To better visualize the changes in the dominant component of the Smith Point hot spot, its dominant periodicity was isolated by the IFFT as a sinusoid with a wavelength of 1000 m and an amplitude of 16.3 m (Figure 2). (In order to accurately compare the surveys the origin for each survey was chosen to be the easting value of 8239005 m.) Over time the hot spot had filled in or "healed" itself. There appeared to be no migration. This erosion hot spot healed in place reducing in amplitude at a maximum rate of about 0.1 m/day for a total reduction in amplitude to 6.5 m. By the end of the survey period (October 19, 2005), however, the amplitude had increased to

7.2 m and it seems to have migrated approximately 60 m to the west (Figure 2). This seemed to have been in response to the nor'easter of 7 October, 2005. Although the average westward migration over the 129 day period was about 0.5 m/day, almost all of the migration occurred in the last month when the westward migration rate was about 2.1 m/day over 27 days (Figure 2).

The two long surveys of Fire Island included the Smith Point hot spot and these were added to the other surveys of the Smith Point hot spot in order to see how the hot spot

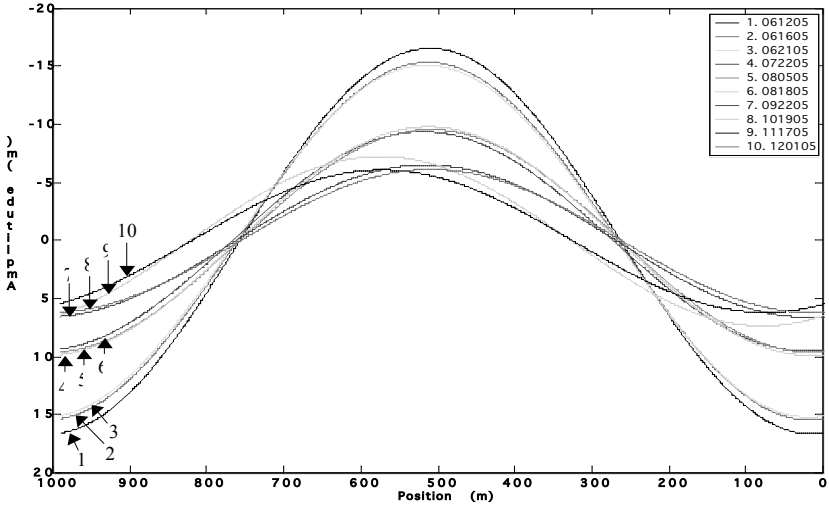

Figure 2. Principal component of Smith Point Hot Spot

had progressed after the nor'easter. The amplitude of the hot spot decreased with time to the approximate height as before the nor'easter (Figure 2). It can also be seen that the hot spot migrated back towards the east to almost its original location in between the two surveys at a rate of 4.2 m/day.

Kates Point

Another shoreline feature monitored at Smith Point was a seaward displacement of the shoreline equivalent to the sand packets or longshore sandwaves studied by Thevenot and Kraus (1995). The feature was found east of the Smith Point hot spot, and was referred to as Kates Point by local surfers. Over the period from 16 June to 19 October, 2005, Kates Point decreased in size and shifted westward in the direction of longshore transport (Figure 3). The erosional area west of Kates Point may have been caused by the point itself interrupting longshore transport and acting like a groin. Groin-like behavior of transient, natural features have been noted in other places (Jay Tanski, Sea Grant Cooperative Extension Service, 2006, personal

communication). Kates Point overall migrated to the west and simultaneously decreased in amplitude. The surveys of 17 and 18 November and 1 December showed that the erosional area has decreased in size at the same time that Kates Point has decreased in size. It appeared that sediment eroded from Kates Point was filling in the erosional area to the west. The position of each of these features has shifted to

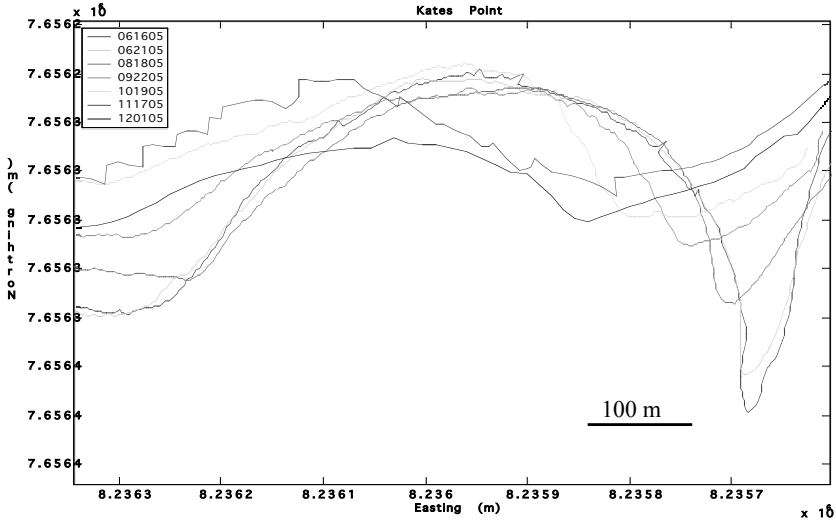

Figure 3. Surveys of Kates Point

the west. During this period the point migrated 110 m to the west at a rate of 0.88 m/day and simultaneously decreased in amplitude 80 m at a rate of 0.64 m/day (Figure 3).

Thevenot and Kraus (1995) had previously calculated a theoretical, advection-diffusion equation to model shoreline change and sand transport of longshore sand waves. Their model showed that the total sand wave body moved west and spread out with a substantial decrease in the amplitude. Although the scale of the model was much larger, the agreement in form suggests that Kates Point is, in fact, behaving according to the combination of longshore advection and diffusion processes.

Fire Island

On 17-18 November, 2005 and 1 December, 2005 surveys were conducted down the length of Fire Island over a four to five-hour period. The spectra generated for each survey were passed through a three-point running average to smooth the results. Dominant wavelengths of 1830 m and 1045 m were found by Gravens (1999) (labeled in red on Figures 4 and 5). From the survey on 17-18 November, 2005, dominant wavelengths appeared at 4779, 3186, 2811, 2276 and 1707 meters (Figure

4). From the survey on 1 December, 2005, dominant wavelengths appeared at 5973, 3186, 2515, 1911 and 1541 meters (Figure 5). The longer wavelengths emerged as the most important but we believe that was, in part, due to the large-scale trends that

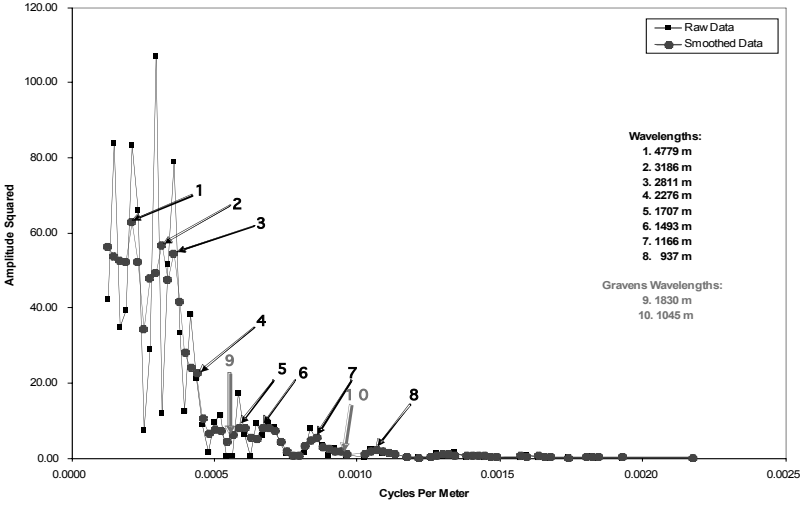

Figure 4. Fire Island Spectra of the survey on 17-18 November, 2005 smoothed with a three-point running average.

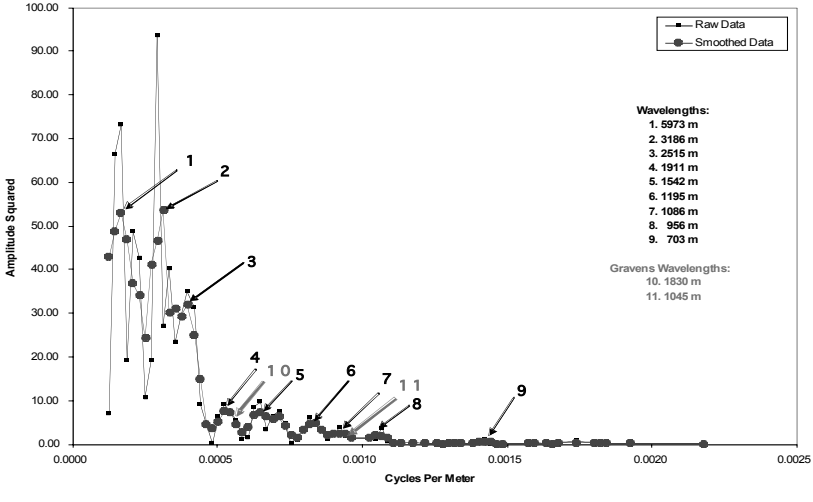

Figure 5. Fire Island Spectra of the survey of 1 December, 2005 smoothed with a three-point running average.

were not completely removed by the de-trending process. There may have been secondary peaks in the spectrum from November, 2005 at 1493 m, 1166 m and 937 m. Secondary peaks may also appear from December, 2005 at 1195 m, 1086 m, 956 m and, perhaps, even at 703 m. The component with a wavelength of 1086 m was close to that found by Gravens (1999) at 1045 m and approximately the size of the individual feature that was studied at Smith Point. The wavelength of 1911 m was also found by Gravens (1999) at 1830 m.

For any particular component, the change in phase between the November and December surveys was used to calculate the migration rate. Previous investigators had suggested that either larger wavelengths migrate faster or smaller wavelengths migrate faster, but these data cannot support either assertion. There does not seem to be a trend in migration rate. In addition, some wavelengths seemed to have migrated to the east in the same period that some migrated to the west. Waves during this period, as recorded at Buoy 44025 <www.ndbc.noaa.gov/station_history.php?station=44025>, would predominantly drive sand along shore from east to west but there were some reversals in the period. As Thevenot and Kraus (1995) remind us, local nearshore bathymetry can substantially influence the sand transport direction.

Some components for both the November and December surveys were of particular interest even though they were not dominant ones. The periodicity along the Fire Island shoreline with the largest wavelength was 24 km and appeared to move to the west at a rate of 44.1 m/day. The 15.9 km wavelength had the largest amplitude at 86.7 m. The 1291 m feature was the fastest migrating feature to the west at a rate of 51.5 m/day. The wavelength, 1493 m migrated the fastest to the east at a rate of 93.1 m/day. The wavelength, 2811 m had the greatest increase in amplitude, 0.27 m/day. It may be that components of different wavelengths respond differently to changing wave conditions but investigating such a phenomenon was beyond the scope of this work.

DISCUSSION

Migration rates of hot spots appear to be between 1 and 100 m/day. It seems, however, that there was no relationship between migration rates and wavelengths of erosional hot spots. In the specific case of the Smith Point Hot spot, the feature healed in place without migrating and migrated when storm activity caused it to grow. The sand packet referred to as Kates Point, on the other hand, migrated and dispersed according to advection-and-diffusion processes for longshore features. The undulations which are the superposition of a continuum of wavelengths had components which migrated at various rates and directions without an obvious pattern. They all were responding to the same water wave climate but that the net displacement over any particular period varied both in the direction and by the degree of the response.

Gravens (1999) suggested that shoreline undulations do not migrate from one end of Fire Island to the other but that migration within the range of the shoreline undulation is possible. Although it seems that shoreline features (e.g. Kates Point sandwave) do migrate in the direction of the long-term longshore transport over periods of weeks,

two considerations are noteworthy. First, individual components of the shoreline features may respond differently to the angle of wave attack. Particular wavelengths may preferentially migrate faster under waves arriving at different angles or slightly different direction. Second, depending on the speed of the longshore currents, it may be possible that some wavelengths migrate in the direction of longshore transport while others migrate in the opposite direction in a manner similar to the migration of antidunes in a river (Freedman and Sanders, 1978).

The presence and characteristics of shoreline undulations may have important implications for beach nourishment projects. Gravens (1999) suggested that nourishment projects be designed with a "shoreline undulation buffer" so that the average width of the beach is wide enough to accommodate the erosional hot spots that naturally develop. Dolan and Stewart (2006) further suggest that renourishment projects be designed to mimic the naturally occurring undulations in order to attempt to improve the rate at which ecological recovery takes place after the disturbance.

CONCLUSION

The behavior of shoreline undulations remains elusive. One feature studied in detail seemed to heal in place with little migration, but the other evidence is consistent with migration rates up to 100 m/day. Over long stretches of shoreline, the superposition of many different wavelengths of undulations obscures individual features and would make predictions difficult.

The sandwave, a positive feature referred to as Kates Point, evolved according to the modeled advection/diffusion process of Thevenot and Kraus (1995; Equation 1), migrating in the net longshore transport direction.

The data collected for this study was close to the results gathered by Gravens (1999). Gravens (1999) had shoreline undulations with amplitudes ranging from 20 to over 30 meters. The amplitude for the shoreline undulation at Smith Point Park was 16.3 m with a wavelength of 1 km. Gravens (1999) found dominant wavelengths of 3010 m, 1045 m, 2050 m, 2135 m, 1385 m, and 1310 m. We found dominant wavelengths of 3414 m, 6826 m, and 4779 m, similar in range to what Gravens (1999) found. Based on the power spectrum the dominant wavelengths for long beach distances were found to be 23893, 15928, 11964 m. Gravens (1999) had found similar wavelengths of 2135 m, 1830 m, 1065 m and 1045m as compared to the values found in our study at wavelengths of 2172 m, 1837 m, 1062 m and 1038 m.

This data does not support the contention that longer wavelengths migrate faster than smaller wavelengths or *visa versa*.

ACKNOWLEDGMENTS

We would like to thank the National Park Service at Fire Island National Seashore, especially Patricia Rafferty, for all their help during this project.

Abstract: This paper examines barrier-spit system morphodynamics on a tropical sandy coast, located on Diogo Lopes Village-RN, northeastern Brazil. The mechanisms of growth and elongation of the coastal spit and tidal inlets from Diogo Lopes are underway to reconstruct the historical evolution and dynamics. The general situation in this area is one of very energetic tidal conditions causing nearly continuous sediment mobility along the bottom close to the coast. The region experiences high-energy, coastal and shelf parallel currents driven by combined flows due to oceanic, tidal and wave processes. Natural inlet was cretaed by overwash processes during more energetic periods. Currents measured inside a new inlet show maximum speed of 85 cm/s during ebb phase, while nearhore it can reaches 100 cm/s. This data set is important to develop a detailed understanding of this kind of barrier-spit system evolution,

INTRODUCTION

The barrier literature has traditionally been dominated by one form of barrier, the barrier island (Hesp and Short 1999). Barrier islands, however, represent one end member in a spectrum of barrier types, with mixed wave/tide-dominated barrier islands and inlets in one direction (Davis 1994) and partially or completely joined to the mainland as a spit (Dingler and Clifton 1994), in the other direction. The Diogo Lopes barrier-spit system (Fig. 1) is a mixed wave/tide shoreline consisting of short barrier separated by inlets, which produce substantial ebb tidal deltas. This barrier-spit system experiences tidal processes but with no appreciable freshwater runoff. Others examples of this category are much of the Wadden Sea of The Netherlands and Germany.

Despite barrier islands have received a far greater proportion of attention from the scientific, engineering community, coastal managers and evironmentalists (e.g. Hayes 1974, 1994; Oretel 1985; Roy et al. 1994; Davis 1994), most of these studies were developed on the north hemisphere. Tropical coast barriers have been poorly studied in comparison to those on the high latitude

The aim of this paper is examine barrier-spit system morphodynamics on a tropical sandy coast. The mechanisms of growth and elongation of the coastal spit and tidal inlets from Diogo Lopes are underway to reconstruct the historical evolution and dynamics. This kind of data is important as contribution to the knowledge of the evolution, and the internal structures of tropical spits. Moreover, we hope these results can be used to comparisons with other barrier systems of the Brazilian coast and the world.

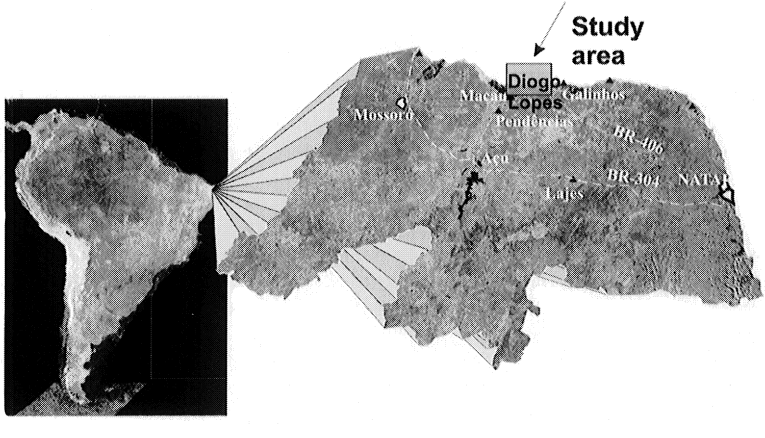

Fig. 1. Location of the study area.

COASTAL SETTING

Barrier island-spit systems on the Rio Grande do Norte cost can range from barrier spits (e.g. Galinhos), to barrier islands (e.g. Ponta do Tubarão, Amaro). Composed of sandy sediments, the barrier-spit systems are often capped by dunes. Evolution of these barrier systems has been cyclic (Xavier Neto et al. 2001; Lima et al. 2001, 2002; Silveira 2002; Souto 2002) indicating an ancient system of barrier islands developing into the current spits, and spits which were recently detached to form barrier islands. Studies of modern coastal environments and sediments in this area (Vital et al. 2003) show that barrier spits and barrier islands occur only on the EW North coast, and that they are confined between two important regional fault systems. But in the past barrier islands were abundant at least on the entire northern coast (Vital in press).

The Diogo Lopes area is located on northeastern Brazil (Fig.1), inserted on the Potiguar Basin. This basin has an economic regional importance because it is the most productive oil basin onshore in Brazil, and the second offshore. Nowadays, the study area is a State Sustainable Development Reserve.

The barrier-spit coast of northern Rio Grande do Norte State - NE Brazil (Fig. 1) is a mesotidal, mixed-energy coast according to the classification of Hayes (1975, 1979). Tides are semi-diurnal, with a maximum tidal height of 3.3 m and 2.5 m respectively during spring and neap tides. The overall wave energy is medium to low with maximum breaker heights of less than 80 cm (Silveira 2002, Chaves at al. 2006).

The Relative Tide Range - RTR (mean spring tide range - MSR / wave height - Hb) for this sector is $4 < RTR < 15$, and so in the mixed wave-tide group according to the classification of Masselink and Turner (1999, Vital in press). During periods of weak winds and waves with small heights the RTR is greater than 15 (predominantly 16-20); The maximum RTR registered was 27, and the beach was classified during this time as tide dominated. The presence of small ebb-tidal deltas along the barrier island-spit system, as well spits perpendicular to the coast indicate the strong tidal influence.

The longshore currents flow toward west-northwest (oblique to the coast) with a maximum of 97 $cm.s^{-1}$ during rising tides, and toward north (perpendicular to oblique to the coast) with a maximum of 50 $cm.s^{-1}$ during falling tides. They are by far the dominant contributor to the net sediment transport along the coast of Rio Grande do Norte. The sediment transport measured on this area is between 101 and 110 m^3/day (Chaves 2005; Vital et al. 2006).

The general situation in this area is one of very energetic tidal conditions causing nearly continuous sediment mobility along the bottom close to the coast. Sediment type in nearshore and barrier-spit system is consistent along the coast and is composed of fine to very fine quartz sand. The lagoon bottom sediments are composed mainly of silt, while tidal channels may have a higher shell content and, therefore, a coarser mean-grain size than the adjacent shorelines. No rivers provide new sediment to the coastal system. Since strong winds are present almost all the time, water masses are well mixed without

any characteristic stratification. Winds velocities measured direct on the coast reached a maximum of 9 m/s between August and October and a minimum of 4 m/s in April (Chaves et al. 2006). The months of worse coastal erosion in this area are related to the increasing wavy energy. This in turn, seems to be related to seasonal climatic variations, with the wave energy and tide currents speed increasing during months of minor precipitations (June to January).

The relative sea-level curves documented for the Northeastern Brazilian coast, for the last 7.000 years (Martin et al. 2003; Bezerra et al. 2003; Caldas et al. 2006; Stattegger et al. 2006) indicate that the sea level was some meters higher than the present, with a tendency to drop during the last 5.000 years.

METHODS

The methods used to attain these objectives included (a) Remote sensing Multitemporal remote-sensing images (aerial photographs and satellite images) and geographic information systems (GIS) were used for monitoring and interpretation ofshoreline change, nearshore bedforms and structural features. A range of digital image processing techniques were used and compared (e.g. Multitemporal Image Analysis, Water Index, Principal Components Analysis, Adaptative Filtering). The clear waters of the northeast Brazilian coast, produced by the dry climate and minimal organic turbidity, favor the visible imagery application. (b) Physical processes measurements: Hydrodynamic processes were measured with S4 and S4a sensor from InterOcean Systems (waves, tides, currents, temperature, conductivity, depth). The sensors were installed monthly for 24 hours during spring tides, one inside the inlet (S4) e the other (S4A) nearshore. Winds were measured with a portable meteorological station. (c) topographic and bathymetric survey: Hydroacoustic data were collected onboard small fishing boats with a Odom Hydrographyc System (echo sounder and side scan sonar) operating with a frequency of 200 kHz. The water depth was recorded both digitally and analogic while sonar data only analogic. Present topographic profiling were collected using a TOPCON HIPER LITE-RTK GPS system, and (d) Investigation of modern surficial facies were derived from vibracores and sediment samples collected using a Van Veen bottomgrab. Because the recovered cores were shorter than 3 m, informations from literature (Silva 1991) were incorporated.

RESULTS AND DISCUSSIONS

Barrier-spit System Morphodynamics

The Barrier on this area was completely joined to the mainland as a spit (Fig. 2A); around 1977 an inlet was created (inlet 1) and the barrier island was called Ponta do Tubarão (Fig. 2B). Since then this inlet is used as navigational access to the lagoon by the habitants from Barreiras and Diogo Lopes villages. The distance between this inlet and Diogo Lopes is quite large, creating public pressure for additional navigational access. Because the presence of a tidal inlet on a shoreline has the drawback that it traps a considerable amount of sand, creating significant potential for beach erosion on the adjacent beaches (Dean and Dalrymple 2002), professionals from the local University (UFRN) discouraged this action. However, in February 2006 a new inlet was created

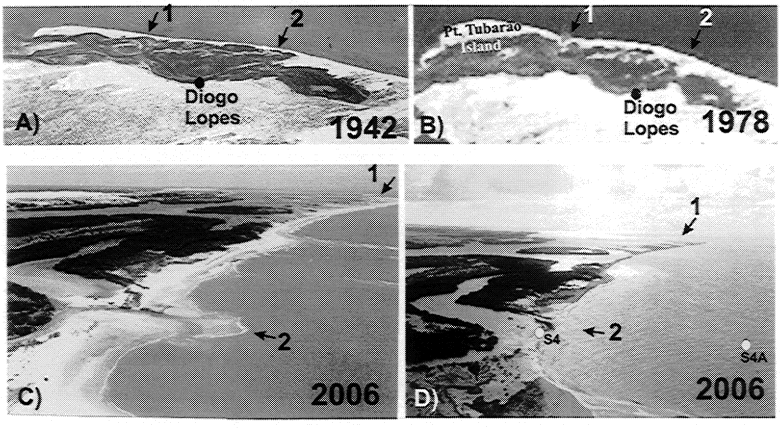

Fig. 2. View of the study area. A) Aerial picture from 1942; B) Landsat MSS image from 1978 (open of inlet 1); C) Low tide and D) High tide Aerial picture from 2006 (open of inlet 2).

(inlet 2, Fig. 2C,D). Waves measured nearshore have an average height of the 56 cm, with a maximum height of 123 cm. The calculated medium wave period for the area was 7.5 s. The broad shallow continental shelf bordering the RN coast causes deep-water swell in the area to decompose into these low, short-period waves. The short period waves tend to pass even this shallow shoreface with little modification in their direction. As a result, there is considerable refraction within the nearshore zone, which results in appreciable and persistent longshore currents. The primary direction of longshore current, from east to west, is controlled by the local shoreline orientation in combination with the direction of wave approach.

The bathymetric data show that the lagoon presents in general relatively shallow depths, between 1 and 3 meters, and maximum depth is 7 meters. Different bottom features were identified, such as small and big dunes (sensing of Ashley 1990), as well as flat bottom.

The new inlet (inlet 2 on Fig. 2) presented in February, one week after it was open, a shallow channel of 10 m width and 1 ,2 m initial depth during low tide. Two months later it shows 22 m width and 1,7 m depth. Six months after the inlet was open, the channel presents 25 m width and 1,6 m depth. At month eight it reaches the shallowest depth with o,6 m and since then becomes deeper until the depth of 1,4 m. However the width is continuously bigger. In month ten it reaches a width of 50 m. The Currents measured inside the channel (S4 sensor, for location see Fig.2D) shows speeds ranging from 85 cm/s during ebb phase to 10-30 cm/s during flood phase (Fig.3). Nearshore (S4A sensor, for location see Fig.2D) the currents reached until 100 cm/s.

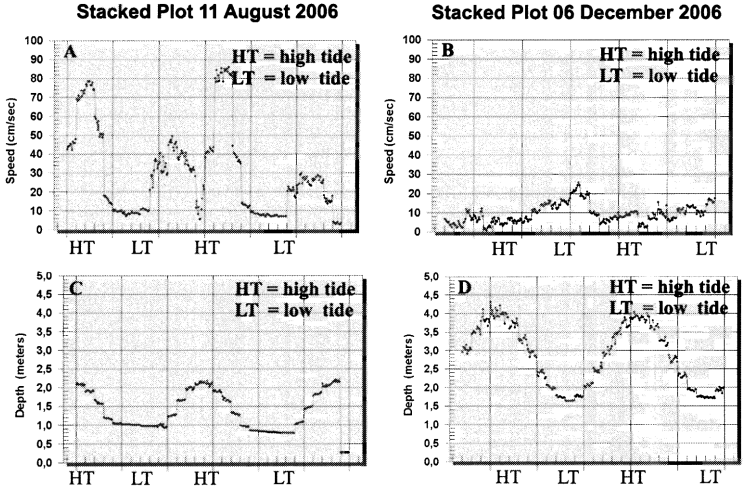

Fig. 3. S4 Stacked plots for August (A, C) and December (B, D) 2006 showing speed currents and depth in the inlet 2. For location of S4 see Fig. 2D.

Barrier-spit System Depositional facies

Diverse depositional facies associated with or immediately adjacent to the spit compose a complex depositional system. This system comprises the shore-parallel barrier island spit itself, the oceanic environment on its seaward side, the enclosed lagoon environment on its landward side, and the inlets that facilitate exchange of tidal.driven circulation. The bottom sediments collected in the channel, were classified in three main classes: terrigenous sandy mud, fine to very fine siliciclastic sands, and medium siliciclastic sands. The oceanic environment adjacent to the spit includes a shallow inner shelf with dune fields

The generalized Holocene stratigraphy of this area shows a transgressive sequence of restricted lagoon, lagoon and shoreface sediments followed by a regressive sequence of lagoon, tidal flats and fluvial sediments behind a barrier spit. The transgressive nature of this barrier-spit system is demonstrated by exposed mangrove muds and peats in the surf zone. Alluvial sediments of the Barreiras Group (Early Pleistocene and older) were reached at 9 meters depth in the landward most core, but the shoreface sediments are absent at this depth. A characteristic change in the environmental conditions towards more “open marine” environments is observed from bottom to top within this transgressive sequence. The basal, restricted lagoonal unit shows a very restricted microfauna, or the absence of microfossils. An intermediate lagoon unit shows a more open microfauna. Finally, the shoreface unit of the transgressive sequence presents a

normal marine microfauna. ^{14}C radiocarbon dating of shells from the base of the shoreface give an age of 6.060 ±80 yr BP and in the transgressive lagoon unit an age of 7.020 ± 100 yr BP (Silva 1991), suggesting an approximate age between 7 – 6 ka for the final stages of the Postglacial Marine Transgression.

The upper regressive sequence presents a greater variety of environments which characterize the prograding nature of this coastal plain. Lagoon, tidal flat and fluvial sediments are deposited behind a barrier spit, while tidal inlet, tidal flat and small secondary spit sediments are deposited seaward of the barrier spit. A restricted microfaunal assemblage is observed behind the barrier spit, while an open marine fauna is present in front of the spit. The environments observed seawards of the barrier spit represent the tidal inlet sub-facies of the ebb-tidal delta facies preserved in the subsurface as the ebb-tidal delta complexes are attached to the mainland promoting shoreline progradation. The contact between tidal inlet sediments and lagoon sediments is gradual, characterized by a change in the microfaunal association (Silva 1991).

Extensive ebb-tidal deltas in the inlets are the site of temporary important sand accumulations. These ebb-tidal delta deposits are composed of swash platform and tidal inlet sedimentary units. Swash platform units are lobate, concave-upwards sand deposits, laterally continuous over the entire ebb-tidal delta surface, usually having a thickness from 1 to 3 m.

Tidal inlet units are composed of sand/mud interbeds that occur in the bottom of the tidal inlets, as well as in the entire subsurface of the ebb-tidal deltas and in the subsurface of the coastal plain. Because of its greater thickness (3-10 m), and its deposition below wave base, the units are more likely to be preserved. The pattern of sand distribution in the littoral area is lobate, with elongate depocenters both parallel and perpendicular to the shoreline representing deposition in the barrier spits/ebb-tidal deltas and in the tidal inlets respectively. The resulting sand body geometry is both concave- or convex-upwards.

CONCLUSIONS

The Diogo Lopes coast has two active inlets, naturally occurring. The net drift is to the West-Northwest along this coast. Natural inlet formation was by breach of the narrow spit by overwash processes during more energetic periods.

The data base from this study suggest that littoral transport processes dominated these inlets with periods when the channel is deeper (maximum 1,7 m depth) and periods when the channel is shallower (minimum 0,6 m depth). If the hydrodynamic conditions persist, to maintain navigational interests, the inlet need to be stabilized over time.

Diverse depositional facies associated with or immediately adjacent to the spit compose a complex depositional system. This system comprises the shore-parallel barrier island spit itself, the oceanic environment on its seaward side, the enclosed lagoon environment on its landward side, and the inlets that facilitate exchange of tidal.driven circulation.

This data set is important to develop a detailed understanding of this tropical barrier-spit system evolution, to provide good architectural analogues for the nearby subsurface reservoir, and will enable the planners and ecologists to make the right decisions for a rational management of the coastal zone.

Abstract: Beach widths and shoreline change along Santa Barbara and Ventura Counties, California were evaluated using a 70-year record of rectified historic air photos. Beach widths have oscillated throughout the study period as opposed to narrowing as predicted by sediment supply reductions. Shoreline change rates evaluated using linear regression and end point rate analyses show differences between the wet/dry shoreline and back beach reference features. Most of these differences occurred along armored backed shorelines where the natural erosion of the back beach was halted while the wet dry shoreline continued to erode. Beach responses to single El Niño events form a predictable pattern of beach reorientation. Similar patterns of shoreline reorientation can be seen in the long-term shoreline change analyses providing evidence that El Niños may play an important role in long-term coastal evolution.

INTRODUCTION

Beaches are significant economic drivers of coastal communities and national economies, supporting commerce, recreation, and ecosystems (Heinz Center 2000, Griggs *et al.* 2005). Economists estimate that without California's beaches the state would lose about $5.5 billion annually and the U.S. economy would lose about $2.4 billion annually (King and Symes 2004). Beaches also provide hazard protection, it is estimated that over the next 60 years, 1 of 4 houses within 150m of the shoreline will be claimed by erosion (Heinz Center 2000). Erosion has threatened public facilities, infrastructure, and oceanfront property. The response has been an increase in shoreline armoring reducing habitat, recreation, and economic opportunities (Griggs *et al.* 2005).

The Santa Barbara Sandshed extends 245 km from the Santa Maria River in the north around Point Conception where the north-south trending shoreline takes an abrupt turn to a west-east trending shoreline orientation along the coast of southern Santa Barbara and Ventura Counties to the Point Mugu submarine canyon in the south (Figure 1).

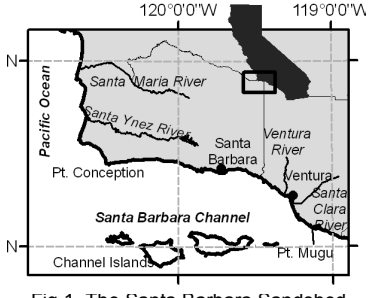

Fig.1. The Santa Barbara Sandshed

The Santa Barbara Sandshed (watershed + littoral cell), is a complex coastline with a variety of rocky outcrops, offshore reefs, and relatively narrow beaches. The beaches receive the majority of their sand inputs from four major rivers the Santa Maria, Santa Ynez, Ventura, and Santa Clara Rivers along with numerous small coastal drainages that pulse large sediment loads during episodic rain events (Inman & Jenkins 1999).

The presence of the Channel Islands to the south and Point Conception to the west create a narrow swell window that reduces and focuses much of the wave energy. The small swell window results in wave heights during 60% of the year of less than 1 meter. During the winter, longer period waves can achieve wave heights around 2.5 meters. Almost unidirectional wave conditions result in a longshore transport of sediment from west to east into the Santa Barbara Channel estimated to be around 1.7 km/yr (1 mi/yr) (Bailard and Jenkins 1982; Revell and Griggs 2006).

Major alterations to the Santa Barbara coastline began with the construction of the Santa Barbara Harbor in 1929 that provides the textbook example of down coast erosion causing by disrupting longshore transport (Wiegel 2002). The effects of dam impoundment and shore protection structures on sand delivery to the coast have been studied in the Santa Barbara cell and show an approximately 40% reduction in sand supplied to the sandshed by the major rivers (Willis and Griggs 2003, and Runyan and Griggs 2003). It was predicted that this reduction would correspond with a decline of sand volume dredged at the harbors. Using dredge records as a proxy for littoral drift, Runyan and Griggs found an average rate of sand at Santa Barbara Harbor since 1933 (~230,000 m3/year), and the Ventura Harbor since 1964 (~450,000 m3/yr) with no sign of reductions in dredge volumes (2002). One potential explanation for this lack of reduction in harbor dredge rates could be that the beaches were narrowing and supplying the sand found in the harbor dredge records.

This hypothesis was tested along the Isla Vista Coast, updrift of the Santa Barbara Harbor where it was found that beach widths had not narrowed but instead oscillated (Revell and Griggs 2006). The oscillations of beach width were found to relate to different phases of the Pacific Decadal Oscillation (PDO), a climate index of sea surface temperature with a periodicity of ~20 years (Mantua et al 1997). During positive PDO phases, El Niño-like patterns of increased precipitation and stream flow narrow beaches while during negative and calmer, drier PDO phases, beach widths widened (Revell and Griggs 2006). The driving mechanisms of beach changes were related to the change in wave directionality that during large El Niño events would more preferentially affect beaches that were normally sheltered in the Southern California Bight (Graham 2003).

The focus of this study has been to extend the beach width and shoreline change assessment to a 70km stretch of the Santa Barbara Sandshed extending from Ellwood Beach to Ventura Harbor in order to evaluate the response of beaches and shoreline to the sediment reduction, El Niños, and human alterations to the coastline.

METHODS

Historical aerial photographs provide one of the best data sources for long-term shoreline and beach change investigations. Many authors have utilized various shoreline reference features to examine changes to the beaches and shorelines (see Crowell and Leatherman 1999; Boak and Turner 2005 for a recent reviews). More recent acceptance of high accuracy lidar data enables a rapid assessment of long stretches of coast and provides additional information on beach volumes and regional shoreline changes caused by extreme storm events (Revell *et al* 2002; Sallenger *et al.* 2003).

The use of air photos for accurate shoreline change assessments requires an understanding of the potential sources of errors. Errors inherent in air photo interpretation can be broken down into 1) source error, 2) interpretation error, and 3) short-term natural variability errors (Morton and Speed 1998). Source error results from photo distortion, scale, and scanning errors (Moore 2000). Interpretation errors come from difficulty in locating shoreline reference features. Short-term variability errors arise from seasonal changes in beach profile and variations in water levels and wave run-up elevations that change the location of the shoreline reference features (Morton and Speed 1998, Ruggiero *et al.* 2003)

For this study, eighteen different sets of vertical air photos were obtained for the period from 1929 to 2003. Photographs selected for this study (at scale 1:24,000 or smaller) were taken during the calmer season (June to November) to reduce seasonal signals and ensure that beaches were near a maximum width. Due to the large study are and specific criteria, few photo sets were available with complete coverage of the study area.

To minimize errors, historic imagery was rectified using known coordinates of ground locations obtained through GPS surveys to reduce photo distortions (Moore 2000). For each image, two shoreline reference features were digitized - the wet/dry line identified

using tonal contrasts and the back beach or toe of the cliff or dune. The beach width is the distance between the wet/dry line and the back beach feature, generally the dry sand portion of the beach at the time of the photo.

Given the short-term variability of water levels, corrections to the wet/dry proxy- based shoreline reference features were based on the tide level portion of the total water level method discussed in Ruggiero *et al*. 2003. Tide level corrections adjusted the wet/dry shorelines to Mean Sea Level (MSL) (0.829m NAVD88) using the historic hourly water level data at Santa Barbara harbor available online from NOAA. These corrections translated the water level at the time of the historic photo onto an average summer beach slope calculated from historic profiles and from the 1997 lidar data for each shoreline segment. The beach slopes used in this tidal correction ranged from 0.045 (sand) to 0.11 (cobble). Due to the typical low energy waves found in the Santa Barbara Channel during the summer and fall, and the lack of hindcast wave data for most of the photography, a wave run-up adjustment was not included in the proxy based shoreline correction.

Error estimates for the identification and absolute spatial location of the shoreline reference features associated with shoreline change analysis are, +/- 9.7, and +/- 9.3 m for the early 1929 and 1938 photography respectively. More recent photography scanned at a higher resolution provides lower spatial errors on the order of +/- 7m. Unlike the shoreline change analysis that depends on different images, the errors in beach width measurements are spatially independent since both reference features can be seen in each of individual images. Therefore the beach width errors are +/- 5m and arise from reference feature identification and water level adjustments.

To better understand the changes caused during the 1997-98 El Niño event, NOAA, NASA, and USGS collected pre- and post- storm lidar surveys in October 1997 and April 1998 for most of this study area (Sallenger *et al.* 1999). Lidar data was obtained for Carpinteria and Isla Vista from the NOAA Coastal Service Center and processed to extract a MSL contour (0.829m NAVD88). The back beach reference feature was hand digitized using visual cues in cross-shore profiles, slope breaks, and hillshade layers. These two reference features were included in the BW change analyses, and the 1997 data set was included in the shoreline change analyses.

Shoreline change and beach widths for all imagery were measured along the same 50-meter transects using the USGS Digital Shoreline Analysis System (DSAS) (Thieler, *et al*. 2003). All shoreline change rates and error statistics discussed in this paper were calculated using DSAS version 3.2 (Thieler, *et al*. 2003). For this study, we focus on the shoreline change linear regression rates (LRR) and end point rates (EPR).

Beach widths were measured by individual years, by setting the back beach reference feature to one year after the date of the MSL shoreline so that the EPR calculation measured the beach width. Tide corrections were applied to the beach widths following DSAS measurement. Beach width measurements and the average beach slopes used in the tide level corrections were multiplied to calculate sand volumes above MSL by

transect (m3/m). These transect volumes were then multiplied by the 50m transect spacing and summed to provide a total volume for a chosen length of shoreline.

The intersection of the 50m transects and the individual MSL shorelines were used to calculate shoreline orientations. By drawing a straight line between adjacent transects at the intersection point between the MSL shoreline and the transect lines, an azimuth angle of this intersecting line was calculated in ArcGIS. From the azimuth angle, a shore normal, perpendicular angle was derived by adding 90 degrees to the azimuth angle. (Note: this azimuth angle is not to be confused with the azimuth angle derived by DSAS). Shoreline orientations were filtered to exclude all transects in front of shore protection structures and near creek and river mouths.

RESULTS

Beach Widths

The beach widths in the study area have varied widely throughout the 70-year time series (Figure 1). Two types of beaches can be identified - stable beaches and storage beaches. A stable beach maintains a wide minimum beach width and a storage beach is one that

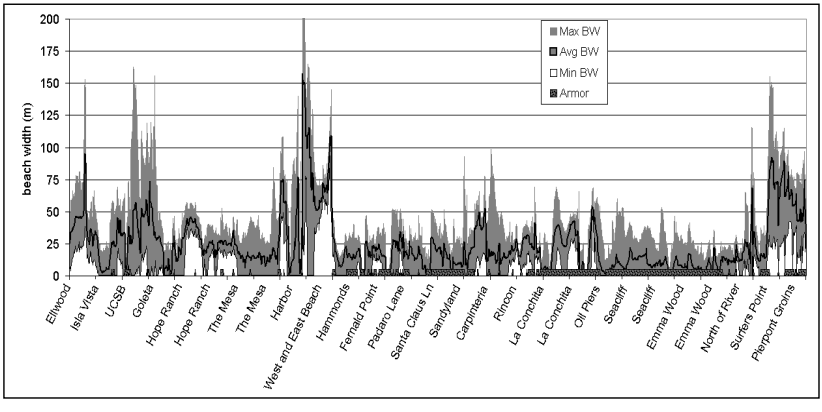

Fig. 2. Beach width variability along 70 km of southern Santa Barbara and Ventura Counties.

exhibits extreme natural variability but has zero minimum beach width. Stable beaches (e.g. Ellwood, Hope Ranch and Carpinteria) provide good locations to examine storm impacts, and provide good locations to observe pulses of sand moving along the coast. The best examples of a storage beach were UCSB and Goleta Beaches that reached their maximum widths (>150m) in the 1960s and 1970s (Revell and Griggs 2006).

This study area can be generally divided up into two locations based on the location relative to the Santa Barbara Harbor. The beaches to the west of the Harbor (toward Ellwood) face more southward and exhibit a wider range of beach widths. These beaches all had their minimum beach widths occur following either the 1982-83 or

1997-98 El Niño. The maximum beach widths for these beaches were reached mostly during the end of the last calm (negative) period of the PDO in the 1970s.

The beaches downdrift of the harbor (toward Carpinteria and Pierpont Groins) have smaller ranges of beach widths and are primarily armored shorelines (Figure 1). The minimum and maximum beach widths along this stretch do not fit any obvious pattern, although the analysis is limited by the lack of photo sets available prior to major transportation infrastructure projects completed in the early 1900s.

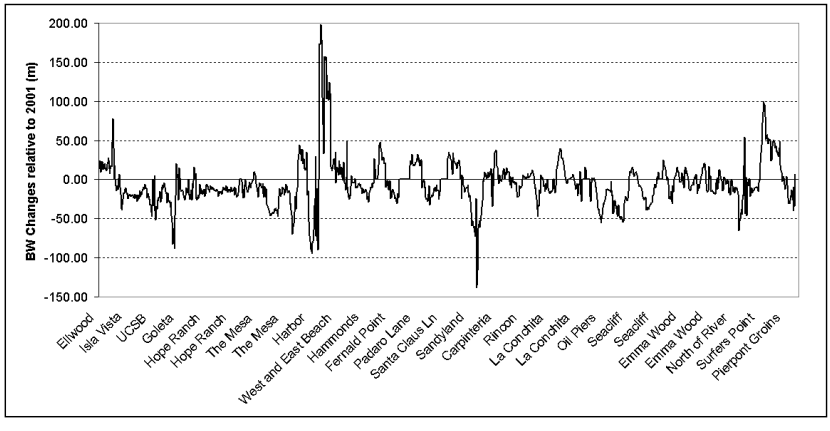

Fig.3. Long term beach width changes relative to the 2001 beach width. A negative beach width change indicates that the beach has narrowed, while a positive change indicates accretion.

One research objective was to examine the long-term changes in beach widths to ascertain whether the beaches may have narrowed supplying sand to the harbor dredge records to compensate for the reduction in sand supply. Figure 2 shows the long-term beach width changes relative to the 2001 beach widths. There does not appear to be a uniform narrowing of the beach widths across the study area.

The largest beach width changes in this study area are related to construction of the Santa Barbara Harbor. Other significant beach width accretions have occurred at the Pierpont groin field in Ventura, and Ellwood Beach. Ellwood Beach is uniquely situated facing west into the dominant wave direction, and is the only natural dune backed shoreline remaining in the study area. The greatest beach narrowing has occurred at both Carpinteria as a result of the Santa Barbara harbor construction and development of the former dunes, and at Goleta Beach as a result of the construction of the Santa Barbara airport and the loss of tidal prism at Goleta Slough (Revell and Griggs 2006). It is important to note that this end point beach width change analysis does not capture the oscillations in beach width that have been previously documented (Revell and Griggs 2006).

Shoreline Orientation

Due to the irregular shape of the coastline and the near uniform wave direction, wave exposure varies greatly depending on shoreline orientation. Periodicities observed in the long-term beach change width analysis (Figure 3) are related to changes in the shoreline orientations that partially control beach widths (Figure 4).

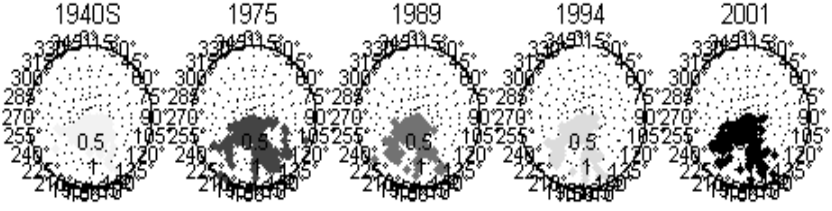

Fig. 4. Beach Widths plotted by Shoreline Orientation for separate years. Data points were extracted from the same shoreline transects and have comparable number of data points.

The shoreline orientation results indicate that most stable and widest beaches are those found facing SSW (255° to 210°, and SSE (165°-150°). The narrowest beaches are found facing close to south (210°-165°). The shoreline orientation analysis demonstrates the impacts of human alterations across the study area through time.

While air photo data from the pre-harbor construction era is sparse, it appears from historic oblique photos that most of the beaches were relatively narrow. By the 1940s (compilation data from 1943 and 1947), the beaches were relatively narrow with the widest being in the east (165°-150°) as a result of Santa Barbara Harbor construction and the trapping of sand to form the updrift Ledbetter Beach. The widest beaches in the west were found in the dunes of Ellwood Beach (255°-240°). By the 1975 data set, there were several human alterations creating wide beaches. The cluster located along 180 degrees is the beach continuously nourished by the sand bypassing at the Santa Barbara Harbor. In the late 1940s, the Pierpont groin field in Ventura oriented southwest (240°- 225°) filled in and has remained stable to present. 1975 was a wide sand year, and the SE facing UCSB storage beach (105°-120°) reached its widest width. By 1989, after the 1982-83 El Niño, the wide beach at UCSB was eroded (Revell and Griggs 2006). Throughout 1994 and 2001, beach widths continued to widen despite the large 1997-98 El Niño. By 2001, beach widths at Ellwood reached their maximum beach widths during the study period.

Shoreline Change

Shoreline change rates were calculated for both the wet/dry and the back beach shorelines at each transect along the entire study area (Figure 5) and summarized in Table 1. These broad rates do little to describe the spatial patterns and trends associated with the different shoreline segments (Figure 5). When averaged over the entire study area, the shoreline change rates calculated with both EPR and LRR are relatively low. The primary differences between the back beach and the wet/dry shorelines can be attributed primarily to the presence of shoreline armoring and engineered structures.

Table 1. Shoreline Change Rates

Shoreline Change (m/yr)	Average	Maximum	Minimum
EPR_Back Beach	0.01	3.10	-2.00
EPR_Wet/Dry	-0.02	2.89	-2.97
LRR_Back Beach	0.07	3.13	-1.59
LRR_Wet/Dry	-0.01	2.81	-2.37

Along an unarmored beach, beach widths would stay relatively stable over the long-term with the beach widths migrating landward or seaward depending on sea level, so one would expect the shoreline change rates for both reference features to be similar.

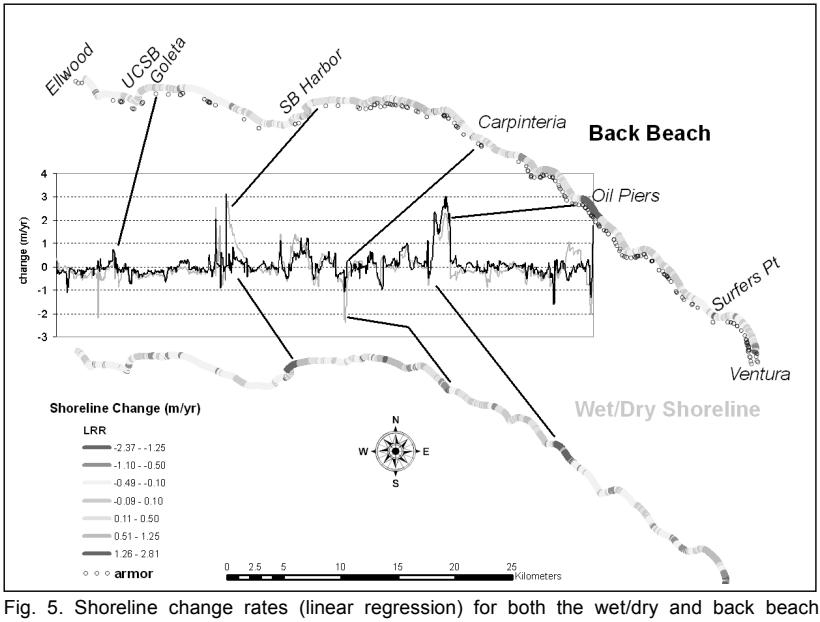

Fig. 5. Shoreline change rates (linear regression) for both the wet/dry and back beach shorelines.

Once the back beach is armored, then the back beach change would appear to accrete due to placement loss (determined by the footprint of the structure). As sea level continues to rise, and the wet/dry shoreline continues to retreat, passive erosion takes place.

Over the study area, the largest erosion rates detected using LRR occur at UCSB Beach, and at the inlet to Carpinteria Salt Marsh with both rates greater than –2 m/year (Figure 5). Maximum accretion rates are a direct result of engineered structures, the construction of the Santa Barbara Harbor and the construction of the oil processing facilities at Oil Piers resulted in 70 year shoreline change rates at ~3m/yr (figure 5). The regional analyses may facilitate regional sediment management, and a better understanding of

cumulative impacts however, most of the decisions directly affecting long-term beach widths and recreational and economic opportunities happen at a much smaller scale.

Case Study: Carpinteria Erosion

Breakwater construction and sand impoundment at the Santa Barbara Harbor led to a well documented erosion wave that migrated downcoast at ~1.7km/yr (~1mi/yr) (Weigel 2002). While the reporting of this erosion wave is not new, the application of the beach width methodology to study this erosion event provides new information on the response of the beach and shoreline (Figure 6).

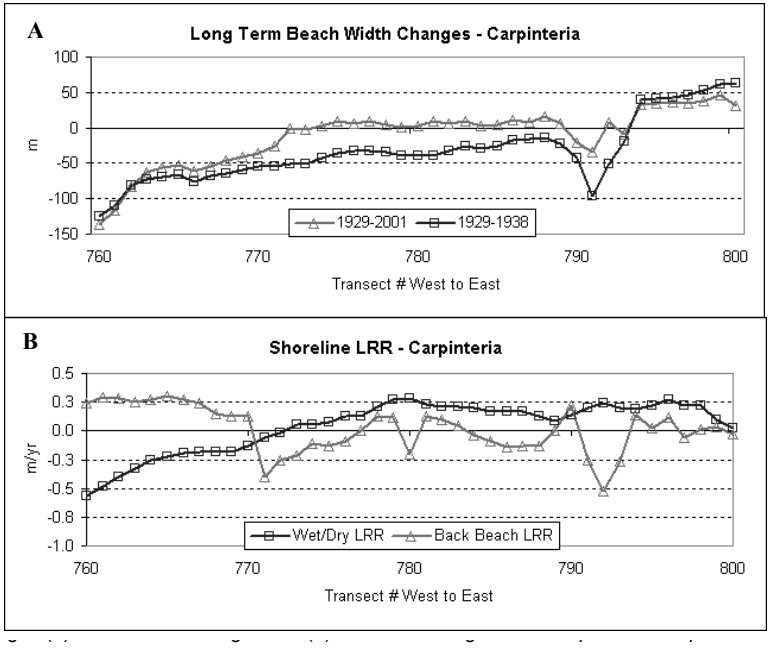

Figure 6 a shows the changes to the beach following the erosion wave determine by subtracting the differences in beach width between 1929-1938. While beach widths were largely eroded in the west (-150 m), there was also accretion of beach at the east end of the shoreline segment (~55m) (past the creek mouth located at transect 792) resulting in a change of the shoreline orientation. The beach has maintained this alignment for the following 63 years (1929-2001) although the center of the beach accreted some 50 meters over the longer time period.

In Figure 6b, the wet/dry shoreline change analyses shows a similar pattern of reorientation. However, the back beach shoreline change rate at the west end of the beach (transects 760-770) shows an accretion trend caused by the construction and encroachment of a revetment onto the beach. While the accretion "rate" of the back

beach is not valid after the structure is built, the reversal in shoreline change rate identifies the human alteration. The shoreline change immediately adjacent to the revetment along the city beach (transects 770-780) follows the overall pattern of reorientation depicted in the wet/dry shoreline change rates.

The beach width analysis was applied with the Lidar derived beach widths and air photos to examine impacts and recovery associated with the large El Niño events of 1982-83 and 1997-98 (Figure 7). By subtracting the Lidar beach widths of 1998 from

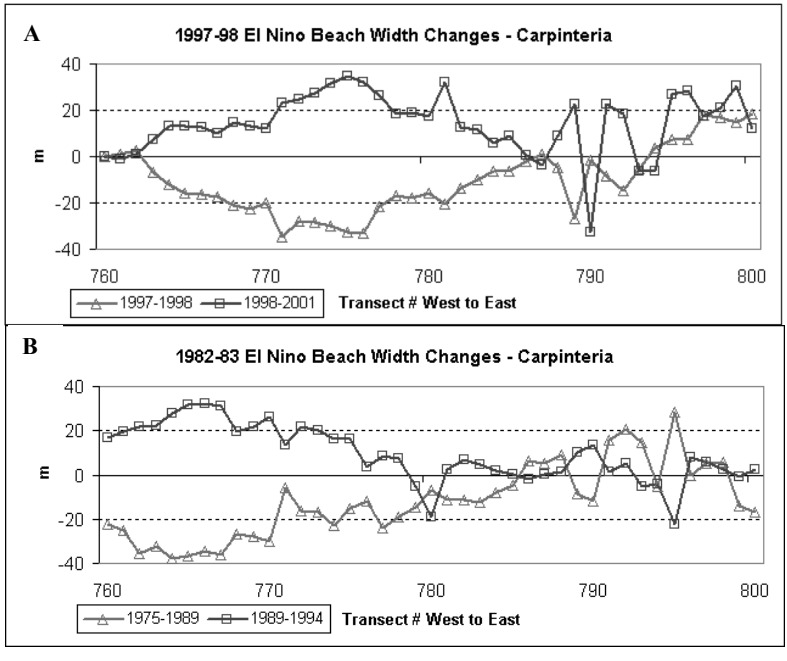

Fig. 7. Beach width changes and recovery following the 1997-98 (a) and 1982-83 (b) El Niños.

1997, the beach response revealed a similar pattern to the long-term beach width and wet/dry shoreline reorientation (Figure 7a). Erosion near the west end of the beach of ~40m was conversely related to east end accretion in beach width of ~20m. The recovery of the beach at the west end was complete by the time of the subsequent available air photo set in 2001 when the west end beach widths accreted nearly 40 meters. The net result by 2001 was that the beach had widened at the east end an additional ~20 meters from the 1998 survey.

The 1982-83 El Niño was the largest El Niño on record and had devastating impacts to UCSB beach (Revell and Griggs 2006). Due to the lack of available air photo sets, the closest available photo sets bracketing the event were taken in 1975 and 1989 (Figure 7b). The beach width changes were analyzed revealing the same pattern of

beach reorientation characterized by nearly 40m of erosion in the west end and ~20m of beach widening near the east end. By 1994, the next available photo set, this reorientation had recovered to the preexisting state in 1975. Note that the location of the maximum erosion shifted to the east roughly 500m between these two time periods (from Transect 767 to 777). Following the 1982-83 El Niño, the revetment was constructed to transect 761 resulting in a migration of the erosion hotspot downdrift.

DISCUSSION

Beach Widths

A 70 year record of beach widths changes were evaluated to determine if there was a long term narrowing of the beaches that could explain the discrepancy between a sediment supply reduction (Willis and Griggs 2003, Runyan and Griggs 2003) and a steady long-term average dredge volume recorded in the Santa Barbara harbor dredge records (Runyan and Griggs 2002). While he beach width analyses did not identify any systematic long term narrowing, the beach width envelopes identified locations of stable beaches, those with wide minimum beach widths and storage beaches, and those that exhibit extreme natural variability in widths and could potentially be a good site for beach nourishment.

The long-term beach width air analyses were complicated by the multiple dates and availability of sets of early air photos (ranging from 1929, 1938, 1943, and 1947). Further complicating the analyses were the beach changes associated with a variety of human alterations that pre-dated airplanes and air photos. Ideally, an air photo set taken during the late summer at lower tide prior to railroad construction (circa 1900), and a pre- harbor 1928 set would be compared to the existing photo sets to better examine this question of long term narrowing. The historic T-sheets provide some shoreline information, but the delineation of a back beach in the early maps is more of an artistic rendering rather than a substantive data set.

The use of shoreline orientation data provides additional information to understanding the response of beaches to wave exposure. The shore normal data aided in identifying stable beaches and storage beaches. Tot better assess the regional behavior and to calibrate the methodology, additional research is needed on less altered beaches. More research is also needed to understand long term changes to shoreline orientation, whether it is driven by a single catastrophic events such as an erosion waves or tsunami, or driven by repeated extreme events such as large El Niños or hurricanes.

Shoreline Change

Overall, the shoreline changes occurring throughout the study area are a balance of mild erosion and large-scale accretion caused by engineered structures. At a more localized scale, differences found between accretion of the back beach and erosion of the wet/dry shoreline can be used to identify locations of placement loss and passive erosion. Once a structure is constructed, and the placement loss occurs, then any rate of back beach shoreline changes largely becomes irrelative.

Storm Event response

The beach width response to the 1997-98 and 1982-83 El Niño match the long term pattern of reorientation observed at Carpinteria with erosion at the west end and accretion at the east end. This provides some evidence that extreme El Niños events may play an important role in creating or sustaining large scale, long-term coastal evolution. The data coverage bracketing the 1982-83 event was rather spread from the actual event, and may be recording a different erosion event. However if the pattern observed in 1989 is remnant from the 1982-83 event, the implication is that the 1982-83 event had a longer lasting impact on the coast than the 1997-98 event.

Beach width methodology

Beach width methodology when used in conjunction with shoreline change analyses provides additional information on the shape of the shape and response of the beach. When shoreline change rates along unarmored sections are similar between the wet/dry and back beach reference features indicating that beach widths remain relatively constant (among the oscillations) as the shoreline retreats. Along armored sections of coastline, however, we often see accretion of the back beach and the erosion of the wet dry line. The application of a beach width methodology can be used to detect both placement loss and passive erosion and assist coastal managers in quantifying and assessing cumulative impacts of shoreline armoring over a much broader spatial scale.

Human Alterations

Along the seventy kilometers of the study area, 60% (41.9km) of shoreline is armored with a variety of revetments and seawalls. Another ten kilometers (14.3%) has been altered by groins, breakwaters, or other littoral barriers. With the high rates of littoral transport, the cross-shore structures perform well at building up beach widths, while alongshore-oriented structures have resulted in placement loss, passive erosion, and had the net result of reducing beach widths. The construction of the revetment along Carpinteria following the 1982-83 event and the similar pattern of erosion in 1997-98 that was deflected down coast may provide some evidence that active erosion and flanking erosion is occurring at the end of the structure, but more research is needed.

CONCLUSION

The 70 year record of beach width changes in the Santa Barbara Sandshed did not reveal any long term beach narrowing that would be associated with a reduction in sand supply. Beach widths instead oscillated widely across the littoral cell. Updrift of the Santa Barbara harbor, beach widths are closely related to strong El Niños resulting in the narrowest widths measured following the events of 1982-83 and 1997-98. Down drift of the harbor, beach widths did not follow the similar El Niño pattern. The greatest narrowing of beach widths occurred at 1) Carpinteria caused by sand impoundment by the construction of the Santa Barbara harbor, and 2), Goleta Beach due to the construction of the Santa Barbara airport and the loss of tidal prism at Goleta Slough. The greatest widening of beach widths occurred immediately updrift

of the harbor (>200m) as a result of sand impoundment and sand bypassing, with a groin field widening beach widths by >100m.

The combination of beach width envelops and changes in shoreline orientation demonstrated that the west facing beaches of Ellwood 255°-240° were naturally the most stable with beach widths between 25 and 75 meters, while the east facing beaches 120°-105° were naturally the most variable ranging from 0 to 150m.

Shoreline change rates were evaluated at both the wet/dry shoreline and back beach reference feature in conjunction with the beach width changes. Average shoreline change rates for the 70km study area show mild accretion of the back beach and a slightly larger erosion rate at the wet/dry shoreline. This is consistent with the placement loss of armoring ~60% of the study area with a variety of structures.

The construction of the harbor breakwater and sand impoundment created an erosion wave resulted in narrowing of Carpinteria and other beaches down drift. The beach width analyses revealed that this erosion wave narrowed the beaches by nearly 150m in places, but served to reorient the coast and resulted in moderate downcoast accretion along the same segment of beach. Long-term shoreline change rates of the wet/dry shoreline show a similar trend of beach rotations.

The beach width response to the 1997-98 and 1982-83 El Niño match a long-term reorientation pattern measured in the wet/dry shoreline and beach width changes with erosion at the west end and accretion at the east end. This provides some evidence that extreme El Niños events play an important role in long-term coastal evolution.

The evaluation of beach widths provides additional information to inform shoreline change analyses and can provide coastal managers with additional information on shoreline orientations and quantitative information to assess cumulative impacts.

ENGINEERING ACTIVITIES INFLUENCING HISTORICAL SEDIMENT TRANSPORT PATHWAYS AT THE COLUMBIA RIVER MOUTH, WA/OR

Mark R. Byrnes[1], Sarah F. Griffee[1], and Hans R. Moritz[2]

2. US Army Corps of Engineers, Portland District, P.O Box 2946, Portland, Oregon 97208, USA. Hans.R.Moritz@nwp01.usace.army.mil.

Abstract: Regional sediment transport dynamics at and adjacent to the MCR were quantified using historical shoreline and bathymetry surveys. Four distinct depositional trends were identified: 1) the modern ebb shoal was deposited approximately 2-mi seaward of the natural shoal in about 90- to 130-ft water depth as a result of jetty construction; 2) the primary area of sedimentation on the ebb shoal is north of the entrance, and it continues to migrate north with time; 3) northward-directed sediment transport from the entrance has resulted in net accretion along the shoreline and on the continental shelf seaward of Long Beach Peninsula; and 4) continual shoreface erosion south of the MCR is the result of sediment diversion by the south jetty to the west and north of the entrance toward the ebb shoal and onto the continental shelf. The long-term sediment budget indicates that approximately 4.4 Mcy of sediment is transported to the continental shelf north of the MCR on an annual basis.

INTRODUCTION

The Columbia River is the largest on the west coast of the U.S., draining about 259,000 mi^2 and extending some 1,200 mi from British Columbia to the coasts of Oregon and Washington (McManus, 1972; Gailani et al., 2003). Average annual discharge is approximately 200,000 cubic feet per second (cfs), more than twice the combined discharges of all other rivers in California, Oregon, and Washington (Barnes et al., 1972; Komar and Li, 1991). Peak discharges of 740,000 cfs occur in May and June as the result of snowmelt, whereas minimum flows (106,000 cfs) occur in August and September (Neal, 1972; USACE, 1999). It is the major source of sediment to the northwest continental shelf (Sternberg, 1986). Suspended sediment discharge from the river is about 1 to 2 x 10^{13} g/yr (5 to 10 x 10^6 yd^3/yr), and bedload discharge is estimated

to be on the order of 10^{12} g/yr (10^6 tons) (Karlin, 1980). Gross and Nelson (1966) estimate that the Columbia River discharges 10^4 times more sediment to the northwest continental shelf than all other sources combined.

The continental shelf seaward and north of Tillamook Head, Oregon to the entrance of Willapa Bay, Washington is characterized as relatively narrow (about 25 mi) and steep (21 ft/mi) (McManus, 1972). South of the Columbia River, ocean beaches, backed by substantial dunes along a stretch of coast referred to as Clatsop Plains, extend for 20 mi to Tillamook Head (Fig. 1). This rocky headland extends seaward to deep water, effectively interrupting any further movement of sand south along the coast by littoral processes (Clemens and Komar, 1988). North of the Columbia River mouth, Long Beach Peninsula extends about 25 mi north from Cape Disappointment (North Head) to Leadbetter Point at the entrance to Willapa Bay. Three prominent sediment texture trends have been identified by McManus (1972) as characteristic of the continental shelf seaward and adjacent to the Columbia River entrance: 1) an inner-shelf sand wedge extends south of the Columbia River to Tillamook Head and offshore to about 230 ft water depth; 2) north of the Columbia River and seaward to a depth of about 165 ft is a blanket of fine sandy nearshore sediment, not forming a pronounced wedge; and 3) a dominant mid-shelf silt deposit extending from the mouth of the river in a north-northwest direction.

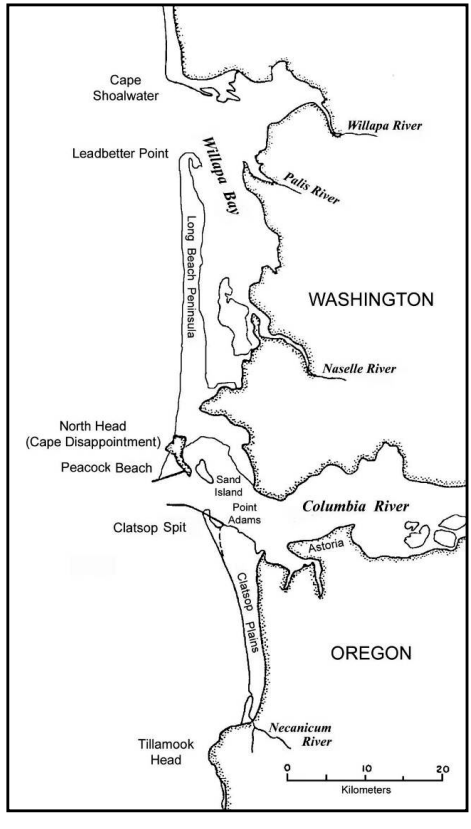

Fig. 1. Washington and Oregon coast north and south of the Columbia River.

Regional sediment transport pathways and rates of change adjacent to the Mouth of the Columbia River (MCR) were documented through geomorphic analysis of historical shoreline and bathymetry data for the period 1868 to 2003. Thirteen digital bathymetric and shoreline surveys of the entrance area and ebb shoal were compared to quantify sediment transport magnitudes and pathways. The U.S. Army Corps of Engineers

(USACE) Sediment Budget Analysis System (SBAS; Rosati and Kraus 2001) was used to calculate and display transport pathways and analyze sediment volume fluxes for the period 1958 to 2003. In addition, USACE, Portland District, channel dredging and placement volumes were included in a sediment budget to accurately reflect dredging activities for the analysis period. Regional sediment transport trends documented throughout the Columbia River Littoral Cell (CRLC) by Buijsman et al. (2003) provided background and information on oceanic boundary conditions for the MCR and vicinity.

HISTORY AND ENGINEERING ACTIVITIES

In the late 1780s, the Boston Fur Company was formed to engage the Pacific Northwest natives in the trading of sea otter furs. On 7 May 1792, Captain Robert Gray, a New England native, sailed his ship, the Columbia, into Bullfinch Harbor (later renamed Grays Harbor). Searching for still more trading partners, Gray sailed into the mouth of the Columbia River, advancing some 15 miles by 10 May 1792, just 3 days after he had sailed into Grays Harbor. To commemorate the event, the river was named Columbia in honor of the ship (Bohlander, 1984).

A chart prepared by Captain George Vancouver, dated 1798, illustrates many of the same major features and shapes in the estuary that exist today (Fig. 2). The first extensive mapping of the harbor was completed in 1839 by Sir Edward Belcher, but the first survey quality map was produced about 30 years later in 1868/77 by the U.S Coast and Geodetic Survey (USC&GS). The most significant geomorphic changes are those associated with construction of jetties at the entrance and the response of the shoreline and shoals to engineering activities (CREDEP, 1983; Byrnes and Li, 2001; USACE, 1999; Buijsman et al., 2003).

Continual adjustments in channel configuration and shoaling patterns at the MCR have caused navigation problems since its discovery in 1792. Ships often had trouble traversing the Columbia River bar, and the natural channels often shifted widely within the course of several tidal cycles. As such, it was decided that structural control of the MCR was needed to maintain safe navigation through the entrance area, so in April 1885, construction on the south jetty began. Nearly 10 years later (October 1895), a 4.5-mi jetty was completed from Point Adams in a northwesterly direction. Although a general improvement in navigation was achieved, shoals began to form along both sides of the jetty causing renewed shoaling problems at the entrance. Extension and rehabilitation of the south jetty were completed in 1913, giving the structure a total length of 7 mi. Construction of the north jetty began in 1913 as a component of the 40-ft entrance project. When completed in 1917, the structure extended about 2 mi in a southwesterly direction from Cape Disappointment (Lockett, 1967; USACE, 1999).

Since 1883, the Portland District has been surveying the harbor and entrance area to monitor shoreline position and changes in shoal and channel morphology. Structures imposed substantial influence on estuarine hydrography and channel characteristics, creating a self-scouring inlet that has moved the crest of the offshore bar seaward into deeper water and significant sand deposition along beaches north and south of the harbor.

Table 1 presents a summary of the construction and rehabilitation history for the entrance jetties since authorization for reference with long-term changes in sediment erosion and deposition at and adjacent to the entrance.

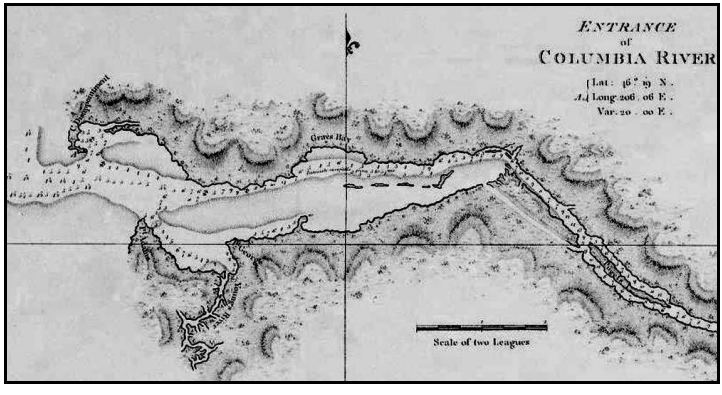

Fig. 2. Map of the Columbia River entrance prepared by Vancouver in 1798 (modified from Washington State Archives).

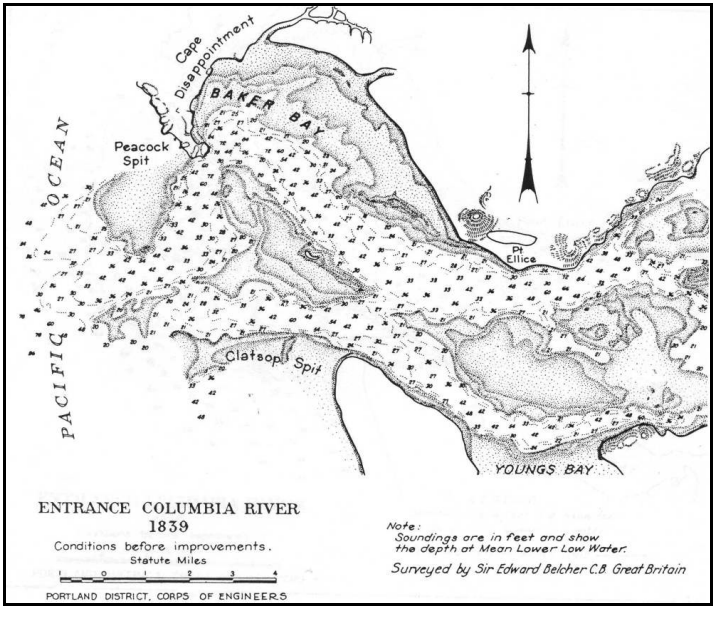

Fig. 3. First extensive mapping of the Columbia River entrance by Belcher in 1839.

Table 1. Engineering Events Affecting the Evolution of the Mouth of the Columbia River

1882	Congress recommends construction of a jetty along the south side of the Mouth of the Columbia River and approves a 30 ft deep entrance channel.
1885	Construction of the south jetty began but proceeded slowly.
1889	Rapid construction of the south jetty commenced; 20 ft. controlling depth in the entrance channel.
1895	South jetty completed to a distance of 4.5 miles from shore with four groins constructed along the north side of the jetty; 31 ft. controlling depth in the entrance channel.
1903	Congress approves extending the south jetty 2.5 miles west of the existing structure, construction of a north jetty extending about 2 miles from Cape Disappointment, a channel controlling depth of 40 ft., and channel dredging.
1904	Initiation of hopper dredging at the MCR.
1913	South Jetty extension completed; North Jetty construction began.
1917	North Jetty completed; channel controlling depth on the bar increased to 37 ft.
1918	Entrance channel controlling depth of 40 ft.
1927	Entrance channel controlling depth of 47 ft.
1931	South Jetty rehabilitation began.
1936	Reconstruction of the South Jetty completed; disintegration of the outer end of the structure continued due to winter waves.
1938	North Jetty rehabilitation began.
1939	North Jetty rehabilitation completed and asphalt added; concrete terminal structure placed at the end of the jetty; Jetty A completed.
1939 to 1955	Dredging at entrance confined to Clatsop Spit.
1942	South Jetty rehabilitated with asphalt mastic, and a concrete terminal structure was completed about 3,900 ft shoreward of the end of the jetty as completed in 1913.
1945	Regular annual dredging of the out bar channel initiated.
1954	Entrance channel controlling depth of 48 ft approved by Congress.
1956	Dredging of the entrance channel to 48 ft began.
1958	Dredged material disposal Sites A and C abandoned; Site B used extensively.
1961	South Jetty and Jetty A rehabilitated.
1977	52 ft. entrance channel project initiated; EPA provides interim designation for MCR ocean dredged material disposal sites.
1984	Entrance channel controlling depth of 55 ft.
1986	Final designation of MCR ocean dredged material disposal sites.
1997	Temporary expansion of dredged material disposal sites B and E.

Sources: Hickson and Rodolf, 1951; Simenstad et al., 1984; USACE, 1999

Channel dredging was initiated in 1904 to maintain a 30-ft navigation channel across the entrance bar. Intermittent shoals formed by sand transport from Clatsop and Peacock spits created navigation hazards that required periodic maintenance (USACE, 1999). Between 1904 and 1940, approximately 8.3 million cubic yards (Mcy) had been dredged from the MCR entrance bar and placed in open water disposal sites. During this time, channel shoaling was tolerated to a certain degree; however, by 1945, consistent annual maintenance dredging at the MCR was required. Between 1945 and 1955, annual maintenance dredging averaged about 1.2 Mcy/yr (USACE, 1999). Quantities increased to an average of about 4.2 Mcy/yr from 1956 to present, most of which was deposited offshore in ocean disposal sites.

DATA SOURCES

Two primary data sources were used to compile shoreline and bathymetry data for this study. U.S. Coast and Geodetic Survey (USC&GS, predecessor to NOS) topographic and hydrographic surveys (T-and H-sheets) and U.S. Army Corps of Engineers (USACE) field surveys provided superior coverage of inlet and nearshore morphodynamics at the Columbia River Entrance. Surveys of the offshore bar and entrance area have been completed annually since construction began on the south jetty in 1885. In addition, shoreline positions interpreted from aerial photography by the Washington Department of Ecology (DOE) and the Oregon Department of Geology and Mineral Industries (DOGAMI) were used in analyzing more recent changes. Time series of change associated with construction and rehabilitation of the jetties isolates sediment transport trends that reflect the performance of navigation structures. A detailed presentation of data sources is described in Byrnes and Griffee (2006). Methods used for compiling and analyzing historical bathymetric and shoreline data sets are described in Byrnes and Hiland (1994), Byrnes and Hiland (1995), and Baker and Byrnes (2004).

INLET MORPHODYNAMICS

Hydrographic surveys of regional nearshore morphology provide a direct source of information for quantifying changes in seabed elevation. This type of analysis is used to document trends in regional-scale coastal evolution, and to evaluate the impact of natural processes and engineering activities on coastal sediment dynamics. The primary feature affecting coastal sediment erosion and accretion throughout the study area is the Columbia River entrance. Seafloor elevations to approximately 200 ft water depth were compiled and analyzed to identify patterns of erosion and deposition associated with the MCR and adjacent nearshore environs.

Prior to jetty construction, the entrance and shoal system appeared typical of fluvial-dominated estuarine entrances (Hayes and Kana, 1976; Reinson, 1992). Regional characteristics of inlet and nearshore morphology for the entrance to the Columbia River estuary and adjacent shelf environs (1868/77) are illustrated in Fig. 4. All significant bathymetric features are associated with the lower estuary and entrance shoal/channel deposits. First, the braided channel features of the lower estuary give way to a single primary channel exiting the coast in a south-southwest direction. Substantial shoal deposits exist in the lower estuary and entrance area as a result of sediment input from

the river and nearshore marine environments (Lockett, 1967; McManus, 1972). A large sand shoal is present along the south margin of the entrance (Clatsop Shoal), extending in a northwest direction off Point Adams. It is about 2.5-mi long and controls channel position and orientation in the entrance area. To the north, seaward of Cape Disappointment, a smaller shoal extends southwestward from the rocky headland along the north margin of the entrance. In between, Sand Island and adjacent shoals and deposits associated with the ebb-tidal delta seaward of the entrance made navigation during peak flows and high-energy events quite challenging. The shield of the Columbia River ebb shoal is defined by the 50-ft depth contour. Continual shifting of these shoals and channels prompted the USACE to propose jetties to control sedimentation processes in the entrance area (Lockett, 1967).

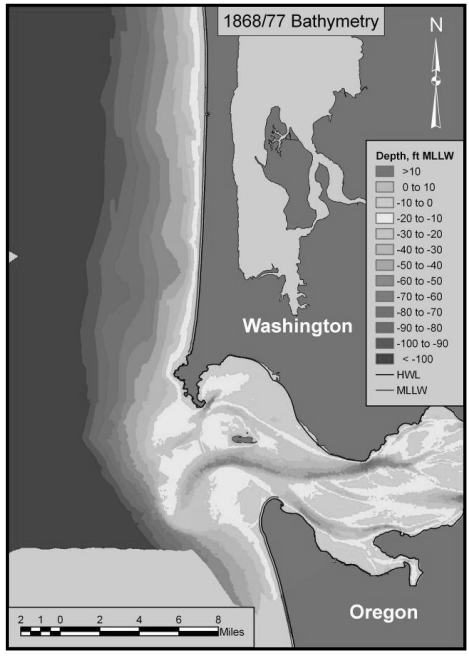

Fig. 4. Nearshore bathymetry (1868/77) at and adjacent to the MCR, WA/OR.

Between 1868/77 and 1926, large adjustments in sediment volume occurred at the entrance where the ebb-tidal shoal moved seaward about 2 mi, depositing approximately 252 Mcy of sediment in 90-ft water depth (Fig. 5). Approximately 70% of this deposition occurred between 1899 and 1926, after the entrance jetties were constructed (Byrnes and Griffee, 2006). The ebb-shoal that formed was skewed to the north, even though the channel exits the coast to the south-southwest. Deposition of northward directed sand from the ebb-shoal created Benson Beach, just north of the north jetty and south of Cape Disappointment. Clatsop Spit evolved in association with construction of the south jetty, creating a 3.5-mi long beach and filling the 1868 entrance channel as the new channel shifted north and displaced Sand Island. Net sediment deposition north of the channel and adjacent to the southern part of Baker Bay (158 Mcy), east of Cape Disappointment, appears to be the result of decreased flow in the area resulting from jetty placement and channel realignment. Conversely, seafloor erosion south of the south jetty is the result of decreased sediment supply to the area when the entrance channel shifted to the north, jetting much of its sediment load seaward to the ebb shoal. Net sediment erosion associated with channel realignment and erosion south of the south jetty (543 Mcy) controlled the sediment budget in the entrance area.

Bathymetric changes recorded for the period 1926 to 1958 illustrate net northward transport of sediment to and northwest of the north-oriented ebb shoal. The shoal depocenter has again moved seaward in response to flow from the increasingly-deeper channel (-40 to -48 ft during this time period; Fig. 6); net sediment deposition on the ebb shoal during this time was 182 Mcy. A substantial zone of erosion exists just landward of the ebb shoal, marking the position of the 1926 ebb-tidal delta. The magnitude of erosion for this feature (81.4 Mcy) is a little less than half of the deposition recorded for the ebb shoal. Another indication of northward sand transport is the apparent streaming of sand north from the ebb-tidal delta to the beaches along the coast of Long Beach Peninsula (Fig. 1). About 94 Mcy of sand deposited along the coast during this period.

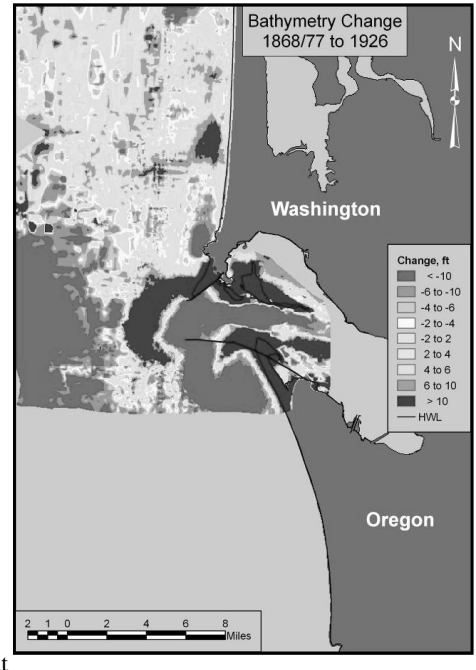

Fig. 5. Bathymetric change surface, 1868/77 to 1926. Bright red reflects maximum erosion, and dark blue reflects maximum deposition.

For the period 1958 to 2003, seafloor changes illustrate the same general trends as those presented for the 1926 to 1958 comparison, except the magnitude of accretion and erosion has increased. The centroid of deposition on the ebb shoal (minus the impact of dredged material placement offshore) shifted to the north (Fig. 7). Sediment accretion north of the entrance along Long Beach Peninsula continued as the shoreline moved seaward. In addition, erosion associated with the 1926 ebb-tidal delta increased, and the magnitude of sediment deficit south of the south jetty was enhanced.

SEDIMENT BUDGET AND TRANSPORT PATHWAYS

Regional sediment transport patterns for the Columbia River entrance and adjacent environs are consistent for all analysis time intervals (Byrnes and Griffee, 2006). Although coastal process measurements identify two distinct seasonal circulation trends, net sediment deposition and erosion in the study area is relatively steady and predictable. Changes in subaqueous spit formation and entrance shoal migration at the MCR since the mid-1800s indicate that net sediment transport in this area is from south to north. Prior to jetty construction, sand shoal accretion north and west of Point Adams (northern Clatsop Plains) would detach from the coast, migrate to the north and force the channel

to the north side of the entrance, thereby supplying large quantities of sand to the north side of the entrance area and eventually onto the ebb shoal. Jetty placement enhanced net northward directed transport by restricting sand movement within the entrance, effectively eliminating sand supply from the MCR to the offshore areas south and west of the Clatsop Spit. Although sand supplied to the shoreface south of the south jetty was blocked once the south jetty was constructed, the erosive power of waves and currents continued to rework the shelf surface in this area, creating a large area of seafloor erosion that persists today (see Figs. 6 and 7). Most eroded sand from this area is transported north to the ebb shoal, eventually making its way to beaches and/or the shelf surface north of the MCR. Sediment deposition to the northwest off the ebb shoal is documented since 1926, and this result supports the findings of previous studies (e.g., Sternberg, 1986). Although south-directed transport has been associated with summer conditions, all regional geomorphic response data suggest that high-energy, northward-directed flow, characteristic of the winter season, controls net transport direction in the study area.

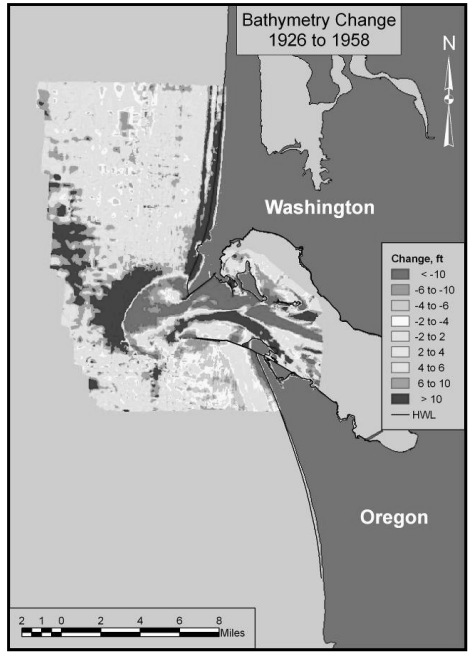

Fig. 6. Bathymetric change surface, 1926 to 1958. Bright red reflects maximum erosion, and dark blue reflects maximum deposition.

The period 1958 to 2003 was evaluated for estimating the net sediment budget and long-term sediment movement at and adjacent to the MCR. Channel dredging and offshore disposal of sediment were included in the analysis. Sediment input to the MCR from the estuary (4.0 Mcy/yr; about 30% sand and 70% fines) was estimated based on USACE dredging records for the lower estuary provided by Kaminsky et al. (2000) and Bisson et al. (2000). This quantity also is consistent with Columbia River sediment supply estimates provided by Sherwood et al., 1990; Gelfenbaum et al., 2001; and Buijsman et al., 2003 for the period 1958 to 1997. Furthermore, long-term bathymetric change from 1868/77 to 2003 indicates a sediment surplus of about 3.5 Mcy/yr. Longshore transport rate estimates for Clatsop Plains (1.0 Mcy/yr) and Long Beach Peninsula (1.5 Mcy/yr) were derived from Kaminsky et al. (2000) and through personal communications (Kaminsky, 2006). However, seasonal shifts in longshore transport do provide sand to beaches south of the entrance (Clatsop Plains) via south-directed transport. Onshore transport of sand via aeolian processes was estimated at 40,000 to 50,000 cy/yr based on the presence of extensive dune deposits along accreting beaches.

Fig. 8 illustrates the net sediment budget for the period 1958 to 2003. Polygon boundaries were based on erosion/accretion areas illustrated in Fig. 7. Volume change quantities shown in parentheses represent net annual change values as derived from erosion/accretion estimates based on bathymetric data comparisons. Sediment dredging (R) and placement (P) are documented for each change polygon. Sediment fluxes are associated with arrows and represent the estimated net quantity of sediment transported from one geomorphic area to another on an annualized basis (Mcy/yr).

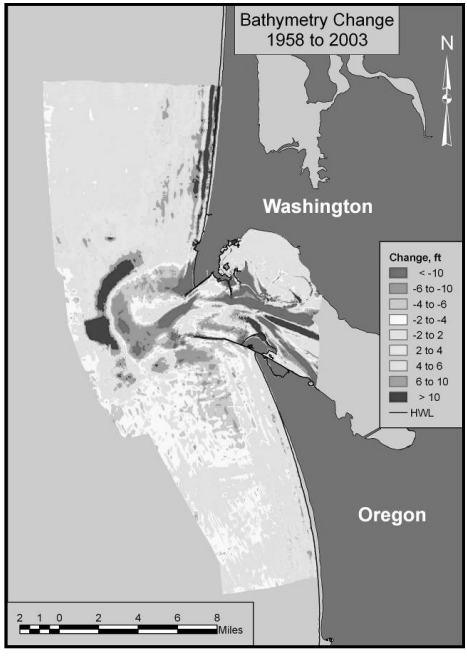

Fig. 7. Bathymetric change surface, 1958 to 2003. Bright red reflects maximum erosion, and dark blue reflects maximum deposition.

