelago; Latrubesse et al., 2005). Fluvial sediment entering the coastal zone will be subject to estuarine, deltaic and marine processes which eventually will determine the fate of the (suspended) sediment (Hoitink et al., 2003; van Maren and Hoekstra, 2005). The coarser fraction commonly directly contributes to estuarine deposition and delta growth but fine suspended matter will be dispersed across the shelf and occasionally may reach deeper oceanic waters. One of the larger islands of the Indonesian Archipelago is the island of Kalimantan and drainage basins on Kalimantan produce about 0.90×10^9 tons of sediment each year (Milliman et al, 1999) and are responsible for the development of some of the largest and most dynamic deltas in the Indo-Pacific region. Coastal progradation in, for example, the Mahakam delta, probably the largest delta in Indonesia, was about 60 km over the past 5000 years (Storms et al, 2005). In the present study we focus on a somewhat smaller system: the Berau river basin and delta, located along the Northeast coast of Kalimantan. The Berau river and delta (Fig. 1) is part of a larger coastal system that includes the delta with a number of estuarine branches (two northern and one southern branch), tidal channels and creeks and extensive mangrove swamps that are already partly converted into fishponds for aquaculture. In a seaward direction, the estuaries are connected with an extensive and relatively shallow lagoon / inner shelf, separated from more oceanic waters by a delta-front barrier reef (Tomascik et al., 1997) and the west part of the passage between the islands of Kalimantan and Sulawesi with some isolated oceanic reefs. Due to this specific coastal setting the Berau river is having a pronounced impact on the coastal zone in terms of water and sediment supply, the presence of nutrients and pollutants and the physical as well as ecological consequences that are associated with these factors such as fluctuations in salinity and turbidity (compare e.g Wolanski et al., 2004).

The purpose of the present paper is to give a general overview of the integrated Indonesian-Dutch research programme “From River Basin to Barrier Reef” that was launched in 2006 to study physical, ecological and socio-economic aspects of the Berau delta system. Leading theme is the transfer of water and sediment from upland river catchments towards estuaries and both shelf as well as oceanic reefs. The study focuses on the role of physical/biological coastal processes and human impact – in particular due to changing land-use patterns and large scale deforestation – on this system. In this paper we will address the fate of (estuarine) suspended sediment in relation to sediment input and dispersion into the coastal zone, based on a pilot study carried out in 2003. The paper starts with a short summary of the aims and objectives of the integrated programme. Next, the general characteristics of the Berau delta system are discussed and the first results from three of the six research programmes are presented. The paper ends with some first and preliminary conclusions based on the pilot campaign of 2003 and ongoing measurements that recently started in 2006.

FROM RIVER BASIN TO BARRIER REEF

Physical and ecological conditions

The Berau river accounts for a substantial annual input of fresh water (delivering buoyancy) and sediment into the coastal zone, creating Regions Of Fresh water Influence (so-called ROFI; Simpson, 1997). This input of water and sediment and the development of a ROFI creates very specific environmental conditions that both provide opportunities as well as limitations for coastal (eco)systems. Sediment input directly contributes to estuarine dynamics and delta growth. Meanwhile, this water and sediment also determine the local and regional salinity, temperature, turbidity and suspended sediment load patterns and act as ecological stress factors for coastal ecosystems such as coral reefs. In particular, turbidity and siltation patterns associated to ROFI behaviour are key-controls of the zoning and morphology of coral reef systems. Likewise, these environmental stress factors will also be reflected by the growth pattern and characteristics of individual coral species and therefore provide high-resolution, proxy records to determine the local, regional or even global variability in climatic (and associated environmental) conditions in the recent past. The latter observation is very relevant since it provides a tool for understanding the natural dynamics of the system on an annual, decadal or even centennial time scale. Physical processes responsible for sediment delivery in the Berau system commonly operate on a range of temporal and spatial scales. Apart from the day-to-day tidal fluctuations (the ebb-flood but especially the spring-neap cycle), the river regime is subject to seasonal as well as annual fluctuations due to alternating wet and dry monsoons. In addition, inter-annual to decadal variability in river discharge, sediment load and marine conditions is determined by the El-Niño Southern Oscillation (ENSO cycle).

The socio-economic activities in the Berau river basin and coastal region are both affecting and affected by the natural dynamics of the system. However, these activities also have their own independent driving factors and momentum related to increasing population pressure, advancing processes of economic development and social change. In the near future, land, forest and reef degradation, man-induced changes in hydrological and fluvial regime, sedimentation and water pollution will result in a further degradation of the natural environment.

Integrated research programme

To study the complex interactions within such a coastal environment a research programme entitled "From River Basin to Barrier Reef" was recently launched. It is a joint Indonesian-Dutch initiative within the framework of the East Kalimantan Programme (2006-2010). The main objectives of this integrated and multidisciplinary study in the Berau delta are to:

- Analyse and define the interaction of physical, biological and socio-economic processes and developments in a river delta – barrier reef system that is at present characterized by a very large natural variability and still (partly) represents a pristine coastal environment;
- Asses the consequences of changing environmental conditions and increased human activities for the coastal and marine ecosystems;
- Use coral reef ecosystems as a bio-monitor for the state of the system.

The overall programme includes six different individual projects all dealing with specific aspects of the Berau system. The programme combines a range of disciplines, dominantly from natural sciences (physical geography, coastal oceanography, marine geology and coral ecology) but also including the human sciences (human geography). The programme includes the following projects: 1) Land degradation, estuarine dynamics and delta development in the Berau system; 2) Human Settlements in the coastal zone: effects of changing land-use patterns and deforestation; 3) Mixing and dispersion in marine waters surrounding coral reefs; 4) Coral condition, coral disease and algal/coral overgrowth in the Berau coral reef system; 5) High-resolution coral proxy analysis of the modern environment and reconstruction on a seasonal to centennial time scale; 6) Remote sensing of marine environment.

Sediment dynamics

Projects 1, 3 and 5 are all dealing with mainly the physical aspects of sediment delivery, dispersion and deposition and cover different aspects of the pathways and impact of coastal sediment. In the present paper we will concentrate further on these issues based on a pilot study carried out in East Kalimantan in July – August 2003 and on preliminary results obtained during recent and ongoing studies which started in September 2006 and will continue in 2007. The first project focuses on the effects of estuarine mixing processes – in relation to river discharges and tidal conditions – on the seaward transfer of water and sediment. The delivery of fluvial sediment itself depends on the hydrological sensitivity of the Berau drainage basin for seasonal and decadal scale climatic fluctuations in rainfall and the associated changes in soil erosion. The latter

process may be enhanced by man-induced changes in land-use patterns and deforestation. The third project aims to establish and understand the mixing and dispersal processes determinative to corals in the Berau barrier reef system. A link has to be established between processes acting on a regional scale such as tidal asymmetry up- and downwelling and the effect of buoyancy in a ROFI (Hoitink, 2004; Hoitink et al., 2003; Hoitink and Hoekstra, 2003; Wolanski, 2001) and the local process knowledge, on the scale of individual corals, of mixing and dispersion , for example in relation to the presence and characteristics of different types of hydrodynamic boundary layers (Shashar et al., 1996). Projects 1 and 3 both benefit from a combination of field measurements, modeling efforts and data obtained by remote sensing.

The coral proxy analysis (project five) determines the natural and anthropogenic induced environmental changes, based on a study of the temporal variability of conjugate proxies of banded massive *Porites* corals across a range of environmental settings in the Berau estuary – barrier reef system. Multi-proxy signals (e.g. high-resolution fluorescence measurements, isotope ratios) will be calibrated against in-situ time-series measurements of environmental parameters such as Sea Surface Temperature (SST), salinity and turbidity. The coral proxy analyis is based on handcores taken in the coral reef and laboratory analysis. During the pilot campaign in 2003 already seismic surveys were carried out and box cores were collected to establish the regional variability in grain size patterns of the clastic material in the area and the local deposition rates based on ^{210}Pb analysis.

COASTAL MORPHOLOGY AND SEDIMENTOLOGY

The seismic surveys, in combination with boxcores and bed samples demonstrate the presence of a lowstand and high-stand system tract (Fig. 2). The inner shelf between the present Berau delta and delta front barrier reef system is characterized by the delta platform and prodelta of the modern (Holocene) Berau delta, extending 25-30 km

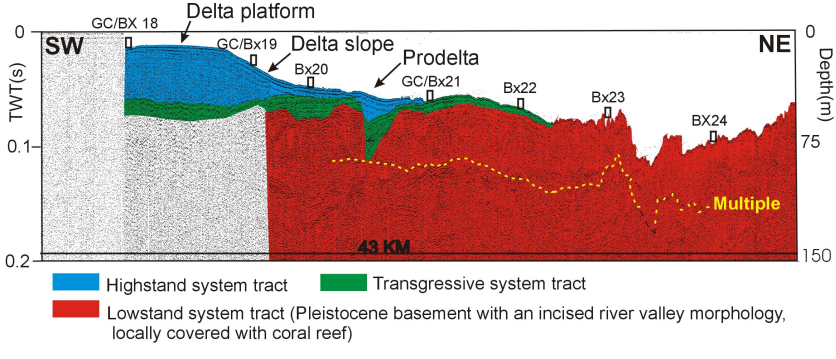

Fig. 2. Geological and morphological development of the Berau delta based on seismic surveys and samples taken from the sea bed.

offshore. The lowstand system tract represents the Pleistocene basement which shows a rather irregular and rugged topography due to the presence of incised river valleys. Locally, this Pleistocene surface is superimposed by transgressive and modern patch reef structures. The lagoon system reaches a maximum depth of about 75 m. Both system tracts are connected with each other by a transgressive system tract (Fig. 2).
Sediment properties vary with distance offshore. The delta platform and prodelta are characterized by very homogeneous, silty sediments; further seaward but still west of the barrier reef the bottom deposits exist of muddy sand alternating with reef structures. The zone between the delta front barrier reef and the oceanic reefs that are located on a

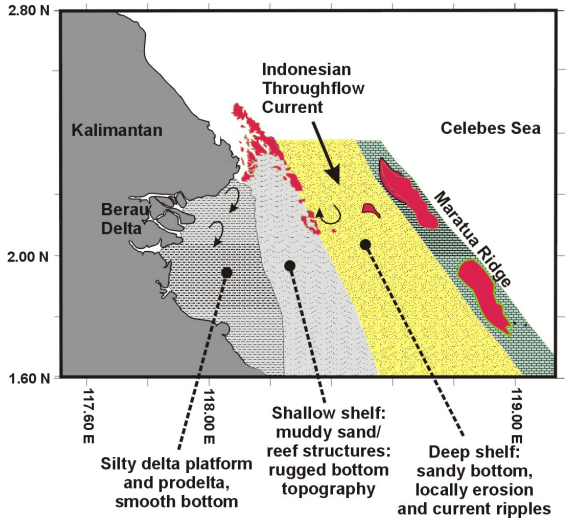

Fig. 3. Sediment properties in the prodelta and lagoonal/shelf environment; the dark red islands represent the coastal reefs, the delta front barrier reef and the oceanic reefs

topographic high, the Maratua Ridge, is characterized by sandy deposits showing the presence of contourites and sandwaves. The strong currents in this region are supposed to be the result of tidal flow in combination with the Indonesian Throughflow since the passage and Makassar Strait (in the south) partly form the link between Pacific and Indian Ocean.

ESTUARINE SEDIMENT DYNAMICS: TRAP OR CONDUIT ?

Hydrodynamic conditions

Rainfall in the river basin and lower catchment area probably varies between 2000 – 3000 mm per year with an average of about 2300 mm/year. The rainfall and associated discharge is not evenly distributed over the year and normally reaches peak values in the period December until March. Our present estimates of mean river discharge vary

between 1500 and 2000 m^3/s based on measurements in the Berau river channel upstream of the point where the river bifurcates in a number of estuarine branches. During the pilot campaign a fixed station was implemented and longitudinal surveys were carried out in both the northern and southern branch of the delta system (Note: this southern branch in the system seems to have a tidal origin instead of being an original part of the distributary network of the delta . Although it is presently connected with the main delta system, our hypothesis is that this connection may have been the result of both a landward extension by tidal erosion and avulsion processes).

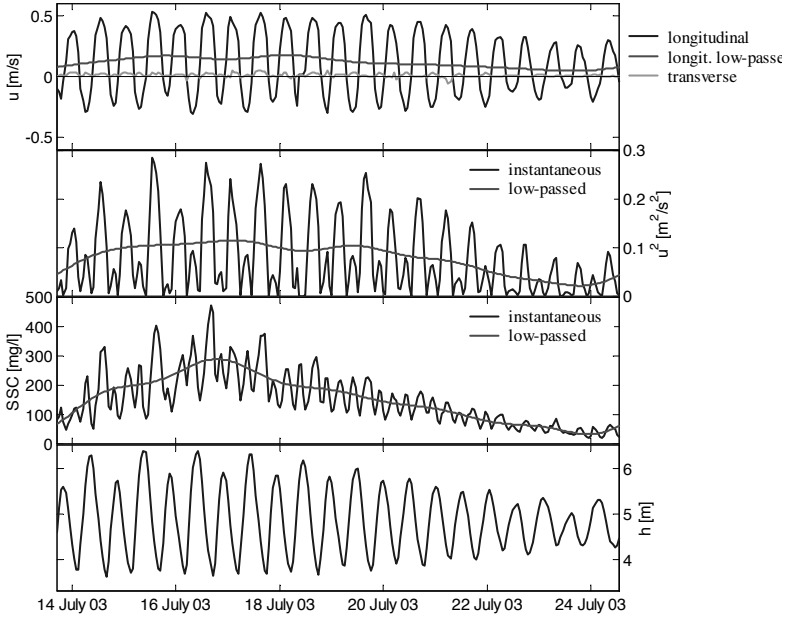

Fig. 4. Measurements in the main river channel of water levels, river flow including squared velocity values to represent shear stress and suspended sediment concentrations

The results of the permanent station upstream of the bifurcation are depicted in Fig 4 ; the station is located at a position approximately 40-45 km upstream of the northern river mouth. The offshore located delta front barrier reef is subject to a semidiurnal tide with tidal ranges varying from about 1.0 m during neap tide (when the tide is becoming diurnal) to about 2.6 m at spring tide (semidiurnal). The semidiurnal tide clearly propagates upstream in the main river channel and is still characterized by a significant tidal range showing a limited amount of damping. Consequently, bidirectional flow is observed with peak values occurring at low tide when river discharge and tidal flow enhance each other; maximum downstream velocities are about 0.5 m/s whereas

upstream flow reaches a magnitude of about 0.25 m/s. Recently measured values with a H(orizontal)-ADCP in a cross-section somewhat further upstream and mid-river show larger velocities in both an upstream and downstream direction. The low-pass filtered signal of the squared values of the velocities – more or less representing the shear velocities - partly correlates with the low-pass filtered trend in Suspended Sediment Concentrations (SSC) with local peak values of 450 mg/l (Fig. 4). Therefore, the trends in SSC are probably explained by a mixture of river discharge, local resuspension, advective transport and tidal mixing.

Longitudinal salinity patterns based on CTD surveys for both the northern and southern branch are illustrated in Fig. 5; the associated distribution in suspended matter is depicted in Fig. 6. Note: the bifurcation is located at km section 25 and the first part of

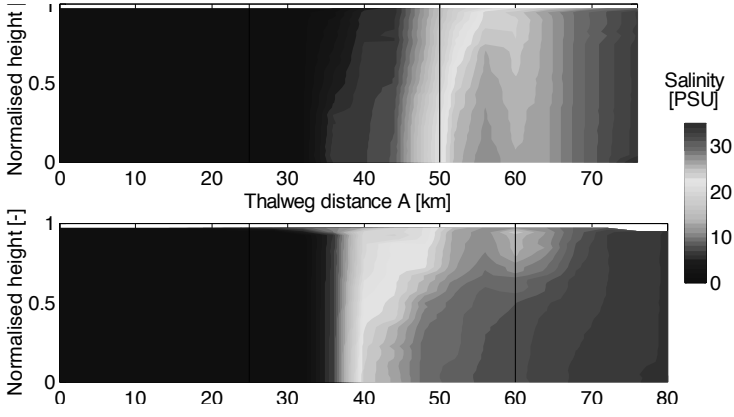

Fig. 5. Salinity patterns as a function of distance along the thalweg in the northern (top, A) and southern (bottom, B) branch; position in the vertical is normalized over depth

the profile (0-25 km) represents the main (single) river channel of the Berau river which is a common part for both branches. In the downstream part of the northern branch a salt wedge is absent and the location of the river mouth (km section 50) more or less coincides with a rapid increase in salinities. A river plume with less saline water masses (20-25 psu) is observed on top of more saline sea water. The buoyant river plume can be traced over an offshore distance of about 10-12 km and shows a kind of plunge point in the frontal zone. The southern branch though (river mouth at km section 60) shows the presence of a salt wedge upstream of the river mouth and the development of partly-stratified conditions in the lower part of the estuary. The fresh-salt interface is located about 20 km upstream of the river mouth.

Two major factors may be held responsible for the difference between both branches. First of all, the northern branch only has a limited depth of about 4 m and an extensive

system of mouth bars limits the landward intrusion of salt water masses. The southern branch though, with an average depth of about 10 m creates more favourable conditions for the tidal intrusion and the development of a salt wedge. Secondly, river discharge will probably vary over the two branches and it is presently assumed that a major amount of water and sediment is using the northern branch to reach the sea. A high river discharge will obviously reduce the amount of salt intrusion.

Estuarine Sediment distribution and offshore dispersion

Estuarine Turbidity Maxima (ETM's) can be observed in both branches. A relatively large turbidity maximum is located in the main river/estuarine channel, approximately at km section 12-14 (11-13 km upstream of the bifurcation) and a smaller one is observed in the southern branch, close to the bifurcation and somewhat landward of the salt wedge in the southern branch. The main ETM is located far upstream of the fresh -salt interface in the northern branch and shows values up to 400 mg/ltr. One may anticipate that the exact location of the ETM varies with the tide (ebb/flood – spring tide/neap tide). At ebb tide, for example, the ETM may be advected down the estuary and may show increasing concentrations due to erosion of sediment from the bed (compare Fig. 4). In this particular case the location of the ETM is located upstream from the fresh – salt interface which suggests that the presence of a null-zone and the existence of a gravitational circulation are less important for the development and location of this ETM. Normally, at the head of the salt wedge sediments settling from the upper seaward flowing layer and sediment carried in the landward flowing bottom layer accumulate – and depending on the actual settling velocity – create a zone of high turbidity, the ETM. Here, a more probable mechanism is local scour and resuspension of the river/estuarine bed in shallow water, in combination with tidal pumping (Dyer, 1997).

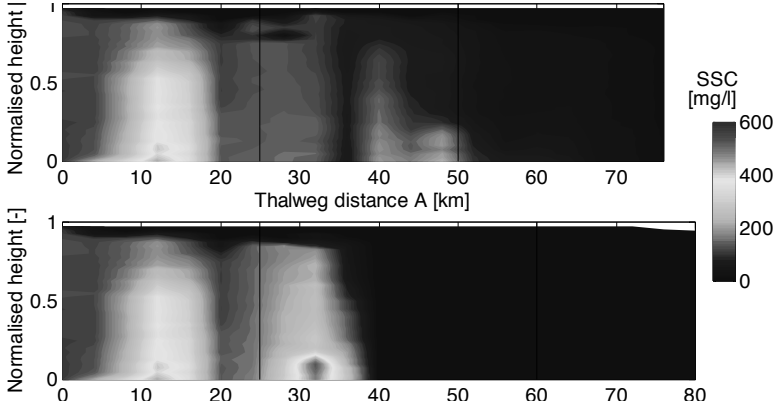

Fig. 6. Distribution of suspended in both the northern and southern branch showing the presence of a major turbidity maximum upstream of the main bifurcation in the delta

The development of (turbid) buoyant plumes, as observed in the field (and indicated in Fig. 7) clearly demonstrates that part of the suspended matter is able to reach the sea (lagoon/ inner shelf).Upstream in the delta, mid-channel bars and bedforms (megaripples and /or sandwaves) demonstrate that the effect of bedload transport cannot fully be ignored in the system. However, its effect rapidly reduces in a seaward direction and the coarsest fractions are building up mouth bars of substantial dimensions, in particular in front of the northern branch.
The offshore dispersion of suspended sediment is partly depicted in Fig. 7. Buoyant plumes are partly advected in a northward direction, as indicated by the low salinity, turbid water masses measured in the area between the mainland coast and the delta front barrier reef.