Substantial erosion took place in the entrance channel and offshore region seaward of Clatsop Spit over this 45 year period. Conversely, net deposition occurred in all areas north of the entrance channel area, again illustrating the net northward drift of sediment from the MCR (Fig. 8). Bakers Bay and the littoral zone of Clatsop Plains recorded minor amounts of net deposition. Significant quantities of sediment were transported from the channel, across the ebb shoal, and to the northwest onto the offshore shelf fronting Long Beach Peninsula. Sediment deposition along southern Clatsop Plains beaches indicates that seasonal south-directed and onshore transport may contribute to net deposition in this region. Net depositional trends throughout the study area are consistent with geomorphic changes recorded for the 1926 to 1958 period (Fig. 6), and with the findings of Barnes et al. (1972), Healy (1983), Nittrouer et al. (1979), Sternberg (1986), and Buijsman et al. (2003). Sediment flux to the northwest on the continental shelf was estimated at 2.2 Mcy/yr.

CONCLUSIONS

A regional analysis of shoreline and bathymetry change was completed to evaluate sediment transport dynamics associated with natural processes and engineering activities at the Columbia River entrance since 1868. Volume change estimates were derived to relate grouped cut and fill relationships with natural processes and engineering activities.

Four distinct depositional trends were identified. One, the modern ebb-tidal delta developed as a result of jetty construction. Currently, it resides approximately 2-mi seaward of the original shoal in about 90- to 130-ft water depth. The deposit contains about 411 Mcy of sediment, approximately half of which comes from the old ebb shoal. Two, the depocenter for sedimentation on the ebb shoal is to the north of the entrance centerline, and it migrates to the north with time. Three, northward-directed sediment transport from the entrance has resulted in net accretion along the shoreline and on the continental shelf seaward of Long Beach Peninsula. Four, erosion south of the south jetty is the result of sediment blocking by the jetty and subsequent transport toward the ebb shoal and onto the continental shelf.

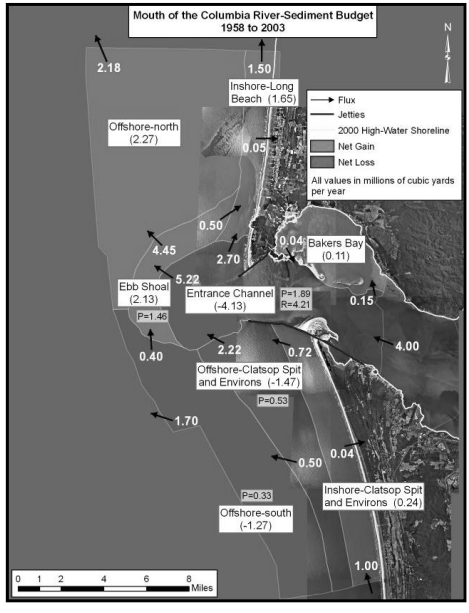

Fig. 8. Long-term sediment budget and net transport pathways for the MCR, 1958 to 2003.

The 1958 to 2003 sediment budget for the MCR reflects sediment movement from the entrance and along the continental shelf after construction and rehabilitation of the jetties. Although seasonal reversal in sediment transport are present, seafloor elevation differences between the 1958 and 2003 surfaces document a long-term flux of sediment from south to north from the MCR, the continental shelf, and coastal environments. Large quantities of sediment have been eroded from the entrance channel (about 4.13 Mcy/yr), transported in a north-northwest direction, and deposited along the beaches (1.65 Mcy/yr) and on the continental shelf (4.4 Mcy/yr). This pattern of change is similar for all time periods after jetty construction was completed.

ACKNOWLEDGEMENTS

Funding for this project was provided by the USACE Portland District under the Regional Sediment Management Demonstration Program. Special thanks to Ms. Doris McKillip (NWP) for RSM guidance early on in the project, to Ms. Jessica Baker for data compilation and analysis assistance, and to Ms. Liz Hunt (Applied Coastal) for technical and editorial assistance.

Abstract: Regional Sediment Management (RSM) is a systems-based approach for managing multiple projects involving sediment. RSM fosters balance between infrastructure and natural system processes, resulting in reduced project costs and achievement of greater benefits. This paper introduces the RSM concept and describes how RSM is being implemented at the Mouth of the Columbia River to sustain the inlet's 100-year old navigation infrastructure and adjacent shore lands. Implementing RSM at this energetic inlet involves feeding the inlet's morphology using dredged material, and letting nature do the work of dispersing the placed dredged material to supplement the inlet's sediment budget, without compromising the reliability of the navigation channel. The paper discusses the types of data that are being collected and analyzed to understand the environmental forcing affecting the inlet's morphology. The paper also addresses how dredged material disposal is being conducted to implement RSM.

INTRODUCTION

This paper summarizes the application of Regional Sediment Management (RSM) at the Mouth of the Columbia River and is composed of three parts. The Mouth of the Columbia River (MCR) is located on the Pacific Northwest Coast of the USA, at Long-Lat 124 W-45 N, between the states of Oregon and Washington (Figure 1). The forces of

nature can be very energetic at MCR, motivating significant yet complex trends in sediment transport. The MCR is also "energetic" in terms of the convergence of political-socio-economic forces that emerge when initiatives are proposed to improve the management of a critical non-renewable resource at the inlet – sand. This paper describes how RSM is being implemented to reconcile the "energies" of the inlet by leveraging management of the MCR maintenance dredging program to sustain the inlet's morphology and jetties; thereby ensuring stability of the MCR navigation channel.

Due to the intrinsic relevance of RSM for many types of water resource projects, the first part of this paper is devoted to describing the RSM concept. The physical attributes of Mouth of the Columbia River are also described, as the evolution of this deep-draft navigation project is related to the present sediment processes and management challenges. The second part of this paper describes recent pilot projects for dredged material placement and initiatives for collection/analysis, in context of the RSM demonstration program at MCR. Lessons learned from the RSM demonstration project at the Mouth of the Columbia River are outlined in the third part of the paper. http://www.nwp.usace.army.mil/op/n/projects/mcr/regionalsediment.asp

Regional Sediment Management

RSM is a programmatic approach employed to reduce the life-cycle costs of infrastructure affected by water-borne sediment transport. The RSM imperative is to adaptively manage infrastructure (projects) in terms of the extended time and space scales as defined by natural sediment processes. By broadening the "planning horizon" for projects and broadening the number of project proponents and funding partners, greater benefits and cost savings can be accrued. In other words, RSM seeks to manage project(s) in a two-way context of how the sediment processes and infrastructure interact within a given region. The "region" is defined by the spatial extent over which a continuum of sediment processes is applicable and may include multiple unrelated projects. Projects may include harbors, navigation channels, dredging actions, in-water structures (jetties, breakwaters, revetments), shoreline preservation, dams, flood control works, biological resources, habitat management, etc. The motivation for employing RSM is to collectively manage groups of possibly disparate projects by linking the projects to regionally continuous sediment processes affecting each project. Projects are linked to address a common sediment process so that the overall cost of managing a group of projects can be reduced or the costs shared among a larger group of beneficiaries, producing greater collective benefits for the region. Consider an example (hypothetical) case where a navigation channel requires annual dredging to maintain depth and the dredged material is normally placed in a disposal site which provides no benefit. An RSM initiative, brokered by an environmental advocacy group and partially funded by the property owner or resource organization, provides an opportunity to utilize the dredged sediment to create riparian habitat. The example RSM initiative provides added benefits of stabilizing an eroding river bank, preventing river channel migration, decreasing channel dredging, increasing biological productivity, and fostering a higher level of collaboration among resource stake-holders, property owners, and project proponents. In this example, consideration of the collective benefits associated with

riparian habitat creation provided the political motivation and financial resources to implement the RSM project.

The objective of implementing RSM is to reduce collective project costs, minimize environmental impacts, and achieve greater overall benefits within the affected region. On a technical basis, successful RSM implementation requires a firm understanding of the processes that drive the transport of sediment within a given region, the related morphological response due to such processes, and effects on infrastructure and the environment. Technical information serves as the basis for rational decision making regarding the proposition and assessment of RSM initiatives. As part of the RSM collaborative framework, technical information should be objectively vetted by peer review with results clearly communicated to project participants, managers, and decision makers. A challenging issue which may impede many RSM projects deals with demonstrating how RSM initiatives will not adversely affect the environment, especially living resources. Since it can be problematic to conclusively demonstrate no impact (i.e., to prove a negative), RSM initiatives may need to be considered/advocated using an adaptive management framework to minimize perceived risk to natural resources. On a socio-economic and political basis, RSM can not be successfully initiated without the active involvement of project proponents, participating levels of government, and stakeholders. The inclusion of project participants during all phases of RSM implementation can not be overemphasized. RSM takes place within the public realm, and all interested/affected parties must be consulted throughout the RSM planning and execution process. RSM is as much about building trust among project participants as it is about understanding the sediment processes affecting the projects of interest. Continual collaboration is an essential ingredient for successful RSM implementation. RSM fosters a balance between infrastructure, sedimentation processes, natural resources affected by sedimentation, and political-socio-economic constraints. Implementation of RSM at the Mouth of the Columbia River is an example where balance between these competing "forces" is being addressed to sustain deep draft navigation.

The Mouth of the Columbia River (MCR)

The MCR is a regionally critical coastal inlet located on the ecologically sensitive Pacific Northwest Coast of the US and is the ocean terminus for one of the largest rivers on the West Coast of North America. A system of convergent seacoast jetties was constructed during 1885-1939 to establish and retain the 8-km long MCR deep draft navigation channel, which passes between the states of Oregon and Washington (figure 1-2). The central project feature at MCR is the navigation channel. The MCR jetties now function in concert with the large tidal shoals to maintain the stability of the navigation channel. At present, more than 12,000 commercial vessels and 100,000 recreational or charter vessels navigate through the MCR annually, transporting $14 billion of U.S. products (48 million tons of cargo) to world markets. The existing authorized deep-draft navigation project at MCR provides for a 905-m wide channel across the Columbia River bar. The northerly 610 m of the channel is maintained at –17 m MLLW (plus 1.5 m for over dredging), and the southerly 195 m of the channel is maintained at –15 ft MLLW (plus 1.5 m for over dredging). Over-dredging is needed to

ensure that the deep-draft channel is passable during winter, when dredging is not possible. Due to its regional importance, the MCR channel must be fully maintained. The MCR plays an important role in the ecology and fisheries of the lower Columbia River and Pacific Northwest. Many of the salmon species that pass through the MCR are listed as endangered or threatened, while the bounty of other fish and shellfish species supports a regional economy based on the heritage of fishing. The regional economy associated with the MCR Dungeness crab fishery alone is estimated at $20 million annually, and there are numerous other commercial and recreational fisheries. Most crab fishing occurs north of the Columbia River mouth at depths ranging from 7 to 76 m. Management of MCR sediment (dredged material disposal activities) must address ecological and other impacts that may be associated with proposed actions.

http://www.nwp.usace.army.mil/op/n/projects/mcr/documents.asp

Dredging and Dredged Material Disposal at MCR

The MCR navigation channel has required periodic dredging to maintain the channel's authorized depth, since 1904. A programmatic approach for dredging the MCR channel began in the mid 1950s, after the channel was deepened to 15 m below MLLW. Presently, the U.S. Army Corps of Engineers (USACE) dredges 2.3 to 3.8 million cubic meters (Mm^3) of sediment per year at MCR to maintain the 8-km long deep draft navigation channel. The total unit cost of dredging the MCR channel normally ranges $2.00-$3.00 per m^3 dredged. Due to the severe wave conditions of fall-spring, maintenance dredging at MCR can only be performed by hopper dredges during the relative calm of summer (June- September, when waves at MCR are typically less than 3 m). Two hopper dredges are used at the MCR, operating 24 hr/day. The per load capacity of each hopper dredge varies between 1,900 to 4,200 m^3, requiring more than 1,000 load cycles to maintain the channel. The dredged material is classified as fine-medium marine sand (0.15-0.27 mm); fine-grained material content is less than 4%. The sand dredged from the MCR channel is placed within designated/permitted open water disposal sites by the hopper dredges. Since 1945, approximately 152 Mm^3 of sand have been dredged from the MCR channel; 60% has been placed in water depths less than 18 m. Placement of MCR dredged material normally occurs during dump-runs that cover a lineal distance of 300-1,000 m. Deposition of dredged material on the seabed, resulting from an individual dump, occurs as the negatively buoyant plume of material is released from the hopper dredge and encounters the seabed. The depositional thickness of an individual dump along the centroid axis can range 4 to 20 cm, for dredged material is placed in water depth of 15-20 m. MCR dredged material disposal sites are located within a finite distance from the dredging area to allow completion of maintenance dredging during a 3 month operational window. Typically, each hopper dredge will spend 0.75-1.5 hr to fill its hopper (actively dredge), 0.5 to 1.5 hr to transit to and return from the disposal site, and 3-12 min placing each load of dredged material within the disposal site. The minimum working depth for the hopper dredges used at MCR is about 10 m. There is little flexibility to significantly modify the disposal sequence of the hopper dredges, due to the scale and schedule constraints of the dredging-disposal operation at MCR. Even modest modifications to the dredging operation can impair completion of the project. For example, increasing the unit cost of MCR dredging disposal by $0.75/$m^3$ can cost the project an additional $2 million/year; funding that may

not be available. Increasing the time (30-60 min) to place each hopper load cycle to facilitate a "special" placement alternative could prevent completion of the annual MCR maintenance dredging program.

Existing MCR dredged material disposal sites are shown in Figure 2. Approximately 65% of all sand currently dredged at MCR is placed within the SWS area, 10% is placed within the NJS area, and 25% is placed within the DWS area. Dredged material placed within the NJS area is intended to protect the south side of the north jetty from severe foundation scour/undermining. Use of the SWS is intended to augment the littoral budget of Peacock Spit; to feed the littoral zone north of MCR and reduce the recession rate affecting the morphology along the north side of the inlet. Use of the DWS area is considered a wasting operation. The DWS is used as "a last resort," after the SWS and NJS have been used to their annual working capacity. Dredged sand placed within the DWS is rendered littorally inert, due to the water depth at the site (> 60 m). A primary goal for RSM at MCR is eliminate use of the DWS, by obtaining additional disposal sites (at locations acceptable to stakeholders) which can be used to place dredged material within the littoral zone north and south MCR. The BB site was used for a pilot study in 2002, when 33,000 m^3 was pumped ashore directly from a hopper dredge (USACE 2002) to evaluate the feasibility of inter-tidal disposal of MCR dredged material. The SJ Experimental Site was used in 2005 to assess the bottom deposition of dredged material placed using hopper dredges (6 loads totaling 23,000 m^3), in context of evaluating the placement of dredged material south of the MCR. Refer to the following document: http://www.nwp.usace.army.mil/op/n/projects/mcr/docs/reports/MCRSiteUsagePlan2006.pdf

The activity of placing 2.3 to 3.8 M m^3 of dredged sand within open water disposal sites at MCR has the potential to affect the environment or interfere with other uses of the inlet's coastal waters. Two primary issues of concern include dredged material harming benthic biota during dredged material disposal (as the placed sand impacts the seabed), and multiple placed loads dredged material coalescing into large mounds which may cause waves to shoal (amplify) or break. Placement of dredged material within the DWS (>60 m) or pump-ashore (inter-tidal disposal) options are favored by the fisheries resource stakeholders as opposed to nearshore disposal. The MCR project proponent (USACE) and state shoreline resource agencies normally advocate nearshore disposal due to the benefit derived from placing large quantities of dredged sand within the littoral zone to augment the coastal sediment budget. Tensions can arise between fisheries-resource stakeholders and the MCR project proponent when modifications or improvements for dredging disposal actions are proposed and evaluated. This means that dredged material "disposal" initiatives at MCR are subject to scrutiny and financial hardship; thus providing a motivating framework to employ RSM.

MCR PHYSICAL ENVIRONMENT - RELAVANCE TO RSM

The ocean entrance at MCR is characterized by large waves and strong currents interacting with spatially variable bathymetry. The Columbia River estuary is the largest fluvially dominated estuary in the Pacific Northwest and its tidal prism is about 1,140 km^2-m. Riverine discharge from the Columbia River is marked by a high seasonal

variability, typically ranging from summer-fall flows of 2,800 m^3/sec to spring freshets of 11,000 m^3/sec (under regulated flow conditions). Astronomical tides at MCR are mixed semi-diurnal with a diurnal range of 2.3 m. The average water depth through the throat of the MCR entrance is about 15 m, with local excursions to 34 m. During the peak of ebb tide, the combination of riverine and estuarine flow through the 3.3 km-wide wide entrance of MCR can produce surface and mid-depth currents greater than 3 m/sec and instantaneous flowrate that exceeds 51,000 m^3/sec; instantaneous flowrate during flood tide exceeds 28,000 m^3/sec. Sustained bottom current through the MCR channel can approach 1.5 m/sec. In coastal waters immediately adjacent to the MCR, the dynamics of the Columbia River plume exerts its influence, tending to draw (denser, 32 o/oo) bottom marine waters into the estuary while discharging low salinity (10 o/oo) estuarine/riverine plume waters at the surface. Between 80-90% of the total sediment through flow at MCR is composed of suspended sediment (silt and clay) and is transported throughout the continental shelf. Sand moving through the MCR is usually transported as bed load; sometimes as transient suspended sediment. The processes governing suspended sediment and bedload transport are based on completely different hydraulic regimes. Suspended sediment is subject to the whims of highly stratified circulation within MCR, while the bedload is governed by bottom current. If the bottom current regime can be reliably modeled, sand transport and morphological evolution within MCR and the nearshore coastal areas can be estimated; a goal of RSM at the MCR. Much of the sediment annually dredged from the MCR navigation channel is believed to originate from the morphology adjacent to the MCR channel. At present, approximately 10-25% of the sand sized sediment deposited within the MCR channel (and subsequently dredged) is believed to originate from the Columbia River estuary (USACE 1999).

The continental shelf break (300 m depth) lies within 30 km from the MCR. As waves propagate shoreward toward the MCR, the waves are modified (waves begin to shoal and refract) by the asymmetry of the MCR's underwater morphology. These modified currents interact with the shoaling waves to produce a complex and agitated wave environment within the MCR. The asymmetric configuration of the MCR and its morphology are characterized by the significant offshore extent of Peacock Spit on the north side of the North Jetty, southwesterly alignment of the north and south jetties and channel, and the absence of a large shoal on the south side of the MCR. Approximately 70% of all storm waves approaching the MCR are from the west-northwest (Moritz 2004). During winter storm conditions, the ocean offshore of the jettied river entrance is characterized by high swells approaching from the north-northwest to southwest combined with locally generated wind waves from the south to southwest. From October to April, average offshore wave height and period are 3 m and 12 sec. During the winter storm season, nearshore wave heights can range between 4 to 10 m with wave period of 12-22 sec. During storms, the nearshore waters at MCR can be subject to significant "stirring" to water depths of 35 m: Wind stress can produce sheet flow conditions where the current throughout the water column exceeds 80 cm/sec; storm waves can produce seabed orbital motion that exceeds 2 m/sec; and shoaling wave groups can produce infra-gravity motions resulting in a transient bottom current having amplitude exceeding 20 cm/sec (Moritz et al 2000, 2001, and 2006). These observations indicate that

significant annual littoral transport occurs deeper than 20 m along the coastal margin of MCR, and that dredged material placed inshore of 20-m depth will be littorally beneficial. From May to September, average offshore wave height and period are 1.5 m and 9 sec, and waves approach mostly from the west-northwest. Occasional summer storms produce waves approaching MCR from the south-southwest with wave heights of 2 to 4 m and wave periods of 7 to 12 sec.

Pre-Jetty Morphology: Baseline Condition

Historically, the Columbia River has been a major source of sediment to the NE Oregon and SW Washington state coasts (Gelfenbaum et al 2001). Estimates for the average annual rate of sand delivered through the MCR to the coast, prior to jetty construction, range from 1.4 to 2.6 Mm^3/year. Prior to jetty construction (1885), a broad system of unstable flood and ebb tidal shoals dominated the 8 km wide inlet at MCR. The seaward extent of the ebb tidal shoal (denoted by the 1885 12-m depth contour in Figure 3) was symmetric across the inlet, indicating that littoral transport was balanced in the north and south direction at MCR. Woxell (1999) had analyzed the evolution of shore lands 30 km north and south of the MCR inlet for the period of 3000 YBP-1800 AD and determined that the shoreline accretion rate of the coast north and south of MCR was approximately equal at 0.6 m/year (Figure 4). Figures 3 and 4 indicate that prior to jetty construction, sand discharged from the MCR was transported by littoral processes in equal proportion to adjacent coastal areas north and south sides of MCR. Given that the pre-jetty littoral transport rate of sand from MCR was distributed equally north and south of the inlet, there would have been 0.7 to 1.3 Mm^3/year of sand moving in both alongshore directions away from the MCR. This is an important pre-jetty baseline condition to acknowledge, especially if the goal of RSM at MCR is to emulate the longterm littoral trend at MCR. Consideration of this baseline condition fosters the RSM concept of "sustainability through balance."

Navigation Development at MCR and Morphological Response

During 1885-1939, three rubble mound jetties were constructed on massive tidal shoals of the MCR to stabilize the inlet, confine flow within a 3.3 km-wide entrance, and prevent encroachment of shoals into the engineered navigation channel. The initial 7.4-km section of the South Jetty was constructed to secure a 12-m channel across the MCR during 1885-1896, with a 3.9-km extension completed in 1914. The 4.1-km long North Jetty was constructed during 1914-1917 to reduce shoaling within the MCR channel. The 1.8 km long Jetty-A was constructed in 1939 to prevent migration of the navigation channel toward the North Jetty foundation. The phased construction of the MCR jetties resulted in a radical realignment of the inlet's tidal shoals, shifting the pre-jetty morphology of the MCR from a symmetric orientation to a highly asymmetric condition (Figure 3). MCR jetty construction facilitated the discharge of 300-600 Mm^3 of sand from the estuary to areas offshore MCR. The displaced sand was dispersed by waves/currents onto nearshore areas north and south of MCR. This huge pulse of sediment resulted in rapid landform accretion, as exhibited by the shore land response shown in figures 3-5. Figures 4-5 show that the post-jetty accretion rate of shoreland for area north and south of MCR was equivalent (at 2-4 m/year), and 4-5 times greater than

the pre-jetty accretion rate. Figure 5 shows that the shoreland accretion rate of the north side lagged the south side accretion rate by about 20 years (due to phased jetty construction). Collectively, these results indicate that littoral transport of sediment displaced by the jetties was similar (symmetric) for the north and south sides of MCR.

Between 1885 and 1919, the 12-m depth contour had migrated 3 km seaward on the north side of the inlet (forming Peacock Spit) while the opposite occurred along the inlet's south side. This north-south offset effect was due to the phased jetty construction (recall that the south jetty was constructed 20 years before the north jetty). Phased jetty construction enabled the ebb tidal shoal north of the south jetty to be discharged offshore and forced the opposite trend south of the south jetty, due in part to the south jetty cutting off the sediment supply to areas south of the MCR. The presence of the very long south jetty acts as a littoral boundary and has created a gyre-like circulation pattern which appears to have forced the ebb tidal shoal south of the jetty to migrate shoreward, as exhibited by the pronounced shoreland accretion (>5 km) of shoreland south of the south jetty.

After 1919, the 12-m depth contour on the north side of MCR began to recede landward as the newly formed morphology (Peacock Spit) was beginning to diffuse its sediment northward and westward, in response to the morphology's protruding orientation within the regional wave and local circulation patterns. The landward recession of the 12-m depth contour south of MCR has continued since completion of the south jetty; as described above (shown in figure 3). The present seabed south of MCR (at water depths of 10-18 m) is at an elevation several meters lower than the pre-jetty seabed as discussed in Kaminksy (2005), indicating that the present sediment budget south of MCR is deficient. The post-jetty sediment flux and circulation patterns differ significantly from north to south across the MCR (due to the post-jetty morphological orientation of the inlet). What may appear as a dominant south to north transport regime (or an apparent down drift offset) at MCR is really an inlet thrown out of equilibrium by a lagged response in post-jetty morphology development; motivated by phased jetty construction. The present northerly flux of sediment emanating from Peacock Spit has been estimated to be 2.3 – 3.8 Mm^3/year, which is 3 times the estimated pre-jetty northerly flux from MCR. The present southerly sediment flux from the MCR inlet appears to be close to zero, based on results from Gelfenbaum et al (2001) and Kaminsky (2005). Most of the sediment presently being supplied to the coastal area south of MCR (to Tillamook Head) appears to be sourced from cross-shore feeding. This implies that the south side of MCR is in a sediment deficit of 0.7 - 1.3 Mm^3/year, as compared to pre-jetty conditions.

Equilibrium Adjustments: Morphology Accretion Turns to Recession

MCR jetty construction produced a huge "pulse" of sediment which was discharged to the adjacent coastal areas; equivalent to several hundred years of "natural" deposition. This sediment pulse and the attendant morphology shift had thrown the littoral system of MCR out of balance. Now, the surplus of sand is beginning to run its course; the surplus is turning to deficit and energetic coastal processes are bringing the system back to equilibrium. Figures 6 and 7 illustrate the effect of recent morphology changes upon the

jetties and the region. The MCR post-jetty ebb tidal shoals have been a source of sediment to the coastal areas north and south of MCR. As sediment continues to be transported off the MCR tidal shoals, the shoals will continue to be diminished in size and the volume of sediment supplied to the littoral areas north & south of MCR will decrease. The shoreline in close proximity to MCR that was rapidly accreting immediately after jetty construction had begun to recede in the 1930s for areas south of the south jetty and in 1950s for area north of the north jetty. As the ebb tidal shoals change shape, nearshore waves and currents will change; adding to the rate and extent of sediment pulse diffusion and shoreline adjustment (recession). The 100-year old MCR rubblemound jetties were built on the inlet's flood and ebb tidal shoals. The shoals have protected the jetties from the full brunt of waves and currents, and the jetties-shoal composites have acted to confine ebb-flood currents within the active inlet and prevent encroachment of shoals in the navigation channel. Due to the present de-evolution of tidal shoals at MCR, the sand foundation of each jetty is receding. As the tidal shoals recede, the water depth near the jetties gets deeper, more vigorous waves batter the jetties, the foundation of jetties is scoured, and the jetties become unstable and unravel (Figure 6). The deterioration or sudden failure of a jetty can significantly impact the inlet's navigation function and the stability of adjacent shorelands.

MCR bathymetry change for 1958-2003 is shown in Figure 7 (Byrnes et al 2006). Note the changes occurring on Peacock Spit (north side of MCR), where a significant volume of sediment was transported northward and made available to the littoral budget of Washington; thus maintaining the accretionary condition north of North Head. However, Benson Beach (located just north of the North Jetty) experienced erosion as did the foundation of the north jetty along the seaward on-third of the structure. Augmentation of the littoral sediment budget immediately north of the north jetty is presently needed. The sediment budget along the south side of the north jetty has been sustained by dredged material placed at the NJS disposal area. Assuming that the north side of MCR may reach equilibrium after 60% of the present volume within Peacock Spit has been dispersed, it is estimated that the north side of MCR may sustain a decreasing accretionary condition for Washington shorelands for 20-40 years from present; by which time the MCR north jetty will have been seriously imperiled. Along the south side of MCR, there is no large accetionary feature to feed the nearshore. It appears that the nearshore south of MCR is feeding on itself, providing cross-shore transport to the shore lands south of MCR. The shorelands immediately adjacent to the south jetty are presently eroding as is the jetty foundation. Augmentation of the littoral sediment budget north and south of the south jetty is presently needed.

IMPLEMENTING RSM at MCR

The MCR is an energetic coastal inlet exhibiting very high potential rates for littoral sediment dispersal at nearshore areas north and south of the inlet (out to water depth of 20 m). Due to recent evolution of the morphology at the MCR inlet, the 100-year old MCR jetties are now susceptible to serious negative consequences arising from erosion of the ebb tidal shoals on which the jetties were built. As the morphology devolves, the supply of sediment to adjacent shorelands is reduced. RSM is being implemented to feed

the inlet's morphology using dredged material, and letting nature do the work of dispersing the placed dredged material to supplement the sediment budget of the inlet and adjacent nearshore coast, without compromising the reliability of the navigation channel or environmental resources. To do this, we need to understand the context of sediment flux for which we should target the RSM. This means that at a minimum we should emulate pre-jetty sediment delivery to coast south of MCR, to the extent possible emulate the present sediment delivery to the coast north of MCR; and to collectively do so with emphasis on supplementing present morphology essential for jetty stability.

In 2002, the MCR was selected by HQ USACE as a location to apply RSM in terms of a demonstration site. HQ provided limited funding, as "seed" money, to initiate a collaborative process with MCR stakeholders to plan and ultimately execute RSM actions. Additional funding and in-kind services from the Portland District and stakeholders provided the budget needed to implement several RSM pilot projects at MCR. There was also Congressional interest in RSM and funding was provided for studies on SW Washington Littoral Drift Restoration (BB) and Clatsop Spit (SJRS), South Jetty, Oregon. All of these pilot projects are discussed below. RSM Demo activities focused on: A) Hosting a series of mentored workshops to instruct MCR stakeholders on Collaborative Learning concepts, B) Collecting data to increase our understanding of how sand is transported at MCR and adjacent nearshore areas, and C) Initiating pilot scale disposal and monitoring actions to assess viability of alternative disposal sites for using MCR dredged material to augment the littoral sediment budget. An essential element of the RSM Demo at MCR was creation of multiple Cooperative Agreements between the Portland District and contributing RSM team members, allowing USACE to work efficiently/collaboratively with diverse groups. Nine RSM pilot projects, completed during 2002-2006, are summarized below and at: http://www.nwp.usace.army.mil/op/n/projects/mcr/docs/MortRSMupdate06.pdf

Bathymetry Data Collection: Collection and analysis of bathymetry data allows one to assess nearshore morphology change and infer littoral sediment transport, which is essential for implementing RSM at an energetic coastal inlet. Since 2002, the USGS and WDOE have been supporting USACE in monitoring the coastal nearshore areas north and south of the MCR inlet to document morphology change and related impacts (Ruggiero 2006). Results from this collaborative monitoring program have been very useful. A multi-beam bathymetric survey of the MCR inlet and adjacent nearshore areas (including the DWS and the SJ Exp. Site) was conducted concurrently with the Aug 2005 mega-transect experiment to provide detailed data for correlating bedform features with process measurements. Backscatter data from the multibeam survey was used to delineate the different sediment materials present on the bed, and allowed for the identification of dredged material in context of ambient seabed materials. Additional MB surveys were performed by Portland District during Aug 2006 to assess the foundation of the MCR jetties and evaluate bedform change within and outside the SWS disposal area.

GIS & Spatial Analysis: During 2003-2005, Applied Coastal Research and Engineering, Inc compiled shoreline and bathymetry data for the Portland District. Some 20 USACE

shoreline and bathymetric surveys of the MCR to be used for analyzing morphologic response to the jetties, channel migration and dredging, and dredged-material maintenance activities. The survey data are compiled in digital format (ArcGIS), for analyzing variations in sediment transport patterns at the Columbia River entrance (Byrnes and Griffee 2006). The compiled data provides valuable historical information on sediment transport pathways and quantities for addressing RSM.

Sediment Cores: A vibracoring project was implemented in September 2003, as supported by a cooperative agreement between the U.S. Army Corps of Engineers-Portland District and the Washington Department of Ecology (WDOE). The field work and core analyses were performed by WDOE to assess the suitability of the existing subsurface for supporting the jetties, and provide greater insights into the severity of erosion problems and the existing habitat that could be affected by dredged material placement operations. Results from the 11 vibracores (from the 7 sites) collected and analyzed under the RSM Demo were combined with previous coring studies to provide vital seafloor surface and subsurface sediment data used for estimating the sediment budget at MCR (Kaminsky and Ferland 2005). Each core was approximately 6 m long and was sufficient to make the assessments required.

ARGUS: As part of the RSM Demo at MCR, the Portland District deployed an ARGUS beach monitoring system (ABMS) to monitor shoreline changes in Peacock Spit response to various dredged material placement scenarios. The Portland District teamed Northwest Research Associated, Inc to install the ABMS within the North Head lighthouse in Feb 2004, where the system has been operational since. Successful ABMS installation was made possible by assistance from the US Coast Guard, WA State Parks, WDOE, ERDC-CHL, and Evans Hamilton, Inc. The ABMS is a video-based remote sensing metric system to monitor the evolution of submerged and emergent morphology on open-coast beaches (Oltman-Shay 2006). The purpose of the MCR ABMS is to cost-effectively monitor shoreline change at Benson Beach (3 km of shoreline between the North Jetty and North Head), and wave shoaling over the SWS dredged material disposal area, with high spatial and temporal resolution and quantify shoreline change with a high degree of accuracy. The ABMS deployment at North Head lighthouse needed to be flexible in terms of adding additional analysis capability and allowing for adjustments to the physical deployment of hardware. http://www.planetargus.com/north_head/

Mega-Transect: A data collection campaign to acquire prototype data describing the three-dimensional circulation within MCR was conducted by the Corps of Engineers, Moffatt-Nichol, Inc, Evans-Hamilton, Inc, US Geological Survey, and PI Engineering, LLP during August-September 2005. The "mega-transect" experiment was intended to improve the hydrodynamic understanding of the processes affecting sediment transport through the MCR and enhance our ability to manage the sediment resources within the inlet/estuary. Data collection consisted of detailed measurements for current profile, water level in terms of sub-surface pressure (short-and long-waves), near-bed suspended sediment, bottom current, and near-bed water conductivity-temperature. Acquisition of vertical profile data for water conductivity-temperature was also made. Data were

recorded concurrently at 5 locations spanning a 3-km transect across the MCR, during 6 Aug – 10 Sept 2005. The data are being used to describe the lateral and vertical variation in water circulation and sand transport through the MCR for the purpose of verifying conceptual (and computer) models for the flux of water and sand through the MCR. A report documenting the "mega-transect" data collection is in preparation.

Crab Burial Study: The USACE Portland District engaged with the Marine Sciences Laboratory of the U.S. Department of Energy's Pacific Northwest National Laboratory to investigate impacts on Dungeness crabs (Cancer Magister) resulting from impacts of dredged material disposal. Preliminary results based on numerical modeling and lab studies indicate that for burial greater than 10 cm, Dungeness crabs were unable to recover the respiratory pathway and switched to moving up through the sediment, a process that occurred over 24 hours. The observation that crabs can take some hours to emerge after burial suggests that multiple dumps over the same area would increase vulnerability. In most cases, the standard disposal practice is to not dump sequentially at the same location but to systematically spread the dumps over the whole of the disposal site (Pearson 2006).

Modeling: Having the ability to simulate/predict sediment transport and morphology change at MCR is an essential element for developing rational RSM-based decisions at the inlet. Portland District has supported a significant body of modeling work at MCR. Much progress has been accomplished by a host of collaborating groups using many types of models (ADCIRC, DELFT-3D, M2D/3D, MDFATE, STWAVE, SWAN, Bouss-2D). Applying multiple models aids in "comparative improvement" of each model and increases understanding of the processes affecting waves, circulation, and sediment transport. Participants included Portland District, NOAA's-Coastal Storm Initiative, ERDC-CHL, USGS, WDOE, OSU, and other. Recent results applying DELFT-3D to simulate the fate of dredged material placed at the SWS area appear most promising (Gelfenbaum et al 2005). Applicable models have benefited greatly from calibration studies using the "Mega-transect" data and will continue to be refined.

Benson Beach Pump-Ashore: Constraints dealing with disposal site capacity and potential impacts of using nearshore disposal sites have led to the perception that placing dredged material on Benson Beach may ameliorate dredged material disposal issues at MCR. As requested by Congress, the Portland District undertook efforts to examine the impacts/benefits of placing dredged material on Benson Beach; located on the southern-most shoreline of the State of Washington, adjacent to the MCR (BB in Figures 2,6,7). During July 2002, 33,000 m^3 of MCR dredged sand was placed on the inter-tidal area of Benson Beach using a hopper dredge (pumped ashore from the dredge at a unit cost of \$22/m^3, or 10 times greater than normal disposal practices). Monitoring activities were undertaken (by USACE, USGS, and WDOE) to assess operational, environmental, and economic effects of dredged material placement. After placement on Benson Beach, the placed dredged material was transported toward the North Jetty. Future placement of dredged material on Benson Beach may be warranted to protect the North Jetty from foundation scour, but the scale-economies of the operation must be further evaluated. More work is needed to evaluate the regional littoral benefit of Benson Beach dredged

material placement. For additional information Refer to: http://www.nwp.usace.army.mil/op/n/projects/mcr/docs/reports/bbreport.pdf

South Jetty Research Site (SJRS): In August 2003, Portland District tasked ERDC-CHL and Evans-Hamilton, Inc to measure oceanographic data 1.5 km south of the MCR south jetty in water depth of 16 m, in anticipation of assessing the viability of dredged material disposal at a location south of the south jetty (Moritz 2006). The data record spanned September –December 2003; included current profile, bottom current, short/long waves, and OBS-CTD; and was used to help motivate a Phase I of the South Jetty Research Sit (SJRS). SJRS-Phase I involved placing 6 discrete loads (each 3,800 m^3/load) of dredged material within the SJRS during 25 September 2005, to assess the physical "effect" of dredged material deposition on the seabed. Stakeholder and state regulatory interests were concerned about potential negative effects of placing dredged material within the nearshore south of MCR; a deposition threshold of 10 cm was selected as defining a minimal impact level for epibenthic fauna. A significant effort was expended by the Port of Astoria, Lower Columbia Solutions Group, and EPA to issue a research permit for the SJRS as a "research disposal site". Monitoring was performed using Sediment Profile Imaging, sediment sampling, and a multibeam survey (backscatter) to measure the thickness and areal extent of each disposal foot print. MDFATE model results had indicated that the maximum foot print thickness would be 10-15 cm (in 16 m water depth). Only the backscatter data from the SJRS multibeam survey could detect the rough areal extend of each deposited load. It was generally accepted by all stakeholders that the maximum thickness deposited on the SJRS seabed was less than 10 cm. SJRS-Phase II was conducted as a series of collaborative modeling tasks during 2006 to determine the feasibility of using MCR dredged material, deposited to form a large accretion feature (LAF), to protect the south jetty from storm wave action and augment the littoral budget south of the south jetty. Various "berm" geometries were evaluated using wave models for wave attenuation/impacts and several circulation models were applied to assess sediment transport off the LAF. Phase II was a highly successful collaboration between Oregon State University, USGS, ERDC-CHL, WDOE, nearshore stakeholders, and federal/state regulatory agencies. Phase II results are pending final reporting. The SJRS is of strategic importance to bring balance back to the MCR regional sediment budget. SJRS - Phase I results are described in: http://www.nwp.usace.army.mil/op/n/projects/mcr/regionalsediment.asp

Although proposals to increase the amount of dredged material placed within the nearshore (littoral zone, where depth is less than 60 ft depth) offer increased littoral benefit and add little burden to the dredging project, nearshore disposal of dredged material at MCR carries the liability of "potential impact" upon living resources within the nearshore benthos. Potential benthos impacts are related to the deposition dredged material on the seabed; burial or disruption of benthic infauna/epifauna. The challenge is to rationally align RSM objectives with the constraints governing maintenance dredging at MCR and the need to address potential environmental impacts associated nearshore dredged material disposal. The pilot projects executed through this RSM Demo program have significantly enhanced our understanding of sediment transport processes and effects associated with littoral dredged material disposal at MCR, and the RSM Demo has greatly improved working relationships between the Corps and various stakeholder

groups. The legacy of the RSM Demo at MCR is that the RSM approach will continue to thrive at MCR and will grow geographically to address wider regional issues dealing with sediment, infrastructure, and environmental resources.

CONCLUSIONS

Long term sustainability of navigation at MCR may be maintained, if dredged material can be used to supplement the sediment budget of the affected tidal shoals. This requires that MCR be viewed as a system of structural features and transient morphology that interact with the environmental forcing at the inlet to attain an ever changing "dynamic equilibrium". The imperative for sustainability at MCR is to employ RSM to manage the inlet in terms of extended time-space scales as defined by natural sediment processes. The key to successfully managing dredged material for effective augmentation of MCR morphology requires a reliable and detailed understanding littoral the sediment budget at the MCR.

The present morphological orientation and sediment transport at MCR is imbalanced, in terms of north and south sediment flux emanating from the inlet. The north side of MCR has a large, yet depleting source of littoral sediment contained in Peacock Spit while the south side of MCR has no appreciable sediment source. The asymmetry of the present post-jetty morphology at MCR does not serve as a good indicator of the net regional littoral transport direction. Based on the results presented herein, it appears that the potential littoral transport is equivalent for nearshore areas north and south of MCR

Existing MCR nearshore (littoral) disposal sites do not have the capacity to accept all disposal of the sand annually dredged from MCR, and there is no nearshore disposal site located south of the inlet. At present 0.6 to 1.1 Mm^3/yr of sand dredged from MCR is placed within the DWS, and represents lost opportunity for augmenting the littoral budget at MCR. As a region it is imperative that alternative disposal areas be located within the MCR littoral zone (north and south of the inlet) and fully utilized, to avoid placing any MCR dredged material within the DWS. If all MCR dredged material (2.3 to 3 Mm^3/yr) were to be placed within the nearshore areas north and south of MCR, the nearshore area south of MCR should receive a minimum of 0.7 to 1.3 Mm^3/yr, and the nearshore area north of MCR should receive 2.3 – 3.8 Mm^3/yr. Additional work is needed to resolve the optimal locations for RSM-based nearshore dredged material disposal sites.

Lessons Learned

When starting an RSM project, define clear objectives and do not over scope the region of interest. When an RSM study is first initiated, minimize the geographical limits of the region, and then expand outward as success grows the project. Strive to determine how the sediment system works within a given region and how infrastructure interacts with sediment. It is best to express known quantities in terms of statistical uncertainty. Visualization of data and concepts is paramount. Well prepared pictorial and graphical explanations for analyses and proposals significantly improve the communication of

RSM initiatives and increase likelihood of a forward progress. Some proactive RSM precepts include: Learn by doing; Sustainability thru balance; Understanding through collaborative learning.

Producing good science and engineering will not guarantee a successful RSM initiative. Collaborative learning by project proponents, stakeholders, regulators, and environmental constituencies is required through every phase of an RSM project to achieve a productive outcome. The "team" has to work together to gain an understanding of how the regional sediment system works, and work together to formulate RSM initiatives. Clear and open communication is paramount. A well crafted and executed monitoring plan (with follow-up contingency actions) can help reduce risks associated with implementing RSM initiatives. Resources and funding should be pooled and leveraged at every opportunity, to combat budgetary restrictions. Formalized cooperative agreements between various levels of government provide an excellent means to build positive working relationships, share resources, and provide contributing services toward RSM implementation. Opportunities should be sought to elicit the support of local universities/colleges on RSM activities.

Integration of all data relevant to a given RSM initiative is essential to gain balanced perspective on the many factors affecting sediment movement, infrastructure, and environmental response within a region. Collaborative learning can be achieved by a thoughtful review of exiting data; by performing a shared literature review. Fully exploit field data collection activities as team building and advertise the data to others in the region. Sharing resources to collect field data builds trust and elevates the outcome and utility of field data collection. In many cases, data are collected and analyzed for a specific purpose; whereas much more can be learned by "mining" the newly collected data for derivative information.

ACKNOWLEDGEMENTS

The authors are grateful for the support and contributions of resources made by their respective participating organizations. The authors thank Charley Chessnutt and Lynn Martin of the Corps of Engineers' Institute for Water Resources for their creative vision and sponsorship of the RSM Demo at MCR. RSM Demo program managers Julie Rosati, Ty Wamsley, Jack Davis, and Jeff Waters, of the Engineering Research and Development Center-Coastal and Hydraulics Lab, provided flexible and effective leadership.

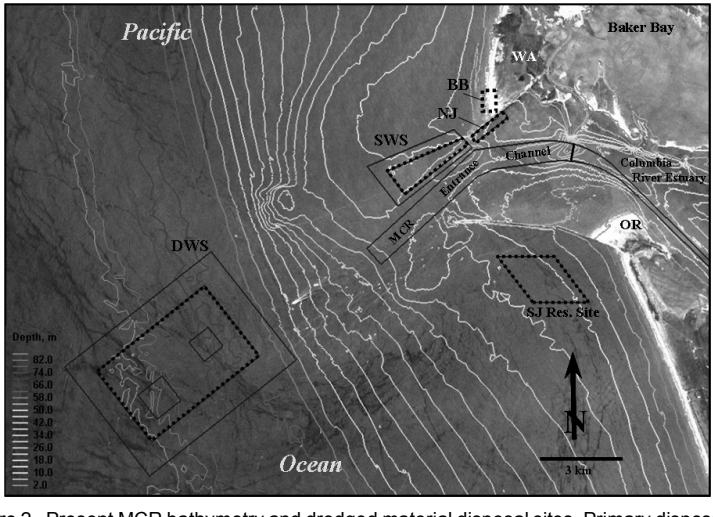

Figure 2. Present MCR bathymetry and dredged material disposal sites. Primary disposal sites are SWS, NJS, and DWS. Site BB is a shore placement area used in 2002 and requires that the hopper dredge to be "pumped ashore". The SJ Research Site is an area that may be used to enable littoral placement of dredged material south of the MCR inlet.

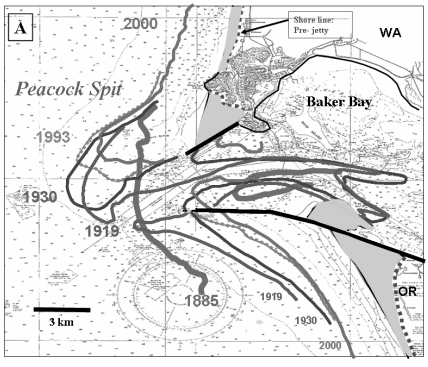

Figure 3. Evolution of the 40-ft depth contour at MCR during 1885 (pre-jetty) to 2000. Note the symmetric orientation of the 40 ft (12 m) contour prior to jetty construction indicating a balanced system of littoral transport north and south of the inlet. The shaded shoreline areas resulted in response to jetty construction. Refer to text concerning asymmetric alignment of the inlet in response to phased jetty construction.

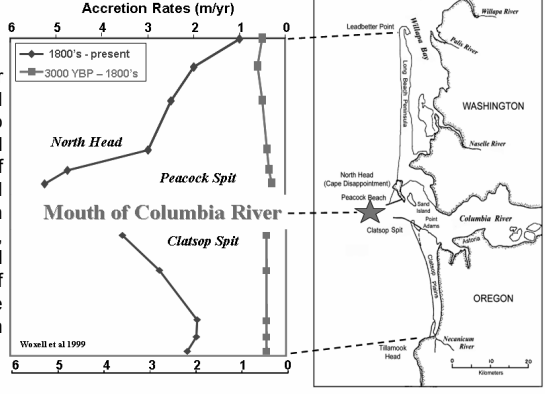

Figure 4. Accretion rates for pre-historical record and recent historical response to jetty construction (Woxell 1998). Note the symmetry of accretion rates north and south of the MCR for both time periods shown, indicating equal littoral transport north and south of the MCR. Alongshore distance shown is for 30 km north and south of MCR.

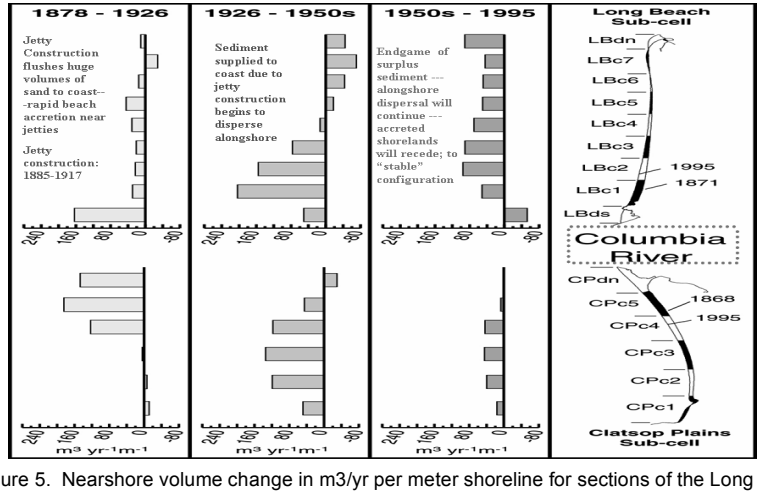

Figure 5. Nearshore volume change in m3/yr per meter shoreline for sections of the Long Beach Peninsula and Clatsop Plains. The alongshore lengths of the boxes are approximately 5 km (Gelfenbaum et al 2001).

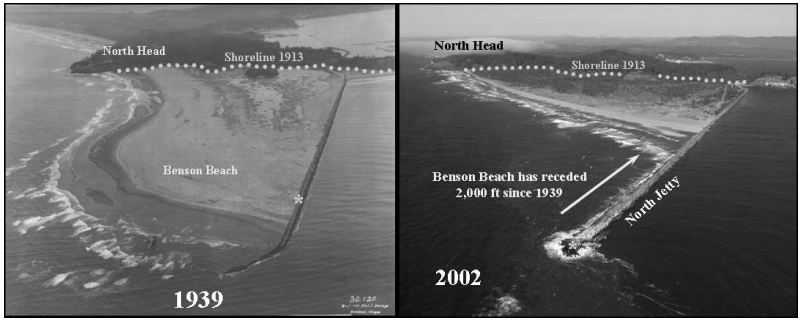

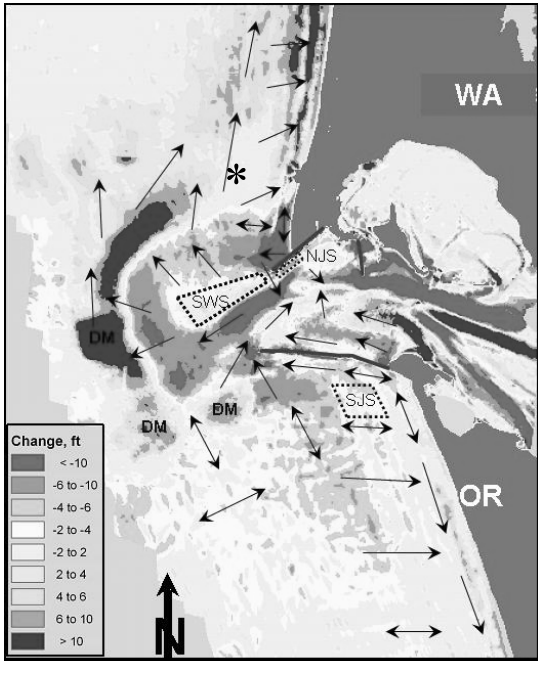

Figure 6. Left panel shows accretion of Benson Beach in 1939 in response to north jetty construction during 1914-1917. Note pre-jetty shoreline location. Right panel shows de-evolution of Benson Beach as of 2002. Benson Beach had receded 2,000 ft (660 m) landward from 1939 affecting the north jetty stability. North jetty has receded landward by 460 m. An Argus BMS has been installed within the North Head light house to monitor the morphodynamics of Benson Beach and its nearshore area.

The arrows indicate present sediment transport direction. Deposition is shown within the NJS. Use of the SWS appears to have significantly reduced the erosion rate on Peacock Spit. The material placed at SWS is moving to the north-northwest onto the spit and ultimately into the littoral zone of WA.

Figure 7. MCR bathymetry change during 1958-2003 (Byrnes and Griffee 2006), indicating the present day trend of bathy change and related sediment flux. Reds indicate erosion, blue deposition. The north side of MCR is dominated by bathymetry change on Peacock Spit. The nearshore area along Benson Beach has experienced significant erosion as manifest in figure 6. Excluding the SWS, the top of Peacock Spit has been eroding, with the eroded sediment being transported toward the west and north. Sediment transported to the seaward base of Peacock Spit is being fluxed along the base of the spit toward the nearshore of WA. Areas marked by DM indicate where dredged material had been previously placed. The area marked by (*) is believed to have large quantities of sediment fluxed

DECADAL EVOLUTION OF SHOREFACE GEOMETRY IN SOUTH CAROLINA, USA

Reynolds, B. M.[1], Wren, P.A.[2] and Gayes, P.T.[3]

3. Center for Marine & Wetland Studies, Coastal Carolina Univ. Conway, SC 29526 ptgayes@coastal.edu

Abstract: A long-term statewide beach surveying program in South Carolina has compiled a substantial record of beach and shoreface geometry across a region of diverse hydrodynamic and geologic framework. Initiated to support statewide beachfront regulatory obligations, the accumulated time-series has also afforded long-term monitoring of several beach nourishment projects and record of evolution of profile geometry in areas progressively interfacing with coastal development as well as relatively undisturbed systems on a decadal scale.

Work to date has focused on the influence of underlying geologic framework on profile geometry and variability. In sediment starved areas of South Carolina's Grand Strand, profile geometry is often better defined as a series of linear segments rather than a smooth concave up form. The breaks in slope frequently reflect stratigraphic changes observed in nearshore geophysical records and cores collected in the lower beachface. The time series documents 13+ years of behavior, revealing decadal-scale changes across the full active shoreface. These changes are relevant to consideration of long term coastal evolution.

Estimates of shoreline change have traditionally been defined by change in subaerial features or datums such as the wet-dry line defined on aerial photos or Mean High Water (MHW) contour. Across the state, and much of the nation's shoreline, these features are progressively encroaching on development and are being influenced by "hard" and "soft" erosion protection strategies. In practice, some sections of the South Carolina coast have been defined as stable (zero long term erosion rates) as the subaerial shoreline features have been artificially stabilized. These same areas continue to require beach nourishment and other engineering efforts to maintain beach volume and function. Profiles across the shoreface over the past 13 years in several such locations show evidence of continued migration of the lower shoreface. The resulting steepening of the

beachface may be expected to modify prevailing hydrodynamics and sediment dispersal and demonstrate change in profile geometry on annual –decadal scales.

Efforts to predict long term coastal behavior are traditionally been based on some variation of the Bruun Rule, which presumes migration of persistent profile geometry in the face of rising sea level. Any approximation of persistent profile geometry requires the subaerial and shoreface systems to migrate uniformly at all depths. The decoupling of the upper beach system by modifications such as groins, seawalls, and beach nourishment from the mid-to lower-shoreface suggests that profile geometry for a site may evolve not only on annual time scales, but on decadal time scales as well. Additionally, at one location experiencing substantial expansion of coastal dune fields over the past 20 years, the shoreface has continued migrating landward also resulting in a net steepening of the nearshore.

Within the time series of shoreface profiles are glimpses of the incremental development of the marine unconformity surface characteristic of transgressing shorelines. The composite envelop of profile minima is locally expressed as a series of scarps into older underlying substrate with limited expression on the fair-weather sea floor. In some areas relief on the order of 0.5 meters exists which may become emergent during storm events and also influences processes and sediment dispersal.

Recent efforts towards modeling morphological behavior in predicting longer term coastal evolution have shown substrate slope influences transgression rates (Stolper et al, 2005). The growing database of actual behavior across the shoreface on decadal scales may provide important verification to developing models and investigating coastal behavior on time periods longer than single "events" but shorter than "geologic time scales" evidence on the inner shelf.

INTRODUCTION

Estimates of shoreline change are traditionally defined by change in subaerial features or datums such as the wet-dry line interpreted from aerial photos and MHW contour. Across South Carolina and much of the nation, the shoreline is progressively encroaching development and is being influenced by "hard" and "soft" erosion protection strategies. In practice, some sections of the South Carolina coast have been defined as stable (zero long term erosion rates) due to artificial stabilization of subaerial shoreline features. These same areas continue to require beach nourishment and other engineering efforts to maintain beach volume and function. The Beach Erosion Research and Monitoring program (BERM) at Coastal Carolina University was initiated in 1993 through support of government agencies to collect cross-shore beach profiles for the entire populated coast of South Carolina. The growing database of shore-perpendicular profiles that extend across the entire active shoreface system provide a better understanding of nearshore dynamics. In addition, the database is used to delineate the setback line for coastal property management (Bernstein et al. 2003, Gayes et. al. 2001). The 13 year time series of profile changes can now be utilized to understand coastal behavior over annual to decadal periods. Profile analysis may provide important verification to developing models.

Slope analysis of several locations demonstrates that uniform profile migration is not occurring. Persistent profile geometry requires uniform migration of the subaerial and shoreface systems at all depths. Instead, profiles show evidence of continued migration of the lower shoreface at several beach locations, despite management practices to stabilize the subaerial beach. This behavior results in decoupling of the upper and lower shoreface and can cause steepening of the beachface. Decoupling of upper and lower beach systems can occur due to 1) differential erosion/accretion of upper and lower shoreface systems, 2) stabilization of upper or lower systems through natural phenomena such as impedance by rocky substrate, and 3) stabilization of upper or lower systems through anthropogenic interactions such as the construction of a seawall or nourishment project. The apparent decoupling of the upper and lower beach systems suggest that profile geometry for a site evolves not only on annual time scales, but on decadal time scales as well.

STUDY AREA

Profiles from several South Carolina beaches were selected for this study. Sites selected include Waites Island, Surfside/Myrtle Beach, DeBordieu Island, and Folly Beach (Fig.1). Although each of these locations differs with respect to coastline orientation, sediment availability, coastal development, and coastal management practices, the long-term profiles at each location reveal similar shoreface behavior over the past decade.

DeBordieu Island, Surfside Beach and Waites Island are all located along the shores of Long Bay in northern South Carolina. Long Bay is bounded by Cape Fear, NC and Cape Romaine, SC and is classified as a sediment starved region due to the lack of local sediment supply (Gayes 2003). The Grand Strand, within Long Bay, is roughly 60 miles long and contains some of the longest uninterrupted stretches of beach along the US Atlantic coast (South Carolina Department of Parks, Recreation, & Tourism, 2004). South Carolina's Office of Coastal Resource Management (OCRM) calculated the 40 year annual erosion rates for Waites Island and DeBordieu Island to be 3.05m/yr and 3.29m/yr, respectively. Surfside Beach is described as stable, with yearly erosion rates close to 0 (OCRM 2006).

Waites Island, the northern most of the study areas, is located at the North Carolina – South Carolina border between Little River and Hog Inlets. Little River Inlet was stabilized by a jetty system in the early 1980's. Over the past 20 years, Waites Island has experienced substantial expansion of its coastal dune fields (OCRM 2006). Expansion of the upper shoreface due to natural causes is unique among the four beaches selected in this study. Prior to the construction of the jetty system, the established shoreline change rates for Waites Island were erosional between 4 and 10 ft yr^{-1}.

DeBordieu Island is a private beach located at the southern end of Long Bay between Pawleys Inlet and North Inlet. The central portion of the island is protected by a seawall which extends roughly from benchmarks 4130 to 4140 (Fig.1). South of this region the calculated long term erosion rates of the upper shoreface range from -8 to -12 ft yr^{-1}.

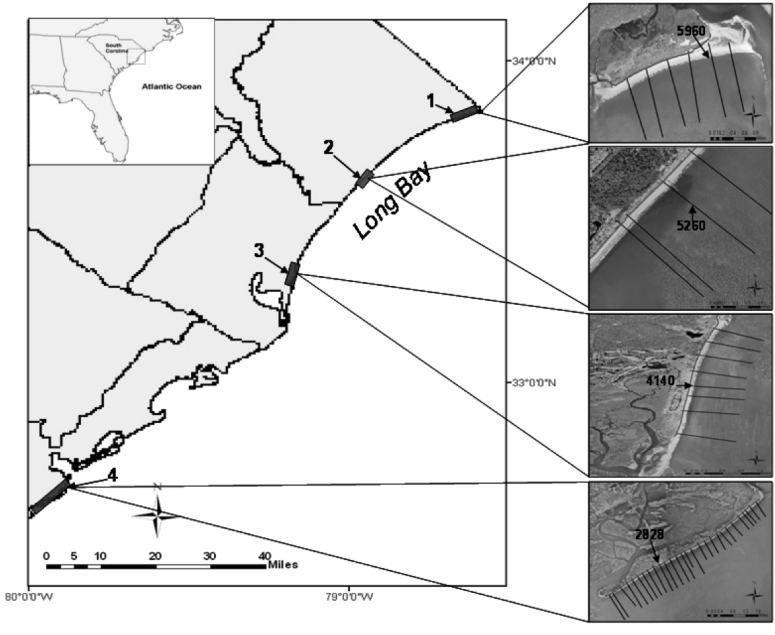

Fig. 1. Study Areas. 1) Waites Island 2) Myrtle Beach 3) DeBordieu Island 4) Folly Beach. Areas 1-3 are located on a stretch of beach known as the Grand Strand.

Benchmarks 4150-4180 are located north of the seawall in an area that is mostly undeveloped with extensive dune fields. This stretch of beach is said to be nearly stable with slight accretion possibly occurring (OCRM 2006). Extensive nourishment projects took place at DeBordieu in 1990, 1998 and 2006. In all three cases, the upper beach was nourished between benchmarks 4125 and 4160 where the majority of the development in the area is located. Due to DeBrodieu's nourishment history, shoreline change rates for the MHW contour were calculated between 1998 and present.

The section of beach between Surfside and Myrtle Beach State Park is one of the only areas in the Grand Strand that has not been nourished. Some sands from nourishment projects to the north and south, however, may have reached this area. Overall, this section of beach is considered stable (OCRM 2006).

Folly Beach is located just south of Charleston Harbor. Folly is characterized by many engineered structures including seawalls, groins, rock revetments, nearby jetties and several substantial nourishment projects. Two nourishment projects were captured by BERM surveys. The first of these large-scale projects took place between 1992 and 1993 and the second in the summer of 2005. Thus, shoreline

change rates were calculated between the1993 and 2005 nourishments. Variability of regional morphology and engineering structures, contributes to variable rates of shoreline change ranging from 8m yr^{-1} erosional to 0.35 m yr^{-1} accretion (Anders et al. 1990). The area known as "The Washout" is one of the most rapidly eroding areas on the Island. The localized, rapid erosion has been linked to the presence of an old paleo-channel (Gayes et al. 1998, Thieler et al. 1999). Therefore, elevated levels of erosion would be expected in this area. Folly is the only populated beach in South Carolina that does not have a jurisdictional setback line. South Carolina's OCRM determined that the jetties leading into Charleston Harbor have severely limited the sediment supply to the region.

METHODS

Profile Collection

Since in 1988, shore-perpendicular beach profiles extending seaward have been collected annually at approximately 400 benchmarks along the entire populated coast of South Carolina. Profiles extend from benchmarks to a pre-determined distance offshore, beyond the predicted depth of closure. Geographic coordinates of benchmarks are precisely known and provide consistent reference points for beach profile surveys. Throughout BERM, survey methods have evolved from the traditional rod-level and sled-based profilers to a GPS orientated system. Starting in 2001, Real Time Kinematic GPS surveys are preformed with sub-decimeter vertical accuracy. Survey methods from 1993 to present use the BERM system described in more detail in Bernstein et al. 2003 and Gayes et al. 2001. The BERM system consists of a boat mounted with an integrated fathometer and GPS system for offshore portions of profiles, and a backpack/ATV mounted GPS system for the subaerial portions of the survey.

Contours

Lack of persistence in profile geometry can be quantified by measuring changes in contour locations at a given benchmark through time. The MHW and a lower contour (LC) were selected as the two standard contours for shoreface migration rate assessment. The MHW contour is a function of the local tide range and mean tide level, and is often used to define shoreline location (List 2006, USGS 2005, Sallenger et al. 2003, Stockdon et al. 2002). MHW contour locations were calculated throughout the study area from National Oceanic and Atmospheric Administration (NOAA) tide station data. Calculated values for each of the four regions was found to be approximately 1.50 ft relative to the NAVD 88 tidal datum.

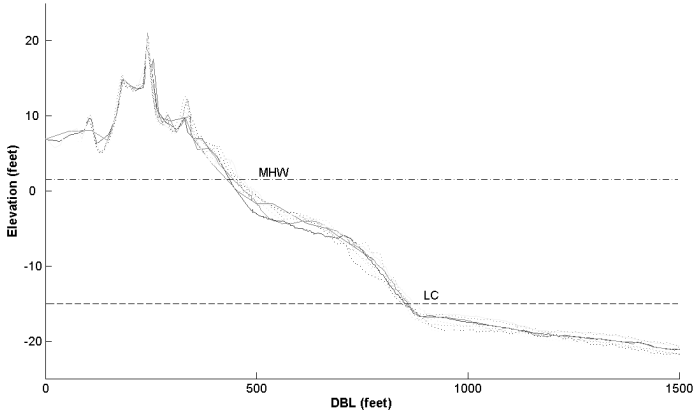

Fig. 2. Example of selected elevation contours

A second contour elevation was picked in order to determine migration rates on the lower shoreface. A contour elevation was selected where non-breaking wave energy prevails (Larson 1999). The LC was selected by visual inspection of profiles at each benchmark. An elevation below the apparent seasonal variations and immediately above the inflection point marking the transition onto the inner-shelf was selected for each benchmark (Fig. 2). The LC is assumed to be unaffected by daily and seasonal wave-driven bar activity. Similarly, the 7ft contour line was used to calculate dune migration rates at Waites Island. This contour intersects the face of the primary dune at all benchmarks throughout the study period.

At each benchmark, the migration rates of the MHW contour and the LC were calculated. Regression analysis was used to get a linear trend-line for each contour over the appropriate sampling interval. A positive value denotes seaward migration, and a landward migration rate is denoted by negative values. The determined migration rates of the subaerial and lower shoreface systems indicate whether a uniform migration of the profile is occurring. If decoupling of the MHW contour and the LC occur, a change in shoreface slope will result.

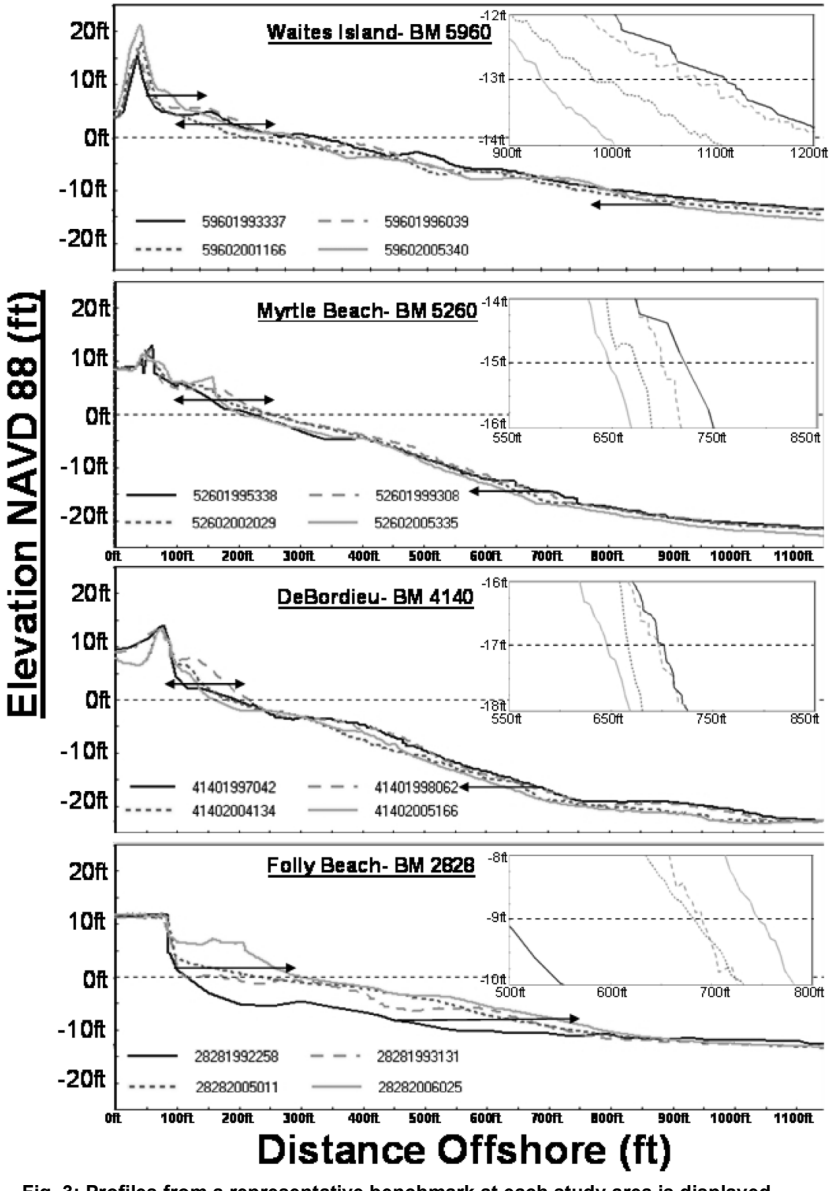

Fig. 3: Profiles from a representative benchmark at each study area is displayed. Insets show migration of the LC. Scales for each cross-section are equivalent.

RESULTS

Waites Island

MHW contours at benchmarks 5945, 5930 and 5915 are migrating seaward at a rate of 5.73-11.22 ft yr^{-1} while the MHW contour at benchmark 5960 is migrating landward at a rate of 2.98 ft yr^{-1}. Surveys at all benchmarks indicate that the coastal dune field has accreted at a rate of 3.00-12.79 ft yr^{-1}, while the LC has been retreating landward at a rate of 3.00-16.60 ft yr^{-1} (Table 1). The data indicate that steepening is in fact occurring at Waites Island which suggest that a non-uniform profile migration may occur naturally as well as due to anthropogenic influences.

Table 1: Waites Island Summary

Waites Island				
Benchmark	**5915**	**5930**	**5945**	**5960**
Lower contour (LC)	-15	-15	-14	-13
LC rate of Δ (ft yr-1)	-3.5	-3	-5.03	-16.6
LC R^2	0.843	0.812	0.841	0.742
MHW rate of Δ (ft yr-1)	11.22	8.65	5.73	-2.98
MHW R^2	0.875	0.713	0.424	0.369
Dune Elevation	7	7	7	7
Dune rate of Δ (ft yr-1)	12.79	8.08	9.74	3
Dune R^2	0.823	0.812	0.841	0.742

Myrtle Beach State Park

MHW contours at benchmarks 5250, 5260 and 5270 are migrating seaward at a rate of 1.56-1.95 ft yr^{-1}. The LC for each of the benchmarks is migrating landward at a rate of 2.45-4.50 ft yr^{-1}. The R^2 values for the MHW contours are rather low and range from .124-.172 while the R^2 values for the LC range from .682-.733 (Table 2). All three benchmarks from this beach demonstrate the same general trend of the lower shoreface eroding while the upper shoreface appears to be rather stable.

Table 2: Myrtle Beach State Park Summary

Myrtle Beach State Park			
Benchmark	**5250**	**5260**	**5270**
Lower contour (LC)	-17	-15	-15
LC rate of Δ (ft yr-1)	-2.45	-4.50	-3.87
LC R^2	0.682	0.733	0.722
MHW rate of Δ (ft yr-1)	1.95	1.56	1.68
MHW R^2	0.172	0.143	0.124

DeBordieu Island

MHW contours at benchmarks 4125, 4130, 4140 and 4150 are migrating landward at a rate of 4.76-17.87 ft yr^{-1}, while the MHW contour at benchmark 4160 is migrating seaward at a rate of 1.91 ft yr^{-1}. The LC at benchmarks 4125, 4130, 4140 and 4160 are migrating landward at a rate of 1.16-24.45 ft yr^{-1} while benchmark 5960 is migrating seaward at a rate of .82 ft yr^{-1} (Table 3). Benchmark 4140 is located at the

northern end of a seawall and is described as being the pivot point of the island. To the south, the upper shoreface is eroding, and to the north, the upper shoreface is stable or accreting (table 3) (OCRM 2006). Benchmark 4130, located at the southern end of the seawall, exhibits the highest rates of landward migration for both the LC and MHW contours of the selected profiles. Benchmark 4125, located just down the beach to the south of benchmark 4130, has "the next highest" rates of erosion.

Table 3: DeBordieu Island Summary

DeBordieu Island					
Benchmark	**4125**	**4130**	**4140**	**4150**	**4160**
Lower contour (LC)	-12	-12	-17	-14	-15
LC rate of Δ (ft yr-1)	-12.21	-24.45	-4.50	0.82	-1.16
LC R^2	0.897	0.823	0.607	0.009	0.156
MHW rate of Δ (ft yr-1)	-16.85	-17.87	-9.58	-4.76	1.91
MHW R^2	0.893	0.490	0.853	0.419	0.144

Folly Beach

MHW contours at benchmarks 2828 and 2830 are migrating seaward at rates of 1.83 and 1.45 ft yr^{-1}, respectively. However, MHW contours at benchmarks 2843 and 2863 are migrating landward at rates of 1.72 and 3.82 ft yr^{-1}, respectively. LCs at benchmarks 2828, 2843 and 2863 are migrating landward at a rate of 0.76-7.01 ft yr^{-1} while benchmark 2830 is migrating seaward at a rate of 0.78 ft yr^{-1} (Table 4).

Table 4: Folly Beach Summary

Folly Beach				
Benchmark	**2828**	**2830**	**2843**	**2863**
Lower contour (LC)	-9	-9	-9	-10
LC rate of Δ (ft yr-1)	-0.76	0.78	-1.97	-7.01
LC R^2	0.008	0.006	0.056	0.568
MHW rate of Δ (ft yr-1)	1.83	1.45	-1.72	-3.82
MHW R^2	0.075	0.101	0.087	0.222

DISCUSSION

Although none of the beaches monitored by BERM are truly pristine and free from the affects of human modification, Waites Island is close to a natural state. The rate of seaward dune migration relative to the lower shoreface is quite substantial at benchmarks 5945, 5930 and 5915. This process alone leads to an increased slope in profile geometry. At benchmark 5960, the MHW and dune contours are migrating at -2.98 and +3.00 ft yr^{-1}, respectively. This trend is quite different from the trend seen at the other three benchmarks, and is likely a result of closer proximity to the Little River jetties. Despite the lack of significant seaward accretion taking place at benchmark 5960 in the upper shoreface, the LC is moving landward at a rate much higher than is seen at the other three benchmarks. Accretion of aeolian-deposited subaerial features suggests an abundant sediment supply at this location, which is atypical along the Grand Strand and is most likely to inlet dynamics as well. The processes occurring at all benchmarks result in a net steepening of the shoreface.

Benchmarks located in the area of Myrtle Beach State Park demonstrate a continued shoreward migration of the lower shoreface. The seafloor in this region has been characterized as hard-ground based on side-scan sonar records (Gayes, P.T. and Donovan Ealy, et al., 1996). Differential rates of erosion are expected for the different types of substrates (i.e. loose sand or compacted-sand/hard-bottoms). Loose sands erode more easily than compacted or lithified sands; however, this is not what is observed. The lower shoreface, composed of compacted sediments is migrating shoreward while the upper shoreface, composed of loose sediments, is holding stable. Sands from adjacent nourishment projects in nearby Myrtle Beach and Surfside Beach have likely bled into this region and may influence the irregular trend at the MHW contour (Table 2).

DeBordieu Island, the southern most of the three study sites selected within Long Bay, also demonstrates a lower shoreface erosion rate exceeding those of the upper shoreface. Historic shorelines from 1872 to 1962 indicate that North Inlet is migrating to the south. Processes associated with the southward migration of North Inlet are likely contributing to elevated levels of erosion at the southern end of DeBordieu Island. Historic shorelines indicate North Inlet was located approximately one mile north of its present location.

Folly Beach, located just south of Charleston Harbor, is complicated by an extensive nourishment history, inlets, and engineered structures. Profile evolution at benchmark 2828 suggests that the system has been "flooded" with sand and remains stable between nourishment projects (Fig. 3). Benchmark 2830, .320m north along the seawall shows the same trend as benchmark 2828. The seaward migration of both the LC and MHW contours is consistent through the seawall area (benchmarks 2828 and 2830) (Fig. 3). Benchmark 2863, located in a paleo-channel (Gayes et al. 1998, Thieler et al. 1999), shows LC retreat at a higher rate than the surrounding benchmarks. It is, however, consistent with migration rates at the other study sites. Large and rapid changes in contour locations in this area may be influenced by excessive use of engineered structures.

CONCLUSION

Measurements of MHW and LC locations through time demonstrate that uniform profile migration is not occurring. Traditionally, engineering design and coastal zone management strategies for protecting our nation's shorelines have focused extensively on the upper shoreface and subaerial beach. Despite efforts to preserve South Carolina's beaches through stabilization and nourishment of the upper shoreface, the natural rate of shoreline migration still occurs which can result in an overall net steepening of the shoreface. Implications of a steepened shoreface include modification of prevailing hydrodynamic and sediment dispersal patterns. Future nourishment and hard structure efforts may be limited due to lack of funds and shoreline management policies. Accelerated levels of erosion will then occur as the steepened shoreface returns to an equilibrium shape. While these results strongly suggest changes in profile geometry on annual to decadal time scales, methodology must continually be refined to better understand and quantify shoreface migration.

ACKNOWLEDGEMENTS
This is a contribution of the SC Coastal Erosion Study. Funding for BERM program was provided through the US Geological Survey, the South Carolina Sea Grant Consortium, the South Carolina Department of Health and Environmental Control-Office of Ocean and Coastal Resource Management, the US Army Corp. of Engineers-Charleston District, Horry County and the City of North Myrtle Beach. We also like to thank Dr. Rich Viso for his scrupulous review of this manuscript.

Abstract: We evaluate three classes of shoreline change rate methods on all sandy beaches of Maui: 1) methods that estimate shoreline change transect by transect, 2) methods that combine data from all transects to estimate shoreline change, and 3) extensions of (2) that include acceleration. Using these, we compare 50 yr hazard zones from beaches exposed to different conditions, natural beaches versus altered beaches, and well-defined littoral cells versus open systems. Acceleration methods fit the data well, but don't predict the erosion hazard zone well. Altered beaches and open system beaches are better fit by methods with acceleration at a higher proportion than natural or pocket beaches. The traditional transect by transect method that calculates shoreline change at discrete points along a beach never qualifies as the best fit model.

INTRODUCTION

Historical shorelines are commonly extracted from aerial photographs and NOAA topographic surveys (T-sheets). They are generally limited and spaced unevenly through time. Currently the most common shoreline change method is the single-transect (S-T) method. S-T uses data from individual shore-normal transects to calculate shoreline change rates. As there are only 5-10 shorelines at each transect, the resulting rates are often uncertain. The equation for S-T at each transect is:

$$y_j - \bar{y} = (t_j - \bar{t})r + n_j \quad (1)$$

where y_j is the shoreline position at time t_j, $\bar{y}$ is the baseline, $\bar{t}$ is the time origin, r is the change rate, and n_j is the noise. As the baseline has been chosen to give a zero intercept, there are effectively two model parameters for each transect. For a beach with I transects, the S-T method requires $2I$ parameters.

Genz et *al*. (in press) recently introduced binning (hereinafter, T-binning) as a new method that improves the significance of fit and lowers uncertainties. T-binning combines transects with rates that are insignificantly different and calculates one rate for each bin. Grouping transects requires heavy user input that can bias results. Frazer et *al*. (in review) improve on T-binning by removing user input. Called A-binning, transects are binned using the corrected Akaike Information Criterion (AICc) to identify best groupings. However, computation-time increases rapidly with the number of bins. In both T-binning and A-binning, change rate is discontinuous at bin boundaries.

Frazer et *al*. (in review) also introduced the PX method (think: polynomial in x), an alternative to binning and single-transect that makes change rate continuous along a beach. The PX method fits transect measurements to the following equation,

$$y_{ij} - \bar{y}_i = \sum_{k_0=0}^{K_0} \alpha_{k_0}^{(0)} P_{k_0}(z(x_i)) + (t_j - \bar{t}) \sum_{k_1=0}^{K_1} \alpha_{k_1}^{(1)} P_{k_1}(z(x_i)) + n_{ij} \quad (2)$$

in which $\bar{y}_i$ is the baseline at transect i, the x_i are the transect locations, $z(x)$ is a mapping from alongshore distance to the interval [-1,1], the $P_k(z)$ are basis functions (e.g., Legendre polynomials), the α_k are coefficients, and n_{ij} is noise. A well chosen baseline causes all the coefficients in the first sum to vanish, hence the number of parameters in the model is $I + K_1$, where I is the number of transects.

After the coefficients have been found, the second sum on the right hand side of equation (2) gives the change rate of the beach at time $\bar{t}$. Frazer et *al*. (in review) suggested three types of basis functions for use in PX, denoting PX by LX when Legendre polynomials are used, by RX when trigonometric functions are used, and by EX when empirical orthogonal functions of the beach data are used (Table 1). The motivation for EX is that, if the beach physics can be represented by a linear system, the beach at any instant in time must be a linear sum of the eigenfunctions of a linear operator.

To allow for a rate that changes with time, the right hand side of equation (2) can be augmented with an acceleration term,

$$\frac{(t_j - \bar{t})^2}{2} \sum_{k_2=0}^{K_2} \alpha_{k_2}^{(2)} P_{k_2}(z(x_i)) \quad . \quad (3)$$

If the acceleration term is present, the PX method is referred to as PXT, since the rate is changing with time. Similar to PX, PXT is divided into three methods according to their basis functions – LXT, RXT, and EXT (Table 1). Genz et *al*. (in review) compared PXT to other methods and found PXT to be more erratic in predicting known positions.

Table 1. Description of Methods

Method	Basis Functions	Acceleration?
S-T	---	no
LX	Legendre polynomial	no
RX	Trigonometric functions	no
EX	Eigenvector of beach data	no
LXT	Legendre polynomial	yes
RXT	Trigonometric functions	yes
EXT	Eigenvector of beach data	yes

In the expressions above, the upper limits K_1 and K_2 can be as large as the number of transects I, so there are I possible PX models and I^2 possible PXT models. Of interest here is the fact that if lower order basis functions are selectively included or omitted, the number of possible PX models increases to 2^I, and the number of possible PXT models increases to 2^{2I}. By testing all combinations, a better-fit model may be obtained. In this paper we use synthetic data to investigate the omission of lower-order terms.

Fletcher et *al*. (2003) calculated shoreline change using S-T for all sandy beaches of Maui. They used Reweighted Least Squares (RLS) to determine shoreline change at each transect. We also calculate shoreline change on all sandy beaches of Maui by predicting the 50-yr hazard zone. We compare S-T, LX, RX, EX, LXT, RXT, and EXT. Our study is motivated by the assumption that when different models predict similar hazard zones, the predicted hazard zones are more reliable.

EXCLUSION OF LOWER-ORDER TERMS IN PX AND PXT

If lower order terms in equations (2) and (3) can be selectively omitted, comparing the AICc score of all possible PX and PXT models is impractical. For example, if there are 25 transects on a beach, all possible PX models would equal 2^{25}, or 33,554,432. All possible PXT models would equal $2^{(2*25)}$, or 1.13×10^{15}. At present, computers are too slow to calculate every possible combination in a timely manner, so usually we do not calculate all possible combinations for PX and PXT; we include all lower-order terms basis functions when calculating higher order polynomials. However, Genz et *al*. (in review) show inconsistent hazard predictions using PXT. This leads us to investigate whether the exclusion of lower-order terms might improve the 50 yr hazard prediction. One way to test a large number of models is by using genetic algorithms (GA). Goldberg (1989) has an excellent explanation of GAs, which we briefly summarize: As the name indicates, genetic algorithms are based on biological ideas of natural selection. Any GA begins with a population of models, coded as strings; each string can be thought of as an individual organism with a single chromosome, and each parameter in the model can be thought of as a gene. Each string has a "fitness" based on how well it fits the data. Fitter strings are passed on to the next generation; thus, each generation evolves from the previous generation, and the best-fit string(s) are found after many generations. In our

application, each string is a binary number with number of bits equal to the number of possible basis functions in the model. Each bit corresponds to a particular basis function. If the first bit is a zero (one) the lowest order basis function is excluded (included) in the model, and so forth. The fitness value of a string is the fitness of the best-fit model with the permitted basis functions.

Each generation is produced by *selection*, *crossover*, and *mutation* of the previous population. Selection is based on the fitness function; a string with higher fitness function has a better chance of being selected. Crossover occurs between pairs of strings that have undergone selection. Each pair is cut at the same location and string segments are swapped to make a new pair. The final, and less important, operation is mutation, whereby the value at each location on a string has a very low probability of being switched from zero to one or vice-versa.

In the shoreline scenario of a beach with 25 transects, we use a Matlab GA to determine the optimal combination of terms for both PX and PXT. In an initial generation with a population size of 100, there are 100 strings, each with a different combination of coefficient terms. The fitness function is the negated AICc score. By specifying the number of generations and acceptable tolerance limits, we can efficiently identify the combination of coefficient terms. Figure 1 is an example of output from a GA in MATLAB.

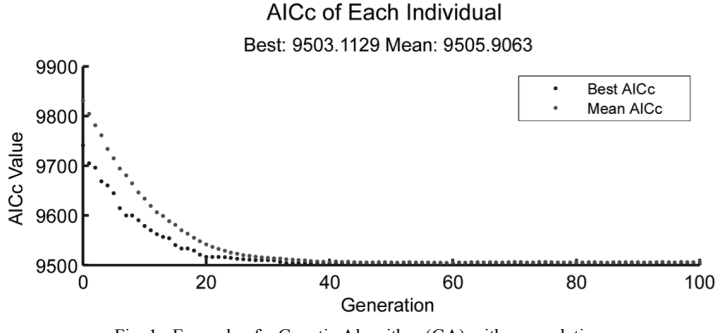

Fig. 1. Example of a Genetic Algorithm (GA) with a population size=100 and a limit of 100 generations.

MAUI SETTING

The sandy beaches of Maui Island form three regions: Kihei, West Maui, and North Shore (Figure 2). Each region is exposed to different wind and wave regimes (Fletcher et *al.,* 2003; Rooney et *al.,* 2003). Kihei is protected by the islands of Molokai, Lanai, Kahoolawe and is subjected to refracted North Pacific swell, south swell, and Kona storm waves (Rooney and Fletcher 2005). Kona is a low-pressure system that creates winds and waves from the south. West Maui is affected by North Pacific swell, Kona storms and south swell (Eversole and Fletcher 2003). The North Shore is strongly affected by

the north swell, and tradewind waves (Fletcher et *al.,* 2003; Makai Ocean Engineering and Sea Engineering 1991; Rooney et *al.,* 2003).

Each beach is classified into one of five categories, based on whether the beach has hardened structures (Table 2). The first classification includes beaches with hardened structures where no backshore fronts the structures. These beaches are severely impacted. If enough shoreline data exists, then only post-hardened shorelines are used to predict the 50 yr hazard zone. If shoreline data are sparse, then pre-hardened shorelines are used to identify beach change without predicting the 50-year hazard zone. Including both pre- and post-hardened shorelines in an analysis violates the underlying assumption of the change rate methods, which is that beach physics are constant.

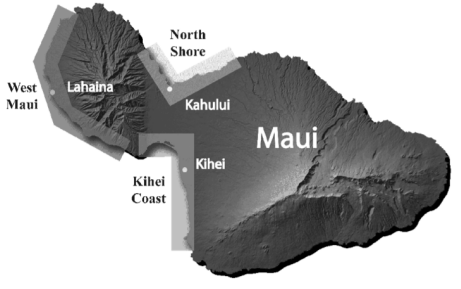

Fig. 2. Three regions of Maui

If a backshore exists in front of hardened structures, we assume the beach is not impacted and all shorelines are used for the analyses. If a beach experienced direct impact (e.g., beach nourishment), then a 50 yr hazard zone is not predicted. If the beach appears to be unaltered by hardened structures (natural), then a 50 yr hazard zone is predicted using all shorelines.

Using the classification scheme, there are 30 natural beaches and 46 hardened beach segments on Maui (Table 3). The 50 yr hazard zone is not calculated for two beaches (classified as category #2 and #4). We do not include these two beaches in our analysis.

Table 2. Beach Classification

Category	Hardened Shoreline?	backshore present?	Hazard Zone Predicted?
1	yes	no	yes
2*	yes	no	no
3	yes	yes	yes
4**	yes	yes	no
5	no	--	yes

* not enough post-hardened data
** excessive human interference

Of the 74 beaches, 27 have well-defined borders (pocket beaches), and 17 have ill-defined borders (open system beaches). Fourteen beaches are actually segments of longer beaches since hardened structures (i.e., groins) serve as borders for these areas. These beaches are not included in the definition of pocket or open system beaches.