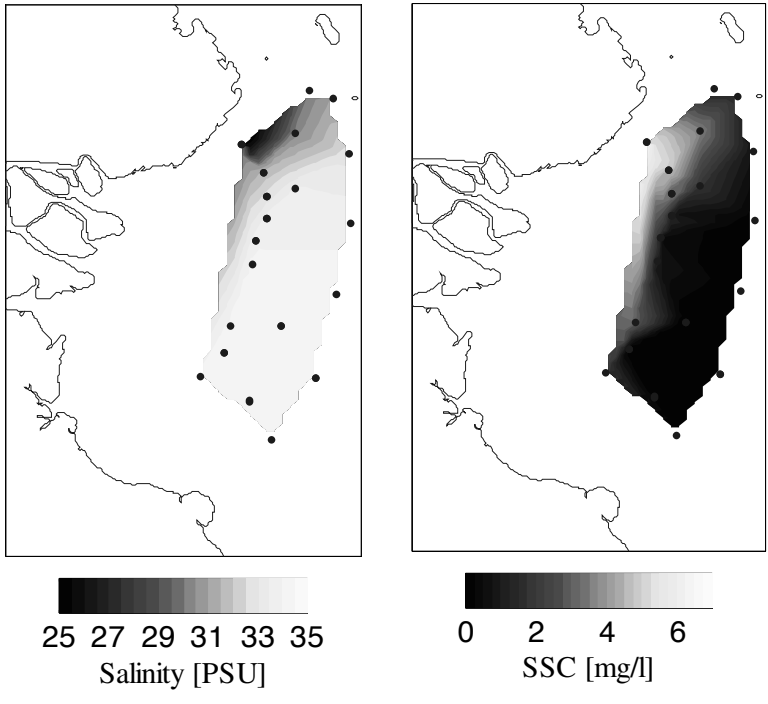

Fig. 7. Distribution of salinity and suspended sediment in the area between river delta and delta front barrier reef showing the offshore dispersion of (buoyant) water masses

DISCUSSION

The present results are based on a pilot study carried out in 2003 and provide more or less a snapshot of the system. The purpose of this pilot study and early reconnaissance

was to collect sufficient information for the definition and implementation of in-depth studies. These in-depth studies for the estuaries, lagoon and delta front barrier reef recently started and will continue in the coming years. Nevertheless, our preliminary results indicate that although the estuaries are able to trap part of the coarser sediment fractions, as visible by the existence of sand bars and mouth bars, a significant part of the suspended matter is still carried in a seaward direction due to the development of buoyant and turbid river plumes. Some of the finer sediment may also be retained in the estuaries, but most probably only on a temporary basis and contribute to the dynamics of the ETM. Main evidence for the seaward dispersion and, subsequently, deposition is the growth of the Holocene delta-platform and prodelta (Fig. 2). The silty and muddy sediments in this region, based on ^{210}Pb analysis of bed samples show deposition rates of about 0.2 – 3.1 cm/year due to the settling of suspended matter. Especially during high river floods the entire system is supposed to be flushed and may result in high deposition rates. As indicated in Fig. 7 part of the suspended matter is even further advected in a seaward direction due to buoyant plumes, tidal and residual currents. Especially the northern branch seems to be an important source for the input of less saline water and suspended matter. Occasionaly, resuspension of sediment may take place due to currents and waves. Wave effects in the northern part of the lagoon though are generally supposed to be limited due to the breakwater effect of the delta front barrier reef, the limited fetch of the lagoon and shallow depths.

Further evidence for the seaward and offshore dispersion of sediment is based on ecological data collected during the pilot campaign (pers. communication R.Bak, Royal NIOZ). There appears to be a clear zonation in coral reefs. Turbidity and suspended load are key-controlling factors in this respect. In the coastal zone, coastal reefs are facing a turbid and low light environment (zone 1). The delta front barrier reef (zone 2) belongs to an intermediate zone, whereas the oceanic reefs are subject to the most favourable conditions for coral growth. This zonation is based on a number of ecological parameters that show the following trends (from zone 1 to 3):

- Coral cover: dead coral cover is high in zone 1 but decreases offshore; likewise living coral cover increases and reaches a maximum in zone 3;
- Partial mortality: is decreasing from shore to open sea;
- Coral colony size: is increasing from shore to open sea;
- Spatial competition: overgrowth of corals is common offshore.

The three zones are also characterized by a difference in coral conditions as reflected by their coral metabolic functioning. The ecological data suggest that the coastal reefs are generally subject to relatively high turbidity levels whereas the delta front barrier reef probably occasionally is affected by higher turbidity levels. At least coral cores show low-density bands that are developed in the Porites skeleton and tend to correspond with luminescent bands, which are formed by the incorporation of land-derived humic acids during growth of the aragonitic skeleton. This suggests that low-density bands are formed during the rainy season, when river discharge and turbidity of the coastal waters increase and light intensity decreases. The offshore zone is characterized by low turbidity levels and very transparent water masses.

CONCLUSION

The Berau delta and its estuaries definitely have a certain trapping efficiency, as observed by the presence of sandy mid-channel bars and mouth bars. Some of the fine-grained suspended matter may be temporary retained within the estuaries and contribute to the development of an ETM. A significant part of the suspended matter, by means of buoyant river plumes and tidal and residual currents, is dispersed in a seaward direction and is able to reach the coral reefs along the coast and those reefs that are part of the delta front barrier reef.

Ongoing and in-depth studies have to reveal in more detail the physical, estuarine processes and mechanisms that operate in the Berau delta and are responsible for the development and dynamics of the ETM, the coastal-marine processes that generate a seaward transfer and dispersion of sediment and the way in which this sediment is finally able to reach the coral reefs.

Abstract: It is well known that surface water waves interact with the fluid mud on the sea bed. Wave-mud interaction results to high wave energy dissipation and mud mass transport. This kind of wave energy dissipation, which generally is much more significant than wave dissipation due to bottom friction, should be considered in simulation of wave evolution and transformation in muddy coastal environments. This paper presents a numerical model of wave evolution and dissipation on fluid mud . For this purpose, the spectral decay of wave due to mud is implemented in SWAN (a third generation numerical model for Simulating WAves Nearshore) using a multilayered wave-mud interaction model. In this numerical model it is assumed that mud layer has a visco-elasic-plastic behavior.

INTRODUCTION

Wave-mud interaction has been long the subject of the scientific research and some aspects of this interaction such as wave attenuation and mud mass transport have been well known. In coastal areas covered with soft mud bed, traveling waves generate inter-surface waves between the water layer and the fluid mud layer resulting to high wave attenuation due to of viscous damping of fluid mud layer. Wave energy dissipation due to wave-mud interaction should be considered in simulation of wave evolution and transformation in coastal muddy environments (Gade 1957; Tubman and Suhayda 1976; Sheremet et al. 2003; Oveisy and Soltanpour 2005 and 2006). In this paper the spectral decay of wave due to mud is calculated in a multilayered wave-mud interaction model which considers the mud layer as a visco-elastic-plastic material. The calculated wave attenuation coefficient is used in SWAN in order to simulate wave evolution and dissipation on fluid mud.

NUMERICAL MODEL

The simulation of wave evolution on fluid mud is carried out by introducing a two dimensional vertical wave-mud interaction model two SWAN. The multi-layered vertical model is used to calculate the wave attenuation rate on mud. The value of wave attenuation rate is then used in SWAN the same as the other dissipation factors to simulate wave dissipation on fluid mud bed.

Wave-Mud Interaction Model

Following Tsuruya et al. (1987), the fluid system is divided into N layers in which the water layer is represented by N=1.

Fig. 1 shows the sketch of the multi-layered model with the water layer on top.

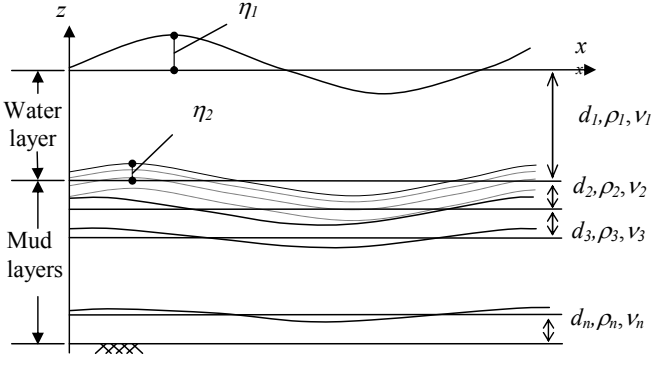

Fig. 1. Definition of multi-layered model

The linearized Navier-Stokes equations, neglecting the convective accelerations and the continuity equation for an incompressible fluid can be expressed as

$$\frac{\partial u_j}{\partial t} = -\frac{1}{\rho_j}\frac{\partial p_j}{\partial x} + \nu_{e,j}\left(\frac{\partial^2 u_j}{\partial x^2} + \frac{\partial^2 u_j}{\partial z^2}\right) \tag{1}$$

$$\frac{\partial w_j}{\partial t} = -\frac{1}{\rho_j}\frac{\partial p_j}{\partial z} + \nu_{e,j}\left(\frac{\partial^2 w_j}{\partial x^2} + \frac{\partial^2 w_j}{\partial z^2}\right) \tag{2}$$

$$\frac{\partial u_j}{\partial x} + \frac{\partial w_j}{\partial z} = 0 \tag{3}$$

where x and z are the horizontal and vertical coordinates, the subscripts j indicate the layers, and the parameters t, ρ, ν_e and p represent the time, density, kinematic viscosity of mud and dynamic pressure, respectively.

The separable, periodic solutions for $\hat{u}_j$, $\hat{w}_j$ and $\hat{p}_j$ are assumed as

$$\hat{u}_j(x,z;t) = u_j(z)\exp[i(kx-\sigma t)] \tag{4}$$

$$\hat{w}_j(x,z;t) = w_j(z)\exp[i(kx-\sigma t)] \tag{5}$$

$$\hat{p}_j(x,z;t) = p_j(z)\exp[i(kx-\sigma t)] \tag{6}$$

where k is the unknown complex wave number, namely

$$k = k_r + ik_i \tag{7}$$

Displacements of water surface and interfaces, η_j, are represented by:

$$\eta_j = a_j \exp[i(kx-\sigma t)] \tag{8}$$

where a_j is the amplitude of the displacement of the j_{th} layer and the water surface is expressed as η_1.Substituting the real and imaginary parts of wave number into Eq. (8), the expression of water surface and interfacial displacements can be obtained as

$$\eta_j = a_j \exp(-k_i x)\exp[i(k_r x-\sigma t)] \tag{9}$$

Therefore, the real part of the wave number, k_r, gives the wave length $L=2\pi/k_r$ and its imaginary part, k_i, presents the wave attenuation rate, assuming the exponential wave height decay. Substituting Eqs. (4) and (5) into the continuity Eq. (3) results to

$$u_j = \frac{iw_j'}{k} \tag{10}$$

where the prime represents the differential with respect to z. Introduction of Eq. (10) into Eq. (1) yields an expression for p_j

$$p_j = \frac{\rho_j \nu_{e,j}}{k^2}(w_j'''-w_j'\lambda_j^{\,2}) \tag{11}$$

where

$$\lambda_j^{\,2} = k^2 - i\sigma\nu_{e,j}^{-1} \tag{12}$$

Substituting p_j into the vertical momentum, Eq. (2), yields the forth order differential equation for w_j

$$w_j''''-(k^2+\lambda_j{}^2)w_j''+k^2\lambda_j{}^2 w_j=0 \tag{13}$$

The solutions can be obtained as

$$w_j(z)=A_j\sinh k(\sum_{n=1}^{j}d_n+z)+B_j\cosh k(\sum_{ne1}^{j}d_n+z)+$$

$$C_j\exp[\lambda_j(\sum_{n=1}^{j-1}d_n+z)]+D_j\exp[-\lambda_j(\sum_{ne1}^{j}d_n+z)] \tag{14}$$

where d_n is the thickness of n_{th} layer. The complex constants A_j, B_j, C_j, D_j, and the unknown variables k and a_j are determined from the boundary conditions.

5N boundary conditions are required for a viscous fluid model of N layers. The unknown constants and variables are determined from the boundary conditions at the water surface, the interfaces and the rigid bottom. The details can be found in Tsuruya et al. (1987).

Rheological Model of Mud

Proper rheological model of mud should be adopted in order to investigate wave-mud interaction. Mud in general can range from being a highly rigid and weakly viscous material to one that can be approximated as a purely viscous fluid, depending on the properties of the constituent sediment and the ambient fluid. Considering the complexity of rheological behavior, the visco-elastic-plastic model has been adopted in the present study to develop a predictive behavior model for wave-mud interaction (Shibayama and An 1993). The constitutive equations are expressed as:

$$\sigma_{ij}=2\mu_e\dot{e}_{ij} \tag{15}$$

$$\mu_e=\mu_1+\frac{iG}{\omega}\qquad \text{for}\quad (\frac{1}{2}\sigma_{ij}\sigma_{ij}\le\tau^2{}_y) \tag{16}$$

$$\mu_e=\mu_2+\frac{\tau_y}{\sqrt{4\,|\,\Pi_e\,|}}\ \text{for}\ (\frac{1}{2}\sigma_{ij}\sigma_{ij}>\tau^2{}_y) \tag{17}$$

where σ_{ij} is the deviator part of stress tensor, $\dot{e}_{ij}$ is the deviator part of strain rate tensor, G is the shear modulus of elasticity, μ_1 is the viscosity of mud in the viscoelastic state, μ_2 is the viscosity of mud in the viscoplastic state, τ_y is yield stress, ω is the angular frequency of wave and $4|\,\Pi_e\,|$ is expressed as

$$4\left|\Pi_e\right| = 2(\frac{\partial u}{\partial x})^2 + 2(\frac{\partial w}{\partial z})^2 + (\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x})^2 \tag{18}$$

where u and w are velocity components in x and z direction, respectively. The rheological viscoelastic parameters of mud, i.e. shear modulus and viscosity, are calculated from the empirical equations offered by Shibayama and An (1993):

$$\mu_1 = 10^{(3.353-9.56\times10^{-3}W)} \times T \tag{19}$$

$$\log G = 3.761 - 1.05\times10^{-2}W + (0.147 - 3.38\times10^{-3}W)\times\log T - (0.522 - 1.23\times10^{-3}W) \tag{20}$$

where T is the wave period and W is the water content ratio of fluid mud (%). The viscoplastic parameters, μ_2 and τ_y were adopted from the laboratory experiments of Tsuruya et al. (1987):

$$\tau_y = 1.494\times10^6 W^{-2.452} \tag{21}$$

$$\mu_2 = 8.465\times10^3 W^{-1.344} \tag{22}$$

Equivalent Viscosity. In the viscoplastic state of the visco-elastic-plastic model, the objective $4|\Pi_e|$ of the representative viscosity, can be approximated by a viscoelastic field using an iterative method. The real parts of Eqs. (4) and (5) are written as

$$\hat{u}_j(z) = \left|u_j\right|\exp(-k_i x)\cos(k_r x - \sigma t + \alpha_j) \tag{23}$$

$$\hat{w}_j(z) = \left|w_j\right|\exp(-k_i x)\cos(k_r x - \sigma t + \beta_j) \tag{24}$$

where α_j and β_j are the arguments of u_j and w_j, respectively. Taking the partial derivatives of Eqs. (23) and (24) with respect to x and z

$$\frac{\partial \hat{u}_j}{\partial x} = -\left|k\right|\left|u_j\right|\exp(-k_i x)\sin(k_r x - \sigma t + \alpha_j + \theta_k) \tag{25}$$

$$\frac{\partial \hat{u}_j}{\partial z} = -\left|u'_j\right|\exp(-k_i x)\cos(k_r x - \sigma t + \alpha'_j) \tag{26}$$

$$\frac{\partial \hat{w}_j}{\partial x} = -|k||w_j|\exp(-k_i x)\sin(k_r x - \sigma t + \beta_j + \theta_k) \tag{27}$$

$$\frac{\partial \hat{w}_j}{\partial z} = -|w'_j|\exp(-k_i x)\cos(k_r x - \sigma t + \beta'_j) \tag{28}$$

where α'_j and β'_j and θ_k are the arguments of u'_j, w'_j and k, respectively. Substituting Eqs. (25) ~ (28) into Eq. (3) leads to

$$4|\Pi_e| = \frac{1}{2}\{|k|^2(2|u_j|^2 + |w_j|^2) + (|u_j'|^2 + 2|w_j'|^2)$$

$$- 2|u_j'||w_j||k|\sin(\beta_j + \theta_k - \alpha_j')\}\exp(-2k_i x) \tag{29}$$

Implementation in SWAN

The evolution of wave at SWAN is governed by wave action balance equation (Booij et al. 1999) expresed as,

$$\frac{dN}{dt} = \frac{\partial N}{\partial t} + \frac{\partial}{\partial x}(c_x N) + \frac{\partial}{\partial y}(c_y N) + \frac{\partial}{\partial \sigma}(c_\sigma N) + \frac{\partial}{\partial \theta}(c_\theta N) = \frac{S}{\sigma} \tag{30}$$

$N= E/\sigma$ is the action density (E is energy density), c_x and c_y are propagation velocities in x and y direction respectively, c_σ is propagation velocity in σ (relative frequency) space and c_θ is propagation velocity in θ (propagation direction) space. S includes all sources and sinks terms. A spectral sink term is needed to describe the wave-mud interaction (Zhang and Zhao 1999). Considering wave spectrum in space of σ, θ and exponential decay of wave height due to wave mud interaction,

$$E(\sigma_i, \theta_i) = \frac{1}{\Delta\sigma \cdot \Delta\theta} \cdot \frac{1}{2} a_{ix}{}^2 \tag{31}$$

$$a_{ix} = a_{i0} e^{-k_i (x - x_0)} \tag{32}$$

where a_{i0} is the amplitude of i-th wave component at point $x=x_0$, a_{ix} is the amplitude of i-th wave component at distant x from point x_0, and σ_i, θ_i are corresponding frequency and direction, the following equation can be derived for sink term in the right hand side of the action balance equation due to wave mud interaction.

$$S_{Mud} = 2k_i c N \tag{33}$$

where c is the propagation velocity and k_i is attenuation coefficient calculated in wave mud interaction model. Above mentioned dissipation term is implemented in SWAN to simulate wave-mud interaction.

MODEL PERFORMANCE AND DISCUSSION

Since wave attenuation of muddy banks in Louisiana coast has been well-known (Gade 1957; Tubman and Suhayda 1976) and significant measurement data are available, the model was used to simulate wave evolution along the Louisiana coast during a storm event which occurred from Jan 29 to Feb 01, 2001. In Fig. 2, CSI3 and CSI5 stations are parts of WAVCIS (Wave-Current Information System, wavcis.cis.lsu.edu), operated by Coastal Studies Institute of Louisiana State University. CSI3 is located in muddy part of the coast while CSI5 is on sandy bottom (Sheremet et al. 2003).

For this simulation wind data are extracted and interpolated on computational grid from ten metrological stations (Fig. 3) of NDBC (National Data Buoy Center), and spectral wave measurement in Buoy 42001 was used as offshore wave boundary condition.

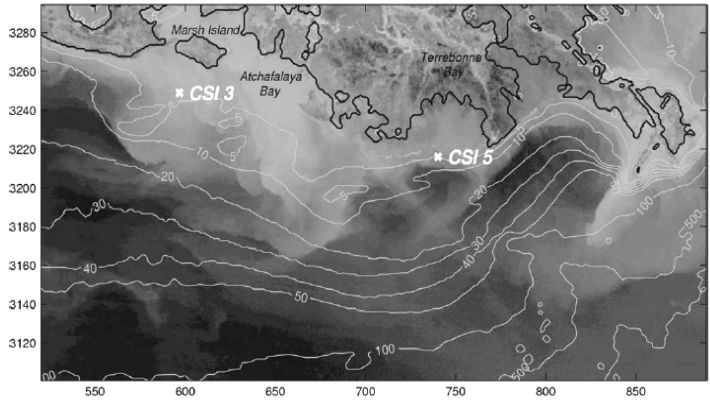

Fig. 2. Louisiana coast and shelf, Coordinates are in Kilometers and contours in meter (Terra-1 MODIS satellite image; Earth Scan Lab, LSU; Adopted from Sheremet et al., 2005)

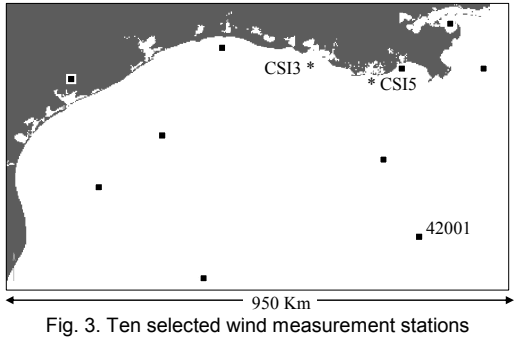

Fig. 3. Ten selected wind measurement stations

The simulation is conducted considering two scenarios. First, assuming no fluid mud layer. Second, 100 (cm) of high sediment concentration layer above the bed covering 8 (Km) around the CSI3. It was assumed that viscosity of the water-sediment mixture is two orders of magnitude greater than viscosity of water (Sheremet et al. 2005).

Fig. 4 shows spectral evolution during above mention storm at CSI3 and CSI5 for the two scenarios as well as measurement. Measurement obviously shows less spectral density in CSI3 than CSI5 (Fig.4-a). Fig. 4-b shows spectral evolution for the first scenario. With no mud dissipations, there is still less intensive spectral density in CSI3 comparing to CSI5. It can be due to the location of CSI3 which is surrounded by very shallow water (Fig. 2) resulting significant refraction and bottom dissipation.

The simulation results for second scenario shows significant wave attenuation. Higher attenuation is recognized for swells (waves with period greater than 5 seconds) since they have more interaction with bottom. The attenuation of short waves in measurement can be due to surface-interface wave interaction and three-wave interaction (Sheremet et al. 2005).