Table 3. Maui Beach Breakdown

Category	Kihei	West Maui	North Shore	Total
1	4	13	5	22
2	1	0	0	1
3	5	2	15	22
4	0	0	1	1
5	11	13	6	30
Total	21	28	27	76

METHODS

Our methodology includes two distinct procedures. The first is to test the exclusion of lower-order terms with GAs. The second is to calculate the 50 yr hazard zone for all sandy beaches on Maui.

Using the genetic algorithm

Synthetic data are used to compare the GA process (testing randomly up to 2^{2I}) with the limited iterative process (testing up to I^2) by predicting a known 50 yr hazard line. We calculate the hazard line for the PX methods (LX and RX) and the PXT methods (LXT and RXT). EX and EXT are excluded from this analysis because the number of possible models is limited by the number of shoreline years (Frazer et *al.,* in review). The synthetic data has 100 transects, a 3 m intercept, an alongshore rate modeled by a quadratic polynomial, and a constant acceleration that equals 0.01 m/yr/yr. The noise is sampled from a Gaussian distribution with zero mean. We repeat experiments using noise processes with different standard deviations. The first experiment has a standard deviation of 1.95 m, which is based on the root mean squared error of a PX fit at an actual beach in Maui. Successive experiments have noise processes with standard deviation equal to 5, 10, 25, 50, 100, and 250 m.

50 yr Hazard Zone

For the 74 beaches, we calculate a 50 yr hazard position using S-T, LX, RX, EX, LXT, RXT, and EXT. We omit the binning methods, as Genz et *al*. (in review), found that results from A-binning and T-binning were insignificantly different from LX, RX, and EX on these beaches. All methods utilize Weighted Least Squares (WLS) to calculate misfit. The 50 yr hazard zone is the 50 yr position with a 2σ (95%) uncertainty band. We calculate the AICc score for each beach to determine which method best fits that beach. We also apply an ANOVA test on the 50-yr hazard prediction to determine whether the resulting predictions from all methods are significantly different or not.

RESULTS

Within Maui beaches, 9 of 22 beaches with hardened structures have only 3 shorelines (category 1, Table 2). Although there are more shorelines at these beaches, hardened structures dominate the beaches starting in 1975. Because 3 shorelines are not enough to

make sizeable predictions (such as the 50 yr hazard position), we remove these beaches and report the results of the remaining 65 beaches.

Genetic algorithms

For all noise processes, predictions using GA and predictions using the limited iterative process were similar (Figures 3 and 4). Figure 3 illustrates the GA 50 yr hazard predictions compared to the 'true' hazard line determined using synthetic data. Figure 4 illustrates the limited iterative process hazard predictions compared to the 'true' hazard line. LXT identifies acceleration in all but one experiment (LXT does not identify acceleration in the limited iterative process when the noise has a standard deviation of 500). RXT never identifies acceleration and equals RX in both the GA and limited iterative process. RX/RXT is more variable than LX and LXT. For both sets of predictions, LXT is closest to the 'true' position when the standard deviation of the noise is less than 100. As noise increases, LX is more consistent than LXT.

Allowing lower-order basis functions to be excluded does not reduce the variability associated with the PXT methods, as the results are consistent between GA and the limited iterative process. However, the AICc values of all methods are slightly lower with the GA.

Maui Hazard Zones

Based on the AICc scores, acceleration methods were the best methods for 48 beaches (Table 4). AICc identified EX, LX or RX as the best method for 17 beaches. For all 17 beaches, EXT, LXT, and RXT did not identify acceleration (i.e., EXT, LXT, and RXT equaled EX, LX, and RX, respectively). AICc did not identify S-T as the best method for any beach. Of the 65 beaches, 83.1% of the beaches had insignificant S-T rates.

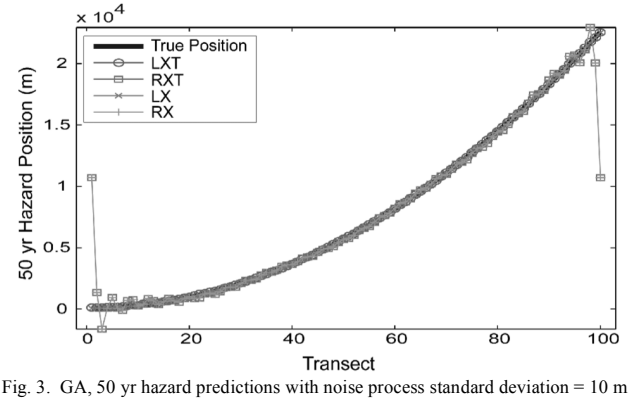

Fig. 3. GA, 50 yr hazard predictions with noise process standard deviation = 10 m.

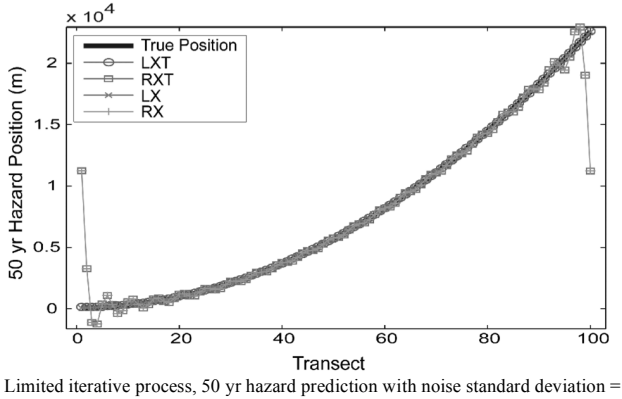

Fig. 4. Limited iterative process, 50 yr hazard prediction with noise standard deviation = 10 m.

Table 4. Number of Beaches Identified by AICc

	Method	Kihei	West Maui	North Shore	Total
Acceleration Methods	EXT	13	11	14	58.5%
	LXT	2	3	1	9.2%
	RXT	2	1	0	4.6%
	LXT ≈ RXT	1	0	0	1.5%
Non-Acceleration Methods	LX ≈ RX	1	2	1	6.2%
	EX	1	3	6	15.4%
	LX ≈ RX ≈ EX	0	1	2	4.6%
	S-T	0	0	0	0.0%

Table 5 reports AICc results of natural beaches and hardened beaches. Hardened beaches tend to identify acceleration more than natural beaches (77.1% hardened beaches vs. 70.0% natural beaches); while natural beaches tend to identify non-acceleration methods more than hardened beaches (30.0% natural beaches vs. 22.9% hardened beaches).

Table 5. Number of Beaches Identified by AICc

	Method	Natural Beaches	Hardened Beaches
Acceleration Methods	EXT	14	24
	LXT	5	1
	RXT	2	1
	LXT ≈ RXT	0	1
	Total	70.0%	77.1%
Non-Acceleration Methods	LX ≈ RX	4	0
	EX	4	6
	LX ≈ RX ≈ EX	1	2
	S-T	0	0
	Total	30.0%	22.9%

Acceleration is recognized in 63.0% of pocket beaches, while 37.0% have no acceleration (Table 6). Open systems tend to pick acceleration methods at a much higher percentage (94.1%) than pocket beaches. S-T is not identified as the best method in any of these beach systems.

Table 6. Number of Beaches Identified by AICc

	Method	Pocket Beaches	Open System Beaches
Acceleration Methods	EXT	13	11
	LXT	2	3
	RXT	1	2
	LXT ≈ RXT	1	0
	Total	63.0%	94.1%
Non-Acceleration Methods	LX ≈ RX	4	0
	EX	5	1
	LX ≈ RX ≈ EX	1	0
	S-T	0	0
	Total	37.0%	5.9%

An ANOVA test is calculated to identify whether the means of 50 yr hazard positions are significantly different. Three main categories emerge as dominant groupings of methods (Table 7). Predictions from all methods are insignificantly different from each other in 36.9% of the beaches. Seven of these beaches have deceptive results because LXT, RXT, and EXT have extreme erosional/accretional predictions that cancel out when the mean is calculated (e.g., Figure 5). S-T was not distinguishable from LX, RX and EX in 24.6% of the beaches. S-T, the PX methods and the PXT methods were significantly different from each other in 18.5% of the beaches.

The hazard zone is composed of the 50 yr hazard position plus an uncertainty band at the 95% confidence interval. Looking at the uncertainty associated with the hazard position, S-T has the highest uncertainties for 31 beaches (Table 8). LXT, RXT, and EXT also have high uncertainties. EX has the lowest uncertainties for 48 beaches.

TABLE 7. ANOVA Results of Hazard Positions

		# of Beaches			
	Method Groupings	Kihei	West Maui	North Shore	Total
1	All Methods	5	6	13	36.9%
2	S-T LX ≈ RX ≈ EX LXT ≈ RXT ≈ EXT	3	5	4	18.5%
3	S-T ≈ LX ≈ RX ≈ EX LXT ≈ RXT ≈ EXT	9	3	4	24.6%

LX and RX also have low uncertainties. LXT, RXT, and EXT have the lowest uncertainties for 25 beaches (highlighted in Table 8). None of these 25 beaches identify

acceleration, hence, in this case LXT, RXT, and EXT equal LX, RX, and EX, respectively.

Table 8. Mean Hazard Uncertainty

Method	# Beaches with Lowest Uncertainty	# Beaches with Highest Uncertainty
S-T	2	31
LX	15	0
RX	13	0
LXT	8	12
RXT	6	21
EX	48	1
EXT	11	6

DISCUSSION

In all beaches, hazard predictions with LX, RX, and EX are always in agreement. These methods also have the lowest hazard position uncertainties. Genz et *al*. (in review) showed that these methods, along with binning, predict known positions more accurately than other methods. With that in mind, and with the consistency shown with these methods in all beaches of Maui, we currently advocate the use of these methods.

Although AICc identifies acceleration in 73.8% of the beaches, Genz et *al*. (in review) showed that predictions of known positions with these methods are inconsistent. AICc finds the best fit model so it is possible that acceleration models fit the data better, but do not enhance predictions. As shown by the GA results, excluding polynomials with lower-order terms did not significantly improve predictions; this is fortunate, as calculations with GA have significantly longer run times than those with the limited iterative process. More research on acceleration methods may be necessary for better predictions.

Beach Comparisons

LX, RX, and EX are identified by the AICc in pocket beaches at a higher proportion than in open system beaches. Compared to open system beaches, pocket beaches are smaller, with defined borders, such as headlands, that restrict sediment movement (Woodroffe 2002). Thus, open system beaches are more influenced by changes, such as interruptions to longshore sediment transport. Acceleration methods better account for the influx and outflow of sediment in open systems; hence 94.1% of these types of beaches show acceleration.

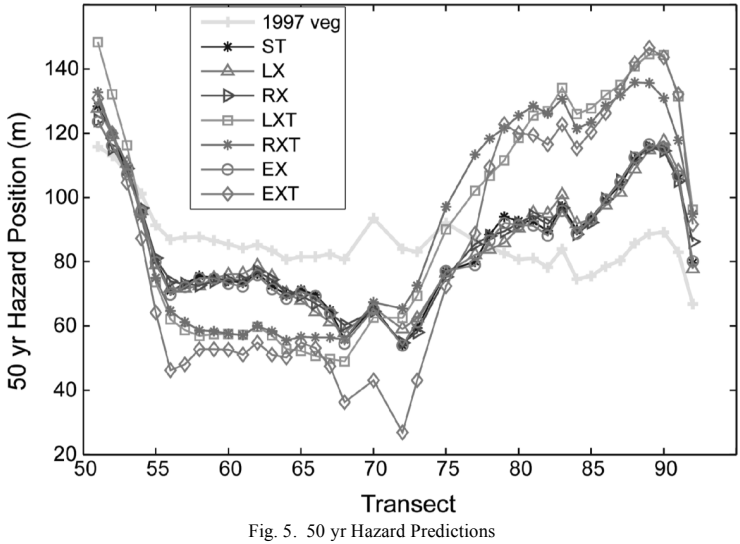

Fig. 5. 50 yr Hazard Predictions

Hardened shorelines fit a slightly higher percentage of acceleration methods than natural shorelines. Although it is a minimal difference, acceleration might be favored in hardened shorelines due to structures causing rates to vary with time. Other factors, such as storms, could influence the high frequency of acceleration found in natural beaches.

Hardened Shorelines

An important assumption of all shoreline change methods is that beach physics remain stable through the time period of interest (Fenster et *al.,* 1993; Morton 1991). Hardened structures and storms are common influences on beaches that violate this assumption. Fenster et *al*. (1993) recognized the impracticality of the change-rate methods on beaches that have undergone structural changes and introduced the Minimum Description Length (MDL) method to minimize violations of this assumption. They proposed fitting higher-order polynomials at each transect to determine the erosional trend shift and using data after the trend shift to predict future hazard positions. However, there might not be enough data to fit a higher-order polynomial at each transect.

It is important to have as long a temporal span as possible to reduce the effects of noise on the long-term trend (Crowell et *al.,* 1993). However, changes such as hardened structures and storms affect the resulting trends of a beach. Many have argued that removing storm-influenced shorelines from long-term rate analysis is valid because post-storm shorelines eventually recover to their pre-storm positions and therefore do not affect the long-term rate (e.g., Crowell et *al.,* 1993; Douglas and Crowell 2000; Galgano et *al.,* 1998; Zhang et *al.,* 2002). Unlike storms, the addition of hardened structures does affect the long-term trend. Removal of post-hardened shorelines in change-rate analysis

would only give predictions based on natural beaches. However, removal of pre-hardened shorelines would result in predictions based on beach behavior with the involvement of structures.

We addressed hardened structures in the following way: If hardened structures were present, and no backshore existed in front of the beach, we removed pre-hardened shorelines (Category 1, Table 2). However, where a backshore persisted in front of a hardened structure, we interpreted the structure as having little influence on beach dynamics, and we included the hardened beaches in our analysis (Category 3, Table 2).

AICc

Nine beaches have three shorelines and are all classified as category 1, which signifies hardened shorelines (Table 2). Only 3 shorelines are utilized in all 9 cases, with RXT identified as the best method for 3 beaches, LXT identified as the best method for 4 beaches, and S-T identified as the best method for 2 beaches. RXT, LXT, and S-T have the lowest AICc scores in these situations because the equation for AICc fails. Burnham and Anderson (2002) present the AICc equation as:

$$AICc = N\log(RSS/N) + \frac{2KN}{(N-K-1)} \quad (4)$$

Where *RSS* is the residual sum of squares, *N* is the sample size, and *K* is the number of parameters. The value of the first half of equation (4) decreases as RSS decreases. The second half of equation (4) is a correction factor that increases as the number of parameters increase. This factor should always be positive in order to penalize the use of extra parameters. Thus, AICc is a tradeoff between the goodness of fit and the number of parameters, preventing over- or under-fitting of the data. However, if $K \geq N$, the correction factor in equation (4) is a large negative number. As the best-fit model is the lowest AICc score, a large negative number leads to nonsense results. This situation occurs for LXT, RXT, and S-T when ≤ 3 shorelines exist. LX, RX, EX, and EXT are not affected by this issue because *K* is never greater than or equal to *N*.

If the beach has ≤ 3 shorelines, LXT, RXT, and EXT should not be used. These methods identify whether rates are changing with time at each transect (Figure 6). Fitting a quadratic model on 3 points is over-fitting, so non-acceleration methods should be used if only 3 shorelines exist.

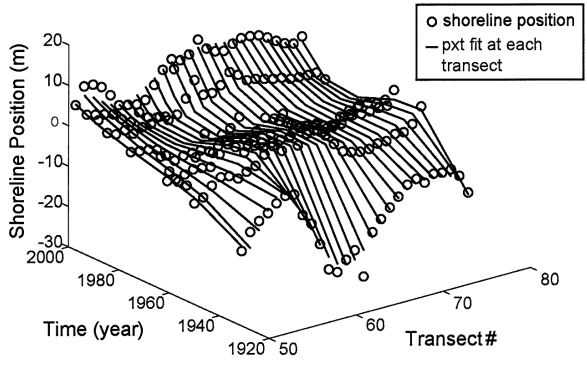

Fig. 6. Rates Changing With Time at Each Transect (PXT)

CONCLUSIONS

Overall, predictions from RX, LX, and EX are insignificantly different from each other and are recommended for use in hazard zone predictions. Predictions using polynomials without lower-order terms are consistent with predictions using all lower-order terms. LXT, RXT, and EXT appear to need more research. Ideally, the more shorelines that are available, the better the hazard predictions are. If, however, beaches have hardened structures without any backshore present in front of the structures, then only post-hardened shorelines should be used to predict future hazard zones. If there are ≤ 3 shorelines, the AICc equation does not function properly for LXT, RXT, EXT, and S-T. Both pocket beaches and open-system beaches identify acceleration methods at a higher percentage than non-acceleration methods. Still, pocket beaches identify non-acceleration methods at a higher proportion than open-system beaches possibly due to less variability in sediment transport in pocket beaches.

ACKNOWLEDGEMENTS

Funding for this research was provided by the U.S. Geological Survey, the University of Hawaii Sea Grant College of the National Oceanographic and Atmospheric Administration, Maui County Planning Department, Kauai County Planning Department, and the City and County of Honolulu. We thank members of the University of Hawaii Coastal Geology Group for their assistance.

Abstract: To assess the long-term safety of a dune-protected coastal area, models are needed for forecasting both long-term coastal evolution and dune erosion due to the occurrence of a super storm. In long-term model forecasts, however, information on dune shape is lost. Explorative calculations show that the output of the event-scale dune erosion model is quite sensitive to the dune height. For a given super storm, a higher dune leads to a larger forecasted erosion volume, but to a less land inward position of the erosion line (the line that indicates how far erosion is expected to reach land inward). Clearly, a solution should be found for adding information on realistic dune shapes to the long-term coastal evolution forecast. EOF decomposition of observed dune profiles provides simple but realistic dune shape functions that could be used to redistribute forecasted dune volumes into realistic dune shapes.

INTRODUCTION

Dunes are part of the coastal system which need to be considered in the scope of

coastal management and engineering practices (Saye et al. 2005), since they form an important link in the coastal sediment budget (Arens & Wiersma 1994). Arens & Wiersma (1994) show that, for the Dutch coast, on a yearly basis, an average of 3 – 3.5 m^3/m to a maximum of $25m^3/m$ sediment is transported into the dunes. In addition, in the Netherlands, dunes protect large parts of the coast during storms (see figure 1, 'soft defenses'). However, dunes are often neglected in (long-term) coastal modeling exercises.

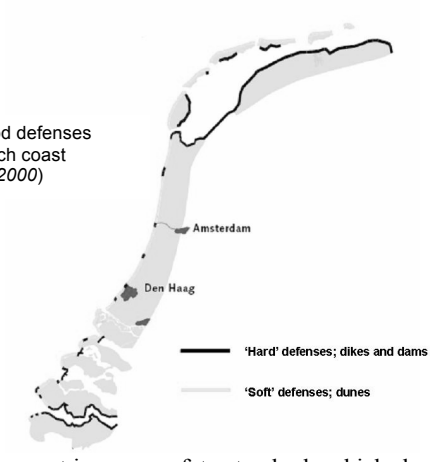

Figure 1. Flood defenses along the Dutch coast *(From: CPD, 2000)*

The Dutch government imposes safety standards which should be met by all sea defenses. Along the Holland coast, flood defenses should be able to withstand a 1:10.000 storm, i.e. conditions corresponding to a storm with a probability of occurrence of once per 10.000 years. In the future however, rising sea-level and more frequent and severe storm conditions might jeopardize the safety provided by the flood defenses.

In 1984, the Technical Advisory Committee for Flood Defenses (TAW 1995) published a guideline on how to test safety of the Dutch dune areas. To assess the current 'strength' provided by the dunes, a method was designed to calculate dune erosion as a result of a storm event. This method is based on the DUROS (DUne eROSion) model. From the dune erosion calculations, the position of erosion lines are determined (figure 2). Erosion lines indicate how far erosion might reach land inward as a result of occurrence of an extreme storm event. Figure 2 illustrates that if a 1:10.000 super storm were to occur today, the land seaward of the solid line would be eroded.

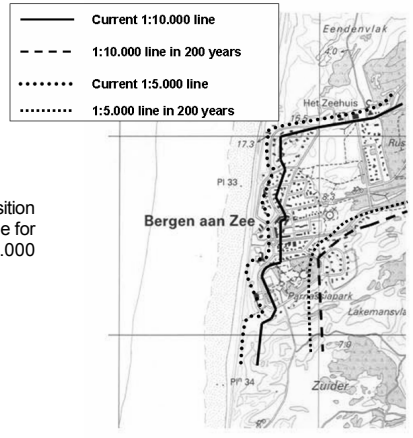

Figure 2. Present and expected future position of erosion lines for a Dutch sea-side village for super storms with a 1:10.000 and 1:5.000 probability of occurrence
(From: RIKZ, 2005)

However, sustainable coastal zone management not only asks for the current dune strength to be known, but also how this dune strength evolves through time, in order to anticipate to future developments. Until recently, long-term safety forecasts involved running the DUROS model with an unchanged beach and dune configuration, but with a higher mean sea level. The dashed line in figure 2 illustrates how the erosion line might shift landward according to this approach. However, evolving morphology might affect the position of erosion lines in the future as well. Therefore, it is of importance to include morphological behavior in long-term safety assessment.

In Dutch coastal management practice, a behavior oriented model called PONTOS is currently used to forecast long-term evolution of the Holland coast (figure 7). In this model, dune morphology is highly schematized, and therefore does not provide the spatially detailed information required for a DUROS calculation.

Apparently, there is a 'gap' between the model that calculates the effects of low-frequency, high-magnitude events (DUROS) and the model that is designed to forecast long-term coastal evolution due to high-frequency, low magnitude processes (PONTOS).

In this paper, we will explore how the 'lost morphological information' can be reintroduced into the PONTOS forecast, in order to make the long-term model forecast suitable for DUROS calculations to obtain erosion line positions (see figure 3).

In order to determine the effect of extreme events 50 to 200 years from now, we need to take into account the temporal and spatial evolution of morphological characteristics of the coastal cross-shore profile. More specifically, we need to consider that part of the profile which is needed for DUROS, i.e. from ca. -2m Dutch Ordnance Level to the dune area.

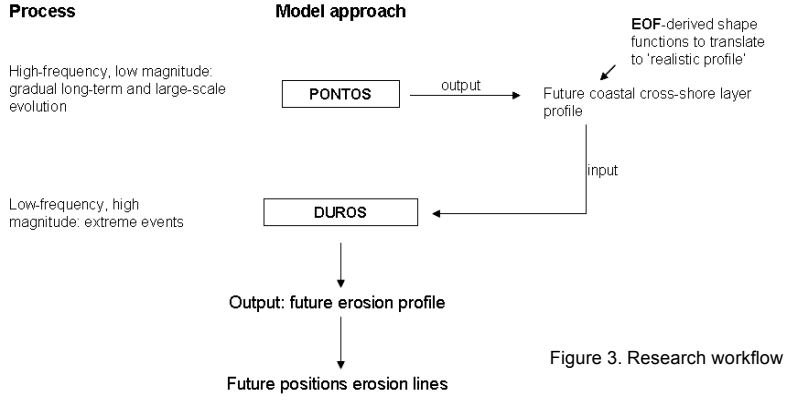

Figure 3. Research workflow

This paper is organized as follows: The next two sections explain the concepts of the DUROS model and the PONTOS model, followed by a section which describes the study area. In the following section, we examine the sensitivity of dune erosion volumes and erosion line positions to the shape of the dune area. Thereafter, we focus on Empirical Orthogonal Function (EOF) decomposition of dune topography measurements. EOF provides realistic shape characterizations for the dunes. The shape functions obtained from EOF may be used to translate the PONTOS dune schematizations to a realistic set of dune profiles.
The gained knowledge might aid in determining the 'optimal' dune configuration to reduce the effects of super storms.

PRESENT SAFETY ASSESSMENT OF DUTCH DUNES: THE DUROS MODEL

DUROS is a cross-shore model that, for pre-defined conditions, calculates the amount of dune erosion as a result of the occurrence of an extreme storm (Van de Graaff 1984; TAW 1995). The DUROS model is used in safety assessment of the Dutch dune area (figure 1 and 7). To determine the amount of erosion, it is required to know the position of the cross-shore profile right *before* a storm, since this will determine the extent of erosion of the dune as a result of the storm, and, hence, the safety provided by the dune as a natural defense against flooding of the hinterland, which in the case of the Netherlands is located largely below MSL.

In DUROS, the amount (volume) of dune erosion is a function of (1) the location (position) of the initial cross-shore profile, (2) the maximum wave height and sediment characteristics and (3) the maximum storm surge level. With these parameters, a sediment balance is calculated, which results in the position of the erosion profile. The shape of the erosion profile is assumed to be known, and is a function of the significant wave height and the fall velocity of the dune sand in standing water (see figure 4).

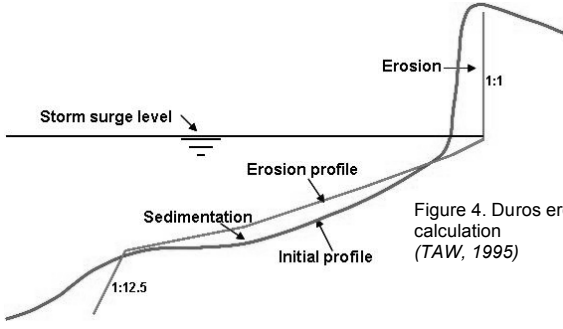

Figure 4. Duros erosion profile calculation *(TAW, 1995)*

The position of the initial profile, rather than the shape of the initial profile, is considered to determine to a large extent the amount of dune erosion (Van de Graaff 1984; TAW 1995). This is because a closed sediment balance in cross-shore direction is assumed. By shifting the erosion profile with respect to the initial profile in such a way that the amount of erosion equals the amount of sedimentation, a closed sediment balance is obtained.

LONG-TERM COASTAL EVOLUTION: THE PONTOS MODEL

The long-term and large-scale evolution of the Holland coast can be simulated by the behavior-oriented PONTOS model (Steetzel & Wang 2003). PONTOS is a physical-mathematical coastline model, in which the coastal cross-section is schematized into five horizontal layers each representing a sediment volume (figure 5). Erosion or sedimentation, modeled per layer, is caused by gradients in the longshore and cross shore sediment transport. PONTOS provides a crude schematization of the cross-shore profile from which a position of erosion lines cannot be obtained. The dune area in PONTOS is represented by one sediment volume layer. This layer is positioned from +3 m with respect to the Dutch Ordnance Level (NAP) to the top of the first dune row.

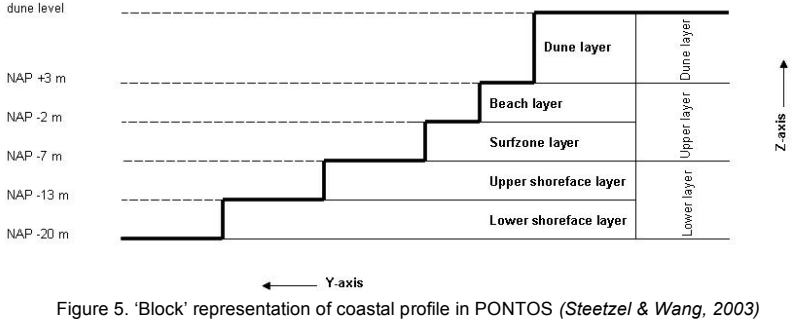

Figure 5. 'Block' representation of coastal profile in PONTOS *(Steetzel & Wang, 2003)*

In order to forecast the amount of dune erosion under extreme storm conditions, we need a cross-shore distribution of sediment as input for DUROS, rather than the layer representation of PONTOS. Recent developments to obtain a cross-shore profile from the PONTOS-layers are made by Wang et al. (2006) who transform the layer representation to a smooth profile as follows (see dotted line in figure 6):

1. The cross-shore profile of each layer is replaced by a straight line according to: $y=a_i z+b_i$, for $z_{i+1} \le z \le z_i$ (1)
2. In each layer, mass conservation is guaranteed in accordance with the principles of the PONTOS model.

This profile is then used to perform a dune erosion calculation. This profile is however still highly schematized and does not reflect a 'real' profile shape (compare in figure 6 the dotted line with the smooth line based on Jarkus measurements (Yearly Coastal Surveys).

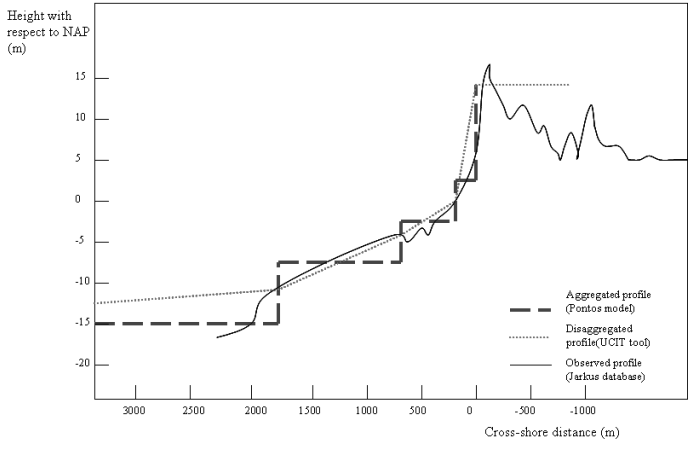

Figure 6. Aggregated profile generated by PONTOS, disaggregated smooth profile and an observed coastal profile by Jarkus data *(Wang et al., 2006)*

DESCRIPTION OF THE STUDY AREA

We use coastal cross-shore data from the coast of Noord-Holland, the Netherlands (figure 7) as input to DUROS to explore the sensitivity of dune erosion to different input profiles. The coastal cross-shore data are obtained from the Jarkus database, which provides year to year measurements of coastal profiles extending from the foredune to app. 1000 m seaward. The distance between the profiles is 200-250 m and there is a total number of about 3000 profiles along the Dutch coast (Guillen et al. 1999). Two Jarkus profiles for the year 2004, viz. transect number 3325 and 4475 (figures 7 and 8) were selected as a first exploration in examining the role of the dune shape on the amount of erosion and position of the erosion line. Transect 3325 is situated close to the coastal town of Bergen aan Zee, whereas transect 4474 is situated near Castricum aan Zee. Hereafter, the transect numbers will be referred

to as the Bergen and Castricum transects. For EOF analysis, 87 profiles from Noord-Holland (also for the year 2004) were used.

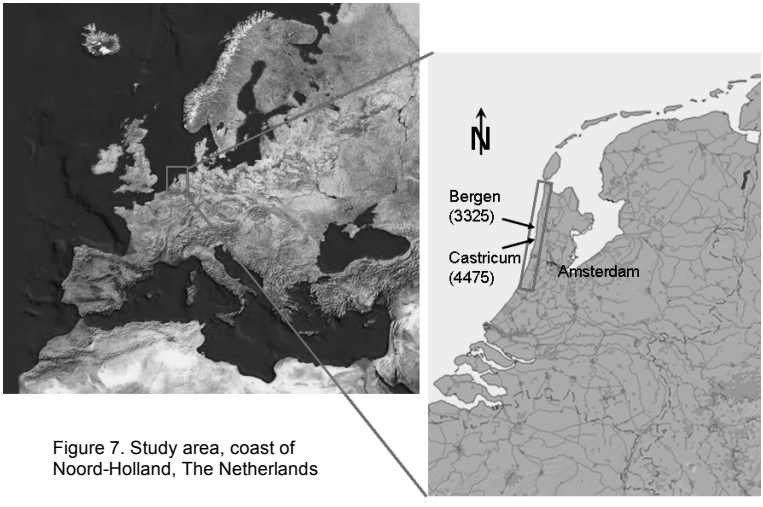

Figure 7. Study area, coast of Noord-Holland, The Netherlands

EFFECT OF DUNE SHAPE ON EROSION VOLUME AND EROSION LINE POSITION

Both the DUROS calculation method and the Jarkus database are embedded in a model environment called UCIT (Universal Coastal Intelligence Toolkit) (Van Koningsveld et al. 2005). For each selected Jarkus transect we can perform a dune erosion calculation, thereby taking into account different forecasting periods, different sea-level rise scenarios as well as user-defined hydraulic conditions, such as storm peak periods and significant wave heights. The selected transects of Bergen and Castricum have different foreshore slopes and the foredunes differ in both transects as well (figure 8). The foredune of the Bergen transect has a height of app. 8 meters, whereas the foredune of the Castricum transect has a height of about 16 meters. This part of the coast of Noord-Holland is intensely used for recreational activities and since most parts of the coast of Noord-Holland are subject to erosion, beach and foreshore nourishments are frequently carried out with positive effects on beach width. The Bergen transect is highly altered by human activity and can be considered an 'artificial' dune (Arens 1994).

Castricum is situated 11.5 kilometers south of Bergen. This transect is in a 'semi-natural' state; sand fences have been placed and marram grass has been planted in order to stabilize the dunes in this area (Arens 1994).

There are no seawalls or groins situated close to the transects which might influence sedimentation or erosion in this area.

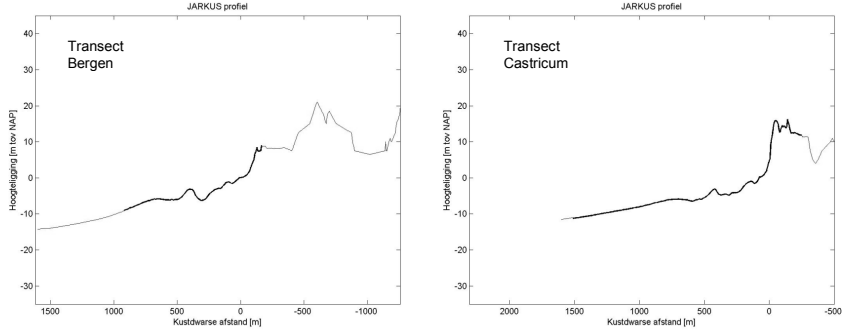

Figure 8. Transects Bergen (3325) and Castricum(4475)

In order to examine the role of dune geometry on the amount and extent of erosion, we performed a model experiment in the UCIT environment for the Bergen and Castricum transects. Each profile was transformed into different hypothetical profiles, varying in height and width, based on a fixed, hypothetical added volume. Figure 9 illustrates two hypothetical profiles for the Bergen transect. We took the +3 m NAP (Dutch Ordnance Level) as the dunefoot position. According to Ruessink & Jeuken (2002), this level roughly corresponds to the break in slope between the beach and the foredune. From this level, we added the artificial dune volume, which we set at 4000 m^3/m, based on expert judgement. We defined the minimum dune width to be 100 m and the maximum dune width to be 500 m. Dune width will be varied in steps of 20 m. According to Volume = width * height, the dune height takes a height belonging to a certain width.

When we plot the different erosion volumes and positions of the erosion lines against the different dune heights (fixed dune volume of 4000 m3/m), we observe in figures 9 and 10 that for the Bergen transect a decreasing dune height leads to a smaller erosion volume, but to a more landward shift of the erosion point position (denoted by R in figure 9). This is because the shape of the erosion profile is fixed, so in order to maintain a closed sediment balance when the shape of the beach and foreshore remain the same, leads to a more landward position of the erosion point if dune height decreases. For the Castricum transect with the same height-width ratios for the dune area as the Bergen transect, similar results are obtained: a decrease in dune height leads to a smaller erosion volume, but to a more landward position of the erosion point. Apparently, the *shape* (height) of the initial dune profile seems to affect to a large extent the dune erosion volume and erosion line position, since a higher dune leads to a higher erosion volume and to a more seaward erosion line position.

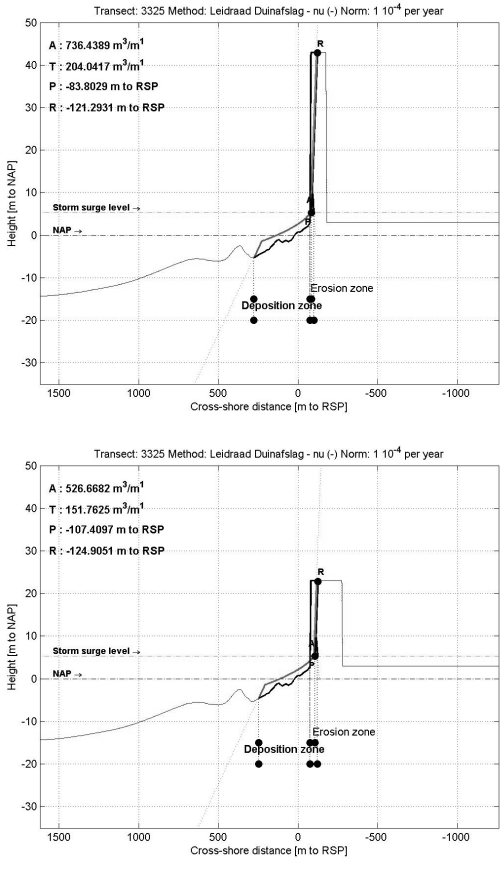

Figure 9. Different erosion volumes and erosion point positions for two hypothetical dune configurations for the Bergen transect
A is the erosion volume
T is an 'extra' erosion volume to account for uncertainties
P is the intersection between the 'new' dunefoot position and the storm surge level
R is the erosion point at the surface

Besides the dune shape, the foreshore configuration also plays a role in the amount of erosion and the position of the erosion point. Figure 10 and table 1 show that although the dune configurations and volumes are identical for both transects, different erosion volumes and erosion line positions arise. A steep foreshore slope 'demands' more sediment from the dunes in order to obtain a closed sediment balance needed for the erosion profile (figure 4).

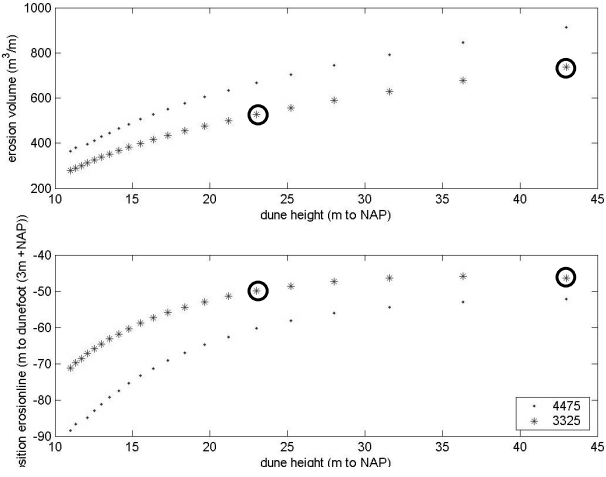

Figure 10. Varying dune heights versus erosion volumes and erosion point positions for Bergen (transect number 3325) and Castricum (transect number 4475). Circles indicate the values of figure 9

Table 1. Erosion volumes and erosion line positions at different hypothetical dune heights for Bergen (3325) and Castricum (4475)

DUNE HEIGHT (M TO NAP)	EROSION VOLUME 4475 (IN M^3/M)	EROSION LINE POSITION 4475 (M TO DUNEFOOT)	EROSION VOLUME 3325 (IN M^3/M)	EROSION LINE POSITION 3325 (M TO DUNEFOOT)

Since profile shape affects the amount of erosion and the position of erosion lines, the question arises whether we can find a simple but realistic representation of profile shape to be implemented into long-term morphological model forecasts (PONTOS). To investigate this, we first concentrate on characterization of the dune profile. We propose to use Empirical Orthogonal Function (EOF) to extract shape functions which characterize dune shape.

EMPIRICAL ORTHOGONAL FUNCTION (EOF) ANALYSIS

EOF analysis provides a method to reduce the number of data variables required to represent our data set (Aubrey 1979). With EOF we attempt to reveal a simple spatial structure that is present within the dune profiles.

If we consider the dune profiles – which extend from the dunefoot position (origin) towards a 200 m landward position - along a 22 km long stretch of the coast of Noord-Holland , we obtain a mean profile shape indicated figure 11 (upper panel). This part of the coastal cross-shore profile corresponds to the dune layer in the PONTOS model, viz. from NAP + 3 m to the dune top. The mean dune top is situated at about NAP + 16 meters, but there is a standard deviation of approximately 4 meters (lower panel figure 11).

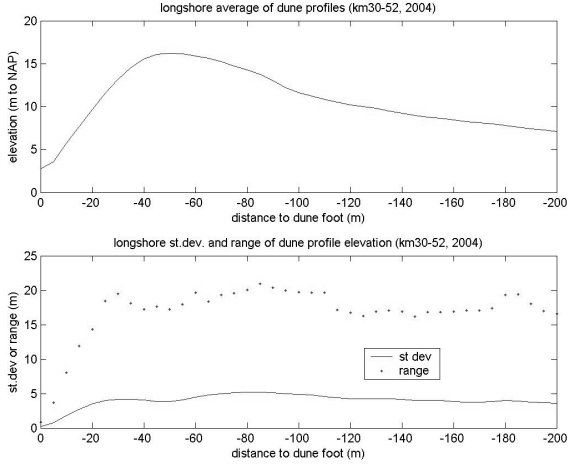

Figure 11. Mean cross-shore dune profile of Noord-Holland and standard deviation and range of the mean profile

The standard deviation does not provide information on how actual deviations from the mean profile are related in space. EOF's describe how the dune profiles differ from the mean profile in terms of orthogonal shape functions (for instance the sine and cosine functions). Since we consider 87 profiles along the coast, each cross-shore position (with respect to distance in meters to the dunefoot) has different heights in longshore direction. Therefore, each cross-shore position has a variation

around the mean profile, which can be expressed in terms of variance (or standard deviation, lower panel in figure 11). The first EOF (upper panel, figure 12) explains 43% of this observed variance. The second eigenfunction explains 24% of the observed variance.

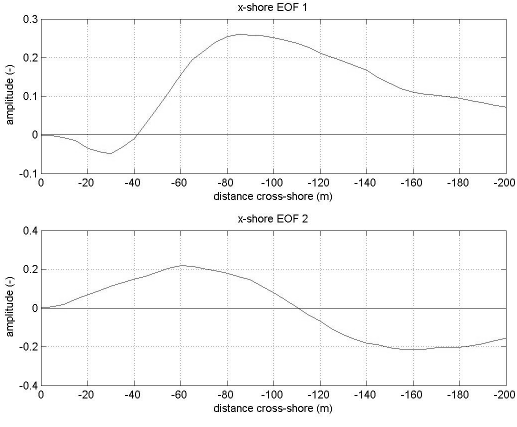

Figure 12. First and second shape functions of the selected profiles from transect 3000 to 5200

Thus, the first two shape functions explain two-third of the observed variance, which means that the shape functions describe to a large extent the variation we observe in the mean profile.

Potentially, the shape functions can be used to remodel the PONTOS dune layer into a (more) natural shape, on which a dune erosion calculation can be performed in DUROS.

It is still premature to assign a physical explanation for these observed variations, but variations are possibly related to the absence or presence of vegetation, sediment supply and management practices (Saye et al. 2005).

DISCUSSION

This research shows the first steps towards examining the importance of the dune/beach configuration in calculating erosion volumes and position of erosion lines. We want to stress the fact that the dune volumes we considered are highly schematized, without accounting for a width-height-slope relationship (Hesp & Hastings 1998). In reality, dune height cannot continue to grow without a corresponding increase in width, although it appears that especially dune height is important in the DUROS calculations. Different dune slopes will also affect the amount of erosion and position of erosion lines, since it will affect the closed sediment balance needed for DUROS. Also, dune slope affects dune stability, which implies that certain dunes might be more prone to erosion than other dunes.

Since the foreshore configuration also plays a role in the erosion calculations, examining a beach-dune morphological relationship might provide additional insight with regard to the state of the dune and a possible trend in dune evolution, i.e. eroding or accreting (Saye et al. 2005).

For the EOF analysis, we have considered all transects within a 22 km long coastal stretch irrespective of differences in dune type such as (1) the developmental stage of the dune, (2) aeolian processes at work (erosion or deposition) and (3) effects of dune management (human-altered vs. natural dunes) (Arens & Wiersma 1994). Whether more refinement in dune shape functions is actually needed is not clear yet. Applying EOF analysis to subsets of dune profiles grouped by dune type, will reveal whether these differences are reflected in differently shaped dune shape-functions or not.

CONCLUSIONS

This research illustrates the importance of dune configuration in dune erosion calculations. For a given storm, dune configuration determines to a large extent the erosion volume and position of erosion lines. Higher dunes result in a more seaward position of erosion lines, but result in higher erosion volumes compared to a lower dune. In addition, it also appeared that foreshore configuration matters in the erosion calculations.

We have proposed EOF analysis as a tool to characterize the dune shape in order to reintroduce the 'small scale information' to long-term forecasts such that a dune erosion calculation in DUROS is possible. It is thus a method to bridge the cap between a small scale, event-based model and a long-term, large scale model.

Abstract: The Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system collects lidar and hyperspectral data for the U.S. Army Corps of Engineers (USACE) National Coastal Mapping Program. CHARTS is owned by the U.S. Naval Oceanographic Office and operated jointly with the USACE through the Joint Airborne Lidar Bathymetry Technical Center of Expertise. Simultaneous collection and shared geo-referencing enables fusion of the two data types into high-level information products that are used to support decision-making at USACE coastal projects. New products resulting from data fusion research currently coming online are bathymetric laser bottom reflectance images, atmospherically-corrected image mosaics, and hyperspectral final bottom images. All of these products are input for automated classification algorithms that generate physical and environmental characterizations of the coastal zone.

INTRODUCTION

Airborne laser and imagery data collected by the Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system are the foundation of the U.S. Army Corps of Engineers (USACE) National Coastal Mapping Program (NCMP). USACE Headquarters funds the NCMP to support planning, engineering, construction, operation and maintenance activities in the coastal zone, like navigation and flood protection projects, and to support

regional sediment management practices. The NCMP is designed to provide high-resolution lidar and imagery data for U.S. shorelines on a recurring basis. At the current level of funding, one survey cycle, including the U.S. Gulf, Atlantic, and Pacific Coasts, the U.S. shorelines of the Great Lakes, and the shorelines of the five largest Hawaiian Islands, is projected to take 8 years. Since its inception in spring 2004, NCMP has completed mapping on the Gulf and Atlantic Coasts, from Mississippi to Maine, and initiated work in the Great Lakes.

The CHARTS sensor suite includes an Optech SHOALS-3000T20 and an Itres CASI-1500 (Wozencraft and Millar 2005). The SHOALS-3000T20 is itself an integrated sensor containing a 3,000 pulse-per-second (pps) bathymetric laser, a 20,000 pps topographic laser, and a digital RGB camera that records one frame every second. The CASI-1500 is a programmable pushbroom hyperspectral imager capable of collecting from 4 to 288 spectral bands over the spectral range from 375 to 1050 nm, at pixel sizes ranging from 20 cm to 5 m depending on system configuration (Wozencraft and Lillycrop 2006). Either laser can be operated simultaneously with the RGB camera and hyperspectral imager, but the lasers are operated separately. CHARTS is owned by the U.S. Naval Oceanographic Office (NAVOCEANO) and operated jointly with the USACE through the Joint Airborne Lidar Bathymetry Technical Center of Expertise (JALBTCX).

CHARTS collects all four data types for the NCMP. Bathymetric lidar is collected from the shoreline to 1 km offshore, or to extinction, whichever occurs first. Bottom determination using bathymetric lidar is limited by water clarity. The lidar can discriminate depths 2-3 times the visible depth of the water column. Topographic lidar is collected from the shoreline to 0.5 km onshore. RGB imagery is collected automatically whenever the lasers fire. Hyperspectral imagery is collected concurrently with both the bathymetric and topographic laser data, but the sensor is operated independently of the laser system from its own operator console.

At the JALBTCX, the high-resolution lidar and imagery data collected for NCMP are analyzed and processed to higher-level information products in GIS format. The products are designed to facilitate the use of the large regional datasets in coastal studies and decision-making processes at USACE projects. The current product line includes bathymetric/topographic Digital Elevation Models (DEMs), RGB orthomosaics, NAVD88 shorelines, building footprints, and bare earth grids. New products coming online in the current year include reflectance images from the bathymetric laser, atmospherically-corrected hyperspectral orthomosaics, and final bottom images from the hyperspectral data. These products are the result of years of research and development efforts in data fusion at the JALBTCX.

JALBTCX activities in data fusion began in the mid-1990's during the field trials of the original SHOALS system (Lillycrop and Estep 1995; Estep et al. 1994). CASI overflights of the SHOALS field test area provided lidar elevation and hyperspectral data for researchers to use in generating a bottom type image in Sarasota Bay, Florida. Work

continued in this area with pilot studies in Laguna Madre, Texas (Estep 1998), Biscayne Bay, Florida (Wozencraft et al. 2002), and Kaneohe Bay, Hawaii (Wozencraft et al. 2003). In 2005, JALBTCX specified an upgrade to the CHARTS sensor that included integration of a hyperspectral sensor with the SHOALS instrument and foundation data fusion software. Currently, JALBTCX is co-sponsoring a 3 year contract with NOAA through the National Ocean Partnership Program (NOPP) to further develop the foundation software for improved bottom classification and to move data fusion techniques onto the land. JALBTCX is in the second year of development on a new lidar and imaging sensor suite called the Coastal Zone Mapping and Imaging Lidar (CZMIL). The goal of the CZMIL project is to produce a state-of-the-art optical system designed for accurate elevation measurement and environmental characterization. The current NCMP product line was developed from a system designed for depth discrimination. CZMIL provides an opportunity to design a system and processing software suite optimized for generation of all the NCMP data products.

This paper will outline CHARTS characteristics that make it an ideal platform for sensor fusion work, describe products coming online for the next field season of the NCMP in spring and summer 2007, and introduce ongoing development efforts focusing on fusing the aforementioned products at the pixel and image level to achieve high-accuracy classifications of the coastal zone.

CHARTS AND DATA FUSION

Data fusion in the context of CHARTS surveys is any combination of data from the active laser system and passive RGB and hyperspectral image systems. Three aspects of the CHARTS system enable advances in data fusion work that have been unattainable in the past. First, simultaneous operation of the laser and image systems eliminates assumptions regarding any temporal disparity between the data collections. Elevations, water column properties, and bottom reflectance derived from the laser measurements coincide nearly simultaneously with collection of the passive image data. The pointing angles of the individual instruments result in a small temporal shift in the data collection of laser and image data at each geographic location (Tuell et al. 2005a). The CASI-1500 looks directly nadir, while both lasers point 22 degrees forward of nadir. This design aspect improves water surface and target detection capability of the bathymetric laser, and reduces the dynamic range of the signal returning to the bathymetric receivers (Guenther et al. 2000). The bathymetric laser pulses are positioned on the water surface using two scanning mirrors to maintain a constant incidence angle on the water surface. The action of the dual mirrors results in a semi-circular pattern of laser spots on the water surface. When the topographic laser is firing, one mirror remains fixed, resulting in a saw-tooth pattern of the laser spots on the ground.

Second, the sensors have similar, very high spatial resolutions. The bathymetric laser is programmable from a 2- to 5-meter grid and the topographic laser from a 1- to 2-meter grid. For the topographic laser the spot spacing is largely determined by flying height. The hyperspectral imager is also programmable, with a trade-off between spectral and spatial resolution (Wozencraft and Lillycrop 2006). For bathymetric data collection, or

collection over water, the hyperspectral imager is set for an integration time of 30 milliseconds, which results in on-ground pixel size near 2 m. For topographic laser collections, the CASI-1500 is set for 16 millisecond integration time, which results in on-ground pixel size near 1 m. The similarity in spatial resolution reduces the generalization, or sometimes oversampling that occurs to bring one dataset to the resolution of the other. The high spatial resolution of both datasets enables characterization at the shoreline, where large pixel sizes often preclude analysis because land corrupts analysis of water pixels and vice-versa.

Third, the laser and hyperspectral instruments both sit on a rigid optical plate above the view window of the aircraft. As such, the hyperspectral data are georeferenced using the same positioning and orientation data stream used to position the laser data. There is no ambiguity regarding datum or projection of the two datasets. Figure 1 shows a view of the installation from immediately outside the aircraft door (a), and from underneath the aircraft (b). The rigid optical plate is labeled in both views, while the sensors are shown in Figure 1(a) and their view windows through the plate in Figure 1(b).

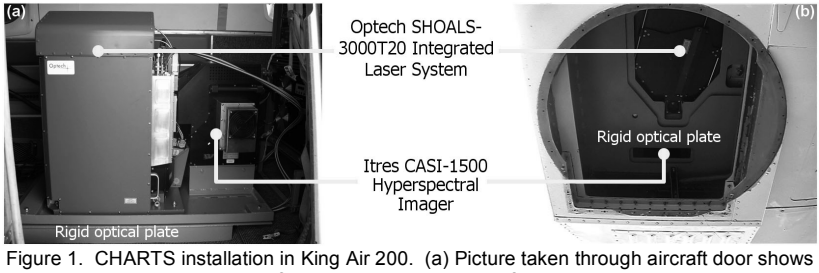

Figure 1. CHARTS installation in King Air 200. (a) Picture taken through aircraft door shows sensors. (b) Picture taken from underneath the aircraft shows sensor view windows.

OPERATIONAL PRODUCTS

Products moving from research and development to operations this year are bathymetric laser bottom reflectance images, atmospherically-corrected hyperspectral image mosaics, and hyperspectral final bottom images. Bathymetric laser bottom reflectance images, or SHOALS bottom reflectance images, are derived solely from the lidar waveform. Atmospherically-corrected hyperspectral image mosaics are a data fusion product in that the mosaicking process uses a DEM created from concurrently collected lidar data to position the pixels in projected map space. Both of these data products, and some intermediate products not designed for release, are inputs for the formation of a data fusion product called hyperspectral final bottom images.

Bathymetric laser bottom reflectance images at 532 nanometers, which is the wavelength of the SHOALS bathymetric laser, are derived from the bathymetric lidar waveform, or the digitized electrical signal generated by photons returning to receivers in the aircraft. These images are similar to topographic lidar intensity images and SHOALS psuedoreflectance images, with one important distinction. To generate bathymetric laser bottom reflectance images, the two receivers in the SHOALS system must be

radiometrically calibrated (Kopilevich et al. 2005). The calibration relates digital counts output from the receivers to input optical power from the target. Reflectance of a target is derived through the lidar equation. Reflectance is an inherent optical property of an object not subject to ambient light conditions, output laser power, laser incidence angle, or other measurement parameters. Topographic lidar intensity images, and SHOALS pseudoreflectance images (Tuell and Park 2004) do not utilize radiometrically-calibrated receivers, so intensity and pseudoreflectance of an object may vary from flightline to flightline and day to day. Intermediate products derived from the lidar data and waveforms as part of this process are SHOALS depth images, images of $a+b_b$, a measure of absorption and backscattering in the water column, at 532 nanometers, and images of water column reflectance at 532 nanometers. Bathymetric laser bottom reflectance images are generated using the Optech, Incorporated, SHOALS Ground Control System and the Optech International Rapid Environmental Assessment (REA) processor. Descriptions of SHOALS radiometric calibration and estimation of bottom reflectance from bathymetric lidar waveforms, see Tuell et al. (2005b).

An example of a bathymetric laser bottom reflectance image is shown in Figure 2. The bathymetric lidar data were collected as a demonstration of capability at Portsmouth Harbor, New Hampshire, in October 2005. Figure 2 (a) shows a true color image, or the red, green and blue bands, extracted from 36 bands of hyperspectral imagery collected concurrently with the lidar data. The overlay in Figure 2(b) is the bottom reflectance image. The range of reflectance values represented by the overlay is 0 to 0.2, where brighter colors have the highest reflectance. The gap in the bottom reflectance image at the shore is caused by an inability of the algorithms to estimate $a+b_b$, and therefore bottom reflectance, in shallow waters. This is an area of ongoing research.

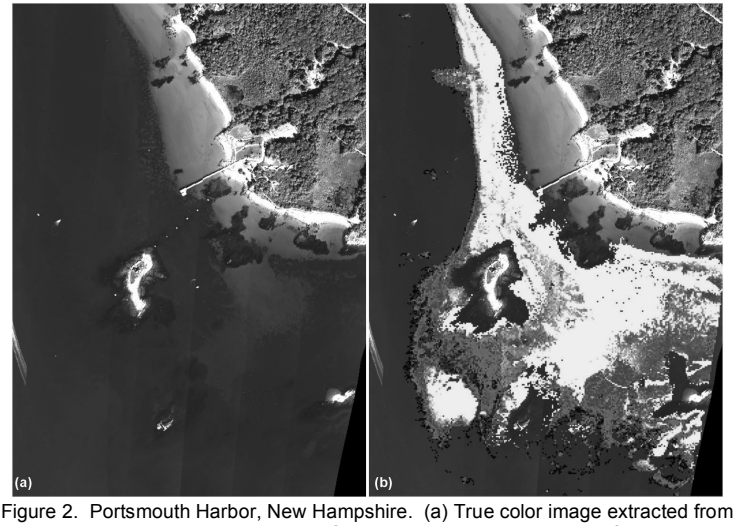

Figure 2. Portsmouth Harbor, New Hampshire. (a) True color image extracted from hyperspectral imagery. (b) Bottom reflectance overlay. Values range from 0 to 0.2.

Atmospherically-corrected hyperspectral image mosaics are created using raw CASI-1500 imagery, navigation data from SHOALS data processing, a lidar DEM, and some ancillary information about the weather and flight parameters, like visibility, flight direction, and collection time. The raw CASI imagery is first corrected to at-sensor radiance using a laboratory radiometric calibration and Itres standard processing software. The at-sensor radiance image strips are processed in two ways depending on whether the flight is over land or water. CASI imagery collected over land is atmospherically corrected using the Tafkaa6s atmospheric correction model developed at the U.S. Naval Research Laboratory (Gao et al. 1993). This model converts at-sensor radiance to reflectance by removing the effect of the atmosphere on light traveling from the sun to the image scene, and from the image scene to the aircraft. Like the bathymetric laser bottom reflectance images, the values of atmospherically-corrected hyperspectral image pixels are reflectance of the objects in the scene, regardless of ambient light conditions or image viewing geometry. Itres standard processing routines are used to combine the atmospherically-corrected image strips, the navigation file generated from the SHOALS system and ground station raw GPS data, and the lidar elevation DEM into an orthomosaicked image product.

Figure 3 shows three stages in the process to create an atmospherically-corrected hyperspectral image mosaic over land at Wells Harbor, Maine. Figure 3(a) are radiometrically corrected CASI image strips, shown as they were flown in flightlines with opposing directions. Figure 3(b) shows a color-scaled DEM created from concurrently collected lidar elevation data. Figure 3(c) shows the final atmospherically-corrected hyperspectral image mosaic. Figure 4 shows an example of at-sensor radiance (a) and reflectance (b) images from Seabrook Harbor, New Hampshire. These image data were collected over three days. Some data were collected in the late afternoon when light conditions change rapidly. In Figure 4(a) the differences in illumination from day to day and during a single flight are visible as differences in brightness across the image. In the atmospherically-corrected, or reflectance image (Figure 4b) these differences have been removed. Based on the inundation of the channels through the wetland, it is evident that the left side of the image was also collected at a different stage of tide than the right.

Path length radiance bias is removed from CASI imagery collected over water using the Optech International REA processor prior to atmospheric correction. Atmospheric correction for images over water is accomplished using Tafkaa_tabular (Montes et al. 2001), because Tafkaa6s cannot correct for the specular reflection of the air-water interface (Montes et al. 2004). Following atmospheric correction, the Optech REA processor removes sun glint from the water surface. Itres standard processing software is used to geocorrect the CASI imagery in a method similar to that described for the hyperspectral mosaic product, but each flight line is placed into its own image and a constant elevation is used in place of the lidar DEM. Finally, the Optech REA processor Color Balancing and Mosaicking (CBM) routine combines the lines into a single image. CBM uses surface reflectance derived from the bathymetric laser bottom reflectance, $a+b_b$, water column reflectance, and depth images to normalize the surface reflectance at all wavelengths of the hyperspectral imagery (personal communication, J.Y. Park).

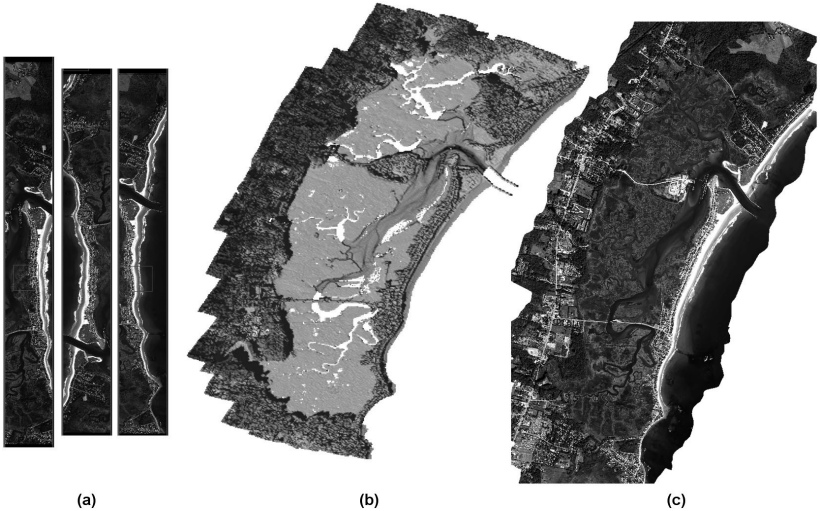

Figure 3. Steps to create an atmospherically-corrected hyperspectral image mosaic, Wells Harbor, Maine. (a) Radiometrically-corrected image strips. (b) Lidar DEM. (c) Final mosaic.

The final bottom image is bottom reflectance at all wavelengths of the hyperspectral imagery. It is created solely in the Optech REA processor. First, homogeneous areas are selected based on the bathymetric laser bottom reflectance image and an approximate bottom image. The approximate bottom image is calculated from the CBM surface reflectance image, SHOALS depth, and an estimate of water column attenuation that is constant across the image. In the homogeneous areas, with known water depth and the same bottom type in every pixel, $a+b_b$, water column reflectance, and bottom reflectance can be calculated for each wavelength of the hyperspectral data. Offsets are calculated between these values and SHOALS derived values for these parameters at the laser wavelength of 532 nanometers. The offsets scale the SHOALS images for these parameters, providing spatially varying values of $a+b_b$ and water column reflectance at every wavelength of the hyperspectral data. These values and SHOALS depth allow for the solution of the radiative transfer equation for bottom reflectance at each hyperspectral wavelength over the entire image area. For details on calculating the final bottom image, see Tuell et al. (2005a).

PRODUCTS IN DEVELOPMENT

Products currently in development at the JALBTCX are coastal zone classifications generated from the current suite of NCMP data products. Work is underway to identify a basic set of coastal thematic classes that can be identified using a combination of lidar elevation and hyperspectral imagery data, and classification algorithms in commercial-off-the-shelf software. One example is shown in Figure 5, where the Spectral Angle Mapper algorithm in ENVI was used to classify hyperspectral imagery at Portsmouth

Harbor, New Hampshire. This classification algorithm, and others like the Maximum Likelihood Classifier, can be used on final bottom images and bathymetric laser bottom reflectance images to create classifications of bottom type. Development in the Optech International REA processor includes some higher-level data fusion techniques that seek to reconcile the differences in bottom classifications from different sources to achieve a classification with higher accuracy. Work for the NOPP contract includes automatic attribution of the shoreline vector extracted from lidar elevation data using classification techniques. In this work, homogeneous areas in the hyperspectral imagery on land are automatically delineated and attributed with information extracted from the lidar data. The homogeneous areas are identified based on these attributes as coastal data features like sand, rock, buildings, roads, etc. Once this identification is made, the shoreline vector is segmented and attributed based on its intersection with the coastal data features.

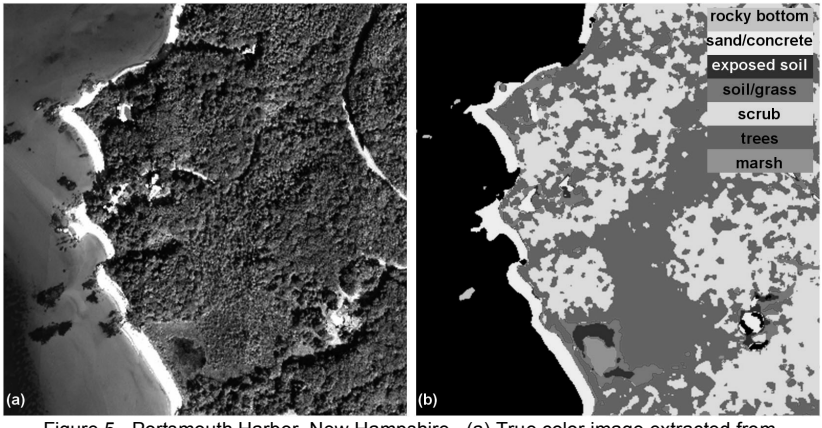

Figure 5. Portsmouth Harbor, New Hampshire. (a) True color image extracted from hyperspectral mosaic. (b) Basic image classification.

CONCLUSION

Data collected by the CHARTS system for the NCMP provide the basis for a rich set of data products to be used in support of planning, engineering, construction, operation and maintenance activities in the coastal zone, and to support regional sediment management practices. These include bathy/topo DEMs, RGB and hyperspectral image mosaics, building footprints, and bare earth grids. New data fusion products are the bathymetric laser bottom reflectance image, atmospherically-corrected hyperspectral image mosaics, and hyperspectral final bottom images. New product development uses each of these either singly or in conjunction to generate accurate land cover and bottom type classifications to characterize the coastal zone. New JALBTCX sensor development effort, CZMIL, will create a hardware and software system optimized to produce accurate elevation measurements and environmental characterizations in the coastal zone.

ACKNOWLEDGEMENTS

The author would like to thank Vinod Ramnath (Optech International) for his assistance in generating the bathymetric laser bottom reflectance images. Information presented herein, unless otherwise noted, is based on work funded by Headquarters, USACE, Operations, Construction, and Readiness Division. Permission to publish this paper was granted by the Chief of Engineers.

Abstract: In North Carolina, shoreline change rates are an important component of the state's coastal management program. To enhance methods of measuring shoreline change, the NC Division of Coastal Management (DCM) is considering using mean high water (MHW) shorelines extracted from lidar data together with traditional wet/dry shorelines digitized from aerial photography. To test their compatibility, a wet/dry line and MHW shoreline derived from a concurrent 2004 oceanfront photography and lidar dataset were compared along a distance of 244 km. Results show that the MHW shoreline was seaward of the wet/dry shoreline by 2.82 m on average, and that this offset biased shoreline change rates by an average of 0.05 m/yr. The offset was greatest on low-sloping beaches experiencing higher water levels at the time of photography, but overall was small enough to suggest that the MHW shoreline can be a reliable substitute for the wet/dry shoreline.

INTRODUCTION

Coastal policy and shoreline change rates in North Carolina

Every five to six years, the North Carolina Division of Coastal Management (DCM) updates the state's shoreline change rates, which have been required for the establishment of oceanfront building setbacks since 1979 under the North Carolina Coastal Area Management Act (CAMA). CAMA rules require that any new

oceanfront structure must meet a specified setback distance measured landward from the first line of stable, natural vegetation surveyed on the beach. In general, the setback distance is a multiplier of the long-term (42 to 71 years) average annual erosion rate. With few exceptions, oceanfront development intended for single-family use must meet a setback distance of 30 times the average annual erosion rate or a minimum of 60 feet (~18 m). Commercial and multi-family development greater than or equal to 5,000 ft^2 (465 m^2) must meet more stringent setbacks, often based on a 60-year multiplier. It follows that the accuracy of shoreline change rates must be high so that setbacks ultimately reflect actual conditions and coastal development can be sited at reduced risk.

In 1999, the North Carolina Coastal Resources Commission's (CRC) Science Panel on Coastal Hazards, a technical committee primarily composed of geologists and engineers that provides scientific and technical guidance to the CRC, recommended that DCM: 1) begin moving towards using linear regression-based erosion rates instead of end-point rates for calculating oceanfront setbacks and 2) explore the use of short-term erosion rates as a complement to long-term rates. However, switching to linear regression rates would necessitate the use of several statewide shoreline positions, and calculating short-term shoreline change rates (<10 years) may require a shoreline indicator of higher accuracy than what DCM traditionally has used (the wet/dry line, see next section). DCM is currently performing a statewide erosion rate update using a concurrent 2004 aerial photo and lidar dataset, and multiple shoreline indicators are being considered for inclusion. A better knowledge of how these different shoreline types compare and contrast to each another (and why) will not only create a better, more accurate understanding of North Carolina's dynamic coastal processes, but will also increase the effectiveness of many coastal management and coastal policies that rely upon shoreline analysis.

The wet/dry line

Traditionally, the wet/dry line interpreted from aerial photography (e.g. Dolan et al. 1980; Martin 1997; Overton et al. 1999; Overton and Fisher 2003) has been used to delineate the shoreline and to calculate shoreline change rates in North Carolina. Acting as a visual proxy for shoreline position, the wet/dry line is defined simply as the boundary observed on the beach between wet and dry sand (Figure 1) and is affected by factors such as tides, wave run-up, sediment characteristics (e.g. grain size and porosity), and groundwater levels (Martin 1997).

Although the wet/dry line can sometimes be considered a surrogate for the high water line (HWL; Boak and Turner 2005), it is important to note the differences between them. The HWL has received thorough consideration (e.g. Shalowitz 1964; Stafford 1971; Pajak and Leatherman 2002; Ruggiero et al. 2003; Moore et al. 2006), and is interpreted as the landward extent of the previous high tide (Shalowitz 1964). Even though it was at one time a wet/dry boundary, it is not necessarily a clearly saturated boundary at the time of photography. Rather than actively migrating seaward and landward during a tidal cycle similar to the wet/dry line (Dolan et al. 1980), the HWL is a more static boundary that can be identified by other visual cues besides saturation such as sand discoloration or debris left by the last high tide (Shalowitz 1964). For the

purposes of this study, "HWL" will refer to this definition. The HWL as so defined is often located higher on the beach face than the wet/dry line, and has been quantitatively defined as the elevation exceeded by 2% of wave run-up maxima (Ruggiero et al. 2003). The wet/dry line, on the other hand, has been approximated in North Carolina as the elevation exceeded by 33% of wave run-up (Martin 1997).

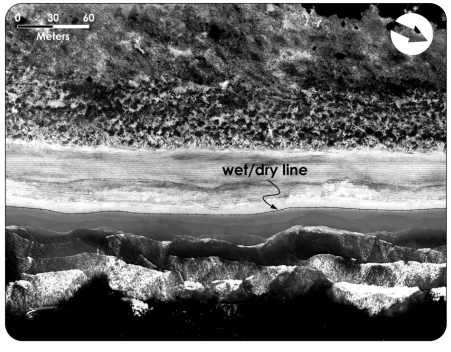

Figure 1. An example of the wet/dry line near Nags Head, NC.

An assessment of lateral short-term wet/dry line instability due to wave run-up and tides in North Carolina showed that the wet/dry line varied by up to 5.8 m during a single tidal cycle (Dolan et al. 1980) and 10.3 m during a single day (Martin 1997). Similarly, the HWL has been shown to vary on the order of 10 m during a month in North Carolina (Pajak and Leatherman 2002). This potential instability can introduce uncertainty into shoreline change rates, as a given rate may be an expression of short-term water level variability rather than a true indicator of shoreline movement (Ruggiero et al. 2003).

Interpretation of the wet/dry line from aerial photography, as with other visual shoreline proxies such as the HWL, can vary (Daniels et al. 2000; Ruggiero et al. 2003) due to the different skill or knowledge levels of the digitizers. Daniels et al. (2000) found, for instance, that two interpretations of the HWL on the same set of photography differed on average by 12.44 m. This, along with short-term variability and the possible positional inaccuracies of aerial photography (Ruggiero et al. 2003), can introduce uncertainty into shoreline change rates and in turn affect the accuracy oceanfront structure setbacks or other coastal policy decisions.

Lidar-derived datum-based shorelines

Recently, topographic lidar surveys have been used to generate shorelines based on the elevation of a tidal datum, such as mean high water (MHW), calculated over an 18.6-year tidal epoch (e.g. Judge et al. 2001; Stockdon et al. 2002; Moore et al. 2006). Such datum-based shoreline positions may offer noteworthy advantages over photo-interpreted shorelines such as the wet/dry line. First, datum-based lidar shorelines can shift only in response to sediment transport, and any short-term variation due to wave run-up and/or tides is eliminated (List et al. 2006). Second, there is no interpretation

necessary and the shoreline extraction procedure is therefore objective and repeatable. MHW is the most common tidal datum used to extract a shoreline from lidar data because its position on a given beach is thought to be analogous to other shoreline indicators such as the HWL and those derived from National Ocean Service T-sheets (Shalowitz 1964).

Before a lidar-derived MHW shoreline can be included in a long-term shoreline change analysis in North Carolina, the degree of consistency between it and the wet/dry line must first be tested so that any bias to shoreline change rates introduced by using two different shoreline indicators can be quantified. Several studies have addressed the relationship between the HWL and MHW, and the HWL has been found to be landward of MHW by approximately 50 m in Washington (Ruggiero et al. 2003), 18.8 m on Assateague Island (Maryland and Virginia; Moore et al. 2006), and 13.4 m in North Carolina (Pajak and Leatherman 2002). Because the wet/dry line falls somewhat lower on the beach than the HWL, we would expect the offset and possible bias to shoreline change rates found in this study to be less than indicated in previous studies.

In August and September of 2004, a concurrent set of orthophotography and lidar was obtained for the entire North Carolina coast that allows for direct comparison between the wet/dry shoreline and the lidar-derived MHW shoreline. Using this dataset, the goals of this study are to assess 1) the degree of interchangeability between the wet/dry and MHW shorelines over a large and morphologically diverse oceanfront shoreline study area (~244 km) and 2) the feasibility of using MHW shorelines to calculate long-term shoreline change rates in North Carolina.

STUDY AREA, DESCRIPTION OF DATASET, AND METHODOLOGY

The Atlantic barrier island coastline of North Carolina (Figure 2) is a wave-dominated, microtidal environment. Mean annual significant wave heights (H_{sig}) are 0.7 – 1.6 m (NOAA 2006), and semidiurnal tides range, on average, from ~1 m along the northern coast to ~1.5 m near the South Carolina border (NOAA 2006). Because "hard" shoreline stabilization structures such as seawalls and groynes have been banned since 1985, the North Carolina coast is largely unaffected by engineered structures.

Between 27 August and 3 September 2004, MD Atlantic Technologies (Huntsville, AL), co-contracted by the US Army Corps of Engineers (USACE) and DCM, collected a dataset of concurrent lidar and aerial photography covering the entire 516 km-long ocean coastline of North Carolina. Figure 3 shows the dates and times of the surveys, as well as the tidal stage and approximate H_{sig} values. Lidar was collected with an Optech ALTM 3100 sensor mounted on a Cessna 206. Vertical accuracy is generally expected to be ±0.15 m (Sallenger et al. 2003), which includes all known sources of error. Digital elevation models (DEMs) gridded from the lidar returns were tested and found to be within this range (MD Atlantic 2005). However, subsequent comparisons between the returns of two lidar passes separated by about an hour over the same 40 km-long area showed a significantly greater amount of vertical error – about 0.3 m – which caused MHW shorelines generated from each pass to be offset

by, on average, 2.45 m. This error is likely due to the potential for the GPS data to drift vertically over time (Sallenger et al. 2003). The GPS error is not well understood, so it is difficult to estimate the appropriate error for each data point within a data set. Although the level of vertical drift error present in some of this lidar data might be much higher than what is normally expected, with only limited data demonstrating this we cannot determine a general increased error term to apply to all the data; therefore, we used the standard vertical error estimate of ±0.15 m.

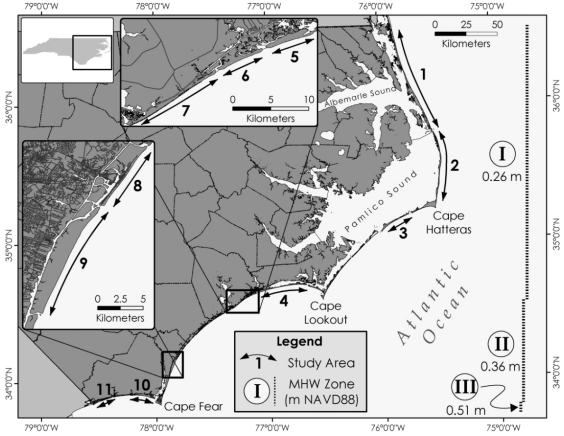

Figure 2. North Carolina location map showing study areas and MHW zones.

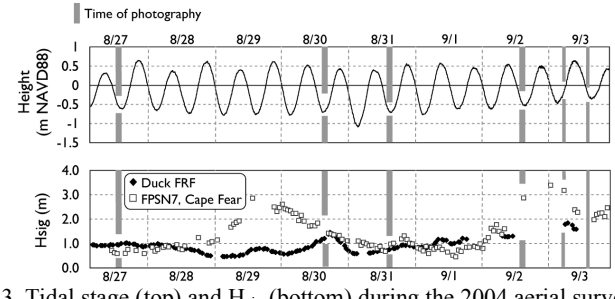

Figure 3. Tidal stage (top) and H_{sig} (bottom) during the 2004 aerial survey dates. Tidal data are from the USACE Field Research Facility (FRF) at Duck, NC; H_{sig} values are from the FRF waverider buoy at Duck and NOAA buoy FPSN7 near Cape Fear.

A method similar to that presented by Stockdon et al. (2002) was used to extract a MHW shoreline from the North Carolina lidar data. Every 20 m alongshore, beach profiles of scattered lidar data were extracted and a linear regression through a selected set of foreshore data points was used to locate the intercept of a MHW elevation with the beach profile. Operational MHW elevation zones as mapped by

Weber et al. (2005) were used to determine the elevation of MHW. Three such zones exist in North Carolina (Figure 2; relative to NAVD88): Virginia to Cape Lookout (0.26 m), Cape Lookout to Cape Fear (0.36 m), and Cape Fear to South Carolina (0.51 m). Given a vertical accuracy of ±0.15 m for all data points and using beach slopes measured at each cross-shore transect, the vertical error was converted into a horizontal error. This term was added in quadrature, i.e. the square root of the sum of the squares, to the 95% confidence interval of the MHW intercept on the regression line and resulted in a composite horizontal error estimate for each MHW data point. There were many areas for which a MHW shoreline position could not be produced due to problems encountered in the lidar data, and as a result, the MHW shoreline contains recurrent data gaps.

Digital aerial photography was collected simultaneously with the lidar survey. Using lidar-generated DEMs, the photography was orthorectified and subsequently tested to have a total root mean square (RMS) error of ±1 m (MD Atlantic 2005). The resulting orthophotos have a ground cell resolution of 0.15 m and are at scale of 1:2400. The wet/dry line was digitized from the orthophotography for use in comparing to the MHW shoreline, and three DCM staff members inspected the shoreline to ensure that the wet/dry interpretation was as consistent as possible.

Eleven study areas totaling a distance of 244 km were chosen in which to compare the wet/dry shoreline with the MHW shoreline (Figure 2). We excluded areas where the photos and lidar were asynchronous, large data gaps existed in the MHW shoreline, and consistent wet/dry interpretation was problematic. Comparisons were made using ArcGIS 9 equipped with the Digital Shoreline Analysis System (DSAS; Thieler et al. 2005) at transects spaced every 20 m alongshore.

MHW AND WET/DRY LINE INTERCHANGEABILITY

Observed proxy-datum offsets

To test the interchangeability of the MHW and wet/dry shorelines, we measured horizontal and vertical offsets between them (i.e. proxy-datum offsets) for all study areas. Vertical proxy-datum offset is defined as the elevation difference between the wet/dry line and MHW, and the elevation of the wet/dry line was measured by intersecting it with the lidar data. The elevation of the wet/dry is assumed to be a relative indicator of water level (i.e. tidal stage and wave run-up) on the beach profile, although other physical variables such as groundwater seepage and sediment permeability can control wet/dry line location (Martin 1997). Figure 4 and Table 1 summarize all observed offsets as well as other results that will be discussed in subsequent sections. On average, the wet/dry line was landward of the MHW shoreline by 2.82 m ($\sigma = 5.31$) and higher on the beach profile by 0.18 m ($\sigma = 0.29$). The position of the wet/dry line varied horizontally from 35.87 m landward to 12.30 m seaward of the MHW shoreline, and vertically from –0.73 m to 2.4 m. Table 1 shows the mean horizontal proxy-datum offsets for each study area, which range from 0.05 m (Oak Island) to 15.61 m (Ocracoke Island). Positive numbers indicate that the wet/dry line is landward of the MHW shoreline.

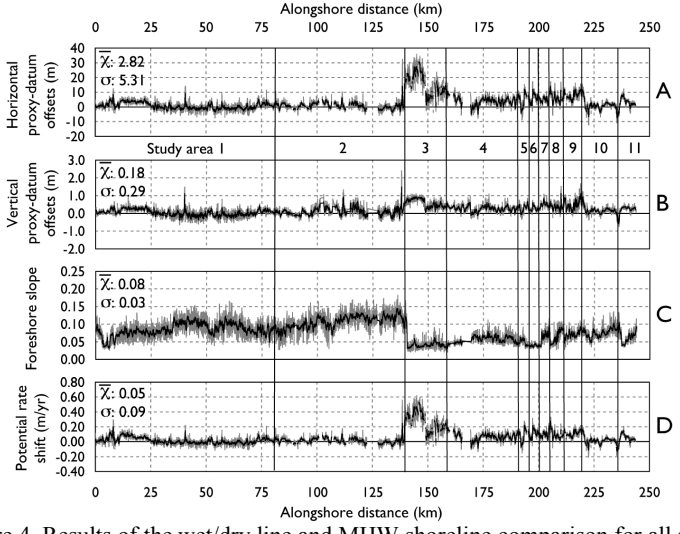

Figure 4. Results of the wet/dry line and MHW shoreline comparison for all study areas. Positive numbers on plots A and B indicate that wet/dry line is landward and higher in elevation than MHW, respectively. Positive rate shift values on plot D indicate an erosion rate decrease. The gray line represents per-transect values, and the black line is a smoothed 340-m average.

Table 1. Shoreline position and comparison data for all study areas

Study Area	ID	Length (km)	Mean Offset (m)	σ Offset	Mean Rate Shift (m/yr)	σ Rate Shift	Mean Slope	2004 Survey Date
Nags Head	1	81	0.65	2.57	0.01	0.05	0.085	8/27
Cape Hatteras	2	59	0.87	2.66	0.02	0.05	0.107	8/27
Ocracoke	3	19	15.61	8.49	0.27	0.15	0.041	9/03
Bogue Banks	4	35	3.68	3.51	0.06	0.06	0.057	8/30
Bear Island	5	4	5.75	4.17	0.10	0.08	0.038	8/30
Brown's Island	6	3	7.34	2.65	0.13	0.05	0.039	8/30
Onslow Beach	7	5	6.19	3.43	0.12	0.07	0.063	8/30
Wrightsville Beach	8	5	4.97	3.28	0.07	0.05	0.072	9/02
Masonboro Island	9	10	7.94	2.99	0.11	0.04	0.072	9/02
Oak Island	10	16	0.05	2.70	0.00	0.05	0.075	8/31
Ocean Isle Beach	11	7	3.68	2.70	0.06	0.04	0.059	8/31
TOTAL		**244**	**2.82**	**5.31**	**0.05**			

Previous studies have shown the HWL interpreted from aerial photography to be landward of the elevation of MHW by approximately 50 m (Ruggiero et al. 2003), 18.8 m (Moore et al. 2006), and 13.4 m (Pajak and Leatherman 2002). As expected, because the wet/dry line falls consistently lower on the beach face than the HWL, the horizontal proxy-datum offsets measured here are comparatively small. This suggests that a lidar-derived MHW shoreline can be used as a reliable substitute for the

wet/dry line and that bias to shoreline change rates will be minimal, especially over the long-term (>50 years).

Causes of observed proxy-datum offsets

Causes of the trends and magnitudes in offset between the shorelines can depend on variables such as beach slope, short-term variability of the wet/dry line due to water level changes, and consistency of wet/dry line interpretation. Ruggiero et al. (2003) and Moore et al. (2006) found that horizontal proxy-datum offsets are larger on low-sloping, high-energy beaches, and that beach slope may be a good general predictor of offset magnitude. Figure 4A shows horizontal proxy-datum offsets aligned with beach slope measurements alongshore, and many regional and local trends in shoreline offset are inversely proportional to beach slope. For example, the increase in horizontal offset beyond ~140 km alongshore (study areas 3-11, Figure 2) is accompanied by a flattening of the foreshore beach profile, and the small shoreline differences in study areas 1 and 2 are accompanied by the steepest overall slopes in North Carolina. It is interesting to compare the variation of vertical proxy-datum offsets (Figure 4B) with horizontal offsets, as they are linked together by beach slope (Figure 4C). Between roughly 100 and 125 km in study area 2 (Figure 4), for example, the vertical offset approaches 1 m, but due to a steep beach the horizontal offsets are minimal (<5 m). Conversely, on Ocracoke Island (study area 3), vertical offset approaches 1 m, but there a low-sloping beach produces horizontal offsets over 30 m.

The position of the wet/dry line can be variable depending on tidal stage and wave run-up (Martin 1997). All photography used in this study was taken during or near low tide (Figure 3); however tidal stage still varied from a maximum of approximately –0.1 m (9/3, Ocracoke Island) to a minimum of –0.7 m (8/31, Oak Island and Ocean Isle). H_{sig}, measured at the USACE FRF waverider buoy near Duck, NC and at NOAA buoy FPSN7 offshore of Cape Fear (NOAA 2006; Figure 3), also potentially varied between surveys. Both buoys indicate that H_{sig} was generally lowest during the surveys on 8/27 and 8/31, higher on 8/30 and 9/2 (although data points are sparse), and highest on 9/3. Consequently, the wet/dry line should not be at a consistent elevation on the beach profile for each survey. Mean horizontal and vertical offsets were lowest on 8/27 and 8/31, higher on 8/30 and 9/2, and highest on 9/3. This suggests, as proposed by Ruggiero et al. (2003), that higher wave energy pushes the wet/dry line higher on the beach profile and increases the horizontal offset at a magnitude inversely proportional to beach slope, while lesser wave energy allows the wet/dry line to be lower on the beach profile and decreases horizontal offsets. On 9/3, in addition to the high H_{sig}, the tidal stage was also the highest observed, and that in combination with a low-sloping beach produced the large mean 15.61 m horizontal offset measured on Ocracoke Island. The majority of the total study area, however, was surveyed on 8/27 and 8/31 when H_{sig} was moderate (0.6-1.3 m). In North Carolina, mean annual H_{sig} is 0.7–1.6 m, and so these dates can be taken as representing average, fair-weather conditions. Horizontal offset between the wet/dry and MHW shorelines on 8/27 and 8/31 averaged 0.80 m, indicating that during low tide and fair-weather wave conditions, the shorelines are nearly equivalent. It is

important to note that for study areas at a large distance from both wave buoys (e.g. Bogue Banks, Onslow Beach), H_{sig} values should be taken as approximations only.

Assuming a relatively constant water level, beach slope alone could theoretically be a good general predictor of horizontal proxy-datum offsets. As discussed above, tides and H_{sig} varied between survey dates, and wave run-up (and therefore the elevation of the wet/dry line and vertical proxy-datum offsets) should be expected to vary alongshore within study areas as a function of beach slope (Holman 1986; Stockdon 2006). The magnitude of horizontal offsets throughout all study areas is therefore dependent on both beach slope and water level and we can test this relationship using a simple equation:

$$X_0 = \frac{H_{proxy} - H_{datum}}{m} \quad (1)$$

where X_0 is the horizontal proxy-datum offset (Moore et al. 2006); H_{proxy} and H_{datum} are the heights of the wet/dry line and MHW, respectively; and m is beach slope (note that the numerator is the vertical proxy-datum offset shown in Figure 4B). Figure 5 (left) shows the correlation between horizontal proxy-datum offset (X_0) and beach slope along 857 cross-shore transects chosen at random throughout all study areas. Even though the trend is significant at the 95% confidence level, the overall relationship is indistinct. A conspicuous subset of points with high values of X_0 from Ocracoke Island is labeled on the graph where the beach is relatively flat but X_0 was exaggerated as a result of the high water levels observed on that particular survey date (9/3). Along the same 857 transects, the elevation of the wet/dry line, assumed to be a relative indicator of water level, was measured and equation (1) was applied to predict X_0. Results were compared with the observed X_0 and are shown in Figure 5 (right). The correlation is very strong and illustrates that X_0 will be larger on low-sloping and/or higher energy beaches. This relationship can explain the mean X_0 magnitudes for all study areas and survey dates, including the high X_0 measured on Ocracoke Island on 9/3 and the low X_0 measured in study areas 1 and 2 on 8/27 wherein the beach profile was relatively steep and H_{sig} was moderate. Plugging the mean beach slope (0.08) and mean vertical proxy-datum offset (0.18 m) for all study areas into equation (1) yields a predicted mean X_0 of 2.25 m, which is close to the observed total mean of 2.82 m. In some cases, the assumption of a linear beach slope between the wet/dry line and MHW shoreline may not hold true, and fluctuations in vertical proxy-datum offset may reflect inconsistencies in digitizing the wet/dry line rather than actual water level changes. These factors can account for the discrepancies between observed and predicted offset values.