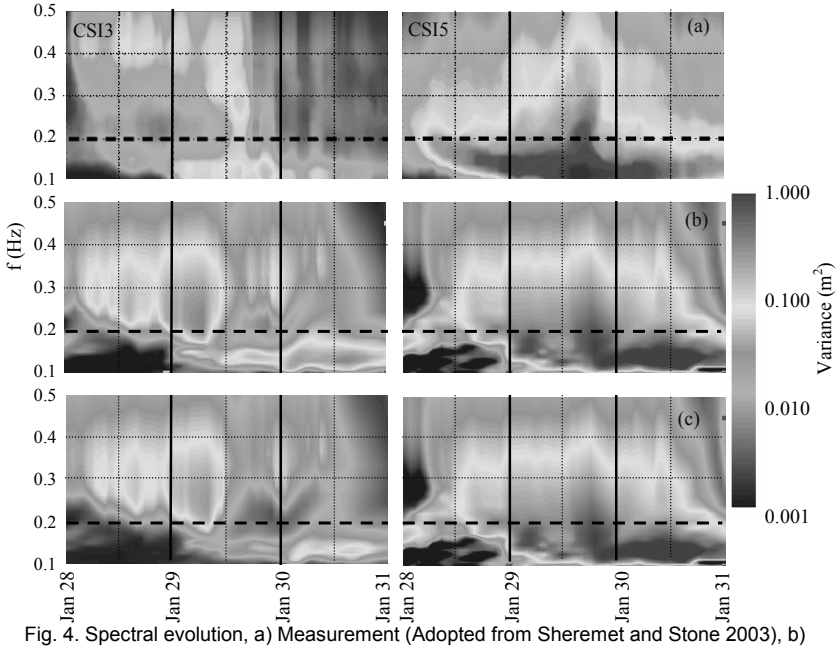

Fig. 4. Spectral evolution, a) Measurement (Adopted from Sheremet and Stone 2003), b) Simulated wave height no fluid mud, c) Simulated wave height with fluid mud

CONCLUSION

The wave attenuation on fluid mud was introduced as a part of dissipation terms in SWAN considering a multi-layer visco-elastic-plastic model. The model was used for simulation of a storm event from Jun 29 to Feb 01, 2001 in coast of Louisiana. The simulation result shows considerable wave height attenuation at CSI3 due to shoals around this point and wave-mud interaction.

A FINE SEDIMENT TRANSPORT MODELING FRAMEWORK AND ITS APPLICATION TO FLUID MUD PROCESSES

Tian-Jian Hsu and Minwoo Son

University of Florida, Civil and Coastal Engineering, Gainesville, FL 32611, USA.

Abstract: A fine sediment transport modeling framework for estuary and coastal environments is developed based on simplified multiphase formulation. The model incorporates turbulence-sediment interactions in a two-equation turbulence closure and a rheology closure based on concentrated viscous suspension. The model has been demonstrated to capture the characteristics of tidal driven lutocline behavior observed at Amazon shelf and wave-supported gravity-driven mudflows observed at Po River prodelta (Hsu et al. 2007). However, these results are obtained by specifying an averaged floc diameter that is independent of flow condition. The floc density is then calculated by a prescribed fractal dimension. In this paper, we report a new but preliminary extension of this model with a more realistic formulation of floc dynamics for steady equilibrium condition. It is found that detailed floc dynamics is sensitive to the predicted suspended mud concentration and flow rate under a steady current.

INTRODUCTION

Understanding the fate of fine terrestrial sediments in the coastal ocean, including the initial sediment deposition from the river plume and the subsequent sediment resuspension, is of great importance for estuarine and coastal morphology. In this paper, a new modeling framework for fine sediment transport based on simplified multiphase formulation (Hsu et al. 2007) is introduced and we report new but preliminary model extensions toward a complete description of floc aggregation and break-up processes.

Fluid mud is highly concentrated suspended sediment from concentrations of about 10 g/l to a few hundred g/l above the consolidated bed (Ross & Mehta 1989). Since the last decade, multi-disciplinary approaches were adopted in several major field research programs, such as, AMASSEDS (e.g., Nittrouer et al. 1991), STRATAFORM (e.g.,

Nittrouer & Kravitz, 1996), EuroSTRATAFORM (e.g., Sherwood et al. 2004), and several others. Research findings resulted from these studies had advanced our understanding on fine sediment transport processes. However, they have also revealed some unexpected small-scale sediment transport processes that can not be captured with the conventional modeling approach. One of these interesting sediment transport problems is, for example, the wave-supported gravity driven mudflows (e.g., Wright et al., 2001; Kineke et al. 1996; Traykovski et al. 2000).

Accurate prediction of fine-sediment transport requires detailed water column models that resolve time-dependent flow velocity and sediment concentration (Winterwerp and van Kesteren, 2004). In general, the dynamics of sediment transport is a multiphase phenomenon. A multiphase approach provides rigorously derived balance equations that incorporate fluid-sediment interactions and granular rheology (Brennen 2005) and hence allows modeling transport continuously from concentrated aggregate network to dilute suspension. Existing water column models for mud suspension (e.g., Winterwerp 2001) incorporate the damping of flow turbulence due to sediment induced stratification, which is a crucial mechanism for the formation of fluid mud. However, the rheology of sediment is often neglected. In order to model the concentrated regime of mud consolidation and fluidization (e.g., Gibson et al. 1967) and other important applications, such as the dissipation of wave energy on muddy coasts (e.g., Dalrymple and Liu, 1978; Maa and Mehta 1987; Sheremet and Stone 2003), the rheology of mud shall be incorporated into the existing transport model.

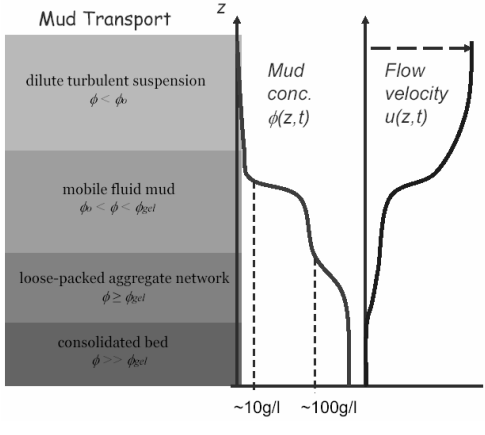

Fig. 1: Schematic description of mud transport according to Ross & Mehta (1988). The 1DV model presented in this paper calculates fluid mud transport above the concentrated aggregate network with $\phi<\phi_{gel}$.

Recently, Hsu et al. (2007) proposed a new fine sediment transport modeling framework based on simplified multiphase flow formulation. The 1DV water column model developed by Hsu et al. (2007) calculates the turbulent flow and mud floc concentration with given (constant) floc diameter and fractal dimension. Without incorporating detailed floc dynamics, they demonstrate that the model is able to capture the characteristics of tidal driven lutocline behavior observed at Amazon shelf (Kineke et al. 1996) and wave-supported gravity-driven mudflows observed at Po River prodelta (Traykovski et al. 2007). This is because the most important mechanism controlling the fluid mud dynamics appears to be the damping of carrier flow turbulence due to sediment (e.g., Trowbridge and Kineke 1994; Winterwerp 2001). However, in order to develop a complete fluid mud model, detailed floc dynamics must be incorporated. After a brief description on the model formulation, we focus on the new model implementation on the floc dynamics following Winterwerp (1998). Preliminary results with floc dynamics incorporated are presented.

MODEL FORMULATION

We consider sediment of diameter D, density s transported in a bottom boundary layer that is locally uniform in the cross-shore x and alongshore y directions. Assuming that fine sediment follows the ensemble-averaged carrier fluid velocities closely, the flow momentum equations for cross-shelf u and alongshelf v velocities are:

$$\frac{\partial u}{\partial t} = \frac{-1}{\rho^f(1-\phi)}\frac{\partial P}{\partial x} + \frac{-1}{\rho^f(1-\phi)}\left[\frac{\partial \tau_{xz}^f}{\partial z} + \frac{\partial \tau_{xz}^s}{\partial z}\right] + g_x\left[\frac{s\phi}{1-\phi}\right] \tag{1}$$

and

$$\frac{\partial v}{\partial t} = \frac{-1}{\rho^f(1-\phi)}\frac{\partial P}{\partial y} + \frac{-1}{\rho^f(1-\phi)}\left[\frac{\partial \tau_{yz}^f}{\partial z} + \frac{\partial \tau_{yz}^s}{\partial z}\right] + g_y\left[\frac{s\phi}{1-\phi}\right] \tag{2}$$

with ρ^f the fluid density, $s = \rho^m / \rho^f$ the sediment specific gravity and g_x, g_y the gravitational acceleration in the cross-shore and alongshore directions. For cohesive sediment, D is considered to be the floc diameter and the specific gravity of the floc is calculated by ρ^m, the floc density (see equation (5) in the next section). In the momentum equations (1) and (2) the flow momentum transport is caused by both fluid and sediment stresses τ_{xz}^f, τ_{xz}^s. The gravitational term contains sediment concentration and allows fluid flow to be driven by downslope gravitational force of the sediment. The cross-shore $\partial P/\partial x$ and alongshore $\partial P/\partial y$ pressure gradients are given as a prescribed flow forcing of the bottom boundary layer flow.

The sediment volume concentration ϕ is calculated by

$$\frac{\partial \phi}{\partial t} = -\frac{\partial}{\partial z}\left[\phi(1-\phi)T_P\left(1-s^{-1}\right)g_z - \frac{\nu_t}{\sigma_c}\frac{\partial \phi}{\partial z} + \frac{T_p}{\rho^s}\frac{\partial \tau^s_{zz}}{\partial z}\right] \tag{3}$$

The first two terms on the right-hand-side of (3) are the settling and turbulent suspension with T_p the particle response time calculated based on drag for sphere with correction for the effect of hindered settling using Richardson and Zaki (1954). The turbulent suspension is calculated here using an eddy viscosity. The third term on right-hand-side of (3) is the vertical gradient of sediment intergranular normal stress, which serves as an additional suspension mechanism for sediment. This is important in concentrated region of mud transport, including consolidation and fluidization of the mud bed (see figure 1, the region with ϕ near or greater than ϕ_{gel}).

Turbulence and rheology closures

In this study, the fluid turbulence and turbulent suspension are calculated by an eddy-viscosity with a two-equation k-ε closure. The effect of sediment on damping the carrier flow turbulence can be appropriately considered by deriving the balance equation of fluid turbulence kinetic energy (TKE) from the multiphase momentum equations (e.g., Hsu and Liu 2004). Detailed implementation on turbulence and its interaction with sediment are reported in Hsu et al (2007) and it not repeated here.

The present model also requires appropriate constitutive relations for mud rheology. Most prior studies on mud transport neglect rheology in the "mobile fluid mud" regime (see figure 1) but focus on sediment effective normal stress closure for mud consolidation (e.g., Gibson et al 1967). The rheology for sediment shear stress is often neglected in mud transport study, however, has long been considered important for studying hydrodynamic energy dissipation using a simple "layered" parameterizations for a high viscosity (e.g., Dalrymple and Liu 1978) or visco-elastic formulation (e.g., Maa and Mehta 1987). Because in the present model both the flow velocities and sediment concentration are calculated continuously across the water column, we adopt a set of rheology closures for both sediment shear and normal stresses that explicitly depends on concentration and shear rate based on concentrated viscous suspension theory (e.g., Zarraga et al. 2004). Detailed implementation of the rheology closure of the present model is referred to Hsu et al. (2007). For fluid mud process above the concentrated aggregate network, the mud concentration is much smaller than gelling concentration and the rheology is of less importance.

Sediment bottom boundary conditions

We use the continuous deposition concept here for the bottom boundary condition of cohesive sediments (e.g., Sanford and Halka 1993). The following simple parameterization for erosion (upward) flux is adopted:

$$E = m\left(\frac{\tau_b}{\tau_c} - 1\right) = mS \tag{4}$$

with m an empirical coefficient, τ_c the critical bottom stress. The bottom stress τ_b is calculated every time step through the flow velocity at the first-grid point above the bed based on logarithmic-law for rough bed. In reality, τ_c and m also depends on the amount of mud eroded and consolidation processes. Complete information requires in-situ sampling and characterization. Here, m and τ_c are considered to be constant for simplicity. Unless stated otherwise, τ_c is set to be 0.05 Pa in this paper and m is specified in the "Model Results" section.

Turbulence induced flocculation

When modeling fluid mud using the present model, the primary particle is not directly calculated. Instead, we prescribe aggregate (floc) diameter D and fractal dimension n_f (Winterwerp and van Kesteren, 2004). The density of the mud floc is given as

$$\rho^m = \rho^f + \left(\frac{D_0}{D}\right)^{3-n_f}\left(\rho^s - \rho^f\right) \tag{5}$$

with D_0 and ρ^s the diameter and density of the primary particle, taken to be $D_0 = 4\ \mu m$ and ρ^s=2650 kg/m^3. ρ^m is used to calculate the settling term in the balance equation (3) of concentration. The model calculates directly the mud floc volume concentration. The mass concentration c can be calculated from volume concentration ϕ as (Winterwerp 1998):

$$c = \phi\rho^s\left(\frac{D_0}{D}\right)^{3-n_f} \tag{6}$$

The floc dynamics is one of the most unique aspects of cohesive sediment. As summarized by Winterwerp (1998), the floc break-up and flocculation processes are in general controlled by several mechanisms but the dominant mechanism for coastal cohesive sediment is due to flow turbulence. Cohesive sediment particles, carried by turbulent eddies, can collide and form larger flocs. On the other hand, strong turbulent shear can also cause floc break-up. Based on such paradigm, Winterwerp (1998) propose a governing equation to describe the evolution of floc diameters:

$$\frac{dD}{dt} = K_A cGD^2 - K_B G^{3/2} D^2\left(D - D_0\right). \tag{7}$$

For simplicity, equation (7) is shown here for a special case with fractal dimension n_f=2, with K_A, K_B empirical coefficients and G the dissipation parameter calculated by turbulent dissipation rate ε and fluid viscosity ν:

The first term on the right-hand-side of equation (7) is a source term that represents the flocculation process. For higher concentration, it is more likely that flocculation occurs through collisions between floc particles carried by energetic turbulent eddies. The second term on the right-hand-side of (7) is a sink term that represents the floc break-up process due to shear generated by the turbulent eddies. According to (7), a simple relation for equilibrium floc size D_e is obtained for $dD/dt=0$:

$$D_e = D_0 + \frac{K_A c}{K_B \sqrt{G}} \tag{9}$$

Because the floc size is unlikely to be greater than the Kolmogorov length scale, an upper limited for D_e is also adopted here:

$$D_e = \min\left[D_0 + \frac{K_A c}{K_B \sqrt{G}}, \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \right] \tag{10}$$

In this paper, we present preliminary results of using (10) for equilibrium floc size. Given a prescribed fractal dimension $n_f=2$, the floc diameter and floc density are determined by equation (10) and (5), respectively. The dissipation parameter defined in (8) is calculated by model solution of turbulent dissipation rate ϵ through the k-ϵ closure.

MODEL RESULTS

A 1-DV water column numerical model is developed to calculate equations (1)-(3) for flow velocities and floc concentration with k-ϵ turbulence closure and appropriate rheology closure. The sediment flux boundary condition shown in equation (4) is utilized in this paper. Model results for tidal driven fluid mud and wave-supported gravity-driven mudflows without explicit consideration of floc dynamics are presented in Hsu et al. (2007) and are not repeated here. To demonstrate the new model capability for floc dynamics, equilibrium floc size formulation (10) is utilized.

Because the flocculation timescale can be very large (Winterwerp 1998), we exam fluid mud transport under a steady current. A constant pressure gradient is applied in the numerical model to drive the steady current (Hsu et al. 2007). The numerical model is initialized with zero flow velocities and mud concentration and marches in time until steady state solutions are obtained. Using suggested values of $K_A=14.6$ m^2/kg, K_B=14000 s$^{0.5}$/m^2 (Winterwerp 1998), model results for flow velocity, concentration, floc diameter and floc density are shown in Fig. 2 (solid curves). Because the current boundary layer extends to the entire water depth, considerable amount of sediment is suspended near the top of the water column. The floc size is smaller in the upper water column due to lower mud concentration. Near the bed the floc size reaches its maximum value about 500 μm.

Within the lower 20 cm above the bed, the floc size is limited by its maximum value, the Kolmogorov length scale (ϵ is usually very large near the bed). Due to small fractal dimension used (n_f=2) and large floc size calculated by the model, the resulting floc density (about 1020 to 1050 kg/m^3) is only slightly larger than the water density (1000 kg/m^3).

According to equation (10), the effects of flocculation due to higher concentration and floc break-up due to higher turbulence are controlled by the relative magnitudes between K_A and K_B. Therefore, model results (dashed curves in Fig. 2) are also shown for the same flow conditions but with K_A=1.46 m^2/kg (i.e., reduced by an order of magnitude). Due to reduced flocculation effect, the floc diameter becomes smaller (dashed curve in panel (c) is ranging from 150 μm near the bed to 50 μm far from the bed) when compared with results obtained by specifying larger K_A (solid curve). Consequently, the floc density becomes larger (dashed curve in panel (d)) according to equation (5). Notice that due to smaller floc diameter, the settling velocity is smaller (not shown) and more sediment is suspended under the same steady flow forcing (dashed curve in panel (b)). Visual inspection also suggests that the overall flow rate is larger for smaller flocs (dashed curve in (a)) because turbulence is damped more significantly due to more suspended sediments. This is the so-called the drag reduction due to the presence of sediment (Winterwerp 2001). Model results indicate that detailed floc dynamics has important effects on the overall suspended mud concentration and flow rate.

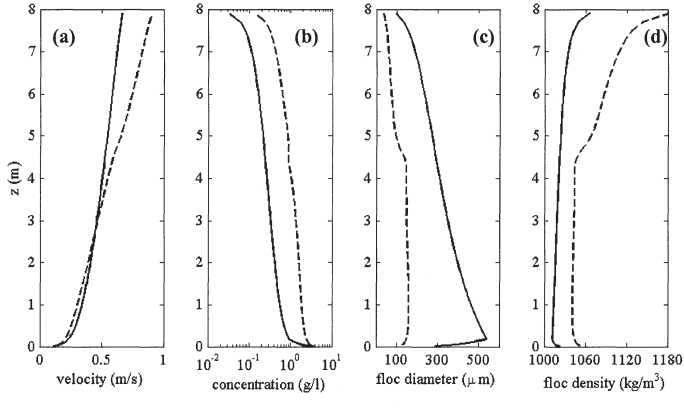

Fig. 2: Model results for (a) flow velocity, (b) mud concentration, (c) floc diameter and (d) floc density. Solid curves are model results with K_A=14.6 m^2/kg and dashed curves are model results with smaller K_A=1.46 m^2/kg. In both cases, the flow forcing used to drive the steady flow are identical. The *m* value in equation (4) for bottom erosion fluxes are specified in such way that both cases have the same magnitude of concentration at the bed.

both cases have the same magnitude of concentration at the bed.

CONCLUSION

Equilibrium floc diameter formulation of Winterwerp (1998) is incorporated in a fluid mud model to calculate steady boundary layer flow and mud suspension. The floc dynamics appears to be important to the overall mud suspension and resulting flow rate. More detailed non-equilibrium floc dynamic formulation shall be implemented in order to study fluid mud transport under tidal flow and waves.

Abstract: The paper presents a set of observed sounding data which shows a tendency of siltation in the access channel for a port in a shallow muddy coast. The data shows the higher siltation rate at offshore part of the channel regardless of occurrence of disturbance by the wind waves. From the data monitored for 25 hours of current and suspended sediment distributions along the channel, apparent increase in the near bottom concentration of suspended sediment were observed around the offshore region of the channel. The high concentration event might be a potential source for the higher rate of siltation in the area. The sediment transport model has been developed for the study site and simulated the sediment transport process mainly dominated by the tidal current as a preliminary work for future study of the estimation of the channel siltation volume.

INTRODUCTION

The understanding of fine sediment transport processes has a significant importance in the economical and ecological aspects of coastal environment. The ability to predict the movement of fine sediments is necessary not only for estimation of a dredging cost to keep the safety ship navigations but also for management of contaminated sediment since that chemicals tend to absorb to fine sediment (e.g. National Research Council, 1997). Siltation in navigation channels and harbor basins at near shore coastal area is mainly caused by wave attacks and several studies have been worked on Japanese ports to minimize maintenance dredging volumes (e.g. Tsuruya et al., 1990). Many ship channels are still necessary to be extended and

dredged in the deeper off shore area for the requirements of economic growth and increase in vessel draft. In a macro- or meso- tidal coastal and estuarine environment, tidal current rather than short wind waves might be a principal external force of the sediment transport processes, resulting in channel siltations, in the relatively deeper region.

In the present study, for the purpose of understanding a shoaling mechanism of a navigation channel dredged through shallow muddy coast, fine sediment transport process especially by the effect of tidal currents are examined by analyses of field data measured in the Suoh-nada sea, Japan. A fine sediment transport model has been developed and the numerical results on the hydrodynamic features of tidal current and suspended sediment concentrations are validated by comparison with the field data as a preliminary work for future applications of siltation rate estimates.

FIELD OBSERVATIONS

Field measurements were carried out in the northern shore of Suoh-nada sea, which is shallow water system with the depth of less than 20 m (Figure 1). Tidal condition of the site could be classified as meso- tidal environment with the range of around 3 meters during spring tide period. A navigation channel with the depth of -12 m from the datum line (D.L.) has been maintained by dredging to the approximately 5 km offshore from the port of Ube through the shallow coastal area (Figure 2). Although further deepening of the channel is required for safety navigations of large draft ships, we should consider minimizing siltation and environmental impacts by the damping of dredged materials for the maintenance of the channel.

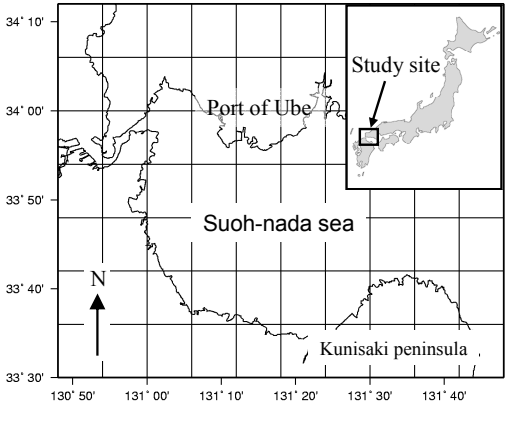

Fig. 1. Location of study site

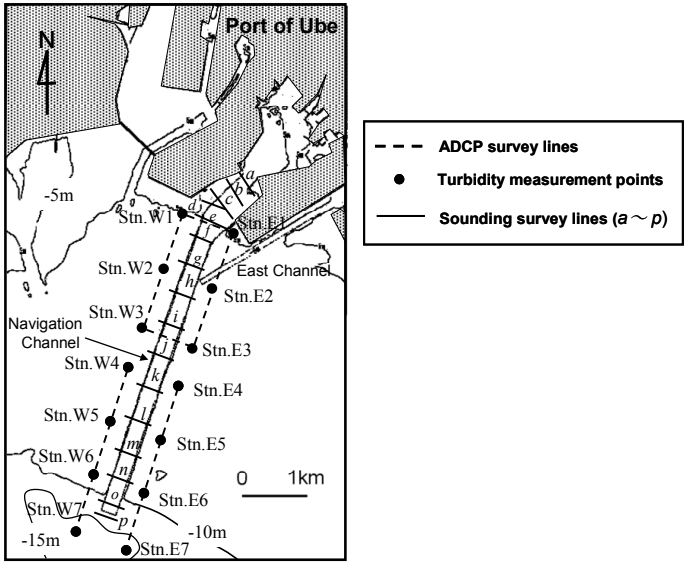

Fig. 2. Survey lines and turbidity measurement points

In order to grasp sediment properties of the study site and characteristics of the channel siltation, several measurements and data analyses were conducted. Bottom sediments were sampled in October, 2002 for the offshore stations (E4, W4, E6, W6 and W7) and in September, 2003 for the shallower stations (E1, W1, E2, W2, E3 and W3) and grain size analyses were carried out. Topography of the navigation channel has been monitored by the port office of the Japanese Ministry of Land, Infrastructure and Transport and some sounding data were used for the study to characterize the bathymetric change in the channel.

For the study of suspended sediment transport dynamics around the channel, current measurements were carried out with an ADCP (RD-Instruments, 1200kHz) towed by a boat running on the lines shown in the Figure 2. The offshore transects along the channel between the stations E4 - E7 and W4 - W7, were measured for 25 hours on October 22 and 23, 2002, and the other onshore transects between the stations E1, E3, W3 and W1 were on September 10 and 11, 2003, respectively. During the current measurement surveys, vertical profiles of suspended sediment concentrations (SSC) at the monitoring points on the ADCP lines were also measured by the operation of optical backscatter sensor (OBS) by another boat when the boat with ADCP run across an each point. OBS data was converted to SSC in mg/l by applying calibrations using sediment samples taken from the study site.

FIELD MEASUREMENTS RESULTS

Sediment properties and Siltation rates

Results of grain size analyses for bottom sediments sampled in the area are summarized in Figure 3. Coarse materials are dominant in the sediment of the shallower area near the port at the stations E1 and W1 and finer components, however, are major in the deeper region and the fraction of silt and clay is over 80 % in weight at the stations E6 and W7.

The channel with the depth of –12 m is maintained by dredging and Figure 4 shows bottom topographies inside and outside of the channel in the cross shore direction. The figure shows also the change in averaged depth during 3 months at each cross

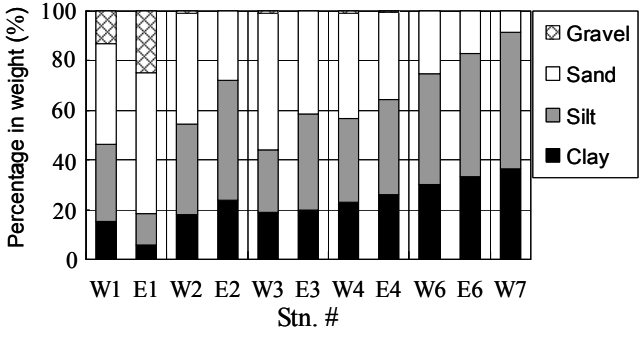

Fig. 3. Sediment characteristics in study area

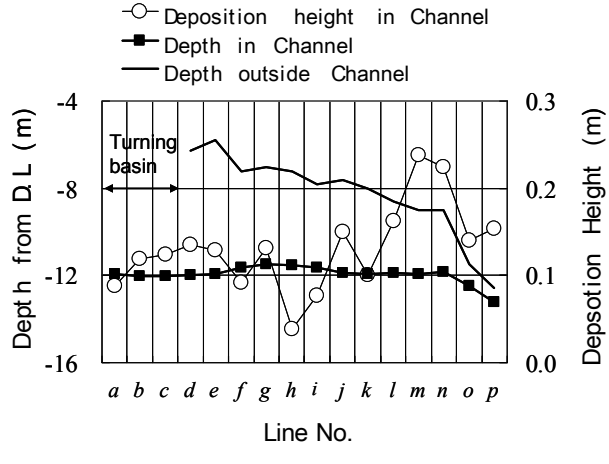

Fig. 4. Topographies inside and outside of channel and deposition height in channel between 3 months from September to December in 2005

section of the channel indicated as lines *a* through *p* in Figure 2. The difference in the averaged depth was analyzed with the sounding data measured in September and December, 2005. The highest deposition with the height of over 20 cm in the channel is observed at the lines *m* and *n* and these are located at the offshore tip of the artificially dredged waterway. Temporal change in the depositions during the monitoring period is shown in Figure 5 considering the data measured in October, 2005. There are high siltation event for all part of the channel during the first half period between September and October, 2005, where a heavy storm attacked the area with the averaged wind speed of over 20 m/s after the first sounding survey. On the other hand, the offshore area at lines *m* and *n* have still experienced higher siltation than other area even in the second half period without a sever storm condition,.

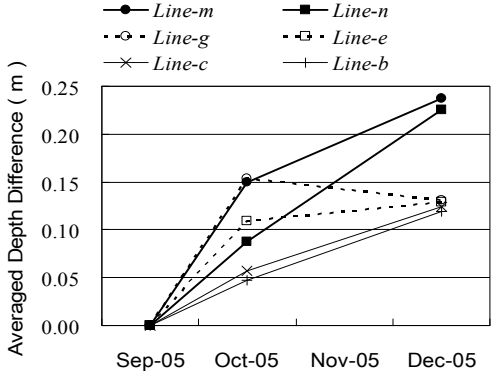

Fig. 5. Change in deposition height in channel during

Current and Suspended Sediment Distributions

Figure 6 (a) and (b) show current field patterns near the sea bed measured during flood and ebb currents of spring tide periods. The principal direction of the currents during both flood and ebb phase are across the navigation channel and it is to the north-west ward during the flood and to the south-east ward during the ebb tide. The current speed is approximately uniform in the offshore measurement line with the speed of over 30 cm/s and it slows down in the shallower region near the port.

In Figure 7, measured tide variation of suspended sediment concentrations (SSC) at 1m above the sea bed at the stations E4 and E6 compared with measured current speeds at the same level. The tide level in the figure is the measured data at the tide station in the port of Ube. The increases in SSC are observed during the ebb and flood periods with higher speed current. The tide variations of SSC at the offshore monitoring stations in the other side of the channel are also of the same pattern with the SSC increases during the ebb and flood tide phase. Vertical profiles of SSC during the high concentration events are shown in Figure 8 and the profiles in the

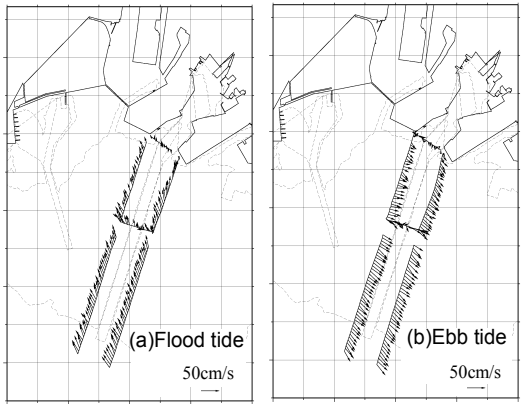

Fig. 6. Observed current vectors of flood and ebb tide current

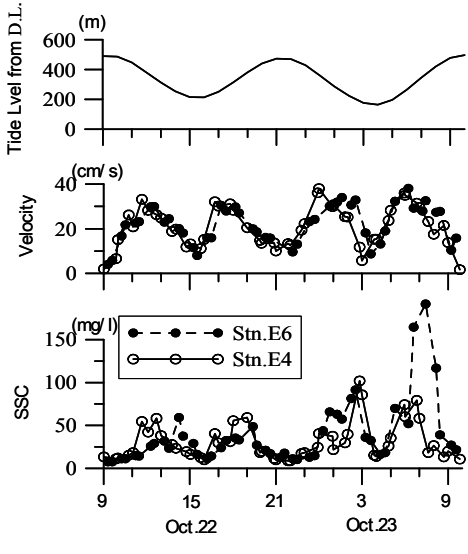

Fig. 7. Observed tide, current speed and suspended sediment concentrations measured at 100 cm above the bed

figure were obtained in the sequential ebb and flood current on October 23, 2002. Each profile clearly shows the rapid increase of SSC near the sea bed and it is considered that the high SSC might be due to resuspension of the sea bottom sediments in the area. The tide variation of SSC with higher concentration near the

bottom observed in the offshore area, however, was not be found in the near shore area, where tidal current becomes weak and coarse sand is dominant in the bottom sediment.

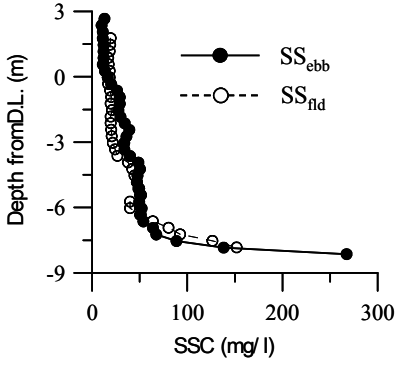

Fig. 8. Observed vertical distributions of suspended sediment concentration during ebb (●) and flood (○) tide

As mentioned above, considering that the high correlation between SSC and tidal current speed variations in the off shore area, resuspension process of the bottom sediments is one of the key factors for the observed increases in SSC. Since the tidal current flows across the navigation channel as shown in Figure 6, it is conceivable that a part of the resuspended fine sediments transported by the current might be deposited inside the channel and cause the higher siltation rate in the off shore area of the channel as shown in Figure 4 and 5.

NUMERICAL MODEL

Model Descriptions

In order to simulate the observed fine sediment transport process by the effect of tidal current in the area, a 3D numerical model was developed. The model consists of classical multilevel hydrodynamic model for flow field and advection-dispersion model for suspended sediment transport. Governing equations are solved with the finite difference scheme in a Cartesian grid system with z-grid in the vertical direction. Under the Boussinesq and hydrostatic approximations, the governing equations for the hydrodynamic model are the following continuity and momentum equations.

$$\left.\begin{aligned} w_{k-1/2} &= w_{k+1/2} - \frac{\partial M_k}{\partial x} - \frac{\partial N_k}{\partial y} \quad (k = 2,3,\cdots,K) \\ \frac{\partial \varsigma}{\partial t} &= w_{3/2} - \frac{\partial M_1}{\partial x} - \frac{\partial N_1}{\partial y} \end{aligned}\right\} \tag{1}$$

$$\frac{\partial M_k}{\partial t} = -\frac{\partial}{\partial x}\left(\frac{M_k^2}{H_k}\right) - \frac{\partial}{\partial y}\left(\frac{N_k M_k}{H_k}\right) - \left(wM\big|_{k-1/2} - wM\big|_{k+1/2}\right)/H_k + fN_k$$
$$- gH_k\left(\frac{\partial \zeta}{\partial x} + \frac{1}{\rho_k}\sum_{i=1}^{k}\left(H_i\frac{\partial \rho_i}{\partial x}\right) - \frac{1}{2}\frac{H_k}{\rho_k}\frac{\partial \rho_k}{\partial x}\right) + \left(\tau_{xz}\right)_{k-1/2} - \left(\tau_{xz}\right)_{k+1/2} + A_x\frac{\partial^2 M_k}{\partial x^2} + A_y\frac{\partial^2 M_k}{\partial y^2} \tag{2}$$

$$\frac{\partial N_k}{\partial t} = -\frac{\partial}{\partial x}\left(\frac{M_k N_k}{H_k}\right) - \frac{\partial}{\partial y}\left(\frac{N_k^2}{H_k}\right) - \left(wN\big|_{k-1/2} - wN\big|_{k+1/2}\right)/H_k - fM_k$$
$$- gH_k\left(\frac{\partial \varsigma}{\partial y} + \frac{1}{\rho_k}\sum_{i=1}^{k}\left(H_i\frac{\partial \rho_i}{\partial y}\right) - \frac{1}{2}\frac{H_k}{\rho_k}\frac{\partial \rho_k}{\partial y}\right) + \left(\tau_{yz}\right)_{k-1/2} - \left(\tau_{yz}\right)_{k+1/2} + A_x\frac{\partial^2 N_k}{\partial x^2} + A_y\frac{\partial^2 N_k}{\partial y^2} \tag{3}$$

where ζ is the water surface elevation, M_k and N_k are the horizontal flow rate in the x- and y-direction of the k-th layer respectively and $w_{k\text{-}1/2}$ is the vertical velocity between the k-th and (k-1)-th layers. In the momentum equations (Eq.(2) and (3)), g is the gravitational acceleration, ρ is the density of the sea water, A_x and A_y are the horizontal eddy viscosity coefficients and τ_{xz} and τ_{yz} are the x- and y-direction components of the shear stress between the layers.

The sediment transport model is expressed as,

$$\frac{\partial C_k H_k}{\partial t} + \frac{\partial M_k C_k}{\partial x} + \frac{\partial N_k C_k}{\partial y} + \left(\left(w - w_f\right)C\right)_{k-1/2} - \left(\left(w - w_f\right)C\right)_{k+1/2}$$
$$- \frac{\partial}{\partial x}\left(K_x H_k\frac{\partial C_k}{\partial x}\right) - \frac{\partial}{\partial y}\left(K_y H_k\frac{\partial C_k}{\partial y}\right) - \left(K_z\frac{\partial C}{\partial z}\right)_{k-1/2} + \left(K_z\frac{\partial C}{\partial z}\right)_{k+1/2} = 0 \tag{4}$$

where C_k represents suspended sediment concentration, w_f is the settling velocity of the suspended particles, and K_x, K_y and K_z are the eddy diffusion coefficients in the x-, y- and z-directions respectively. For the erosion rates of cohesive sediments, so called *Ariathurai-Partheniades'* type of equation is applied in the model as follows (e.g. van Leussen and Dronkers, 1988),

$$E = M\left(\frac{\tau_b}{\tau_e} - 1\right) \quad \text{for } \tau_b \geq \tau_e\,, \quad E = 0 \quad \text{for } \tau_b < \tau_e \tag{5}$$

$$D = w_f C_b \qquad \text{for all } \tau_b \tag{6}$$

where τ_b is the bottom shear stress, τ_e are the critical shear stress for erosion and

deposition and M is the erosion rate coefficient. In order to take the effect of the variability of the sediment quality on the erosion characteristic into account, the critical shear stress for erosion and the erosion rate coefficient depend on the mud content in the bottom sediments.

The parameters such as erosion rate constant and critical shear stress for the erosion flux estimation by Equation (5) are summarized, for examples, in Whitehouse et al. (2000). However the parameters depend on the sediment characteristics site by site and we obtained the parameters by using the relationship between observed bottom shear stress and total suspended load from the field data (Figure 9) in the present study. The erosion rates in the figure were estimated as the time difference of vertically integrated suspended load in the water column with observed SSC profiles. The bottom shear stress, on the other hand, was simply calculated by the quadratic law with observed current speed at 100cm above the sea bed. From the relationships between them for the stations from E4 through E7during the accelerating phase in the figure, erosion rate coefficient, M, is estimated as 0.019 mg/cm^2/min. and τ_{ec} as 0.021 Pa. The method is based on the assumptions of homogeneous of horizontal gradient of SSC and it could be applied reasonably well under such a condition that resuspension of the bottom sediment is dominant for the temporal change in SSC variation (e.g. Hill et al., 2003, Nakagawa et al. 2006).

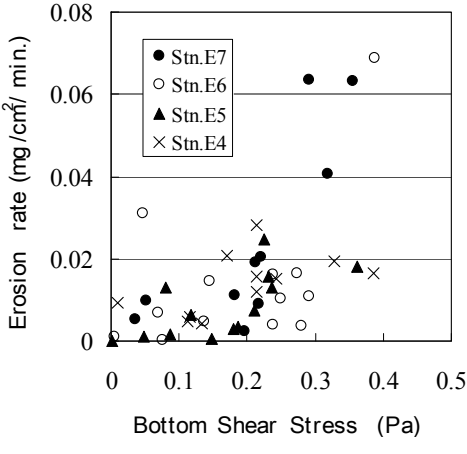

Fig. 9. Relationship between erosion rate and bottom shear stress

Numerical Results

Numerical results for the tide variations of water surface level, current velocities and SSC near the water surface at 100cm beneath and near the sea bottom at 100 cm above are shown in Figure 10 comparing with the field data of 25 hours under the spring tide condition. The model reasonably well reproduces the hydrodynamic

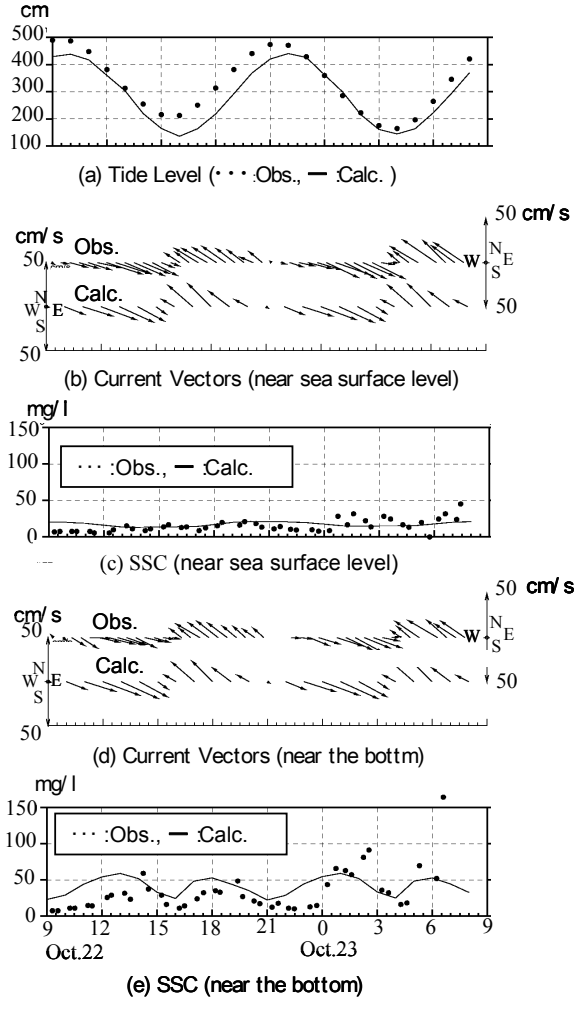

Fig. 10. Comparison between numerical results and observed data for tide, current velocities and SSC near surface and near bottom

features of the tidal currents and does simulate also well the temporal change in SSC especially near the bottom which has high correlation with the current speed variation. Furthermore, computed result of spatial distribution of SSC in the cross shore direction along the survey line is compared with observed data in Figure 11. The figure shows the snap shot at the high concentration event during the ebb tide current. Although the vertical resolution of the model does not so fine with at most 6 layers in

the area, the characteristics of the spatial distribution of SSC are reasonably reproduced by the model with the higher concentration in the offshore and the deeper

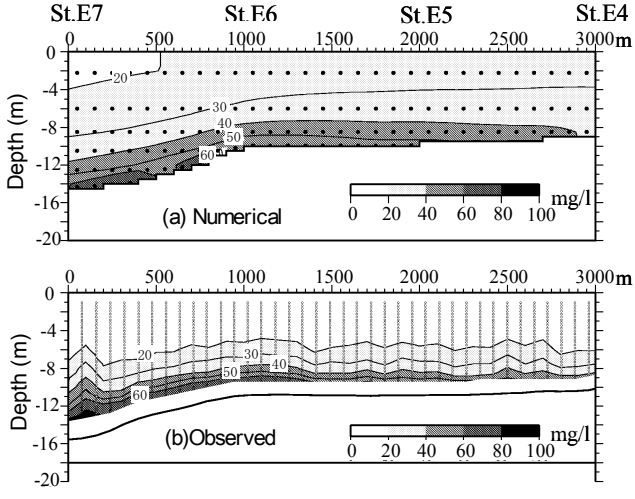

Fig. 11. Contours of numerical and observed data on suspended sediment concentration

area.

CONCLUSION

In this paper, we presented a set of observed sounding data which shows a tendency of siltation in the access channel for the port of Ube in a shallow muddy coast. According to the analyses of the data, the higher siltation rate was found at offshore part of the channel regardless of frequency of disturbance by storm events or wind waves. On the other hand, from the monitoring data of current and suspended sediment concentration, apparent increases in the near bottom concentration of suspended sediment were observed around the offshore region of the channel. The high concentration events are mainly due to the resuspension of the sediment around the channel by the tidal current and it might be a potential source for the higher rate of siltation in the area. The sediment transport model, furthermore, has been developed for the study area and the reasonable results were obtained for the fine sediment transport due to tidal currents. The model will be applied for the study to predict siltation rate in the channel. In a future work of siltation rate estimates in the channel, formation of fluid mud (e.g. Ross and Mehta, 1989) just above the sea bed by the settling of the observed suspended sediment should be also considered and modeled if necessary.