Rate shifts

If the horizontal offset between the wet/dry line and MHW shoreline is large enough, (i.e. if water level is high and/or beach slope is low) it may begin to bias, or shift, change rates when one shoreline indicator is used as a substitute for the other. If the proxy-datum offset and the time elapsed between shoreline positions is known,

however, this rate shift is predictable when using end-point rates and can be determined as follows (Moore et al. 2006):

$$R_{Se} = \frac{X_0}{t} \tag{2}$$

where R_{Se} is the end-point rate shift; X_0 is the measured horizontal offset between the wet/dry and MHW shorelines (also defined in equation 1 as $[H_{proxy} - H_{datum}/m]$); and t is the temporal span between the recent and historic shorelines used to calculate the shoreline change rate. The effects of the horizontal proxy-datum offset, X_0, will thus be greater at short time intervals (Moore et al. 2006).

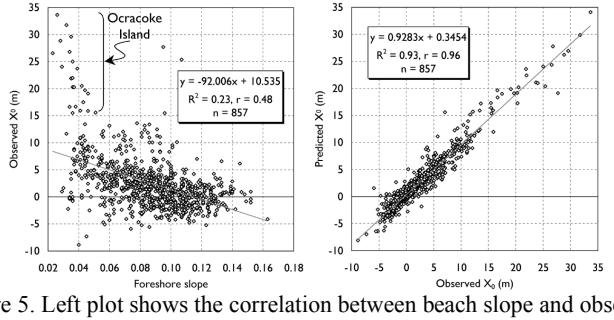

Figure 5. Left plot shows the correlation between beach slope and observed horizontal proxy-datum offset. Right plot shows the correlation between observed horizontal offsets and horizontal offsets predicted using equation (1).

DCM uses a composite statewide historical shoreline for calculating long-term end-point shoreline change rates that dates between 1933 and 1962; with the 2004 shoreline, t in equation (2) varies from 42 to 71 years. Figure 4D shows the per-transect rate shifts that are possible if the 2004 MHW shoreline is used instead of the 2004 wet/dry line to calculate change rates with the historical baseline shoreline, and Table 1 lists the mean rate shifts for each study area. The total mean rate shift is 0.05 m/yr (positive number indicates erosion rate will be reduced and accretion rate will be increased) for all study areas and ranges for individual study areas between 0 (Oak Island, t = 60 years) and 0.27 m/yr (Ocracoke Island, t = 58 years). If the rate of shoreline change is rapid or the temporal span between shoreline positions is sufficiently long, the rate shift will only be a small fraction of the total change rate and may be small enough to completely disregard (Moore et al., 2006). Since horizontal proxy-datum offsets are relatively small in North Carolina and the time spans used are typically >50 years, much of the offset will produce negligible rate shifts. On the other hand, if the rate of change is slow and/or the proxy-datum offset is large, the rate shift may be a much greater fraction of the total rate. In this case, equation (2) can be used to correct for the shift if the mean horizontal offset is known or approximated.

Relative shoreline uncertainties

Some horizontal differences between the MHW and wet/dry shorelines may not be significantly different than zero due to the inherent positional uncertainties of the shorelines. To understand this, we must first assemble an approximate uncertainty budget for the wet/dry shoreline. As discussed above, there are three main sources of wet/dry line uncertainty: interpretation, short-term variability due to water level changes, and source error (Daniels et al. 2000; Ruggiero et al. 2003). Source error of the orthophotos used in this study was determined to be ±1 m (MD Atlantic 2005) after comparing locations on the photos with ground control points. To assess the uncertainty associated with interpretation, two wet/dry lines digitized by DCM staff were compared over a distance of 85 km. The first shoreline was checked for accuracy and consistency by DCM staff to act as a baseline for comparison, and specific visual cues were defined so that shoreline identification would remain consistent for the second iteration. Comparisons of the two shorelines revealed that the second shoreline was seaward of the original by 0.6 m with a total root mean square (RMS) uncertainty of ±2.6 m.

It was not possible to determine the short-term variability of the wet/dry due to water level changes because we lack the necessary frequent observations. In areas where 2004 photography from two different dates was available, the wet/dry line was seen to migrate landward approximately 10 m over a 12-hour period (Ocracoke Island), seaward 20 m over 3 days (Bogue Banks), and around 20 m landward over a month (near Cape Hatteras). Pajak and Leatherman (2002) assessed the variability of the HWL in North Carolina during July, August, and September from 1994-1996 over hourly, daily, and monthly time periods. Excluding storm events, they established a generalized estimate on the order of ±10 m. In addition, field measurements of the wet/dry line in North Carolina by Martin (1997) indicated a variability of ±10.3 m during a single day. These measurements agree with our cursory observations and provide a useful estimate of wet/dry variability in North Carolina, acknowledging that further work needs to be completed to assess its true variability.

Summing the source error (±1 m), interpretation uncertainty (±2.6 m), and potential short-term variability (±10 m) in quadrature yields a total wet/dry line uncertainty of ±10.4 m. Other similar uncertainty budgets for HWL shorelines total ±20 m (straight sum of ±3 source error, ±2 interpretation, ±15 short-term variability; Daniels et al. 2000) and 51-150 m (quadrature sum of ±4 source error, ±11 interpretation, ±50-150 m short-term variability; Ruggiero et al. 2003). Mean uncertainty of the MHW shoreline for all study areas is ±2.22 m (σ = 0.92). Taking the total uncertainty estimate for both shorelines into account, only 6% (694 out of 11,159) of measured horizontal proxy-datum offsets are significant, most of which are located on Ocracoke Island. This suggests a high degree of interchangeability between shorelines.

DISCUSSION

Lidar-derived, datum-based shorelines can offer an increase in accuracy over the wet/dry line for use in end-point rates and can also be used as a supplement to existing wet/dry lines in linear regression models. Short-term change rates (<10 years) that may be difficult to resolve using wet/dry lines are possible using MHW

shorelines, and DCM is considering using them for areas where long-term change rates are heavily biased by beach fill projects (e.g. Wrightsville Beach, Bogue Banks, Oak Island) so that the change rate can be more accurately measured between beach fill episodes. Results presented here suggest that a lidar-derived MHW shoreline is interchangeable with DCM's traditional shoreline proxy, the wet/dry line, given a steep sloping beach and/or low water levels at the time of photography. Under these circumstances, a MHW shoreline will introduce minimal bias to long-term end-point shoreline change rates in North Carolina. However, during times of high water level and on low-sloping beaches, as demonstrated at Ocracoke Island, the proxy-datum offset is much greater and the interchangeability between the wet/dry line and MHW shoreline is decreased. Here, rate shifts will be a larger fraction of the total change rate, and it is therefore difficult to determine categorically that the shoreline indicators are equivalent because it depends on the conditions at the time of photography as well as beach morphology. On average, though, the observed rate shifts and proxy-datum offsets were small enough that the shorelines can be considered compatible. In future studies, the height of the wet/dry line can potentially be estimated using numerical wave run-up models as discussed in Martin (1997). This could allow proxy-datum offsets and rate shifts to be estimated without a rigorous proxy-datum comparison as described herein, and could also facilitate an assessment of the short-term variability of the wet/dry line.

Horizontal and vertical proxy-datum offsets, based on beach slope and the elevation of the wet/dry line, and the effect of resultant rate shifts on shoreline change rates can be connected through a simple equation using variables from equations (1) and (2) (after Moore et al. 2006):

$$R_A = \left(\frac{\left(\frac{H_{proxy} - H_{datum}}{m} \right)}{t} \right) + R_0 \qquad (3)$$

where R_0 is the original shoreline change rate and R_A is the adjusted shoreline change rate after the incorporation of the rate shift. H_{proxy}-H_{datum} is the vertical proxy-datum offset, the vertical proxy-datum offset divided by slope (m) is the horizontal proxy-datum offset (or X_0), and the horizontal proxy-datum offset divided by time span (t) is the rate shift. Because horizontal and vertical offsets are relatively small in North Carolina and shoreline change rates are calculated over sufficiently long time spans, the R_0 and R_A values should be very similar and the wet/dry line and MHW shoreline can be considered generally interchangeable. The overall mean difference between R_0 and R_A values for our study was 0.05 m/yr.

CONCLUSIONS

The 2004 photo-derived wet/dry shoreline presented here, measured over a distance of 244 km in North Carolina, is on average 2.82 m (σ = 5.31) landward of the 2004 lidar-derived MHW shoreline (Figure 4A) and 0.18 m (σ = 0.29) higher on the beach profile (Figure 4B). The magnitude of mean horizontal proxy-datum offset varies by

study area and ranges from 0.05 to 15.61 m (Table 1). Considering the uncertainty of the wet/dry line and MHW shoreline, 6% of measured offsets were significantly different than zero. Given a low tide and fair-weather wave conditions at the time of photography and/or a steep-sloping beach, these results suggest that the MHW shoreline can be used as a reliable substitute for the wet/dry line in regional shoreline change analyses. Rate shifts caused by using the MHW shoreline instead of the wet/dry line average 0.05 m/yr for all study areas (Figure 4D) and vary between zero and 0.27 m/yr for individual study areas (Table 1). Rate shifts either a) are a small percentage of the overall change rate and can potentially be disregarded or b) can be corrected using equation (2) providing that the mean proxy-datum offset is known or approximated through equation (1).

ABSTRACT: U.S. Geological Survey (USGS) scientists used 1999 multibeam data, and 2002 lidar data collected on the inner shelf off southern California to investigate a field of (<1 m) features, termed "Rippled Scour Depressions" (RSDs). RSDs are elongate, shore-normal, and bathymetrically depressed features; their morphology was determined from multibeam and lidar bathymetry. Wavelengths of ripples seen within RSDs and on the surrounding seafloor were calculated from photography and video collected in 2004 and related to sediment samples collected in the same year. The RSDs were divided into two areas: Region I RSDs contained large (~80 cm wavelength), straight-crested ripples with coarse-grained lag, and decreased in area between 1999 and 2002; Region II RSDs were smaller, in shallower water, closer to shore, and contained shorter (~30 cm wavelength) ripples, and increased in area from 1999-2002. The RSDs did not display marked alongshore asymmetry.

INTRODUCTION:

Active continental margins, such as off of California's coast, tend to be narrow with deep, steep shelf breaks, all of which significantly affect cross-shelf circulation and transport (Nittrouer and Wright 1994). Sediment deposits on the inner shelf are impermanent features that can be deposited or eroded rapidly and episodically (Nittrouer and Wright 1994; Storlazzi and Jaffe 2002), even after long periods of apparent stasis. Many datasets gathered in shelf sedimentary environments represent a transitory condition. Modern marine research often utilizes temporally repeated datasets (e.g., Goff et al. 2005) not only to document changes within the dynamic inner shelf environments, but also to identify the likelihood for perturbation. As coastal research increasingly focuses on erosion, benthic habitats, and the impact of hard structures, improved understanding of inner-shelf dynamics will enable managers to more effectively monitor and manage the coastal zone.

Multibeam backscatter and bathymetric data collected in 1999 from the inner San Pedro shelf seaward of Long Beach, CA (Dartnell et al. 2004) show a relatively flat shelf pitted by a series of high-backscatter elongate features near Huntington Beach (Fig. 1). These shore-normal features, defined by Cacchione et al. (1984) as Rippled Scour Depressions (RSDs), are approximately one meter lower than the surrounding seafloor. Typically RSDs are hundreds of meters wide, and up to kilometers in length. Often they are characterized by large, shore-parallel ripples, which are composed of coarser sediment than that on the surrounding seafloor. While a number of recent studies have identified RSDs in diverse coastal environments (Green et al. 2004; Murray and Thieler 2004; Garnaud et al. 2004; Goff et al. 2005), the origins of these features are not well understood.

RSDs were originally noted to be roughly symmetric in transverse bathymetric profile, although RSDs have since been described in other regions as having marked asymmetry (Murray and Thieler 2004; Goff et al. 2005). Hydraulic roughness created by the large bedforms within the RSDs has been proposed to increase local turbulence, inhibiting settlement of finer-grained sediment, explaining their persistence during periods of low wave energy (Goff et al. 2005). Cacchione et al. (1984) proposed initiation of individual RSDs through scour induced by storm-driven downwelling that removes finer-grained surficial sediment typically seen on the seafloor adjacent to RSDs. Local steep seafloor gradients associated with rocky outcrops and high current-induced bed stress were originally proposed to concentrate downwelling flows with localized intensification leading to preferential scour. A lack of correlation between rock outcrops and RSD along-coast spacing, however, as well as the occurrence of RSDs in regions without rocky outcrops indicate that other causes are locally important (Murray and Thieler 2004). Recent work in South Carolina and Massachusetts indicate that strong along-shore currents can also influence the formation and migration of RSDs, causing them to be asymmetrical in transverse bathymetric profile (e.g., Fig. 2 of Murray and Thieler 2004; Goff et al. 2005). Murray and Thieler (2004) also suggest that these alongshore currents could lead to differential sand transport of coarse and fine fractions, resulting in self-organization of RSDs in some cases.

This paper investigates RSDs offshore of Huntington Beach, CA. High-resolution bathymetry data, gathered in 1999 and 2002, show changes in the spatial extents of these features. These data in conjunction with seafloor photographs and video of small-scale bedforms collected in 2004, shed light on the dynamics affecting these features.

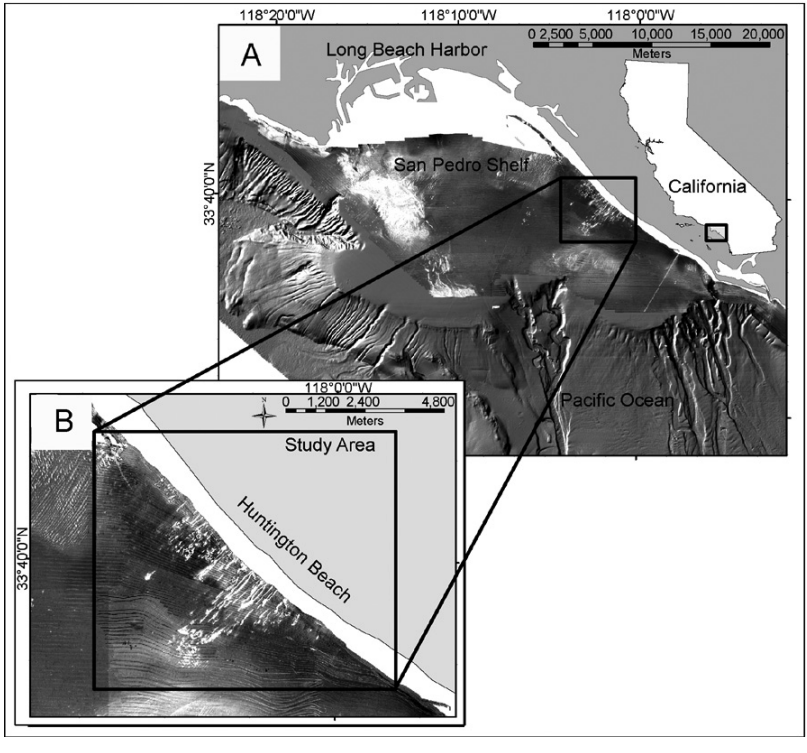

Figure 1. A) Multibeam backscatter mosaic overlain on shaded relief bathymetry of San Pedro Shelf and slope offshore of Long Beach, CA. B) Enlarged view of the study area located immediately offshore of Huntington Beach, CA, showing the location of the highly reflective (bright), elongate, shore-normal rippled scour depressions (RSDs), which contrast sharply with the adjacent, less-reflective (darker) seafloor.

STUDY AREA

The study area is located from one to six km offshore of Huntington Beach, CA on the San Pedro Shelf, the widest section of continental shelf in southern California; this area is part of the Southern California Borderland. The seafloor is characterized by unconsolidated to poorly consolidated Quaternary sediments that blanket the shelf (Karl et al. 1980; Fisher et al. 2004; Bohannon et al. 2004). Extensive urbanization in the region has had a major impact on the sediment budget. While anthropogenic

affects such as flood-control by the damming and channelization of rivers and bluff armoring are mostly offset by nourishments, there is an estimated loss to the inner shelf of ~90 m^3/yr (~120 yds^3/yr) of sand (Slagel 2005; Patsch and Griggs 2006).

The Southern California Borderland is characterized by submarine canyons, banks, and offshore islands, which shadow the shelf from wave directions other than the west and the south (Emery 1960; O'Reilly 1993; O'Reilly and Guza 1997; Noble et al. 2003; Xu 2005). Midshelf significant wave heights for the area are typically 0.5 m to 0.7 m from April to October and 1.0 m with storm peaks at 2.5 m from November to March (Drake et al. 1985). The Southern California Eddy, a poleward recirculating limb of the south-flowing California Current (Hickey 1992), dominates currents on the shelf during the summer months. A recent study shows the presence of strong downcoast flows to the southeast during the summer months as well (Noble et al. 2003; Xu 2005) with the subtidal currents on the order of 5 cm/s to 10 cm/s dominating innershelf currents (Xu 2005).

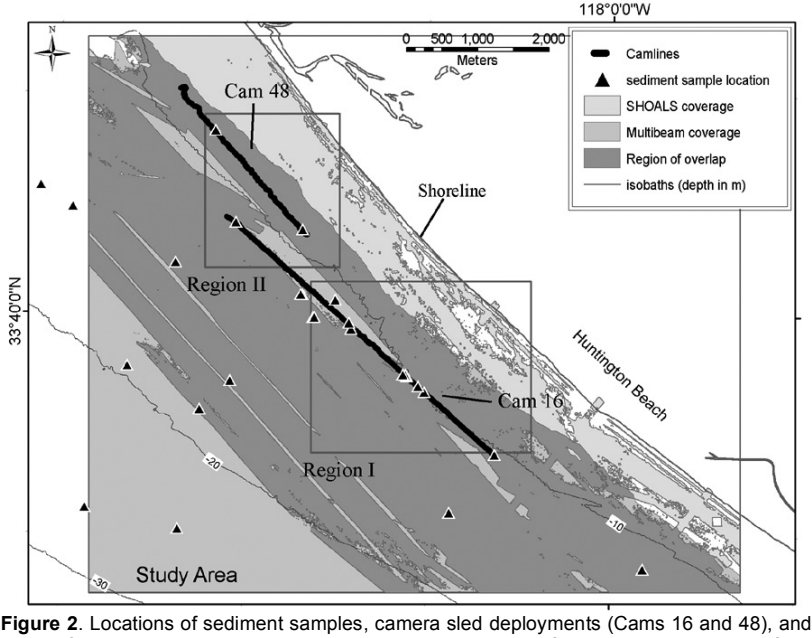

Figure 2. Locations of sediment samples, camera sled deployments (Cams 16 and 48), and areas of multibeam and lidar coverage. A dark grey region defines where the extents of the multibeam (medium grey) and the lidar (light grey) data overlap. All subsequent areal coverage calculations for the RSDs were restricted to the zone of overlap. Also shown are the extents of RSD Regions I and II discussed in the text.

METHODS

USGS researchers collected multibeam data in 1999 from the San Pedro shelf as part of a regional mapping project (Gardner and Dartnell 2002). Subsequently, in

conjunction with scientists from the Los Angeles County Sanitation District (LACSD) and Orange County Sanitation District (OSCD), USGS researchers collected seafloor video and still photography and sediment samples in 2004 to map the dominant seafloor facies and benthic habitats on San Pedro Shelf, including our study area (Dartnell et al. 2004; Edwards et al. 2006). The 1999 multibeam data were compared with existing SHOALS bathymetric lidar data collected in a narrow alongshore strip from the beach to 20 m water depth by the U.S. Army Corps of Engineers (USACOE) in 2002 (Fig. 2). Data pertaining to the study area were loaded into a Geographical Information System (GIS) database using ESRI ArcInfo™ and analyzed to quantify changes in the RSD field during the five-year period.

Sediment Samples

Thirty-eight seafloor sediment samples were collected in December 2004 within the study area (Fig. 2). The samples were analyzed for grain size using a coulter counter and settling tubes. These data were added to the GIS database, and ancillary data—depth, backscatter intensity and closest seafloor photograph—were assigned to each data point.

Digital Video and Photography

Ten hours and 7.3 line-kilometers of seafloor video data were collected within the study area in 2004. Two video camcorders recorded oblique and vertical-looking video of the same field of view, in which two dots from the laser beams provided scale. RedHen™ Systems' proprietary hardware/software package recorded navigational GPS data onto the videotapes. Layback, the offset incurred by towing a sled, was calculated and applied to the navigation data. The resulting navigation data were associated with the video and photographs and loaded into the GIS dataset. Three-minute segments of video were also mosaicked into jpegs, as described in Rzhanov et al. (2002) and added to the GIS dataset (Fig. 4A).

Onboard scientists used a remote switch to capture seafloor images with a 6 mega-pixel digital camera approximately every 30 seconds during the sled deployment (termed a "Cam"). The Huntington Beach region of interest contains Cam 16 and Cam 48 (Fig. 2), which traverse two sections of the RSD field. Cam 16 was run shore-parallel along the 11 m isobath; Cam 48, located northwest of Cam 16, was run shore-parallel along the 9 m isobath. Over 750 photographs were collected during those deployments. Measurements of the ripple wavelengths, determined by measuring from one ripple crest to the next, were made for all images that have one or both sets of lasers and identifiable ripple crests. Because the limited field-of-view (~1 m^2) resulted in an inability to identify two lasers (for scale) and/or two complete ripple crests, the size of large ripples (wavelength >50 cm) typically could not be quantified in still photographs (Fig. 4B). When the ripples were too large to measure on photographs, ripple wavelengths were determined from the video, again using laser dots to determine scale, with measurements taken approximately every 30 s. The resulting measurements and associated depth values, taken from the multibeam bathymetry data, were added to the GIS dataset.

Multibeam Data

Regional multibeam bathymetry and acoustic backscatter data for water depths between 8 m and 900 m were collected in 1999 with a Kongsberg Simrad EM3000D multibeam echosounder (Fig. 2; Gardner and Dartnell 2002). Mosaics of these data gridded to 4 m pixels (Dartnell et al. 2004) were used in this study. Polygons were visually identified and hand-drawn in the GIS dataset, identifying elongate bathymetric depressions with continuous, distinct contours. A co-registered backscatter intensity mosaic was inspected to distinguish RSDs from small bathymetric data artifacts. Where RSDs extended to the limits of the dataset, the perimeter of the polygon coverage was defined as the edge of the dataset. To avoid false positive identification, only regions of high backscatter that ran shore-normal and had smooth, depressed bathymetric profiles were identified as RSDs (Fig. 3). The resulting polygons were used to make areal comparisons of RSDs identified in both bathymetric datasets, and were compared to the photography, sediment samples, and video collected in 2004.

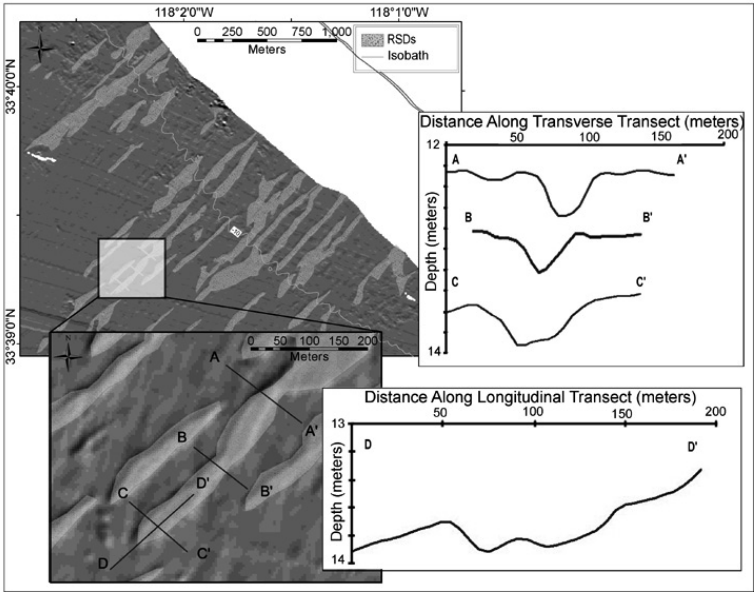

Figure 3. Shaded relief multibeam bathymetry of the study area with RSDs identified in light grey. Enlarged region shows bathymetric profiles of transects across selected RSDs, showing both transverse transects (A-A', B-B', C-C') and a longitudinal one over the offshore edge (D-D'). Transverse transects are run over progressively deeper locations on the RSD; each transect displays a region of bathymetric depression with a relatively symmetrical profile. The offshore extent of the RSD is also characterized by a distinct bathymetric gradient boundary, as shown in D-D'.

SHOALS Lidar

In 2002, the USACOE gathered SHOALS bathymetric lidar data from the shoreline to depths of 20 m offshore of the Los Angeles region. Areal coverage is complete except for limited regions of missing data due to breaking waves and other visibility issues (Fig. 3). The raw SHOALS data were gridded to 4 m pixel resolution to match the resolution of the multibeam data. The two datasets were aligned and registered using Orange County Sanitation District sewer outflow pipes, located outside of the Study Area, and rock outcroppings north of Huntington Beach, visible in both the lidar and the multibeam data. Few data artifacts were present within the SHOALS data, and the boundaries of the RSDs were easily determined. RSDs were identified in the GIS using the methodology previously described for the multibeam dataset. A polygon defining the region of overlap of multibeam and lidar datasets was created, and the RSD polygons identified in multibeam and lidar datasets were restricted (clipped) to the region of overlap. Two areas, Regions I and II (Fig. 2), were identified to maximize coverage of RSDs within the area being analyzed, and percent coverage and areal change between 1999 and 2002 were calculated for RSDs both within the entire study area and in the two subregions.

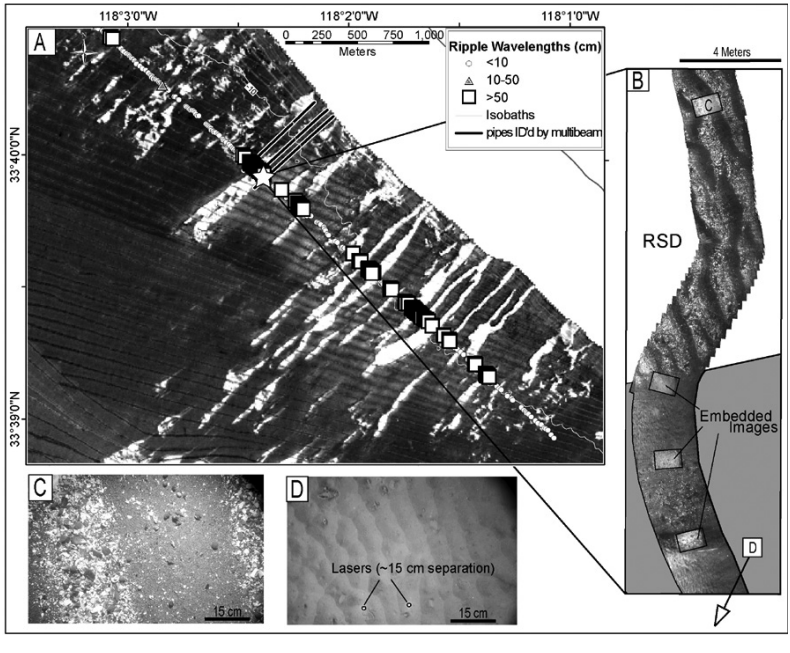

Figure 4. A) Multibeam backscatter mosaic of Region I displaying a section of ripple wavelength measurements, as well as the pipes that were identified through backscatter intensity and bathymetry data. The large ripples (>50 cm) identified on the map do not correlate exactly with the multibeam background image, indicating migration of the RSDs. A star indicates the location of a section of B) a videostrip from Cam 16 with embedded photographs. This section of video imaged the boundary of a RSD, and displays the location

of C) a photograph of large ~70 cm wavelength shore-parallel ripples with shell debris and gravel in the troughs. D) A photograph of small ripples with a measured wavelength of 6.6 cm, located ~5 meters from the edge of the videostrip.

RESULTS

The backscatter mosaic offshore of Huntington Beach is predominantly characterized by low-backscatter (dark) returns, with isolated well-defined elongate, shore-normal regions of high (bright) backscatter returns. Co-registered bathymetric data were used to identify these acoustically bright features (RSDs) as depressed approximately ~0.5 m below the surrounding seafloor.

The main RSDs identified in our dataset extend offshore 2.5 km to the 14 m isobath from the nearshore boundary of the overlap region (~1.0 km offshore at 8 m water depth). Nearby, additional RSD fields occur outside of our study area up to 5.5 km offshore (18 m to 23 m water depth). Video and photography taken of and sediment samples recovered from the RSDs in 2004 indicate that the majority of RSDs identified offshore of Huntington Beach contain sediment coarser than that of the surrounding seafloor with shore-parallel sand ripples (λ = 40 cm to 120 cm), that have gravel and shell debris in the troughs. These RSDs are up to 1.5 km long, and are often greater than 100 m wide. They are sharply defined by both strong acoustic backscatter returns and clearly identifiable, continuous margins in the bathymetry data that delineate the 0.3 m to 0.5 m depressions. Interspersed between these RSDs are rock outcrops that outcrops, which protrude0.5 m to 1.0 m from the seafloor 0.5 m to 1.0 m, and are typically surrounded by slight depressions. The RSDs do not have an alongshore rhythmic spacing, and rock outcrops do not appear related to the alongshore spacing of the RSDs.

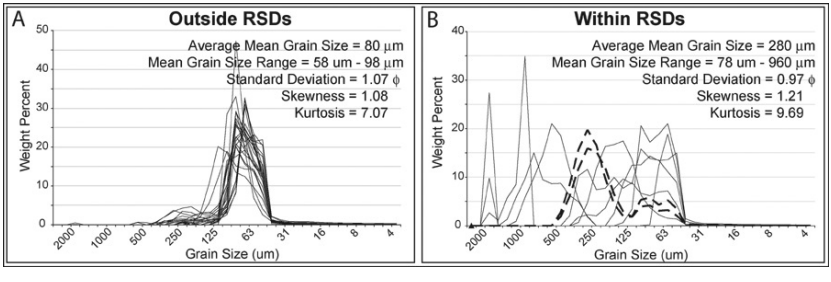

Figure 5. Grain size distributions of sediment samples collected A) on the seafloor surrounding the RSDs with a moderately-sorted very fine sand and B) within RSDs with a poorly-sorted medium sand. Bold dashed lines in B represent sediment samples collected within Region II; solid lines in B represent samples in Region I.

Sediment Size

The sediment outside of the RSDs was characterized by moderately sorted (average σ = 0.97 φ) very fine sand (average mean = 80 μm) (Fig. 5A). Ripple wavelengths were less than 10 cm. The sediment in the RSDs was characterized by poorly sorted (average σ = 1.07 φ) medium sand (average mean = 280 μm). Coarse sediment

samples do not show a trend based on depth or subregions: two coarse sediment samples, recovered in a single sampling location in Region II (bold dashed lines in Fig. 5B), fall well within the range of grain size distributions of sediment samples collected from within Region I (solid lines in Fig. 5B).

While the sediment samples correlate well with the video and photographic data gathered in the same year (2004), they do not always correlate positively with the multibeam and lidar data (collected in 1999 and 2002, respectively) (Fig. 4A).

Ripple sizes

Region I (Cam 16) was characterized by large wavelength, straight-crested ripples with shell debris and gravel in the troughs (Fig. 6A-1). Region II (Cam 48) was characterized by smaller, less orderly ripples, and lacked visible coarse lag deposits within the RSDs. Large ripples located in both Region I and II do not exactly correlate with either the 1999 multibeam-identified RSDs or the 2002 lidar-identified RSDs, and offsets between these data are irregular.

The ripples can be separated into three distinct groups. Within the RSDs in Region I, ripple wavelengths were 72±25 cm. Within the RSDs in Region II, ripple wavelengths were 29±9 cm. Small, well-organized ripples with wavelengths of 7±1 cm occur outside of the RSDs in the fine-grained sediment of Regions I and II (Fig 6 B-E).

RSD Coverage

The combined multibeam and lidar overlap datasets cover 25.3 km^2, and the statistics for Regions I and II are summarized below in Table 1. Between 1999 and 2002, RSD coverage decreased by 0.7 km^2 with variability within the Regions. In Region I, most RSDs whose shoreward extent lay closer than 1 km to shore in 1999 disappeared or decreased in area by 2002 (Fig. 8A), and total coverage decreased from 0.9 km^2 to 0.7 km^2. In Region II, the RSDs grew from 0.2 km^2 to 0.3 km^2, primarily in the shoreward (northeast) direction (Fig. 7B).

Table 1. RSD Coverage by Region and Year

	Total Coverage	RSDs - 1999 multibeam	RSDs - 2002 lidar
Study Area	25.0 km^2	11.3 km^2 (45%)	10.6 km^2 (42%)
Region I	4.6 km^2	0.9 km^2 (20%)	0.7 km^2 (15%)
Region II	2.3 km^2	0.2 km^2 (9%)	0.3 km^2 (13%)

DISCUSSION

Both lidar and multibeam datasets contain regions that do not overlap, and those regions were not treated in the quantitative analyses. There are, however, some general trends that appear when inspecting the entire datasets. Many Region I RSDs appear to have migrated offshore or decreased in areal coverage from 1999 to 2002

(Table 1). Examination of the 2002 lidar data shoreward of the 1999 multibeam data extent does not show more identifiable RSDs in Region I. In Region II, the RSDs, appear to have expanded shoreward and become more extensive, and examination of the 2002 lidar shows continuation of the RSD field shoreward of the 1999 multibeam data extent. The smaller RSDs seen in Region II extend further inshore to shallower water (8 m as opposed to 11 m in Region I) in both 1999 and 2002, and are likely to thus more frequently become mobilized.

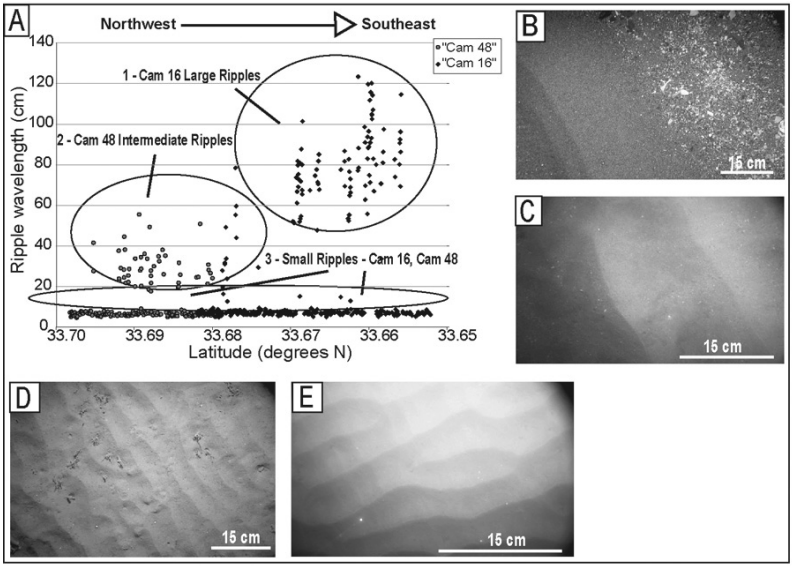

Figure 6. A) Ripple wavelengths (in cm) identified by video and still photography plotted versus latitude. B-E) Photographs, taken from northwest to southeast, of typical ripple morphologies for each size class. Data for Cam16 are shown as black triangles and for Cam 48 as grey circles. Ellipses identify three size class clusters: 1) the largest ripples with λ = 40 cm - 120 cm, located in Cam 16, 2) intermediate ripples with λ = 18 cm – 55 cm, located in Cam 48, and 3) short ripple wavelengths withλ = 5 cm – 10 cm, characterizing the seafloor outside of the RSDs for both Cams 16 and 48.

All of the ripples in the study area are symmetric with sharp, narrow crests and flat, broad troughs. In other ways, however, the ripples differ between the RSDs in Regions I and II. Within Region I, the median ripple wavelength in the RSDs is 75 cm with 84% of the measurements falling above 50 cm. The median RSD ripple wavelength in Region II is 28 cm. The larger ripples in Region I RSDs were straight crested with gravel or shell hash in the troughs. On the other hand, the larger ripples in Region II RSDs were short-crested without gravel or shell debris in the troughs.

The depth of a RSD does not appear to be a function of its size, and RSDs from both Regions I and II have approximately the same amount of bathymetric depression.

The interfaces between the RSDs and the surrounding seafloor, which is characterized by very fine sand and small ripples, are sharp. Areas with the largest ripples tended to have the straightest and the most continuous ripple crests, and the most gravel exposed in the ripple troughs. Medium ripples (~10 cm to 50 cm) within Region I were also generally less organized, suggesting an intermediate stage in RSD development, for instance a transition after recent mobilization and reorganization under different flows than those that initially formed the RSDs.

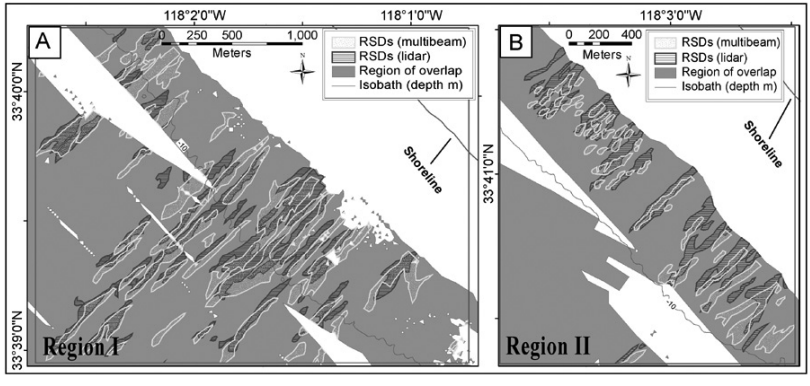

Figure 7. RSD locations in1999 (light grey) and 2002 (dark grey) for A) Region I and B) Region II.

Gravel, shell debris, and coarse sand are major constituents of the RSD floor; however, the RSD sediment samples show that there is not one grain size class, or grain size distribution, that dominates the system (Fig 5B), and there is no significant difference between Region I and II RSD sediment samples. Fine sediment is largely absent from some, but not all, of the RSD sediment samples. The homogeneity of the fine-grained sediment cover outside of the RSDs extends far outside of the study area. The heterogeneity of the RSD samples, which likely represents a coarse-grained basal lag, is similar to the coarse-grained intertidal lags exposed on many southern Californian Borderland beaches during the winter when much of the sediment has been stripped off the beaches. The heterogeneous nature of this lag reflects the mode of its emplacement, likely by stream action during the previous sea level lowstand (Drake et al. 1985).

RSDs most likely form and expand under high-energy conditions. Storms produce downwelling currents capable of removing the overlying fine-grained material that is suspended by storm waves, thus exposing the underlying coarser-grained lag (Cacchione et al. 1984; Garnaud et al. 2004). Within our study area, large, extensive RSDs typically contain well-organized, straight-crested, shore-parallel ripples with shell hash and gravel in the troughs that end abruptly at the edges of the RSDs. These RSDs decreased in coverage from 1999 to 2002. Smaller, less extensive RSDs contained intermediate, short-crested ripples lacking gravel and shell debris in the

trough. These smaller RSDs were also distinct from the surrounding seafloor, and increased in coverage between 1999 and 2002. Unlike the RSDs reported elsewhere (Murray and Thieler 2004, Green et al. 2004, and Goff et al. 2005), the lack of asymmetry in the RSDs' bathymetric profiles and their irregular alongshore spacing in both Regions, as well as the presence of shore-parallel ripple crests within the RSDs, does not support longshore currents as a dominant causal factor offshore of Huntington Beach. The relatively minor change in spatial extent and form of the RSDs likely reflects the quiescent nature of the inner shelf in the years between the surveys. The wave climate of the Southern California coast has been well documented as being strongly affected by ENSOs (El Niño-Southern Oscillation), (e.g. Storlazzi and Griggs 2000, Xu and Noble 2007). ENSO events have been documented to produce mean significant wave heights 50-100% higher than normal along the Southern California coast for the same months in non-ENSO years (Xu and Noble 2007) and these storm waves arrive more frequently out of the west and southwest (Storlazzi and Wingfield, 2005). 1998 was a strong ENSO event year, (Storlazzi and Griggs 2000), and as such the study area was impacted by larger, more southerly waves that directly impacted the southeast-trending shoreline, causing less energy loss to refraction and resulting in greater wave-driven set-up; this increased set-up likely drove the offshore-directed near-bed flows that either formed or help maintain the RSDs. Between 1998 and 2004 no new large regions of RSDs formed in the study area. A lack of large storms between the 1999 multibeam and 2002 lidar surveys, however, has not resulted in the burial of the RSDs or even a large reduction in their extent, suggesting that self-maintenance due to hydraulic roughness (Murray and Thieler 2004) is a likely characteristic of the dynamics of this system. The frequency of sampling and a lack of data before 1998, however, does not support definitive conclusions on the evolution or maintenance of these features.

CONCLUSIONS

The symmetrical RSDs offshore of Huntington Beach fall into two distinct categories: those observed in Region I, a collection of 1 km to 2 km long, greater than 100 m wide features containing large wavelength (>70 cm), straight-crested ripples with gravel and shell debris in the troughs, and those observed in Region II to the northeast, a grouping of shallower, smaller, shorter RSDs containing short-crested ripples with wavelengths less than 30 cm. The RSDs within Regions I and II showed differential areal change between 1999 and 2002 with those in Region I shrinking, and those in Region II becoming more extensive during the same time period. No trends were recognized in grain size between groups of RSDs, as there were limited sediment samples recovered, and the grain size distributions of sediment samples from RSDs were highly variable. However, there was a distinct difference in grain-size distribution between the sediment surrounding the RSDs and the coarser material within them.

ACKNOWLEDGMENTS

We wish to thank Jingping Xu and John Dingler for their critical reviews of the draft manuscript as well as Dave Cacchione and Greg Gable for valuable discussion. The officers and crews of the Los Angeles County Sanitations District (LACSD) R/V Ocean Sentinel and the Orange Country Sanitation Districts (OCSD) contract vessel,

the R/V Early Bird II and Hank Chezar, Kevin O'Toole and Gerry Hatcher provided able support for the data collection phase of the study. Funding for the study was provided by the LACSD and the USGS Coastal and Marine Program. We thank Joe Meistrell (LACSD) and George Robertson (OCSD) for providing ship time, and acknowledge the scientific contributions of the science staff of both LACDS and OCSD. We particularly appreciate the insight and encouragement provided by Joe Meistrell, Dave Montagne, and Don Cadien of LACSD. Unpublished SHOALS bathymetric lidar data were provided courtesy of Art Shak (USACOE). A STUDY OF INTERTIDAL BAR DYNAMICS USING THE ARGUS VIDEO SYSTEM

Amaia Ruiz de Alegria Arzaburu[1], Suzana Ilic[1], Yohama Gunawardena[1]

1. Department of Geography, Lancaster University, Lancaster, LA1 4YB, UK. a.r.alegria@lancaster.ac.uk; s.ilic@lancaster.ac.uk; y.gunawardena@lancaster.ac.uk.

Abstract: The following paper describes the cross-shore and longshore seasonal intertidal beach dynamics along the macro-tidal beach of Cleveleys (UK). The studied beach is characterised by the presence of shore-parallel runnel (channels) and ridges (tabular bodies), and intersecting drainage channels. Argus video images and *in-situ* field measurements have been used in order to quantify the spatial and temporal variability of the complex and dynamic runnel-ridge system. In the short-term, the impact of a major storm has been analysed and correlated to the changes in intertidal bathymetry. The long-term ridge position has been determined using the Argus image contouring technique and existing beach surveys since 1991. It has been demonstrated that the frequent cross-shore ridge migration mainly occurs during high energy conditions and is governed by surf zone processes. The longshore ridges' migration occurs at larger time scales and is associated with the dynamics of intersecting or mini rip channels.

INTRODUCTION

Many macro-tidal beaches, such as those around the British Isles, have complex topography as a result of the strong interaction between tide, waves, currents, groundwater and sediments. These beaches are often intersected with runnels (channels parallel to the shore) and drainage and/or rip channels (transverse channels) resulting in a difference in elevations across the beach. A runnel and ridge beach is a special case. The ridges are

formed as shore-parallel intertidal bars and separated from each other by shore-parallel runnels. Often, the ridges are also transversely cut by drainage channels, which usually follow irregular patterns and have high depth variability from several centimetres to several tenths of centimetres.

Although the intertidal bars have been studied since the 1940's (King and Williams, 1949), little is still known about their generation, evolution and decay (Wijnberg and Kroon, 2002). Most studies in the past used large numbers of beach surveys, (King and Williams, 1949, Masselink and Anthony, 2001) and cross-shore hydrodynamic measurements (Voulgaris *et al*. 1998) in order to determine the offshore/onshore beach dynamics and the bar formation and position. A recent study of intertidal bars dynamics using aerial photography and Lidar images (Van Houwelingen *et al*., 2006) showed that the intertidal bars not only migrate across-shore but also in the alongshore direction. Not much is known about transverse channel formation and their impact on the intertidal bars. It is still unknown whether these channels are rip channels formed due to surf zone processes during high tide, or drainage channels developed due to the tidally-induced ebb flow. They might also be formed due to a combination of wave induced, tidal and groundwater flow.

The beach volumes seem to be strongly related to the presence and deconstruction of ridges as well as their volume (Parker, 1975, Ilic and Ruiz de Alegria, 2006). Hence, it is necessary to get a better understanding of the intertidal morphodynamics in order to be able to predict the risk of future flooding and undertake proper shoreline management plans. The aim of this study is to investigate the cross-shore and longshore intertidal beach dynamics and the channels formation and migration by using long-term beach survey data, Argus video images and *in-situ* measurements.

STUDY AREA AND DATA COLLECTION

The study is conducted on the macro-tidal beach in Cleveleys at the eastern edge of the Irish Sea (Fig.1), several kilometres north from Blackpool, where the first investigations of intertidal bars were conducted and the "ridge" and "runnel" terms come from. The researched area is a macro-tidal beach with a mean tidal range of about 8m during spring tide and exposed to waves of limited fetch. Coastal defences such as groynes and a seawall have been built at Cleveleys to prevent beach erosion and protect the area from future flooding.

The Fylde coast where Cleveleys is located is an almost straight stretch of coastline, and is orientated NNW-N-NNE. However the shoreline at Cleveleys is slightly concave. The intertidal zone, which is 400-450m wide is characterised by the presence of two ridges (Fig.2.1 and 2.2). This area is also intersected by shore-normal, rip/drainage channels and shore-parallel runnels. The crest of the upper ridge is currently located between 110-160m and the crest of the lower ridge around 220-260m from the shoreline.

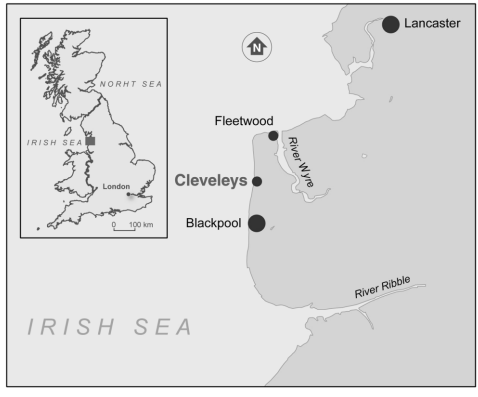

Fig.1. Site location map.

The Wyre Borough Council undertakes beach surveys between Fleetwood and Cleveleys at irregular intervals, but mostly twice per year since 1991. In addition, the Council deployed the ARGUS video imagery system (Holman *et al*., 1993, Aarninkhof *et al*., 2003) to monitor the beach changes due to the replaced seawall on the top of the beach. Two Argus stations are about 700m apart and cover the area up to 700m offshore. Argus video images have been collected from both stations every 30 minutes. On several occasions, a 5 minute continuous image collection has been set up in order to get a better resolution of beach profiles derived from the images.

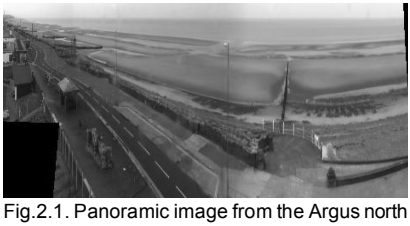

Fig.2.1. Panoramic image from the Argus north station (August 2005)

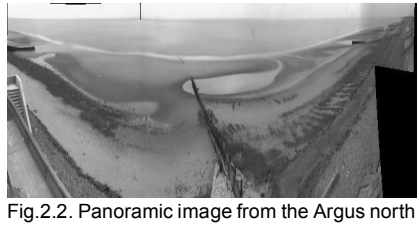

Fig.2.2. Panoramic image from the Argus north south (August 2005)

In-situ field measurements were conducted between 23rd September and 15th October 2006 in the area in front of the Argus north station. Hydrodynamics measurements were taken at two self-logging instrument rigs placed on the top of the outer ridge, (see X2 in Fig.3) and at the bottom of the runnel, (see X1 in Fig.3). Each rig contained an Acoustic Doppler Velocitymeter (ADV), an external pressure transducers (PT), and an optical backscatter sensor (OBS).Data were collected at 4Hz for about 6-7h when the instruments were submerged. The tidal elevation data from Heysham (north of the site), and wave data from two offshore buoys in Irish Sea are used to complement the field measurements. Also, wind velocities and directions were measured at the Argus Northern Station.

Fig.3. Location of the study area. The yellow rings indicate the location of the Argus video stations at Cleveleys. X1 is the location of the instrument rig in the channel and X2 shows the location of the second instrument rig on the top of the ridge.

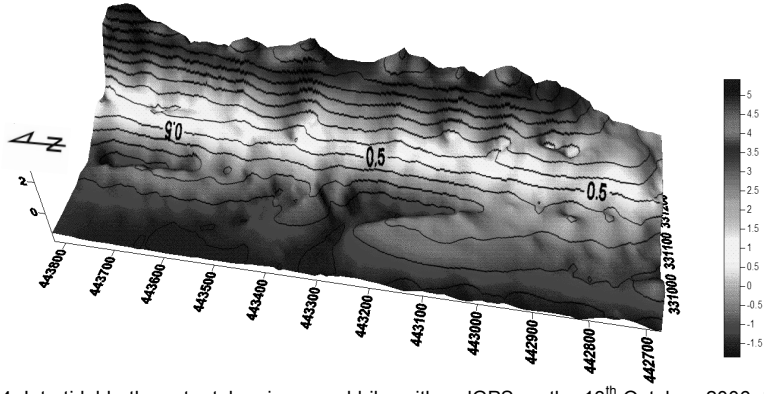

Fig.4. Intertidal bathymetry taken in a quad bike with a dGPS on the 13th October, 2006; the cross-shore and longshore distances are Ordnance Survey's Easting and Northing respectively. The colour scale indicates the elevation in metres.

Morphological measurements of intertidal bathymetry were conducted from 19th September until 15th October 2006 using a Trimble differential GPS (dGPS). A shore-normal profile through the instrument locations and two adjacent profiles were surveyed each day. These surveys were validated with surveys obtained with a total station in the first week of fieldwork. Additional profiles were surveyed as time allowed. At two occasions (6th and 13th October), the whole beach between two Argus stations was surveyed using a quad-bike and dGPS. The overall bathymetry of the intertidal area between two Argus stations derived from a dGPS survey is presented in Fig.4, which nicely shows the location of the runnel and ridges and the intersecting channels. Analysis of sediments collected on the outer ridge and runnel in the first week of fieldwork did not reveal much difference between the ridge and runnel sediment size (D_{50}=0.18 and 0.21mm respectively).

RESULTS

The intertidal area between the Argus north and south stations (Fig.3) has been analysed.

Long-term dynamics from beach surveys

Figure 5 shows beach profiles for Profiles 1, 2 and 3 (see Fig.3 for their locations) surveyed during or immediately after winter months. Unlike stationary ridges on the neighbouring Blackpool beach (Masselink and Antony, 2001; King and William, 1949) the ridges on the Cleveleys beach are highly dynamic. Most of the time two ridges are present, one immediately below the upper steeper shingle beach (inner ridge) and one on the lower beach (outer ridge). Both are located between mean low water neap and high water neap elevations. Inner ridges move onshore for about 120m over a period of approximately 3 years while outer ridges can move for about 160m in a shorter period of time. Inner ridges are more persistent and there are no outer ridges when the inner ridges are at their most offshore location.

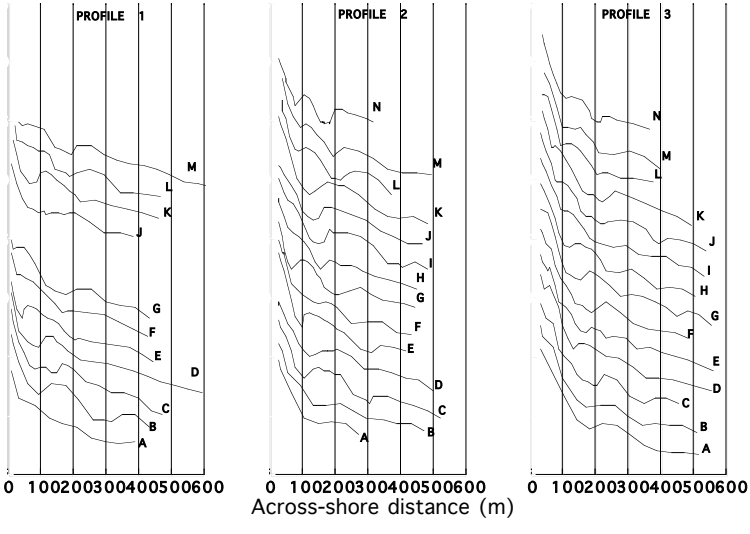

Fig.5. Intertidal beach profiles measured over the period 1991-2006 (data from the Wyre Borough Council, UK). The profiles have been vertically offset by 1m. The surveys were taken on: A=Oct 91, B=Sep 92, C=Sep 93, D=Sep 94, E=Sep 95, F=Sep 96, G=Sep 97, H=Sep 98, I=Sep 99, J=Nov 00, K=Mar 01, L=Oct 04, M=Oct 05 and N=Nov 06.

Figure 5 also illustrates the difference in the longshore position of ridges and runnels indicating their longshore migration. However, it is difficult to distinguish longshore and cross-shore migrations from beach profiles only. Particularly, the longshore dynamics is characterized by the movement of the intersecting drainage and mini rip channels. This is clearly seen from aerial photographs but it is difficult to track a position of a particular bar or a channel due to irregular and infrequent sampling (van Houwelingen *et al*.,

2006). The Argus video images taken at regular and more frequent intervals enable to track migrations of a particular ridge or channel.

Seasonal dynamics from Argus video images

The outer ridge contours, at a constant but arbitrary tidal level, approximately -1.7 m below ordnance datum Newlyn, UK, have been derived from the plan view Argus images from northern station for several days in 2005 and 2006. Figure 6 shows the variation in the length, width and shape of the outer ridge and the high mobility of the intersected channels. There were two ridges, separated by a rip channel, present in May 2005. In August 2005, the southern ridge advanced to the north, and a new intersecting channel was formed further north. After the winter, the southern ridge became flattened and the northern ridge expanded further south. In August 2006, the northern ridge became shorter but more pronounced while in October 2006 the ridge became flattened again. The intersecting channels moved north and south in this period. The northern ridge also moved onshore between May 2005 and May 2006 but expanded again offshore in August 2006. From August until October 2006, the ridge had moved again slightly towards onshore. Figure 6 clearly shows cross-shore and longshore dynamics of ridges and associated channels through winter/summer seasons.

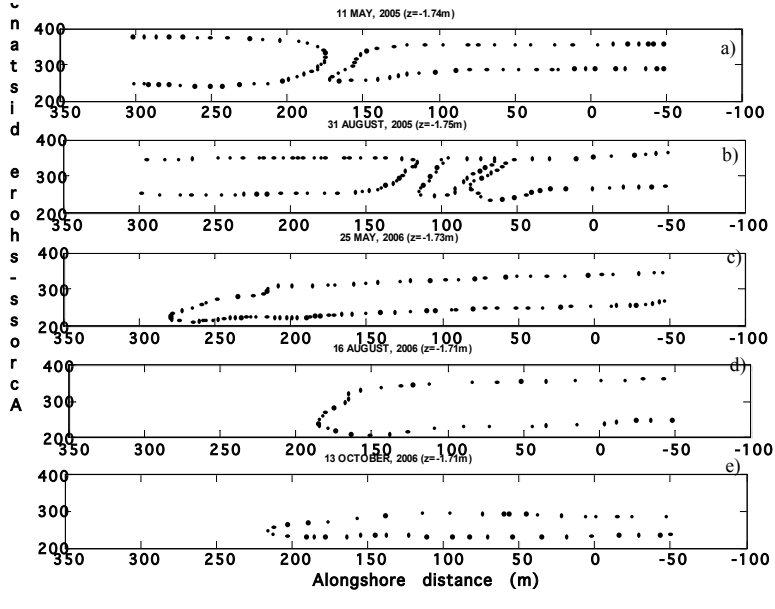

Fig. 6. Outer ridge contours derived from the Argus plan-view images at an approximate depth of -1.7m below ordnance datum, Newlyn, UK, for: a) 11th May 2005, b) 31st August 2005, c) 25th May 2006, d)16th August 2006, and e) 13th October 2006.

Short-term dynamics from *in-situ* measurements

The tidal elevation at Heysham, significant wave height and nearshore currents measured on the outer ridge between 24th September and 15th October are shown in Figure 7. Each of the dots represents measurements over 17min. Almost two complete spring-neap tidal cycles are covered. The second spring tide on 9th October was the second largest spring tide in the year and a total tidal range of 10.44m was recorded. Calm and more energetic periods were recorded, with significant wave heights between 0.03 and 0.87m. During spring tides, the high water level reaches the seawall and some wave energy is reflected back increasing the nearshore wave height. The mean wave period is 5.53s, which is also associated with more energetic waves. The wave direction varied from south-west up to north-west with westerly direction being more frequent. However the waves are mostly refracted by the time they reach the intertidal zone. The most energetic periods were on 27th September, between 2nd and 5th October and on 12th October. A severe storm (Hs=3.4m in Liverpool Bay) coincided with large spring tidal ranges of 9.25m and 10.16m on 6th and 7th October respectively. Unfortunately the equipment had to be rescued and there is no field record for this storm.

Time-averaged cross-shore and longshore currents plotted in Figure 7 show a presence of tidal modulation. During low wave activity, cross-shore and longshore currents are nearly symmetrical in respect to the high water. Both maximum cross-shore and longshore currents occur mid way between low and high and high and low tide and there are slack conditions during high tide. Maximum recorded longshore velocity of 0.32 m/s during spring tide and 0.19m/s during neap tide was recorded during low wave activity. They are northward directed during flood and southward directed during ebb. Cross-shore currents are onshore directed during flood and offshore during ebb with a maximum velocity of 0.12m/s during spring tide. During larger wave activity, the presence of wave-induced currents increased northward longshore currents and decreased southward directed longshore currents, but this is highly dependant of the wave direction. Cross-shore currents were mostly offshore directed through whole tidal cycle.

Several beach profiles were surveyed daily using the dGPS through the duration of field campaign. The beach profile through instrument location, starting on the 19th of September, (bottom) and finishing on the 15th of October, (top) is shown in Figure 8. The figure shows clearly the onshore migration of inner runnel and ridge, narrowing of the outer runnel and flattening of the outer ridge throughout the observation period. Also, the landward and seaward slopes of the outer runnel became less steep and the runnel became shallower. The main changes in profile occur after the storms on 27th September, 2nd/3rd October and 6th/7th October.

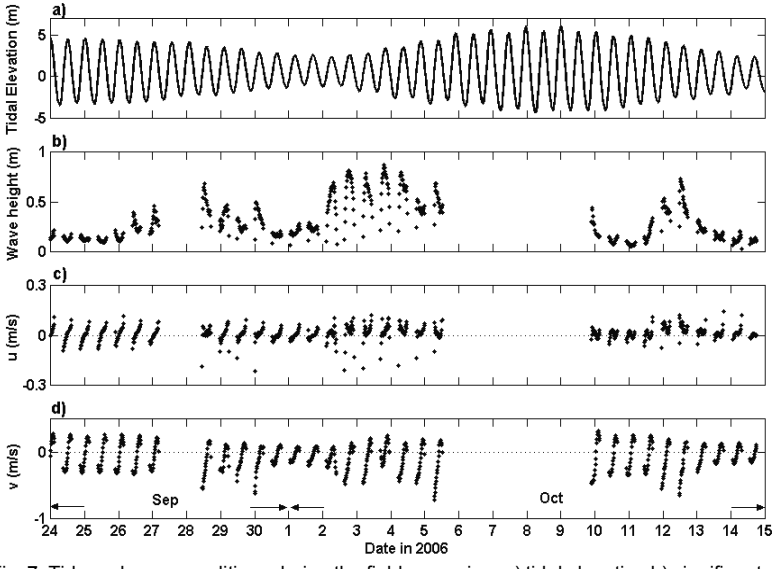

Fig. 7. Tide and wave conditions during the field campaign: a) tidal elevation b) significant wave height, c) cross-shore current velocity, d) longshore current velocity. Positive cross-shore and longshore currents are toward offshore and the south, respectively.

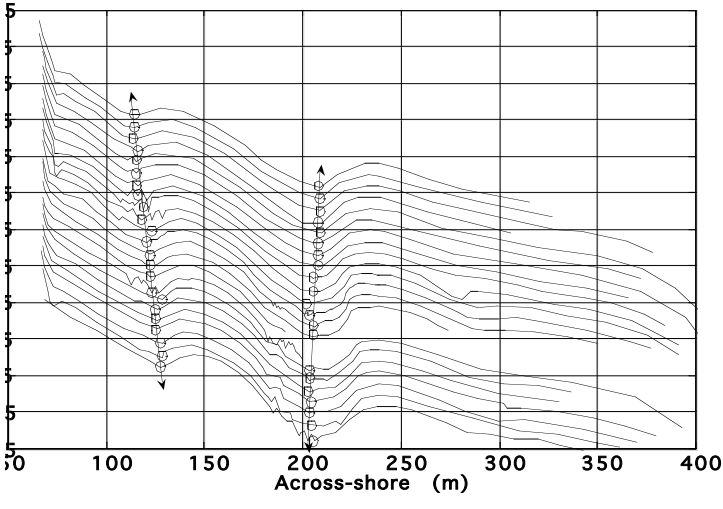

Fig. 8. Beach profiles collected from the 19th September till the 15th October 2006 (except 23rd, 24th, 29th and 30th September) respectively from the bottom to the top of the figure. All the profiles were collected *in-situ* with the differential GPS.

Figure 9 shows more clearly the changes in the profile given in Figure 8, after two storms in October ($6^{th}/7^{th}$ and 12^{th} October). The crest of the upper ridge has migrated inshore, whereas the crest of the lower ridge remained fairly stationary. The runnels have narrowed and the seaward slope of runnels and ridges decreased. The seaward slope of the upper ridge through the lower runnel was calculated for these three profiles (m1.1, m2.1, m3.1). It decreased from 1/27 to 1/34 during the first storm, and then further to 1/37 during the second storm. The landward slopes of the outer ridge, (m1.2, m2.2, m3.2) changed uniformly from 1/33 to 1/39 and then to 1/45. The seaward slopes (m1.3, m2.3, m3.3) of the outer ridge changed again uniformly from 1/64 to 1/67 and then to 1/70. Finally, the areas of the lower ridge reduced from A1=36.1 m^2 to A2=28.3m^2 during the first storm and then to A3=25.9m^2 during the second storm. These results indicate that the onshore migration of the inner ridge and erosion of the outer ridge was mainly caused due to larger wave activity during the storms.

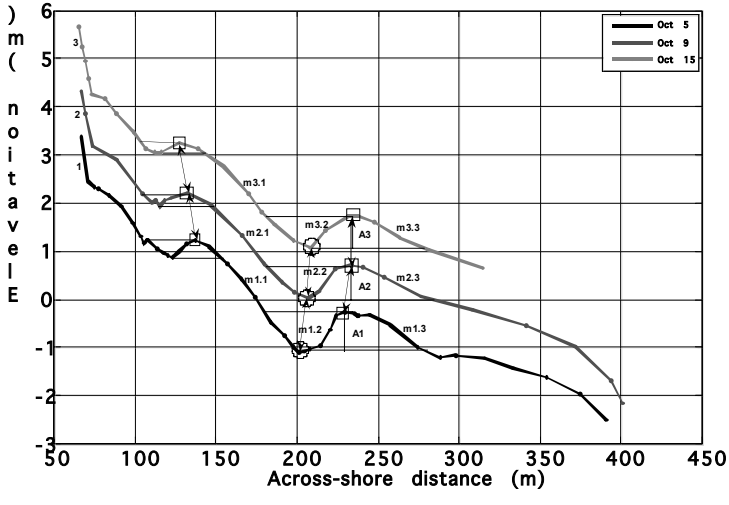

Fig.9. Differential GPS beach profiles for the 5^{th}, 9^{th} and 15^{th} of October 2006.

In addition, a presence of different bedforms was observed during storm and calm conditions. Large mega-ripples, dune like forms of width about 40cm, could be observed in both runnels after the large wave activity. They are also apparent in surveyed profiles in Figure 8. Those bedforms have been covered with smaller ripples. In these conditions the material deposited in runnels was mainly sand and no bedforms were observed on the top of ridges. During calmer conditions ripples were observed on the ridges and runnels and silty material was deposited between ripples crests in the runnels.

DISCUSSION

The analysis of existing beach profiles since 1991, Argus images since 2005, and short term field measurements of beach morphology showed spatial and temporal variability of the ridges and runnels. Although the observed changes during the field campaign have been small in comparison with inter-annual changes, the same trend of onshore ridges migrations was present. The cross-shore sediment transport from the ridge to the runnel, which moves ridges slowly onshore, occurred mainly during energetic conditions during neap and spring cycles. This onshore sediment transport is associated with bore propagation after the wave breaking on the ridge (Kroon and Masselink, 2002). Cross-shore currents measured on the top of the ridge were mainly shoreward orientated during energetic wave conditions causing offshore sediment transport on the seaward side of the ridge filling adjacent runnels and changing the size of the ridges and their seaward slope. These findings are in agreement with those of Kroon and Masselink (2002) confirming that the onshore bar migration is mainly due to surf zone processes.

The intersecting channels have been stationary during the field campaign but there is an evidence of their movement, within a year, from the Argus images. It is not clear yet how these channels are formed and deconstructed and beach structures such as groynes might influence their formation (Short, 1993). However, the sediment transported from ridges into runnels is then moved by the longshore tidal and wave-induced currents in the runnels and through intersecting channels. Also, sediment that is transported longshore on the ridge gets trapped in intersecting channels. Parker (1975) put forward a conceptual model for a multi-barred foreshore, which includes surf zone processes on ridges as well as processes due to a combination of tidal and wave-induced currents in runnels and intersecting channels which need to be verified.

So far Argus images have been used here for qualitative study of beach changes. Quantitative analyses have not been possible mainly due to poor spatial coverage of waterlines derived from images taken every 30min. As the beach slope is quite gentle and the tide range is large, the tide is progressing rapidly over the intertidal area and hence a reduced number of waterlines can be derived from the images. A more frequent setting of 5min gave much better resolution and better coverage of a complex bathymetry. Figure 9 compares the beach profiles derived from Argus images, with 30 and 5min settings, with beach profiles surveyed with dGPS on 23rd June 2006. A very good match can be clearly seen between a profile derived from Argus images collected every 5 min and dGPS in Figure 9a. Hence, there is a possibility that with this setting, the detailed study of cross-shore and longshore beach dynamic can be conducted.

Future work will include further analysis of data collected in the runnel and Argus video images to clarify the importance of nearshore circulation on morphology and their mutual feedback.

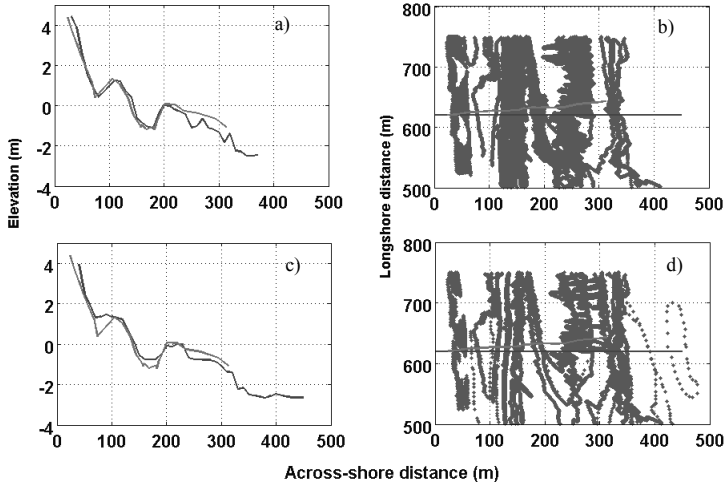

Fig. 9. Argus image analysis for the 23rd of June 2006. The blue profile is the Argus derived profile for a certain location in the Argus south station area. The red profile is a dGPS-collected beach profile for the same location as the Argus one but with a slight rotational angle. a) and b) have been processed using a 5 minute image collection lag whereas c) and d) have been derived from a 30 minute image derived waterlines. The blue profile in a) and c) is derived from the previously plotted waterlines and the black lines in b) and d) are the waterlines derived from the plan-view images.

CONCLUSION

This study demonstrates the spatial and temporal variability of a runnel and ridge system on the Cleveleys beach. Cross-shore migration is governed by surf zone processes during energetic wave conditions equally during the spring and neap tidal cycle. Longshore ridge migration is a seasonal and long-term feature governed by longshore sediment transport due to tidal and wave-induced currents. Argus video images with appropriate time setting are potentially useful for getting comprehensive information of 3D intertidal bathymetry over different time scales.

ACKNOWLEDGEMENTS

We would like to thank to the Wyre Borough Council for funding this project and in particular, to Mr Carl Green, Paul Long and Chris Atherton for their help with maintaining cameras and the field surveys. We are also thankful to Dr Stefan Aarninkhof, Mr Irv Elshoff and Ms Anna Cohen from the Delft Hydraulics for setting up and calibrating the cameras, and for setting up the analysis software. Our thanks also go to Peter Ganderton from University of Plymouth for his help with the field equipment, and to our 'field helpers', Igor Ruzic, Richard Peters and Dr Howard Southgate.

Abstract: This study develops a method to identify the depth of closure using airborne laser bathymetric data, and compares the measured depth of closure with estimated depth of closures. Airborne laser data sets were collected before and after the 2004 hurricane season in southeast Florida. Estimated depth of closures in terms of wave data is compatible to the measured depth of closures. However, the estimated depth of closure is on average larger than was measured, especially in the southern end of the study area, which could be due to geologic influence. Further research is needed to determine if geology plays a critical role in the depth of closure at this study's location.

INTRODUCTION

Soft stabilization (beach nourishment) has become the principal coastal defense from the encroaching ocean (Finkl et al. 2005). It is essential to mine the sediments from an offshore area that does not have significant sediment exchange with the active sediment movement zone in the nearshore. The locations for beach sediment extraction often rely on the determination of the depth of closure (DOC). The DOC is the location at which repetitive cross-shore profile surveys show little change (Hallermeier 1978). Cost limitation in profile measurement, especially for underwater portions, has motivated researchers to develop methods to estimate the DOC based on the sediment movement induced by waves.

By using linear wave theory, Hallermeier (1978) proposed an equation for estimating

DOC:

$$DOC_e = aH - b\left(\frac{H^2}{gT^2}\right) \quad (1)$$

where DOC_e is the estimated DOC, H is deep wave height, g is gravity, and T is the deep wave period. DOC_e for any specific location changes as the wave condition varies. Wave climates for most U.S. coasts undergo seasonal variation. Sediments are transported offshore to form sandbars when storm or winter waves dominate, while sediments move toward the shore to form berms when the swell or summer waves dominate (Komar 1998). In order to determine the offshore limit of an active zone where yearly onshore and offshore cycle of sediment movement occurs, Hallermeier (1977) proposed to use an extreme wave height, which exceeds 12 hours per year from the distribution for cumulative wave heights, and corresponding wave period. Coefficients a and b are 2.28 and 68.5, respectively, when the extreme wave height and period are used. However, other research has shown that the coefficients can vary (Table 1). In fact, Birkemeier found a reasonable fit to Duck, North Carolina data by applying only wave height with the equation:

$$DOC_w = cH \quad (2)$$

where c is 1.57. Further research is needed at other beach types in order to test the effectiveness of each set of coefficients.

Table 1. DOC Coefficients*

Data Source	Wave Condition	a	b
Hallermeier	12 hr. Wave	2.28	68.5
Birkemeier	12 hr. Wave	1.75	57.9
Nicholls	12 hr. Wave	1.70	82.3
	Peak Wave	1.33	43.9
This Study	Peak Wave	2.49	192.8

*Coefficients obtained from Hallermeier (1977), Birkemeier (1985), and Nicholls (1998).

Large scale bathymetric measurements are required to locate the DOC and adequately test DOC models. Advances in remote sensing techniques have improved our ability to measure large scale coastal change, and airborne laser bathymetry (ALB) provides unprecedented resolution of bathymetric measurements at relatively high accuracies (Irish et al. 2000). Multiple ALB data measuring the same areas over time yield 3-dimensional spatial change and can be used to determine the DOC location.

Southeast Florida is an ideal location for comparing measured DOC with calculated DOC due to an extensive ALB data collection. Two ALB flights were flown before and after the 2004 hurricane season, thus providing a data set for measuring onshore and offshore sediment movement. The main objective of this study is to develop a method for extracting DOC information from multiple ALB data sets, and to compare the measured DOC with estimated DOC based on wave data.

STUDY AREA

The peninsula of Florida is located on the southeastern tip of the United States. This study focuses on southeast Florida, including Palm Beach, Broward, and Miami-Dade Counties (Figure 1). The study area is determined by the extent of overlapping ALB data, covering almost 2 km north of South Lake Worth Inlet (south-central Palm Beach County) to the southern point of Miami Beach (Government Cut) and approximately 600 m offshore. The total length of coastline is over 100 km with 6 inlets.

Figure 1. Map showing southern Florida with hurricane tracks and southeastern Florida. Black polygon along coastline shows the extent of the November 2004 CHARTS data.

DATA

The U.S. National Oceanographic and Atmospheric Administration's (NOAA) Coastal Services Center (CSC) houses many airborne laser data sets measuring coastal environments. This study utilizes the Joint Airborne Lidar Bathymetry Technical Center of Expertise's (JALBTCX) compact hydrographic airborne rapid total survey (CHARTS) ALB data collected on the southeastern coast of Florida in June and November 2004. The CHARTS system produced a nominal 8 m point spacing for the bathymetry and a 2 m point spacing for the topography for each flight line. Due to multiple flight lines, the resulting point density for each airborne laser data collection is slightly higher.

Airborne laser data processing involved interpolating the irregularly spaced laser measurements onto a regularly spaced grid to produce a set of digital elevation models (DEMs). The data were gridded at 4 m resolution using kriging interpolation with a linear variogram. DEMs for each flight were produced with a common origin and cell size for overlaying analysis. The DEMs were then analyzed in a ESRI's ArcGIS to produce elevation contours and transects.

In order to compare the measured DOC with estimated DOC using Equations 1 and 2, wave heights and periods from various locations along the shore are required. Unfortunately, there are no measured alongshore wave data available in the study area. The closest NOAA wave buoy to our study area is located off Cape Canaveral, approximately 200 km north. Therefore, we used offshore wave heights and periods estimated by NOAA's Wavewatch III model for 19 locations along the study area spaced approximately 5 km apart. Peak conditions during Hurricane Frances were tabulated. Although Hurricane Jeanne (Category 3) was one category larger than Hurricane Frances (Category 2) on the Saffir-Simpson scale, the relatively slow moving Frances produced wave heights in excess of 9 m, while Jeanne produced wave heights less than 5 m (Beven 2004; Lawrence and Cobb 2005). This study only analyzes Hurricane Frances data. Hurricane Frances estimated wave heights ranged from 9.4 to 6.4 m, with a period from 10 to 9 seconds. The higher values were found to the north and steadily decreased to the south.

METHODS

DOC_m Extraction

Identification of the DOC is a multi-step process that requires an understanding of measurement limitations. The first step is to produce a difference grid by subtracting the DEM derived after the hurricane season from the DEM derived before the hurricane season. The resulting raster image contains pixels that represent change in volume. Theoretically, locations of zero change should represent the location of the DOC. However, the resolving ability of the CHARTS sensor is limited by noise in the measurements. An in-depth accuracy assessment for the CHARTS system was carried out prior to the June 2004 data collect (Optech 2004). Mean offsets between CHARTS measurements and known elevations ranged between -0.18 to 0.23 m, but most measurements were within ±0.15 m. The noise in the measurements ranged between

0.05 to 0.28 m, which suggests that changes within this range would yield unreliable results.

The three dimensional change can be represented two dimensionally by contouring the change grid. We contoured the change surface at 5 cm steps to empirically determine the level of change that yielded a contour that can be relatively consistent and measurable. We found that changes with absolute values greater than ±0.3 m can be detected reliably in the difference grid. Therefore, the difference grid was contoured at 0.3 and -0.3, and the most seaward intersection of either contour with a transect represented the location of the DOC at this transect.

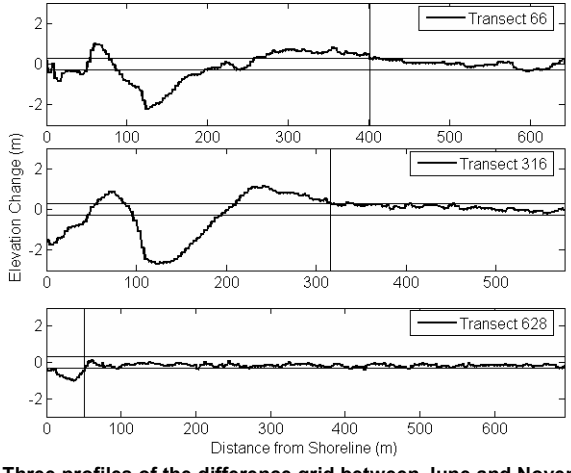

Figure 2. Three profiles of the difference grid between June and November CHARTS data. Thin horizontal lines are the ±0.3 m change. Vertical thin lines are the location of the DOC_m.

Analysis of change greater than ±0.3 m is confirmed by analyzing the profiles in the difference grid. Three representative transects were extracted to explain the profile of the change grid. Transects 66, 316, and 628 represent the change profile offshore of Palm Beach, Boca Raton, and Fort Lauderdale, respectively (Figure 2). Each profile sustained large change near the shoreline, but the change diminished to low level fluctuations further offshore. The low level fluctuations correspond to locations of hard grounds or sand flats that sustain little change if any during storm conditions, thus it is reasonable to assume that these fluctuations are partly due to instrument noise (Finkl and Warner 2005). The low level fluctuations are effectively filtered out when only analyzing change that occurs landward of the most seaward change greater than 0.3 m or less than −0.3 m. When confirming Equation 1 with field data, Hallermeier (1977) determined that change less than ±0.3 m was negligible due to limitations in fathometer measurement resolution.

Comparison of DOC_m and DOC_e

The relative positions of DOC_m were measured using an ArcGIS based shoreline and beach volume mapping system (Robertson et al. 2005; Zhang et al. 2005). This system generates a set of transects perpendicular to the coastline and calculates distance to the intersection of each transect with other linear features. One thousand and forty-six transects spaced 100 m were analyzed over the 104 km length of shoreline. Intersections between transects and the DOC_m contour are converted to points using ESRI's Intersect command. Depths are assigned to each point with ESRI's Extract Values to Points tool based on the CHARTS November DEM. Since DOC_m exhibits considerable changes alongshore, a moving average filter with a window size of 5 (500 m) was employed to reduce possible outliers.

To compare the DOC_e and DOC_m, DOC_e was estimated using Equations 1 and 2 at 19 locations along the shore using wave data from NOAA's Wavewatch III model and were converted into ArcGIS point Shapefiles. As a result, DOC_e can be directly compared to DOC_m alongshore using spatial overlaying.

RESULTS

All data are presented as distance along the coastline, from north to south. Each successive transect represents an alongshore position 100 m south of the previous position. Since we are trying to locate the DOC of typical beaches, we removed data that contain transects surrounding inlets.

Table 2. Measured DOC Values*

Location	DOC Dist.	DOC_m				Sign Count	
	Mean	Mean	Min	Max	St.D.	Positive	Negative
North limit to South Lake Worth	266	-7.8	-4.5	-10.3	0.93	97	66
South Lake Worth to Boca Raton	259	-6.7	-4.3	-9.0	0.74	161	61
Boca Raton to Hillsboro	163	-4.7	-2.6	-6.7	1.00	39	35
Hillsboro to Port Everglades	54	-2.2	-0.3	-6.8	1.00	24	133
Port Everglades to Haulover	124	-2.9	-0.3	-6.3	0.93	76	123
Haulover to Government Cut	116	-3.0	-0.1	-6.5	1.30	48	98

*Measured DOC values split by inlets, from north to south. DOC Dist. is the distance from the shoreline to the DOC_m. DOC_m is the depth, in meters. Sign count is the number of positive or negative contours that are most seaward and represent the DOC_m.

The DOC_m measured from the difference between two ALB data sets appears to be highly variable alongshore, but there is a clear progression of reducing depth from north to south. DOC_m ranges from −10.3 m north of South Lake Worth Inlet to only −0.1 m located off of Miami Beach (Table 2). The −10.3 m represents localized areas of change in Palm Beach County, and the −0.1 m is an unusual location of almost no change offshore of Miami Beach. When separating the results by inlet location, the average DOC_m reduces from −7.8 m in the north to −3.0 m in the south. The reduction in DOC_m depth appears to stop south of Hillsboro Inlet, and the Pompano Beach to Fort Lauderdale section of coastline (Hillsboro Inlet to Port Everglades Inlet) shows a relatively shallow DOC_m average of −2.2 m. The same signal is found when analyzing the distance of DOC_m from the shoreline. DOC_m is on average located 266 m from the

shoreline in the north and 116 m offshore in the south, with the Pompano Beach to Fort Lauderdale section averaging only 54 m offshore.

Table 3. DOC_m vs. DOC_e*

Coefficients	Data	dMean	dMin	dMax	dSt.D.
Hallermeier	raw	-8.4	-5.2	-10.9	1.6

	filtered	-2.2	-0.1	-5.4	1.6
This Study	raw	-0.9	0.1	-3.4	1.8
	filtered	-0.6	-0.1	-3.3	1.8

*Vertical difference between measured and estimated DOC, in meters. Data were filtered by a 5 point (500 m) moving average.

Similarities between the DOC_m and DOC_e suggest that the DOC is physically linked to wave dynamics. Since both Hurricanes Frances and Jeanne made landfall immediately north the study area limits (Figure 1), the increased wave activity to the north should contribute to deeper northern DOC values. For coefficients used to estimate DOC during Hurricane Francis, Nicholls' peak wave coefficients of 1.33 and 43.9 for *a* and *b* in Equation 1, respectively, best matched DOC_m being 2.6 m deeper, on average (Figure 3, Table 3). The average difference between filtered DOC_m and DOC_e is about 2.2 m. Although the mean differences for Hurricane Frances are large, each estimated DOC curve matched the general trend of the measured DOC where the DOC is reduced from north to south.

DISCUSSION AND CONCLUSIONS

The DOC_m is extremely variable alongshore. Depending on which transect is observed, the DOC_m ranges from −10 m to just below the water surface. Since extreme values at various alongshore sections differ from the mean by as much as 3 m (Table 2), the alongshore variability in the DOC indicates that a single transect cannot explain the DOC for the immediate area. The use of ALB data appears to be an effective method for measuring the DOC in relatively clear waters like south Florida.

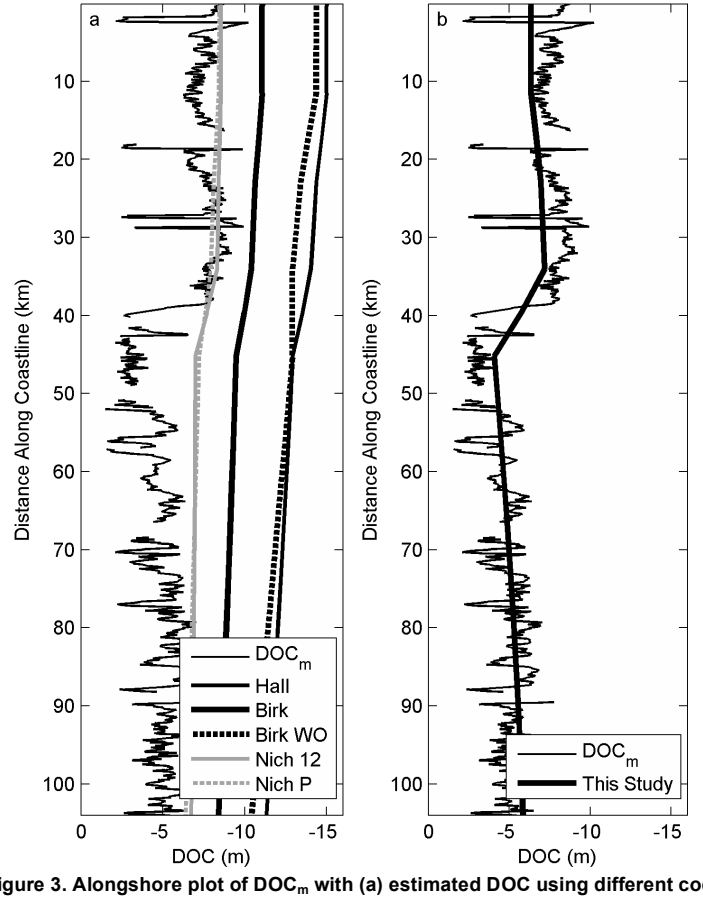

Figure 3. Alongshore plot of DOC_m with (a) estimated DOC using different coefficients and (b) coefficients calculated using this study's data. Estimated DOC include Hallermeier, Birkemeier, Birkemeier wave only (Eq. 2), Nicholls 12 hour waves, Nicholls peak waves.

Hallermeier's estimate of the depth of closure is determined by an average annual wave condition. Hurricanes often induce storm waves with large heights and long periods; therefore the depth of closure for a storm wave condition should be larger than those from a typical annual wave condition. The estimated DOC in Table 3 that used peak wave heights caused by the hurricanes are larger than the measured DOC. Two explanations could account for this difference. Since the airborne laser bathymetry was not collected immediately following the hurricanes, the survey may not completely capture the change caused by only the hurricanes. In addition, previous studies from this area suggest that the active profiles consist of more than only loose sands. There are hardgrounds comprised of exposed bedrock and reefs landward of the DOC, especially

south of Hillsboro Inlet (Brown 1998; Finkl and Warner 2005). Further research is needed to compare the extracted DOC with local geologic units to gain a perspective on the level of local geologic control.

ACKNOWLEDGEMENTS

We would like to thank Jeff Lillycrop and the Joint Airborne Lidar Bathymetry Technical Center of Expertise's (JALBTCX) team for providing the CHARTS data. NOAA's Florida Hurricane Alliance supported Mr. Robertson.

ASSESSING NEARSHORE BAR MOVEMENTS DURING STORMS USING TIME-AVERAGED X-BAND RADAR IMAGES

Abstract: The study examines temporal and spatial changes in nearshore morphology using time-averaged images obtained by X-band radar along a 3-km long section of Cassino beach, southern Brazil. A GIS platform has been used to quantify the mean position and magnitudes of cross-shore movements of the three nearshore bars identified on the radar images in a time period between April 15 and May 31, 2005. Analysis of the time-averaged images show that increasing wave energy results in straight bars while reducing wave energy gives rise to crescentic features. The first bar responds rapidly to changes in wave energy while the two other bars respond only to extended periods of hydrodynamic forcing and generally exhibit a lagged response time in relation to the first bar. A storm with significant wave height of 1.1 m, period of 8 s and currents reaching 1.5 m/s resulted in migration rates of about 30 m/day for the first bar and 13 m/day for the second and third bars that lasted two to four days.

INTRODUCTION

This study presents results from a standard marine X-band radar deployed at Cassino Beach, southern Brazil between April and July 2005 during an international project studying wave attenuation over muddy sediments[1]. In the past, X-band radars have been used to obtain two-dimensional directional wave spectra, estimates of near surface currents, and bathymetry over a relatively large area in offshore and coastal waters (e.g. Young et al. 1985, Reichter et al. 1998, Bell 1999). Deployed from a relatively low vantage point, the X-band radar offers a relatively low-cost and reliable technology able

1 http://cassino.log.furg.br

to monitor a radial area of approximately 3 km, 24 hours a day, irrespective of the weather conditions (Bell et al. 2005). It provides an undistorted plan view of the area, making complex image rectification unnecessary. This paper presents preliminary results of an ongoing study that aims to analyze cross-shore and alongshore changes in the position and the morphology of nearshore bars using sequences of time-averaged radar images in a Geographical Information System (GIS) platform. Specifically, this study focuses on the temporal and spatial changes in bar location before, during, and after storms that occurred from April 15 to May 31, 2005. Estimates of mean bar positions and rates of change for specific time intervals are provided, as well as a description of the longshore variations in bars dynamics.

STUDY AREA

Cassino Beach is the only major coastal urban area found in the southernmost 490 km of the Brazilian coastline. It is located about 215 km north of the Uruguayan border, in the municipality of Rio Grande, state of Rio Grande do Sul (Figure 1). The field site was situated 3 km south of the main urban area and 9 km south of the Patos lagoon mouth. The X-band radar was installed in the grounds of the Aquaculture Marine Station (FURG), at 32°14'56"S; 052°9'36"W (Figure 1). Here, the beach is composed of fine to very fine quartzose sands (median grain size, D_{50} = 0.150 mm). The beach has a slope of 1/30, and usually three nearshore bars are present. The area is subject to a microtidal regime with semidiurnal mean tidal range not exceeding 0.5 m (Tomazelli et al. 1998). The most important water level changes are caused by meteorological forcing, with storm surge elevations reaching 1m (Calliari et al. 1998a, Saraiva et al. 2003). Waves are the main hydrodynamic agent with mean significant height (H_s) of 1.4 m and peak period (T_p) of 7 s to 9 s that can exceed 3 m and 12 s, respectively during the passage of extra-tropical cyclones (Almeida and Toldo 1997).

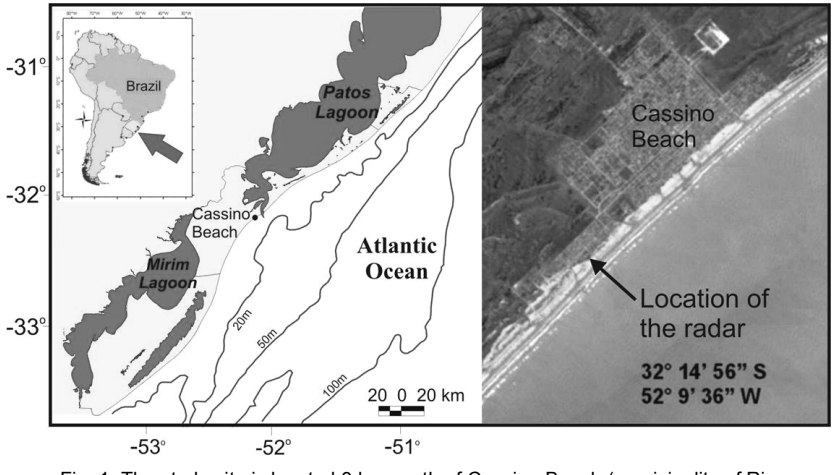

Fig. 1. The study site is located 3 km south of Cassino Beach (municipality of Rio Grande) at the southern coast of Brazil.

The beach at Cassino has an orientation of 240º (NE-SW) and the angle of waves approach at the breaker line is generally 5º to 15º. It is usually more than 100 m-wide with the waterline position changing with the same magnitude and frequently reaching the base of the dunes during storms (Esteves et al. 2006). The beach width changes seasonally, accreting in the summer (December to March) as a result of the dominant fair weather conditions, and eroding in the winter (June to August) due to the more energetic conditions (Calliari and Klein 1993, Esteves et al. 2006). Several studies have shown that this part of the coast is accreting in the short and long-term (Calliari et al. 1998b, Dillenburg et al. 2000, Esteves et al. 2006). Probably this is a result of longshore gradient of wave energy that favors deposition in large-scale coastal embayments resulting in positive sediment budget (Dillenburg et al. 2004).

Although field observations show that longshore currents are bi-directional, flows to the south dominante (Esteves et al. 2007) due the north-easterly and easterly waves generated by the dominant north-easterly winds. However, coastal geomorphic features (Tomazelli and Villwock 1992) and modeling results (Williams and Esteves 2005) indicate a net northward sediment transport driven by larger storm-associated waves approaching from the south. Although modeling results show that longshore sediment transport can explain the majority of measured shoreline changes in the area (Williams and Esteves 2005), the presence of offshore bars suggests that complex cross-shore sediment transport is also important.

METHODS

The nearshore sandbar morphology can be assessed indirectly through the visualization of waves breaking over the bar. This was first applied in studies of surf zone morphology by examining time-averaged images from digital video cameras (e.g. Lippmann and Holman 1989, Holland et al. 1997), and later to X-band radar images (Ruessink et al. 2002). In the present study, sequences of 256 radar images spanning approximately 10 minutes were recorded digitally every hour and resultant time-averaged images were used to quantify temporal and spatial changes in the surf zone morphology. During moderate to high wave conditions three bars were visible in most of the images. Hereafter these will be referred to as first (closest to the shoreline), second (at a mid-position in the surf zone), and third (furthest offshore). During acquisition of radar images, high wave energy events occurred around April 22 to 26, May 8 and 23, June 16 and 21, and July 5, 2005 (Figure 2). During May, waves and water levels were measured by pressure sensors (installed by Naval Postgraduate School/USA) and beach profiles were measured daily during fair-weather conditions (FURG/Brazil).

The X-Band Radar Data Collection

A standard marine X-band radar operating at 9.41 GHz (approximately 3 cm wavelength) was installed behind the dunes in Cassino Beach, about 300 m from the waterline, on top of a 6-m high scaffold tower (Figure 3). The X-band radar was installed from April 8 to July 30, 2005 and collected more than 400 h of data. The main

field experiment occurred in May when other instruments were simultaneously installed at the site, including a 4-camera Argus system (Naval Research Laboratory, USA); PUVs and OBSs in different elevations and positions across the surf zone (Naval Postgraduate School, USA); ADVs and ADCPs at 9m and 12m depths (UNIVALI and UFRJ, Brazil); one waverider placed offshore (UFSC, Brazil), and tidal gauges placed in three different locations along the coast.

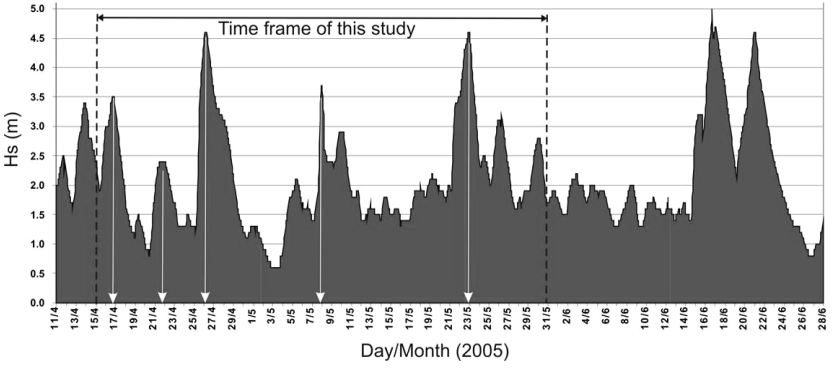

Fig. 2. Prediction of significant wave heights (H_s) for deep waters offshore of Rio Grande (32º00S, 48º75W). Vertical arrows point to dates of high-energy waves. Source of data: NOAA/NCEP WaveWatch III model (http://polar.ncep.noaa.gov/waves/main_table.html).

The 1.8-m long antenna provided a horizontal beamwidth of 1.2º and presented a rotation rate of 2.4 s. The returned echo of each pulse was digitally recorded at 20MHz corresponding to a radial resolution of 7.5 m. For the Cassino Experiment, the X-band radar was set to record 256 images in a 10-minute interval every hour, starting to record at the beginning of the hour. The snapshot radar images collected information of waves in a 4-km range, as is presented in Figure 3 for calm wave and storm conditions, respectively. The bright areas correspond to regions of high radar backscatter from the front face of the waves with respect to the radar. The very large signals in the lower part of the image relate to regions of breaking waves. The radar position is indicated by the zero mark at the bottom middle part of the images.

The time-averaged X-band radar images can be used to identify areas where waves are breaking on submerged sand bars (e.g. Lippmann and Holman 1989, Ruessink et al. 2002). Using sequences of these images it is possible to followed through time the movement and morphological evolution of the sand bars. According to Lippmann and Holman (1989), the bar crest location can be identified using the maximum video intensity. Ruessink et al. (2002) showed that the same applies when using radar images, although their results suggested that the maximum radar reflection could be displaced $O(10)$ m from the actual bar crest position due to variations in water level. The authors consider that changes in depth over the bar crest have to be at least $O(0.5)$ m to affect the position of maximum reflection in relation to the location of the bar crest. Although

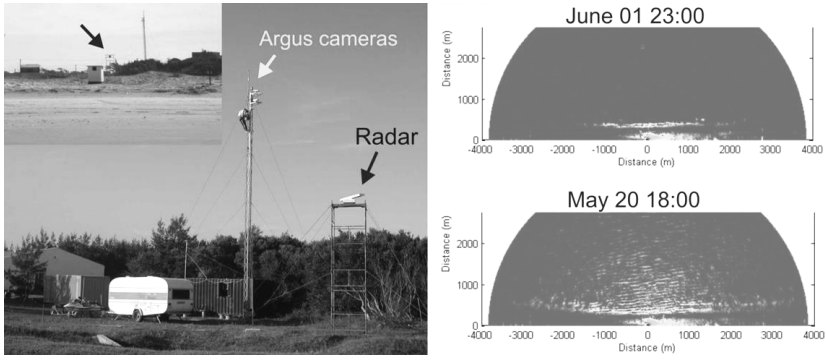

Fig. 3. The X-band radar was installed at the top of 6-m high scaffold tower at the grounds of a Marine Station belonging to the Fundação Universidade Federal do Rio Grande about 300m from the shoreline. At the right, examples of snapshot images obtained during calm (top) and stormy wave conditions (bottom). The X and Y axis show alongshore and cross-shore distances, respectively, from the radar position.

assessment of the effect of water levels on the position of bars has not yet been conducted in the present study, the position of digitized features is assumed here to be subject to an error of 10 m. Hourly time-averaged images were produced to give sufficient contrast to allow identification of the main nearshore morphological features along 2 or 3 km of the coastline.

Mapping the Position of the Shoreline and Nearshore Bars

The processing of the time-averaged images was conducted on ArcGis© 9.0 and consisted in three phases:

(1) *Referencing the images to a local coordinate system*. Local coordinates of fixed objects clearly identifiable on the time-average X-band images were used as control points. Since the *x,y* origin of the local coordinate system is the starting point of the transect of the beach profiles, all figures and distances presented hereafter will be referenced to it. In some cases the exact location of the control points was difficult to find in images with low contrast (i.e. during high water levels) resulting in errors that were always submetric.

(2) *Digitizing the position of the shoreline and the crest of the bars.* These features were always visible on the images and associated with the pixels showing the strongest reflection. Here 18 time-averaged images were used to digitize the position of the bars, covering a time interval of 46 days from April 14 to May 31. The date and time of the radar images analyzed were chosen based on the availability of beach profile data, *in situ* measurements of waves and currents, and the occurrence of storms and fair weather conditions. Five images were chosen to represent the changes observed from April 15-30, six images represent the period May 01-19, and seven images illustrate the changes from May 20-31. The reflection of the third bar was very faint in several images causing a greater inaccuracy on the location of the crest. The first and second bars were always easier to map.

(3) *Spatial analysis to determine cross-shore movement of the bars*. The distance between the digitized features, and the envelope of each one of the feature groups (i.e. shoreline and the three bars), were measured using shore-normal transects from a baseline drawn parallel to the shoreline at the position of the radar. Measurements were obtained at 250 m intervals along the shore to identify alongshore differences in the behavior of the bars. Measured distances between identified features were used to quantify changes in bar positions. These were then corrected to the local coordinate system.

RESULTS AND DISCUSSION

Visual analysis of 82 images (a set of about two time-averaged images per day) from April 15 to May 31 obtained at Cassino Beach shows rhythmic bars forming when there is a reduction in wave energy and straight bars forming as wave energy increases. The first and second bars were crescentic in 50% of the images, and straight in the other 50%. The analysis of the third bar was more difficult as it was very faint in 22% of the images and there was not enough contrast to define the position of the crest in another 20% of the images. For the remaining images, the third bar was identified as straight in most cases (87%) and crescentic in only 13% of the images. Based on the digitized images, figure 4 shows the changes in the cross-shore mean position of the three bars within a band representing the minimum and maximum values through time. It shows also when the morphology of the bars was straight (S) or rhythmic (R). The mean position of the shoreline is around 205 m (standard deviation, std = 17.1 m), with maximum and minimum distances of 264 m and 152 m (variation of 112 m), respectively (not illustrated). The first bar has a mean position around 239 m (std = 8.3 m), with maximum variation *O*(130)m (maximum and minimum values of 322 m and

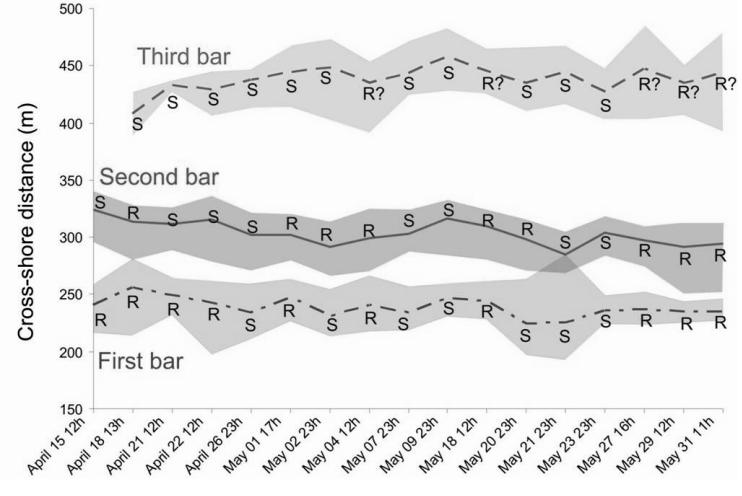

Fig. 4. Mean position of the bars crest through time based on the digitized images. The shading bands around the mean position lines represent maximum and minimum positions observed in each day. Straight bars are indicated with 'S' and rhythmic bars with 'R'

193 m, respectively. The mean position of the second bar is around 303 m (std = 10.5 m), with maximum variation *O*(90) m (maximum and minimum values of 340 m and 250 m, respectively). The mean position of the third bar is around 438 m (std = 11.21 m), with maximum variation *O*(100) m and maximum and minimum values of 485 m and 386 m, respectively). Thus the distances from shoreline to the first bar and between successive bars are 34 m, 64 m, and 135 m. It is noted that the distance between the shoreline and the second bar and the third bar are approximately twice and four times the distance between the shoreline and the first bar.

The response of bars to changing wave conditions is difficult to visualize in figure 4 as bar positions are not represented equidistantly through time. However, it is evident that the response of the three bars is not always in phase. The first bar responds rapidly to increasing wave energy with a retreat *O*(15) m, as can be observed after the storms of April 17 and 26, and May 8 and 21. Reducing wave energy results in a landward movement of the bar *O*(20) m which can eventually weld to the shore. The response of the bars seems to depend also on the frequency and magnitude of the events that represent changes in wave conditions. The second bar appears to respond only to changes that are more consistent in time, instead of moving according to oscillations within longer lasting trends. The major landward changes were *O*(20-30) m and occurred from April 15 to May 02 (not taking notice of the April 17 and 26 events), May 09 to 21 and from May 23 to 29 (only the last two time intervals clearly represented reducing wave energy). Retreat of this bar *O*(20) m resulted from well defined events of increasing wave energy from May 02 to 09, and May 21 to 23. The third bar behaves the in opposition of the second bar from April 18 to May 02 showing a retreat *O*(40) m. During the May events, the third bar responds similarly (in direction and magnitudes) to the second bar but with a time lag of two days. Generally, the features associated with crescentic bars migrate alongshore and landward during calm wave conditions. This adds to the complexity of analyzing changes in bar morphology and position using mean statistical parameters. There are also alongshore differences on the way bars respond both on the amount and direction of change. Details on the measured changes and bar behavior will be provided below for the three analyzed time intervals.

Bars Migration and Morphology – April 15 to 30, 2005

The radar mean images clearly show three straight bars at April 13 with the first bar changing into a rhythmic well developed 3D morphology at April 18 (Figure 4), returning to a 2D morphology at April 24. For the same time, the second bar shows a 3D morphology with a three-day delay that has a much shorter duration than at the first bar. As a result of reducing wave energy, the first bar starts to show a 3D morphology after April 27 while the second bar only show similar changes two days later. It was described previously that the second bar did not retreated as a result of the higher wave energy events of late April, it rather responded changing its shape and remaining as a 2D feature for the entire period. Figure 5 presents digitized positions of the three bars for April 18 and 26, and May 01 to illustrate cross-shore movements and alongshore variations. The third bar migrated seaward showing a mean displacement *O*(50) m (std=10 m), with the biggest changes occurring from April 18 to 21, when it moved 8 m/day in average (std=4 m), slowing gradually to 1.5 m/day (std=1.9 m) from April 26

to May 01. In contrary, the second bar moved mainly landward showing less cross-shore movement and greater alongshore differences in the magnitude and direction of changes (Figure 5). The mean displacement was 11.5 m (std=13.6 m), with reducing net changes

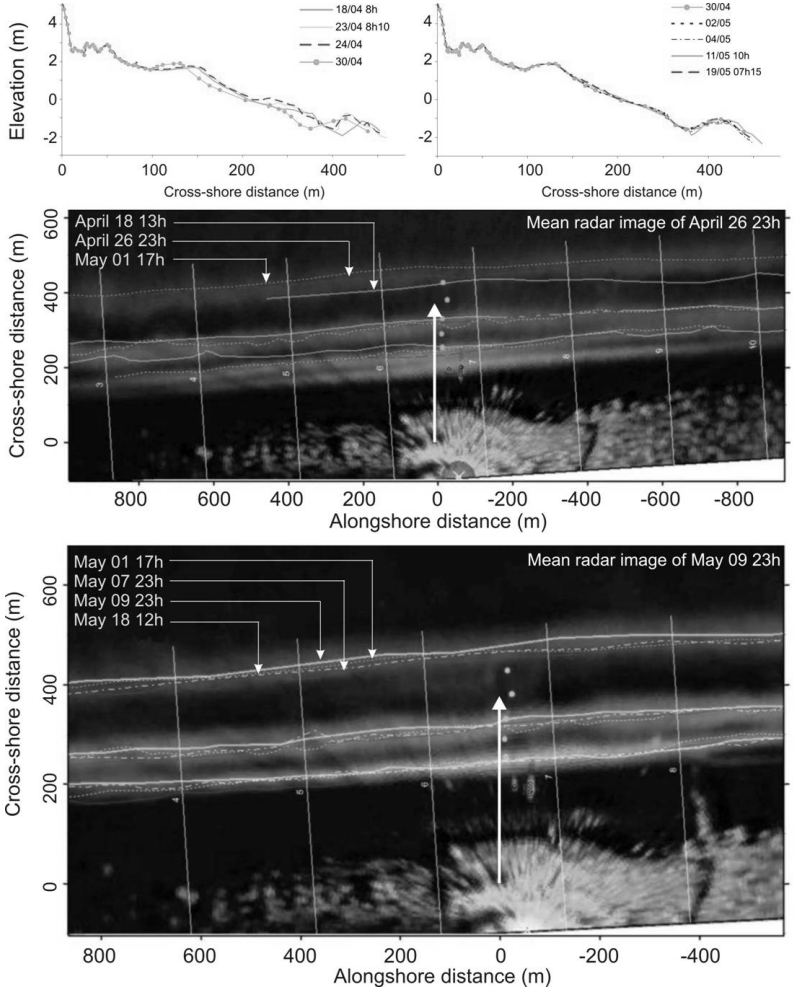

Fig. 5. Mean radar images and digitized position of bars crest for periods from April 18 to May 01, and May 01 to 18. White arrow represents the location of the beach profiles shown at the top. Green dots in the surf zone show position of in situ measurements (PUV1, PUV2, tower, PUV3, and PUV4, from the closest to shore to the most offshore). Thin white lines perpendicular to the shore represent transects of measured distances between the bars and origin of the beach profiles (zero, *x,y* position).

towards the south. Bar migration occurred with rates *O*(3.5) m/day from April 15 to 18 and April 21 to 26, and insignificant mean changes were from April 26 to May 01 that resulted mainly from the 3D bar morphology in May 01. The second bar presents the greatest variability of the three, showing stability or small seaward migration in the south (transects 7 to 10) and landward migration in the north (Figure 5). The largest changes occurred from April 15 to 18 when the bar retreated across the area with mean *O*(5) m/day (std=7 m) and April 21 to 22 with a landward migration *O*(18) m/day from transects 5 to 12 and a seaward migration *O*(12) m/day at the north. Although the displacement of bars is highly variable alongshore, the measurements obtained at the central part of the image where the beach profiles were taken (represented by the white arrow in Figure 5) agree well with the profile measurements. At the central transect, the first and second bar moved landward around 32m and 9m from April 18 to 26. Beach profiles show that the first and second bars moved onshore 38 m and 18 m, and became shallower 0.7 m and 0.2 m, respectively, from April 18 to 24. The April 30 profile shows a berm retreat of about 20 m and bar morphology indicating migration seawards (although the position of the second bar is still landward of the previous profiles indicating that it continued to move landward after April 24). This is associated with increasing wave heights around April 27 (Figure 2).

Bars Migration and Morphology –May 01 to 19 2005

This period is characterized by calm wave conditions with increasing wave energy from May 05 to 08 and reducing wave energy from May 09 to 11 (Figure 2). Changes shown in beach profiles are not significant either vertically or cross-shore (Figure 5) but analysis of mean radar images show a significant retreat of the three bars from May 07 to 09 (during and after a storm when profiles are not available) while landward movements dominate at other times. Note also that at the position of the profiles (white arrow at the bottom of figure 5), net changes in the position of the second bar are smaller compared to other areas alongshore. The mean images show 3D bars for most of this period, except around May 07-09. The third bar was not visible in many of the mean X-band images during lower energy conditions probably because local winds are too low to generate capillary waves and waves are too small to break at that location. The available data show small displacement values (around 10m) that were landward for most of the time except from May 07 to 09 (Figure 5). The overall net displacement of the third bar for the period is *O*(7) m landward from transects 2 to 6 and seaward from transects 7 to 12. The largest changes occurred from May 07 to 09 as a result of increasing wave energy with a mean seaward migration *O*(7) m/day (std =7 m), although magnitudes of changes were highly variable alongshore. The second bar presents the characteristic alternating seaward and landward movements in adjacent transects as a result of a 3D bar migrating alongshore, except between May 07 and 09 when the bar migrated seawards *O*(6.5) m/day (Figure 5). From May 09 to 18 mean values of change are relatively insignificant *O*(0.7) m/day. The first bar presents the greatest alongshore variability and the greatest changes also occurring from May 07 to 09 *O*(6) m/day and less changes from May 09 to 18 *O*(0.5) m/day similarly to the other bars. The first bar shows a behavior indicating a more 2D morphology (as can be also seen at the images), as it does not show the

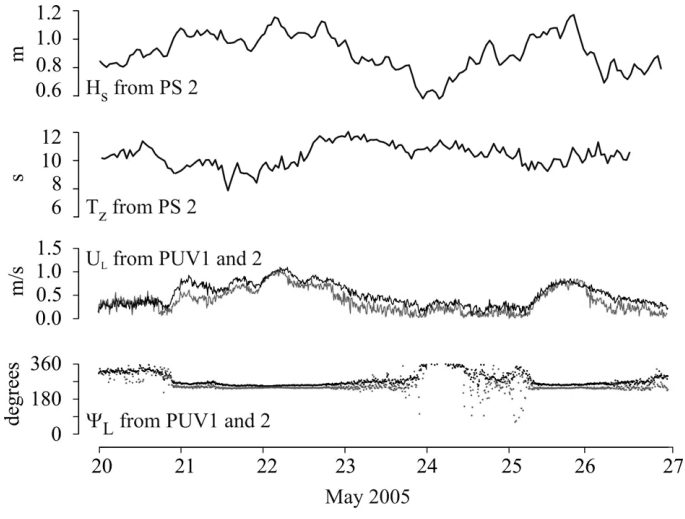

Fig. 6. Data from PUV1 and PUV2 measurements for the period of May 20 to 27 showing changes in significant wave height (H_s), zero-crossing period (T_z), current speed (U_L)and direction (ψ_L).

alternating seaward and landward movements in adjacent transects. It seems that here, a more well defined increase in wave energy after an extended period of reducing wave energy results in similar behavior in the three bars.

Bars Migration and Morphology –May 20 to 31 2005

At this period, there were three consecutive peaks of wave energy at May 22-23, 26, and 29 with short times of reducing wave energy in between (Figure 2). Figure 6 shows in situ measurements from PUV1 and PUV2 (the two instruments located between the first and second bars in Figures 5 and 7) of waves and currents from May 20 to 27. Significant wave heights (H_s) vary from 0.6 m to 1.1 m, zero-crossing period (T_z) reduces from 12 s to 8 s with increasing H_s and longshore current speed (U_L) increase from less than 0.5 m/s to 1.0 m/s and usually flow to the north (ψ_L=360º). Although this was not a particular strong storm it caused considerable bar movements (Figure 7) probably because it followed an extended period of relatively lower wave conditions. Figure 7 shows that the bars did not presented a significant net movement in the period, especially for the second bar and at the southern section of the third bar; however, the largest migrations have occurred in between the illustrated dates as described next. Most of the retreat measured at the third bar actually occurred from May 25 to 27 with mean O(13)m/day reaching up to 36m/day in the northern sector. The following two days accounted for a landward bar migration in proportions similar to that described previously, resulting in the bar returning to a position similar to May 23 in the southern part of the study area. Net changes for the second bar result mainly from the 3D bars presented at the beginning and end of the period being out of phase (Figure 7).

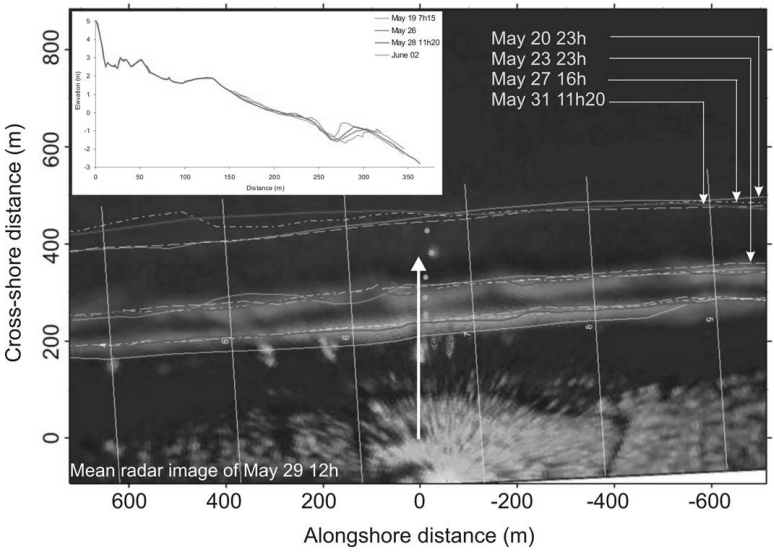

Fig. 7. Mean radar image and digitized position of bars crest for the period from May 20 to 31. White arrow represents the location of the beach profiles shown at the top. Green dots in the surf zone show position of in situ measurements (PUV1, PUV2, tower, PUV3, and PUV4, from the closest to shore to the most offshore). Thin white lines perpendicular to the shore represent transects of measured distances between the bars and origin of the beach profiles (zero, *x,y* position).

Measurements show that the largest displacement of the second bar occurred from May 20 to 21 when it migrated landward *O*(13) m/day (std =13 m) and from May 21 to 23 when the average movement was *O*(19) m seawards (std = 8 m) or about 9 m/day. After that there was a slower landward migration *O*(13) m (std = 13 m) from May 25 to 29. At the center of the image, where the beach profile is taken, a continuous landward migration of the second bar is observed, with magnitudes matching with the measured profiles (Figure 7). The first bar retreated *O*(40) m from May 21 to 23 (in opposition to the second bar that was already moving landward) and continue to retreat from May 23 to 25 with even higher rates, reaching a mean *O*(32) m/day. Such retreat was balanced by a fast landward migration *O*(40) m/day from May 25 to 27 that continued in much slower rates afterwards. A simple calculation using the shape of the beach profiles measured in May 19 and June 02 (Figure 7) indicated that there was a gain in sediment volume of approximately 135 m^3/m of beach width in that sector of the beach and that the migration of the second bar involved about 38 m^3/m. However, as beach profiles are not existent for the time of greatest bar movements (during the storm) there is no assessment of the volume changes during high energy events.

CONCLUSIONS

Time-averaged images generated by X-band radar provide a valuable data set to quantify temporal and spatial evolution of nearshore bars independently of weather conditions. The approach of high-energy waves changes the inner bar from a crescentic shape (which dominates during fair weather conditions) to a more continuous and straight configuration. Generally, the features associated with crescentic bars migrate alongshore and landward during calm wave conditions while during storm conditions the bar becomes straight and migrates offshore. However, the first bar responds rapidly to changes in wave conditions while the second and third bars respond only to the major trend of longer-lasting events and usually with a time lag in relation to the first bar. This will result in bars moving to opposite directions in certain times. There are also alongshore differences on the way bars respond both on the amount and direction of change. A storm presenting significant wave height of 1.1m, period of 8s and currents reaching 1.5m/s (that is not considered a major storm for the area) resulted in migration rates of about 30m/day for the first bar and 13m/day for the second and third bars. In that storm, bars were rapidly migrating seaward for two days followed also by a rapid migration landward in the next two days. After the storm faded, most of the migration occurred alongshore with cross-shore movements resulting from alongshore migration of crescentic bars without resulting in net changes in the bars position.

ACKNOWLEDGEMENTS

The authors want to thank Ed Thorton and Mark Orzek from Naval Postgraduate School (USA) for providing the wave and current data from the in situ measurements, Todd Holland from Naval Research Laboratory (USA) for providing the coordinates of the instruments and control points to reference the images, Rafael Guedes and Pedro Pereira from FURG (Brazil) for providing the beach profiles data, and all the students (especially Maria Aline Lisniowski and Heitor Perotto) and technical people (especially Milico and Marco) that helped making sure the radar was working properly after the many power cut offs.

Abstract: Intertidal morphology was monitored continuously with an X-band radar at research pier HORS located in Hasaki, Japan facing Pacific Ocean. The horizontal extent of a radar image is approximately 5.6 km and hourly averaged radar images were processed to observe longshore distributions of shoreline and bar positions. Longshore mean shoreline and bar positions and their variation showed a seasonal change, which follows so-called beach-cycle. Wavy features with wavelength of several hundred meters were observed in shoreline locations at low energy periods, which migrated to the down-wave. Migration speeds show high correlation with the longshore current velocities measured at the pier. Wavy appearances were also observed in bar locations and their migrations are also correlated with the longshore velocities.

INTRODUCTION

Longshore migrations of coastal features, like shoreline, foreshore morphology, rip channels, bar system etc are observed at coasts in the world, which are fascinating for scientists and annoying for engineers (e.g. Van Enckevort et al. 2004; Holman et al. 2006; Turner et al. 2007). Reported mean migration speeds of the features vary from order of several meters to several tens of meters per day, and no generally accepted explanations are given for migration mechanisms. There are also reports in Japan, which describe unidirectional longshore migrations of eroded areas and try to

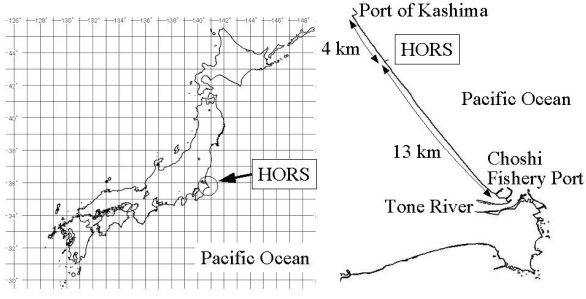

Fig. 1. Research Pier HORS

predict arrival time of erosion at downstream areas on the coast (e.g. Itabashi and Uda 1999; Tsuchiya 1997). From engineering viewpoint, if a better understanding on the migration mechanism and speeds is available, coastal prevention works may be planned more adequately.

This work displays the results of continuous X-band radar observations of shoreline and bar features for years at Hasaki Coast, Japan facing Pacific Ocean. Seasonal changes of the coastal area and down-wave, longshore migrations of shoreline and bar features are described in respect to their speeds and correlations with measured longshore current velocities.

FIELD EXPERIMENT

X-band radar measurements were conducted at the research pier HORS of the Port and Airport Research Institute (PARI), located in Hasaki, Japan (Fig. 1). The main facilities are a 400 m length pier extending into the Pacific Ocean and a research building located nearly 110 m backward from the mean shoreline position. HORS is on an almost straight sandy coast approximately 17 km long with Choshi Fishery Port at the south end and Kashima Port at the north end of the coast. The pier is located approximately 4 km from Kashima Port. Bottom profile and longshore velocities along the pier are surveyed on weekdays.

The radar system employed in this study is a conventional marine X-band radar, usually installed on fishing or recreational boats. The radar antenna is installed on the roof of the research building 17 m above the mean sea level. The antenna rotates with a period of approximately 2.5 s and transmits with a beam width of 0.8° horizontally and 25.0° vertically. The echo signals from the sea surface, generally called sea clutter, are captured with a specially designed A/D board installed on a computer.

Individual echo images sampled at every 2 seconds are averaged yielding a "time-averaged image" or so-called "time exposure". Figure 2 shows images averaged over 17 minutes for complicated shoreline and bar system for calm sea state and straightened situation during stormy condition. The horizontal extent of an image is

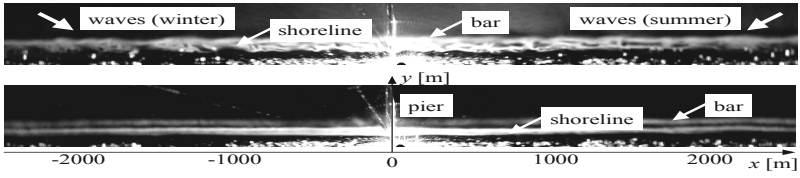

Fig. 2. Time averaged echo images and coordinate system.
Upper panel: calm condition (2005/April/28).
Lower panel: stormy condition (2005/July/28).
Length of the pier is approximately 400 m.

5556 m (3.0 nautical miles). Individual waves disappear in the time-averaged image and an edge extending in the long-shore direction becomes visible. Several features such as the breaker zone, shoreline position, near-shore bar crest locations etc can be estimated using the averaged image. The accuracy of intertidal morphology mapping with averaged images has been examined with survey results (Takewaka 2005). The x-axis corresponds to the long-shore extent and positive towards Choshi Fishery Port and the y-axis coinciding with the pier and oriented in the offshore direction.

Time-averaged images are processed hourly and accumulated from year 2004 to the present almost continuously. There are several missing periods due to system trouble; however, these don't affect the following analyses.

The offshore waves are measured by the Nationwide Ocean Wave Information Network for Ports and Harbors (NOWPHAS) station at Kashima Port where the mean water depth is approximately 24 m. Tide level is measured by Japanese Meteorological Agency at Choshi Fishery Port.

RESULTS AND DISCUSSION

The results of the observations of year 2005 are shown here to demonstrate the unique ability of radar measurements and to discuss the morphological behaviors of the site.

Longshore Mean: Shoreline and Bar Locations and Their Variability

Shoreline positions $Y_S(t, x)$ at longshore position x were digitized at time t when tide levels were between 0.75 m and 0.8m (local Datum Level), which are the most frequent tide levels observed at the site. Then the longshore mean shoreline position $\overline{Y}_S(t)$ at t

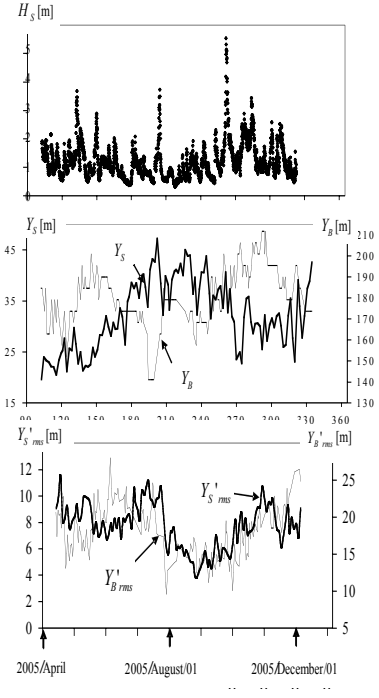

Fig. 3. Variation of longshore mean shoreline and bar locations and their variability

$$\overline{Y}_S(t) = \frac{1}{x_1 - x_0}\int_{x_0}^{x_1} Y_S(t,x)dx \tag{1}$$

and intensity of the fluctuation $Y_{S'rms}(t)$ at t

$$Y_{S'rms}(t) = \sqrt{\frac{1}{x_1 - x_0}\int_{x_0}^{x_1}(Y_S(t,x) - \overline{Y}_S(t))^2 dx} \tag{2}$$

are estimated, where x_0 = -2727 m and x_1 = 2829 m are the starting and ending locations of the imaging extent. In a similar manner, bar positions $Y_B(t, x)$, its mean $\overline{Y}_B(t)$ and fluctuation intensity $Y_{B'rms}(t)$ are estimated.

Figure 3 displays seasonal variations of significant wave height measured by NOWPHAS, longshore mean shoreline and bar positions and their fluctuation intensities observed in year 2005.

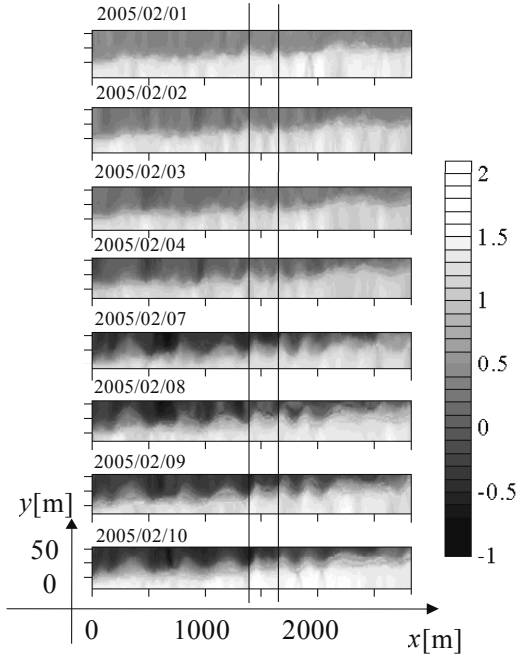

Fig. 4. Intertidal morphology mapping
Wavy features (wave length ~ 350 m) in the foreshore are migrating in +*x* direction with a speed of 16 m/day. Bottom elevations (local D.L., [m]) are displayed in gray scale.

Macroscopic movements of mean shoreline position $\overline{Y}_S(t)$ are seawards shift during the period from April to September, and landwards shift during the following period. Several high waves attacked the shore and mean shoreline position $\overline{Y}_S(t)$ showed quick recessions and fluctuation intensity $Y_S{}'_{rms}(t)$ decreased suddenly.

Mean bar position $\overline{Y}_B(t)$ shifted landwards during the period from May to July keeping relatively large fluctuation intensity $Y_B{}'_{rms}(t)$. After the high waves attacked the shore in the end of July 2005, mean bar position $\overline{Y}_B(t)$ shifted seawards and fluctuation intensity $Y_B{}'_{rms}(t)$ decreased.

The features observed in mean shoreline and bar positions are almost consistent with the result reported by Kuriyama and Lee (2001) who analyzed the daily bathymetric data measured along the pier and described the seasonal behavior of the beach. The changes observed here are parts of the so-called beach-cycle (Wright and Short 1984).

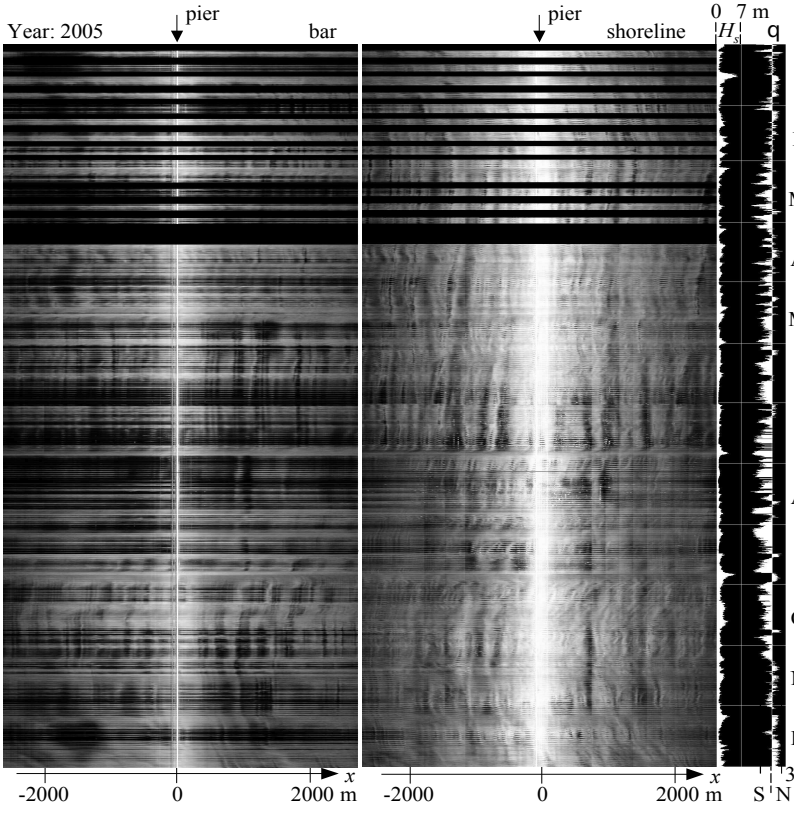

Fig. 5. Longshore migrations of wavy features in shoreline and bar locations observed in year 2005

Time-stack images whose horizontal extent is the longshore extent and vertical is the elapsed time from January to December 2005.

H_S: significant wave height, full scale = 7 m.
θ: significant wave angle, S = southern incidence, N = northern incidence.

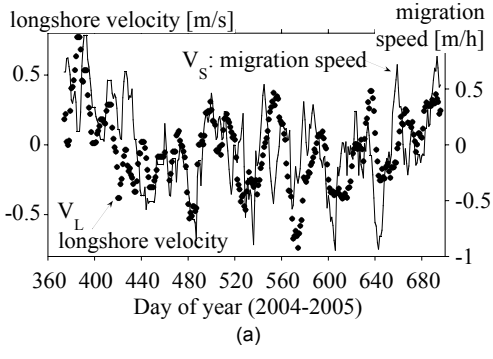
Oblique streaks correspond to longshore migration of wavy features of shoreline and bar. During winter seasons (mostly January, February and December, and waves are incident from northern), the streaks are extending from upper left to lower right, implying migration is directed to +*x*. During the other months, like June and July, migration is directed to -*x*. The propagations of the features are almost headed for the down-wave.

During energetic sea state (e.g., end of July), the streaks become blurred due to regularization of the shoreline and bar, or so-called coastal reset.

Longshore Migration of Coastal Features

Figure 4 shows an example of intertidal morphology mappings processed from time averaged radar images and tidal record (Takewaka 2005). Wavy patterns with wavelengths of approximately 350 m are moving to positive x direction with a speed of approximately 16 m/day. The movements are directing to the down-wave and follow the longshore current observed at the pier.

This kind of migration in the intertidal region was observed through the year, especially during low energy periods. To visualize the temporal and spatial situation of the migration, time-stack image was processed: longshore pixel intensities are extracted from time averaged images for every hour close to the waterline. The cross-shore locations of the extractions have been shifted in accordance with the observed tide level. The result of this processing is shown in the right panel of Fig. 5 with the observed significant wave height and wave angle by NOWPHAS. The horizontal extent of the diagram is the longshore extent and the vertical is the elapsed time from January to December 2005.



Black-white pattern in the diagram shows the locations of waterlines and dried area: seawater exists at bright areas and dried shore appears dark. The vertical and bright streak in the diagram is the pier.

Oblique patterns or streaks are observed in the diagram: they are extending to the lower right mostly in January, February and December, the winter months, and to the lower left in the other months. These indicating that wavy features observed in the intertidal morphologies are migrating to the directions of the streaks and with speeds proportional to the slope of the streaks.

Oblique patterns become blurred when high waves attack the shore, for example at the end of July. The coast is straightened at stormy periods as shown in Fig. 2, the longshore variation of pixel intensities become small and it appears as uniform parts in the time-stack image.

The migrations speeds V_S (t) of wavy shoreline patterns were estimated by analyzing the slopes of the streak patterns in the time-stack image. Figure 6 depicts the variation of migration speed V_S (t) displayed with the longshore current speed V_L (t) observed at the pier (y = 115 m), showing a fairly high correlation between V_S and V_L. The maximum absolute V_S (t) observed in the study is approximately 25 m/day, which is in the same order compared to the results reported by Turner et al. (2007), but larger than the annual mean value reported by Itabashi and Uda (1999).

The movements of the bar are analyzed in a similar manner as described above. Time-stack image to visualize the bar migration is depicted in the left panel of Fig. 5. The oblique patterns appearing in the diagram resemble to those in the time-stack of the shoreline positions, although the overall appearance is somewhat unclear. Figure 7 compares the migration speed of the bar V_B (t) and longshore current speed V_L (t)

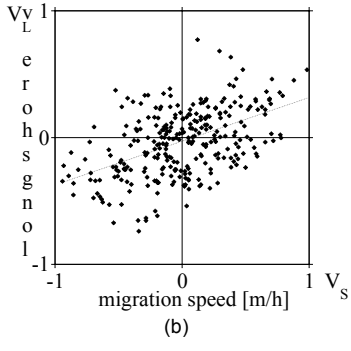


Fig. 6. Variation of shoreline migration speed V_S and longshore current velocity V_L.

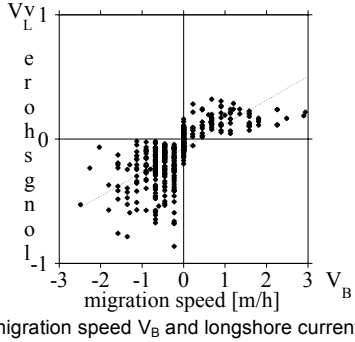

Fig. 7. Bar migration speed V_B and longshore current velocity V_L.

observed at the pier. Migration speeds of the bar are higher compared to those of shorelines at certain conditions, which is not specified yet.

Wavy migrating patterns of shoreline and bar locations, and variations of V_S and V_B showed organized appearances for certain periods. This suggests that sediment

motion between shoreline and bar should have certain organized structure to maintain the migration, which is not well understood at the present.

CONCLUDING REMARKS

Intertidal morphology was monitored continuously with an X-band radar at research pier HORS. The horizontal extent of a radar image is approximately 5.6 km and hourly averaged radar images were processed to digitize longshore distributions of shoreline and bar positions.

Longshore mean shoreline and bar positions and their variation showed a seasonal change which follow the so-called beach-cycle proposed by Wright and Short (1984): Shoreline position shifted seawards in spring-summer months and landwards during the following period. During this seasonal variation, several high waves attacked the shore and mean shoreline position showed quick recessions and sudden decreases in its longshore fluctuation intensity. Bar position shifted landwards in spring months keeping relatively high fluctuation intensity. So-called coastal resets are observed if high waves attack the shore, in which mean bar position shifted seawards and its fluctuation intensity decreased instantly.

Wavy features with wavelength of several hundred meters were observed in shoreline and bar locations at low energy periods, which migrated to the down-wave. Migration speeds showed a high correlation with the longshore current velocities measured at the pier.

ACKNOWLEDGEMENTS

The authors are grateful to the members of the Littoral Drift Division, PARI, who provided assistance in radar measurements and results of the depth surveys, wave and current measurements. Part of this study was financially supported by the Grants-in-Aid of the Japan Society for the Promotion of Science (JSPS).

DETAILED 3-D MODELS OF NEW ZEALAND BARRIER STRATIGRAPHY PROVIDE INSIGHT INTO COASTAL EVOLUTION IN VARIOUS SPATIAL AND TEMPORAL SETTINGS

Amy J. Dougherty[1] and Scott L. Nichol[1]

Abstract: The application of ground-penetrating radar (GPR) to five prograding barriers around northern New Zealand has produced detailed three-dimensional morphostratigraphic models. These barriers exist within a variety of geologic settings ranging from the high-energy, sediment rich west coast to the lower-energy, sediment starved east coast. Additionally, a composite Pleistocene-Holocene barrier exists along the east coast providing the unique opportunity to study barrier evolution not only through space but time. Nearshore, beach and dune facies delineated within each barrier lithosome form regressive facies successions with differences in shoreface geometry between sites. These differences detected within the stratigraphy are reflected in the contrasting depositional settings of the west coast dissipative morphodynamic state versus the east coast intermediate morphodynamic state. The replication of this stratigraphic form along shore and over successive sea-level stands indicates that the present day barrier evolution and depositional setting is similar over various spatial and temporal settings.

INTRODUCTION

Barriers exist along every heavily populated continent, spanning a range of geologic settings and time scales. Research over the past few decades has focused on deciphering how barriers have evolved in order to predict their response to physical influences such as accelerated sea-level rise. Progradational barriers maintain the highest preservation potential for recording past nearshore, beach and dune sedimentary processes within their accreting layers. Previous studies of coastal evolution on both Holocene and Pleistocene barriers around the world have produced generalized stratigraphic models that lack facies detail due to their construction from point source data (Figure 1).

Recently, Ground-Penetrating Radar (GPR) has been utilized to remotely sense a continuous cross-sectional view of the subsurface stratigraphy within sandy barriers, revealing large-scale features and facies boundaries previously undetected by coring alone (Jol et al., 1996). This technology enables detailed three-dimensional models of barrier stratigraphy to be constructed providing greater insight into the influences sea-level, sediment supply and accommodation space on their evolution.

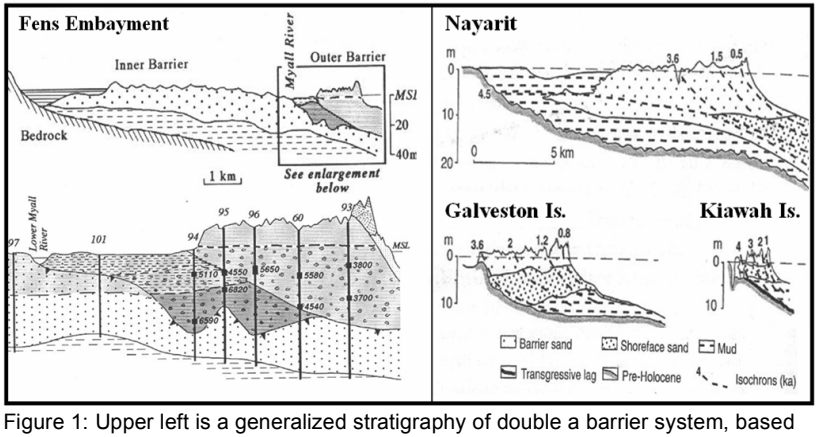

Figure 1: Upper left is a generalized stratigraphy of double a barrier system, based on core and dating techniques shown lower left (modified from Thom et al., 1992). Right are examples of general models of prograding barrier stratigraphy found in textbooks (modified from Woodroffe, 2002 and Davis and Fitzgerald, 2004).

Sea-level, sediment supply and accommodation space have long been recognized as the primary variables controlling barrier evolution, but singling out the role of any one is difficult due to their complex interactions during progradation. The northern coast of New Zealand offers an opportunity to achieve this due to spatial variability in sediment supply regimes and antecedent geology as well as temporal fluctuations in sea-level over the last two successive highstands. The influences of sediment supply and wave energy are inter-coastal variables created between the high-energy, sediment rich west coast and the lower-energy, sediment starved east coast and the influence of accommodation space is an intra-coastal variability determined by varied preservation of Pleistocene depositional sequences and irregular bedrock topography. Ultimately, by comparing barrier stratigraphy along and across shore, a comprehensive study of evolution from a spectrum of sediment-rich with poor accommodation space to sediment starved with good accommodation space has been completed. Additionally, by studying a composite Quaternary barrier system that formed during two highstand configurations, it is possible to look at the influence of sea-level in barrier evolution.

This study augments existing coring and dating techniques with digital GPR to produce detailed 3-D stratigraphic models of five prograding barriers which span the east and west coast of New Zealand and incorporate deposits laid down during oxygen isotope

stage 5e and stage 1. The aim of this paper is two fold: 1) present detailed 3-dimensional morphostratigraphic models of prograding barriers in a range of coastal settings, 2) compare differences in barrier architecture to decipher the influence of sea-level, sediment supply and/or accommodation space in barrier evolution. This information will not only fill a gap in knowledge about New Zealand barriers, but because of their diverse nature they are representative of prograding landforms the world over.

NORTHERN NEW ZEALAND

Barriers are a common landform throughout New Zealand's long and varied coastline (Healy and Kirk, 1992), yet despite being frequently regarded as a 'world class natural laboratory of coastal geomorphology', remarkably little is known about them (Hesp et al., 1999). Approximately 12 % of New Zealand's 18,200 km of coast is fronted by barriers (Rouse and Goff, 2003; Shepard and Hesp, 2003). Due to the distinctive geology of New Zealand, barriers have evolved in a variety of settings ranging from the high-energy, sediment rich west coast to the lower-energy, sediment starved east coast. The stark contrast between the east and west coasts is particularly pronounced in the sub tropical northern portion of the North Island, which unlike its southern counterpart has no active tectonism or volcanism eliminating these evolutionary complications.

In Northland the supply of sediments from local fluvial inputs is negligible due to small stream drainage basins within the hinterlands. The majority of the sand in this northern region originates from central north island and delivered to the coast by the Waikato River, where it is then distributed northward by longshore currents. The Waikato River has switched its course between the two coastlines and has been discharging its load on the west coast since ca. 18 ka creating a sediment-rich littoral system (Figure 2). In contrast the east coast sediment budget is limited to offshore sands deposits from when the Waikato flowed through the Firth of Thames (Figure 2). The west coast littoral drift system is driven by open ocean swells from the Tasman Sea resulting in high-energy conditions, while the leeward east coast maintains a more benign wave climate of low to moderate wind and wave regime, disturbed only occasionally by extra-tropical cyclones (Brander, et al., 2003). The tides in New Zealand are classified for the most part as meso-tidal and are strongly semi-diurnal (de Lang et al., 2003).

Over the last 140 ka years sea-level has only been close to present levels twice on the New Zealand Coast, about 120-125 ka (oxygen isotope stage 5e) and mid-late Holocene (stage 1), having risen from glacial levels of 120 meters below present to roughly present-day level some 5 000 to 7 000 years ago. Studies of sea-level change over the remaining part of the Holocene vary between a still stand and up to a two meter fall (Chappell and Shackleton, 1986 and Gibbs, 1986). Presently, sea-level is rising in New Zealand at a rate of 1.6mm/yr ± 0.2mm (Hannah, 2004), which is similar to global estimations of 0.15 m per century (Gornitz and Lebedeff, 1987).

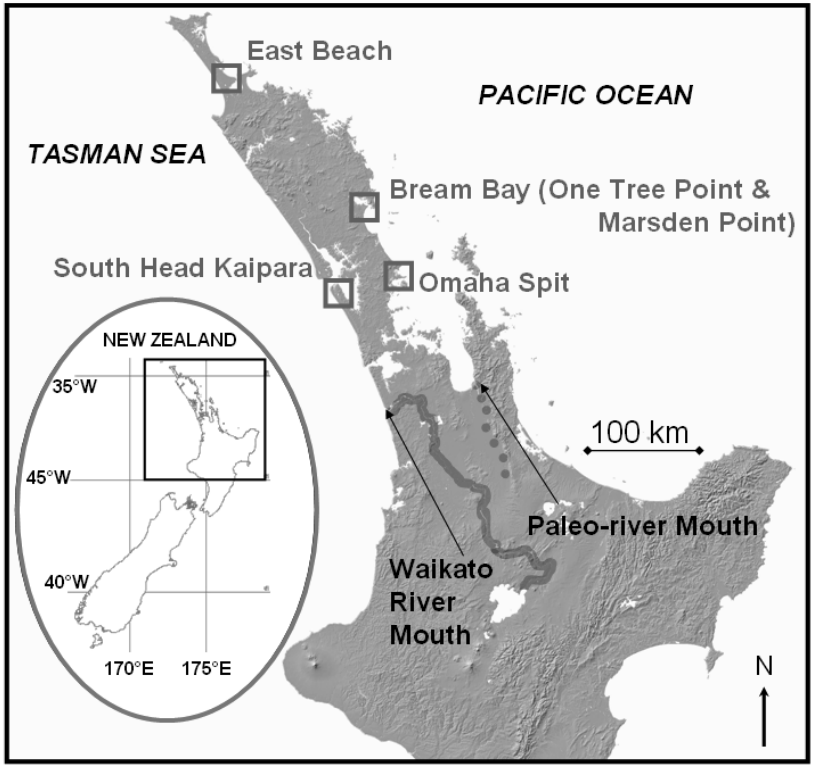

Figure 2: Location map of study sites throughout the Northland region of the North Island, New Zealand. Note the alternate route of the Waikato River.

As a result of contrasting geologic and oceanographic settings, with variable accommodation space and sporadic sediment supply, the coastal landforms differ widely with close proximity. East Coast Holocene barriers in Northland began to form at the cessation of sea-level rise around 6,000 years ago (Shepard and Hesp, 2003). During the ensuing relative stillstand offshore sediment was reworked onshore by wave action. Sand accumulated within embayments to form progradational barriers confined to coastal compartments disconnected by a predominantly rocky indented coastline. These headland-attached barriers and spits display characteristic foredune / beach ridges with beaches comprised of white quartzo-feldspathic sands and are intermediate to reflective in nature (Figure 3). The West Coast barriers began forming around the same time as the East Coast, but the added influence of longshore sediment supply from the Waikato River resulted in a long continuous coastline where barrier spits form in front of large harbors. These large Pleistocene-Holocene composite barriers contain black

titanomagnetite sand, with wide dissipative beaches and inland dunes over 100m in places. These embayment barriers are separated by dune-capped coastal cliffs (Figure 2).

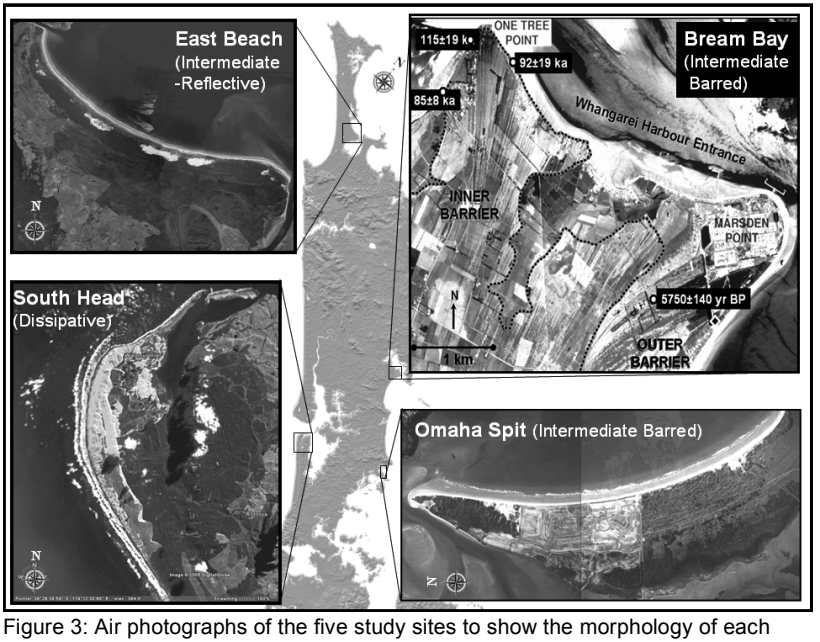

Figure 3: Air photographs of the five study sites to show the morphology of each barrier.

To represent these various barrier types four Holocene barriers and one Pleistocene barrier were selected for field investigations. Work on New Zealand barriers lacks stratigraphic and chronological detail, resulting in classification based on morphology. Therefore, the five study sites are classified using barrier types compiled by Shepard and Hesp (2003) as follows; One Tree Point is a Pleistocene Beach Ridge Barrier, Marsden Point and East Beach are Holocene Foredune Barriers, Omaha Spit is a Holocene Beach Ridge Barrier and South Head Kaipara is a Transgressive Dunefield Barrier (Figure 4).

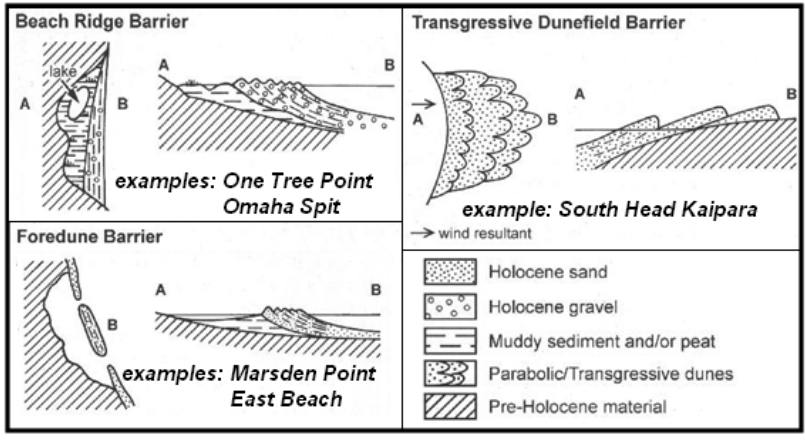

Figure 4: Characteristics of New Zealand barrier types relevant to this study (modified from Shepard and Hesp, 2003).

METHODS & DATABASE

This investigation is a combination of five individual studies involving an integrated high-resolution geophysical and sedimentological approach. The internal stratification of each barrier was investigated using a GSSI SIR-2000 ground-penetrating radar (GPR) system with a 200 MHz transceiver. Initial large-scale shore parallel and perpendicular GPR transects were collected on the order of several hundred meters in length at each site. Topographic corrections were applied using a Sokkia Electronic Total Station on profiles that had over 0.5 m variation in elevation. A representative subsection of each barrier was then selected to acquire a dense grid network optimal for constructing a 3-D model (Grasmueck et al., 2005). Finally, the nature of the reflectors in the geophysical data was ground-truthed using scarp exposures and core data. GPR analysis was performed using Radan 6.5 Software and interpretations of the recorded facies are described following the terminology of van Heteren et al. (1998). Textural and compositional characteristics of sediment samples were examined using Malvern particle analyzer for grain size, in addition to standard sedimentological techniques to provide a basis for interpreting barrier facies.

RESULTS

Geophysical data delineate three barrier facies (nearshore, shoreface and dune) within the lithosome of each study site. The geometry of the sedimentary layers was documented to sub-meter scale in the digital record, as demonstrated by replicating the stratigraphy exposed along an outcrop at One Tree Point (Figure 5). These remotely sensed continuous cross-sectional views of the barrier subsurface stratigraphy are described in two and three dimensions below.

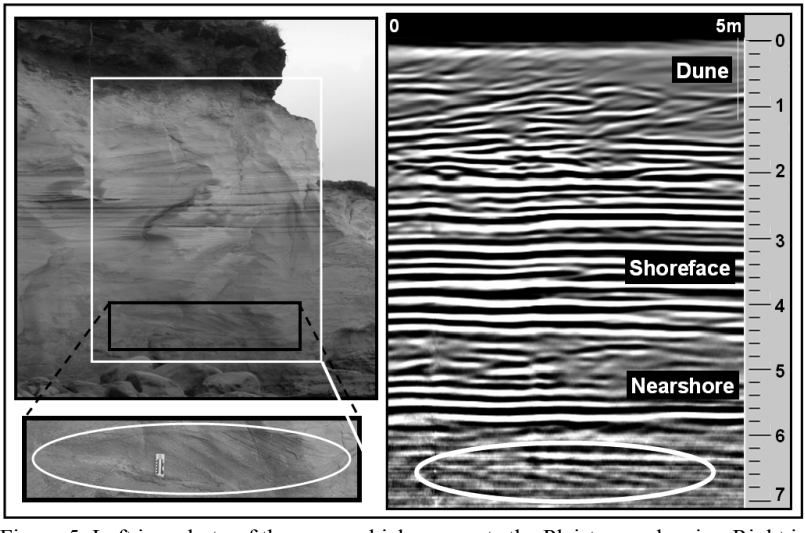

Figure 5: Left is a photo of the scarp which crosscuts the Pleistocene barrier. Right is a GPR record collected from along the top of this outcrop.

East Beach

The uppermost radar facies is characterized by generally weak / reflector free areas with faint steeply dipping reflectors mainly in the seaward direction (Figure 6, AI). The capping dune facies averages about 3 meters thick and consists of well-sorted, fine-grained quartz sand. The middle radar facies is dominated by a series of stacked high amplitude reflectors that dip gently in a seaward direction (Figure 6, AII). These sediments contain moderate- to well-sorted quartz with coarse grains and shell hash within the beachface. The basal radar displays overall flat-lying geometry with some small-scale, landward-dipping trough and planar cross-beds detected within the nearshore facies (Figure 6, AIII). The corresponding lowermost sedimentary facies consists of moderately-sorted, fine-to medium grained quartz sand with small amounts of broken shell.

One Tree Point

The topmost radar facies is characterized by generally weak / reflector free areas separated by distinct steeply dipping reflectors mainly in the seaward direction (Figure 6, BI). This dune facies comprises a massive 2 meter bed of well-sorted, fine-grained quartz sand with heavy mineral layers. The middle radar facies consists of a series of high amplitude reflectors that dip slightly in a seaward direction with a measured strike slope of about 1° (Figure 6, BII). These beachfaces are highlighted by stark contrast of alternating laminated beds of moderate- to well-sorted quartz and heavy minerals. The basal radar facies displays overall flat-lying geometry with some small-scale, landward-dipping trough and planner cross-beds (Figure 6, BIII). The corresponding lowermost

sedimentary facies consists of moderately-sorted, fine-to medium grained quartz sand with some gravel and heavy minerals.

Marsden Point

The capping radar facies is characterized by an opaque, reflector-free record with faint structures including indistinct medium to large-scale trough cross-bedding and high angle planner cross bedding (Figure 6, CI). This dune facies consists of well-sorted, fine-grained, quartz-rich sand to a depth of 5 meters. The middle radar facies is displays multiple closely spaces high amplitude, tangential-oblique to curvilinear reflectors (Figure 6, CII). These beachfaces consist mainly of medium-sized quartz sand with shells, often forming a sharp contact at the top of the facies and contain very little heavy mineral sands. The lowermost facies displays overall flat-lying geometry (Figure 6, CIII). The overlying beachfaces grades into silt with increased shell and organic matter to around a depth of 10 meters.

Omaha

The uppermost radar facies is characterized by generally weak / reflector free areas with faint steeply dipping reflectors mainly in the seaward direction (Figure 6, DI & Figure 7, BI). The capping dune facies averages about 2.5 meters thick and consists of well-sorted, fine-grained quartz sand. The middle radar facies is dominated by a series of evenly space reflectors that dip gently in a seaward direction (Figure 6, DII & Figure 7, BII). The corresponding sediments consist of moderate- to well-sorted quartz with coarse grains and shell hash the beachface. The lowermost facies displays overall flat-lying geometry (Figure 6, DIII & Figure 7, BIII). The overlying beachfaces grades into silt with increased shell and organic matter to around a depth of 10 meters.

South Head Kaipara

The uppermost radar facies is opaque towards the top but grades into more prominent with medium- to large-scale trough cross bedding and high angle planner cross-bedding dipping in both a seaward and landward directions (Figure 7, AI). This capping dune facies consisted of well-sorted, fine-grained sand with a higher heavy mineral content than the east coast barriers. This dune sequence is about 2.5 meters thick in the swale of the large dunes where the GPR was collected. The middle radar facies has three or four stacked high amplitude flat-lying reflectors that dip gently in a seaward direction (Figure 7, AII). The basal radar displays overall flat-lying geometry with some small-scale, landward-dipping trough and planar cross-beds detected within the nearshore facies (Figure 7, AIII). The corresponding lowermost sedimentary facies consists of moderately-sorted, fine grained sand with a high percentage of heavy minerals.

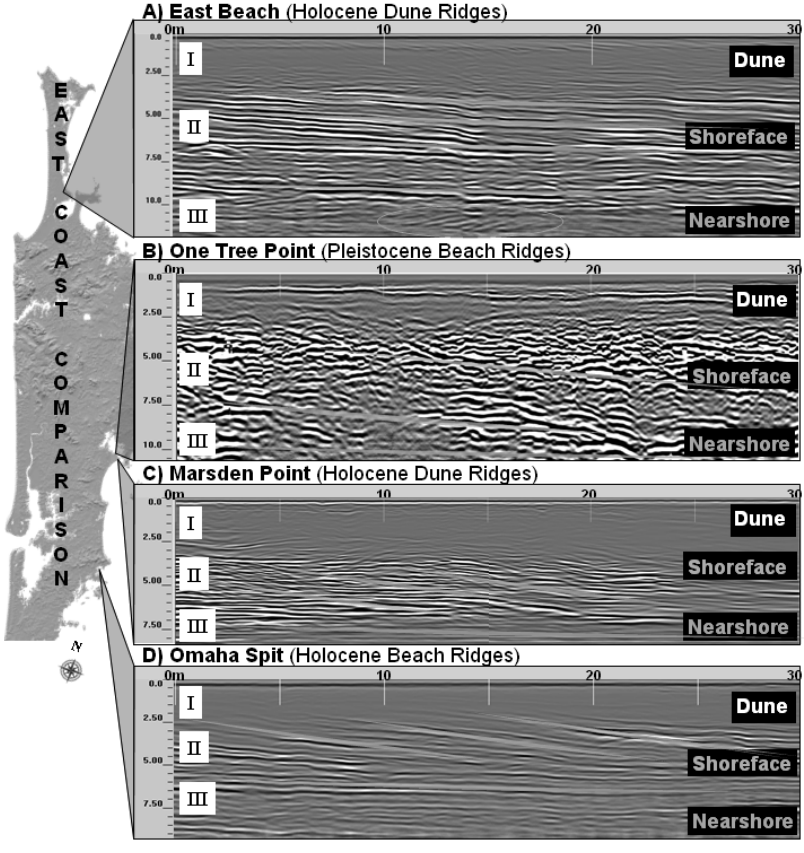

Figure 6: GPR transects from each of the east coast barriers set to same scale for comparison of internal stratigraphy. Reflectors within the shoreface and nearshore have been digitally highlighted to accentuate bedding geometry within these facies. Note dune facies are represented by diffuse or opaque as a lack of contrast with well sorted sand produces no strong reflectors.

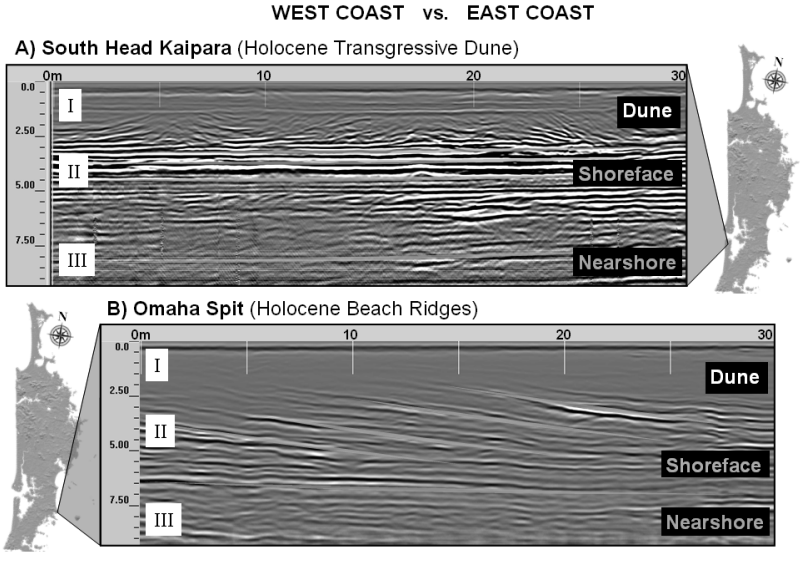

Figure 7: GPR transects from the west coast barrier compared to its longitudinal east coast component. Again reflectors within the shoreface and nearshore have been digitally highlighted accentuating the flattened, stacked geometry within the west coast shoreface as compared the evenly spaced curvilinear geometry within the east coast.

DISCUSSION

Nearshore, beach and dune facies were delineated within each barrier lithosome, but the geometry and spacing of the paleo-beachfaces varies between sites. The overall internal stratigraphy of barriers along the east coast is similar for each site. The stratigraphy is dominated by uniform, curvilinear, seaward-dipping reflectors that represent paleo beachfaces. Despite their similar geometry, the slight differences in spacing appear to be related to morphology in that barriers with beach ridges displayed evenly spaced beachfaces that are directly related to individual overlying beach ridges; where foredune barriers maintained closely spaced beachfaces that do not appear to correlate directly with surface morphology. The result is that GPR transects from the east coast barriers show similar stratigraphy for the two beach ridge barriers (One Tree Point and Omaha Spit) regardless of age difference, and the stratigraphy of the two Holocene dune ridge barriers (Marsden Point and East beach) are alike.

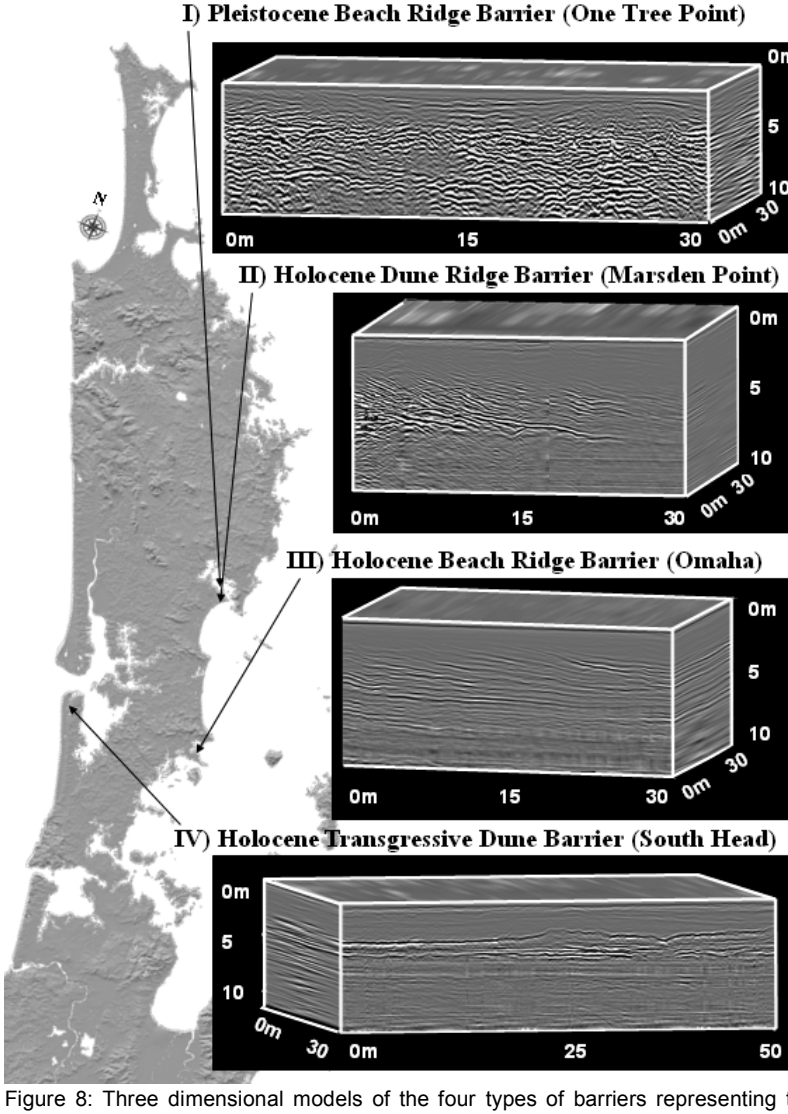

Figure 8: Three dimensional models of the four types of barriers representing the Northland Region. Note the lateral continuity of the nearshore, shoreface and dune stratigraphy as evidenced by the flat lying bedding planes alongshore in the Z-direction.

The beachfaces of the South Head Kaipara are completely different to all of the east coast sites exhibiting a more flattened, low-gradient, stacked configuration. The differences in beachface stratigraphy between the two coasts can be explained by considering the depositional setting in which the barrier formed, with the high-energy west characterized by a dissipative morphodynamic state while the lower-energy east coast maintains a more intermediate morphodynamic state. The replication of stratigraphic form along the east coast shoreline and over successive sea-level stands indicates that the depositional setting is similar throughout space and time on the east coast.

Three dimensional stratigraphic models were constructed for the four various barrier types identified in this study: Pleistocene Beach Ridge Barrier, Holocene Dune Ridge Barrier, Holocene Beach Ridge Barrier and Holocene Transgressive Dunefield Barrier (Figure 8). The representative three-dimensional stratigraphic models highlight the subsurface architecture of the beach and dune facies recorded in the geophysical record. These models show that the barrier stratigraphy is laterally continuous along shore as indicated by the flat lying shore parallel bedding planes in the Z-direction. To show the correlation of these laterally continuous stratigraphic beds with the overlying dunes, detailed morphostratigraphic models were constructed (Figure 9). To create these models large scale shore perpendicular GPR transects were used in conjunction with the topographic profiles.

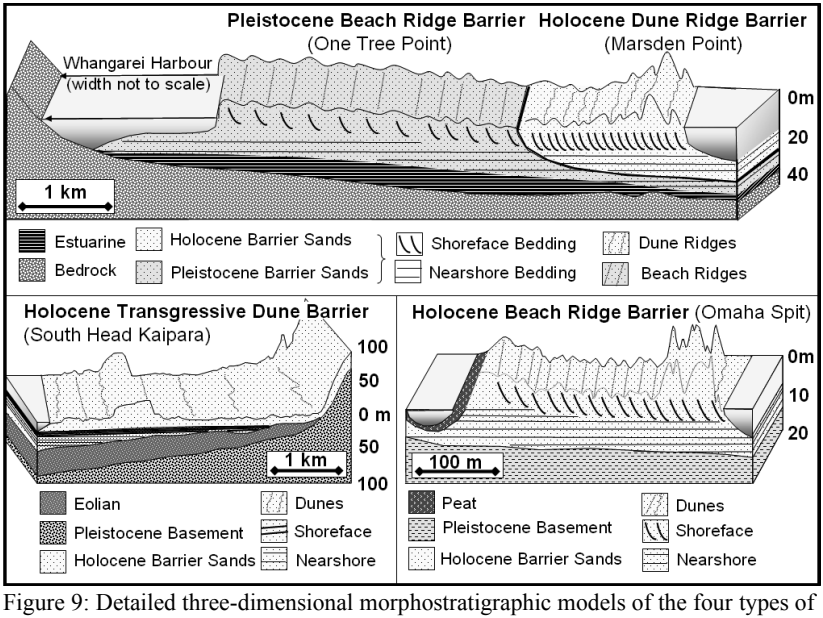

Figure 9: Detailed three-dimensional morphostratigraphic models of the four types of prograding barriers in Northland.

CONCLUSIONS

- High-resolution geophysical and sedimentological data has produced detailed three-dimensional morphostratigraphic models for prograding barrier around the coastline of northern New Zealand.

- The internal architecture of the morphostratigraphic models presented in this paper differs slightly from existing general models of prograding barrier stratigraphy.

- The difference in shoreface geometry between the east to west coast can be explained by the depositional setting in which they formed, with the high-energy west characterized by a dissipative morphodynamic state while the lower-energy east coast maintains a more intermediate morphodynamic state.

- The replication of this stratigraphic form along the Holocene shoreline and over successive sea-level stands indicates that the present day barrier evolution and depositional setting is similar throughout space and time.

- Due to the variation of barrier types along the lower energy east coast, wave energy is not considered a factor in determining if progradation style results in beach or dune ridge barriers. This makes intuitive sense in that dunes are formed by wind, but interesting when considering that the beachface is linked directly with over lying morphology. Even though prevailing wave energy does not appear to be a defining factor, intermittent / dominant conditions such as storms could play a key role.

- Sea-level does not appear to be a determining factor in the construction of a beach ridge barrier as One Tree Point has formed during the rapidly dropping sea-level during oxygen isotope stage 5e and Omaha during stage 1.

- The difference in sediment supply, relative to accommodation space, plays a major role in the contrasting inter-coastal prograding barrier types. The west coast has a steady supply of sediment moving along shore creating barrier spits in front of large embayment. Once the spits formed sand remains offshore in the littoral system that runs along the straightened coastline or is stored onshore in large dune complexes. In comparison east coast barriers have formed by the reworking of limited offshore sand deposit that has accumulated in embayments along this rocky indented coastline.

A FORMULA FOR LONGSHORE SEDIMENT TRANSPORT IN THE SWASH

Magnus Larson[1] and Ty V. Wamsley[2]

Abstract: A formula is proposed for the longshore sediment transport in the swash based on the study by Larson *et al.* (2004) on swash-zone transport and foreshore evolution. Hydrodynamics needed to predict the local transport rate were derived from ballistics theory, where both the cases with and without friction were investigated. The formula was validated with data from two experiments carried out in the Large-scale Sediment Transport Facility (LSTF) of the Coastal and Hydraulics Laboratory. In total five experimental cases were reproduced using a typical value on the transport rate coefficient from Larson *et al.* A simple exponential decay with distance offshore was employed to model the transition between the swash zone and the inner part of the surf zone. The LSTF data on transport rates measured in this region supported such a simplified model.

INTRODUCTION

The swash zone constitutes the area of the beach where the waves run up and down, dissipating or reflecting their remaining energy after traveling towards shore. Propagation of waves up the beach is typically referred to as uprush, whereas the return of the water is denoted as backwash (thus, uprush and backwash together encompass a swash cycle). The morphologically active part of the beach corresponding to the swash zone is often called the foreshore (or beach face), that is, the part of the beach that is shaped by the hydrodynamic forces in the swash. Although the swash zone is a very narrow strip, it is of great importance for the sediment exchange between land and sea, which in turn affects both the subaerial and subaqueous evolution of the beach.

Morphological processes such as erosion during severe storms, post-storm recovery, seasonal variation in foreshore shape, subaerial accumulation updrift of structures (e.g., jetties), and evolution of rhythmic features are all related to this exchange.

Hydrodynamic and sediment transport conditions are highly complex in the swash zone involving, for example, rapidly varying flow (in time and space), nonlinear wave transformation, wave-wave interaction, and multiphase flow with possible infiltration and exfiltration effects. In spite of these difficulties, significant progress has been made in the last decade concerning the hydrodynamics and sediment transport conditions in the swash zone and the associated response of the foreshore (see Elfrink and Baldock 2002; Larson *et al*. 2004). However, most previous studies have focused on the water and sediment transport in the cross-shore direction (i.e., perpendicular to the main orientation of the contour lines on the foreshore), and only limited work has been carried out on the transport in the longshore direction.

The main objectives of the present investigation were to develop a formula for the longshore sediment transport rate in the swash and to validate it towards high-quality data from laboratory experiments carried out in the Large-scale Sediment Transport Facility (LSTF) at the Coastal and Hydraulics Laboratory in Vicksburg, MS. The swash-zone sediment transport formula proposed by Larson *et al.* (2004) was generalized to describe the longshore transport rate. Hydrodynamic quantities needed in the formula were derived from ballistics theory and assuming self-similarity in the flow variation along the foreshore. Theoretical expressions were obtained both for the cases with and without friction. Measurements of the longshore sediment transport rate in the swash-zone carried out in the LSTF were employed to validate the new formula. Good agreement was achieved using coefficient values from Larson *et al.* determined when modeling cross-shore sediment transport in the swash.

THEORETICAL DEVELOPMENTS

Swash-Zone Sediment Transport

Madsen (1991, 1993) proposed the following formula for calculating the instantaneous bed load transport rate (q_b),

$$\frac{q_b(t)}{\sqrt{(s-1)gd}\,d} = \frac{8}{1+\dfrac{\tan\beta(t)}{\tan\phi_m}}\left(|\psi(t)|-\psi_{cr,\beta}\right)^{3/2}\frac{\tau_b(t)}{|\tau_b(t)|} \qquad (1)$$

where s is the specific weight of the sediment ($s=\rho_s/\rho$ in which ρ_s and ρ is the density of sediment and water, respectively), g the acceleration of gravity, d the sediment diameter, β the local beach slope ($=\mathrm{d}h/\mathrm{d}x$, where h is the bottom elevation and x a cross-shore coordinate), ϕ_m the friction angle for a moving grain (about 30 deg), t time, τ_b the instantaneous bed shear stress, and $\psi=\tau_b/(\rho_s-\rho)gd$ (Shields parameter). The subscript cr,β refers to incipient conditions for sediment movement at the slope β. Although Eq. 1 was obtained for bedload transport under waves and currents in a homogenous fluid,

Larson *et al.* (2004) assumed that the general relationship is also valid in the swash when a particular location x is subject to a flow (during time periods when there is no flow, the transport is set to zero). At x, the transport is onshore during the uprush phase and offshore during the backwash phase.

Integrating the transport rate over a swash cycle at x gives a mean transport $q_{b,net}$,

$$\frac{q_{b,net}}{\sqrt{(s-1)gd}\,d} = \frac{8\tan\phi_m}{\tan^2\phi_m - (dh/dx)^2}\left(I_U + I_B\right)\left(\frac{dh}{dx} - \tan\beta_e\right) \tag{2}$$

where I_U and I_B are integrals of the Shields parameter (*i.e.*, shear stress) over the uprush and backwash phase, respectively. The condition for the local equilibrium slope $\tan\beta_e=(I_U-I_B)/(I_U+I_B)$ was used to derive Eq. 2 (see Larson *et al.*, 2004). In order to compute the net transport, the time history of τ_b at x during a swash cycle must be known. If the shear stress is assumed proportional to the local velocity (u) squared, the problem reduces to estimate the variation in u at x. Larson *et al*. (2004) assumed that properly scaled, the velocity variation in time is approximately similar across the swash zone, that is, $u/u_o = \Gamma\left((t-t_s)/t_o\right)$, where u_o and t_o is a scaling velocity and time, respectively, and Γ a function that characterizes the non-dimensional velocity variation in time at all locations in the swash zone (cf., Masselink and Hughes, 1998; Waddell, 1973). The velocity u_o is taken as the wave front velocity at uprush and t_o as the duration of the swash at the particular location, determined as discussed in the following sections.

Developing Eq. 2 by solving the integrals I_U and I_B using the self-similar velocity variation (employing a quadratic dependence of τ_b on u and neglecting the critical shear stress), and absorbing the various non-dimensional coefficients (including friction factors and the integral of the function Γ) into one coefficient K_c, gives for the cross-shore transport rate:

$$q_{bc,net} = K_c \frac{\tan\phi_m}{\tan^2\phi_m - (dh/dx)^2}\frac{u_o^3}{g}\left(\frac{dh}{dx} - \tan\beta_e\right)\frac{t_o}{T} \tag{3}$$

Eq. 3 describes the net transport in the cross-shore direction, whereas the transport in the longshore direction may be estimated as,

$$q_{bl,net} = K_l \frac{\tan\phi_m}{\tan^2\phi_m - (dh/dx)^2}\frac{u_o^2 v_o}{g}\frac{t_o}{T} \tag{4}$$

where K_l is an empirical coefficient, possibly with a different value from K_c. Eq. 4 was heuristically derived by looking at Eq. 3 and assuming that the mobilization of the sediment is proportional to u_o^2 and the transporting velocity to v_o (compare with general sediment transport formula by Camenen and Larson 2004). Eq. 3 implies that the net cross-shore sediment transport rate is zero in the swash when the foreshore slope is in equilibrium, whereas longshore transport may still occur if the waves approach at an angle. The cross-shore velocity will still affect $q_{bl,net}$ at equilibrium since the mobilization of sediment is a function of u_o^2.