ACKNOWLEDGMENT

The authors would like to sincerely thank the Ube port office of the Ministry of Land, Infrastructure and Transport for their assistance of the field observation.

Abstract: A numerical cross-shore model for wave-mud interaction is presented that can be used to predict time dependent variations of fluid mud thickness and irregular wave transformation along soft mud profiles. The rheological constitutive equations of visco-elastic (VE) material are adopted for the behavior of fluid mud layer under the wave action. Spectral calculation method is used for the simulation of irregular wave transformation. The application of the numerical model at a field site shows the capability of the model to predict the wave height transformation along muddy profiles.

INTRODUCTION

The upper part of muddy beds may be fluidized when high water surface waves travel on consolidated mud layers. The fluidized mud layer absorbs wave energy and, in turn, moves due to the wave action. The determination of the thickness of fluidized mud layer is essential for the simulations of wave height transformation and mud mass transport. Since Gade (1958), the interaction between water waves and muddy beds, particularly wave height attenuation and mud mass transport, has been studied in several ways. There have also been some efforts to formulate the fluidization of mud, based on the characteristics of the wave and undisturbed mud layer (Chou, 1989; Foda et al., 1993). Conducting a series of laboratory experiments, Mehta et al. (1995) presented an empirical equation for the time-dependent fluidization of mud layers. Recently, the effect of irregularity has also been included in few studies (e.g., Zhang and Zhao, 1999,

Soltanpour et al., 2004). Soltanpour et al. (2006) studied the fluidization of mud and wave transformation under irregular waves along real mud profiles. In spite of these researches, the effects of the time changes of the depth of fluidized mud layer along mud profiles have not been studied yet.

The present paper offers a numerical cross-shore wave-mud interaction model that can be used to determine the time-dependent thicknesses of the fluidized mud and the transformation of waves along muddy profiles during high wave conditions. The performance of the proposed model is examined by using laboratory experiments and field data.

FLUIDIZATION OF MUD LAYER

It is assumed that a water layer of a given thickness is sitting on top of a stratified two-layered mud bed, where the upper one is a generalized visco-elastic (VE) layer (Foda et al., 1993). The behavior of this fluidized mud layer is simulated, using a complex viscosity coefficient, which is a function of the imposed strain in some nonlinear manner. The lower stationary layer is assumed to be elastic. The thickness of the fluid mud layer is related to the resulting strains due to the imposed wave height. the experimental results of Mehta et al. (1995) are employed to include the time-dependent variations of mud fluidization

$$d(t) = M[1 - \exp(-0.021 t^{0.346})] \tag{1}$$

where t represents the total time under wave action, d is the time-dependent thickness of fluidized mud layer and M is the ultimate depth of fluid mud.

WAVE-FLUID MUD INTERACTION MODEL

After the fluidization, the fluid system above the stationary mud, i.e. the fluidized mud layer and water layer, is divided into N sub-layers, in which the water layer is represented by N=1 (Fig. 1). The vertical distribution of mud properties can be considered using different mud characteristics in the horizontal sub-layers of the fluid mud layer. The rheological equations of VE are used for fluid mud. The visco-elastic parameters are adopted from the laboratory experiments of Shibayama and An (1993). The governing equations are linearized Navier-Stokes equations and the continuity equations which are solved considering the boundary conditions. The mud mass transport in fluid mud as well as the wave attenuation rate, k_i, can be calculated by this wave-mud interaction model. The details can be found in the original work of Tsuruya et al. (1987).

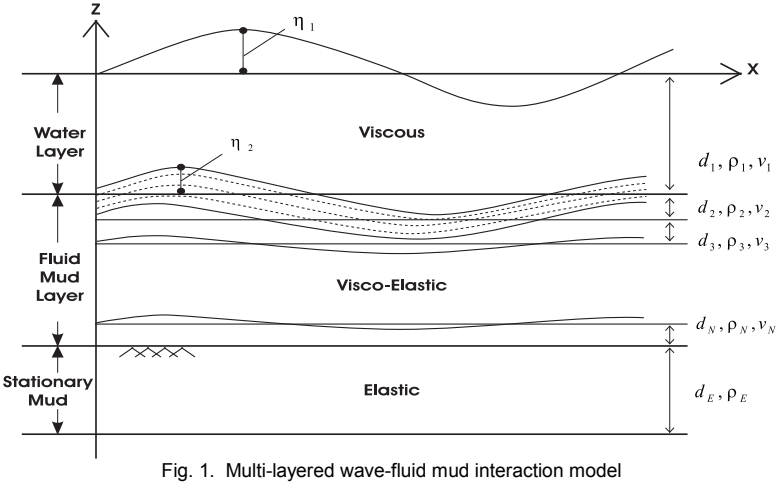

Fig. 1. Multi-layered wave-fluid mud interaction model

IRREGULAR WAVE TRANSFORMATION

Assuming the exponential decay of wave height over a horizontal mud bed, the energy dissipation rate of mud bottom is related to the wave attenuation rate, k_i (Soltanpour et al., 2003)

$$\varepsilon_{Dm} = -\frac{d}{dx}(C_g E) = 2C_g k_i E \tag{2}$$

where $E = \rho g H^2 / 8$ is the wave energy per unit surface area, ρ is the water density and C_g is the group velocity.

After the breaking line, energy dissipation rate reflects both dissipation effects of wave breaking and fluid mud.

$$\varepsilon_D = \varepsilon_{Dm} + \varepsilon_{Db} \tag{3}$$

where ε_D is total energy dissipation and ε_{Db} is the energy dissipation rate of wave breaking (Winyu and Shibayama, 1996).

Assuming that the irregular wave consists of an infinite number of component regular waves with different wave amplitudes and frequencies, the spectrum is divided into a number of wave components (Fig. 2). The irregular wave attenuation is simulated by superimposing the obtained regular component waves. The modeling wave spectra at $x = x_j$ is defined as

$$\hat{S}_j(\bar{f}_n) = \frac{1}{2} a_{jn}^2 \Delta f_n \tag{4}$$

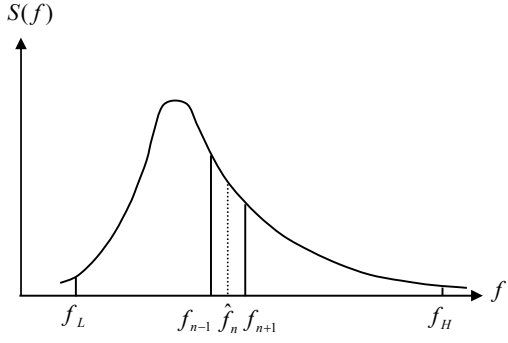

Fig. 2 Sketch used for definition of the amplitude and frequency of regular wave component

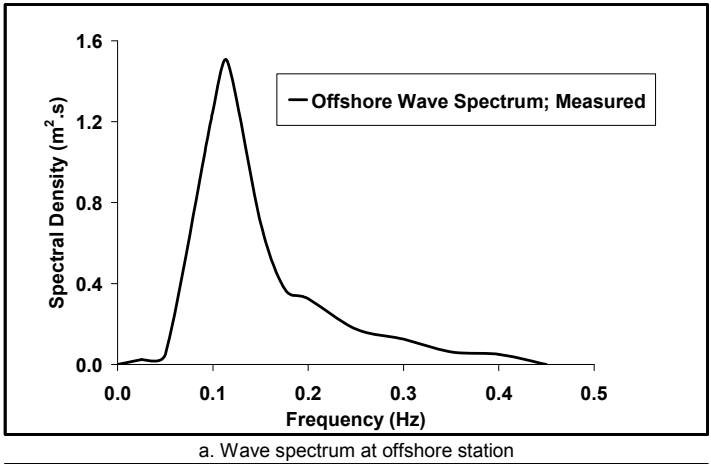
IRREGULAR WAVE-INDUCED MUD FLUIDIZATION

The fluidization model of Foda et al. (1993) is extended to irregular waves. Considering the periodic response of the imposed shear strain (Chou et al., 1993), the maximum shear strain of an irregular wave at the elastic mud line is calculated by superimposing of maximum shear strains of regular wave components, respectively

$$\gamma_{imp} = \sqrt{\sum_{n} \left(\gamma_{\max,n}{}^{2} \right)} \tag{5}$$

where $\gamma_{\max,n}$ is the maximum shear strain of each wave component at the elastic mud line. The thickness of the fluidized mud layer is determined by comparing the maximum shear strain, i.e. γ_{imp}, at the top of the elastic bed with the limiting or yield strain for the given mud material. A try and error procedure will result in the desired depth of fluidized mud layer under the overlaying irregular wave.



MODEL PERFORMANCE

Table 1 shows two cases of simulated and measured fluid mud thicknesses in a laboratory flume. As it is observed, the simulated ultimate depth of fluidized layer agrees with the observed data of Mehta et al. (1995). This supports the compatibility of different parts of the proposed fluidization model; i.e. time-dependent depth of fluid layer and ultimate depth of fluidization.

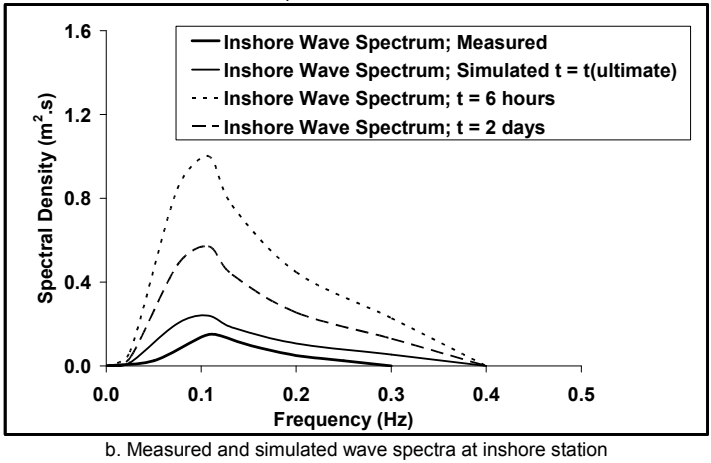


Table 1. Measured and Simulated Fluidized Mud Thickness (Data from Mehta et al., 1995)

Tests	Wave Period, s	Wave Height, cm	Water Depth, cm	*M* (cm) Measured	*M* (cm) Simulated
Case 1	1.00	4.00	19.0	18	20
Case 2	1.00	8.00	19.0	35	34

Fig. 3 shows an example of the measured and calculated wave spectra in monsoon conditions at a site offshore of the town of Alleppey in Kerala, India, where the measurements are at two stations with a distance of about 300 m (Mathew, 1992). A good agreement is observed between the measured and simulated wave spectra when the infinite time after wave action corresponding to the final fluidized depth, is reached. Two inshore wave spectra before final equilibrium state have also been presented. It is observed that considerable wave energy dissipation occurs at the initial stage of wave action, i.e. a few hours after the beginning of storm.

a. Wave spectrum at offshore station

b. Measured and simulated wave spectra at inshore station

Fig. 3 Measured and simulated wave spectra at Alleppey in Kerala, India (Data from Mathew, 1992), (W=210%, G=5kPa, ρ_E=1300kg/m^3, ρ_{VE}=1250kg/m^3)

CONCLUSION

A dynamic fluidization model is introduced to predict the time-dependent depth of the fluidized mud under wave action. Irregular wave height transformation on muddy profiles is simulated and the results are compared with a field data. It is observed that the model is capable to predict wave heights along muddy beds. However, more wave measurements, particularly during high wave actions, are needed to validate model performance on muddy profiles.

Coastal Sediments '07

Volume 3

Edited by
Nicholas C. Kraus
Julie Dean Rosati

ASCE

COASTAL SEDIMENTS '07

VOLUME THREE

PROCEEDINGS OF THE SIXTH INTERNATIONAL SYMPOSIUM ON COASTAL ENGINEERING AND SCIENCE OF COASTAL SEDIMENT PROCESSES

May 13–17, 2007
New Orleans, Louisiana

SPONSORED BY
Coasts, Oceans, Ports, and Rivers Institute (COPRI)
of the American Society of Civil Engineers

IN COOPERATION WITH
American Shore and Beach Preservation Association
Dept. of Oceanography and Coastal Science, Louisiana State University
Geological Society of America
International Association of Geomorphologists
International Union of Geological Sciences
U.S. Army Corps of Engineers, Coastal Inlets Research Program
U.S. Geological Survey, Coastal and Marine Geology Program

EDITED BY
Nicholas C. Kraus
Julie Dean Rosati

Foreword

The COASTAL SEDIMENTS '07 conference was organized as a technical specialty conference devoted to the physical aspects of sediment processes and morphology change in the coastal and inlet environment. Following previous conferences in the Coastal Sediments series that were held in 1977, 1987, 1991, 1999, and 2003, COASTAL SEDIMENTS'07 celebrated 30 years of the Coastal Sediments series and promoted exchange of information and views among specialists in the fields of coastal engineering, geology, oceanography, and related disciplines. The theme of COASTAL SEDIMENTS '07 was "Coastal Engineering and Science in Cascading Spatial and Temporal Scales," which established the trend of thinking and approach of the conference, as well as determined in part the composition of the papers that were presented. This theme was chosen to stimulate research devoted to the various scales of processes and their interactions at which coastal engineers and scientists must work in developing knowledge and capabilities to assist society in managing the coast under present and future conditions. Emphasis was on papers that recognize and relate to coastal morphology change of long-term consequence.

The COASTAL SEDIMENTS '07 conference returned to the site of the 1987 conference, New Orleans, Louisiana, because of the extraordinary morphologic change along the coasts of Louisiana, Mississippi, and Texas, caused by Hurricanes Katrina and Rita that struck in August and September, respectively, of 2005. In addition to the recent hurricanes, this coast is experiencing long-term natural and anthropogenic change including rapid and differential subsidence, severe reduction in renewable sediment supply, deltaic adjustment of fine-grained material, and oil and gas exploration and extraction. The theme is intended to generate papers and discussion of coastal sediment processes from the micro-scale to the regional scale at which integrated coastal design and management must be accomplished. Participants were given an overview of recent hurricane damage within the context of the long-term morphologic change in Louisiana in the Keynote Address delivered by Mr. James R. (Randy) Hanchey, Deputy Secretary of the Louisiana Department of Natural Resources.

Professor Leo van Rijn of Delft Hydraulics and the University of Utrecht, The Netherlands, accepted the 2007 Coastal Award at the Conference Awards Luncheon on May 16th. Starting in 2001, the Coastal Award has been presented every 2 years alternately at the Coastal Dynamics conference and the Coastal Sediments conference through coordination between the organizing committees of these two technical specialty conferences. The Organizing Committee of Coastal Sediments '07 joins conference participants and the extended research community in celebrating Professor van Rijn's research contributions that have greatly influenced engineers and geologists working in the areas of coastal sediment transport and morphology change.

These *Proceedings* volumes are the permanent record of the conference, containing the latest thinking and progress of the world's leading scientists and

engineers in the areas of coastal sediment transport and morphology change. The contents are a valuable source of information on coastal sediment and morphology processes ranging from basic research to case studies and lessons learned. The papers contained herein provide the most recent results and ideas in a wide range of approaches and viewpoints not assembled elsewhere in both quality and breadth. The *Proceedings* were produced in hard copy in two volumes in black and white and also provided to conference participants as a CD ROM with searchable index of PDF files in color. All papers are available to the public in PDF format via the ASCE Research Library at www.ascelibrary.org.

Three-hundred fifty abstracts were submitted to the Conference Steering Committee. On average, each abstract received five reviews, and 225 submissions were invited for development into full papers and presentation over 3 days of technical sessions. The 197 papers appearing in these Proceedings originated from approximately 24 countries, demonstrating the international scope of COASTAL SEDIMENTS '07. Each paper included in these *Proceedings* received positive peer review. Each paper is eligible for discussion in the *Journal of Waterway, Port, Coastal and Ocean Engineering* and can be nominated for ASCE awards.

The Steering Committee of COASTAL SEDIMENTS '07 gratefully acknowledges the assistance of many individuals, both known and anonymous, in the 2 years of preparations by an all-volunteer committee. Numerous individuals assisted the Steering Committee in review of abstracts and final papers. The efforts of the following persons are acknowledged: Matthew Arsenault, U.S. Geological Survey (USGS); Mark Byrnes, Applied Coastal Research and Engineering, Inc.; Duncan FitzGerald, Boston University; Guy Gelfenbaum, USGS; Cheryl Hapke, USGS; John Headland, Moffatt & Nichol; Todd Holland, Naval Research Laboratory; Peter Howd, USGS; Bruce Jaffe, USGS; Magnus Larson, University of Lund; Jeffrey List, USGS; Randy Parkinson, Coastal and Environmental Geological Consulting; Robert Morton, USGS; James O'Connell, Woods Hole Oceanographic Institution; Lisa Robbins, USGS; Vladimir Shepsis, Coast and Harbor Engineering; Donald Stauble, U.S. Army Corps of Engineers; Marcel Stive, Delft Hydraulics; Hilary Stockdon; USGS; and Curt Storlazzi, USGS.

We also thank the session moderators for agreeing to lend their time and experience to run the conference smoothly and productively. We are indebted to the tour leaders and their organizations for arranging and conducting memorable and stimulating technical trips. The "Geology of the Louisiana Coastal Zone: Implications for Coastal Management and Restoration" tour was led by Mark Kulp, University of New Orleans (UNO); Mike Miner, UNO; Duncan FitzGerald, Boston University; and Ioannis Giorgiou, UNO. The "Wax Lake-Atchafalaya Delta Complex Sedimentation, Stratigraphy" tour was led by Harry Roberts, Louisiana State University. Finally, we thank Lucy King of ASCE for assisting and often leading in conference logistics; Donna Dickert of ASCE for accurately producing the Proceedings; and Lesa Rair and Chris Hanson of COPRI for assisting with conference arrangements, including exhibitors and sponsors.

We also would like to thank our exhibitors and sponsors for Coastal Sediments 2007 for their support:

Contents

Volume One

Sediment Transport Fundamentals I

Wave-Related Transport and Nearshore Morphology 1
Leo van Rijn, Gerben Ruessink, Bart Grasmeijer, Jebbe van der Werf, and Jan Ribberink

Closed Form Solution for Threshold Velocity for Initiation of Sediment Motion under Waves 15
Hans Hanson and Benoît Camenen

Influence of Velocity Moments on Sand Bar Movement During CROSSTEX 28
Gregory Guannel, H. Tuba Özkan-Haller, Merrick C. Haller, and James T. Kirby

Development of a New Practical Model for Sand Transport Induced by Non-Breaking Waves and Currents 42
Jebbe J. van der Werf, Jan S. Ribberink, and Tom O'Donoghue

A Total Load Formula for the Nearshore 56
Benoît Camenen and Magnus Larson

Sediment Transport Fundamentals II

Longshore Sand Transport Rate Measurements Using Small-Scale Physical Models 68
Roshan Suminda Ranasinghe and Shinji Sato

Pressure-Induced Subsurface Sediment Transport in the Surf Zone 82
Ole Secher Madsen and William McKinney Durham

Tracking Sediment Particles under Wave-Current Coexisting Field 96
Yoshimitsu Tajima, Masayuki Kozuka, Masahito Tsuru, Toshimasa Ishii, Takeharu Sakagami, Kazuo Momose, Nobuo Mimura, and Ole S. Madsen

Sediment Transport in Response to Wave Groups Generated by High-Speed Vessels 110
Philip D. Osborne, Neil J. MacDonald, and Shaun Parkinson

Sediment Transport Fundamentals III

Flume Experiments under Cat-Scan to Measure Internal Sedimentological Parameter During Sediment Transport 124
Stéphane Montreuil and Bernard F. Long

The Effects of Bed Slope and Wave Skewness on Sediment Transport and Morphology 137
D. J. R. Walstra, L. C. van Rijn, M. van Ormondt, C. Briére, and A. M. Talmon

Sediment Transport off Northeast Florida Outside the Surf Zone during Hurricanes 151
Michael Krecic, Christopher Bender, and Kristen Odroniec

Longshore Transport

Geomorphic and Sedimentologic Evidence for Net Littoral Drift—A Review 165
Terry Healy

Cross-Shore Variation of Predominant Longshore Sediment Transport Rate 179
Yoshiaki Kuriyama and Hikari Sakamoto

Longshore Sand Transport Calculated by Time-Dependent Shear Stress 193
Ernest R. Smith and Nicholas C. Kraus

Sediment Budget of the Danube Delta Coastal Zone 207
Sebastian Dan, Marcel Stive, Dirk Jan Walstra, and François Sabatier

Field Measurements and Modeling of Longshore Sediment Transport 221
J. J. Williams, L. S. Esteves, M. A. Lisniowski, and H. L. S. Perotto

Sediment Transport Fundamentals IV

Infragravity Waves in Mobile-Bed Laboratory Experiments 235
Florent Grasso, Hervé Michallet, and Eric Barthélemy

Large-Scale Laboratory Modeling of Suspended Sand Concentration Fluctuations under Irregular Waves 248
Joachim Grüne, Ruben Kos'yan, Hocine Oumeraci, Igor Podymov, Reinold Schmidt-Koppenhagen, and Chris E. Vincent

Change in Longitudinal Profile Using Sand of Mixed Grain Size in Large Wave Tank and its Numerical Simulation 259
Massaya Fukuhama, Takaaki Uda, Masumi Serizawa, and Toshinori Ishikawa

Probabilistic-Deterministic Modelling of Swash Zone Morphology 272
T. E. Baldock, P. Kim Son, P. Manoonvoravong, M. P. Barnes, and J. M. Alsina

Modelling Sheet Flow Sediment Transport Using Convolution Integrals 286
P. Guard, I. Teakle, P. Nielsen, and T. Baldock