Swash-Zone Hydrodynamics without Friction

The transformation of the waves as they travel up and down the foreshore is quite complex and many existing models have limited predictive capability concerning details of the flow during a swash cycle. However, it has been shown that the speed of the wave front as it propagates up the foreshore may be reasonably well described using simple theory in which the front is regarded as a slug of water moving under the action of gravity (and possibly friction). The solution to the wave front propagation is analogous to the so called ballistic theory in mechanics. Thus, the movement of the front is governed by the following equation,

$$\frac{d^2 x_o}{dt^2} = -g \sin\beta \tag{5}$$

where x_o is the position of the wave front as it travels along the foreshore (positive in the onshore direction and x_o is taken along the foreshore), β is the foreshore slope taken as a constant and t is time ($u_o = dx_o / dt$). Eq. 5 is easily integrated to yield the velocity and position of the wave front as a function of time as $u_o = u_s - g \sin\beta t$ and $x_o = x_s - g \sin\beta t / 2 + u_s t$, respectively, where u_s is the wave front speed at the start of the uprush and x_s the location at the start of the swash zone where u_o=u_s (x_s taken to be zero at the still-water shoreline; SWS). These equations are applicable for both the uprush and backwash phase, making the variation in u_o and x_o symmetric with respect to the two phases.

The time (t_{max}) when the maximum runup height is attained, implying that u_o=0, is given by $t_{\max} = u_s / (g \sin\beta)$ and the corresponding location is $x_{\max} = u_s^2 / (2g \sin\beta)$. Transforming x_{max} into a vertical distance and denoting this distance as the runup height (R) yield $R = u_s^2 / (2g)$. The value of u_s may be difficult to estimate and this velocity can instead be substituted with R for which there is a wide range of predictive equations to choose from (e.g., Hunt, 1959; Mase, 1988; Mayer and Kriebel, 1994). Based on the equations governing the movement of the wave front one can derive the duration (t_o) any location on the foreshore will be submerged according to,

$$\frac{t_o}{T} = \sqrt{1 - \frac{z_o}{R}} \tag{6}$$

where z_o is the vertical distance from the reference level to x_o and R was introduced instead of u_s. It was assumed that the duration of the swash cycle is similar to the incident wave period (T), which is appropriate for values approximately larger than one

on the surf similarity parameter (ξ_o) defined based on deepwater conditions (Holman 1986). For smaller values on ξ_o the swash period is longer than the incident wave period and marked interaction between consecutive waves is expected in the swash (Erikson *et al.* (2005). The following expression may be derived for the wave front speed:

$$\frac{u_o}{u_s} = \sqrt{1 - \frac{z_o}{R}} \tag{7}$$

Eqs. 6 and 7 were employed to scale the local velocity variation at a point x on the foreshore when further developing Eq. 2 to calculate sediment transport in the swash zone (Eq. 3).

If the waves approach the foreshore at an angle, the wave front speed will have both a cross-shore and a longshore component. Employing simple theory again, Eq. 5 has to be supplemented with the equation $d^2 y_o / dt^2 = 0$ to describe the complete movement of the front, where y_o is the longshore position of the front (the foreshore is uniform alongshore so there are no gravitational effects in this direction). Assuming a velocity U_s at the start of the uprush oriented at an angle α with respect to the y-axis, with the cross-shore and longshore components $u_s = U_s \sin\alpha$ and $v_s = U_s \cos\alpha$, respectively, yields the solution for the longshore direction $v_o = v_s$ and $y_o = y_s + v_s t$, whereas the solution for the cross-shore direction is given by the previously discussed equations.

Swash Hydrodynamics with Friction

Some previous studies have included friction in the simple theory used to describe the swash motion (e.g., Kirkgöz, 1981; Hughes, 1995; Erikson *et al.*, 2005). Typically, a frictional force is added in the governing equation, where the force is taken to be proportional to the velocity square,

$$\frac{du_o}{dt} = -g\sin\beta - Ku_o^2 \tag{8}$$

where K is an empirical coefficient. Hughes (1995) expressed this coefficient as $K = f / 8h_o$, in which f is a friction factor and h_o a representative water depth (assumed to be a constant). Eq. 8 has the solution,

$$u_o = \frac{u_s - \frac{1}{\sqrt{\varepsilon}}\tan\left(\sqrt{\varepsilon} g \sin\beta t\right)}{1 + u_s\sqrt{\varepsilon}\tan\left(\sqrt{\varepsilon} g \sin\beta t\right)} \tag{9}$$

where $\varepsilon = K / g\sin\beta$ and u_o=u_s when t=0. Integrating Eq. 9 ($u_o = dx_o / dt$) with respect to t yields the position of the wave front during uprush:

$$x = \frac{1}{\varepsilon g \sin\beta}\ln\left(\frac{\cos\left(\arctan(u_s\sqrt{\varepsilon}) - \sqrt{\varepsilon} g \sin\beta t\right)}{\cos\left(\arctan(u_s\sqrt{\varepsilon})\right)}\right) \tag{10}$$

Setting u_o=0 in Eq. 9 yields the time when the runup height is obtained:

$$t_{\max} = \frac{1}{\sqrt{\varepsilon} g \sin\beta} \arctan\left(\sqrt{\varepsilon} u_s\right) \tag{11}$$

Combining Eqs. 10 and 11 gives the runup height including friction:

$$R = \frac{1}{\varepsilon g} \ln\left(\frac{1}{\cos\left(\arctan(\sqrt{\varepsilon} u_s)\right)}\right) \tag{12}$$

For the limiting case of no friction ($\varepsilon \to 0$) Eq. 12 reverts back to $R = u_s^2/(2g)$.

Eq. 8 is valid for the uprush case, whereas during the backwash the frictional force is acting in the opposite direction and the following equation should be solved:

$$\frac{du_o}{dt} = -g\sin\beta + Ku_o^2 \tag{13}$$

Using the initial condition that u_o=0 for τ=t-t_{max}=0 gives the solution:

$$u_o = -\frac{1}{\sqrt{\varepsilon}} \frac{1-\exp\left(-2\sqrt{\varepsilon} g \sin\beta\tau\right)}{1+\exp\left(-2\sqrt{\varepsilon} g \sin\beta\tau\right)} = -\frac{1}{\sqrt{\varepsilon}} \tanh\left(\sqrt{\varepsilon} g \sin\beta\tau\right) \tag{14}$$

For $\tau \to \infty$, Eq. 14 has the limit $u_o = \sqrt{g\sin\beta / K}$, which is the steady-state solution to Eq. 13. The position of the wave front during backwash is obtained by integrating Eq. 14 yielding,

$$x_o = x_{\max} - \frac{1}{\varepsilon g \sin\beta} \ln\left(\cosh\left(\sqrt{\varepsilon} g \sin\beta\tau\right)\right) \tag{15}$$

where the initial condition that x_o=x_{max} at τ=0 was used.

In order to describe 2D runup with friction, the alongshore equation of motion should be modified to,

$$\frac{dv_o}{dt} = -Kv_o^2 \tag{16}$$

bearing in mind that $v_o = dy_o / dt$. The solution to this equation, applying the initial condition v_o=v_s when t=0, yields:

$$v_o = \frac{v_s}{1 + Kv_s t} \tag{17}$$

Integrating Eq. 17 with respect to time gives the longshore position of the wave front,

$$y_o = \frac{1}{K} \ln\left(\exp\left(Ky_s\right)\left(1 + Kv_s t\right)\right) \tag{18}$$

assuming that y_o=y_s when t=0. Replacing t in Eq. 17 with x by using Eq. 10 will illustrate how the longshore front speed varies with position on the foreshore during the uprush. Similarly, employing Eq. 15 to substitute t with x, the variation during the backwash phase is obtained.

Similar to the runup height, the swash duration is affected by friction and the uprush phase has a different duration than the backwash phase. The uprush lasts until the wave front speed u_o becomes zero, which yields the following duration T_{uf} (from Eq. 9):

$$T_{uf} = \frac{\arctan\left(\sqrt{\varepsilon} u_s\right)}{\sqrt{\varepsilon} g \sin\beta} \tag{19}$$

The backwash ends when the wave front has returned to the starting point of the swash (*i.e.*, the SWS), which corresponds to x_o=0. During the backwash the wave front location is given by Eq. 15, and applying the condition that x_o=0 yields the backwash duration T_{bf} (after some manipulation),

$$T_{bf} = \frac{1}{\sqrt{\varepsilon} g \sin\beta} \ln\left(A + \sqrt{A^2 - 1}\right) \tag{20}$$

where:

$$A = \frac{1}{\cos\left(\arctan\left(\sqrt{\varepsilon} u_s\right)\right)} \tag{21}$$

Thus, the swash duration with friction is given by T_f=T_{uf}+T_{bf}, whereas the duration neglecting friction (T_s) is obtained as $T_s = 2u_s / (g \sin\beta)$. It is convenient to present the influence of the friction on the swash properties, such as the runup height and swash duration, by introducing the non-dimensional parameter $\delta = Ku_s^2 / (g \sin\beta)$ $(= \varepsilon u_o^2)$. This parameter expresses the ratio between the friction force and the gravitation force. Fig. 1 illustrates the influence of friction on the runup height (R_f) and the swash duration (T_f, T_{uf}, and T_{bf}), where the corresponding values for no friction was used as normalizing

quantities. The figure shows that the swash duration is always shorter if friction is included, and that the duration of the backwash is always longer than the uprush. In the following comparisons with the experimental data, friction was not included to avoid introducing another calibration parameter. However, when applying Eqs. 3 and 4 in the general case, u_o, v_o, and t_o should be estimated based on the solution with friction,

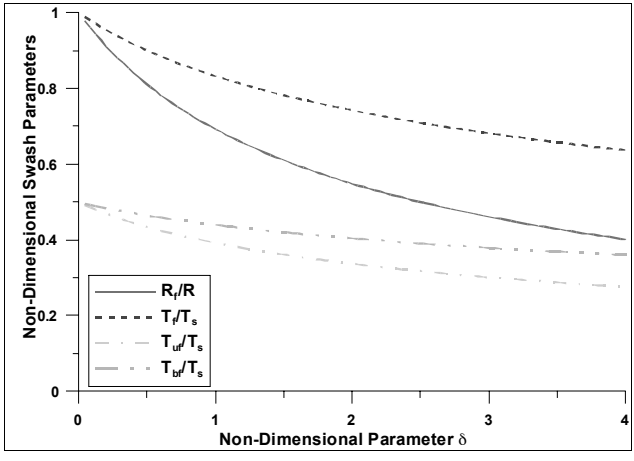

Fig. 1. Influence of friction on runup height and swash duration.

COMPARISON WITH EXPERIMENTAL DATA

The proposed formula for the longshore sediment transport rate in the swash (Eq. 4) was validated with data from movable-bed experiments carried out in the LSTF (Wang *et al.*, 2002; Gravens and Wang, 2007). Previously the cross-shore transport formula (Eq. 3) was validated using field data from Japan (Larson *et al.*, 2004), where appropriate values on the transport coefficient (K_c) were determined through calibration against measured data on the profile response on the foreshore. It will be assumed that the transport coefficient for the longshore direction (K_l) has a similar value to K_c. Data on the longshore sediment transport in the swash zone is available from LSTF experiments, including the spilling/plunging wave experiment conducted by Wang *et al.* (2002) and the detached breakwater experiment by Gravens and Wang (2007; base cases performed before any structure was put in). Results from comparison between predictions with the formula and the data for these two experiments are reported in the following.

The general experimental setup and measurement procedure were similar for the two LSTF experiments. Measurements of the longshore sediment transport rate in the swash zone encompassed only two locations on the foreshore using traps at a distance of -0.3 m and -0.9 m from the initial still-water shoreline (negative values refer to a distance shoreward of this shoreline). However, this still gave a basis for assessing how appropriate the formula is and for a rough estimate of suitable coefficient values. More

detailed measurements were available for the surf zone and the region where it is expected that the swash and surf zone would significantly interact. In order to describe the latter region, as a first approach, sediment from the swash zone is assumed to diffuse out into the surf zone in manner that may be described by an exponential decay. The measured transport rate in the inner part of the surf zone was relatively constant, which was a result of the beach profile being in equilibrium with similar rate of energy dissipation for sediment mobilization and similar longshore current for transport alongshore. Thus, the decay in the transport rate from the swash zone was made to approach this constant value (estimated from the data) defining the value of the rate coefficient in the exponential decay.

In order to compute the transport rate in the swash, several input quantities and coefficients are necessary, including the runup height (used to estimate initial velocity of runup waves in the ballistics model), the wave angle prior to runup, the transport rate coefficient, and the foreshore slope. For general validation of the formula a typical coefficient value of $K_c=10^{-3}$, which was a typical value obtained by Larson *et al*. (2004) when modeling the cross-shore sediment transport in the swash for field data, was employed for the coefficient (K_l) in the longshore sediment transport formula. The runup height was computed with the Hunt (1959) formula and the wave angle in a water depth of about 0.05 m was used as input to the swash calculations using Snells law to estimate the wave angle in shallow water. This water depth is somewhat arbitrarily chosen, but approximately corresponds to the limit of the backwash.

Experiments by Wang *et al.*

Wang *et al*. (2002) performed movable-bed experiments in the LSTF to study the spatial and temporal variations in the surf-zone currents and sediment transport rates due to obliquely incident breaking waves. The beach and wave conditions were uniform alongshore (water was recirculated to simulate an infinite beach) and two main cases were investigated where spilling and plunging breakers were predominant, respectively. The sand had a median grain size of 0.15 mm and the waves were allowed to act a sufficiently long time to ensure near-equilibrium conditions (the foreshore slope was approximately linear with $\tan\beta_e=0.18$). The (calculated) deepwater wave conditions for the spilling and plunging case were H_{mo}=0.27 m, T_p=1.5 s, ϕ=10.4 deg, and H_{mo}=0.24 m, T_p=3.0 s, ϕ=16.3 deg, respectively, where H_{mo} is the significant wave height, T_p the peak wave period, and ϕ the wave angle. The transport rates measured by sediment traps at the downdrift end of the LSTF were used for the comparison in the present study (rates were converted to include porosity and correspond to a yearly amount).

Figures 2 and 3 display the results for the spilling and plunging case carried out by Wang *et al*. (2002), respectively, indicating good agreement between the predictions by the proposed formula and the measurements. Although the measurement points in the swash zone are only two, the transport magnitude seems to be well predicted with the typical transport coefficient value as well as the extent of the swash zone and the distribution of the transport rate. The results presented in the figures give rise to the following observations: (1) The simple Hunt formula seems to give a reasonable

estimate of the runup height (using the foreshore slope and the significant wave height). Since the runup height basically depends on the surf similarity parameter the predictions are quite different for the spilling and plunging case, in agreement with observations; (2) The value on the cross-shore transport coefficient obtained from the Japanese field data seems to yield good quantitative predictions and to be applicable for the longshore transport coefficient as well; and (3) The simple decay formulation applied seaward of the swash zone produces reasonable results, although for a case where the longshore transport in the inner part of the surf zone is not nearly constant (*i.e.*, equilibrium conditions prevail) some modifications are needed.

The decay coefficient was set to 1.0, although it should scale with the wave properties in the general case, and the equilibrium longshore transport rate in the inner part of the surf zone was given as 150 and 200 m^3/m/yr for the spilling and plunging case, respectively. When applied in simulations of beach topography change some procedure is probably needed to smooth the distinct peak at the still-water shoreline, which is a result of switching from the transport formula in the swash to the exponential decay.

Experiments by Gravens and Wang

Further testing of the swash-zone sediment transport formula was carried out by comparing with data on the longshore transport rate from the experiment by Gravens and Wang (2007) on beach topography evolution in the vicinity of detached breakwaters. In this experiment, four base cases were conducted on a natural beach without any structure present. Three of the experimental cases included waves (BC1, BC2, and BC4) and data

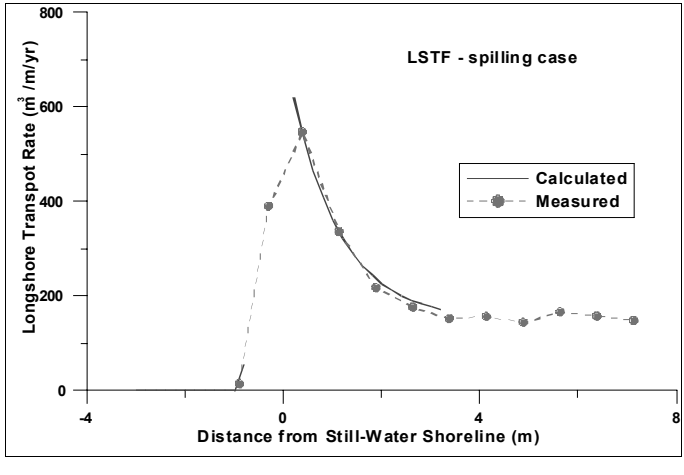

Fig. 2. Comparison between calculated and measured longshore transport rate in the swash and inner part of the surf zone for the spilling case from Wang *et al.* (2002).

from these cases were employed in the present study. All cases had the same offshore wave conditions (H_{mo}=0.32 m, T_p=1.5 s, and ϕ=8.5 deg), whereas Case BC1 had a recirculating current in the basin corresponding to the wave-generated current (simulating the current induced by the breaking waves on an infinitely long beach). Cases BC2 and BC4 encompassed recirculating currents corresponding to 2 and 1.5 times the wave-generated current, respectively, in order to simulate an external current (e.g., generated by tide or wind) superimposed on the wave-generated current.

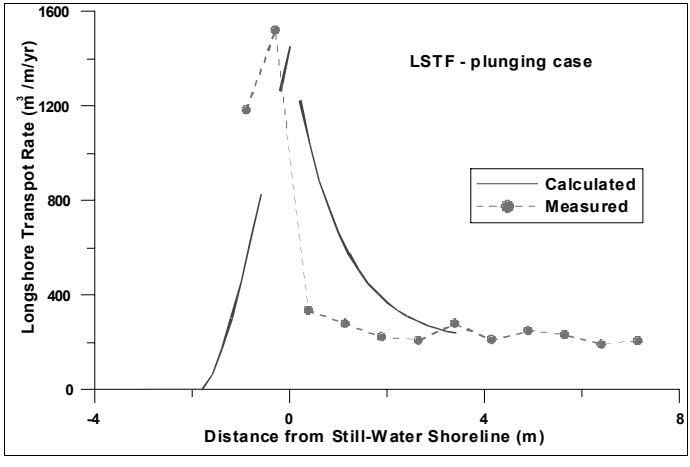

Fig. 3. Comparison between calculated and measured longshore transport rate in the swash and inner part of the surf zone for the plunging case from Wang *et al*. (2002).

The sediment was the same as in the experiment performed by Wang *et al*. (2002), and the foreshore profile was similar. Wave conditions recorded at the break point were used to derive input wave data (the waves were backed out to deep water from the break point, and the runup height was computed with the Hunt formula using deepwater wave conditions). Since the breaking wave conditions reported by Gravens and Wang (2007) were the same for all experimental case, the calculated runup height was the same, as well as the transport rate distribution in the swash zone. However, the equilibrium longshore transport in the inner part of the surf zone that the calculated transport rate was set to decay towards was different for the three cases studied, namely 130, 270, and 200 m^3/m/yr for Cases BC1, BC2, and BC4, respectively (approximate estimates from the measurements). This estimate scales well with the magnitude of the current employed in the various cases.

The same procedure and coefficient values were employed as for the Wang *et al*. (2002) comparisons without any additional tuning. Figures 4, 5, and 6 show the results for Cases BC1, BC2, and BC4, respectively. For Cases BC1 and BC4 there is some overestimation, but the result for BC2 is in good agreement.

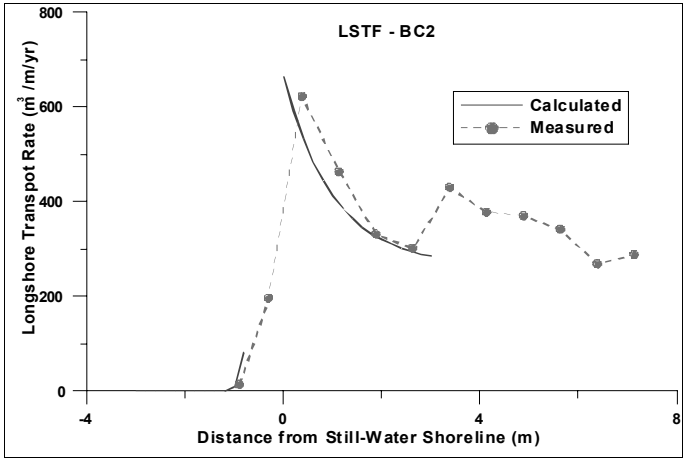

Fig. 5. Comparison between calculated and measured longshore transport rate in the swash and inner part of the surf zone for Case BC2 from Gravens and Wang (2007).

CONCLUSION

A formula for the longshore sediment transport rate in the swash zone was proposed based on the work by Larson *et al.* (2004) on cross-shore sediment transport in the swash. Needed hydrodynamic input on the wave front speed and swash duration was

derived from ballistics theory, where both the cases of no friction and friction were studied. Comparisons between calculated and measured transport rates were performed based on previous movable-bed experiments in the LSTF encompassing in total five cases. These comparisons indicated that the typical value on the transport rate coefficient determined by Larson *et al.* for cross-shore transport in the swash using field data from Japan provided a good estimate for the LSTF data as well.

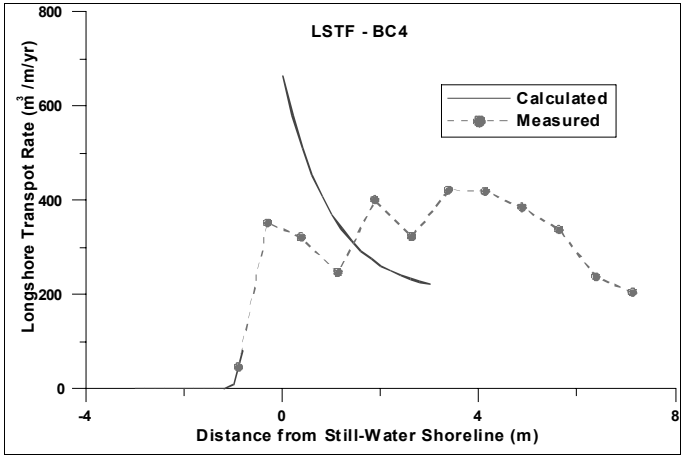

Fig. 6. Comparison between calculated and measured longshore transport rate in the swash and inner part of the surf zone for Case BC4 from Gravens and Wang (2007).

The transition from the swash zone to the surf zone was described through a simple exponential decay from the peak in the swash zone transport rate at the still-water shoreline to the rate observed in the seaward portion of the inner surf zone, where the transport seemed to take on a fairly constant value. The value on the decay coefficient employed was on the order of one for the experiments, but this value should scale with some hydrodynamic quantity in the general case (e.g., wave height). In the present study the foreshore slope was taken as constant. If the slope is more complex, the presented solutions may be applied for piecewise sections of the foreshore where the slope is approximately constant. Although the present study indicated the potential applicability of the proposed formula, more comparisons with data are needed to validate the formula and to obtained appropriate transport coefficient values.

ACKNOWLEDGEMENTS

This work was conducted under the Inlet Modeling System Work Unit of the Coastal Inlets Research Program, U.S. Army Corps of Engineers. The experimental data from the LSTF provided by Dr. Ping Wang, University of South Florida, and Mr. Mark Gravens, Coastal and Hydraulics Laboratory are greatly appreciated.

Abstract: This paper discusses the effect of the longshore sediment transport in the swash zone on the evolution of the shore line. The beach evolution model presented here is based on an N-line approach including a local estimation of the sediment transport function of the local current and wave characteristics. A simple model for the longshore sediment transport in the swash zone is implemented to the beach evolution model. The erosion and the accumulation of sediments around a groin appear to be significantly influenced by the introduction of the swash sediment transport.

INTRODUCTION

2-DH and N-line models were developed in order to take into account both longshore and cross-shore beach topography changes and allow short and mid-term modeling (including storm effects etc...). Hanson & Larson (2000) argued that realistic predictions for the cross-shore distribution of the longshore and cross-shore sediment transport are the fundamental part for these types of models. To use a local sediment transport formula which includes current and wave interaction seems to be the most adequate method to correctly estimate the beach topography changes. However, these formulas are generally not valid on the swash zone as the sediment processes are different in this zone (effect of the equilibrium slope, infiltration...). In the cross-shore direction, to neglect the swash zone dynamic does not affect significantly the formation of the longshore bar and the beach profile equilibrium in general, although this zone is very dynamic in a short term period. On the other hand, in the longshore

direction, it seems that the role of the longshore sediment transport in the swash zone is much more significant and does strongly affect the evolution of the shoreline (Van Wellen et al, 2000; Elfrink & Baldock, 2002). Indeed, Uda & Kawano (1996) proposed a N-line model with a typical cross-shore distribution of the longshore sediment transport which basically corresponds to the swash zone transport only, and obtained interesting results for the evolution of the shoreline. The purpose of this paper is thus to quantify the effects of the swash zone on the evolution of the shoreline.

MODEL THEORY

The numerical model presented here is made up of four main components with the following objectives:

1) wave propagation

2) calculation of the depth-averaged current in the longshore direction and cross-shore direction (mean undertow)

3) sediment transport simulation

4) beach profile change using an N-line approach

Most of the hydrodynamic and sediment transport calculations are performed along individual profile lines, and the coupling between the lines occurs through a semi-empirical model to take into account the effects of a structure on the currents and waves and the sediment volume conservation equation. The details concerning these components were illustrated by Baba et al (2004) and Baba et al (2006).

As the model does not include the hydrodynamic and morphodynamic swash zone, a simple model is proposed to estimate the cross-shore profile of the total longshore transport in the swash zone. The swash zone is particularly complex, involving rapidly varying flow (in time and space), nonlinear waves transformation, and possible infiltration and exfiltration effects (Elfrink and Baldock, 2002; Larson *et al.*, 2004). To be taken into account in an N-line model, which is depth and time averaged, many simplifications on the swash dynamic are necessary.

Hydrodynamic model in the swash zone

The swash zone may be delimited around the still water level (SWL) from an estimation of the run-up R_{up} and run-down R_{down} heights. The classic formulation by Hunt was used:

$$R_{up} = A_R \tan\beta_f \sqrt{H_\infty L_\infty} \quad (1)$$

where $\tan\beta_f$ is the foreshore slope, H_∞ and L_∞ the wave height and length, respectively, in deep water, and A_R a calibration coefficient ($A_R=2.0$ using the data from LSTF). R_{down} has been chosen as a fraction of R_{up} ($R_{down} = R_{up}/4$). Then, the "mean" water depth in the swash zone is estimated assuming a linear law from both edges of the swash zone (*cf.* Fig 1).

Using the mean water level (MWL) and the Snell law, the wave direction may be estimated at x=0 (limit of the SWL). Then, following Shen and Meyer, 1963, and Larson *et al.*, 2004, the trajectory of the bore front follows a parabolic movement.

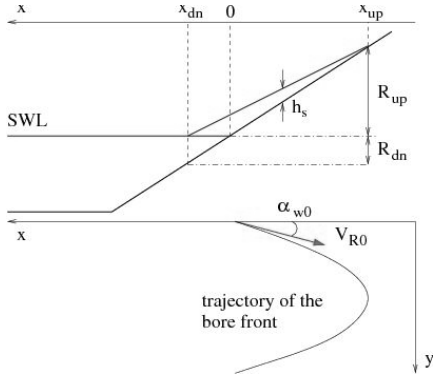

Fig. 1. Schematic view of the swash zone

The celerity of the bore at the foot of the swash zone and the swash period are then found respectively:

$$V_{R0} = \sqrt{2gR_{up}} \tag{2}$$

$$T_s = \frac{2V_{R0}}{g \sin \beta_f} \tag{3}$$

From this system, the longshore component V_{ry} of the bore velocity is presumed constant whereas its cross-shore component V_{rx} decreases linearly in the swash to be null at $x=x_{up}$. In the same way, the effective swash duration T_{sx} decreases linearly from T_s at $x=0$ to 0 at $x=x_{up}$. Thus, the temporal variation of the cross-shore velocity in the swash may be simulated by a saw-tooth shaped velocity profile with a period T_{sx} and a maximum velocity V_{rx}.

Sediment transport model in the swash zone

The model proposed by Camenen and Larson (2005, 2007; i.e. the "Lund-CIRP" formula) may be used to estimate both bed load and suspended load in the swash zone using the hydrodynamic conditions presented above. The bottom shear stress is estimated assuming a linear interaction between a cross-shore oscillatory flow and a longshore steady flow. As Camenen and Larson (2005, 2007) used a mean value of the shear stress (or its dimensionless value, the Shields parameter), it is found for the a saw-tooth shaped velocity profile:

$$\theta_{cw,m} = \frac{1/6\left(V_{rx}^{\ 2} + V_{ry}^{\ 2}\right)}{(s-1)gd_{50}} \tag{4}$$

where $_s$ is the relative sediment density and d_{50} the median grain size.

This model was compared with the experimental data obtained by Wang *et al.* (2002) at the LSTF (Vicksburg, Mississippi, USA). In Fig. 2, the longshore sediment transport is plotted on a cross-shore section for two different experiments. The first

one (test1) corresponds to a spilling breaking case whereas the second one (test3) corresponds to a plunging breaking case. The proposed model yields correct results for the longshore sediment transport in the swash zone (dashed line). It significantly improves the results for the estimation of the cross-shore profile of the longshore sediment transport compared to the model with the swash zone excluded. There are however some uncertainties on the position of the maximum (assumed to be at *x=0*, edge of the SWL) and on the maximum which is highly function on the estimation of the run-up height.

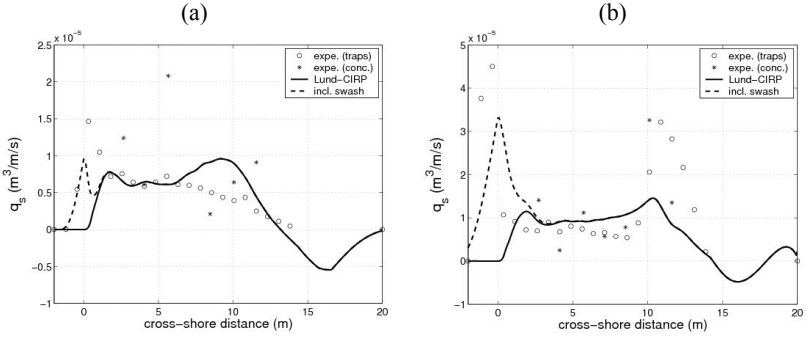

Fig. 2. Cross-shore profile of the longshore sediment transport for the LSTF experiments (a: spilling case; b: plunging case)

In the swash zone, the bed load appeared to prevail whereas the suspended load is prevailing in the surf zone, which is in agreement with the experimental observations (Wang *et al.*, 2002; Larson *et al.*, 2002).

MODEL TESTS AND RESULTS

Fig 3 displays the schematized computational domain for tests of the model. The computational domain is 15000m wide and 5000m long in longshore and cross-shore directions, respectively. The initial bottom slope is 1/100, and a groin (L=2000m) is set in the middle of the calculating area. Each cell of the N-line model is 50m wide and 0.5m deep.

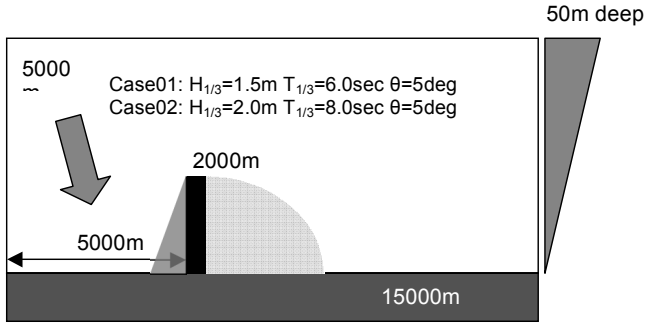

Fig. 3. Schematized computational domain

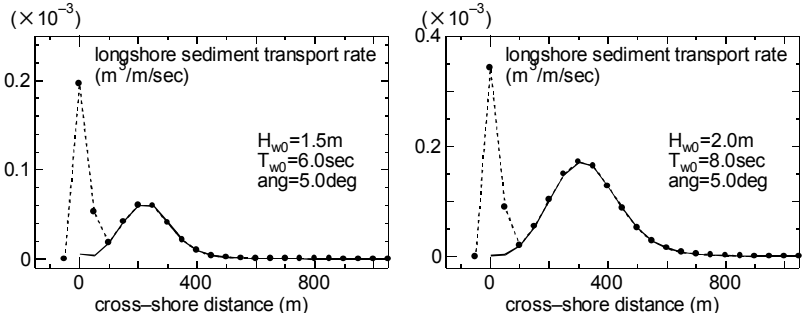
The sediment transport rate in shadowed area in Fig 3 is assumed to be affected by the groin. In the calculation here, sediment transport rate around the groin is depressed according to the inverse of the distance from the groin without the effects of diffraction and the existence of counter flow and so on.

Fig 4 shows cross-shore profile of the longshore sediment transport in both Case01 and Case02. The offshore boundary conditions in those cases are as follows;

Case 01: $H_{1/3}$=1.5m $T_{1/3}$=6.0sec θ=5.0deg
Case 02: $H_{1/3}$=2.0m $T_{1/3}$=8.0sec θ=5.0deg



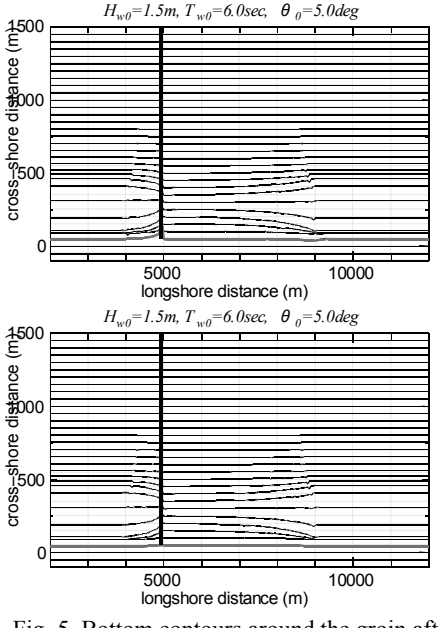


Fig. 4. Cross-shore profile of the longshore sediment transport
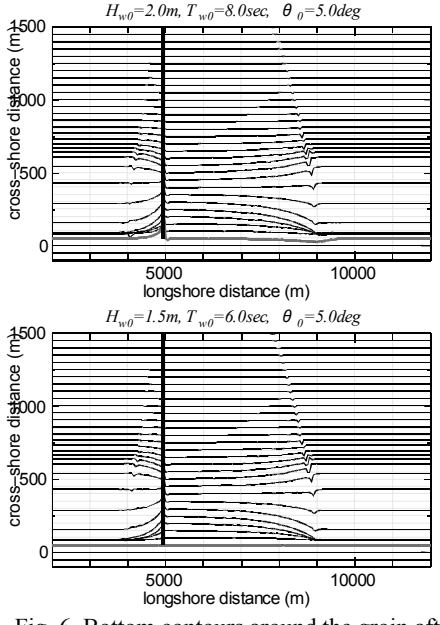
(solid: without swash model, dash & dots: include swash model)

In both profiles in Fig 4, longshore sediment transport rates in swash zone are calculated relatively higher than those under sea water, and these profiles have similar characteristics with the experimental results in Fig 2. Though this sediment transport model in swash zone have need of further quantitative verification, the

longshore sediment transport model in swash zone presented here is applied the following model tests.

Fig 5 shows the plane views of bottom contours around the groin after 10 days exposure to the continuous wave conditions for the case 01. The bold line in the figure is the shore line, and the black thin rectangle is the groin. In each figure, the accumulation in the left hand side of the groin is generated. As the total longshore sediment transport in a cross-shore line is larger when longshore sediment transport in swash zone is included, the magnitude of the accumulation is also larger. The inclusion of the swash longshore transport also yields a modification of the shoreline whereas the shoreline does not move when the longshore sediment transport in swash zone is not included. Moreover, some erosion downdrift of the groin occurs in the case with longshore sediment transport in swash zone. On the contrary, in the case without longshore sediment transport in swash zone, the shoreline (bold lines in the figures) downdrift of the groin still keeps the initial profile. It is thus observed that the erosion and the accumulation around the groin appear more clearly due to the introduction of the longshore sediment transport in swash zone.

Case 01
With longshore sediment transport in swash zone
(bold line: shore line SWL=0)



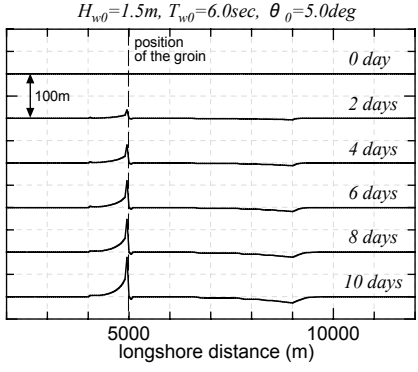
Case 01
Without longshore sediment transport in swash zone
(bold line: shore line SWL=0)

Fig. 5. Bottom contours around the groin after 10 days exposure for the Case 01

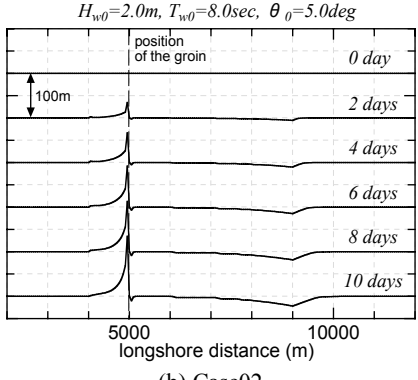
In Fig. 6, similar calculations are presented for the case 02 which is more energetic. Again, if the longshore sediment transport in the swash zone is not included, no movements of the shoreline are observed. On the contrary, when the longshore

sediment transport in the swash zone is included, a significant movement of the shoreline (with a larger magnitude as for the case 01) is observed in both side of the groin (accumulation close to the groin and erosion downdrift to the groin). From these computations, no real differences are observed in the surf zone close to the groin although an influence of the shoreline movement on this part of the domain was expected.

In both Fig 5 and Fig 6, some of the perturbations on the contour lines are observed in both side of the groin. These perturbations occur around the boundary between affected and no-affected areas by the groin. Some modifications of sediment transport around the groin are required to simulate appropriate profile change.



Case 02
With longshore sediment transport in swash zone
(bold line: shore line SWL=0)



Case 02
Without longshore sediment transport in swash zone
(bold line: shore line SWL=0)

Fig. 6. Bottom contours around the groin after 10 days exposure for the Case 02

Fig 7 shows the temporal variations of contour line at SWL=0 in the case with longshore sediment transport in swash zone. As time passes, the erosion and the accumulation proceed around the groin. The magnitude of the erosion around x=9000m reaches more than 20m, and the eroded area have the tendency to expand to downward region. The accumulation updrift to the groin develops more rapidly than the erosion downdrift of the groin. This erosion appeared however on a longer domain. This kind of beach erosion is not generated without longshore sediment transport in swash zone.

(b) Case02

Fig. 7. Temporal variations of contour line at SWL=0

CONCLUSIONS

In this study, a longshore sediment transport model for the swash zone is implemented to a beach evolution model based on N-line approach. The influence of the introduction of the longshore sediment transport in the swash zone on the evolution of the shore line is discussed. The erosion and the accumulation around the shore line are clearly represented by the introduction of sediment transport in swash zone, especially for the shoreline change. The sediment transport model in the swash zone needs however some further considerations and validations. It is found from the results that sediment transport in swash zone has an important role for the beach evolution and could be one of the main contributors for the erosion/accumulation processes close to the shore line.

DIRECT BED SHEAR STRESS MEASUREMENTS IN BORE-DRIVEN SWASH AND SWASH INTERACTIONS

Matthew P. Barnes[1], Tom E. Baldock[1]

1. University of Queensland, Department of Civil Engineering, Brisbane, Queensland, 4072, Australia. mbarnes@uq.edu.au; t.baldock@uq.edu.au

Abstract: Bore-driven swash and swash interactions are investigated experimentally. Direct bed shear stress measurements suggest bore/swash backwash interactions act to interrupt backwash (seaward) sediment transport. Catch up and absorption causes landward directed bed shear force (enhanced by impact forces onto the bed) of a short duration that does not follow the measured flow velocity trend. A single swash interaction is likely to restrict seaward direct transport and/or suspend sediment in large volumes but not directly contribute to the landward advection of sediment. Bore-driven swash hydrodynamics for a single swash event were predicted well using a non-linear shallow water wave equation model. In the mid-swash region measured uprush bed shear stress was predicted well using the drag law estimate with constant friction factor $C_f \approx 0.02$. A smaller or time-varying C_f is required to accurately predict measured backwash bed shear stress.

INTRODUCTION

In simplified terms, the swash zone is characterised by fluid uprushes and subsequent backwashes on the beachface. The uprushes and backwashes transport sediment in higher concentrations than elsewhere in the nearshore zone and largely dictate beachface morphology. Swash zone hydrodynamics are primarily controlled by the inner surf zone and beach face gradient (Elfrink and Baldock, 2002). In terms of sediment transport, the backwash is not simply a mirror of the uprush. A common finding in many field investigations of swash hydrodynamics is that, for a given velocity, the uprush transports more sediment than the backwash (e.g. Hughes *et al*., 1997; Masselink and Hughes, 1998; Puleo *et al*., 2000). The asymmetrical nature of swash transport is a requirement for beach equilibrium. If the uprush and backwash sediment transport rates were equal, the longer backwashes would gradually erode more sediment than the uprushes could contribute (Masselink *et al*., 2005).

It is generally accepted that turbulence due to bore collapse is a contributor to the sediment advected into the swash zone; however a greater knowledge of the process is required to allow its inclusion in swash models. Boundary shear stress and bore turbulence are unlikely to operate independently and therefore the interaction of the two processes requires attention.

As a fully developed bore travels landward through the surf zone, where the water depth h_o is sufficiently large relative to the bore height H ($h_o/H > 0.75$) turbulent motions produced at the bore front are unlikely to significantly influence sediment suspension. As a bore continues to propagate through the inner surf zone towards the swash zone, h_o generally reduces and the incident bore typically encounters:

a) No impeding flow and collapses onto the intermittently wet/dry beach (i.e. the initial stage of swash uprush) referred to herein as 'true bore collapse';
b) A thin accelerating seaward directed flow (i.e. a preceding swash backwash; generally supercritical flow conditions) referred to herein as a 'collision'; or
c) A decelerating landward directed flow (i.e. a preceding swash uprush; generally subcritical flow conditions) referred to herein as 'catch up and absorption'.

For these three cases the flow depths may be sufficiently small for the bore turbulence to affect the seabed and/or beachface.

A 'true bore collapse' drives a single swash event with the location of bore collapse defining the seaward swash boundary. Providing the bore period T_b is larger than the swash period T_s, the uprush and subsequent backwash are not impeded by preceding nor subsequent swashes and large run-up distances generally occur. The energetic bore collapse is expected to play a significant role in suspending sediment in the early stages of the uprush (Jackson *et al*., 2004) and may in fact counterbalance erosive processes in the swash. Pritchard and Hogg (2005) developed an analytical description of sediment transport by a single swash event following bore collapse, proposing a relationship between sediment entrained by the initial bore collapse and the net transport direction. During the decelerating uprush stages, sediment is transported predominantly by sheet flow with some sediment settling on the beachface. The subsequent stronger backwash that follows transports any sediment still in suspension seaward. In a laboratory investigation, Kobayashi and Lawrence (2004) reported sediment being transported in backwash flow beyond the seaward swash boundary (note that Kobayashi and Lawrence referred to bores described by (a) as "positive solitary waves").

'Collisions' and 'catch up and absorption' are often referred to as swash interactions. A swash flow interacting with an incident bore may be a sediment transport mechanism. Remaining largely unknown, however, is the direction and magnitude of these forces during the passage of the bore front as it propagates with or against swash flow.

Kobayashi and Lawrence (2004) found collisions (referred to by Kobayashi and Lawrence as 'negative solitary waves') to suspend less sediment in comparison to true bore collapse. Wave run-up against the impeding seaward flow was much smaller. The weak backwash that followed the small run-up deposited sediment only on the beachface and not seaward of the run-down. No beach face erosion by the backwash was observed. Van Wallen *et al*. (2000) presented a nearshore sediment transport model that included swash interactions and associated transport rates. However the study was limited by available data sets to test the model. More recently Erikson *et al*. (2005) presented modifications to a hydrodynamics model describing swash motions (Baldock and Holmes, 1999) by including swash interactions. Model comparisons with laboratory data suggested the modifications improved swash duration prediction for a mild sloping beach ($\tan\beta = 0.07$). While Erikson *et al*. (2005) included the process of catch up and absorption in their swash duration model, to the authors' knowledge the process is yet to be investigated experimentally. Of particular interest in the present investigation is the role catch up and absorption may play in enhancing sediment suspension process.

Kobayashi and Lawrence's (2004) laboratory results imply that the presence of collisions may play an important role in maintaining beach equilibrium. This theory was originally proposed by Kemp (1975). Models presented by Van Wellen *et al*. (2000) and Holland and Puleo (2001) suggest that when the incident bore period T_b exceeds the duration required for a swash event to be completed, no collisions will occur and the accelerating backwash will be able to entrain and transport sediment seaward of the point of the initial bore collapse. Under such erosive conditions, the beach profile is likely to flatten and in turn gradually lengthen the swash duration. In contrast, swash interactions can be expected when the incident bore period T_b is less than the swash period T_s. Collisions between the swash flow and subsequent uprush may cause sediment to be stranded landward of the initial uprush position (i.e. the point of the initial bore collapse). Shorter swash periods will lead to accretion and steepening of the beach profile. For each case, the beach profile is adjusting towards equilibrium and conditions where T_s and T_b are approximately equal.

The aim of the present work is to investigate how an incident bore affects the bottom boundary in experimental flow conditions replicating swash interactions. Particular focus has been given to forces felt at the bed at the locations of bore/backwash collision, and the incident bore's ability to retard and/or reverse the direction of flow and shearing stress. Furthermore, in an effort to simulate catch up and absorption, the measured effects at the bottom boundary when a bore engulfs a stationary bore (hydraulic jump) are also reported. Finally, bore-driven swash and the variation of bed shear stress over the swash cycle are investigated experimentally and compared to a finite volume shallow water wave equation model.

EXPERIMENTS

Swash interactions

Considering a bore propagating toward the true swash zone to be analogous to a fully-developed positive surge (or a *quasi-steady* hydraulic jump), the flow conditions can be

solved using the continuity and momentum principles. With a control volume across the front of the bore (refer to Figure 1) travelling at celerity C the continuity equation yields,

$$q = (U_o + C)h_o = (U_{conj} + C)h_{conj} \tag{1}$$

where q is the discharge per unit width, U is the horizontal flow velocity and h is the depth. Subscripts o and $conj$ refer to conditions in front of and behind the bore respectively. Flow conditions behind the bore are often referred to as 'conjugate'.

Neglecting friction, the momentum equation sums all the forces acting on the same control volume, yielding

$$\frac{1}{2}\rho g h_o^2 - \frac{1}{2}\rho g h_{conj}^2 = \rho q\left(U_{conj} - U_o\right) \tag{2}$$

where ρ is the fluid density and g is acceleration due to gravity. The relationship between flow depth before and after the passage of the bore is provided by

$$\frac{h_{conj}}{h_o} = \frac{1}{2}\left(\sqrt{1 + 8Fr_1^2} - 1\right) \tag{3}$$

where Fr_1 is the surge Froude number before the passage of the bore:

$$Fr_1 = (U_o + C)/\sqrt{g h_o} \tag{4}$$

Similarly, the momentum equation can be used to describe the relationship between Froude numbers before and after the passage of the bore

$$\frac{Fr_{conj}}{Fr_1} = \frac{2^{\frac{3}{2}}}{\left(\sqrt{1 + 8Fr_1^2} - 1\right)^{\frac{3}{2}}} \tag{5}$$

where Fr_{conj} is the surge Froude number after the passage of the bore:

$$Fr_{conj} = (U_{conj} + C)/\sqrt{g h_{conj}} \tag{6}$$

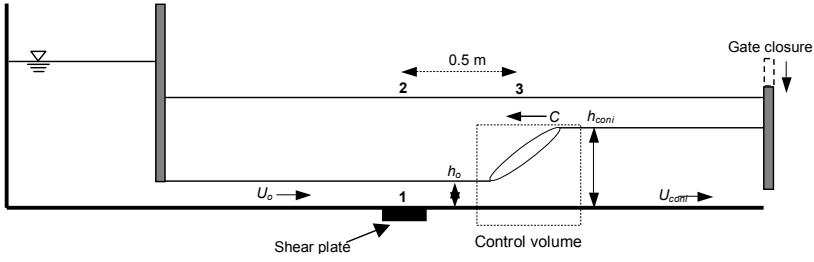

Fig. 1. Propagating bore with control volume experiment sketch

Experiments were conducted in a rectangular open channel (3.2 m long, 0.5 m wide and 0.3 m deep) with a smooth PVC bed (slope = 0º) at the University of Queensland Hydraulics Laboratory (Figure 1). The initial flow depth d_o was controlled by a 'rounded gate' and flow rate measured via venturi meter.

Instantaneous velocities were recorded using a SonTek micro Acoustic Doppler Velocimeter (ADV) 16 MHz at sampling rate of 50 Hz. The ADV probe had a two-dimensional side-looking head positioned at the bed with a horizontal distance to sample volume of 5 cm. The micro-ADV sample volume is cylindrical in shape with a diameter of 4.2 mm and a height of 6.2 mm. The U_x velocity component was aligned longitudinally with the flow direction, and U_y component orientated normal to the channel side wall. Recorded velocities were < 1.7 ms^{-1} within a 1% accuracy of the measured velocity. However, air entrainment (small bubbles) in turbulent flows can lead to signal dropout and may also influence absolute velocities. ADV data was acquired using HorizonADV v1.04 software. Velocity data was post-processed using WinADV v2.010.

Free surface elevation was recorded at two locations (0.5 m spacing) along the channel centreline using non-intrusive Microsonic Mic+35/IU/TC acoustic displacement meters (ADM) with an accuracy of 0.18 mm and a response time of 70 ms (Microsonic, 2005). Koch and Chanson (2005) compared Microsonic ADM measurements to pointer gauge measurements in steady open channel flow and against digital images for non-horizontal free-surface profiles and found comparisons to be within the stated accuracy of the systems. Spacing of the ADMs allowed bore front development to be examined and the bore celerity to be estimated.

Direct measurements of bed shear stress were performed using a shear plate (SP). Prior calibrations of the SP force/displacement relationship were performed *in-situ*. During operation the shear cell below the SP is filled with water. The pressure that exists in the gap at each longitudinal plate edge is measured via two Druck PMP 317-2780 pressure transducers with ±0.15% accuracy (GE Druck, 2006). The pressure in the gaps is a secondary force capable of producing work on the small area of the plate's edge (i.e. plate width × thickness). The additional force in the gaps must be removed from the total

force measured by the shear plate in order to resolve the shear stress. More detail on the SP may be obtained in Barnes and Baldock (2007).

Velocity components close to the bed, surface elevation, and bed shear stress as a bore propagates against supercritical flow, simulating typical swash collisions, were recorded for various initial steady flow conditions. Weak ($1.7 < Fr < 2.5$) and oscillating ($2.5 < Fr < 4.5$) bores were generated by the abrupt closure of a tainter gate located at the downstream end of the channel. Bore propagation distance from the gate to instrumentation was 2 m, a similar distance to that used by Yeh and Ghazali (1988) and Yeh *et al*. (1989) in their experimental studies of bore run-up. It should be noted that the bores in the present investigation differ from most previous studies due to the presence of an initial inflow velocity thus simulating a bore/swash backwash interaction.

The effects at the boundary following catch up and absorption were investigated using a propagating bore engulfing a stationary hydraulic jump. In nature catch up and absorption is likely to occur when the bore period T_b is significantly smaller than the swash period T_s. Repeated experiments were conducted with a hydraulic jump positioned approximately 0.1 m seaward of the SP centreline. A single bore was generated following the abrupt closure of a tainter gate. The bore propagated across the subcritical region behind the hydraulic jump. A plunging collapse onto the supercritical inflow and impacting onto the bed was observed immediately following the bore engulfing the hydraulic jump.

Bore-driven swash

Separate experiments investigating a single swash cycle driven by "true bore collapse" were conducted at the University of Aberdeen (UA) Fluids Mechanics Laboratory. The UA swash facility (Figure 2) is built into an existing flume 20 m long, 0.45 m wide and 0.9 m deep. A reservoir of water of depth D is held by a dam gate at one end of the flume. In front of the gate is a quiescent body of water of depth d. Adopting the dam-break concept, a single fully-developed bore is generated following the high-speed vertical removal of the dam gate. The bore travels for approximately 4 m before collapsing at the still water shore line (SWL) and initiating the swash cycle. The flume has an impermeable Perspex bed with a 1/10 beach slope. Care was taken to reproduce the experimental conditions reported by Honderbrink (2006) and O'Donoghue *et al*. (2006) who obtained high detail fluid velocity measurements using Particle Image Velocimetry (PIV) for a highly repeatable swash event.

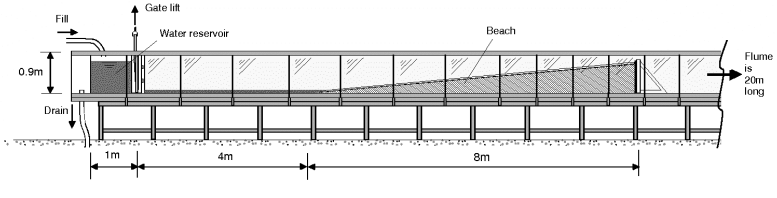

Fig. 2. The University of Aberdeen swash facility (O'Donoghue *et al*., 2006).

In this paper measurements obtained at an offshore location (x = -1.8 m), at the SWL (x = 0 m), and at two positions on the beachface (x = 2 m and 3 m) are presented. Swash depth h and bed shear stress τ were measured using ADMs and SP previously described. Depth average velocity time-series at x = 2 m and 3 m obtained by Honderbrink (2006) and presented by O'Donoghue *et al*. (2006) are used.

Bore-driven swash measurements are compared to the ANUGA (Australian National University and Geoscience Australia) hydrodynamic modelling tool. ANUGA is a two dimensional finite volume Non-Linear Shallow Water wave Equation (NLSWE) solver. The model is useful for wetting and drying scenarios including a swash event on a beachface. Frictional resistance is implemented using Manning's formula (represented by n) with the present work offering a validation with regard to bottom friction. More details of ANUGA may be obtained in Nielsen (2005).

RESULTS

Swash interactions

In a fully developed bore, flow conditions immediately upstream and downstream of the bore front must satisfy the continuity and momentum principles. This may be investigated through the comparison of the measured conjugate depths ratio (h_{conj}/h_o) and the relationship given by (3). Figure 3 shows results for the present investigation. Water depths were resolved using ADM measurements at single location before and after the passage of the bore. Conjugate depth was obtained by averaging approximately 1s of the recorded samples immediately behind the bore front. An averaged value for h_{conj} was considered necessary since free surface oscillations immediately behind the bore front can lead to a misleading measured depth if a single instantaneous measurement is used. The surge Froude number given by (4) was calculated using ADV measured inflow
velocity and bore celerity deduced from ADM measurements at two locations.

The experimental data in Figure 3 show a very good agreement with classical theory. Small discrepancies may be due to the bore not being fully developed and/or difficulty in accurately defining h_c. For breaking bores, Koch and Chanson (2005) cited possible small errors in determining water depths using ADM. Air entrainment and turbulence may affect water depth measurements in front and immediately behind the bore front. Discrepancy between experiments and theory may also be due to the measured velocity being affected by the presence of the bed. Figure 3 suggests that the bores in the present investigation are a good approximation to a steady bore and gives confidence in the experimental method and instrumentation.

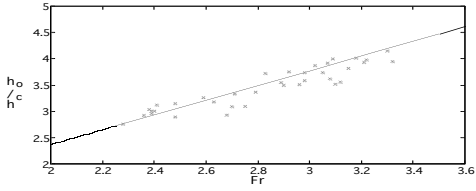

Fig. 3. Comparison of measured conjugate depths ratio (crosses) and momentum principle (dot-dash line).

Measured ensemble average "bore collision" flow characteristics for two initial inflow conditions are presented in Figure 4. Inflow velocity U_o = -1.29 ms^{-1} and -0.86 ms^{-1} for bores with surge Froude number Fr_1 = 2.7 and Fr = 2.1 respectively. Taking a typical inner surf/swash zone approach, negative values are seaward or offshore directed and positive values are landward or onshore directed. For both bores the initial inflow depth h_o = 0.04 m. Time t = 0 s was determined as the time the bore arrived at x = -0.5 m measured from the shear plate centre line. Bore celerities were C = 0.4ms^{-1} (Fr = 2.7) and 0.43 ms^{-1} (Fr = 2.1).

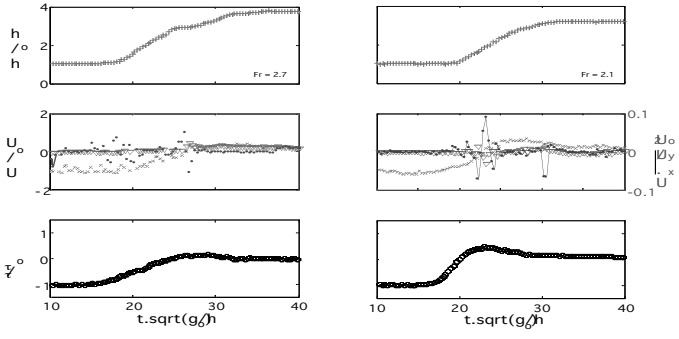

Fig.4. Bore collision; ensemble average non-dimensional depth h/h_o (pluses), velocity U/U_o (U_x crosses; U_y triangles), Reynolds stress $\rho\overline{U_x U_y}/U_o^2$ (solid line), and bed shear stress τ/τ_o (circles) as a function of dimensionless time $t\sqrt{g/h_o}$. Fr_1 = 2.7 left; Fr_1 = 2.1 right.

Reasonably steady velocity components were measured in the inflow region. The decrease in seaward directed velocity coincides with the arrival of the bore toe. U_x continues to decrease as the flow depth increases during the passage of the bore front, thus satisfying continuity. Flow reversal close to the bed was measured in the region of the turbulent roller for the bore collision with the weaker inflow velocity (Fr_1 = 2.1). In contrast, little (virtually zero) flow reversal was detected for the higher inflow velocity collision (Fr_1 = 2.7) despite the stronger bore. Maximum instantaneous Reynolds stresses and bed shear stress were measured close the mid point within the turbulent roller region. A more prominent landward directed stress for a longer duration was measured for the weaker inflow velocity. Measured longitudinal velocity U_x close to the

bed and bed shear stress followed a similar trend for both bore collision conditions. Measurements suggest backwash velocity is important in controlling the effect of swash interaction on sediment transport.

Measured ensemble average "catch up and absorption" flow characteristics are presented in Figure 5. Inflow velocity U_o = -1.31 ms^{-1} with an initial inflow depth h_o = 0.035 m. The bore generated following the sudden closure of the gate propagated relatively quickly (C = 0.58 ms^{-1}) across the subcritical region seaward of the hydraulic jump. Non-dimensional depth measurements indicate a steep, plunging bore front following absorption. A rapid decrease in seaward directed velocity combined with sharp peaks in instantaneous Reynolds stresses were measured at the early stage of the plunging collapse. Weak flow reversal close to the bed was measured throughout the roller region and for a short period behind the bore front. The peak in measured landward directed bed shear stress enhanced by roller turbulence reaching the bed was approximately equal in magnitude to the seaward directed bed shear stress. In contrast to the bore collisions, within the bore roller region the bed shear stress displayed a notably different trend to the longitudinal velocity component.

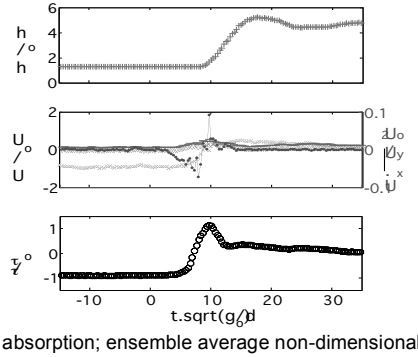

Fig.5. Catch up and absorption; ensemble average non-dimensional depth h/h_o (pluses), velocity U/U_o (U_x crosses; U_y triangles), Reynolds stress $\rho\overline{U_x U_y}/U_o^2$ (solid line), and bed shear stress τ/τ_o (circles) as a function of dimensionless time $t\sqrt{g/h_o}$.

The measured peak in shear stress following catch up and absorption is likely to be a sediment suspension mechanism and is more likely to occur when $T_b << T_s$. Field observations indicate shorter inner surf zone [bore] periods occur during quiescent intervals when infragravity energy is low (e.g. Holland and Puleo, 2001). During such time the beachface may steepen due to accretion.

Bore-driven swash

Measured and ANUGA predicted depth h time series at offshore location x = -1.8m and at the SWL x = 0m is given in Figure 6. Following the abrupt removal of the reservoir gate, the dam water plunges into quiescent water and forms a bore. The early stages of bore development are not predicted accurately due to the two-dimensional nature of

ANUGA. The model cannot resolve vertical convection such as wave breaking or three-dimensional turbulence. Nevertheless Figure 6 shows reasonable depth comparison at the offshore location for $t < 5$ s and excellent agreement for the remaining time. Good agreement between the measured and predicted h was obtained at the SWL.

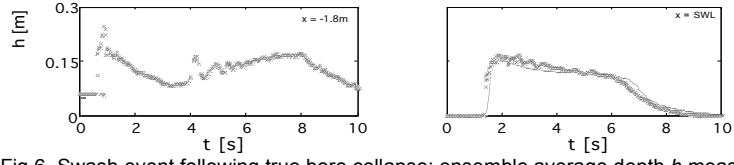

Fig.6. Swash event following true bore collapse; ensemble average depth h measured (crosses) and modelled (dash line) at x = -1.8 and x = 0m (SWL).

Figure 7 presents measured ensemble depth h, longitudinal velocity U_x, and bed shear stress τ at x = 2 m and 3 m for a swash event with maximum runup $R_{max} \approx 5.8$ m measured along the slope. ANUGA predicted depth and velocity with a Manning's n = 0.01 are given by the dash-line. The additional lines in the shear stress subplot are predicted shear stresses using the drag law estimate

$$\tau = C_f \frac{1}{2} \rho U |U| \tag{7}$$

where C_f is a constant friction factor (Darcy friction factor $f = 4C_f$). Solid line, dash line, and dash-dot line are calculated using (7) and $C_f = 0.005$, 0.01, and 0.02 respectively.

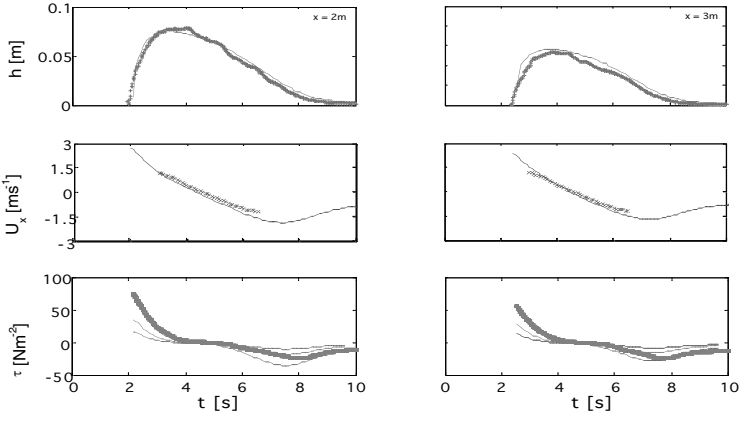

Fig.7. Swash event following true bore collapse; ensemble average depth h (pluses), longitudinal velocity U_x (PIV) (crosses), and bed shear stress (circles) τ as a function of time at x = 2 m and 3 m; model results (dash line); predicted bed shear stress using constant C_f = 0.005 (solid line), 0.01 (dash line), 0.02 (dash-dot line).

Good agreement between measured and modelled depth was obtained at both locations. PIV measurements were difficult to resolve during the arrival of the uprush at the measurement location and late in the backwash when flow depths became sufficiently small. Nevertheless, velocity measurement presented show reasonable agreement with the modelled velocity. Shear stress time series show a maximum positive (landward directed) shear stress at the fluid tip followed by a rapid decay throughout the decelerating uprush interior. Following flow reversal (approximately t = 4.5 s) the maximum negative (seaward directed) shear stress occurs late in the accelerating backwash phase. The measured shear stress tends to zero as the backwash flow depth decreases, the relative roughness increases, and flow velocity is reduces due to friction. Predicted shear stress using a constant friction factor and ANUGA predicted velocity suggest C_f = 0.02 gives excellent agreement with the measured shear stress throughout the uprush phase and a slightly over predicted shear stress throughout the backwash.

DISCUSSION

The present bore/backwash interaction experiments suggest the process acts to interrupt seaward direct transport rather than significantly contributing to the landward advection of sediment. Measurements may support Puleo *et al*. (2000) who observed sediment suspended by bores to quickly settle out behind the bore. Following simulated catch up and absorption the peak in shear stress was of short duration with the hydrodynamics behind the engulfed bore only weakly landward directed. Similar to bore collisions, the role of a single catch up and absorption event may contribute to the suspension of sediment but not necessarily to the landward advection of sediment. Considering that bore collisions and catch and absorption are more frequent when the incident bore period T_b is less than the swash period T_s it is likely suspended sediment will be encountered by a subsequent propagating bore. It remains unknown whether a propagating bore encountering sediment in suspension is an efficient transport mechanism however measurements (Kobayashi and Lawrence, 2004) and observations (Holland and Puleo, 2001) suggest that small incident bore periods (in the absence of high infragravity energy) may promote accretive conditions.

The present work supports Van Wellen *et al*. (2000) who argued that the interactions between waves [bores] and swash flow and the resulting sediment transport rate was not a monotonic relationship. Their simplistic Swash TRansport and Nearshore Dynamics (STRAND) model treats interaction by replacing swash flow hydrodynamics and associated transport with that of the incident bore. STRAND sensitivity testing suggested transport rate and direction was strongly related to the ratio T_b /T_s. While it was not possible to measure swash period in the present bore collision experiments, the relative T_b/T_s ratio can be assumed by considering the initial inflow velocity. For example, a weaker inflow (backwash) velocity simulates a collision that occurs early in the backwash phase prior to the seaward directed flow reaching its maximum velocity as it accelerates down the beachface. For a collision to occur early in the backwash phase one would expect T_b to be smaller than, maybe close to half, T_s. A stronger inflow velocity is simulating a collision that occurs late in the backwash phase and therefore T_b is only slightly smaller than T_s. Catch up and absorption would be indicative of T_b being

significantly smaller than T_s. It should be noted that random waves experienced in nature makes T_b difficult to quantify. STRAND predicts that landward transport rates decrease with increasing T_b/T_s ratio until the ratio reaches 1 (greater than 1 indicates no collisions are occurring), perhaps consistent with the bed shear stress measurements in the present study where largest landward directed forcing close to the bed was measured following catch up and absorption ($T_b << T_s$) and a decrease in landward directed forcing with increasing backwash velocity following a bore collision. It would appear the potential for swash interactions and the T_b/T_s ratio are important components of beach morphological prediction. However, further work is required since low amplitude long period swell, giving $T_s < T_b$, would be expected to also result in beach accretion.

Measured bore height, swash flow depth, and velocity compared well with a NLSWE solver (ANUGA). Comparative results support the use of two-dimensional NLSWE models tuned with an appropriate friction coefficient for inner surf and swash hydrodynamics despite the simplification of the true processes (in particular vertical convection and turbulence due to wave [bore] breaking). The optimal Manning's coefficient for the present experiments was $n \approx 0.01$, consistent with appropriate n values for smooth beds suggested in the literature.

Directly measured uprush bed shear stress in the mid swash region was predicted well following (7) and a constant friction factor $C_f = 0.02$. A similar C_f value closely predicted the measured peak shear stress for dam break flows (analogous to swash uprush) presented by Barnes and Baldock (2007). However, in their study prediction throughout the flow interior was less favourable when using a constant friction factor. It should be noted the dam break measurements presented by Barnes and Baldock (2007) were lower in the "swash" region and on a horizontal bed. In the present investigation backwash shear stress prediction using $C_f = 0.02$ was less favourable at $x = 2$m, however was more reasonably predicted at $x = 3$m. A time varying friction factor may be more appropriate in the backwash, particularly late in the phase as flow depths become small and the relative roughness increases. Eulerian measurements in the present investigation suggest that swash bed shear stress may closely follow conventional theory at higher cross shore positions on the beach where pressure gradients and the effects of bore induce turbulence are smallest. Future work will investigate this further.

CONCLUSION

Inferences from the present investigation are based on simplified experimental inner surf and swash processes. Processes likely to influence sediment transport rates in nature not accounted for include longshore currents, beach face permeability, groundwater/beachface interactions, and the effects of sediment suspension on swash hydrodynamics. Further experimental work for a wider set of initial conditions will allow simplified swash processes to be understood and described. It is inappropriate to attempt to predict sediment transport rates on beaches when a complete understanding of simplified experiments is lacking. Significant findings supported by the experimental data presented include:

- For bore collisions bed shear stress and longitudinal velocity follow a similar trend.
- The effect of bore turbulence at the bed is strongly related to backwash depth and velocity.
- Experimental inner surf zone bores colliding with a strong seaward directed flow (analogous to swash backwash) interrupt seaward directed bed shear stress but don't significantly contribute to landward directed sediment transport.
- Catch up and absorption causes landward directed shear forces (possibly enhanced by impact forces into the bed) for a short duration. This is likely to be a process causing sediment suspension.
- Bore propagation, bore collapse at the SWL, swash depths, and fluid velocity is predicted reasonably well using a two-dimensional NLSWE solver.
- For swash uprush directly measured shear stress in the mid swash region compares well with predicted shear stress using modelled velocity and conventional constant friction factor ($C_f \approx 0.02$); a smaller or time-varying friction factor is required to reasonably predict backwash bed shear stress.

ACKNOWLEDGEMENTS

The authors acknowledge support from the UQ Graduate School and Sustainable Tourism CRC in the form of research scholarships and travel grant for MB. Assistance with bore-driven swash experiments from Dr Tom O'Donoghue and the University of Aberdeen Fluids Group is greatly appreciated.

LIMITS OF BEACH AND DUNE EROSION IN RESPONSE TO WAVE RUNUP ELUCIDATED FROM SUPERTANK

Abstract: The unique dataset from SUPERTANK is analyzed to examine the upper limit of beach change in response to elevated water level caused by wave runup. Thirty SUPERTANK runs are investigated, including both erosional and accretionary wave conditions under random and monochromatic waves. The upper limit of beach change approximately equals the maximum vertical excursion of swash runup. Exceptions to this direct relationship are those with beach or dune scarps. The vertical extent of wave runup above mean water level on a non-scarped beach is approximately equal to the significant breaking wave height. Scarps substantially limit the uprush of swash motion, resulting in a much reduced maximum runup. Predictions of wave runup are not improved by including a slope-dependent surf-similarity parameter. The limit of wave runup is substantially less for monochromatic waves than for random waves, attributed to absence of low-frequency motion for monochromatic waves.

INTRODUCTION

Quantification of wave runup and its relationship to the upper limit of beach-profile change are required for understanding and predicting beach and dune erosion, especially during storms. Wave runup is composed of wave setup, defined as a super-elevation of the mean water level, and swash runup, or fluctuations about that mean (Holman and Sallenger 1985; Nielsen 1988; Yamamoto et al. 1994; Holland et al. 1995). Numerous studies on the limits of wave runup have been conducted, resulting in the development of several predictive models, from three approaches.

The earliest physics-based approach is developed upon a theoretical derivation for monochromatic waves. Bowen et al. (1968) derived a wave setup slope inside the surf zone for monochromatic (sinusoidal) waves as:

$$\frac{\partial \bar{\eta}}{\partial x} = -K\frac{\partial h}{\partial x} \qquad K = (1 + 2.67\gamma^{-2})^{-1} \tag{1}$$

where h = still-water depth, $\bar{\eta}$ = wave setup, x = cross-shore coordinate, $\gamma = H/(\bar{\eta} + h)$ and H = wave height. Based on both theory and laboratory measurements, the maximum set-up under a monochromatic wave, $\overline{\eta_M}$, was found to occur at the shoreline:

$$\frac{\overline{\eta_M}}{H_b} = 0.3\gamma \tag{2}$$

where H_b = breaking wave height (Battjes 1974). The above equations concern only the wave setup portion of the runup.

The second approach is based mainly on field measurements made on dissipative beaches. Guza and Thornton (1981) suggested that the setup at the shoreline, $\overline{\eta_{sl}}$, is linearly proportional to the significant deepwater wave height H_o:

$$\overline{\eta_{sl}} = 0.17H_o \tag{3}$$

In a following study, Guza and Thornton (1982) found that the significant wave runup, R_s, (including both wave setup and swash runup) is also linearly proportional to the significant deepwater wave height:

$$R_s = 3.48 + 0.71H_o \qquad \text{(units of centimeters)} \tag{4}$$

Comparing Eqs. (3) and (4), the entire wave runup is approximately 4 times the wave setup, i.e., swash runup constitutes a significant portion of the total elevated water level. According to Huntley et al. (1993), Eq.(4) is the best choice for predicting wave runup on dissipative beaches. Based on field measurements on highly dissipative beaches, Ruessink et al (1998) and Ruggiero (2004) also found linear relationships, but with different empirical coefficients.

The third and more recent approach, proposed by Holman (1986) and several similar studies (Holman and Sallenger 1985; Ruggiero et al. 2004; Stockdon et al. 2006), argued that more accurate predictions can be obtained by including the surf similarity parameter, ξ:

$$\xi = \frac{\beta}{(H_o / L_o)^{1/2}} \tag{5}$$

where L_o is the deepwater wavelength, and β is the beach slope. Holman (1986) found a dependence of the 2% exceedence of runup R_2 on the deepwater significant wave height and the surf similarity parameter:

$$R_2 = (0.83\xi_o + 0.2)H_o \tag{6}$$

Stockdon et al. (2006) expanded upon the Holman (1986) analysis and developed the empirical equation:

$$R_2 = 1.1\left(0.35\beta_f (H_o L_o)^{\frac{1}{2}} + \frac{\left[H_o L_o (0.563\beta_f{}^2 + 0.004)\right]^{\frac{1}{2}}}{2}\right) \quad (7)$$

Realizing the variability of beach slope in terms of both definition and measurement, Stockdon et al. (2006) define the foreshore beach slope as the average slope over a region of two times the standard deviation of continuous water level record.

Most field studies were conducted on gentle sloping dissipative beach and found wave runup within the swash zone to be dominated by infragravity frequency components, or surf beat. Mechanisms for generating low-frequency motion at the shoreline include 1) obliquely incident wave groups (Gallagher 1971; Bowen and Guza 1978), 2) time-varying wave breaking (Symonds et al. 1982; List 1992), and 3) bound long wave generated by periodical variations of mean water level due to wave groupiness outside the surf zone (Longuet-Higgins and Stewart 1962). In contrast to numerous studies on wave runup, little data are available relating the limit of wave runup with that of the beach-profile change.

In this paper, data from the prototype-scale SUPERTANK experiment (Kraus et al 1992; Kraus and Smith 1994) are examined to study the limit of wave runup and corresponding limit of beach dune erosion. Specifically, this study examines 1) the level of swash run-up and wave setup; 2) time-series beach-profile changes under erosional and accretionary waves; 3) the relationship between the above two phenomena; and 4) the accuracy of existing wave runup prediction methods. A new empirical formula predicting the limits of wave runup and that of beach change is proposed based on the SUPERTANK data.

SUPERTANK EXPERIMENTS

One of the largest and most densely instrumented laboratory movable-bed studies to date is the SUPERTANK experiment. This multi-institutional effort sponsored by the Corps of Engineers was conducted at the O.H. Hinsdale Wave Research Laboratory at Oregon State University from July 29 to September 20, 1991 (Fig. 1). This facility is the largest wave channel in the United States that can contain a sandy beach through which experiments comparable to the magnitude of naturally occurring waves can be conducted (Kraus et al. 1992).

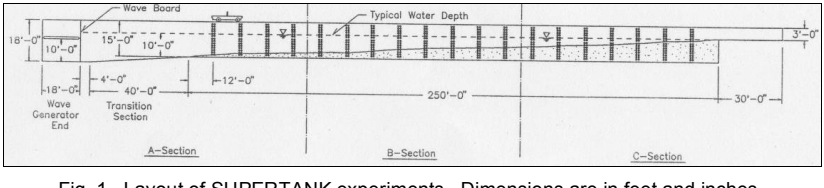

Fig. 1. Layout of SUPERTANK experiments. Dimensions are in feet and inches.

The SUPERTANK experiment measured total-channel hydrodynamics and sediment transport along with the resulting beach-profile changes. The wave channel was 104 m

long, 3.7 m wide, and 4.6 m deep (the still water level was typically 1.5 m below the top) with a constructed sandy beach extending 76 m offshore (Fig. 1). The beach was composed of 600 m^3 of fine, well-sorted quartz sand with a median size of 0.22 mm and a fall speed of 3.3 cm/s. The wave generator and wave channel were equipped with a sensor to absorb the energy of reflected waves. The water-level fluctuations were measured with 16 resistance and 10 capacitance gauges. These 26 gauges, spaced 3.7 m apart, provided detailed wave propagation patterns, especially in the swash zone. The beach profile was surveyed following each wave run. The initial profile was constructed based on the equilibrium beach profile developed by Dean (1977) and Bruun (1954) as:

$$h(x) = Ax^{\frac{2}{3}} \tag{8}$$

where h = still-water depth, x = horizontal distance from the shoreline, and A = a shape parameter corresponding to a mean grain size of 0.30 mm. The initial beach was built steeper with a greater A-value to ensure adequate water depth in the offshore area (Wang and Kraus 2005). For efficiency, most SUPERTANK tests were initiated with the final profile of the previous run. Approximately 350 surveys were conducted using an auto-tracking, infrared Geodimeter targeting prism attached to a survey rod mounted on a carriage pushed by researchers. Although three lines, two along the wave-channel wall and one in the center, were surveyed, only the center line is examined in this study. Wave-processing procedures are discussed in Kraus and Smith (1994). To separate incident-band wave motion from low-frequency motion, a non-recursive, low-pass filter was applied. The period cutoff for the filter was set to twice the peak period of the incident waves.

After inspection of all 20 SUPERTANK tests, 5 tests with 30 wave runs were selected for analysis in the present study. The selection was based on the particular purpose of the wave run, the trend of net sediment transport, and measured beach change. Time-series beach-profile changes and cross-shore distribution of wave height and mean water level were analyzed. The breaker point is defined at the location with a sharp decrease in wave height (Wang et al. 2002). The maximum runup is defined by the location and beach elevation of the swash gauge that contained a value larger than zero wave height, i.e., water reached that particular gauge. There may be some differences in the runup measured in this study as compared to the video method (e.g., Holland et al. 1995) and horizontally elevated wires (e.g., Guza and Thornton 1982). The differences are not expected to be significant.

RESULTS AND DISCUSSION

The subject 30 wave runs are summarized in Table 1. The thirty cases are composed of 12 erosional random wave runs (ER), 3 erosional monochromatic wave runs (EM), 7 accretionary random wave runs (AR), 3 accretionary monochromatic wave runs (AM), and 5 dune erosion random wave runs (DE). The first two numbers in the Wave Run ID "10A_60ER" indicate the major data collection test, the letter "A" indicates a particular wave condition, and "60" describes the minutes of wave action. The erosional and accretionary cases are designed based on the Dean number N,

$$N = \frac{H_b}{wT} \tag{9}$$

where w = fall speed of the sediment, and T = wave period.

n = spectral peakedness; β_s. = beach slope defined as the slope of the section approximately 1 m landward and 1 m seaward of the shoreline; H_{b_h} = incident band wave height at the breaker line; H_{b_l} = low frequency band wave height at the breaker line; H_{sl_h} = incident band wave height at the shoreline; H_{sl_l} = low-frequency band wave height at the shoreline.

Beach Profile Change

Typically, erosion is defined as a net offshore transport of sand resulting in a loss of beach volume above the mean water line. Accretion is defined as a total net onshore transport of sand, building the beach above mean water level. As expected, a larger Dean number N resulted in erosion, and a smaller N induced accretion (Table 1).

Significant profile change occurred during the first erosional wave run case, 10A, over the monotonic initial profile (Eq. 8). Substantial shoreline recession occurred along with the development of an offshore bar (Fig. 2A). Initially, the foreshore exhibited a convex shape while the end profile was concave. The 270-min profile was substantially steeper near the shoreline than the initial profile. A bar formed after 60 min of wave action.

After 270 min, the bar moved 4 m further offshore. The maximum beach-face recession occurred at the +0.37 m contour line. The subsequent wave runs were conducted over the barred beach. The beach-profile changes are detectable, but much more subtle. Fig. 2B shows an example of shoreline accretion and onshore bar movement.

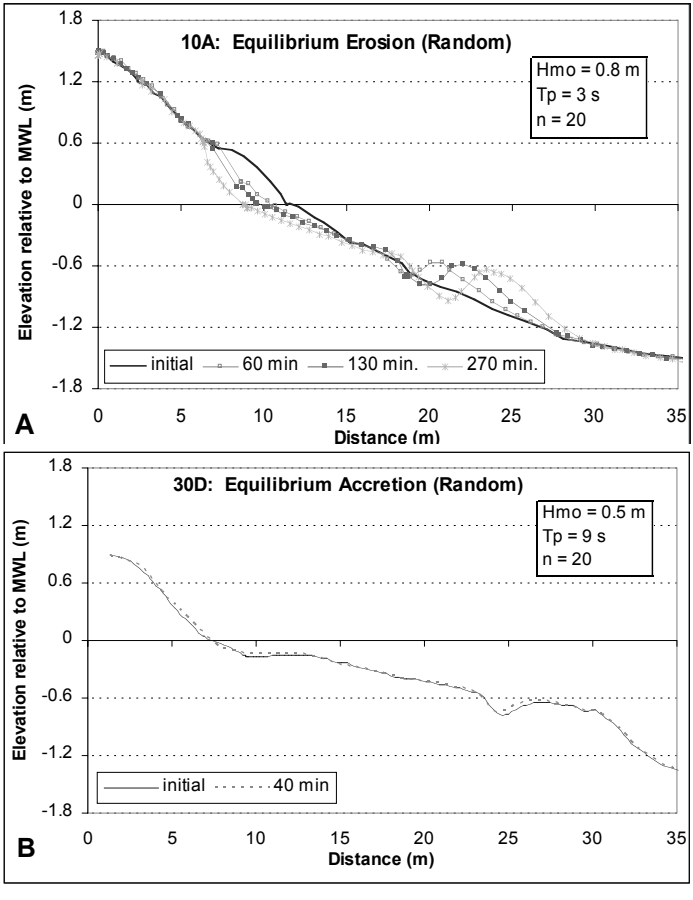

Fig. 2. (A) Bar development over monotonic equilibrium beach-profile, and (B) profile developed under accretionary random waves

In some of the erosional wave runs, a scarp developed (Fig 3A). Beach slope immediately seaward of the scarp tends to be steeper than on a non-scarped beach. The nearly vertical scarp had significant influence on the wave runup, limiting the swash uprush abruptly. Monochromatic waves tend to create erratic and undulating profiles (Fig 3B), in contrast to the smooth profiles under random waves, likely because of wave

reflection. The erratic profile evolution did not seem to approach a stable equilibrium shape. In addition, the profile shape developed under monochromatic waves does not represent profiles typically measured in the field (Wang and Davis 1998).

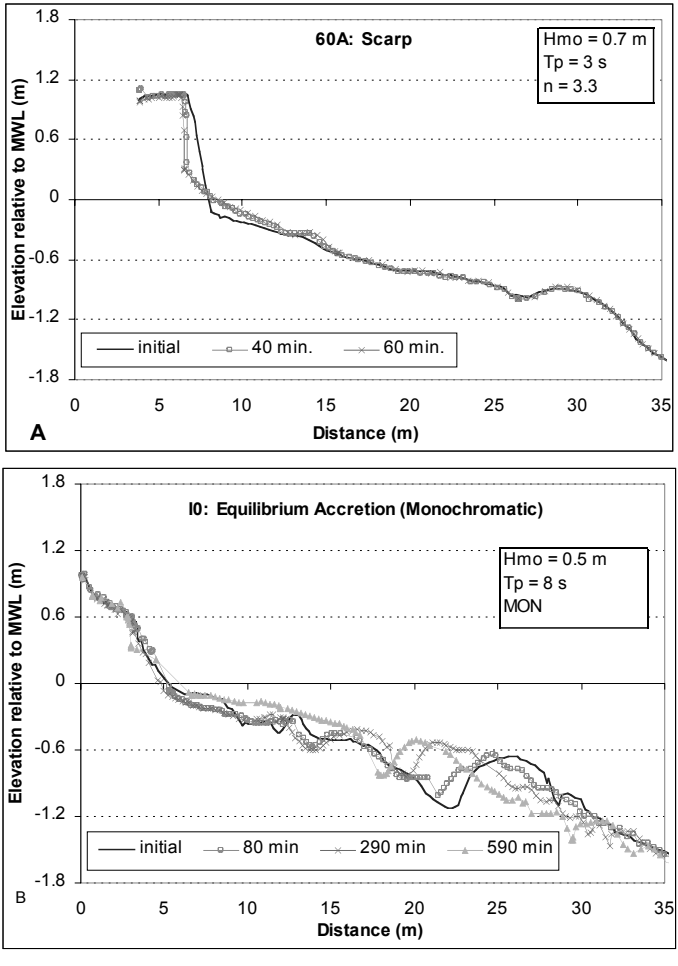

Fig. 3. (A) Scarp development, and (B) beach profiles under monochromatic waves.

The time-series of beach profiles (e.g., Figs. 2 and 3) were examined to determine the trend of erosion or accretion, and the upper and lower limits of change during each wave run (Table 2). Table 2 also summarizes the measured and predicted limits of wave runup, discussed in the following section. For the scarped cases, the upper limit of profile change was at the top of the scarp. Thus, it is controlled by the height of the

beach berm or dune, and does not directly represent the extent of wave action. In Table 2, the listed upper limit used for the scarped cases was the elevation of the scarp toe. The purpose is to link toe erosion or accretion to the wave condition.

For the studied 30 wave runs, the incident breaking wave height ranged from 0.39 to 1.18 m (Table 2). The measured upper limit of profile change, including the scarped cases, ranged from 0.27 to 0.70 m. The lower limit of beach change ranged from 0.65 to 1.61 m. Relationship between the profile change and wave condition is discussed in the following sections.

Table 2. Summary of Upper and Lower Limit of Beach Changes and Measured and Predicted Wave Runup Equations.

R_{max} = measured maximum wave runup; **UL, LL** = upper and lower limit of beach change, respectively.

Wave Runup

Measured and predicted wave runup is summarized in Table 2. Three examples, a random wave run without scarp (Fig. 4A), a random case with scarp (Fig. 4B), and a monochromatic case (Fig. 4C), are given. The non-scarp random wave cases are most compatible with existing field studies. The measured wave runup for the scarp cases are much lower than that for the non-scarp cases, apparently limited by the steep scarp. Wave runup generated by monochromatic waves is also much smaller than that by random waves with similar statistical wave height and period.

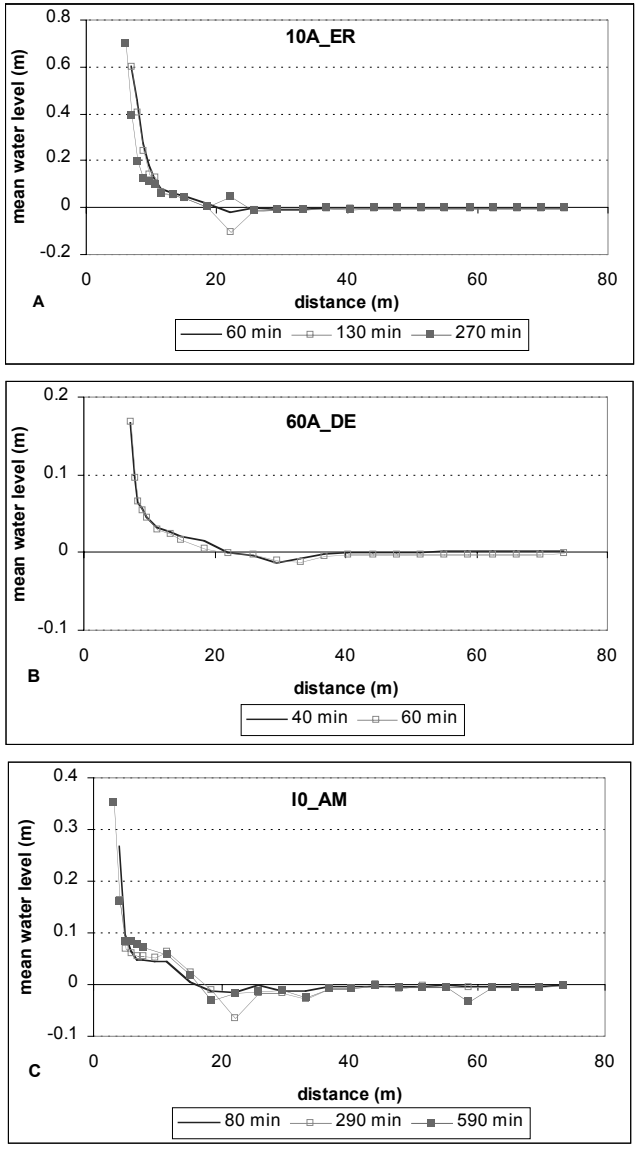

Fig. 4. Examples of wave runup under random wave (A), over a scarped beach, and (B) under monochromatic waves (C).

A direct relationship between the measured runup height on non-scarp beach and breaker height as developed with the SUPERTANK data is:

$$R_{max} = 1.0\ H_b \tag{10}$$

Compared to the various existing empirical formulas, Eq. (10) adopts the approach introduced by Guza and Thornton (1982) and is simple, involving only the breaking wave height. Except for three wave runs, the observed wave runup equals the breaking wave height. Eq. (10) reproduced the measured values closely (Fig. 5). Agreement between measured and predicted values was reduced by including the surf similarity parameter, ξ. Eqs. (6) and (7) under-predicted the measured wave runup significantly for the erosional cases with steep waves, while over-predicted for accretionary cases. Loss of predictive capability is caused by the substantially greater ξ for the gentle long-period accretionary waves than the steep short-period erosional waves (Table 1).

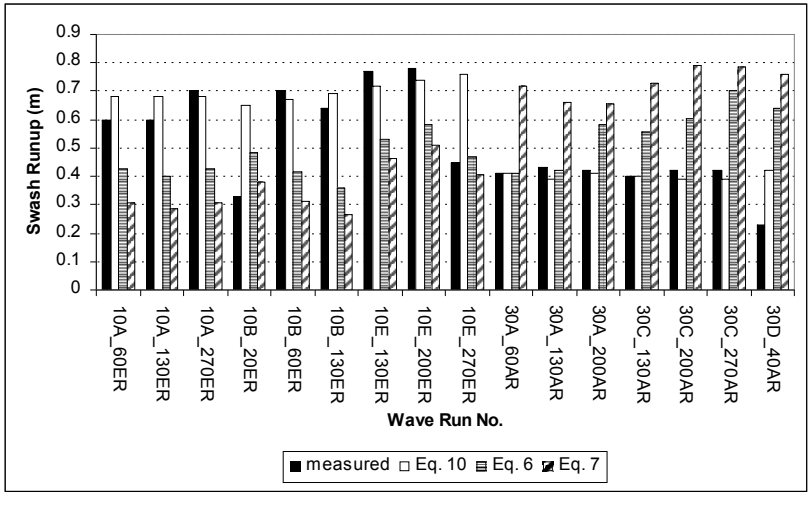

Fig. 5. Comparison of measured and predicted wave runup by three equations.

Douglass (1992) re-analyzed the Holman (1986) data set and found no correlation between runup and beach-face slope. He further argued that beach slope is a dependent variable that is free to respond to the incident wave energy and should not be included in a runup prediction. In practice, beach face slope is a difficult parameter to define and determine. Except for Stockdon et al. (2006), a clear definition of beach slope is not given in most studies. However, the Stockdon et al. definition of beach slope is difficult to utilize. In the present paper, the slope is defined over that portion of the beach extending roughly 1 m landward and seaward from the shoreline. The accretionary cases tend to have greater slope, 0.13 to 0.20, whereas the erosional case have slopes of 0.08 to 0.14 (Table 1). Examination of Fig. 3 indicates that the beach face is curved instead of planar. Therefore, substantially different beach slopes can be obtained by imposing different definitions. Including the beach slope thus adds ambiguity in applying the

empirical formulas. Determining offshore wave height may also cause uncertainty. In most field studies, the offshore wave height was taken to be that measured at a wave gage in the study area. Similarly, here it is taken as that from the offshore-most gauge. Under extreme storm conditions, estimating the offshore wave height may not be straightforward (Wang et al. 2006).

One of the first empirical formulas (Eq. 4) predicting the significant runup height R was developed by Guza and Thornton (1982) based on field measurements. As discussed previously, wave runup height measured here is expected to approximate the maximum runup R_{max}. If a Raleigh distribution of wave height is assumed, the maximum wave height should be 1.4 times the significant height. Multiplying the proportional constant of 0.71 in Eq. (4) by 1.4 yields approximately 1, which is the empirical coefficient obtained here. Therefore, the simple formula found in this study agrees with the form found by Guza and Thornton (1982).

It has been documented in many field studies performed on gently sloping beach that the swash motion and, therefore runup, is dominated by low-frequency wave energy. Typically, the low-frequency energy is defined as that carried by the wave components exceeding twice the incident peak period. The magnitudes of the incident and low-frequency energy are compared at the breaker line, H_{b_h} and H_{b_l}, and at shoreline, H_{sl_h} and H_{sl_l} (Table 1). For monochromatic waves, little low-frequency energy was measured at the breaker line and the shoreline. Lack of low-frequency modulation may explain the relatively low swash runup measured during the regular wave cases (Table 2).

For the random wave cases, energy from the incident band dominates at the breaker line (Table 1). The incident-band energy decreased significantly at the shoreline, whereas the low-frequency energy increased. This is readily apparent for the short-period steep erosional waves, where low-frequency energy dominated at the shoreline. The wave spectral peakedness n does not seem to have great influence on this trend. For the longer period gentle accretionary waves, the decrease of incident-band energy was not as rapid and low-frequency energy did not become the dominant band at the shoreline (Table 1). The low-frequency component is defined dynamically here as exceeding twice the incident peak period. For the erosional waves, the low-frequency component starts at 6 or 9 s, whereas for the longer accretionary waves, it starts at 16 or 18 s.

Relationship between Wave Runup and Limit of Beach-Profile Change

A major goal of studying the maximum wave runup is to predict the upper limit of beach changes. Knowledge of the maximum runup is valuable in evaluating the limit of storm-induced beach or dune erosion. For the random wave runs without scarps, the measured upper limit of beach-profile change roughly equals the measured wave runup (Fig. 6). Thus, the wave runup, predictable using significant breaking wave height, can be directly used to calculate the upper limit of beach erosion. For cases with beach or dune scarps, the upper limit of the beach change is controlled by the elevation of the back-beach berm or dune (Fig. 3A). Once a scarp forms, the overlying sediment will eventually collapse under gravity and cause significant change above the upward limit of water excursion.

The measured wave runup is subdued by the nearly vertical scarp and the steep beach slope directly seaward of the scarp; and it cannot be predicted by known empirical formulas.
Beach-profile change under monochromatic waves differs greatly from that under the more realistic random waves. Both wave runup and upper limit of beach-profile change are significantly smaller than those under random waves with similar statistical wave height and period. Findings from laboratory monochromatic movable-bed studies are not directly applicable to field conditions, as also discussed by Wang and Kraus (2005).

Although not a focus of this study, the lower limit of beach changes was also measured and is listed in Table 2. Typically, the lower limit of beach-profile change is 1.5 to 3 times the significant breaking wave height. Longer period waves seem to influence beach change in deeper water (~ 3 times H_s), as compared to shorted period waves (~ 2 times H_s). It was beyond the scope of this paper to examine factors controlling the lower limit of the beach change.

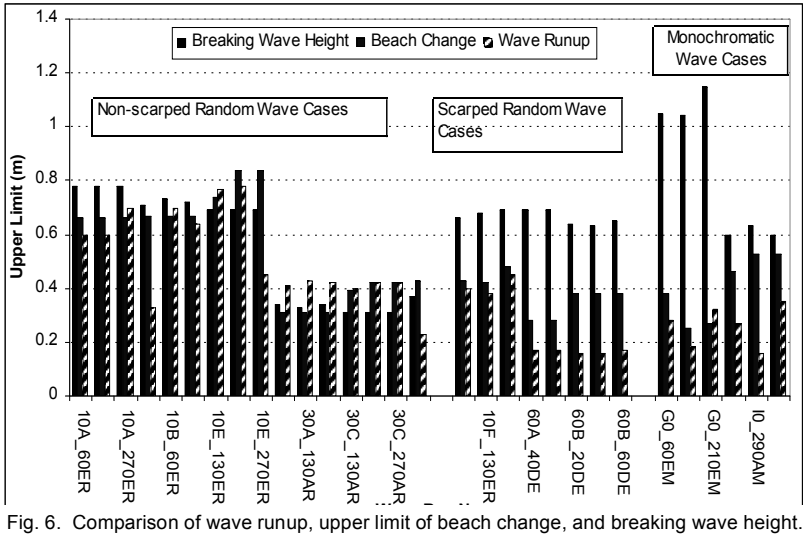

Fig. 6. Comparison of wave runup, upper limit of beach change, and breaking wave height.

CONCLUDING DISCUSSION

SUPERTANK's unique dataset was analyzed to examine the effects of elevated water level caused by wave setup and swash runup on the upper limit of beach and dune change. Thirty SUPERTANK wave runs were investigated. The investigated runs demonstrate that the Dean Number is a reliable indicator for predicting the general trend of beach erosion and accretion. In fact, the SUPERTANK experiments were designed in this way (Kraus and Smith 1992).

The SUPERTANK data indicate that the vertical extent of wave runup above mean water

level on a non-scarped beach is approximately equal to the significant breaking wave height. A simple empirical formula for predicting the maximum wave runup, *Rmax*: $R_{\max} = 1.0\, H_b$, is therefore developed. This formula agrees with the original runup formula concept of Guza and Thornton (1982). The reliability of the calculated wave runup decreased, as compared to measured values, by including the surf similarity parameter. An exception to the direct relationship between breaking wave height and runup concerns dune or beach scarping. The steep scarp substantially limits the uprush of swash motion, resulting in a much reduced maximum level, as compared with the non-scarping situation. For monochromatic waves, the measured wave runup is much smaller than the breaking wave height. The lack of low-frequency modulation limits the wave runup for monochromatic waves.

Based on the SUPERTANK experiments, the upper limit of beach-profile change was found to be approximately equal to the maximum vertical excursion of swash runup. Therefore, the limit of swash runup can serve as an estimate of the landward limit of beach change. Physical situations that are exceptions to this direct relationship are those with beach or dune scarping. For the scarping cases, the upper limit of beach change is much higher than the maximum swash runup and is controlled by the elevation of backbeach/berm or dune.

Abstract: The objective is to develop a physical based wave impact driven erosion model for the dune face and fore shore morphology under extreme conditions. Both (stereo) video and in-situ measurements from a large scale dune erosion experiment are available to develop this model. Visual observations during the experiments and image intensity time stacks are used to make a first analysis of dune face slumping characteristics. Three-dimensional dune and beach morphology are reconstructed from stereo video imagery to quantify morphodynamic response. Also a preliminary investigation of the relationship between wave impact and dune face erosion is presented.

INTRODUCTION

During severe storms a significant surge can flood the beach causing large storm waves to impact the sandy dunes. These wave impacts cause episodical slumping of sand from the dune face onto the active beach. In turn, inner surf and swash zone processes redistribute this sand over the foreshore resulting in a beach profile evolving toward equilibrium with the extreme hydraulic conditions. The system is characterized by a feedback between the evolving beach profile and inner surf and swash zone processes eroding the dune (Figure 1).

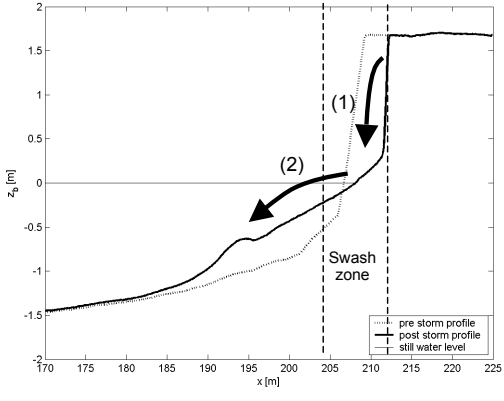

Figure 1: Dune erosion during severe storms. Sand slumps from the dune face onto the active beach (1) where it is transported further offshore by inner surf and swash zone processes (2).

Progress in understanding and modeling dune erosion during extreme storm surges requires better knowledge of inner surf and swash zone processes and the interaction of these processes with the dune face and fore shore. Hydrodynamics of inner surf and swash zones are complex due to limited water depth, non linear interactions, and high turbulence rates. Furthermore the addition of sediment from the collapsing dune face is irregular in time and significantly influences near shore hydrodynamics and sediment transports.

Several approaches have been proposed to describe sediment fluxes over the dry dune face and swash zone. A first approach relates dune face erosion and swash zone sediment transports to the capacity of the near shore flows to transport sediment offshore (Steetzel 1993; Steetzel 1994). Sediment transports are computed with a physical based model up to a critical water depth. Then, the sediment transport at the critical water depth is empirically extrapolated over the swash and dune face till a computed run-up level. In the model waves do not necessarily have to impact the dune face in order for it to retreat and the geotechnical properties of the dune face are not considered in the model.

Another approach is to directly decouple inner surf and swash zone sediment transports from dune face erosion by relating dune face wave impacts to dune face erosion as proposed by Fisher et al. (1986). In addition a wave impact driven dune face erosion model may be coupled with a process based morphodynamic model for the fore shore to model dune erosion. In this model the beach morphology in front of the dune foot does not evolve from an empirical sediment transport function but is free to be shaped by the near shore hydrodynamics. This allows for a physical feedback between near shore hydrodynamics, dune face erosion and the evolution of the fore shore from that erosion.

The objective is to develop a process-based dune erosion model driven by wave impact. To that end this paper examines the relation between wave impact and dune face retreat using data from a large scale dune erosion experiment in the Delta flume, a WL|Delft Hydraulics research facility. Characteristics of dune face slumping such as slump volume, frequency and failure mode are investigated using visual observations and image intensity time stacks derived from video. Detailed analysis of the morphological response of the dune face is obtained stereo video images. Preliminary conclusions arising from the observations are also presented.

DUNE EROSION EXPERIMENT

Eight large scale dune erosion experiments were conducted in the WL|Delft Hydraulics Delta flume (length width and depth respectively 225 m, 5m, 7m) from November 2005 through February 2006 (Van Gent et al. 2006). The total duration of each test varied, but was at least six hours. Tests were temporarily interrupted to carry out bed profile measurements. Other measurements were obtained using both in-situ instruments and video cameras.

In-situ hydrodynamic measurements were obtained from a cluster of instruments deployed on the flume wall. Ten pressure sensors spaced along the flume measured wave transformation over the foreshore, three resistance wires and a combined pressure and current velocity sensor were used to distinguish between incoming and shore line reflected waves, and two electromagnetic current velocity sensors measured the inner surf and swash zones hydrodynamics (Figure 2). The collocated pressure and current velocity sensors deployed at 205 meters from the wave board may best be used to obtain further insight into wave impacts on the dune face.

Two synchronized video cameras (referred to as camera C1 and C2) were deployed to obtain stereo video data with the objective of three-dimensional reconstruction of the dune face, inner surf and swash zone. Images were collected from video streams with a sample frequency of 2 Hz or 4 Hz depending on the experiment and the two cameras were synchronized using an 11 volt trigger signal. Video data were synchronized with in-situ measurements using a small led light visible in camera C2 that illuminated at the start of in-situ measurements.

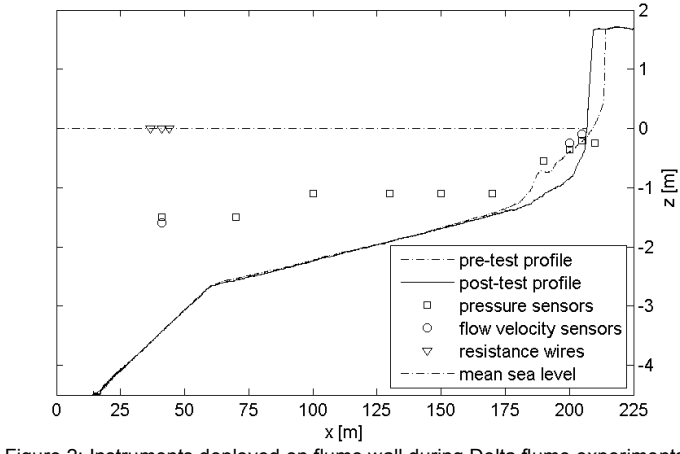

Figure 2: Instruments deployed on flume wall during Delta flume experiments

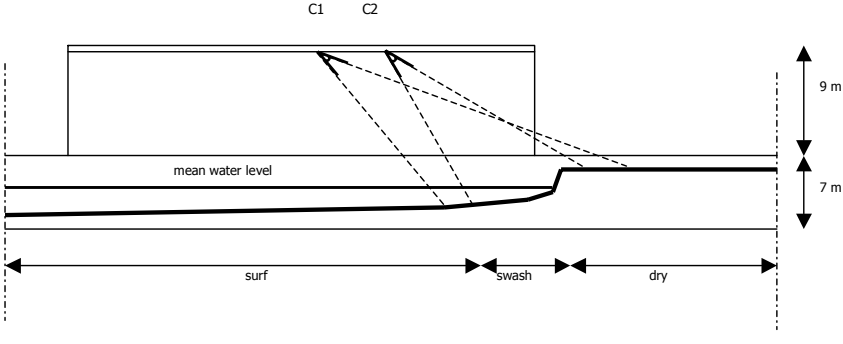

Figure 3: Camera configuration C1 and C2 during Delta flume experiments

Cameras C1 and C2 were fixed to the roof of the flume's enclosure approximately above the flume centre line (see Figure 3). Both cameras were pointed in the direction of wave propagation and resolve bathymetries in an area covering about twelve meters in along flume direction and six meters in cross flume direction. Camera positions and orientation are listed in Table 1. The coordinate system originates at the wave board ($x = 0$), the flume centre line ($y = 0$) and the top of the flume wall ($z = 0$).

Table 1: camera geometries

Camera	*x* (m)	*y* (m)	*z* (m)	*fov* (°)	Tilt (°)	Roll (°)	Azimuth(°)
C1	190.474	0.032	8.331	30.3496	55.06	-87.62	89.49
C2	196.811	0.022	8.312	38.2679	45.98	-90.58	91.40

VISUAL OBSERVATIONS

A first analysis of in-situ profile measurements during the experiments show that after one hour waves, time averaged, spatial sediment transport gradients on the newly formed fore shore are relatively small (Figure 4). It seems the vertical elevation of the fore shore is close to equilibrium if a longer period of time is considered. However, observations on a shorter time scale indicate that the beach in front of the dune face is frequently far away from equilibrium elevation due to slumping sand deposited on the beach. Near shore hydrodynamics constantly reshape the beach and on average sediment is transported in seaward direction where the sand settles and extends the fore shore. Developing a physical based dune erosion model requires that the shorter time scale slumping and its interaction with the fore shore hydrodynamics has to be simulated correctly in order to predict the behavior on a longer time scale.

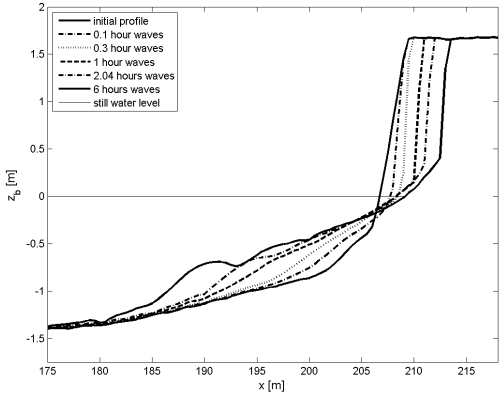

Figure 4: Profile development during the first six hours in the seventh test of the dune erosion experiment. The vertical elevation of the fore shore remains approximately the same on a longer time scale meaning time averaged spatial sediment transport gradients are small.

Visual observations during the experiments revealed that the dune face will retreat as long as incoming waves run-up the beach and hit the dune face. Considering this it is hypothesized that the rate of dune face retreat should be related to the wave impact frequency. However a direct relation between wave impact and dune face erosion was not observed. Collapsing of the dune face also occurred after an experiment in the absence of waves. In general, the dune face is overhanging slightly before slumping suggesting the dune face becomes unstable reaching a critical slope. The apparent decorrelation between discrete wave impacts and dune face retreat suggests examining a relation between dune face retreat and the accumulated dune face wave impacts between two slumps.

At the beginning of an experiment the dune foot is just below mean water level, the

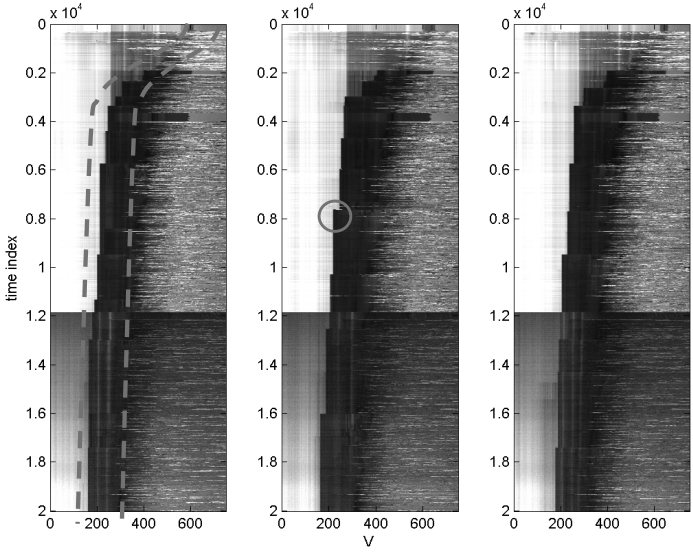

Figure 5: Time stacks for three transects in cross tank direction comprising the first two hours of the seventh test (Figure 6 left panel). The dune crest (lying between the dashed lines in left panel) is indicated by the transition from light to dark, where light is the top of the dune. Slumps are indicated by a discontinuity of the dune crest in time (i.e. circle middle time stack)

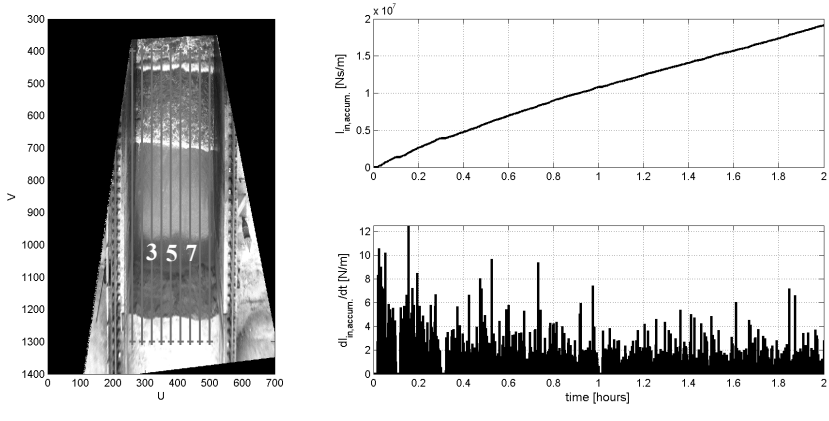

Figure 6:(left): Rectified image with transects used to generate time stacks. Transect 3,5 and 7 are used in elaborating Figure 5. (right upper): Accumulated shore ward directed momentum at the collocated pressure and current velocity sensor at 205 meter from the wave board. (right lower): Ten minutes averaged gradient of shore ward directed momentum at the same location.

erosion rates are large and so is the number of waves reaching the dune face. Due to continuing dune erosion the fore shore starts to develop causing waves to dissipate more energy further offshore. In addition the retreating dune foot becomes located above the still water level and waves have to run-up the newly formed beach before the dune can be impacted. Consequently, the number of waves reaching the dune face and the wave impact intensity are expected to decrease as the experiment progresses The resulting decrease in dune erosion rate with time is confirmed by the dune crest position in time stacks for three transects along the flume axis (Figure 5). The rate of dune face retreat decreases whereas the time interval between successive slumps becomes larger as the experiment continues. Time stacks from the various transects illustrate that a slumping event does not necessarily extend over the full width of the flume.

At the start of the experiment the dune face is rapidly eroded and steepened as waves run up the dune face instead of impacting it (Figure 5). It is hypothesized that erosion mechanisms during the transient steepening of the dune face are different and are also due to shear stress driven sediment transports exerted by the flow.

Accumulated on-shore directed momentum obtained from the collocated pressure and current velocity sensors at 205 meters from the wave board decreases with time and illustrates the reduction in wave energy reaching the dune face as the result of fore shore development and dissipation of incoming wave energy further offshore (Figure 6, upper panel).

DETAILED ANALYSIS

To examine a relation between wave impact and dune face erosion a linear relation ship is assumed between the change in momentum of waves impacting the dune face (a force F) and the weight of the sediment volume eroded from the dune (ΔW) (Fisher et al. 1986; Overton et al. 1987; Nishi and Kraus 1996; Larson et al. 2004;):

$$\Delta W = C_E F \tag{1}$$

In this expression C_E is an empirical coefficient to be obtained from data and ΔW is computed from the eroded sediment volume from the dune (ΔV) (Figure 7 left panel):

$$\Delta W = \Delta V \rho_s (1 - p) g \tag{2}$$

where ρ_s is sediment density, p is porosity and g is the gravitational acceleration.

Coefficient C_E in relation (1) is calibrated for the Delta flume experiments by computing the change in dune face volume (ΔV) for a slump event using stereo video data to reconstruct the dune face just before and after a slump event. The average wave impact (F) is derived from in-situ data.

Slump events in the available video data are detected using time stacks of nine uniformly

spaced transects in cross flume direction (Figure 6 left panel and Figure 8). The real world distance between transects is about half a meter which is close enough to detect most slump events. Since retreat of the dune face does usually not extend over the full width of the flume, slump events are not necessarily visible in all time stacks. Consequently, accumulated wave impacts between successive slumps (assumed to be uniform in cross flume direction) are related to the cross flume integrated volume change of the dune.

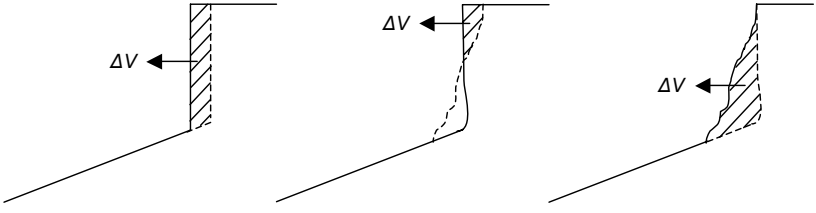

Figure 7: (left): Sketch of eroded sediment volume from the dune as computed in the wave impact model. (middle): Sketch of morphological response of the dune dune face over a slump. (right): Sketch of morphological response of beach and dune face between two slumps.

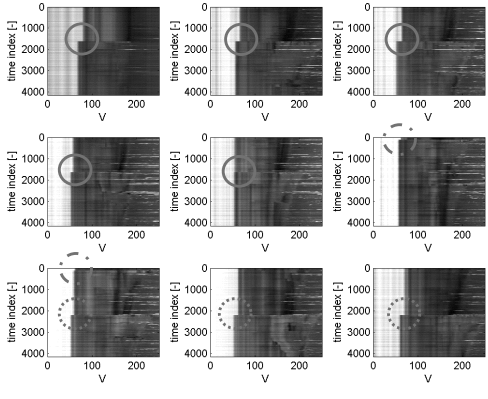

Figure 8: Time stacks for nine transects at January 13th 2006. Three slumps are observed indicated by the solid, dashed-dotted and dotted circles. Successive slumps are not necessarily in the same transect.

Near shore morphodynamic response

Three dimensional reconstructions of the dune face and near shore are obtained from a single image pair (for example Figure 9). The image required camera geometries including camera orientation, position and focal length (as described in Table 1) were computed following Holland et al. (1997).

Synchronous images from C1 and C2 are preprocessed to enhance contrast and remove

lens distortion. Features in images from C1 are mapped to corresponding features in images from C2 using an automated algorithm (Clarke et al. 2007, in preparation). The three-dimensional coordinates (XYZ) of imaged features are computed using the differences in feature pixel coordinates from the two views in conjunction with camera geometries. Computed XYZ may be obtained for any point in the image providing there is a significant local gradient in pixel intensity to uniquely identify the point in both images. Computed XYZ are interpolated on a grid to reduce noise, reduce the number of data points and simplify further analysis.

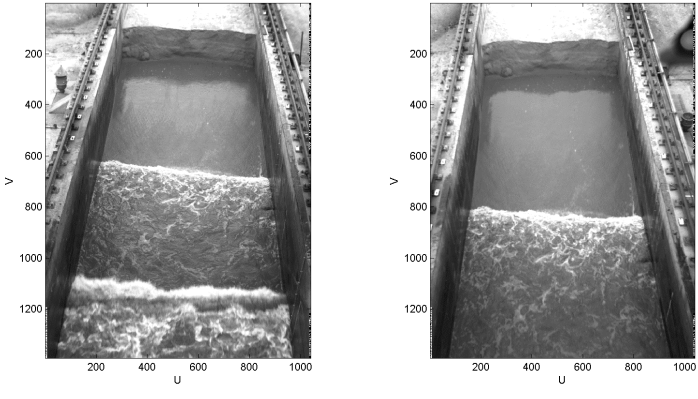

Figure 9: (left): Raw image camera C1 (right): Raw image camera C2

For the dune experiments there are some areas in the flume where features appear as reflections on either the water surface or the wet sand surface during shallow swash up rush or down rush. Computed coordinates for reflected features are erroneous compared to the coordinates in the absence of such reflections. To guard against spurious feature matches the water surface, dry beach and reflection areas are identified using a series of empirical image processing algorithms prior to the feature matching process (Figure 10). The water line is detected using the contrast between wave breaking induced foam and the dry beach. Using intensity variance images, large variance areas are identified as wet whereas small variance areas are marked as dry. In addition, the most shoreward bore edge (indicated by the white arrow in the right panel of Figure 10) is detected as the continuous line maximizing the sum of variance across the flume. If the resulting bore edge is within a user specified number of pixels from the water line the bore edge is marked as being the water line. When the bore edge marks the boundary between water and dry beach it is used as a strong feature to generate high confidence coordinates along contour lines on an otherwise poorly featured beach. Areas in the image containing reflected features are marked and excluded from further analysis (Figure 10 right panel).

Computed XYZ are interpolated onto a regular grid with spacing 1cmx1cm. Since the dune face is nearly vertical, this feature is resolved in the interpolation by first rotating computed XYZ to a new coordinate system, XYZ', where the plane XY' represents a

best fit through XYZ. Transformed points XYZ' are interpolated onto a regular grid in XY'. Interpolated grid points are then transformed back to the unrotated reference frame (Figure 11).

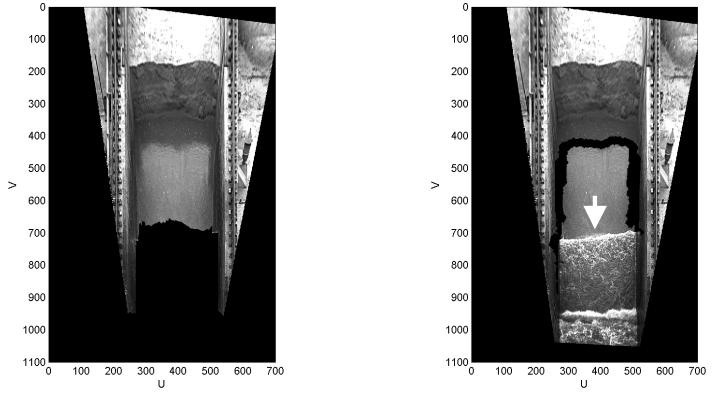

Figure 10: (left): Distinguish between water surface and dry beach. Here the water surface is masked. (right): Masking of edges reflection area. The white arrow points to the most shoreward bore

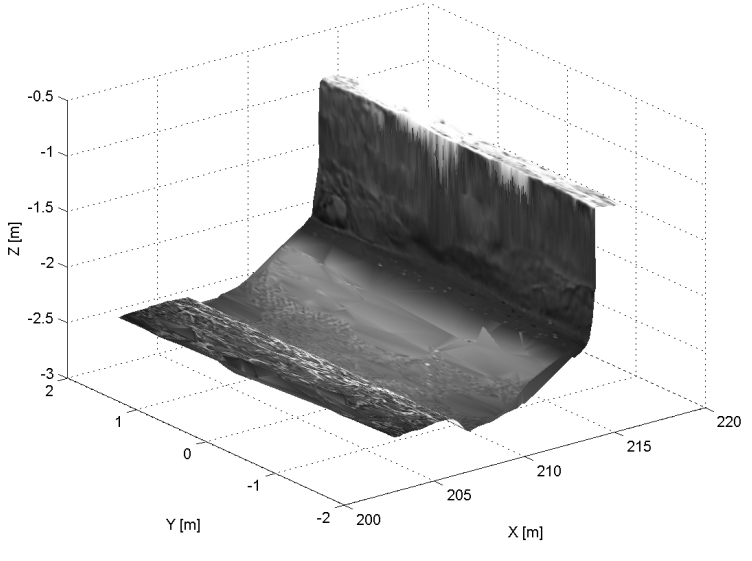

Figure 11: Three dimensional reconstruction of near shore area using two images.

Reconstructed dune and beach morphology immediately before and after an slump event (Figure 12, upper panels) are differenced to determine volume changes of the dune face (Figure 12, lower panels). From this quantified morphodynamic response an erosion volume has to be specified in order to relate wave impact to dune face erosion. In the wave impact model this volume is expressed as the sediment volume eroded from the dune (see Figure 7 left panel). However obtaining the relevant volume from the measured morphological response over a slump is not straight forward since it is not obvious from this response what sand is active and behaves like a sediment source to the swash zone (Figure 7 middle panel). Taking the eroded sediment volume from the dune, as proposed in the model, probably results in an underestimation of dune face erosion since a significantly larger volume of sand is redistributed by the near shore hydrodynamics in the interval between successive slumps. From a physical point of view it might be better to compute the wave impact related sediment erosion volume from the combined volume change of the beach and dune between two slumps (Figure 7 right panel) instead of computing it from the volume change of the dune alone for a single slump (Figure 7 middle panel).

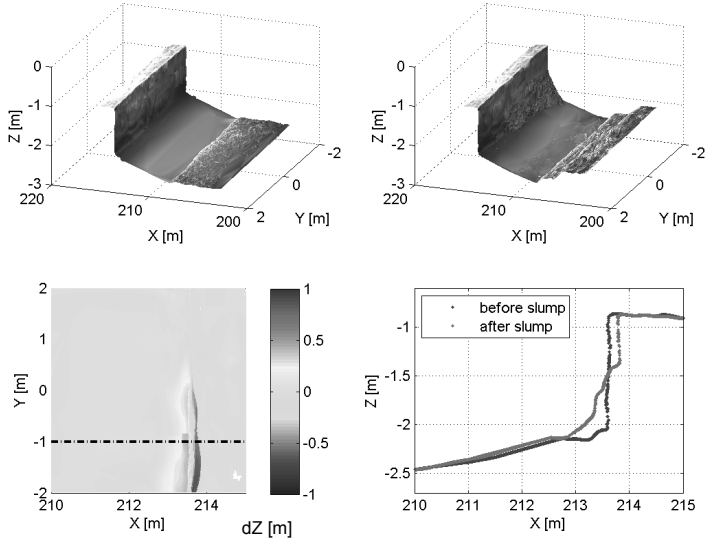

Figure 12: Morphodynamic response during dune face slump. Upper panels show the three dimensional reconstruction of the near shore area just before and after the slump. The lower panels show the morphodynamic response of the dry beach and dune. The profiles in the lower right panel are obtained from interpolated grid data with Y values between -1.05 [m] and -0.95 [m]. The still water level is at -2.5 [m]

Wave impacts

To examine relation (1), in addition to slump volumes also wave impacts are needed. Wave impacts are derived from measurements from the most shoreward located (205 [m] from the wave board) pressure and current velocity sensor. Using shallow water linear wave theory pressure time series are translated into water surface elevations. Current velocity time series are de-spiked such that velocity peaks with a minimum amplitude of 0.25 [m/s] and a maximum width of 1 second are removed. Both pressure and current velocity time series are used to distinguish between incoming and shoreline reflected waves assuming shallow water (Guza et al. 1984):

$$\eta_{in} = \frac{\eta + u\sqrt{h/g}}{2} \text{ and } \eta_{out} = \frac{\eta - u\sqrt{h/g}}{2}, \tag{3}$$

where η_{in} and η_{out} are respectively the water surface elevation associated with the incoming waves and outgoing waves, η (= η_{in+} η_{out}) is the measured water surface elevation, u is the measured velocity, h is water depth and g is the gravitational acceleration.

Only the incoming wave signal is considered in elaborating wave impacts. The amount of incoming wave momentum is separated into two contributions, respectively a term representing advection of momentum by the flow and a term taking in account the dynamic water pressure:

$$I = \rho u_{in}(t)^2 h_{in}(t) + 0.5\rho g \eta_{in}(t)^2, \tag{4}$$

where u_{in} is the current velocity associated with the incoming waves and h_{in} the water depth associated with the incoming waves ($h_{in} = h_{mean} + \eta_{in}$).

The incoming momentum is absorbed in the swash zone and by the dune face. Since the dune face retreats during the experiment, the distance between the most shoreward located sensors and dune face will increase. In addition the momentum absorbed over this distance is expected also to increase. To include this effect requires the modeling of intra wave forces that act on the fluid in the swash zone.

CONCLUSIONS

Initial review of some of the video imagery and hydrodynamic measurements from the series of large-scale dune erosion experiments confirm a complex relationship between waves and morphodynamic response of the fore shore and dune face. Dune retreat may be characterized by two stages. In the initial stage the dune face evolves to a vertical face and sediment transport from dune to near shore environment is affected by wave up-rush over the full dune height. In the later stage sediment is delivered in bulk to the upper swash zone by intermittent failure of the vertical dune face where it is subsequently transported offshore by swash and near shore flow.

Accumulated wave momentum at the most shoreward sensor indicates a non-linear decrease in energy available for dune erosion as the newly formed fore shore evolves progressively into deeper water. Bar formation and increased dissipation of wave energy further offshore characterizes the later stage of the experiment.

Time stacks and morphology reconstruction from stereo provide high resolution measurements in time and space with demonstrated capability of resolving dune and foreshore response to waves. Integrating over an extended sequence of slump events and associated wave impacts will allow calibration of the dune erosion model cited in this paper. A detailed analysis of video and hydrodynamic data is required to fully exploit existing measurements but they represent a valuable suite of observations with which to formulate and quantitatively test improved models for dune response to extreme wave conditions.

ACKNOWLEDGEMENTS

The Dr.ir Cornelis Lely Foundation and Delft Cluster are thanked for financing this work as part of a PhD study on dune erosion. Also we thank RWS RIKZ for their contribution to the large scale dune erosion experiments in the Delta flume.

CRITICAL WIDTH OF BARRIER ISLANDS AND IMPLICATIONS FOR ENGINEERING DESIGN

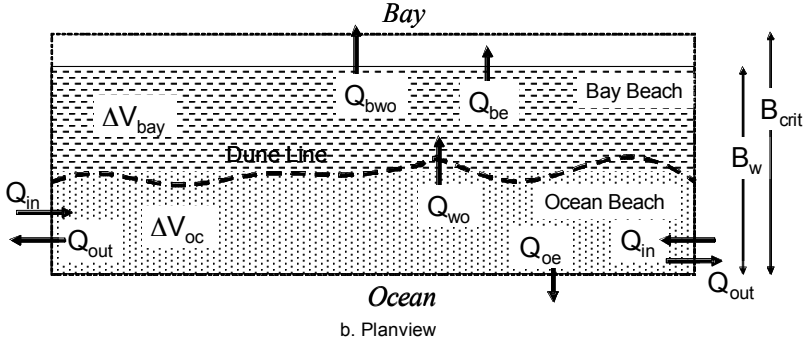
Abstract: The critical width of a barrier island is defined as the smallest cross-shore dimension that minimizes net loss of sediment from the island over periods from decades to centuries. This concept is of importance for large-scale restoration of barrier islands which involves rebuilding these islands to a specified geometry. Within constraints of coastal forcing and geologic and regional characteristics at the site, islands having critical width will capture deposition of washover sediment onto the subaerial beach over the project lifetime. This study reviews previous investigations of barrier island critical width and applies a newly-developed model of barrier island migration, consolidation, and overwash to assist engineering design.



INTRODUCTION

The term "critical width" has been discussed with reference to barrier islands, overwash, and washover deposits since the 1970s (e.g., Leatherman 1976, 1979; Jiménez and Sánchez-Arcilla 2004). Critical barrier width is defined herein as the smallest cross-shore dimension that minimizes net loss of sediment from the barrier island over periods from decades to centuries. The magnitude of critical width is related to availability and volume of littoral sediment in addition to that in the dune system. In addition, the influx of sediment via longshore sediment transport is important, for example during post-storm recovery. To illustrate the definition and introduce terminology, Figure 1 shows a barrier island and sediment transport pathways. If the barrier width equals or exceeds the critical value, transport of washover sediment from the ocean beach, Q_{wo} , is deposited

entirely on the bay beach, and residual loss of this washover into the bay, Q_{bwo}, equals zero. For barrier widths less than the critical value, $Q_{bwo} > 0$.

a. Cross-section

b. Planview

Legend

Q_{in} = longshore transport rate into barrier system	Q_{oe} = rate transported offshore
Q_{out} = longshore transport rate out of barrier system	Q_{be} = rate transported into bay
ΔV_{oc} = volume change rate on ocean beach	Q_{wo} = washover rate from ocean beach
ΔV_{bay} = volume change rate on bay beach	Q_{bwo} = washover rate lost into bay
B_w = barrier width	B_{crit} = critical barrier width

Fig. 1. Definition of terminology

Application of this concept is important for the large-scale restoration of barrier islands such as is being considered for degraded islands along the Northern Gulf of Mexico, particularly in Louisiana. These barrier islands have lost subaerial volume through time due to a combination of factors, including a lack of littoral sediment in the regional system, wave erosion due to tropical cyclones and winter storms on both the Gulf and Bay shores, and rapid relative sea level rise. Large-scale restoration involves

reconstruction of the island to specified height, width, length, and spacing (for multiple islands) using sediment derived from an external source. The goal in large-scale restoration is to maximize the lifetime of the island in protecting the bay, estuary, and mainland shores, while minimizing the cost of the project. In the North-Central Gulf of Mexico, loading of the compressible substrate with additional sediments increases consolidation. Thus, the volume of sediment used to restore a barrier becomes critical in that a larger restoration project will incur more losses due to consolidation when compared to a smaller volume (Rosati et al 2006, 2007).

In this study, we applied a migration, consolidation, and overwash model to determine the critical barrier island width given forcing and geologic parameters. Storm characteristics and consolidation characteristics of the underlying substrate were varied. The study concludes with preliminary recommendations for critical design width for large-scale restoration of barrier island systems that overlie a compressible substrate.

PREVIOUS STUDIES

Leatherman (1976, 1979) investigated overwash and washover along the northern end of Assateague Island, Maryland, and found that overwash processes were effective in migration of the barrier "…only where the barrier width is less than a critical value (122 to 213 m)." The island did not narrow below these values because overwash processes were effective at transporting sediment to the bayshore, therefore keeping pace with the rate of ocean shoreline migration. Sections of the island with greater widths experienced washover deposits that did not reach the bayshore, and the island narrowed due to ocean shoreline migration until it reached the critical width. The only process that widened the barrier beyond the critical width was breaching, formation of a partially subaerial flood shoal, and subsequent inlet closure (Leatherman 1976).

Eitner (1996) discussed potential response of the East Frisian barrier islands due to a 1-m rise in sea level occurring over approximately 170 years. Although critical width is not discussed, the most likely future outcome proposed is one in which the barrier islands maintain width while increasing in height and migrating landward. This stability of barrier cross-section implies that a critical width is maintained over the long term.

Jiménez and Sánchez-Arcilla (2004) applied the concept of critical width in a decadal-scale barrier evolution model to determine when overwash processes would contribute to bayshore accretion. They developed the model for the Ebro Delta, Spain, and estimated the critical width of the barrier spit as 225 m. When the barrier island was wider than the critical width, washover deposition on the bayshore was zero. When the barrier width was less than or equal to the critical width, washover deposition was estimated as:

$$Q_{bwo} = Q_{wo}\left(\frac{B_{crit}}{B_w}\right)^{\alpha} \quad or \quad B_{crit} = B_w\left(\frac{Q_{bwo}}{Q_{wo}}\right)^{1/\alpha} \tag{1}$$

where Q_{bwo} is the volumetric washover rate of deposition to the bayshore, Q_{wo} is the volumetric washover rate on the oceanside of the barrier, B_{crit} is the critical barrier width,

B_w is the barrier width at any time, and α is a parameter greater than or equal to 1 to incorporate sediment eroded from the subaerial barrier during overwash events (notation has changed slightly from original reference for consistency herein). Jimenez and Sanchez-Arcilla evaluated the influence of α values ranging from 1 to 2; greater α values increased the rate at which the barrier reaches an equilibrium condition, but did not change the final equilibrium state. For α values greater than 1, volumetric overwash into the bay will be greater than that transported from the ocean for all values of barrier width less than the critical width.

A sediment budget approach can be applied to estimate the critical width (Figure 1). Applying the requirement that Q_{wo} remain on the subaerial beach at critical width (i.e., $Q_{bwo} = 0$ when $B_w = B_{crit}$), and assuming that transport of the washover sediment into the bay, Q_{bwo}, is linearly related to the critical width, then:

$$B_{crit} = B_w \left(\frac{Q_{wo}}{Q_{wo} - Q_{bwo}} \right), \quad or$$
$$B_{crit} = B_w \left(\frac{Q_{in} - Q_{out} - Q_{oe} - \Delta V_{oc}}{Q_{be} + \Delta V_{bay}} \right) \tag{2}$$

Stone et al. (2004) compiled total volumes for four barrier sub-environments at Santa Rosa Island, Florida (Gulf, Berm, Dune, Bay Beach, and Bay Platform) over a 6.5-year period which can be used in Eq. 2 to determine the critical width. Considering volumetric change from February 1996 to 2002, a sediment budget can be formulated as shown in Figure 2. In formulating this budget, it was assumed that all volumetric change was due to cross-shore transport, and the gradient in longshore transport was zero. Applying Eq. 2 with a barrier width B_w = 220 m, Q_{in} - Q_{out} = 0 cu m/yr, Q_{oe} = 12.8 cu m/yr, ΔV_{oc} = -40.8 cu m/yr, Q_{be} = 0 cu m/yr, and ΔV_{bay} = 24.5 cu m/yr, the critical width can be estimated as B_{crit} = 220* (0-12.8+40.8)/(0+24.5) ~ 250 m.

MCO MODEL

The Migration, Consolidation, and Overwash (MCO) model (Rosati et al. 2006, 2007) was applied to develop guidance for barrier island critical width. This model simulates cross-shore evolution of a barrier island over periods extending from years to centuries, with given substrate and storm characteristics. Methodology underlying the model is briefly reviewed in this section.

Overwash

Overwash is any wave uprush which passes over the crown or crest of the barrier beach, and the feature created by the overwash is the washover deposit (Leatherman 1980). Overwash and the associated washover are one of the mechanisms through which the barrier island migrates towards the bay, in the cross-shore direction.

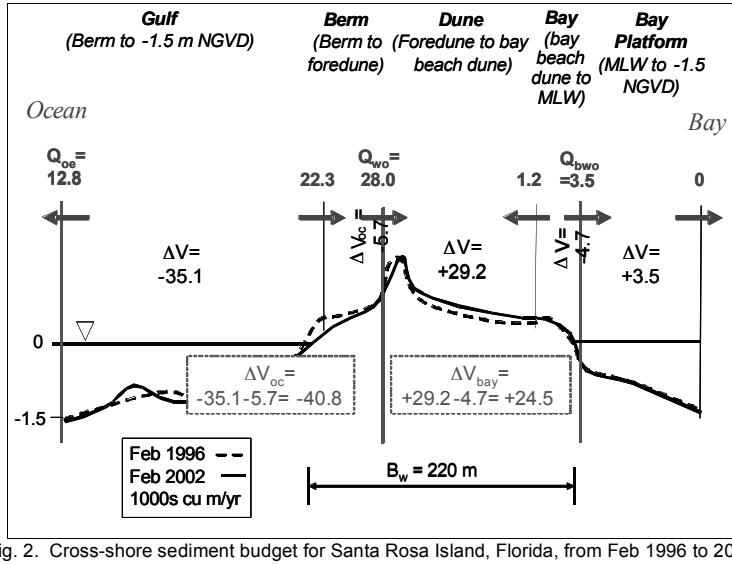


Fig. 2. Cross-shore sediment budget for Santa Rosa Island, Florida, from Feb 1996 to 2002 (data from Stone et al. 2004)

The overwash transport rate over the beach crest due to runup overwash per unit length of beach, $q_{DR}(t)$, can be described as (Donnelly et al. 2006):

$$q_{DR}(t) = 2K_R\sqrt{2g}\,\frac{z_R(t)^2}{R(t)}, \quad 0 < z_R(t) \text{ and } S(t) < b_h(t) \tag{3}$$

where K_R is a calibration coefficient that accounts for sediment stirring and properties of the wave bore; g is the acceleration due to gravity; $z_R(t)$ is the elevation of the runup, $R(t)$, relative to the dune crest elevation, $b_h(t)$, and S(t) is the total water depth (including storm surge). For calculations herein, K_R was set equal to 0.005 (Donnelly et al. 2006).

The two-percent runup, $R_{u2\%}(t)$, is calculated as (Hughes 2004):

$$R_{u2\%}(t) = 4.4\,S(t)\tan\beta(t)^{0.70}\left[\frac{M_F(t)}{\rho g S(t)^2}\right]^{1/2} \quad \text{for } \frac{1}{30} \le \tan\beta(t) \le \frac{1}{5} \tag{4}$$

in which $\tan\beta(t)$ is the beach slope, ρ is the density of water, and the maximum dimensionless depth-integrated wave momentum flux per unit width is:

$$\left[\frac{M_F(t)}{\rho g S(t)^2}\right]_{\max} = A_0(t)\left[\frac{S(t)}{gT_p(t)^2}\right]^{-A_1(t)}$$

$$\text{where} \quad A_0(t) = 0.6392\left(\frac{H_{mo}(t)}{S(t)}\right)^{2.0256} \tag{5}$$

$$\text{and} \quad A_1(t) = 0.1804\left(\frac{H_{mo}(t)}{S(t)}\right)^{-0.391}$$

The zeroth-moment deep water wave height is $H_{mo}(t)$, with associated peak period, $T_p(t)$. In applications described herein, these were randomly generated about a user-specified mean.

If the barrier island is submerged, the transport rate over the beach crest per unit width of beach, $q_{DI}(t)$, is given by (Donnelly et al. 2006) as:

$$q_{DI}(t) = (K_I + K_R)\, 2\sqrt{2g}\; z_R(t)^{3/2}, \quad 0 < z_R(t) \text{ and } S(t) \geq b_h(t) \tag{6}$$

in which K_I is an empirical coefficient, and $z_R(t)$ is as defined previously. For calculations, K_I was set to 0.001 (Donnelly et al. 2006).

The rate of washover deposition q_f varies as a function of distance over the dune crest (Larson et al. 2004):

$$q_f = \frac{q}{1 + \mu s / B_D} \tag{7}$$

where q is the transport rate over the dune crest as calculated in Eq. (1) or (4), s is a coordinate originating at the dune crest and increasing with distance over the dune, μ is an empirical coefficient, and B_D is the width of flow over the dune crest. For calculations, μ/B_D=0.12 (Larson et al. 2004).

Erosion

If the storm surge plus wave runup do not exceed the barrier island elevation, the time-dependent berm erosion, $E(t)$, is calculated using the Convolution Storm Erosion Method (Kriebel and Dean 1993):

$$E(t) = \frac{E_\infty}{2}\left\{1 - \frac{\beta_t^2}{1+\beta_t^2}\exp\left(-\frac{2\sigma t}{\beta_t}\right) - \frac{1}{1+\beta_t^2}\left[\cos 2\sigma t + \beta_t \sin 2\sigma t\right]\right\} \tag{8a}$$

in which the maximum potential erosion retreat distance is given by:

$$E_\infty = S(t)\left(\frac{W_b(t) - \dfrac{h_b(t)}{\tan\beta(t)}}{B + h_b(t) - \dfrac{S(t)}{2}}\right) \tag{8b}$$

and β_t is the ratio of the erosion time scale to the storm duration,

$$\beta_t = \frac{2\pi T_s}{T_D} \tag{8c}$$

In Eq. (8a), the term $\sigma = \pi/T_D$, where T_D is the total storm duration. The characteristic erosion time scale of the system is given by:

$$T_s = 320 \frac{H_b(t)^{1.5}}{g^{0.5} A^3} \left(1 + \frac{h_b(t)}{B} + \frac{\tan\beta(t) W_b(t)}{h_b(t)} \right)^{-1} \tag{8d}$$

in which $H_b(t)$ is the breaking wave height, $h_b(t)$ is the breaking depth, B is the berm elevation, and $W_b(t)$ is the distance to the wave breaker line calculated as:

$$W_b(t) = \left(\frac{h_b(t)}{A} \right)^{1.5} \tag{8e}$$

in which A is the equilibrium beach profile scade parameter, set to 0.063 $m^{1/3}$ representing 0.1 mm sand typical of Louisiana barrier islands.

Consolidation

Sediment has the potential to compress significantly under load due to factors such as reduction in void space, biochemical decay of organic materials, and grain shifting and breakage. Pore pressure increases if a load is applied to a saturated soil. For sands, the excess pore pressure is dissipated quickly due to their high permeability. However, clays, organic soils, and silts have much smaller permeability; thus, the excess pressure dissipates much more slowly, and consolidation continues for a much longer time.

Coastal substrates that have the potential for significant consolidation include fine-grained sediment that have not been previously loaded, for example, clays and silts deposited by river systems, organic peaty sediment, and sediment with interlaying organic strata. Sediment loaded at an earlier time in its geologic history, e.g., due to glacial loading or construction of infrastructure, will rebound slightly once the load is removed. If reloaded with a greater weight, they will continue the consolidation process. Terzaghi (1943) derived a relationship for primary consolidation based upon hydraulic principles. For one-dimensional vertical flow, the final consolidation, z_c, for a given increase in loading, $\Delta W(t)$, can be calculated as:

$$z_c = z_0 \left(\frac{C_c}{1 + e_0} \log_{10} \frac{W_0 + \Delta W(t)}{W_0} \right) \tag{9}$$

where z_0 is the initial thickness of compressible sediment; C_c is the compression index, which can be determined experimentally from a consolidation test; e_0 is the initial void ratio, equal to the volume of voids divided by the volume of solids, and averaged over z_0; and W_0 is the initial loading on the sediment. In a study of the consolidation potential for Louisiana sediment, Kuecher (1994) found values of $C_c = 4.7$ to 5 for peat and organic mud; 1 to 3 for prodelta mud; 0.86 for bay sediment; 0.123 for natural levee sands and

silts, and 0.063 for point bar sands. Larger C_c values indicate a greater potential for consolidation. For calculations presented herein, C_c was 0.86. The depth of undisturbed sediments, z_0, was determined to be 4.7 m through iteration with the model by reproducing the rate of relative sea level rise measured at Grand Isle, Louisiana (9.9 mm/year) given the eustatic rate in the region (2.4 mm/year, Stone and Morgan 1993).

Terzaghi's (1943) time-dependent relationship for consolidation is:

$$\frac{\partial u}{\partial t} = c_v \frac{\partial^2 u}{\partial z^2} \tag{10}$$

where u is pore water pressure in excess of hydrostatic pressure, t is elapsed time, c_v is a property of the compressible sediment, referred to as the coefficient of consolidation, and z is the vertical coordinate with the origin at the initial sediment surface. The proportion of the initial pore water pressure remaining at any time, $M(t)$, can be expressed as:

$$M(t) = \frac{1}{z_0}\int_0^{z_0} \frac{u}{u_0} dz = \frac{e(t) - e_f}{e_0 - e_f} \tag{11}$$

in which u_0 is the initial pore water pressure, $e(t)$ is the average void ratio at any time, and e_f is the final average void ratio. The variable $M(t)$ varies from 1 and 0, at time $t = 0$ and infinity, respectively. The proportion of vertical consolidation that occurs at any time can also be expressed as:

$$z(t) = z_c \left(\frac{e_0 - e(t)}{e_0 - e_f} \right) \tag{12}$$

Combining Eqs. (11) and (12) gives,

$$z(t) = z_c (1 - M(t)) \tag{13}$$

where $M(t)$ can be expressed as (Dean 2002, p. 119)

$$M(t) = 8 \sum_{n=1}^{\infty} \frac{e^{-\left[(2n-1)\pi\right]^2 c_v t / 4 z_0^2}}{(2n-1)^2 \pi^2} \tag{14}$$

APPLICATION

To determine the influence of barrier island width on migration, barrier island evolution was simulated with a storm surge and wave climate randomly generated about a mean value that ranged from 0.5 to 2 m relative to Mean Sea Level (MSL) (Figure 3). Dune elevations for the barrier islands were independently varied from 0.75 to 2 m MSL, with and without consolidation of the underlying substrate. All simulations ran for 100 years, and results from the MCO model are shown in Figures 4 through 8.

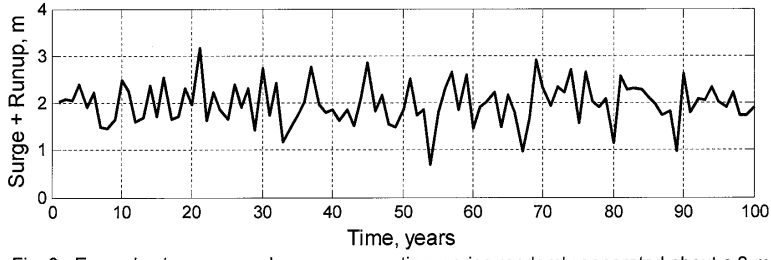

Fig. 3. Example storm surge plus wave runup time series randomly generated about a 2-m MSL mean

For each simulation, the minimum width at which migration does not change has been noted as the critical width. Results from these simulations can be summarized as:

(1) The magnitude of critical width increases for decreasing dune height. This finding implies that there is a critical cross-section required for minimum migration.

(2) The critical width increases with magnitude of storm surge plus wave runup.

(3) Figures 4 through 6 (storm surge plus wave runup from 0.5 to 1.5 m) show that barrier islands with greater consolidation of the substrate (dashed lines) result in greater migration distances and larger values of critical width as compared to barrier islands with lower consolidation substrates (solid lines). This is logical, because islands with greater consolidation reduce elevation as compared to lower consolidation substrates, and thus migrate more rapidly. However, Figures 7 and 8 (storm surge plus wave runup from 2 to

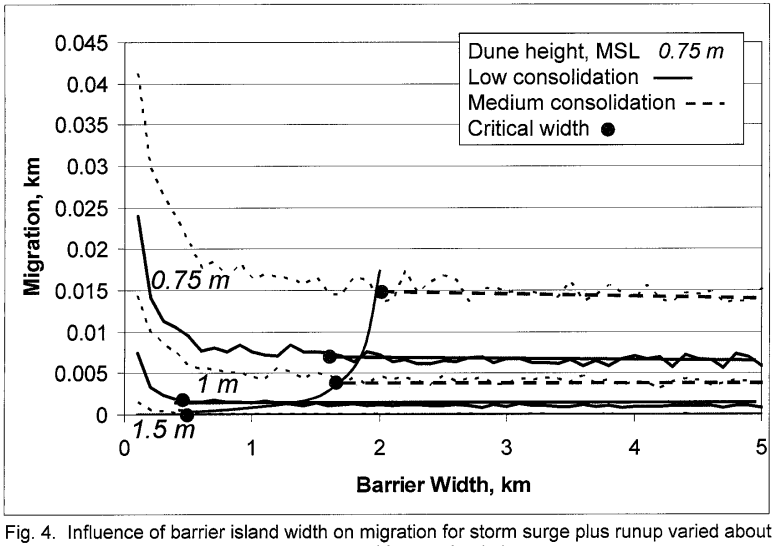

Fig. 4. Influence of barrier island width on migration for storm surge plus runup varied about 0.5-m mean, 100-year simulation

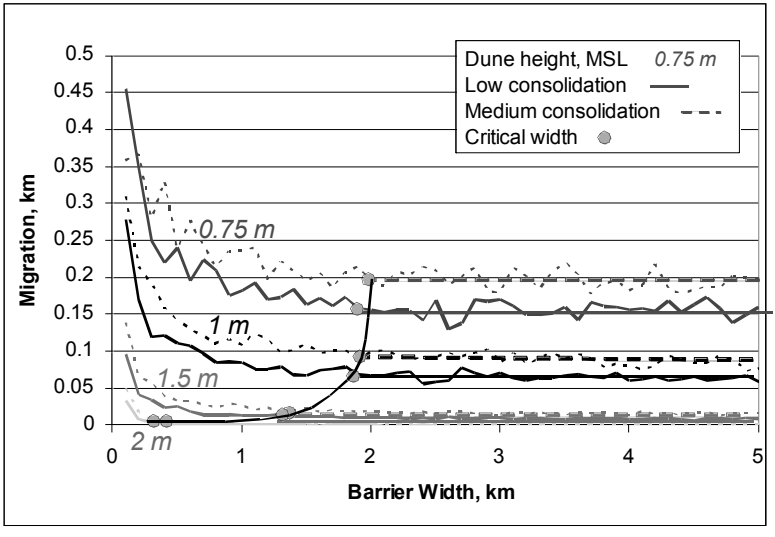

Fig. 5. Influence of barrier island width on migration for storm surge plus runup varied about 1-m mean, 100-year simulation

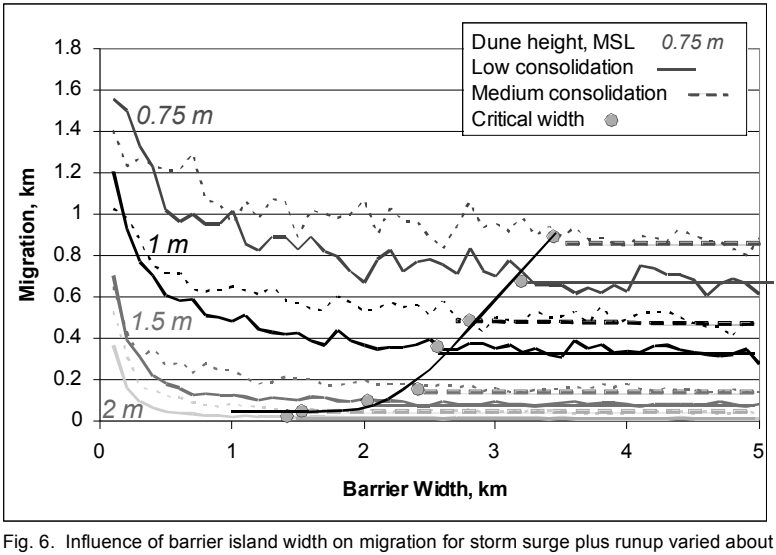

Fig. 6. Influence of barrier island width on migration for storm surge plus runup varied about 1.5-m mean, 100-year simulation

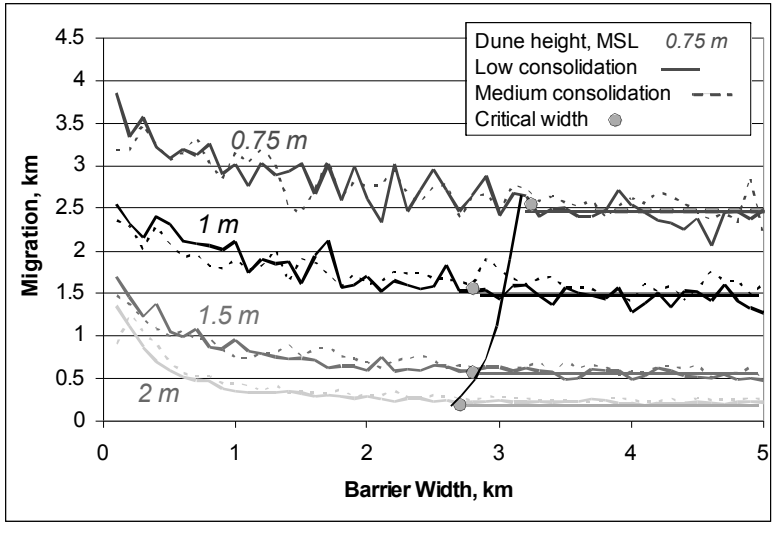

Fig. 7. Influence of barrier island width on migration for storm surge plus runup varied about 2-m mean, 100-year simulation

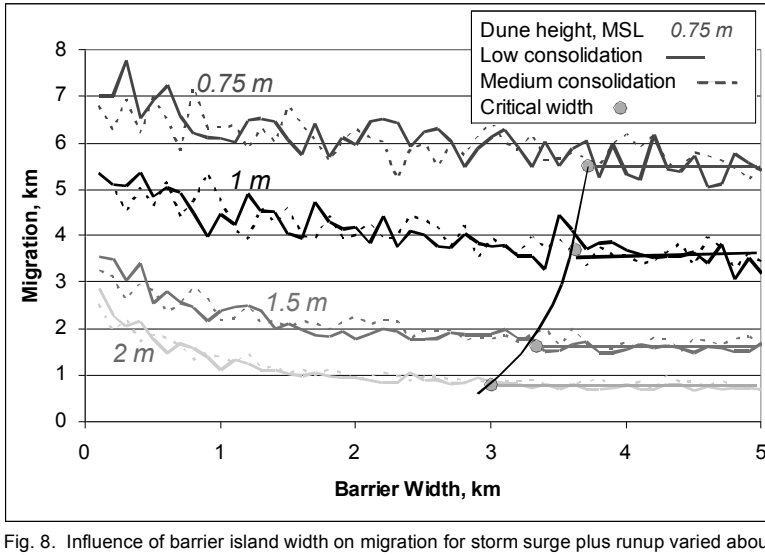

Fig. 8. Influence of barrier island width on migration for storm surge plus runup varied about 2.5-m mean, 100-year simulation

2.5 m) show that both types of substrates have similar migration and critical width values. The explanation for this result is that the barrier loading does not overlay the substrate for sufficient time for consolidation to be significant.

For each simulation with small consolidation, values of critical width and initial dune elevation were correlated with the storm surge plus wave runup. Figure 9 shows that the critical cross-sectional area, A_*, is slightly better correlated (R^2=0.72) to the storm surge plus runup, S, as compared to the critical width, W_* (R^2=0.64). These results indicate that, for barrier islands with small rates of consolidation of the underlying substrate, the critical cross-sectional area and width to reduce migration of the barrier island are 1,420 and 880 times the long-term (100-year) average surge plus wave runup, respectively.

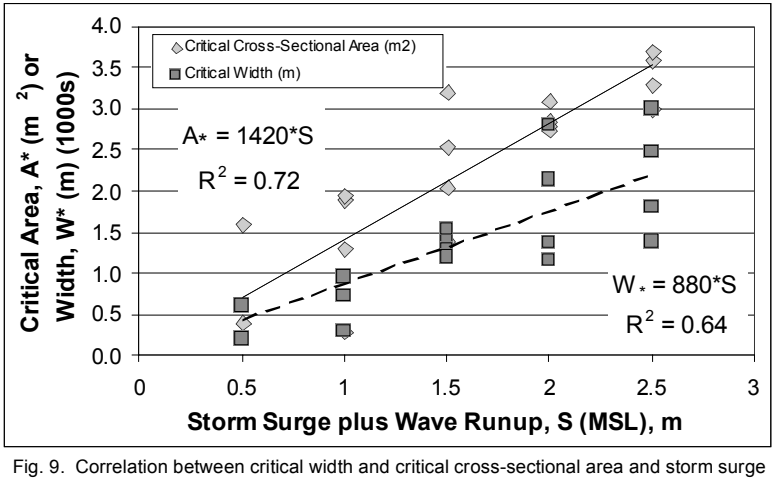

Fig. 9. Correlation between critical width and critical cross-sectional area and storm surge plus wave runup, low consolidation

SUMMARY AND CONCLUDING DISCUSSION

Critical width is the smallest cross-shore dimension that minimizes net loss of sediment from a barrier island and thus reduces migration of the island over periods of decades to centuries. The concept of critical width is important for large-scale barrier island restoration, in which islands are reconstructed to optimum height, width, and length for providing protection for estuaries, bays, marshes and mainland beaches. In this study, a recently Migration, Consolidation, and Overwash (MCO) model was applied to evaluate the dependence of barrier island width on migration rates and longevity of the island. Storm surge and wave forcing were randomly generated about mean values ranging from 0.5 to 2.5 m MSL, and barrier widths ranged from 100 m to 5 km and dune heights from 0.5 to 2 m. Low and medium values of consolidation were applied. Each MCO run simulated 100 years of hydrodynamic forcing and barrier island response.

Results indicated that there is a minimum width, the critical width, at which barrier island migration reaches a relatively constant value, regardless of increasing initial width. However, the barrier island critical cross-sectional area is better correlated to average long-term storm surge plus wave runup as compared to critical width. Preliminary recommendations from this study suggest that the critical cross-sectional area (with initial dune height and width, in square meters) to minimize long-term migration of a barrier island is 1,420 times the average surge plus wave runup (m), relative to a common datum. A slightly weaker correlation was obtained for the critical width, which is recommended as 880 times the average surge plus wave runup (m).

The above findings are based on hypothetical simulations for wave transformation over and sediment transport of non-cohesive sediment. For coastal settings such as in Louisiana, numerical predictions have been shown to overestimate measurements of wave energy during storms as waves are transformed over muddy seabeds (e.g., Sheremet and Stone 2003). Thus, actual storm waves for sandy barrier islands in a muddy environment may be less than predicted here, and this preliminary guidance may be slightly conservative. Also, barrier islands in Louisiana consist both of sand and a partially consolidated core of clay and silt sediments (Stone et al. 1995), which will respond differently to storms than these hypothetical simulations. During erosional wav and water level conditions, the sand surface sand may be eroded from these islands, leaving partially consolidated core clay and silt sediments that are more readily eroded during typical wave and water-level conditions as compared to non-cohesive sediment. Future research will compare these preliminary recommendations to field estimates of critical width.

ACKNOWLEDGEMENTS

This research was partially supported by the System-Wide Water Resources Program at the Engineer Research and Development Center's Coastal and Hydraulics Laboratory, U.S. Army Corps of Engineers. Permission was granted by the Chief, U.S. Army Corps of Engineers to publish this information. We thank Drs. R.G. Dean, N.C. Kraus, and H.H. Roberts for integral contributions to this research. We also thank Dr. Kraus for excellent review of the paper.

BARRIER ISLAND VULNERABILITY TO BREACHING: A CASE STUDY ON DAUPHIN ISLAND, ALABAMA

Mark Hansen[1] and Asbury H. Sallenger[2]

1. U.S. Geological Survey, Florida Integrated Science Center, Coastal and Watershed Studies, 600 4th Street South, St. Petersburg, FL 33701-4846, USA. mhansen@usgs.gov

Abstract: Breaching of barrier islands can adversely impact society by severing infrastructure, destroying private properties, and altering water quality in back bays and estuaries. This study provides a scheme that assesses the relative vulnerability of a barrier island to breach during storms. Dauphin Island, Alabama was selected for this study because it has a well documented history of island breaches and extensive geological and geomorphic data. To assess the vulnerability of the island, we defined several variables contributing to the risk of breaching: island geology, breaching history, and island topography and geomorphology. These variables were combined to form a breaching index (BI) value for cross island computational bins, each bin every 50 m in the alongshore direction. Results suggest the eastern section of Dauphin Island has the lowest risk of breaching with the remaining portion of the island having a moderate to high risk of breaching. Two reaches in the western section of the island were found to be particularly vulnerable due primarily to their minimal cross-sectional dimensions.

INTRODUCTION

The recent trend of numerous major hurricanes has significantly increased awareness of coastal impacts in terms of geomorphic changes and the vulnerability of society to storms. Even with improved data sets, such as lidar, and better numerical models, the magnitude and geographic extent of significant impacts and the prediction of vulnerability is still difficult. Island breaching is one impact that forces coastal changes on a local scale but also can affect a large portion of society by cutting off vital transportation routes for evacuation, rescue, and post-storm recovery. Costs to

repair a breach are significant. In addition to societal impacts, coastal breaching can adversely impact the environment by degradation of estuarine water quality and loss of sensitive habitats, exposure of bay waters to increased waves and currents, and accelerated destabilization of jetties (Kraus and Wamsley, 2003).

Barrier island breaches created during hurricanes form a conduit that allows water to flow between ocean and bay/lagoon water bodies at all stages of the tide. They typically occur in narrow areas of barrier islands or barrier spits. During storms in the Atlantic Ocean and Gulf of Mexico, seaward side breaching typically occurs because of a gradient in water level across the island caused by wave setup and storm surge. Bay side breaching is initiated by long periods of higher than normal water levels in the bay relative to the ocean. Inundation allows seepage into porous island sediments creating a liquefied condition (Kraus and Wamsley, 2003). Once the breach occurs, large volumes of sediment can be quickly transported as the sediments are already in a liquefied state. The underlying geological framework, geomorphology, and topography influence the location and evolution of coastal breaches. This study analyzes these basic parameters in order to create an index that ranks all stretches of a barrier island for their relative potential to breach. Island breaching history, if know, can also be used to indicate weaknesses in the island's internal and external structure, and indirectly measure critical physical processes that cannot be currently assessed or are otherwise unknown. The intent is not to predict exact breaching locations, but to provide guidance on barrier island vulnerability and to assist numerical modeling studies focus their domain boundaries.

Dauphin Island, Alabama (Fig. 1) was chosen for this study as it has a history of island breaching, a well documented geological framework, and high resolution topographic lidar surveys that cover the entire island. We anticipate applying techniques and results developed for Dauphin Island to the remaining Gulf of Mexico and Atlantic barrier islands as part of the U.S. Geological Survey's Hurricane and Extreme Storm Impact Studies. Our preliminary efforts and results are summarized below.

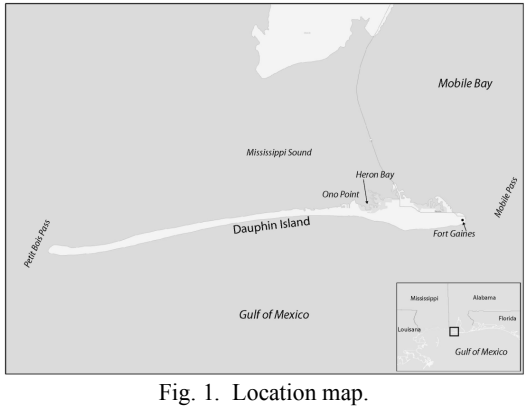

Fig. 1. Location map.

RISK VARIABLES
Geology

Dauphin Island is bounded by Mobile Pass to the east and Petit Bois Pass to the west, and protects Mississippi Sound and the Alabama mainland from direct wave attack. The eastern 5.5 km of the present island is composed of a Pleistocene (10,000 to 2 million years bf) core (Fig. 2) that was once a coastal ridge on the mainland (Otvos, 2005). As sea level rose, the former mainland was flooded leaving the peaks of the ridges emergent. Holocene (modern) sediments moving westward across the Mobile Bay ebb-tidal delta were deposited on the topographic highs forming beaches and dune fields. Juxtaposed on the Pleistocene core, the eastern end of Dauphin Island has active dune fields and is heavily forested with oaks and pines. Active sand dunes rise 14 m above sea level near Fort Gaines (Canis, et al., 1985). Sediments transported further westward formed a low lying (near sea-level) sand spit that now extends 22 km from Dauphin Island's eastern tip. The sand spit is typical of an active barrier island in that it lacks well developed continuous dunes, vegetation cover, and is backed by a marsh on the bay side. Since 1882, the length of Dauphin Island has varied from 16 to 25 km (Otvos, 1997). Petit Bois Island was once part of western Dauphin Island spit until a hurricane 150 ybp cleaved it and formed Petit Bois Pass.

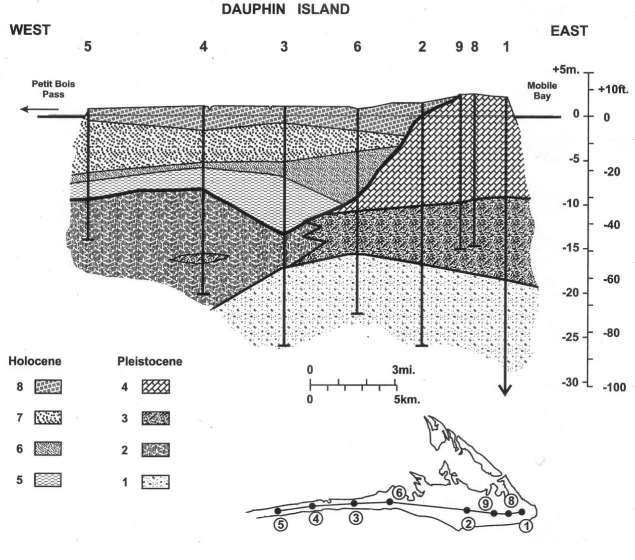

Fig. 2. W-E geologic cross-section across eastern Dauphin Island (Otvos, 2004).

Island Breaching History

The impacts of hurricanes have been documented on Dauphin Island for the past 150 years. An 1863 Civil War map of Alabama (Fig. 3) identifies an extensive breach in the central section of Dauphin Island. This breach had filled as revealed by the 1892 U.S. Coast and Geodetic Survey Chart #188. Chart #188 indicates Dauphin Island was a contiguous island, narrow through the center section, widening to the west, with a bulbous end on the western end. In 1916, a hurricane breached the island immediately west of the Pleistocene core near Oro Point creating an 8 km-wide shallow inlet (Canis, et al., 1985). The 1933 U.S. Coast and Geodetic Survey chart #1267 documents the breach, comparable in size to the one shown on the 1863 map. In 1947, another hurricane breached the island in the same central location. Hurricane Frederic impacted the island in 1979, creating multiple breaches west of Oro Point and formed continuous overwash deposits along the entire sand spit portion of the island. The 1981 National Oceanographic and Atmospheric Administration (NOAA) chart #11376 reveals the breach from Hurricane Frederic had filled in, leaving a thin band of sand backed by marsh. Prior to Hurricane Ivan in 2004, numerous roads and residential homes had been constructed along most of Dauphin Island. Hurricanes Ivan in 2004 (Fig. 4) and Katrina in 2005 created significant breaches and overwash deposits from Heron Bayou to the western end of the island.

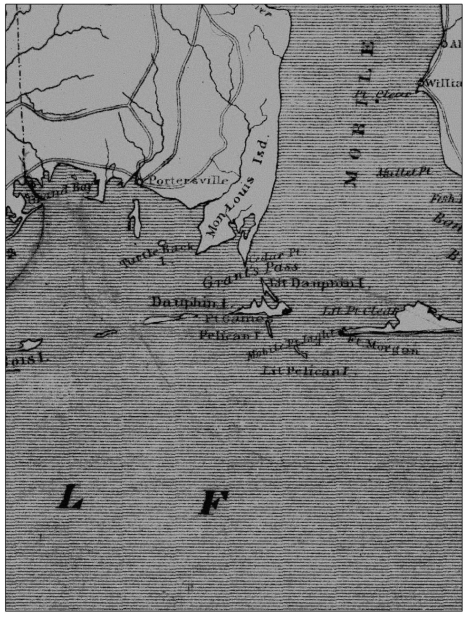

Fig. 3. Civil War era (1864) map indicating an island breach on Dauphin Island (NOAA archives).

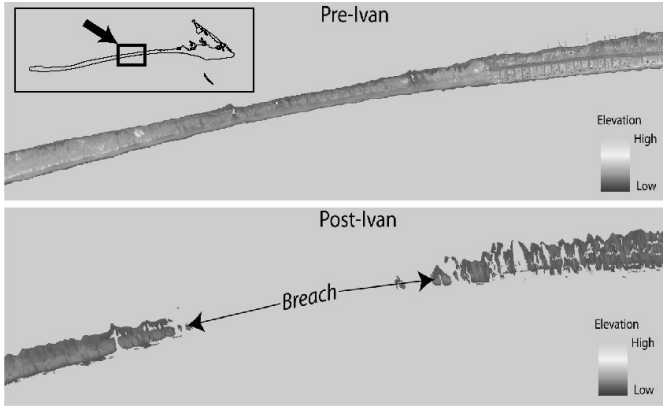

Fig 4. Dauphin Island, Alabama topography before and after Hurricane Ivan indicating multiple island breaches. Darker colors represent lower elevations and lighter colors represent higher elevations (USGS, 2007).

Topography

The topography of a barrier island greatly influences the response of an island to storms. We know that island width and height control the hydrodynamics of water flow across an island, e.g. areas with low elevation and narrow island width are more susceptible to overwash and breaching. Topographic information for Dauphin Island was derived from post Hurricane Katrina data acquired with the National Atmospheric and Space Administration (NASA) Experimental Advanced Airborne Research Lidar (EAARL) aircraft lidar system. Lidar data was processed to XYZ coordinates, and a surface grid was produced using an inverse distance weighting technique. To best model the true land surface, a structure and vegetation removal technique was applied to the surface grid. Grid values within the footprint of structures and vegetation were set to null or NaN.

Computational bins, 50 m in width, were generated normal to a shoreline parallel baseline along the entire length of the island, for a total of 510 bins for the entire island. Two measurements were computed for each bin, island width and a height.

Measuring island width is straightforward; however, assessing island height is complex due to beach, dune, and inland topographic features with an unlimited number of combinations. Island width was computed for each bin along a transect that bisected each bin. Width was computed as the distance from the shoreline (0 m NAVD88) on the ocean side to the shoreline on the bay side. When marsh islands or low-lying sand flats were present on the bay side, their bay fronting shorelines were considered the bay shoreline. Island height was derived in the following manner. Transects were generated normal to the shoreline parallel baseline at 2 m spacing, thus 25 transects were created for each computational bin. The maximum elevation along each transect was then identified. Island height for each bin was defined by the

minimum value of the maximum elevations. We believe this measurement of height best represents the inundation potential within each bin.

BREACHING INDEX

A breaching index (BI) was calculated for each bin. The breaching index used in this study was based upon the following categories: geology, island width, and island height. These categories were selected because of prior knowledge that each greatly influences island breaching (Kraus, 2003). The last category, breaching history, is included as an indicator of unknown structural weaknesses and physical processes. We believe there are numerous other categories that contribute to breaching, and our plan is to investigate these in future studies. For each category, a scaling value from 1 to 3 was assigned to each bin with 1 defined as the least risk and 3 the greatest risk.

For the geology category, bins where manmade structures (seawalls, revetments) are located contribute the lowest risk and were assigned a value of 1. Those located where resistive sediments (Pleistocene core) outcrop at the surface where given a value of 2. Bins in which Holocene sands are located contribute the greatest risk, thus were assigned a value of 3.

Island width was subdivided based upon standard deviations from the mean value. A scaling value of 1 represents values that are between the mean plus one standard deviation to the max, a scaling value of 2 represents values between plus and minus one standard deviation from the mean, and a scaling factor of 3 represents values that are between zero to the mean minus one standard deviation.

Island height was subdivided based upon the computed height relative to the maximum of the maximum (MOM) hurricane surge levels for Dauphin Island, derived from NOAA's SLOSH (Sea, Lake and Overland Surges from Hurricanes) numerical model. The SLOSH model estimates storm surge heights at specific locales based upon hurricane pressure, size, forward speed, track and winds. MOM estimates were calculated at the center of Dauphin Island for Category 1, 3, and 5 (Saffir-Simpson Scale) hurricanes. Estimated surges levels for the three hurricane categories was 1.55 m, 3.47 m, and 5.12 m NAVD88, respectively. Computational bins that had island heights between 0 and 3.47 m (Category 3) were assigned a scaling value of 3, those between 3.47 m and 5.12 m (Category 5) assigned a value of 2, and bin heights greater than 5.12 m given a scaling value of 1.

Zones that have not experienced breaching in the documented past have a value of 1, a single breach event is assigned a value of 2, and multiple breach events are assigned a scaling value of 3.

The breaching index calculation developed for this study is similar to that of Thieler and Hammar-Klose (2000) and Gornitz, et al. (1994). The contribution of each of the four categories to island breaching is unknown, thus each category has equal weighting when calculating the breaching index for each bin. This method clearly identifies those bins where all categories have either a minimum or maximum value;

however, it can artificially group bins having a mixed range of values. The index does not correlate directly with physical processes; however, each category is a result of geologic and coastal processes acting on the barrier island. Thus, the index implies the relative likelihood of where a breach may occur on the barrier island.

For each bin, a breaching index (see Eq. 1) is computed based upon assigned values from each category (Table 1). BI values have a potential range of 0.5 to 4.5. The breaching index is calculated as

$$BI = \sqrt{((a*b*c*d)/4)} \quad (1)$$

where: a = geology ; b = island width; c = island height; and d = breaching history.

Quartile BI divisions were created within this range: 0.5 to 1.5, low; 1.5 to 2.5, medium; 2.5 to 3.5, high; and 3.5 to 4.5, very high. Low values are considered to have a minimal risk of island breaching with high values a relatively greater risk of breaching. The calculated BI values for Dauphin Island (Fig. 6) range from 0.7 to 4.5.

Table 1. Ranking for each Breach Index (BI) category.

Ranking of Breaching Index Categories			
	Low	**Medium**	**High**
Variable	1	2	3
Geology/ Geomorphology	Hardened shore	Resistive core	Holocene sands
Island Width	(μ + δ) to max	(μ - δ) to (μ + δ)	0 to (μ - δ)
Island Height	< 3.47 m	> 3.47 m to < 5.12 m	> 5.12 m
Breaching History/Events	0	1	>1

DISCUSSION

The eastern section of the island from Mobile Pass to Heron Bay, is located on top of a Pleistocene core, has high relief and is significantly wider than other sections of the island. Here, the geological framework of Dauphin Island is expressed in the present day geomorphology and topography. As a result, the BI for this section is relatively low with values in the 0.7 to 1.5 range (Fig. 6). Since the 1850's, there have been no documented breaches from Heron Bay east to Mobile Bay. Results here suggest this section has a low risk of breaching.

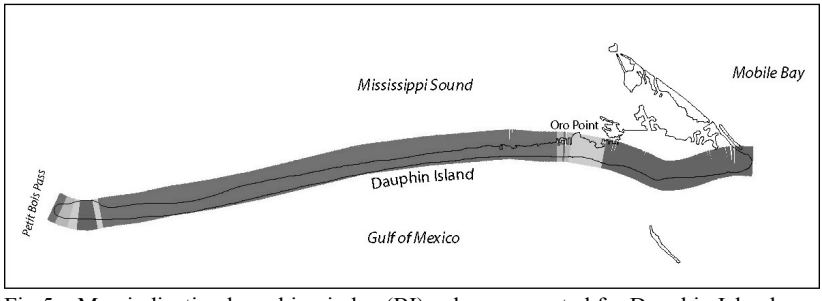

Fig 5. Map indicating breaching index (BI) values computed for Dauphin Island, Alabama. Color explanation: dark blue indicates low risk, light blue moderate risk, orange high risk, and red very high risk. (USGS, 2007)

A transition section in the region of Oro Point has moderate BI values in the range from 1.5 to 2.5. The section is characterized on the gulf side by absent or low lying dunes backed by a rather extensive marsh system on the bay. Extensive overwash deposits have been created in this region as a result of repeated hurricanes, most recently hurricanes Ivan and Katrina. These deposits in addition to marshes and islands near the bay shoreline widen the island relative to western sections, thus the width category strongly influences the BI values computed here.

Unlike the eastern section, the section of Dauphin Island from Oro Point to the western end is a sandy spit composed of coastal sands. Over the past 150 years, island breaches have been document numerous times in this section. It has no antecedent core and being relative young in age, has a relief of 0.5 to 2.0 m above MSL and is relatively narrow. Non-contiguous, low relief dunes are the only coastal protection. Significant overwash deposits are located here indicating total inundation of the island during recent storms. The bay side of this section is composed of coastal marshes and overwash fans. Low elevation and narrow width contribute significantly to the high BI values in this section. The BI values range from 3.5 to 4.5 suggesting this section has a high risk of breaching.

The bulbous, western end of Dauphin Island is composed of substantial dunes with a maximum relief of 3.5 m and is relatively wide. These factors contribute to low BI values ranging from 0.7 to 2.5. From this stretch to the western tip of the island, the BI values are high (2.5 to 4.5) due to low topography and narrow island width.