Shoreline Change Modeling

A Middle-Term Evolution Model for Beaches 300
Soledad Requejo, Raul Medina, and Mauricio Gonzalez

Model for Predicting Beach Changes on Coast with Sand of Mixed Grain Size Based on Bagnold's Concept 314
Masumi Serizawa, Takaaki Uda, Toshiro San-nami, Kou Furuike, Toshinori Ishikawa, and Takayuki Kumada

A Circulation Modeling Approach for Evaluating the Conditions for Shoreline Instabilities 327
Jeffrey H. List and Andrew D. Ashton

An Alternative Explanation for the Shape of 'Log-Spiral' Bays 341
Ryan Littlewood, A. Brad Murray, and Andrew D. Ashton

The Response of Spit Shapes to Wave-Angle Climates 351
Andrew D. Ashton, A. Brad Murray, and Ryan Littlewood

Observed Shoreline Change

Historical Shoreline Changes and Morphodynamics of Parramore Island, Virginia (1852-2006) 364
Trent M. Richardson and Randolph A. McBride

Temporal and Spatial Scales of Profile and Planform Adjustment on a Nourished Beach 378
Nicole A. Elko and Ping Wang

Shoreline Response to Dike Failure at Grand Marais Harbor, Lake Superior, Michigan 392
Rachel R. Roblin, Mohammad Dibajnia, Robert B. Nairn, and James P. Selegean

Successful Beach Modelling, Monitoring and Management for a Large LNG Facility 406
Jonathan A. Kemp, Tom C. Coates, Richard Head, and Jenny S. Harcourt

Gravel Coasts I

The Design of Stable and Aesthetic Beach Fills: Learning from Nature 420
Paul D. Komar

Variation in the Organization of Gravel-Dominated Coastal Systems: Evidence from Nova Scotia and Southern England 434
Julian D. Orford and Simon C. Jennings

Profile Dynamics and Particle Tracer Mobility of a Cobble Berm Constructed on the Oregon Coast 449
Jonathan C. Allan and Roger Hart

Mixed Sediment Beach Processes: Kachemak Bay, Alaska 463
Peter Ruggiero, Peter N. Adams, and Jonathan A. Warrick

Mixed Sand and Gravel Beach Design and Construction for Habitat Restoration 477
David Simpson, Michael Wray, John Houghton, and John Klekotka

Gravel Coasts II

Influence of Changing Management Regimes on the Morphodynamic Response of a Mixed Gravel and Sand Barrier Beach 492
Andrew P. Bradbury and Julian D. Orford

The Influence of Groundwater on Profile Evolution of Fine and Coarse Sand Beaches 506
Diane P. Horn, Tom E. Baldock, and Ling Li

Effects of Permeability on the Performance of Mixed Sand-Gravel Beaches 520
Kaiming She, Louise Trim, Diane Horn, and Paul Canning

Cross-shore and Longshore Transport of Tracer Pebbles on a Macrotidal Mixed Sediment Beach, Somme Estuary, France 531
J. Curoy, U. Dornbusch, C. A. Moses, D. A. Robinson, and R. B. G. Williams

Why Are Shingle Beaches Replacing Sandy Beaches? (Coastal Zone of NW Portugal) 545
Helena Granja and Eduardo Loureiro

Gravel Coasts III

Field Measurements of Shore Conditions to Assess Bulkhead Effects in Thurston County, South Puget Sound 561
Susan P. Tonkin, Tim Abbe, José Carrasquero, and Steve Morrison

Coral-Gravel Storm Ridges: Examples from the Tropical Pacific and Caribbean 572
Bruce M. Richmond and Robert A. Morton

Field Observations of Step Dynamics on a Macrotidal Gravel Beach 584
Daniel Buscombe, Martin J. Austin, and Gerhard Masselink

Large-Scale Scour of the Sea Floor and the Effect of Natural Armouring Processes, Land Reclamation Maasvlakte 2, Port of Rotterdam 598
Sander Boer, Edwin Elias, Stefan Aarninkhof, Dano Roelvink, and Tiedo Vellinga

Dunes and Profiles

Dune Erosion Prediction Methods Incorporating Effects of Wave Periods 612
Marcel R. A. van Gent, E. Martijn Coeveld, Hans de Vroeg, and Jan van de Graaff

Reevaluation of Equilibrium Beach Profile Scale Parameter 626
Zhanxian Wang and Robert G. Dean

Shoreface Response to Sediment Deficit 633
G. M. Kaminsky, M. A. Ferland, P. J. Cowell, H. R. Mortiz, and P. Ruggiero

Louisiana Coast

The Challenges of Restoring Louisiana Barrier Islands: From Design through Construction 647
Gordon G. Thomson, Greg M. Grandy, and Rachel Sweeney

Field Observations of Wave-Current-Sediments Dynamics, Atchafalaya Shelf, Louisiana, USA 661
Sergio Jaramillo, Alex Sheremet, and Mead Allison

Investigation of Morphosedimentary Processes on a Schematic Louisiana Barrier Island Using Process-Based Numerical Modeling 671
T. Campbell, B. de Sonneville, L. Benedet, D. J. W. Walstra, and C. W. Finkl

Restoration-Quality Sand from Ship Shoal, Louisiana: Geotechnical Investigation for Sand on a Drowned Barrier Island 685
Syed M. Khalil, Charles W. Finkl, Jeff Andrews, and Christopher P. Knotts

Mississippi River Sand for Barrier Island Restoration in Louisiana: Geophysical and Geotechnical Investigations for Sand Mining 699
Jeffrey L. Andrews, Syed M. Khalil, Charles W. Finkl, and Lindino Benedet

Mississippi River Delta

Re-Engineering the Mississippi River as a Sediment Delivery System 712
Harley S. Winer

Sediment Flux and Fate in the Mississippi River Diversion at West Bay: Observation Study 722
T. Mitchell Andrus and Samuel J. Bentley

Initial Morphologic and Stratigraphic Delta Evolution Related to Buoyant River Plumes 736
Joep E. A. Storms, Marcel J. F. Stive, Dano (J.) A. Roelvink, and Dirk Jan Walstra

Physical and Numerical Modeling of River and Sediment Diversions in the Lower Mississippi River Delta 749
Clinton S. Willson, Nathan Dill, William Barlett, Samantha Danchuk, and Ryan Waldron

A Geomorphic Process-Response Model for Chenier-Plain Evolution in Southwestern Louisiana, USA 762
Randolph A. McBride, Matthew J. Taylor, and Mark R. Byrnes

Marshes and Wetlands

Sediment Analysis for Habitat Restoration: Adaptation of Open-Coast Beach Nourishment Principles 776
Daniel J. Heilman, Joel T. Darnell, and M. Cameron Perry

Subsurface Exploration and Containment Dike Design Criteria for Coastal Louisiana Marsh Restoration 785
Russ Joffrion, Michael Poff, and Mitch Andrus

Ice Raft Formation, Dispersion and Sedimentation on New England Salt Marshes 798
Brittina A. Argow, Zoe J. Hughes, and Duncan M. FitzGerald

Effects of Large Scale Morphological Changes to a Back-Bay System 814
Lee L. Weishar, Theodore Keon, and Donald K. Stauble

Volume Two

Deltas and River Mouths

Morphodynamic Feedbacks on Deltaic Coasts: Lessons from the Wave-Dominated Danube Delta 828
Liviu Giosan

Coastal and River Mouth Morphology Change in Sri Lanka Due to 2004 Indian Ocean Tsunami 842
Hitoshi Tanaka, Kazuo Ishino, Bandara Nawarathna, Hajime Nakagawa, and Shinichiro Yano

Holocene Evolution of the Merrimack Embayment, Northern Massachusetts, Interpreted from Shallow Seismic Stratigraphy **856**
Christopher J. Hein, Duncan M. FitzGerald, and Walter A. Barnhardt

REGIONAL BEACH/CLIFF SYSTEM DYNAMICS ALONG THE CALIFORNIA COAST

Cheryl J. Hapke[1] and Dave Reid [2]

1. U.S. Geological Survey, Coastal Field Station, University of Rhode Island, 339 Woodward Hall, Kingston, RI 02881, USA. chapke@usgs.gov.
2. U.S. Geological Survey, Pacific Science Center, 400 Natural Bridges Dr., Santa Cruz, CA 95060, USA. dreid@usgs.gov.

Abstract: The coast of California is comprised of both sandy shorelines and cliffed coastline, and in many areas these features spatially coincide. In order to better understand the regional trends of change along the California coast, the U.S. Geological Survey is quantifying both sandy shoreline change and coastal cliff retreat for the state. The resulting database was used to examine the dynamics of the beach/cliff system. We found inconsistent evidence of a relationship between rates of cliff retreat and shoreline change on the spatial scale of 100-km cells. However, when the data are correlated within individual regions, a strong relationship exists between the geomorphology of the coast and the behavior of the beach/cliff system. Areas of high-relief coast show negative correlations, indicating that higher rates of cliff retreat correlate with lower rates of shoreline erosion. In contrast, low- to moderate-relief coasts show strong positive correlations.

INTRODUCTION

The coast of California is comprised of approximately 800 km of sandy shorelines. Additionally, 1300 km of coast are backed by cliffs and bluffs (California Department of Boating and Waterways and State Coastal Conservancy, 2002). In many areas, these geomorphic features coincide in that the sandy beaches are backed by low to moderate relief cliffs. Erosion of the beaches and retreat of the coastal cliffs are chronic hazards along the California coast, frequently resulting in property damage and land loss.

Several previous studies have included analyses of regional sandy shoreline change in California (U.S. Army Corps of Engineers 1971; Griggs and Savoy 1985; Griggs et al. 2005; Hapke et al. 2006), although most of these are compilations of existing data produced by different groups or agencies using a variety of techniques. The report by Hapke et al. (2006) is the first to systematically calculate and present rates for the entire state. Regional analyses of coastal cliff retreat are less available than shoreline change studies. The most comprehensive study to date is Hapke et al. (in press) where cliff retreat rates are calculated

for over 350 km of the California coast. Previous regional cliff retreat analyses are presented by Moore et al. (1999), where rates were determined for two California counties: Santa Cruz and San Diego.

Few previous studies have examined the spatial relationship between shoreline change rates and cliff retreat rates. Sallenger et al. (2005) documented the relationship between these systems during the 1997-98 El Niño along a single beach in Central California. Their analysis indicated that hotspots of cliff erosion correlated to areas of decreased beach width and beach elevation over time scales of individual storms or storm seasons. If this holds true over much longer temporal scales, it might be expected that areas undergoing high rates of sandy shoreline erosion in the long-term would correspond to areas with high rates of bluff retreat. Exceptions would include areas with wide beaches and cliffs that are undergoing only subaerial erosion (i.e. waves no longer reach the cliff base) and/or areas where the cliff is armored. This paper explores the relationship between coastal cliff retreat and shoreline change for California to determine if there are areas of chronic erosion in which both systems are behaving similarly (i.e. eroding at similar rates over the same temporal scale).

Coastal cliffs, as defined here, are steeply sloping geomorphic features, generally the seaward face of an elevated land surface, formed at the coast. Across the literature, "cliff" frequently refers to a slope formed in stronger more resistant rock units, whereas bluffs are slopes eroded in softer, unlithified material such as glacial till or ancient dunes. For the purposes of this paper the terms cliff and bluff are used interchangeably.

METHODS AND DATA

The U.S. Geological Survey has recently undertaken a nationwide assessment of historical shoreline change rates and trends for open-ocean coasts of the U.S. To date, analyses have been completed for the Gulf of Mexico (Morton et al. 2004), the Southeast U.S. (Morton and Miller, 2005) and the California coast (Hapke et al 2006). In addition, an analysis of coastal cliff retreat is currently underway for the California coast using a subset of the data sources used in the shoreline assessment. The primary data sources for the shorelines and cliff edges used in these studies are NOS T-sheets from the 1800s, 1930s and 1950s/70s for the historical shorelines, and lidar data (1998 or 2002) for the modern shoreline and cliff edge.

The historical shorelines are high water lines which are visual estimates of the high water line on the beach. The lidar shoreline, however, is a mean high water shoreline which is based on a local tidal datum. For this analysis, a proxy-datum adjustment was applied to the shoreline change rates (see Hapke et al. 2006, for details) to account for the bias in the data that occurs from using two different shoreline proxies. In order to statistically evaluate the relationship between cliff retreat and shoreline change, it was necessary to use the same data sources and generate rates over the same time period. As a result, shoreline change was generated as end point rates using only the 1930s and 1998/2001 shorelines rather than all four available shorelines because it was determined that the cliff edge was not a consistently valid feature on T-sheets from the other eras.

The cliff edge was digitized directly from the 1930s T-sheets after several pilot areas of

known low cliff retreat (e.g. granitic headlands) were evaluated to verify that the cliff and cliff edge as rendered on the T-sheets were valid features. The modern cliff edge was derived from the same lidar data used for the shoreline analysis. The data was gridded using a natural neighbors algorithm, at a 1 m cell size. A hillshade, which is a shaded surface based on the reflectance values and shading effects of surrounding surface features, was created from each grid. Hillshading is a useful tool for enhancing the visualization of a surface, and the resulting 3D rendering was used to interpret and hand-digitize the cliff edge using the visual break in slope. This visual rendering approach has advantages over slope or second-derivative methods of edge enhancement in that objects such as buildings or vegetation that are near the cliff edge are easier to identify and omit from the dataset. Oblique aerial photographs as well as historical maps were utilized during the digitization process to resolve ambiguities in the identification of the cliff edge.

The Digital Shoreline Analysis System (DSAS; Thieler et al., 2005) was used to calculate change along coast-perpendicular transects spaced at 20 m intervals. Although transects were generated along the entire coastline, only transects that intersected both the 1930s and 1998/2002 cliff edges and shorelines were used. There are large areas of data gaps for the cliff edges, as the edge was not used if it was an ambiguous feature on the historical maps, and there are many areas where the lidar data did not extend far enough inland to capture the cliff edge. In total, we were able to correlate the rates of change of the shoreline and cliff edge on 7,618 transects, covering a total of 152 km of the California coast. These data are assessed and presented for fifteen regions, as shown in Figure 1. Although data are distributed along the entire length of the coast, the number of transects per region varies dramatically (Table 1), as a function of both the geomorphology within each region and the data gaps described above. Central California consistently has the most data coverage. Northern and Southern California have more areas where sandy shorelines and coastal cliffs do not coincide.

RESULTS AND DISCUSSION

For the 152 km of coastline along which we calculated coincident shoreline change and cliff retreat, the average shoreline change rate (-0.1± 0.2 m/yr) is lower than the average cliff retreat rate (-0.3± 0.2 m/yr). In certain areas, the shoreline is prograding, and as such the net shoreline change contains averages of positive and negative values. The average shoreline *erosion* rate (the average of those transects with an erosional trend, 72% of the transects) is -0.3±0.2 m/yr, the same as the cliff retreat rate. This implies that based on a regional average, the beach and cliffs along the California coast are eroding at an equivalent rate.

It is important to note that the average change rates presented here will not be the same as those reported in Hapke et al. (2006) and Hapke et al. (in press), as different transects were generated for this analysis in order to increase the density of the data and to assure transects intersected both the 1930s and 1998/2002 shorelines and cliff edges. Additionally, there is a much more limited amount of data (covering a total of 152 km for the entire state) due to the requirement that there were coincident cliffs and shorelines for each transect.

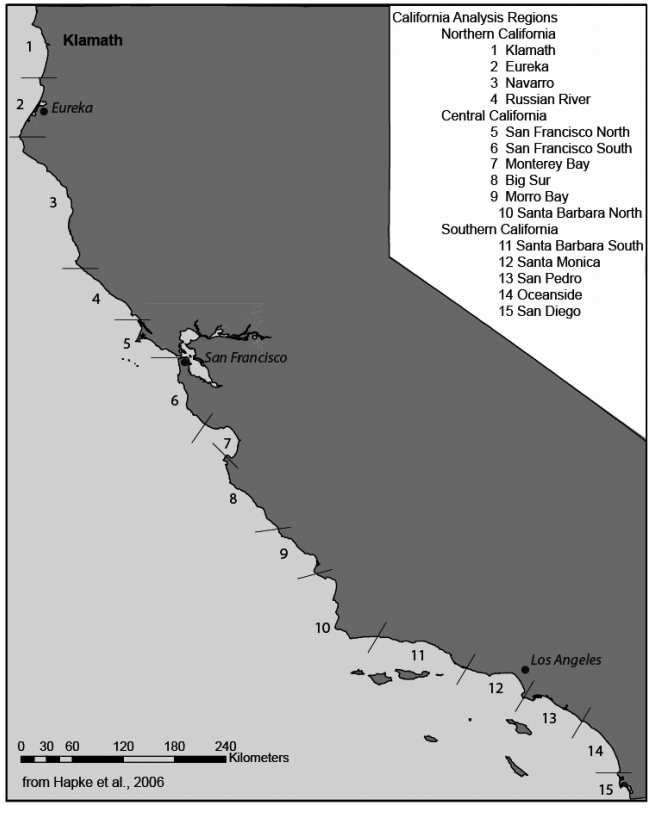

Figure 1. Location map of California showing the fifteen analysis regions.

Figure 2 shows the average rates of shoreline change and cliff retreat for each of the fifteen analysis regions. In general, the cliff retreat rates are highest in Central and Northern California, with the exception of the San Diego region in Southern California. Rates of shoreline change are highest in Central California. Besides some overlaps in these broad regional trends (i.e. high rates of both erosional shoreline change and high cliff retreat rates), there is no consistent evidence of a strong relationship between shoreline change rates and cliff retreat rates when values are averaged along the ~100-km analysis regions. In some regions where the average cliff retreat rates are high (>0.4 m/yr), such as the Eureka, Navarro San Diego regions, the average shoreline change is <0.1 m/yr. Central California exhibits the most consistent relationship between shoreline change and cliff retreat. It is likely that the lack of similar behavior between the beach and cliff in Southern California is related to the impact of human manipulations to the system (seawalls, groins, nourishments projects, etc.). In Northern California, the coastal system is dominated by high-relief, steep

slopes where large, deep-seated landslides are the dominant process of coastal retreat. Beaches tend to occur at river and stream mouths where valleys interrupt the coastal slope. Since the beach/cliff systems are rarely coincidental, it is not surprising that there is little apparent relation between the shoreline change and cliff retreat rates.

Table 1. Shoreline change and cliff retreat rate data for the 15 analysis regions

	Region	No. of transects	Length of coast (km)	Mean Shoreline Change Rate (m/yr)	Mean Cliff Retreat Rate (m/yr)
Northern California	Klamath	210	0.21	-0.3	-0.4
	Eureka	10	0.01	< 0.1	-0.5
	Navarro	350	0.35	0.1	-0.4
	Russian River	36	0.036	0.1	-0.1
Central California	San Francisco North	431	0.431	-0.4	-0.5
	San Francisco South	564	0.564	-0.3	-0.3
	Monterey Bay	547	0.547	-0.4	-0.6
	Big Sur	264	0.264	-0.1	-0.2
	Morro Bay	105	0.105	-0.3	-0.3
	Santa Barbara North	2273	2.273	-0.2	-0.2
Southern California	Santa Barbara South	15	0.015	-0.1	-0.2
	Santa Monica	829	0.829	< 0.1	-0.2
	San Pedro	219	0.219	-0.1	-0.1
	Oceanside	1712	1.712	0.1	-0.2
	San Diego	53	0.053	< 0.1	-0.6

One of the objectives of this analysis is to assess the relationship between the mechanisms of *retreat* of the coastline. Since the average rates of shoreline change contain both erosional and progradational data, they do not provide information only on shoreline retreat. To better understand the relationship between the trends of cliff retreat and shoreline retreat, we compared average rates of cliff retreat in areas were the shoreline is erosional to the cliff retreat rates in areas where the shoreline is accreting. The results of this are displayed in Figure 3, which demonstrates that cliff retreat rates are usually higher in the areas where the beach is eroding. Of the fifteen regions, 60% have higher cliff retreat rates where the beaches are undergoing long-term erosion. The average difference between the rates in these regions is -0.2 m/yr. Most of the regions where the cliff retreat rates are the same regardless of whether the beach is eroding or accreting are in Southern California, and again, this is likely related to the extensive manipulation of the beach and cliff systems in this part of the state. The Eureka region in Northern California is unusual in that it is the only region where the cliff retreat rate is higher where the shoreline is accreting. There are very little data available in this region (Table 1), and the specific location where the cliff and shoreline data coincide (10 transects) is the site of a large landslide complex just north of Cape Mendocino. The narrow beach is rapidly replenished by material from the landslide, thus resulting in high shoreline accretion rates where there are also high cliff retreat rates.

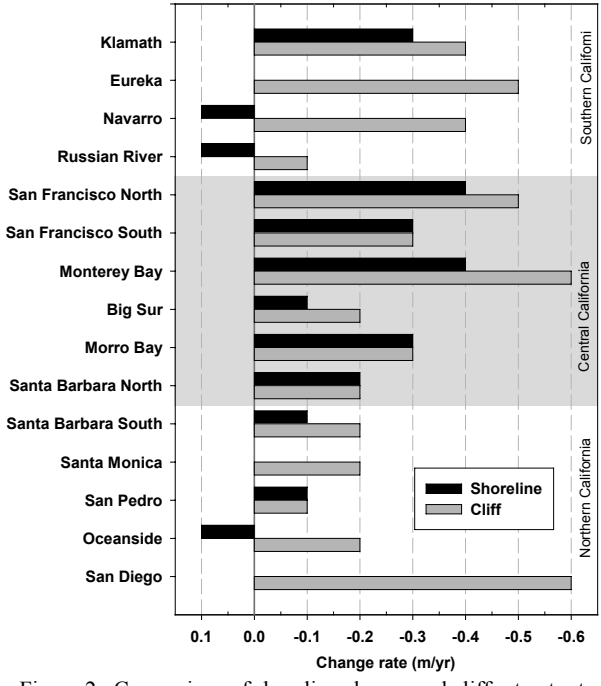

Figure 2. Comparison of shoreline change and cliff retreat rates for the fifteen regions analyzed in this study.

The previous discussion focused on assessing the average trends of the shoreline change and cliff retreat data on a large spatial scale (i.e. the state of California). In order to explore the relationship of the beach/dune system on a somewhat more localized scale, we generated plots of cliff retreat versus shoreline change for each of the fifteen analysis regions (Figures 4-6). The scatter plots show the relative distribution of the data and these data were correlated to assess the relationship between cliff retreat and shoreline change within each individual region.

Northern California

Figure 4 shows the cliff retreat versus shoreline change plots for the four regions in Northern California. Two of these regions (Eureka and Navarro) show a strong negative correlation between the data sets, which indicates that cliff retreat may be influencing rates of shoreline change. In areas of the coast where the characteristic geomorphology is steep, high-relief coastal slopes, large deep-seated landslides are the dominant process of coastal retreat. These landslides can contribute large volumes of material to the base of the slope, and this material may be stored on the subaerial beach, causing a seaward progradation of the shoreline.

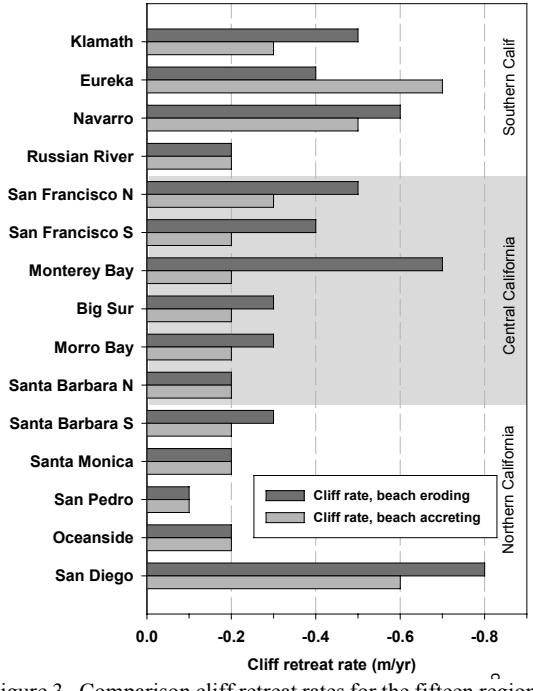

Figure 3. Comparison cliff retreat rates for the fifteen regions separated by whether the fronting beach is eroding or accreting.

Although the slopes of the regression lines in Figure 4, for the Eureka and Navarro regions, are not steep, there is evidence from the data that areas where cliff retreat is higher correlate to areas where the shoreline is prograding or retreating more slowly. The highest positive correlation and regression slope occur in the Klamath region (Figure 4). Although Northern California in general is dominated by high-relief coastal slopes, the areas for which we have Klamath data are all beaches backed by low cliffs or flat marine terraces. The processes resulting in retreat of these geomorphic settings tend to be lower volume, shallow failures of the cliff. Therefore, it is expected that the relationship between the beaches and cliffs will be different than in the large landslide-dominated regions.

Central California

All six of the analysis regions in Central California show some relationship between the beach and cliff system (Figure 5). In all regions except Big Sur, the correlation is positive, indicating larger cliff retreat rates in areas with larger shoreline retreat rates. As discussed above for the Klamath region, it appears that positive correlations occur in datasets from areas where the geomorphology is dominated by low- to moderate- relief cliffs that retreat via shallow failures of the cliff. This retreat mechanism results in a much lower

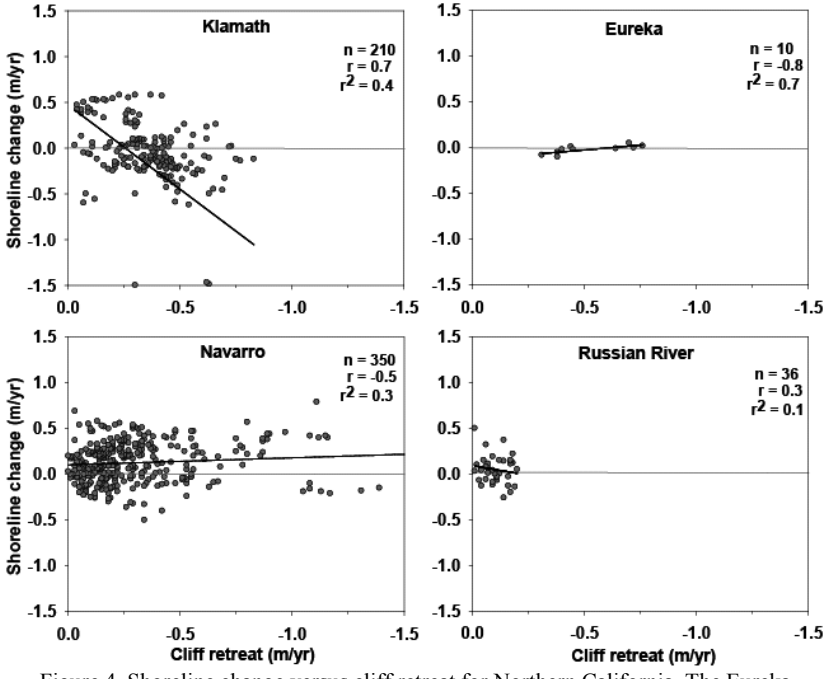

Figure 4. Shoreline change versus cliff retreat for Northern California. The Eureka and Navarro regions show a reverse trend between the rates Indicating lower shoreline retreat in areas of higher cliff retreat.

contribution of material to the beach system relative to that delivered by large, deep-seated landslides. It appears that in these low- to moderate-relief cliffed areas, the rates of shoreline retreat influence the retreat rates of the cliff. This observation is supported by the negative correlation in the Big Sur region (Figure 5) where the coastal geomorphology is much more dominated by large landslides, and the beach/cliff system behaves more similarly to that observed in Northern California. The Monterey Bay region has the strongest correlation in the state. In Figure 5, the dashed oval in the Monterey Bay region delineates data that is primarily from the southern part of the Bay where high rates of shoreline retreat and cliff erosion are well documented (Thornton et al., 2006). Based on our data, this area is the largest and most well-defined erosion "hotspot" in the state, at least over the temporal scale of the 70-years of this analysis.

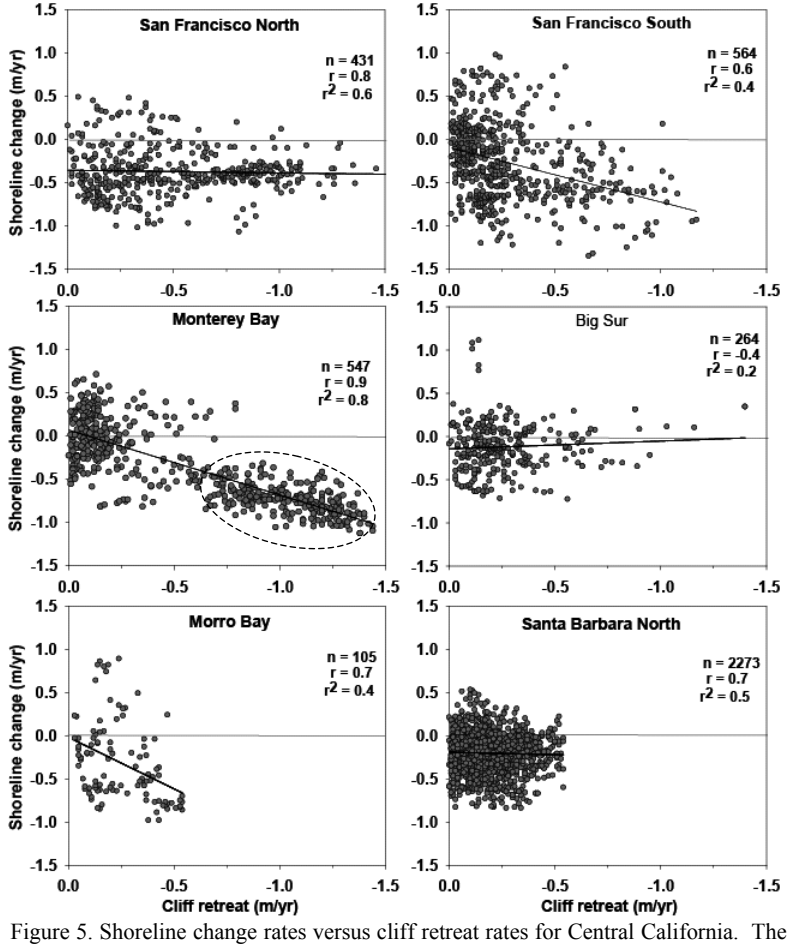

Figure 5. Shoreline change rates versus cliff retreat rates for Central California. The Monterey Bay region shows a strong correlation between high rates of shoreline and cliff erosion.

Southern California

Southern California, which is divided into five analysis regions for this study, has the most highly human-manipulated coastline in the state. As a result, the correlations between the shoreline change and cliff retreat datasets are poor (Figure 6). Most of the regions are lacking distinct trends in the data (i.e. Santa Barbara South, Santa Monica, San Pedro). The Oceanside and San Diego regions visually appear to have some positive trend in the data but

that correlation coefficients are relatively low (0.4). Santa Monica is the only region in the state to have a correlation coefficient of zero.

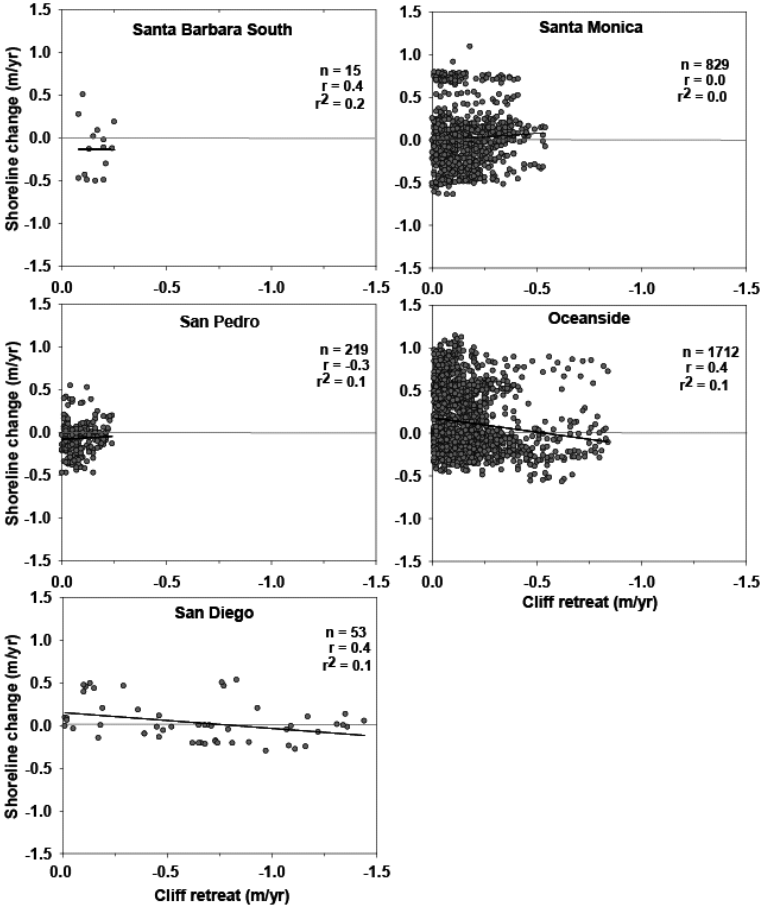

Figure 6. Shoreline change rates versus cliff retreat rates for Southern California. The regions all have low correlation values, and the Santa Monica region is the only one in the state to have a zero correlation.

CONCLUSIONS

Cliff edges and shorelines derived from 1930s historical maps and modern lidar data were used to produce a set of data whereby cliff retreat and shoreline change were calculated on the same transects and could therefore be statistically correlated to assess how the beach/cliff systems behave relative to one another. The final dataset covers 152 km of the California coast and samples the coastline along it entire length, albeit discontinuously.

Geomorphology and geology are strong controls on the relationship between the coastal retreat rates. In areas characterized by high-relief coasts, where the dominant coastal retreat process is movement on large, deep-seated landslides, the correlation between shoreline change and cliff retreat is negative. In these areas, transects showing higher cliff retreat rates correlate to areas of lower shoreline erosion or shoreline progradation. The mechanism of retreat, deep-seated landslides, results in the contribution of large volumes of material to the subaerial beach environment, thus slowing erosion or increasing accretion. Negative correlations were observed in the Eureka and Navarro regions in Northern California, and in the Big Sur Region in Central California.

In areas where the geomorphology is dominated by low- to moderate-relief cliffs, there tends to be a strong positive correlation between rates of shoreline change and cliff retreat such that areas of higher shoreline erosion are also areas of higher cliff retreat. In areas of more rapid shoreline erosion, waves will have more frequent opportunity to impact the cliff base. In addition the mechanisms of retreat of low- to moderate-relief cliffs (shallow landslides and slumps) do not contribute high volumes of material to the subaerial beach system. This positive correlation between cliff retreat and shoreline erosion was observed largely in Central California, with the exception of the Big Sur region. Additionally, the Monterey Bay has the highest positive correlation in the state, and the data indicate a chronic erosion hotspot in Southern Monterey Bay.

Human modified systems have the poorest correlation. This is demonstrated throughout Southern California where lack of correlation suggests that the beaches and cliffs behave independently in terms of rates of retreat.

ACKNOWLEDGEMENTS

We would like to thank Krystal Green (USGS), Mark Borrelli (URI) and Brian Spear (UCSC) for their assistance in generating many of the baseline data used in this study.

FACTORS INFLUENCING THE LONG-TERM STABILITY OF THE CARBONATE SAND BEACHES OF MAURITIUS

Michael J. Risk[1], Robert B. Nairn[2] and Mark O. Kolberg[3]

Abstract: The long-term stability of the carbonate beaches of Mauritius is the result of the net balance of the supply of carbonate sand from the coral reef environment and the loss of sand to adjacent depositional beaches and through passes in the fringing coral reef to off-reef environments. Carbonate sand is supplied from the lagoon and the balance has been tipped in the favor of losses over supply due to a range of anthropogenic factors including: historic coral harvesting for lime kilns servicing the sugar cane refining industry; removal of coral for water ski lanes; coral health degradation through a decrease in water quality; over-fishing; and creation of navigational passes. This paper presents a technique for quantifying the supply of sand from the various lagoon facies using sediment constituent analysis and hyperspectral imagery. Numerical models are used to describe the sand loss. Non-structural management recommendations are designed to reverse the long-term beach erosion trend.

INTRODUCTION

The 320 km long coastline of the island of Mauritius, in the southwest Indian Ocean, is mostly surrounded by coral reef and associated lagoons. The economy is based to a large extent on tourism, with relatively stable sandy beaches being essential to the success of the tourism sector. Several cyclones pass by the east or west side of the island each year moving from north to south. Mauritius is also strongly influenced by swells generated in

the southern ocean due to forcing from the passage of extra-tropical cyclones. Wherever beaches exist, a near-continuous relict fringing reef system protects a wide shallow lagoon and the beaches along the shoreline from a high-energy wave environment. While beach erosion has been documented in the past, it is only over the last 10 to 15 years that the erosion has become apparently irreversible. This paper presents the results of an investigation of the factors influencing the net balance between the supply and loss of carbonate sand that results in either erosion or accretion at Flic en Flac beach on the west coast of Mauritius. This was one of several sites evaluated by Baird (2003) as part of an extensive study of coastal erosion in Mauritius for the Ministry of Environment.

EXISTING BEACH CONDITIONS

The Flic en Flac beach and coral reef-lagoon system is shown in Figure 1. Near the center of this system is one of the most heavily used public beaches on Mauritius. In 1995, in response to a growing erosion problem over the previous 10 years, a gabion wall and small gabion groynes were constructed to protect the southerly 450 m of public beach shoreline. By 2002, the gabion structures were in an advanced state of deterioration, particularly towards the south end of the wall (see Figure 2). Flanking erosion was also occurring at either end of the gabion wall.

Fig. 1. Oblique Aerial Photo of Flic en Flac Looking South Along the West Coast of Mauritius (November, 2002)

Based on a constituent analysis of the beach sand and reconnaissance of the 300 to 500 m wide lagoon, it was determined that sand along this shore is entirely derived from lagoon corals and the associated marine community (Baird 2003). The median grain size is temporally and spatially variable but on average has a D50 in the range of 0.3 to 0.5 mm. The beach sand quickly diminishes to a thin veneer of sand over Pleistocene reef rock in depths greater than a 1 m below MSL.

Fig. 2. Deterioration of the Gabion Wall and Groynes Protecting the Public Beach (November 2002)

This section of the Mauritius coast has suffered from a range of human impacts including: mining of beach and dune sand; removal of coral to feed a kiln to create lime used in processing sugar from the cane crops; construction of seawalls for hotel developments that encroached on the dynamic beach zone; removal of native coastal vegetation; over-fishing of the lagoon; and removal of coral for water ski lanes. Other sections of the Mauritius coast show initial signs of deterioration through algal growth related to excessive nutrient loading.

HISTORIC PROFILE AND SHORELINE CHANGE

The geomorphology of the beach and landform suggest that in the long-term this beach has been progradational, although accretion rates were likely slow (Baird, 2003). More recent shoreline changes were documented through GIS analysis of air photos from 1967 (prior to development of this section of Mauritius) and 1997. The results of this analysis for the south end of the Public Beach at Flic en Flac show that the vegetation line retreated 15 m during this period (see Figure 3).

Erosion along this shore typically occurs during cyclone events. The only available information on erosion in response to a cyclone were pre- and post-storm profiles completed for several locations on the island by McIntire and Walker (1964) before and after Cyclone Carol hit the island in February 1960 (see Figure 4). McIntire and Walker (1964) postulated that the berm marked by an "x' on the profile represents post-storm beach recovery and that the actual profile at the height of the storm may have featured much greater erosion. Based on the surveyed profiles, the beach crest retreated 4.6 m inland as a result of the cyclone and the eroded volume was approximately 10 m^3/m.

(interpreted from McIntire and Walker, 1964)

WAVE AND WATER LEVEL CLIMATE

The waves affecting Mauritius' coastal areas are generated through three different meteorological phenomena (Baird, 2003): 1) locally generated seas by the southeast trade winds (from which the Flic en Flac site on the west coast of the island is mostly sheltered); 2) swells generated by extra-tropical cyclones in the southern Indian Ocean; and 3) tropical cyclones that develop in the southwest Indian Ocean and typically approach Mauritius from east and north. Owing to the shallow reef protecting much of the island, beach erosion is primarily driven by surge and wave setup associated with tropical cyclones that allow wave energy to pass over the reef into the lagoon and towards the beaches. It is only the waves from tropical cyclones with associated storm surge that result in significant erosion of the island's beaches. A wave climate for all three sources of wave energy was modeled using a Baird-modified version of the well-known WAVAD model originally developed by Resio (1981) for the U.S. Army Corps of Engineers. A total of twenty-five different historical cyclones over the 1979 to 2002 time period were simulated. The model was validated against Waverider data for Cyclone Davina in 1999 with a peak measured H_s of 8.5 m (see Baird, 2003). Storm surges were also estimated for these historical cyclones. Figure 5 shows the cyclones that passed within 100 km of the island between 1979 and 2002. During this period, nine storms of tropical cyclone intensity passed within 100 km of Mauritius, or once every 2.5 years. These events feature peak significant wave heights in the range of 10 to 15 m with peak periods of 14 to 16 s. In addition to the detailed assessment for the period since 1979, a qualitative assessment of the frequency and intensity of cyclone attack dating back to 1848 was completed.

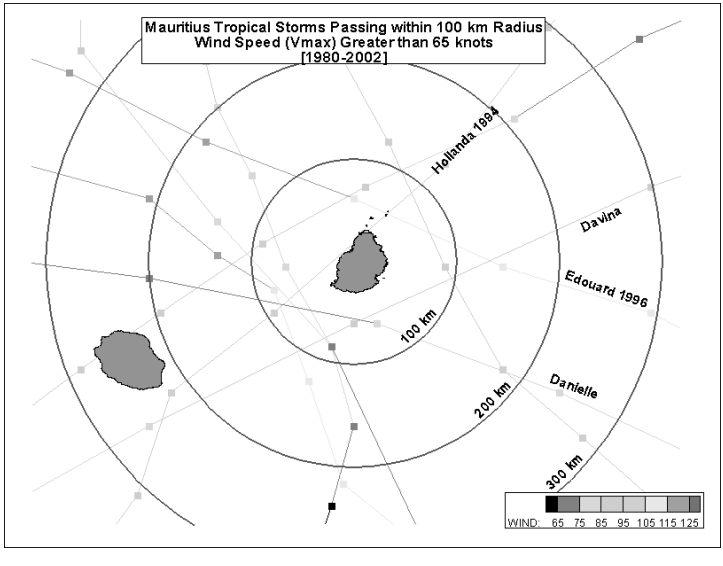

Fig. 5. Tracks for the Various Tropical Cyclones Simulated with WAVAD

As noted previously, the reefs surrounding Mauritius are wide and shallow-crested with the crest elevation being just slightly below low water level on this microtidal coast (typical tidal range of about 0.3 m to 0.5 m). The wave attenuation during average conditions and during cyclone storm surges was estimated with the COSMOS model (Nairn and Southgate, 1993). The ability of the model to predict wave attenuation across the reef was successfully tested against wave measurements made on either side of the reef (see Baird 2003). Figure 6 shows a sample of the COSMOS results for wave conditions with H_s=2 m and T=10 s and a surge of 0.3 m. The 90% reduction in incident wave height is representative of the degree of wave attenuation under most wave conditions.

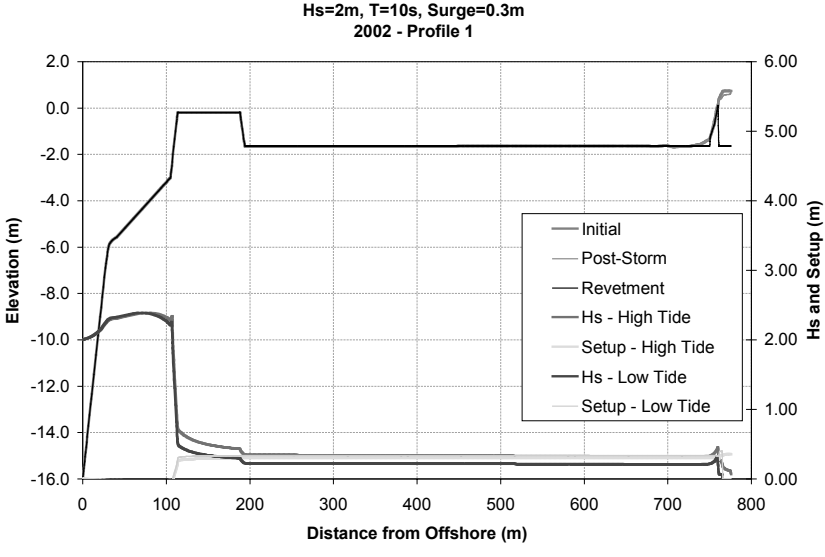

Fig. 6. Wave Height and Period Sensitivity Testing for Flic en Flac

SAND LOSS DUE TO CROSS-SHORE CHANGE AND LST GRADIENTS

During those cyclone events where storm surge and wave setup allows waves to pass over the protective reefs, the result is both cross-shore profile change (eroding the upper part of the steep 5:1 beach face) and longshore sand transport. The beach erosion at Flic en Flac was simulated for all the cyclones between 1979 and 2002 using the COSMOS model. The model was successfully validated against the estimated profile change immediately following Cyclone Carol (see Figure 7).

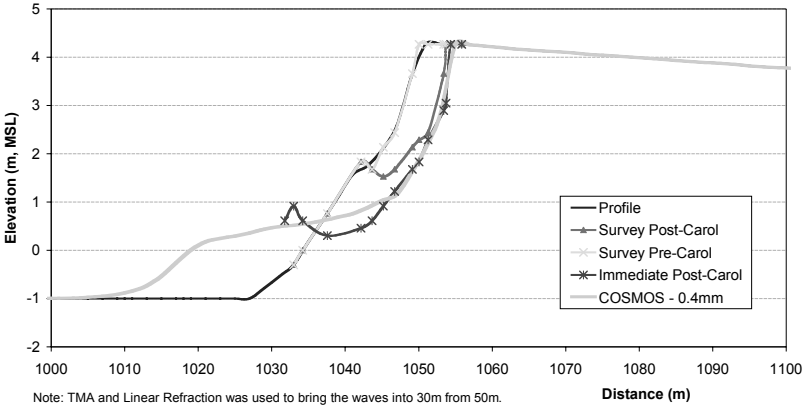

Fig. 7. Predicted vs. Measured Erosion for Cyclone Carol

Based on the COSMOS numerical model estimates, the rates of sand loss for all of the major cyclones during the period 1979 – 2002 were determined. Table 1 provides a summary of loss rates in terms of beach crest retreat and sand volume eroded.

Table 1. Lateral Crest Retreat and Eroded Volume for a Range of Cyclones

Return Period (years)	Greatest Retreat (m)	Erosion Volume (m^3/m)
5	7 – 10	12 – 17
10	8 – 11	13 – 19
25	8.5 – 12.5	16 – 23
50	9 – 13	17 – 24
100	11 - 14	20 - 27

For the Flic en Flac Beach sector, the gradients in longshore sand transport were also estimated with the COSMOS model. Sand is eroded from the middle section of the beach in the vicinity of the public park and transported to the north and/or south depending on the incident wave direction (see Figure 8). The sand that is eroded from the middle section of this sector is deposited in beaches to the north or south and also transported offshore through passes in the reef line and deposited in deepwater immediately offshore of the reef.

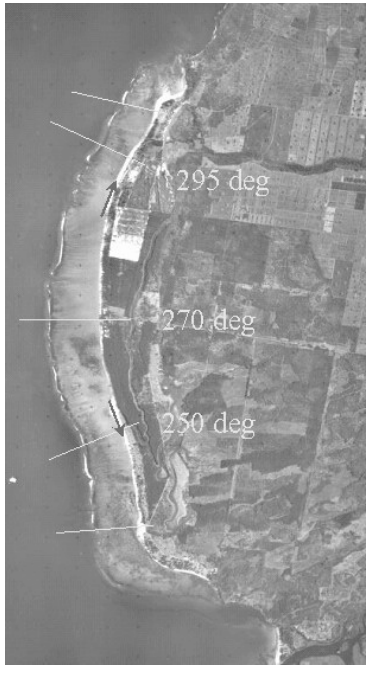

Fig. 8. Azimuths Along the Flic en Flac Shore and Direction of Longshore Sand Transport

QUANTIFYING THE CARBONATE SAND SUPPLY RATE

The coral reef habitat of the island of Mauritius was mapped with CASI (Compact Aerial Spectral Imagery) in 1996 for the Ministry of Fisheries. During the work by Baird, this data on coral reef facies was partially ground-truthed in specific areas of interest. The rate of supply of carbonate sand was estimated by integrating facies coverage by production rates estimated from previous work in the literature (e.g. Smith, 1973; Stearn et al. 1977; Hubbard et al., 1990). Using the CASI data and an estimated carbonate sand supply rate of 5 kg/m^2/year for the various reef areas, an estimate of the sand supply per meter of shoreline was made using GIS. This supply rate was successfully validated for the site on the east coast of Mauritius that featured long-term beach accumulation in a closed bay (see Baird, 2003).

Table 2 shows the range of carbonate sand supply rates along the shore reflecting the variability of coral patch reef coverage within the lagoon (with higher density of coral resulting in higher sand supply rates). The range in values for each reach represents the integrated uncertainty in production rates for different types of lagoon facies. The reaches are shown in Figure 9 and it is noted that the lowest supply rate corresponds to the reach

containing the public park shoreline at Flic en Flac. There is little or no patch reef in this zone, possibly owing to the historic harvest of coral in the mid-1900's to feed the lime kiln that is located at the north end of the park.

Table 2. Estimates of Sand Production Rates at Flic en Flac

Reach	Sand Production Rate (m3/m/yr)
A	0.43 – 0.84
B	0.43 – 0.65
C	0.57 – 1.00
D	0.52 – 0.77
E	0.95 – 1.34

SEDIMENT BUDGET

In order to evaluate the balance between sediment production and sediment loss, a sediment budget was completed for the period of shoreline change data from 1967 to 1995 (this latter date corresponding to the construction of the gabion wall at the Flic en Flac public beach). Only the sediment budget for the park area is presented here; the budget for the entire Flic en Flac reach is presented in Baird (2003). It may be recalled that the shoreline in the public park retreated 15 m during this period. This 15 m retreat over the 4 m beach height (from the beach toe to the beach crest) amounts to approximately 60 m^3/m of sand lost from the beach during the 28-year period.

Based on the simulation of historic cyclones, there were four 5-year events and one 10-year event during this period from 1979 to 1995, on the west coast of Mauritius. From 1967 to 1979 only two other events occurred (Gervaise in 1975 and Fleur in 1978). Taking the average values of 14.5 m^3/m and 16 m^3/m erosion loss during 5- and 10-year cyclone events respectively from Table 1, the total beach erosion for this period is estimated to be 74 m^3/m.

From Table 2, the estimated supply rate for Reach B for the 28-year period from 1967 to 1995 would be in the range of 12 to 18 m^3/m. Therefore, the predicted difference between erosion due to cyclones and supply from the reefs would be in the range of a 56 to 62 m^3/m net loss. This prediction compares well to the measured loss of 60 m^3/m for this period. However, it must be considered that the numerical model estimates of beach erosion did not consider any post-storm recovery.

IMPLICATIONS FOR LONG-TERM BEACH STABILITY AT FLIC EN FLAC

Net erosion in typical cyclones (i.e. with return periods of less than 1 in 10 years) is in the range of 5 to 10 m^3/m, once every 3 to 10 years giving a net loss rate in the range of 0.5 m^3/m/year (5 m^3/m every 10 years) to 3.33 m^3/m/year (10 m^3/m every 3 years). The low end is the long-term norm whereas the higher rate is more indicative of the last 25 years in Mauritius due to a greater than normal frequency of cyclones.

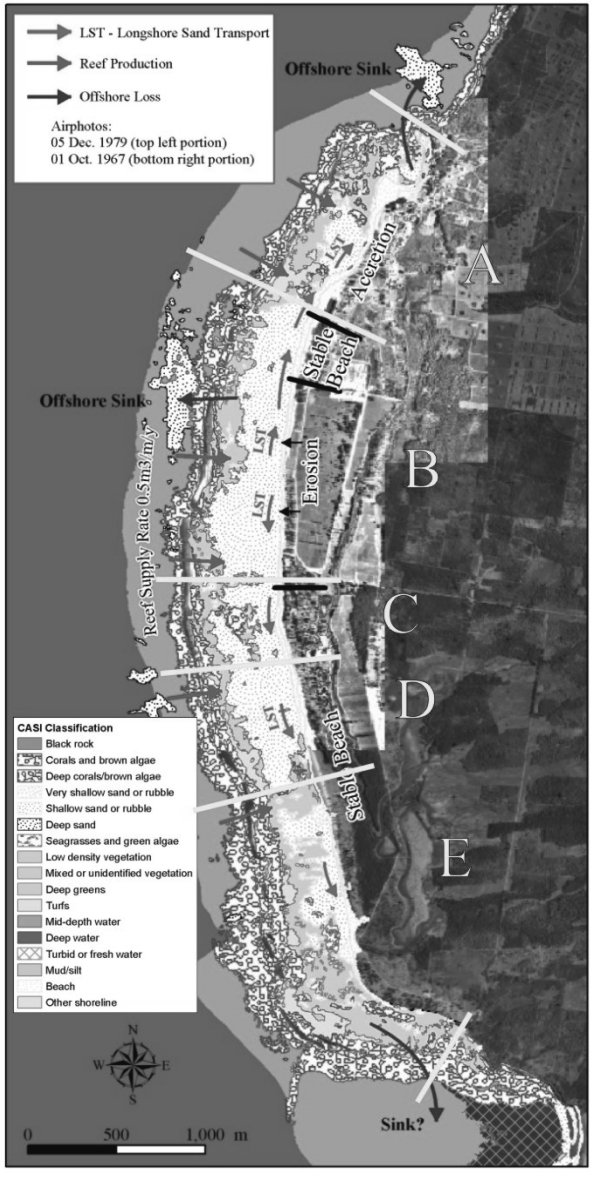

Fig. 9. Overview of Sediment Sinks and Sources at Flic en Flac

The GIS analysis of beach sand production from the reef-lagoon system found that the rates ranged from 0.4 to 1.3 m^3/m/year for the Flic en Flac lagoon depending on the extent and coverage of coral coverage in the lagoon. Therefore, in areas where coral is plentiful and healthy (i.e., high end of the range), the sand production rate will surpass the erosion rate under the normal frequency of cyclone attack and stable or accreting beaches will be the outcome. However, there is a fine balance between an accreting shore and an eroding shore in the long term. Once reef-lagoon sand production rates drop below about 0.5 m^3/m/year, even under normal cyclone frequency, long-term erosion will be sure to set in. While coastal zone managers have little control over the frequency of cyclones they can make a difference in preserving, protecting and even enhancing the reef-lagoon system and the resulting sand production rates.

MANAGEMENT ALTERNATIVES FOR BEACH PRESERVATION

At Flic en Flac, the local authorities initially believed the necessary solution was reconstruction of the gabion wall and groynes. However, the assessment of the root causes of erosion revealed that the solution at Flic en Flac was to redress the deficit in sand supply in order to re-establish the long-term stability of the beach. The recommended long-term solution consists of restoration of the lagoon coral in areas where production rates were determined to be less than 0.5 m^3/m/year. A hard substrate is to be placed above the hard, thinly covered bedrock floor of the lagoon in order to allow the coral spat to successfully recruit. It is anticipated that the coral restoration would sufficiently augment the natural supply within 5 to 10 years. The constant movement of a thin layer of sand supplied by the outer reef front across the bedrock lagoon floor explains why the patch coral has not naturally recovered since its removal to supply the lime kiln in the mid-1900's.

To address the short-term need to re-establish a healthy beach, it was proposed that the beach should be restored and widened through nourishment. Sand is typically sourced from licenced inland quarries. Another possible source of sand for the nourishment project is the large deposits of sand in approximately 10 m depth of water at the base of two passes in the reef at Flic en Flac. It was proposed that 12,000 to 24,000 m^3 of sand be placed along approximately 600 m of the public beach. This amounts to unit volumes of 20 to 40 m^3/m. Even if the frequency of cyclone attack were to continue at the current high rate, and providing that an even greater frequency or intensity of attack is not experienced, the nourishment quantity should last 10 to 20 years even without the benefit of the augmented supply through coral restoration.

It was recommended that the wider beach created with the beach nourishment should be planted with native vegetation layered from creepers to low shrubs to higher shrubs moving inshore promoting dune growth. This vegetation prevents the inshore loss of sand through wind and overwash during cyclone events. Once the beach nourishment, dune and vegetation are in place, it will be necessary to manage the beach by means of controlling pedestrian access by walkovers and limiting vehicle intrusions through designated parking areas. A final aspect of the proposed solution to the erosion problem

at Flic en Flac is the removal of a hotel seawall located immediately south of the public beach. It was shown in Baird (2003) that this seawall has also likely contributed to the erosion of the beach.

At other locations around Mauritius, the solutions also consisted of: implementing improvements to local water quality to preserve and restore coral reef health, implementation of development setbacks, controls on the construction of hard structures and strict guidelines on creation of artificial passes.

CONCLUSION

The beautiful carbonate sand beaches of Mauritius are generally well protected by coral reefs and are naturally stable or progradational. The onset of beach erosion at several locations on the island over the last 25 years has mostly resulted from a combination of the loss and removal of patch coral in the lagoons and a higher than average frequency of cyclone attack. There is a fine balance between supply of sand from the patch coral in the lagoons and loss of this sand to accretional zones and deposits offshore of passes. The reduction of supply from the lagoons was a direct result of several human factors including: coral mining to supply lime kilns in the 1950s; removal of coral for water ski lanes and navigation; degradation of water quality through elevated loadings of sediment and nutrients; and over-fishing. Preservation of the patch coral in the lagoon through management of these human activities and restoration of the coral where required are the fundamental long-term solutions to beach stability.

Based on this foundation of understanding the root causes of coastal erosion, an action plan was formulated with specific and general recommendations (Baird 2003). The recommendations represent a blueprint for integrated coastal zone management. A summary of these recommendations for each part of the reef-lagoon-beach system is depicted in Figure 10. Short-term and interim solutions consist of beach nourishment providing adequate sediment controls are implemented. Development setbacks must be implemented and enforced to prevent encroachment of structures in the coastal zone. Native coastal vegetation should be restored to reduce onshore losses of sand during cyclones. The preservation and restoration of the natural and integrated reef, lagoon, beach and coastal vegetation systems will help to avert the widespread onset of irreversible erosion.

Abstract: The distribution and evolution of local, shoreline features was examined by repeated mapping of the shoreline using a sub-meter GPS to map Fire Island from June to December. One region of erosion or "hot spot" was documented to migrate to the west, in the direction of the net longshore transport, at a rate of 2.1 m/day and then to the east at a rate of 4.2 m/day. Another shoreline feature followed the progression of a theoretical advection/diffusion model created earlier by other investigators to predict the migration of longshore sandwaves. This feature migrated to the west at 0.83 m/day. Similar features on the barrier island migrated to the west up to 51.5 m/day while others migrated to the east at rates up to 93.1 m/day. No trends in migration rate with the wavelength of the hot spot could be found. Rates tended to range between 1 and 100 m/day.

INTRODUCTION

Shoreline undulations are alternating landward and seaward displacements of the shoreline. Shoreline undulations manifest themselves in many different forms. Beach cusps, longshore sandwaves, and erosion hot spots are all classes of shoreline undulations. An erosion hot spot is defined for this paper as a specific section of the shoreline, of limited extent, which has become scoured of sand while nearby stretches of beach go relatively unscathed. The main goal of this study was to address whether or not erosion hot spots consistently appear in the same locations and whether or not

they migrate in the direction of net longshore transport. While mapping the ocean shoreline of a barrier island, Fire Island, we were able to study an erosional hot spot, a possible longshore sandwave and the wavelengths that compose undulating characteristics of the shoreline along the total length of Fire Island.

Study Area

Fire Island was chosen as the site for this research based on the previous works by Allen and Labash (1996), as described by Gravens (1999), and by Batten (2003). Fire Island is one of the south shore barrier beaches of Long Island, New York. It extends from Fire Island Inlet to Moriches Inlet and is approximately 50 km long and averages less than 0.5 km in width (National Park Service, 2006). Robert Moses State Park occupies its western extremity; to the east, Fire Island National Seashore encompasses most of its length and Smith Point County Park is found at its eastern terminus. Winds are primarily from the west but can vary from the southwest in summer to the northwest in winter. Waves generally approach from the south-southeast with an approximate wave height of 1 meter (Batten, 2003). Fire Island has a semi-diurnal tidal cycle (Batten, 2003). The direction of net longshore sand transport is from east to west (Gravens, 1999).

METHODS

The shoreline was mapped using an Ashtech Reliance Submeter GPS with an Ashtech BR2 Beacon Receiver and a Psion handheld controller. The technique used to map the shoreline was similar to that used by Allen and LaBash (1996), and described in Gravens (1999). The shoreline was defined as the boundary between the saturated and the unsaturated sand; this wet/dry contact is usually used in interpreting shoreline position from aerial photographs (Anders and Byrnes, 1991). Multiple surveys were conducted from June 2005 through December 2005. The surveys of individual features taken for this study were 4 hours or less in duration. Surveying the total length of Fire Island took about 4 to 5 hours to complete using four-wheeled vehicle, a Polaris Ranger.

Shoreline undulations were subjected to spectral analysis to look for dominant frequencies and changes of phase, which might indicate migration. The spectral analysis was conducted using MATLAB. The data was detrended using equal spacings of 1 meter. After the data was detrended it was run through a Fast Fourier Transform (FFT) in order to identify the dominant wavelengths. Individual wavelengths could then be processed using and inverse FFT (IFFT) in order to obtain information about changes in amplitude and shifts in phase.

RESULTS

Smith Point Hot Spot

On 12 June, 2005 a shoreline undulation or “hot spot” was first mapped approximately 5 km east of Smith Point County Park. Smith Point County Park was then surveyed seven more times during the five month interval of June through October and twice afterwards on 17 and 18 November and 1 December, 2005. The majority of the surveys were conducted during the falling tide in order to catch the

high tide shoreline as well as possible. The dune line remained stationary throughout the period. Several of the surveys were conducted specifically to see the results of a variety of passing storms. Between 12 June and 22 September, 2005 the hot spot became significantly less prominent in part because of shoreline recession to the east (Figure 1).

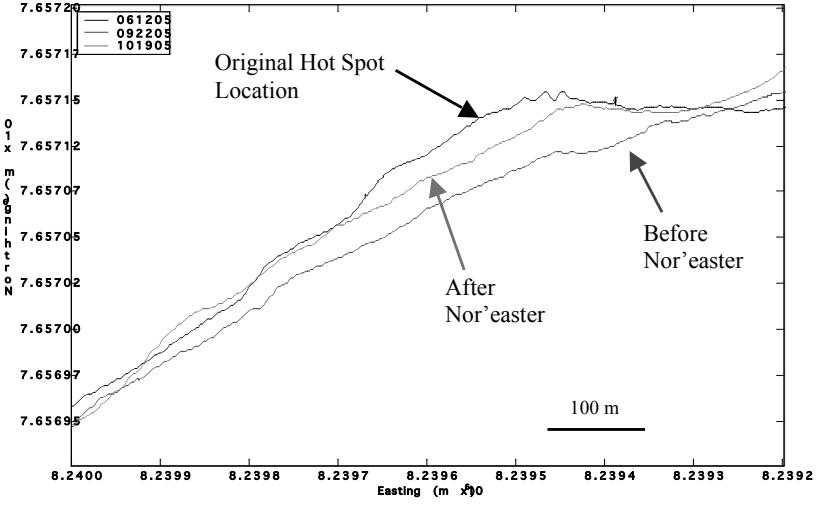

Figure 1. Condition of the Smith Point Hot Spot: original position, before and after a nor'easter in October, 2005.

In mid October, the area suffered the effects of a nor'easter that lasted for over a week. Wave heights were in excess of 5 meters and wave periods were over 14 seconds. The general direction of the storm waves were to the northwest, which would drive a westward longshore transport of sand. A survey was conducted on 19 October, 2005 after the storm had passed and the beach had experienced extensive damage. Significant change occurred between the 22 September, 2005 and 19 October, 2005. The erosional hot spot appeared to have persisted in the same location after the passage of the nor'easter (Figure 1).