CONCLUSIONS

The breach index (BI) developed for Dauphin Island is a methodology for assessing the relative risk of island breaching during storms. It is based upon a limited number of known variables that control coastal processes or indicate physical weaknesses. For this study, each variable is assigned an equal weight or influence. An improvement would be a proportional weighting scheme with additional variables considered, such as bay volume and tidal prism.

We have documented the geological framework and geomorphologic anomalies of Dauphin Island, AL and found a correlation to documented breach locations. Hurricane induced inland breaches have occurred in the same general zones many times in the past 100 years. These breach zones are composed of island spit sediments, and are topographically low and narrow compared to other stretches. The BI values computed for these zones suggest they are at higher risk for future island breaching. Conversely, zones that are structurally more resistant to erosion and are relatively dimensionally larger have no documented island breaches. The BI values for these reaches are relatively low, suggesting a low risk for island breaching.

This study on Dauphin Island suggests potential hurricane induced coastal breach locations can be identified by applying existing knowledge of barrier island framework combined with detailed topographic and geomorphic information. Numerical modeling studies on island breaching could use these results to help focus domain boundaries. This information would be beneficial to coastal planners and emergency management teams for preparing evacuation routes and planning post-storm infrastructure recovery and repair. Coastal engineers may also benefit from such studies by redirecting dredge disposal locations to minimize the coastal breach potential, and thus reduce construction cost of post-event breach mitigation.

ACKNOWLEDGEMENTS

The lidar data used for this study was acquired through a joint agreement between the USGS, NASA, and the US Army Corps of Engineers. We would like to thank H. Stockton, P. Howd, L. Fauver, D. Thompson, E. Otvos, and R. Morton for their technical assistance and advice. This work was funded by the USGS Coastal and Marine Program's *Hurricane and Extreme Storm Impact Studies* Project.

Abstract: This paper introduces a time-dependent model of regional barrier island breaching for multiple openings, whether as permanent inlets or as new breaches to the same bay. The model allows an arbitrary number of breaches and is forced by tide, storm surge, and wave set up. Limitations on the hydrodynamics, hence calculated breach evolution, are those associated with the Keulegan inlet model. The model includes possible closure or limited breaching by shoaling of the breach channel by longshore transport. Capabilities of the multiple breaching model are examined through eight sensitivity tests.

INTRODUCTION

A breach in a barrier island occurs if inundation with strong flow develops a channel through the barrier. The inundation may be forced from the ocean side or the bay side. During a breach, the initial channel typically expands vertically and horizontally in exponential manner (Kraus 2003) to dynamic equilibrium dimensions. Forcing of the water flow in the breach is caused by a difference between bay and ocean water levels, influenced by wave runup and overwash.

High ocean water surface elevations and large waves associated with severe storms can produce multiple breaches along a coastal barrier island complex at regional spatial scales. Occurrences of multiple breach channels cut by storms has been reported (e.g., Price 1947; Terchunian and Merkert 1995; Wamsley and Hathaway 2004; Wutkowski 2004; Freeman et al. 2004), but there remains a paucity of quantitative barrier island

breach field data. Reviews of coastal barrier island breaching causes, processes, and remediation are given by Kraus and Wamsley (2003) and Wamsley and Kraus (2005).

Kraus and Hayashi (2005) developed a process-based numerical model to simulate morphologic evolution of coastal barrier island breaching for engineering use. The objective of the present study is to extend the capabilities of the Kraus and Hayashi model to include development and evolution of multiple breaches in areas along a barrier island, which may include presence of permanent inlets. This multiple-breach morphological model is applied on regional spatial scales by integration with the Cascade model of regional sediment transport and shoreline change (Larson et al. 2002; Larson and Kraus 2003; Larson et al. 2006; Connell and Kraus 2006; Larson et al. 2007).

COASTAL BREACH MODEL

The morphologic breaching model is based on analytical models for inlet stability and inlet channel cross-sectional area (Kraus 1998, 2003), and it has been extended to include morphologic evolution of a rectangular barrier island (Kraus 2003) and a stacked rectangle pyramidal barrier island (Kraus and Hayashi 2005). Studies have examined predictions of the coastal breach morphology model by comparison to field and laboratory breaches (Kraus and Hayashi 2005; Wamsley et al. 2006; Wamsley et al. 2007). The coastal breaching model simulates breaching by iteratively solving the 1-D Keulegan (1967) equations for inlet hydrodynamics to determine breach current velocity and bay elevation through time based on breach channel cross-sectional area and area of the bay. The coastal breaching model calculates under the assumptions that the bay must accommodate uniform water surface deviation, the bay is composed of vertical walls so that volume and surface area are directly correlated, and the breaches do not overlap.

If multiple breach channels are calculated to occur in the simulation, the Keulegan equations become:

$$\frac{\partial U_i}{\partial t} + \frac{g}{L_i}\left(\eta_B - \eta_O\right) + \left(K_{en,i} + K_{ex,i} + \frac{2c_{f,i}L_i}{R_{h,i}} \right) \frac{|U_i| U_i}{2L_i} = 0 \tag{1}$$

for momentum, and:

$$\sum_{i=1}^{N} (A_c)_i U_i = A_{Bay} \frac{d\eta_B}{dt} \tag{2}$$

for conservation of water volume, where U_i = depth-averaged and inlet-length integrated current velocity at breach or inlet i of N openings; t = time; g = gravitational acceleration; L = width of breach through the barrier island; η_O = water surface deviations from Mean Sea Level (MSL) in the ocean; K_{en} and K_{ex} = entrance and exit losses, respectively (non-dimensional); R_H = hydraulic radius of the breach or inlet (m); A_C = breach or inlet channel cross-sectional area below MSL (m^2); A_{Bay} = surface area of the bay (m^2). The bottom friction coefficient c_f is represented by Mannings formula,

$$c_f = g n^2 / h^{1/3} \tag{3}$$

in which n = Mannings coefficient typically set as 0.025 s/m$^{1/3}$; and h = water depth.

Sediment transport through the breach is calculated employing the Watanabe et al. (1991) total load formula:

$$q_B = \alpha \frac{(\tau_m - \tau_c)}{\rho g} U \tag{4}$$

in which α = empirical coefficient typically of order 0.1 to 10 (non-dimensional); $\tau_m = c_f \rho \langle |U| U \rangle$, the time-averaged bottom shear stress for waves and current; $\tau_c = (\rho_s - \rho) g d_{50} \Psi_c$, the critical shear for sediment motion, where ρ_s is the density of sand (kg/m^3), ρ is the density of water (kg/m^3), d_{50} = median grain size diameter (m); and Ψ_c = critical Shields parameter, set to 0.05 for fine to medium sand.

If waves are not included in the breaching simulation, Eq. 4 becomes:

$$q_B = \alpha \left[\frac{n^2}{h^{1/3}} U^3 - \left(\frac{\rho_S}{\rho} - 1 \right) d_{50} \Psi_c U \right] \tag{5}$$

Sediment transport along the walls of the channel is calculated as a fraction of the transport along the breach floor. A typical value for side transport is approximately 70% of the transport along the channel.

$$q_S = \beta q_B \tag{6}$$

where β is the calibration factor for the channel wall fraction (e.g., 0.7).

The wave setup contribution to mean water level at the shoreline is calculated following Stockdon et al. (2006):

$$\eta_{setup} = 0.35 \beta_f \sqrt{H_0 L_0} \tag{7}$$

where β_f = beach foreshore slope; H_0 = deep-water wave height (m); L_0 = deep-water wavelength (m). Kraus and Hayashi 2005; Wamsley et al. (2006) discuss calculation of channel infilling and shoaling due to longshore transport estimates calculated from wave input data. Longshore transport is implemented in the coastal breaching model with the CERC formula in the *Coastal Engineering Manual* (Headquarters, U.S. Army Corps of Engineers 2002):

$$Q_l = K\left(\frac{\rho\sqrt{g}}{16\kappa^{\frac{1}{2}}(\rho_s-\rho)(1-n)}\right)H_{b\,rms}^{\frac{5}{2}}\sin(2\alpha_b) \quad (8)$$

where K = dimensionless sediment transport coefficient based on wave energy, κ =breaker index (non-dimensional ~ 0.8), n = sediment porosity, $H_{b\,\mathrm{rms}}$ = root-mean-square wave height at breaking point (m), and α_b = wave breaking angle.

The present study extends the capabilities of the morphologic breaching model by implementing multiple breaches with variable (in time and space) breach forcing. Furthermore, breaching model connectivity with the Cascade model is now possible by employing a subset of the wave and water surface elevation data used as inputs to Cascade, and spatially and temporally variable longshore sediment transport. Cascade output can control breach infilling and shoaling rates by longshore transport in place of Eq. 8 in the breaching model, subject of a planned future paper.

METHOD

An idealized alongshore barrier dune-crest topography (Fig. 1) was developed to simulate breaching at topographic lows in the dunes. This topography can be arbitrary, and the topographic lows function as potential pilot channels for the breaching model. Pilot channels of different elevations may exist, providing selective inundation for different water levels at various times in a storm and thereafter. Morphologic evolution of breach channels occurs only if the pilot channel is inundated. Local forcing, including longshore transport, waves, water level, and shoreline position for the breaches is provided at regional scale by the Cascade model. Sensitivity tests are conducted to isolate some of the complex processes that force change in breach morphology and to evaluate the functionality of the model under hypothetical forcing.

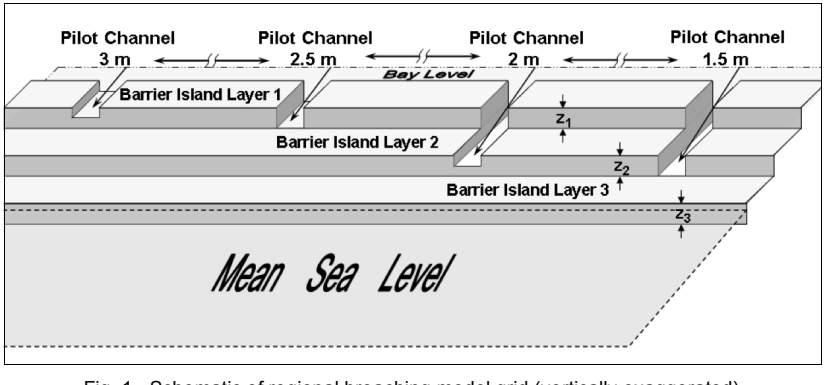

Fig. 1. Schematic of regional breaching model grid (vertically exaggerated)

Eight 14-day simulations of the evolution of multiple breach channels were conducted (Table 1) with the idealized barrier alongshore topography. Dune crest elevation was 3.5 m, and four different pilot channels 10 m wide by 50 m long were cut with elevations of 3, 2.5, 2, and 1.5 m. The location of the pilot channels along the barrier island is arbitrary and influenced only where input forcing is (optionally) extracted from Cascade. It is assumed that the breaches cannot converge, and therefore, pilot channels cannot be located at points along the barrier where the potential exists for two or more breaches to merge into one. Bay surface area was held constant at 5×10^8 m^2. The time-step for the simulations was set at 10 s. Empirical coefficients for sediment transport along the bottom and along the side of the breach were set to 0.5 and 0.7, respectively. Sediment porosity was 0.4, and the *K*-coefficient of the CERC formula was set to 0.39 (based on significant wave height). Finally, water (sediment) density was set to 1,025 kg/m^3 (2,650 kg/m^3).

The first sensitivity test (Case HD) held a constant 0.2-m head difference along the entire length of the barrier generated by a constant ocean water surface elevation at 3-m above MSL and a constant bay water surface elevation at 2.8-m above MSL. Two other cases were conducted employing the same constant head difference water level forcing between ocean and bay, added wave forcing to simulate wave setup forcing and sediment infilling due to longshore transport. Case HD-H1_T8_D0 includes waves with constant $H_0 = 1$ m, $T_0 = 8$ s, and $б_0 = 0$ deg, and Case HD-H1_T8_D30 includes waves with constant $H_0 = 1$ m, $T_0 = 8$ s, and $б_0 = 30$ deg.

Three sensitivity tests were conducted forced with a 1-m amplitude M_2 (12.42-hr period) tidal wave with 90-deg phase lag between the ocean and bay levels, applied along the entire length of the barrier with a vertical datum shift of 2-m above MSL. These cases are listed in Table 1 as Case M2, Case M2-H1_T8_D0, and Case M2-H1_T8_D30. Two cases also included wave forcing to estimate wave setup and sediment infilling due to longshore transport. Case M2-H1_T8_D0 includes waves with constant $H_0 = 1$ m, $T_0 = 8$ s, and $\alpha_0 = 0$ deg, and Case M2-H1_T8_D30 includes waves with constant $H_0 = 1$ m, $T_0 = 8$ s, and $б_0 = 30$ deg.

The two remaining sensitivity tests examined response of the model to a synthetic storm surge. The first of the storm surge simulations (Case Surge in Table 1) was forced with a constant water level 1 m above MSL until day 5, after which a 2 m simulated parabolic storm surge extending over 2 days was added to initiate breach inundation (Fig. 2). This surge was set out of phase for each breach channel so that each breach would be initiated 6 hr after the previous breach. The second surge case (Case Surge+M2 in Table 1) consisted of the same synthetic surge as Case Surge, but the surge arrival was equal for all breaches, and a simple 1-m M_2 tide with 90-deg phase lag between the ocean and bay levels was added to the surge (Fig. 3). This M_2 tide differed from Case M2 in that it did not reach 2 m above MSL to prevent breach inundation prior to the surge arrival.

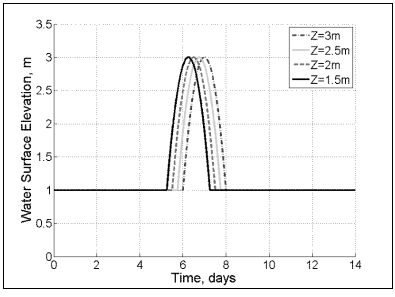

Fig. 2. Ocean and bay water level – Case Surge

Table 1. Regional Breach Model Sensitivity Test Cases

Case Name	Water level forcing	Deep Water Wave Height (H_0), m	Deep Water Wave Period (T_0), s	Deep Water Wave Deg (α_0), deg
HD	Constant ocean = 3 m constant bay = 2.8 m	N/A	N/A	N/A
HD-H1_T8_D0	Constant ocean = 3 m constant bay = 2.8 m	1	8	0
HD-H1_T8_D30	Constant ocean = 3 m constant bay = 2.8 m	1	8	30
M2	M_2-tide amp: 1 m phase: ocean = 0° phase: bay = 90°	N/A	N/A	N/A
M2-H1_T8_D0	M_2-tide amp: 1 m phase: ocean = 0° phase: bay = 90°	1	8	0
M2-H1_T8_D30	M_2-tide amp: 1 m phase: ocean = 0° phase: bay = 90°	1	8	30
Surge	2-m storm surge w/6-min arrival delay for consecutive breach	N/A	N/A	N/A
Surge+M2	2-m storm surge + M_2-tide amp: 1-m phase:ocean = 0° phase: bay = 90°	N/A	N/A	N/A

RESULTS

Calculated evolution of breach channel depth, width, total transport through the four breaches, and cross-sectional area are shown in Figs. 4-7. Breaches that started in pilot channels at lower elevation (e.g., elevation $z = 1.5$ m, $z = 2$ m) were cut deeper (Fig. 4) and at a faster rate than those that developed in pilot channels at higher elevations (e.g., $z = 2.5$ m, $z = 3$ m). Conversely, the lateral growth of higher elevation channels in Fig. 5 is greater than the deeper, low-elevation channels. The greater lateral growth is explained by increased shear stresses by bottom friction in the sediment transport and hydrodynamic models. Breaching is not induced at the pilot channel stating at $z = 3$ m, because this elevation is the same as the ocean water surface elevation. Stair-shaped behavior observed in Fig. 6 is an artifact of the layered pyramidal barrier island, corresponding to the transport rates being reduced as a result of channel cuts into incrementally longer (in cross-shore orientation) barrier island layers. As breach channel depth increases, the transport can increase in magnitude and duration.

Figure 7 shows the breach cross-sectional area over the simulation period for Case HD. Breach channel cross-sectional area is a representation of the channel dimensions and serves as a good indicator of channel stability and channel evolution morphology. A delayed and extended incipient breaching stage occurs in the breach channel initially at $z = 2.5$ m relative to the channels at $z = 2$ and $z = 1.5$ m. This is, again, explained by the increased shear stress associated with shallow water over the channel bottom. A shallower channel is forced to grow laterally if sediment transport rates (Fig. 6) increase due to greater shear stress applied over a larger channel bottom surface area than generated in deeper breach channels.

Figures 8 and 9 compare breach channel cross-sectional area for Cases HD-H1_T8_D0 and HD-H1_T8_D30, respectively. Figure 8 retains many of the same patterns observed in the cross-sectional area plots of Case HD (Fig. 7). However, because of the presence of waves and the associated wave setup, a shorter incipient breaching stage is observed at the breach of $z = 2.5$ m, and the channel cross-sectional area for each breach in Fig. 8 at the end of the simulation is greater than those observed in Fig. 7. Figure 9 shows an entirely different pattern. In fact, due to the large incident wave angle relative to shoreline, significant longshore transport causes most of the channels to shoal. Breach closure does not occur for the breach at $z = 1.5$ m because this breach pilot channel is sufficiently deep to avoid closure during the incipient phase of the breach.

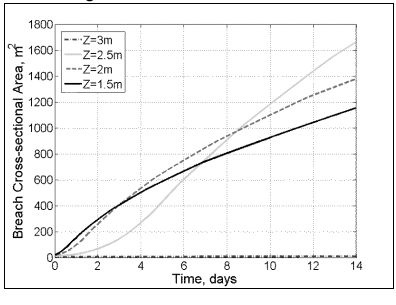

Fig. 8. Calculated Breach channel cross-sectional area evolution, HD_H1_T8_D0

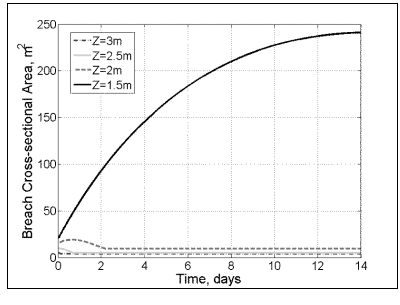

Fig. 9. Calculated Breach channel cross-sectional area evolution, HD_H1_T8_D30

Figures 10-13 illustrate breach transport and cross-sectional area for the M2, M2-H1_T8_D0, and M2-H1_T8_D30 cases. Figure 10 demonstrates the periodicity of sediment transport associated with the M_2 water elevation forcing. Depending on level of the breach channel relative to the forcing water level, transport rates may never approach zero, whereas sometimes the breach channel may be completely depleted of water as seen in Fig. 10 (z = 2.5 m). This switching on and off of transport rates

significantly reduces total transport through the breach as shown by the relative difference in cross-sectional area plots (Fig. 11) between $z = 2.5$ m and the much greater cross-sectional area represented in the $z = 1.5$ m and $z = 2$ m pilot channels. Case M2-H1_T8_D0 (Fig. 12) also demonstrates similar morphologic response as Case M2 (Fig. 11), but with slightly greater cross-sectional area and shorter incipient breach phase times. It appears that, in this case, the addition of wave setup has increased flow through the breaches, thereby increasing the channel area. Significant differences in cross-sectional area are achieved in Case M2-H1_T8_D30 with waves approaching at an incident angle (Fig. 13). This case suggests that a breach channel can be overwhelmed by longshore sediment transport, and infilling occurs to the point of closure such that the breach cross section remains constant, and the channel is no longer inundated.

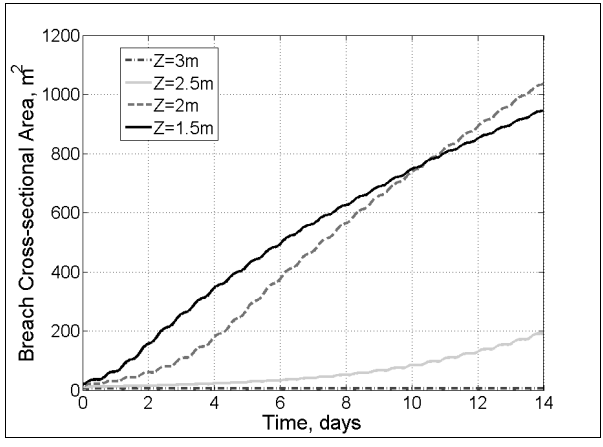

Fig. 12. Breach channel cross-sectional area evolution, Case M2-H1_T8_D0

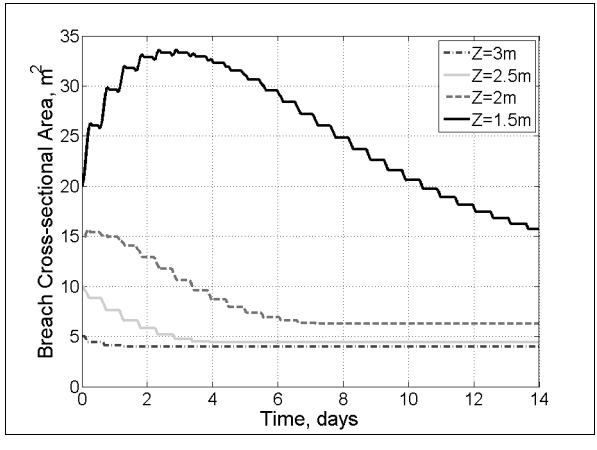

Fig. 13. Breach channel cross-sectional area evolution, Case M2-H1_T8_D30

Figures 14-17 illustrate breach transport and cross-sectional area for the Surge and the Surge+M2 cases. Because of the rapid increase in water level fromr the simulated storm surge, peaks in sediment transport (Fig. 14) are present immediately after inundation. These peaks grow progressively as pilot channels of initial elevations z = 1.5 m, z = 2 m, and z = 2.5 m are separately inundated and expanded. The growth of the peaks corresponds to the increase in incipient transport according to the depth of water in the breach channel. Shallow channels can transport more sediment because of larger bottom shear stress. Figure 15 indicates a rapid increase in cross-sectional area associated with the time of the storm surge.

Figure 16 illustrates the difference caused by addition of a tide to the storm surge. Because of the higher frequency M_2 tide relative to the surge, sediment transport (Fig. 16) goes to zero at periods of low tide during the surge. After the surge, transport rates for breaches at z = 1.5 m and z = 2 m continue to oscillate at the tidal frequency, indicating an open breach remains. Intermittent drying of the inlet causes a much reduced transport for the breach channels that had high pilot channels (z = 3 m, z = 2.5 m) where little to no inundation is present. Because of the reduced transport, the higher elevation channels remain closed after the surge, and cross-sectional area is constant (Fig. 17).

CONCLUDING DISCUSSION

This study investigated predictions of a new numerical model of multiple coastal barrier breaches at a regional scale allowing, for example, investigation of processes associated with independent evolution of each breach. Numerical simulations of coastal breaches at regional scale improve understanding of the physical processes by isolating forcing mechanisms and comparing responses of breach channels of varying dimensions. Enhancements to the morphologic breaching model add the capability to simulate multiple breach development at the regional scale with boundary condition forcing interaction with Cascade.

Calculation results indicate that slow, shallow inundation of breach pilot channels tends to produce breach width expanding at a greater rate than breach depth. This is likely due to the increased shear stress applied over a wider breach channel surface area in the model. A shallow breach also promotes a longer incipient breach phase and longer time before developing a tidally efficient channel. Fast and large inundation appears to promote rapid increase in depth as well as a more rapid incipient breach phase, where the cross-sectional area quickly changes.

Future research will examine model performance by comparison of predictions with observations of multiple breaches serving the same bay. Developments of the regional breaching model are expected to continue with an embedded form in Cascade for fully automated forcing and interaction. Finally, interaction between breaches serving the same bay will need to be represented for examining multiple inlet stability for a nearly fixed available tidal prism.

ACKNOWLEDGEMENTS

This study was conducted as an activity of the Coastal Morphology Modeling and Management (Cascade) work unit of the System-Wide Water Resources Program (SWWRP) with support from the Coastal Inlets Research Program (CIRP) conducted at the U.S. Army Engineer Research and Development Center. Permission was granted by Headquarters, U.S. Army Corps of Engineers, to publish this information.

Abstract: The formation of a new breach through coastal barrier islands is relatively common occurrence during extreme storm events. In fact, breaching has a significant role in the development and long-term morphological evolution of natural barrier islands by providing the backbarrier with sediments that accommodate both barrier island migration and the establishment of new intertidal and subtidal habitats. However, breaches also have the potential to adversely affect adjacent bays and inlets with conditions including increased water levels, damages to buildings and infrastructure on the barrier island, and impacts to existing inlets which may experience increased shoaling or even closure in the event of a breach. This paper examines the analytical/empirical tools presently used to assess breach stability and long-term growth, and it presents preliminary results from an initial attempt to simulate these processes using a numerical morphological model.

INTRODUCTION

Due to some or all of the impacts related to breaching listed above, there is generally an interest in the part of local stakeholders to close a new breach as soon as possible typically by means of placing sand from an available borrow source. In fact, in places like Long Island, New York, contingency plans have been developed to respond quickly to any barrier island breaches that may occur (USACE, 1996). Design, economic justification, and even environmental mitigation measures associated with such contingency plans require knowledge of the likelihood that a new breach will remain

open at a specific location (i.e., breach stability) and its long-term growth potential, including sediment accumulation in the ebb and flood shoals.

Until very recently, the only tools available to coastal engineers to analyze these processes consisted of simplified analytical models of breach/inlet stability based on the Escoffier closure curve concept (van de Kreeke, 1984) and analytical breach cross-sectional growth functions fitted to available empirical data (USACE, 1996). Although these tools are still considered indispensable, recent developments in numerical modeling have allowed scientists and engineers to explore in more detail the hydrodynamic, sediment transport, and morphologic processes associated with breach stability and growth.

This presents the results of an initial attempt to model breach stability and long-term breach growth using the Delft3D morphological modeling system. The advantage of this numerical, process-based approach is that it does not require schematization of the inlet/bay system and it specifically accounts for all of the relevant coastal processes (i.e., tides, currents, waves, and sediment transport). The analytical approach to determine breach and inlet stability based on the Escoffier inlet closure curve concept requires significant schematization of the hydrodynamic and sediment transport processes, which leads to results that are extremely sensitive to input assumptions regarding controlling inlet cross-sectional area and inlet length, friction losses, and equilibrium shear stress/flow velocity. Needless to say, the reliability of breach growth estimates based on empirical data is a direct function of the amount and quality of the data, as well as its applicability to the area of interest. For most coastal areas this type of data is non-existent.

ANALYTICAL/EMPIRICAL TOOLS

The following paragraphs provide a brief summary of the analytical and empirical tools commonly used by coastal engineers to study breach and inlet processes and some of the drawbacks associated with these techniques. An application example and results are also presented below. In the following section, these examples will be used as a benchmark to evaluate the performance of the morphological models.

Breach/Inlet Stability

Escoffier (1940), O'Brien and Dean (1972), Bruun (1978) and many others have developed methodologies which can be used to assess the stability of a tidal inlet against closure. Each of these authors advance the argument that inlet stability depends on the balance between tidal flows which tend to keep the channel open and littoral drift which tends to close the inlet. The O'Brien and Dean (1972) theory has been applied to both Moriches and Shinnecock Inlets by the New York District (1983, 1987) to assess the overall stability of those inlets. Van de Kreeke (1984, 1990a, 1990b) extended tidal inlet stability theory to address the matter of multiple inlets connected to a single bay. The analysis provides a means for determining whether: (1) the bays can support more than one inlet, and (2) if not, which opening, i.e. the breach or existing inlet, is most likely to remain open.

Inlet stability analyses focuses on the equilibrium between inlet cross-sectional area and inlet hydrodynamics. The controlling variables are the actual tidal maximum velocity (or shear stress) in the tidal inlet, and the equilibrium tidal velocity (or shear stress) that is required to flush sediments carried into the inlet by longshore currents. According to Bruun (1978), Van de Kreeke (1990), and others, the equilibrium velocity for most inlets is 1 meter per second (3.28 feet per second). This velocity corresponds to an equilibrium shear stress of about 4.5 Newton per meter squared (N/m^2). When the actual velocity equals the equilibrium velocity the inlet is in equilibrium. When the actual velocity exceeds the equilibrium velocity then the inlet is in a scouring or erosional mode, and conversely, when the actual velocity is lower than the equilibrium velocity the inlet is in a shoaling or depositional mode. The equilibrium velocity, among other factors, depends on the magnitude and direction of longshore sediment transport rates. Specifically, the equilibrium velocity increases with littoral transport rate.

Escoffier (1940) was the first to present the concept of a closure curve which is a plot of inlet cross-section (abscissa) versus inlet velocity or shear stress (ordinate axis). An illustrative example is presented in Figure 1 which shows that shear stress (and velocity) initially increases with inlet area, reaches a maximum value, and then steadily decreases with increasing area. The first portion of the curve (i.e., $A < Au$) pertains to flow conditions that are dictated by frictional forces, i.e., flow is restricted by friction in the inlet. On the right hand side of the curve, flow velocities and attendant shear stress ($A > As$) are controlled by continuity considerations where the discharge remains constant and velocity decreases with an increase in flow area. The equilibrium flow velocity is normally plotted on the closure curve in order to make judgments about the inlet stability, see Figure 1.

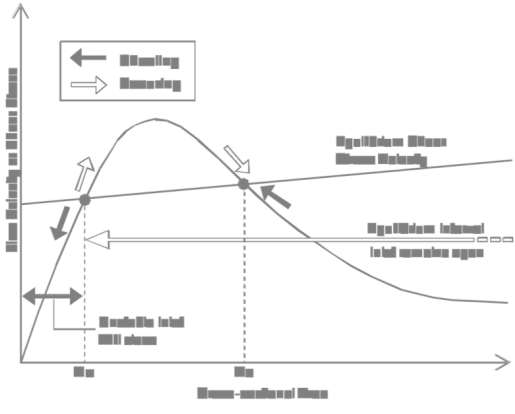

Fig. 1. Escoffier's Inlet Stability Diagram

Referring to Figure 1, *Au* represents an unstable inlet cross-sectional area, while *As* represents a stable cross-sectional area. An inlet is considered stable when the cross-section area is in the equilibrium interval which is defined as the portion of the closure curve which has cross-sectional area characteristics of $A > Au$. For $A < Au$, inlet velocities are incapable of clearing the inlet of shoaled sediment and will eventually close. Similarly, for $A > As$, inlet velocities are insufficient to keep the inlet from shoaling and the inlet cross section will eventually return to an area within the equilibrium interval. The actual area of the inlet will tend to vary over time depending on the continuous balance between scouring potential and longshore sediment transport. Stable inlets will have areas which remain in the equilibrium interval. An inlet can close, however, if a severe storm deposits a large amount of sediment in the inlet resulting in a cross-section lower than *Au*. Inlets which are marginally stable or those which remain open through dredging are most vulnerable to closure.

The stability analysis of a two-inlet bay system has been the subject of studies of Van de Kreeke (1985; 1988; 1990a; 1990b). Generally, for both inlets to have a stable cross-section, the enhanced parts of the equilibrium flow curves must intersect. This situation does not often occur in nature. Therefore, where two inlets connect the same bay to the ocean it is more likely that, at best, one inlet will remain open.

One drawback with this stability curve methods is that the analysis is typically based on a more or less schematized description of the inlet/bay hydrodynamics that allows for analytical computations or relatively simple numerical methods (Seabergh and Kraus, 1997). This makes the choice of input parameters such representative inlet and dimensions, representative tide levels, and friction energy losses a very sensitive task. Conversely, however, these methods allow for rapid evaluation of multiple scenarios and are simple to use and calibrate.

Application to FIMP

As part of the U.S. Army Corps of Engineers' (USACE) Fire Island to Montauk Point (FIMP) Reformulation Study (http://www.nan.usace.army.mil/fimp/reform.htm) multiple inlet stability analyses were carried out for the inlets and bays within the study area. (Figure 2). The work concluded that all three bays are vulnerable to breach formation. In the case of Great South Bay, results suggest that the existing Fire Island Inlet would shoal and maybe even close, while the breach would remain open. In the case of Moriches and Shinnecock Bays, the analyses also concluded that one of the openings would tend towards closure in the long-term, however which opening (the existing inlet or the breach) would depend on the exact location of the breach (Headland et al, 1999).

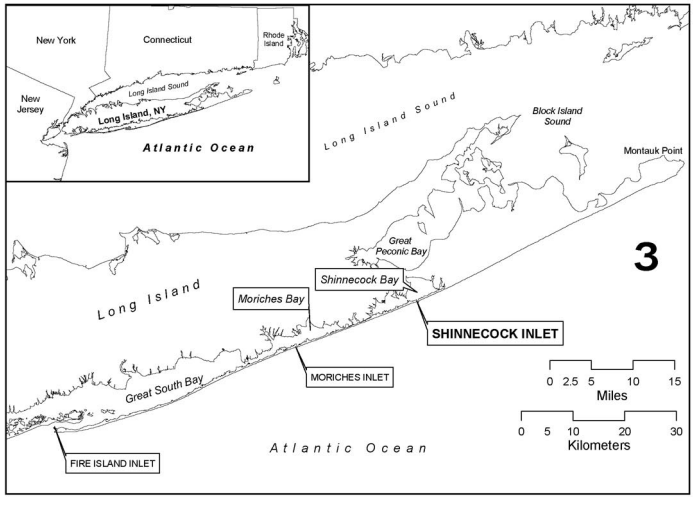

Fig. 2. FIMP Study Area

Long-term Breach Growth

As part of the FIMP study, a Breach Contingency Plan (BCP) was developed to determine what measures can be taken by Federal, State and local governments to react quickly to breach conditions along the FIMP study area (USACE, 1996). The BCP examined historic breach data to determine long-term growth characteristics and sediment transport processes. Of the breaches that have occurred within the FIMP study area during and after 1938, three remained open for long periods (i.e., several months or more). Shinnecock Inlet opened on September 21, 1938 and was subsequently stabilized. The January 14, 1980 northeaster opened a breach adjacent to Moriches Inlet. A fill project completed on February 25, 1981 closed this breach. The northeaster that struck Westhampton on December 10, 1992, created two breaches. One of the breaches was closed mechanically using dredged material from the Intracoastal Waterway (ICW) within a month of opening. The one that remained open expanded to an average width of 1,800 feet before being closed mechanically in October, 1993. Based on the growth of these three breaches the BCP presented a method for estimating breach along-shore cross-sectional area versus time according to the following exponential breach growth equation:

$$A(t) = A_0\left(1 - e^{-kt}\right) \tag{1}$$

Where t is the time in months from breach initiation, A_0 is the maximum breach cross sectional area, and k is the breach growth coefficient which varies from 0.15 to 0.30 month^{-1}. These parameters vary depending on the bay where the breach occurs and were obtained as part of the breach inlet stability analysis (USACE, 1996). Specifically, the maximum breach cross sectional area is based on long-term stable values corresponding

to existing tidal inlet areas. As such, breach growth would be attended by a reduction of tidal inlet area, although the trade-off between inlet and breaches areas may not be absolute. This behavior was observed during the breach at Moriches Inlet in 1980 when cross-sectional surveys of the breach and inlet indicated that the total area of both inlets was constant at approximately 2,000 m^2. Estimated growth parameter values are summarized for Great South Bay, Moriches Bay, and Shinnecock Bay in Table 1. These breach growth equation and selected parameter values compare favorably with survey data for the 1980 and 1992 breaches at Cupsogue and Pikes Beach, respectively (USACE, 1996).

Table 1. Breach Growth Parameters

Project Reach	A_0 *(sq. m.)*	k *(month)*$^{-1}$
GSB	3,350	0.15-0.3 (0.2 average)
MB	1,500	0.15-0.4 (0.3 average)
SB	1,640	0.15-0.4 (0.3 average)

Estimated potential breach cross-sectional areas are shown in Figure 3, assuming probable breach closure scenarios based on the experience at Westhampton Beach and recommendations of (i.e., 1 to 12 months).

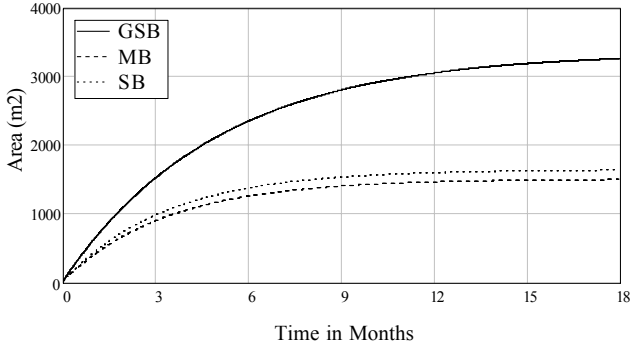

Fig. 3. Breach Growth Curves

MORPHOLOGICAL MODELING

Generic bay-inlet-breach morphological models were developed using the Delft3D modeling system. Geometry and dimensions of the bay and inlet are roughly representative of bay-inlet systems within the FIMP area. Specifically, a rectangular grid was built covering an area roughly equal to Great South Bay and with an inlet similar in geometry and dimensions to Fire Island Inlet. A second, also rectangular, grid representative of Moriches and Shinnecock bays was also built. The geometry was kept very simple to minimize required grid resolution and computational expense.

Delft3D Modeling System

Delft3D is a surface water modeling system which allows for flexible integration of hydrodynamic, wave, sediment transport, and morphology update models (WL | Delft Hydraulics, 2001). The model solves the coupled equations for shallow water flow and sediment transport including bed load using the Van Rijn (1993) formulations. Hydrodynamic, sediment transport and bottom update computations are performed simultaneously (or "online"). A detailed description of the approach, including results of several validation tests is included in Lesser et al. (2004). By using an "online" approach changes in bathymetry are immediately fed back to the hydrodynamic calculations and data exchange between each module (which requires large data files when using a decoupled modeling approach) is relatively simple and efficient.

In the "online" version of Delft3D, sediment (up to five sand and/or mud fractions) is treated as any other constituent and added modeled using an advection-diffusion transport solver. Additional formulations generally following the approach described by van Rijn (1993) are included to describe relevant sediment processes such settling, bed sediment exchange, and bed load transport.

The elevation of the bed is dynamically updated at each computational time-step. This is one of the distinct advantages over an "offline" morphological computation as it means that the hydrodynamic flow calculations are always carried out using the correct bathymetry. At each time-step, the change in the mass of bottom sediment that has occurred as a result of the sediment sink and source terms is calculated. This change in mass is then translated into a change in thickness of the bottom sediment layer using the density of the bed material. This change in thickness is equivalent to a change in bed elevation, which is applied to the depth values stored at computational points.

Erosion of Dry Cells (Lateral Breach Growth)

Initial efforts to simulate the morphological evolution of a new inlet (Roelvink et al., 1994) were hampered by the model's inability to erode existing "dry" points and allow for alongshore widening and migration of the inlet mouth. Nonetheless, these preliminary efforts demonstrated that the model could at least reproduce the initial morphodynamic response observed in a similar physical model. Erosion of dry points and "avalanching" of steep slopes is very difficult to solve using a process-based approach because it requires an extremely fine numerical grid that would make model application impractical. To solve this problem the version of the Delft3D model used in this study includes a mechanism by which a fraction of the sediment eroded from a wet cell is withdrawn from adjacent dry cells, if present (Roelvink et al., 2003). This fraction is user-specified and can be calibrated to available data. Comparison of this model to the Zwin breach growth experiment (as reported by Visser, 1998) suggests that a fraction on the order 0.9 yields a good comparison between model results and prototype breaching data.

Morphological Acceleration Factor

Analysis of medium- to long-term breach stability requires long morphological simulations over periods ranging from a few weeks to several months. On the other

hand, hydrodynamic and sediment transport processes have a much shorter time scale and require modeling time steps of minutes or even seconds depending on spatial resolution. Accommodating both short and long time-scales requires use of so-called "morphological updating" strategies that allow for significantly faster simulation times. These techniques include "tide-averaging", "continuity corrections", and "morphological acceleration factors" (Roelvink, 2006).

In the "online" version of Delft3D the bottom is updated at the same time intervals as the flow and sediment transport but the morphological change rates can be multiplied by "morphological (acceleration) factor" which effectively extends the morphological time step (Lesser et al, 2004). Work by Roelvink (2006) and Lesser at al (2004) suggest that for tidal and wave-driven situations "morphological factor" values in the order of 50-100 do not significantly alter the solution and are therefore feasible. Nonetheless, sensitivity to morphological factor selection should always be carefully tested.

Model results

Figures 4 through 8 show results for a new breach into a bay roughly the size of Great South Bay an with the existing Fire Island Inlet open. This particular simulation was made over a 1 month period including two spring-neap cycles. A morphological factor of 12 was applied to simulate a total of 12 months of morphological evolution. Initial breach width was 300 meters. As shown in the figures, the model seems capable of simulating long term breach growth as well as the accumulation of sediment in ebb and flood shoals. Note that waves were not included in the simulation, and therefore lateral growth is fairly symmetrical.

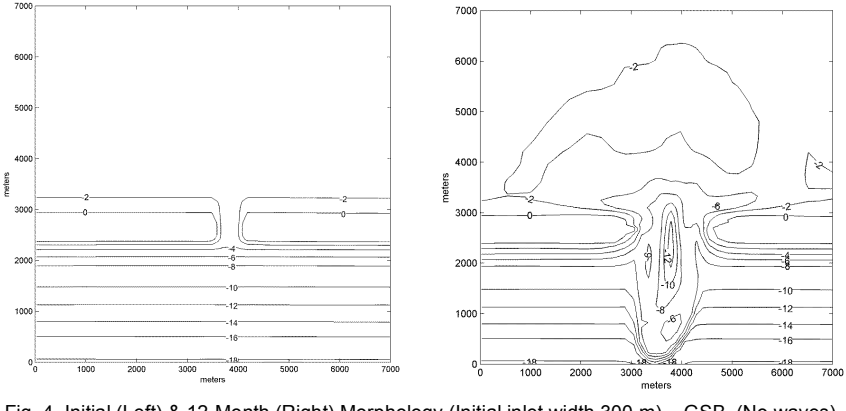

Fig. 4. Initial (Left) & 12-Month (Right) Morphology (Initial inlet width 300 m) – GSB (No waves)

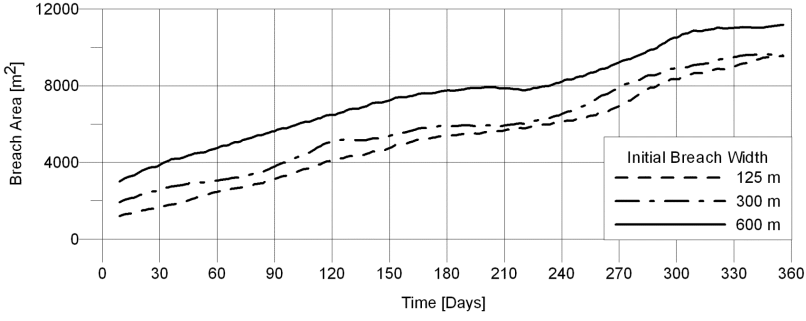

Fig. 5. Breach Area Evolution – GSB (No waves)

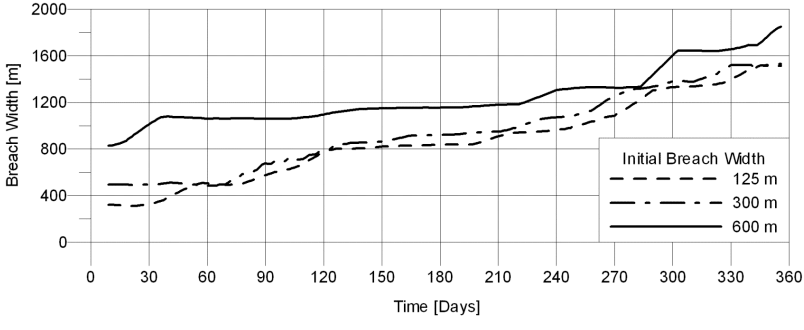

Fig. 6. Breach Width Evolution – GSB (No waves)

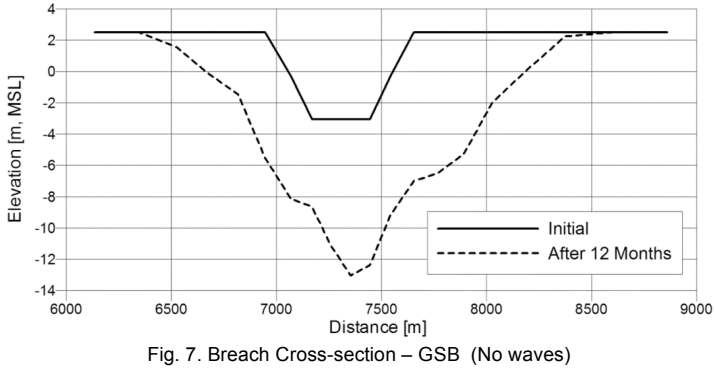

Fig. 7. Breach Cross-section – GSB (No waves)

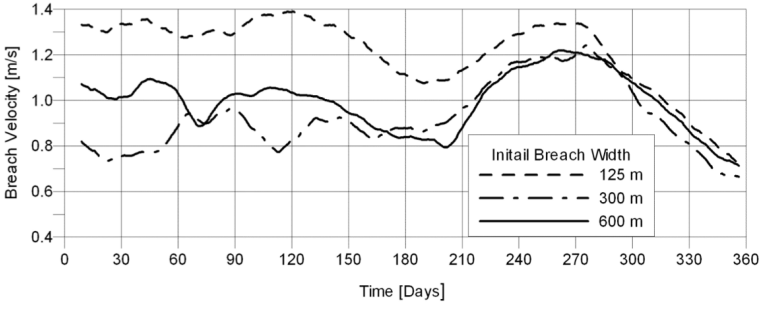

Fig. 8. Max. Velocity at Breach - GSB (No waves)

The time scale of the observed morphological evolution also appears to be reasonable as cross-sectional area and especially maximum flow velocities through the breach appear to taper off after 10 months suggesting that the breach is reaching a more stable condition.

However, when compared to the analytical/empirical estimates of potential breach growth in Great South Bay, model results suggest a significantly larger cross-sectional area (10 to 11,000 m^2 vs. 3,400 m^2) after 12 months. Recall, however, that the maximum breach cross sectional area in the analytical model is based on long-term stable values corresponding to existing tidal inlet areas and these may not be representative of the maximum possible area at the breach location. This is particularly true in the case of Great South Bay where the existing Fire Island Inlet has a very different (and much less hydraulically efficient) geometry than a new breach would. More importantly, this simulation does not include the effect of the waves and longshore sediment transport, which would tend to place sand in the inlet and reduce its cross-section.

Figure 9 shows the results for a breach in Shinnecock Bay, this time including the effects of waves (Hs=1.5 m, Tp=7 sec and θ=26 degrees offshore) and staring from a much narrower initial breach (30 m width). As shown on the figure, longshore sediment transport generated by the waves forces the channel to move alongshore causing increased erosion of the downdrift shoreline. In this case, the cross-sectional area predicted by the model after 6 moths (1,500 m^2) is very similar to the analytical/empirical estimate (1,200 m^2).

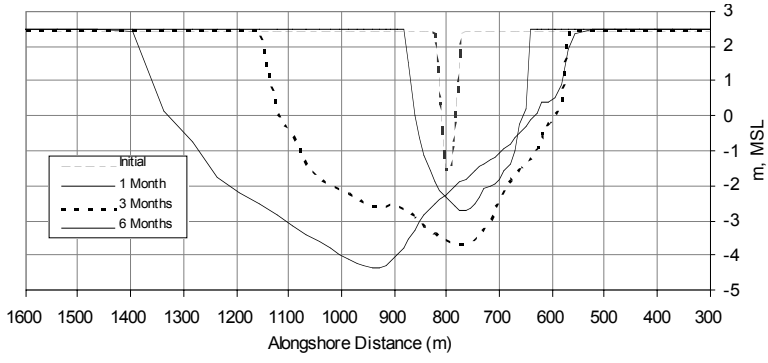

Fig. 9. Breach Cross-section Evolution – Shinnecock Bay (with waves)

One interesting finding from this simulation was that in this case the results were very sensitive to the choice of a morphological acceleration factor. Initial runs with factor of 12 resulted in rapid closure of the breach due accumulation of sediment transported by the waves. However, close inspection of the results suggested that changes were too rapid to use a morphological factor and therefore a hybrid approach was used. The first month was run with a factor of 1 (i.e., no acceleration), months 2 and 3 were run with a factor of 2, and months 4, 5, and 6 were run with a factor of 3. This approach of slowly increasing the morphological factor proved to be stable and to yield results very similar to those obtained with no morphological acceleration included in the model.

Nonetheless, not being able to use a larger morphological factor, particularly at the beginning, makes simulating initial breach stability (i.e., when the beach is relatively small) very difficult and computationally expensive. This problem is compounded by the fact that both empirical data and simulations suggest that the initial stability of the breach and its growth rate in the case of a stable one is very dependent on water level and wave climate conditions. Therefore, a proper analysis of the risk of a breach in particular location would require simulation of not just typical conditions but various storm and tide conditions. The statistical probability of each result would then need to be combined to provide for a representative estimate of the risk the breach would grow.

SUMMARY

An initial attempt to simulate breach stability and long-term growth using an "online" morphological model suggests that important processes (lateral growth, alongshore migration, and shoal accumulation) can be represented with the model and that results that compare reasonably well with the limited available empirical data can be obtained.

However, this preliminary work suggests that the results are very sensitive to the choice of "morphological acceleration factor", particularly during the initial evolution of small, recently opened breaches. Under those conditions it seems like using anything higher than a factor of 1 (i.e., no acceleration) may lead to erroneous results (e.g., breach

closing instead of opening). This constraint leads to longer simulation times and may significantly reduce the practicability of using these models to assess breach stability and long-term growth, particularly when compared to the more efficient analytical/empirical tools.

On the other hand, a process-based morphological model allows for a detailed description of the water levels and wave climate which drive the morphological processes. Relatively small differences in these environmental conditions following the storm that opened the breach (e.g., a spring tide combined with an average nor'easter storm vs. a neap tide during calm wave conditions) may mean the difference between a breach that closes quickly and one that "explodes". Therefore, both process-based morphological models combined with more conceptual analytical tools are likely required for comprehensive studies in which probability-based results are needed.

Abstract: A 2.5-year data set of beach profiles was used to examine the characteristics of berm shape and the spatial distributions of the cross-shore sediment transport rate for berm formation and erosion. The seaward distance, x, is normalized by the distance of the investigation area, X, which is from the maximum wave run-up position, $x/X = 0.0$, to the position where the standard deviation of the beach profile takes the lowest value seaward of the mean shoreline position, $x/X = 1.0$. Analysis of the data reveals that the landward sediment transport rate for the berm formation increases from $x/X = 0.0$ to 0.4 and reaches a constant value toward $x/X = 1.0$. As for berm erosion, the landward sediment transport rate peaks at $x/X = 0.10$ and the sediment transport rate changes in the seaward direction at $x/X = 0.20$. From this position, the rate decreases until $x/X = 0.60$.

INTRODUCTION

Beach topography in the swash zone responds to wave run-up and run-down. In the swash zone, sediments are transported by both bed load transport and suspended load transport owing to very shallow water with high velocity. The sediment transport

above the mean sea level is caused by swash, which is strongly asymmetric (e.g. Hughes *et al.*, 1997; Osborne and Rooker, 1999). Thus, a beach profile in the swash zone is formed by the imbalance between uprush and backrush sediment transport on the beach face.

Berms are commonly formed between the mean sea level and the maximum wave run-up level. During mild wave conditions, berms form on the foreshores (e.g., Thomas and Baba, 1986; Katoh and Yanagishima, 1992). In contrast, during severe wave conditions, the enhanced wave run-up washes sediment over the berm crest which is transported seaward with the backwash, and berm erosion occurs (e.g., Eliot and Clarke, 1986; Katoh and Yanagishima, 1993). In order to understand the berm topography change, we need to investigate the sediment transport rate for both berm formation and erosion. The sediment transport rates in the swash zone have been studied by a number of researchers. Horn and Mason (1994) investigated the relative proportions of bed load and suspended load by carrying out field experiments at four beaches in the United Kingdom. The bed load transport was found to dominate the backwash, and more sediment was transported on the flood tide than on the ebb. Masselink and Hughes (1998) measured swash flow velocity and sediment transport on a natural beach and observed strong correlation between the sediment load and the velocity cubed. Puleo *et al.* (2000) studied the swash zone sediment transport using field data. They found that vertical profiles of backwash differed from that of the uprush and that bore-derived turbulence may affect local sediment transport. Also, Puleo *et al.* (2003) reported that suspended sediment transport rates obtained from the sediment concentration and the velocity measurements showed the best comparisons with a modified sediment transport model that includes a physical mechanism for enhancing transport rates due to flow acceleration. Austin and Masselink (2006) observed the morphological change and swash sediment load at a steep gravel beach. They found that the morphological change is directly related to the maxima in shoreline elevation and identified four modes of berm adjustment. However, sediment transport rates during berm formation and berm erosion have not been fully investigated.

The main objective of this study was to investigate the spatial distributions of the cross-shore sediment transport rate for berm formation and erosion on the basis of a 2.5-year data set of beach profiles obtained at a stable dissipative beach.

DATA DESCRIPTION

Beach Profile Data

Beach profile data were obtained from August 1987 to January 1990 at Hazaki Oceanographical Research Station (HORS), a research facility for field measurements of various phenomena in the nearshore zone on the Hasaki coast of Japan facing the Pacific Ocean (Fig. 1). HORS has a 427-m-long pier, which is located perpendicularly to the shore. The cross-shore distance along the pier is defined relative to the reference point of HORS, located near the entrance of the pier, and the seaward direction is set as being positive.

The Hasaki coast is stable, and the bathymetry around HORS is almost uniform alongshore. The beach profiles along the pier were measured at 5-m intervals everyday, except for weekends and holidays, with a 3-kg lead from the pier and with a level and a staff shoreward of the pier. The median sediment diameter is approximately 0.18 mm and almost uniform along the pier. Based on the data, the sea levels at the Hasaki coast (Tokyo Peil -0.687 m) show high, mean and low water levels of 1.252 m, 0.651 m, and -0.196 m, respectively.

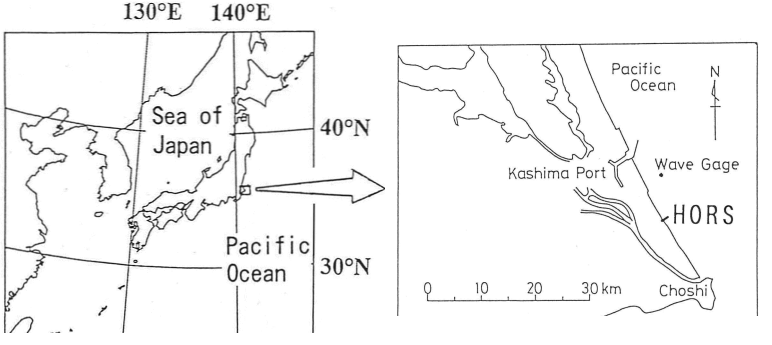

Fig. 1. Location of Hazaki Oceanographical Research Station (HORS)

Figure 2 shows the mean beach profile and its standard deviation in the offshore, the surf zone, the inner surf zone, foreshore and backshore. The beach slope around the shoreline, where the seaward distance is -4 m, is about 0.024. From the figure, several peaks can be seen in the distribution of the standard deviation. The relatively high values around the seaward distance of -10 m are due to berm formation and berm erosion, and the high values from the seaward distance 200 m to 350 m are due to bar movement.

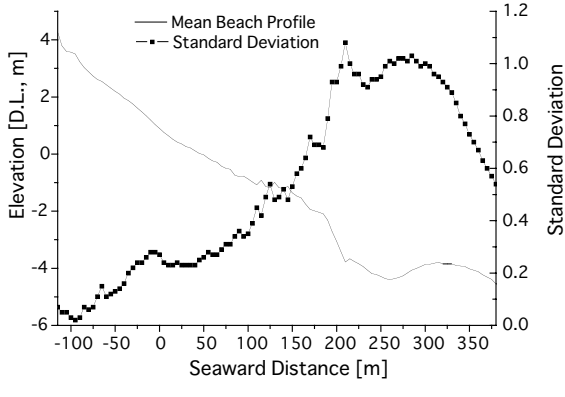

Fig. 2. Mean beach profile and its standard deviation.

Offshore Wave Data

Offshore waves have been observed at the mean water depth of 23.4 m offshore the Port of Kashima, which is about 8 km north from HORS, by using a current meter type wave directional gage (CWD) sensor for 20 minutes every 2 hours. During the investigation period, the offshore significant wave height and the offshore significant wave period varied from 0.37 m to 5.66 m and from 4.88 s to 14.98 s, respectively.

The offshore wave energy flux is calculated from the offshore wave height and the celerity.

$$E_f = \frac{1}{16}\rho g \left(H_{1/3}\right)_0 C_{g0}, \tag{1}$$

where ρ is the sea water density, g is the gravity acceleration, $H_{1/3}$ is the significant wave height and C_{g0} is the celerity. In this analysis, the daily wave energy flux is used.

Wave Run-up Position

The shoreline position varies predominantly owing to beach topography, tide and wave set-up near the shoreline. In this study, the wave run-up level is defined as the total sum of mean sea level, run-up level of infragravity waves and that of incident wind waves. Katoh and Yanagishima (1993) proposed an equation for estimating the wave run-up level $R_{\max}$, which had been empirically derived from field observation data obtained at HORS.

$$R_{\max} = \overline{\eta}_0 + 0.96H_L + 0.31 \ \ [\mathrm{m}], \tag{2}$$

where $\overline{\eta}_0$ is the mean sea level and H_L is the height of the infragravity waves at the shoreline. The second term and the third constant term are considered to present the run-up heights caused by the effect of infragravity waves and incident wind waves, respectively. The wave run-up level is based on the datum line.

BERM FORMATION AND BERM EROSION

Beach Topography Change

The space-time map of the variation from the mean beach profile at HORS and the wave energy flux from August 1987 to January 1990 are shown in Figs. 3(a) and 3(b), respectively. For Fig. 3(a), the elevation above and below the mean beach profile is shown by warm and cold colors, respectively. The solid line indicates the mean wave run-up position, which is averaged from the wave run-up positions calculated from the beach profile obtained once a day and the wave run-up level estimated every 2 hours.

From the figure, the shoreline position and the beach topography changed greatly in 1987. However, their fluctuations become small after 1988. Berm formation mostly occurs above the mean wave run-up position, and the cross-shore scale of the berm

which is the cross-shore distance area above the mean beach profile is nearly the same scale, 25 m. Berms are generally formed during non-storm conditions, e.g., February 1988 and July 1989, and are eroded during storm conditions. Therefore, it can be considered that the berms are formed when a low wave energy flux continues and disappear in the presence of a relatively large wave energy flux.

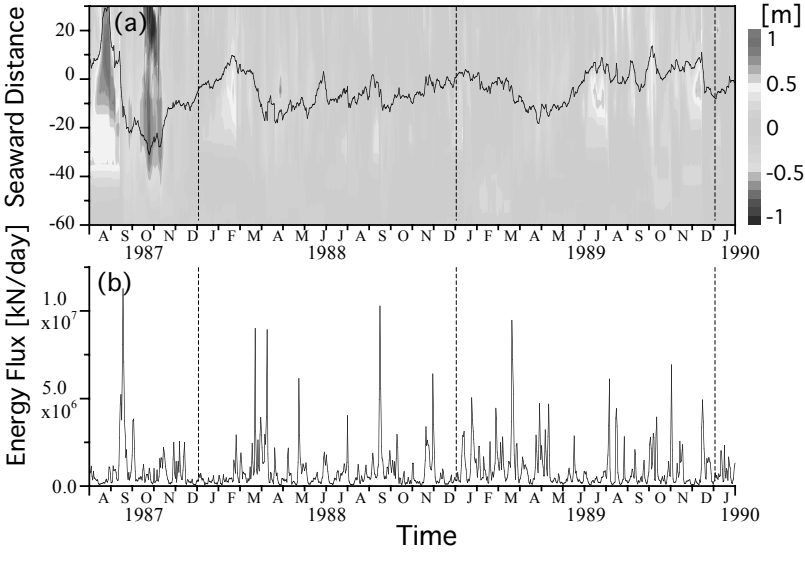

Fig. 3. (a) Variation from the mean beach profile at HORS. Elevations above and below the mean beach profile are shown by warm and cold colors, respectively. (b) Wave energy flux

Characteristics of Berm Shape

Based on the daily beach profile data, the topography changes of berm formation and berm erosion were selected. Katoh and Yanagishima (1992) identified 219 cases of berm formation and 58 cases of berm erosion from the 2.5-year (August 1987 to January 1990) beach profile data set obtained at HORS. This data was used to investigate the characteristics of the berm shape and the cross-shore variations of the cross-shore sediment transport rate for berm formation and erosion.

As mentioned above, berm formation occurred during calm wave conditions, and the berm crest grew up to the maximum wave run-up level (Katoh and Yanagishima, 1992). Berm erosion occurred when the enhanced wave run-up passed through the berm crest. Thus, the maximum wave run-up position is important for examining berm formation and erosion. Figure 4 shows the histogram of the maximum wave run-up position, where the maximum daily wave run-up position, for berm formation and erosion. The maximum wave run-up position changes from x = -58.0 m to -0.5 m for berm formation and from x = -78.3 m to -23.2 m for berm erosion, and the averaged wave run-up positions are x = -29.7 m and x = -49.9 m, respectively.

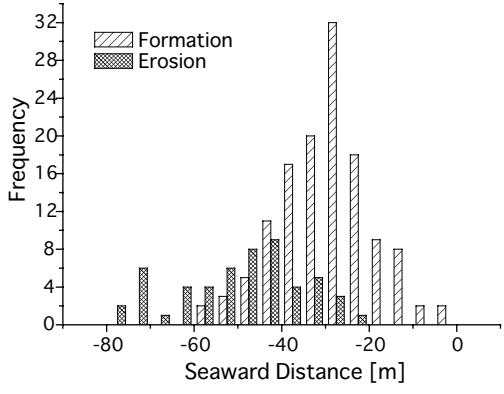

Fig. 4. Histogram of maximum wave run-up position for berm formation and erosion.

In this analysis, the investigation area is set from the maximum wave run-up position, which is defined as the onshore boundary, to x = 25 m, where the standard deviation takes the lowest value seaward of the high peak of the standard deviation x = -10 m (see Fig. 2) and is defined as the offshore boundary. Since the maximum wave run-up position varies owing to the beach profile and the wave run-up level, the investigation area is normalized by using the distance from the onshore boundary to the offshore boundary. Namely, the onshore boundary is set as x/X = 0.0 and the offshore boundary is set as x/X = 1.0.

Let us first examine the cross-shore position of the berm crest. Figure 5 shows the histogram of the berm crest position, which is defined as the place where the vertical distance between the beach profile and a straight line, which begins at the maximum wave run-up position and extends to the intersection point between the onshore boundary and the beach profile, is the largest. The positions are decided on the basis of the beach profile of the day before berm erosion occurs. The histogram of the berm crest position is observed from x/X = 0.0 to 0.6, and the averaged berm crest position is located at x/X = 0.29. This indicates that during the berm formation, although the wave reaches the maximum wave run-up position, the sediments mainly settle at around x/X = 0.29.

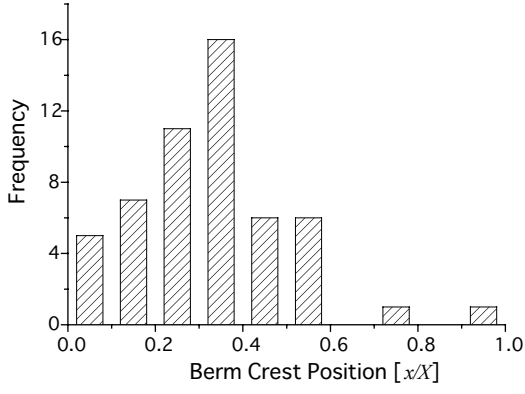

Fig. 5. Histogram of berm crest position.

In spite of the various berm crest heights, the beach profile becomes mild after berm erosion. Figure 6 shows a comparison of berm slope before and after berm erosion. Although the spread of the berm slopes before the erosion reach 0.0385, it becomes small after the erosion, and the data plots gather around 0.0242, which is approximately the same as the mean beach slope around the shoreline, 0.024.

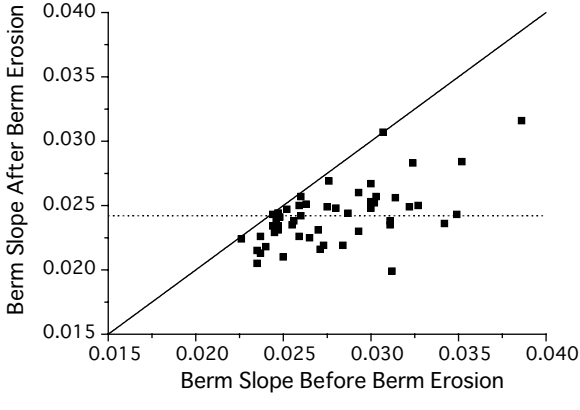

Fig. 6. Comparison of berm slopes of before and after beach erosion

Cross-shore Distribution of Cross-shore Sediment Transport Rate

The sediment transport volume of each cross-shore section is estimated from beach profile changes on the basis of a mass conservation equation, which is expressed as Eq. 3.

$$\frac{\Delta Q}{\Delta x} = \gamma \frac{\Delta z}{\Delta t}, \tag{3}$$

where Q is the cross-shore component of sediment transport rate per unit length in the alongshore direction, Δx is the spacing interval in the cross-shore direction, γ is the volume of sediment in a unit volume of the bed (= 0.7, Nielsen, 1992), z is the elevation, and t is the time.

The estimation of the cross-shore sediment transport rate with Eq. 3 is based on the assumption that the beach profile changes were induced by the cross-shore gradient of the cross-shore sediment transport, and the alongshore gradient of longshore sediment transport rate is ignored due to the alongshore uniformity of the topography around HORS (Kuriyama, 1991). This method has been applied to estimations of the cross-shore sediment transport rates in the surf zone (e.g., Kuriyama, 2002). Equation 3 becomes Eq. 4.

$$\left[Q(i,t) - Q(i-1,t)\right] = \gamma \frac{dz}{dt}\Delta x = \gamma \left[z(i,t) - z(i,t-1)\right]\frac{\Delta x}{\Delta t}, \tag{4}$$

where i is the number of the point where the cross-shore sediment transport rate is defined. The sediment transport rate for each position from the foot of the foredune, x = -115 m, to the offshore boundary is estimated using Eq. 4. The positive and negative values indicate the landward and the seaward sediment transport rate, respectively.

In order to consider the characteristics of the sediment transport rate for berm formation and erosion, the spatial distributions of sediment transport rate are calculated using Eq. 4. Figure 7 shows the spatial distribution of sediment transport rate for berm formation. Each line indicates the distribution of the sediment transport rate, and the berm formation cases total 219. The horizontal axis is the seaward position, x, normalized by the distance from the onshore boundary to the offshore boundary, X. The onshore boundary is set at the intersection point of the beach profile and the maximum wave run-up level. Therefore, the sediment transport rate at x/X = 0.0 should be zero or an extremely small amount. However, the rate at x/X = 0.0 has some value. Since the maximum wave run-up level is calculated using the statistical values derived from 20-minute data, which is observed every hour, the calculated maximum wave run-up level is not equivalent to the run-up level of the largest wave during the time. This may affect the variation of the sediment transport rate at x/X = 0.0.

The value of the sediment transport rate increased until approximately x/X = 0.40, and the variation of the sediment transport rate was relatively small between x/X = 0.0 and x/X = 0.4.

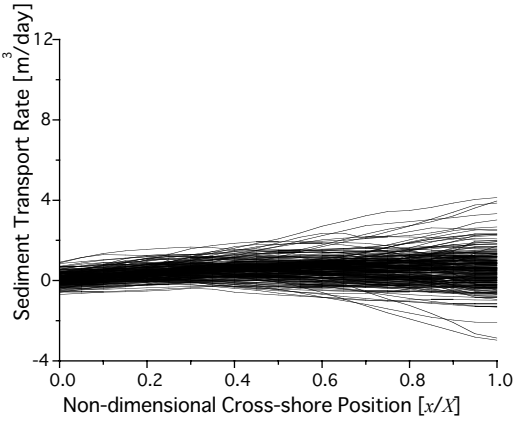

Fig. 7. Spatial distributions of sediment transport rate for berm formation (219 cases).

Figure 8 shows the spatial distribution of sediment transport rate for berm erosion. Each line indicates the distribution of the sediment transport rate, and the berm erosion cases total 58. For the same reason as the berm formation, the value of the sediment transport rate at $x/X = 0.0$ varies. The variation of the sediment transport rate is larger than that of the berm formation.

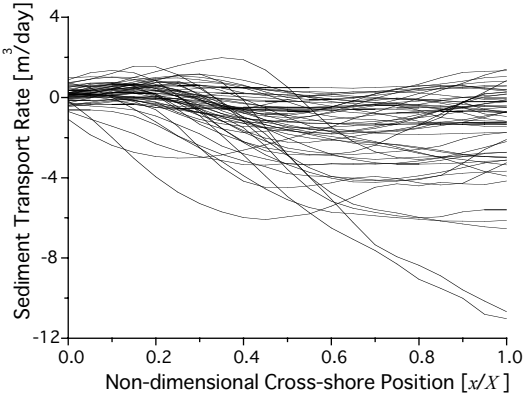

Fig. 8. Spatial distributions of sediment transport rate for berm erosion (58 cases).

The spatial distributions of the averaged sediment transport rate for berm formation and erosion are shown in Fig. 9. The bars indicate the standard error of the mean.

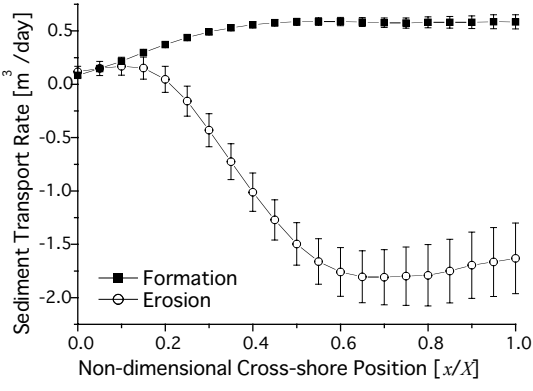

Fig. 9. Spatial distributions of averaged sediment transport rate for berm formation and erosion.

For berm formation, the landward sediment transport rate gradually increases until $x/X = 0.4$ and takes a steady value seaward of $x/X = 0.4$. This finding indicates that sediments mainly accumulate from $x/X = 0.0$ to 0.4 and a berm will be formed in this area. This can be inferred from the histogram of the berm crest position (Fig. 5). As for berm erosion, initially, the run-up wave washes sediment over the berm crest and sediments are transported landward. For this reason, the landward sediment transport rate has a high peak at $x/X = 0.10$ and sediment accumulation occur from $x/X = 0.0$ to 0.1. Next, the run-up water moves seaward with sediments washing over the berm. Therefore, after the peak of the landward sediment transport rate, the rate decreases until around $x/X = 0.6$. From $x/X = 0.6$, the rate becomes steady. Considering the distribution of the histogram of the berm crest position (Fig. 5), the peak seaward sediment transport rate occurs at nearly the same position as the berm crest position, $x/X = 0.29$.

Since the spatial scales of the berms is considered to be of nearly the same scale (see Fig. 3) and the berm slope becomes constant after berm erosion (see Fig. 6), the mass of the sediment transport volume due to berm erosion may be proportional to the berm height. Figure 10 shows the comparison of the berm height and the area of the berm, which is estimated by integrating the area above the straight line which begins at the maximum wave run-up position and extends to the intersection point between the onshore boundary and the beach profile.

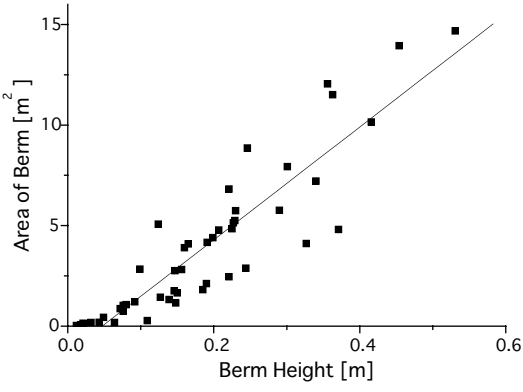

Fig. 10. Comparison of berm height and area.

The figure shows a linear correlation between the two (R^2 = 0.81). Thus, it can be assumed that the sediment transport rate for berm erosion can be estimated by using the berm height.

From Fig. 9, the spatial position at x/X = 0.4 for berm formation and at x/X = 0.1 and x/X = 0.6 for berm erosion are particular points of the spatial distributions of the sediment transport rate. Once the sediment transport rates of these points are formulated by using the wave energy flux, the berm height or any other parameters, the spatial distributions of the cross-shore sediment transport rate for berm formation and erosion can be estimated.

CONCLUSIONS

Beach profile data were obtained at HORS every weekday for the two and a half years, and the data set was used in order to investigate the characteristics of berm shape and the spatial distributions of the cross-shore sediment transport rate for berm formation and berm erosion. The investigation area is normalized by the distance from the onshore boundary, at the intersection point of the maximum wave run-up level and the beach profile, to the offshore boundary, where the standard deviation of beach profile takes the lowest value seaward of the mean shoreline position. Namely, the onshore boundary is set as x/X = 0.0 and the offshore boundary is set as x/X = 1.0. The conclusions obtained in the present study are as follows:

(1) The landward sediment transport rate for berm formation increases from x/X = 0.0 to x/X = 0.4 and becomes steady toward x/X = 1.0.
(2) The landward sediment transport rate for berm erosion peaks at x/X = 0.10, and the sediment transport rate changes in the seaward direction at x/X = 0.20. From that point, the rate decreases until x/X = 0.60.
(3) The averaged berm crest position just before berm erosion occurs is located at x/X = 0.29. During berm erosion, the peak seaward sediment transport occurs at nearly the same position as the berm crest position.

ACKNOWLEDGEMENTS

The authors would like to express our appreciation to the Kashima Port and Airport Construction Office, Ministry of Land Infrastructure and Transport and the Marine Information Division, Port and Airport Research Institute for allowing us to utilize the wave data of the Port of Kashima. We also thank all the staff members at HORS for conducting the field surveys.

Abstract: Overwash is an important process in the evolution of barrier systems. The main aim of this paper is to present short-term measurements on sediment transport induced by overwash processes. For that purpose fieldwork campaigns were performed including measurements of oceanographic conditions, overwash flows, overwash-induced morphology variations, and sediment transport patterns. The sediment dynamics induced by overwash varied according to the washover morphology even though the tidal levels or incident energy were similar. The sediment movement inside the washover plain during an overwash event can be divided into three main stages: Stage 1 – Crest Accretion, Stage 2 – Onshore Transport, and Stage 3 – Dynamic Equilibrium. The sediment transport inside the washover lobe can be characterized by one onshore flow stage, but with variations in magnitude related to the tidal levels and breaking wave height.

INTRODUCTION

Overwash corresponds to a seawater intrusion over the frontal dune or, when absent, over the washover seaward limit. The main types of washover morphologies are: (1) washover plain, and (2) washover lobe (Matias, 2006). The washover plain is a wide and low-lying denuded area where overwash is frequent, and have been named also as washover ramp (Fisher and Simpson 1979), washover sheet (e.g. Ritchie and Penland 1988), washover flat (e.g. Holland *et al.* 1991), and washover terrace (e.g. Bray and

Carter 1992). The washover lobe is a laterally confined feature that cut the dune field in specific places, and has also been named as hurricane channel (e.g. Hayes 1967), washover breach (e.g. Hosier and Cleary 1977), overwash features (e.g. Armon and McCann 1979), washovers (e.g. Fisher and Simpson 1979), washover fan (e.g. Kochel and Wampfler 1989), individual washovers (e.g. Bray and Carter 1992), and perched fans (Morton and Sallenger 2003).

The evaluation of sediment transport induced by overwash constitutes a major issue in coastal processes, predominantly moving sand from the beach face to the washovers and backbarrier environments (e.g. Hayes 1967; Schwartz, 1975). The sediment transport during overwash events has been measured through surveys performed before and after a storm (e.g. Fisher *et al.* 1974; Stone *et al.* 2004), and also by measuring the washover dimensions and deposit thickness (e.g. Schwartz 1975; FitzGerald *et al.* 1994). The overwash sediment transport has also been semi-quantitatively evaluated with ground photographs and aerial vertical or oblique photographs by measurements of overwash intrusion, normally identified by the contact between fresh sand and marsh/dune vegetation (e.g. Cleary *et al.* 2001; Morton and Sallenger 2003), or by the existence of a debris-line, particularly noticeable in developed coasts (e.g. Nordstrom and Jackson 1995; Webb *et al.* 1997).

Despite the variety of studies related to overwash processes, there is still a lack of detailed knowledge about short-term overwash sediment transport at washover plains and lobes. In situ measurements of overwash sediment transport are scarce, and no application of tracers was found in the literature. Sediment transport studies using fluorescent tracers (FT) have been very important in the development of coastal theories and were used for diverse purposes like the quantification of sediment transport on swash platforms (Oertel 1972), on submarine sand banks (Collins *et al.* 1995), on tidal inlet margins (Vila-Concejo *et al.* 2004), longshore sediment transport (Komar and Inman 1970), and harbour infilling processes (Ferreira *et al.* 2002). The objective of this work is the definition of sediment transport stages and patterns under confined and unconfined overwash flows, using detailed field studies.

STUDY AREA

The study area is the western part of Barreta Island, located on the Ria Formosa barrier island system, Algarve, Portugal (Figure 1). The system is composed of five islands and two peninsulas that extend over 55 km.

The western part of Barreta Island is on the downdrift margin of the Ancão Inlet (Figure 1). This inlet undergoes eastwards migration cycles, and the study area is located inside the inlet migration path. In June 1997 Ancão Inlet was artificially opened, and reached its dynamic equilibrium as a "mature migrating inlet" in May-July 1999 (Vila-Concejo *et al.* 2003).

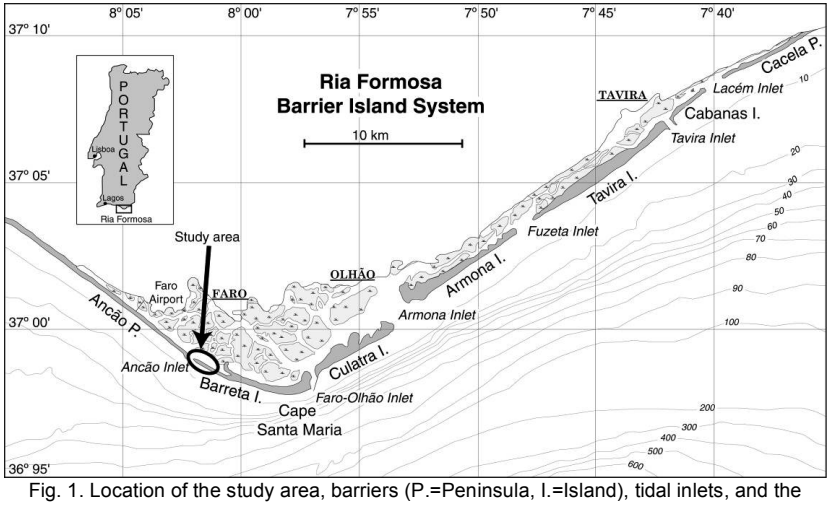

Fig. 1. Location of the study area, barriers (P.=Peninsula, I.=Island), tidal inlets, and the bathymetry of the adjacent continental shelf (in meters).

Whilst Ancão Inlet was evolving towards dynamic equilibrium, it was acting as a sediment trap, and therefore Barreta Island was undergoing sediment starvation that caused dune erosion and shoreline retreat. Due to the erosion of the dunes, overwash processes were frequent forming washover lobes and an extensive washover plain.

The Ria Formosa barrier island system is mesotidal, with mean tidal range of about 2 m that can reach up to 3.5 m during spring tides. Offshore wave climate is dominated by west-southwest waves (71% of occurrences; Costa *et al.* 2001). SE waves that consist of short period waves generated by regional winds (locally called "Levante") are also frequent (about 23%; Costa *et al.* 2001). Wave energy is moderate with an average annual significant offshore wave height (H_{SO}) of 1.0 m and average peak period (Tp) of 8.2 s (Costa *et al.* 2001). Between 1986 and 1993, storm conditions (defined as $H_{SO} > 3$m) corresponded to 1% of the offshore wave climate (Costa 1994). The western part of Barreta Island has a northwest-southeast orientation, therefore directly exposed to the W-SW longer fetch waves, but sheltered with respect to SE waves.

METHODS

Fieldwork data collection

Two fieldwork campaigns were made: GO.1 (February 9-10, 2001) and GO.3 (February 18-19, 2003). Fieldwork was undertaken on a washover plain during GO.1 and on a washover lobe during GO.3 (Figure 2).

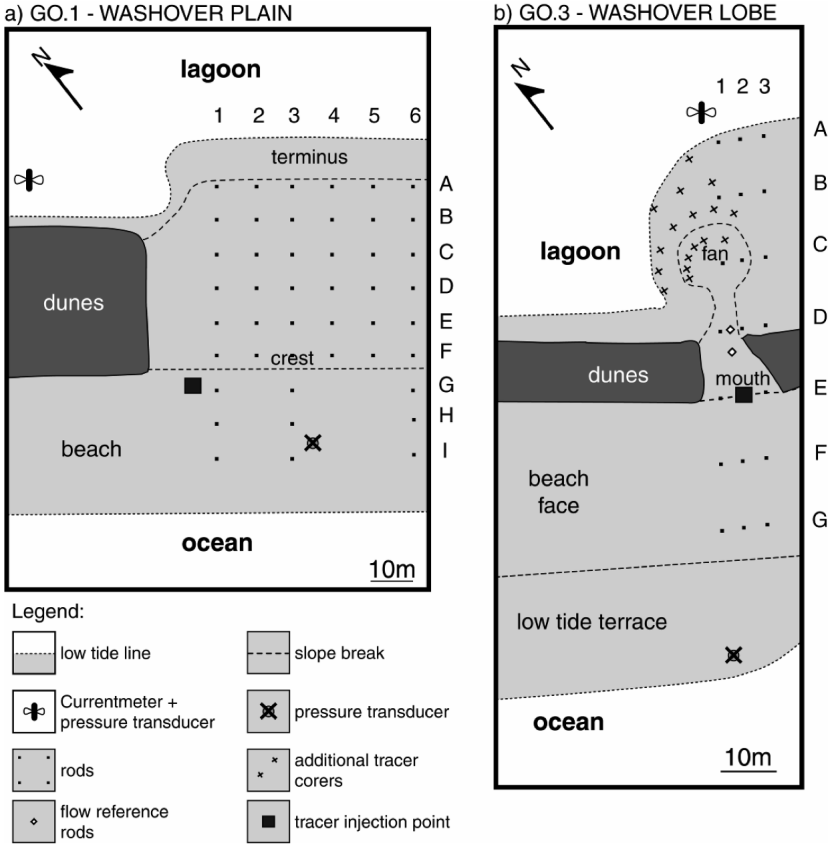

Fig. 2. Setting of the GO.1 and GO.3 fieldwork campaigns.

Pressure transducers were deployed on the beach (at a sample rate of 4 Hz), and on the lagoon side (at a sample rate of 0.1 Hz) for both campaigns. During GO.3 the overwash velocity was measured by timing the passage of the overwash water front between rods located at the washover channel (Figure 2b).

For GO.1, a 10×10 m grid of rods was established over the beach and washover plain (Figure 2a), covering an area of about 4,000 m^2. For GO.3, an irregular grid was established that was composed of three cross-shore profiles (1 to 3 in Figure 2b), 4 m apart, seven longshore profiles (A to G in Figure 2b), 10-12 m apart, and two additional rods on the central lobe (diamonds in Figure 2b) and 17 on the fan (crosses in Figure 2b). Surveys were made using a total station (GO.1) and a real-time kinematic DGPS (GO.3). During both fieldwork campaigns surveys were conducted before and after

overwash, and the rod heights were measured every 30 minutes, during the overwash events.

During GO.1, 40 kg of FT were placed at the top of the beach face, 1 m from the washover crest; and during GO.3, 42 kg of FT were dropped into the flow at the washover mouth. Shallow cores were taken manually after the overwash event, next to each rod. The obtained cores (41 for GO.1 and 31 for GO.3) were sub-sampled every 5 cm. Figure 2 shows detailed sketches of set up for the fieldwork campaigns.

Data processing and laboratory procedures

The PT data was used for wave and tide computations (sensor location in Figure 2). The PT on the lagoon side was also used for tidal computations. The procedures to determine the tidal elevation can be found in Matias (2006). The wave parameters (significant wave height at breaking, H_{sb} and peak period, Tp) were calculated using the methods of moments (described in USACE, 2002).

For all topographic surveys, the cross-shore profiles were obtained and the volume computations were made, using the kriging interpolation method with a linear variogram to make the upper surface and using the mean sea level (MSL) as base line.

From the sub-samples of the cores an aliquot of 20 g was obtained, the number of FT grains was counted under UV light and the counting was used to generate maps of FT distribution for each 5 cm layer. The definition of FT mass centroids was obtained by applying the Spatial Integration Method (Komar and Inman 1970; Madsen 1987) that is an average location of the FT cloud weighted by the mass of FT at each position of the grid. The percentage of remaining tracer (i.e. the relation between the FT injected and the FT sampled; named percentage of recovery in Madsen 1987 and Ciavola *et al.* 1998) was estimated using the method developed by Vila-Concejo *et al.* (2004). This method consists in determining the mass of FT remaining in the study area (the sum of all FT in each layer) by obtaining an estimation of FT mass in the volume represented by each sample, through a density relation.

RESULTS

Both campaigns were made during equinoctial spring tides, with a maximum oceanic tidal level of 1.71 m above MSL for GO.1 and 1.69 m above MSL for GO.3. For the lagoon side, approximately the same maximum tidal levels were reached for both campaigns (1.67 m above MSL).

Average H_{sb} for GO.1 was 1.28 m and average Tp was 11.1 s. For GO.3, the average H_{sb} was 1.21 m and average Tp was 16.0 s. For both campaigns, H_{sb} was somewhat variable during fieldwork (GO.1: 0.57-1.39 m, GO.3: 0.62-1.25 m) because the instruments were located inside the beach system, and therefore the recorded waves were greatly influenced by the nearshore topography.

The overwash event during GO.1 fieldwork started at 01:27 and finished at 06:02, February 10th 2001, with complete overwash occurring between 02:10 and 04:54. The overwash event during the GO.3 fieldwork started at 01:59 and finished at 05:27, February 19th 2003, with complete overwash occurring between 02:44 and 04:39. The overwash flow velocities measured between rods during GO.3 fieldwork varied between 0.9 m/s and 5.7 m/s; however the most frequent velocities range between 2.5 and 3.0 m/s.

The six cross-shore profiles measured before and after the overwash event of GO.1 fieldwork, showed relatively similar morphologic variations. The greatest variation occurred on the washover crest, where an overall accretion of about 16 cm of sand occurred (Figure 3).

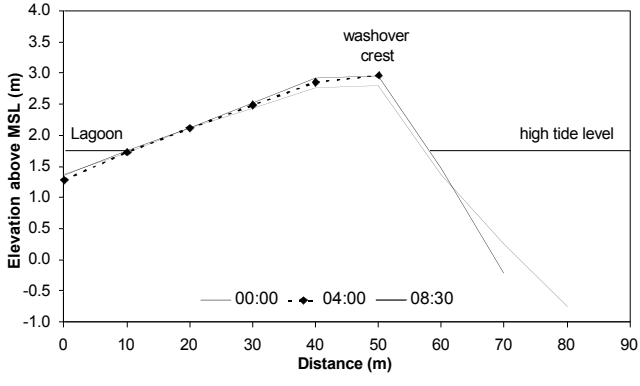

Fig. 3. Washover plain morphologic variations for an average cross-shore profile (profiles 1 to 6 of Figure 2), during GO.1 fieldwork campaign.

The accretion was wedge shaped, with a null point located above lagoon high tide level, below which the small variations (generally less than 10 cm) can be attributed to the lagoon currents. The accretion mostly occurred until 04:00; after which time small morphologic variations were noticed. The average volume variation in the study area was approximately +3.4 m^3/m.

During GO.3 fieldwork, the washover lobe central profile showed erosion on the mouth and channel, and accretion on the fan (Figure 4). On the contrary to the washover plain, some morphological changes were noticed, after 04:00. The volume variation of the central lobe profile was +4.7 m^3/m.

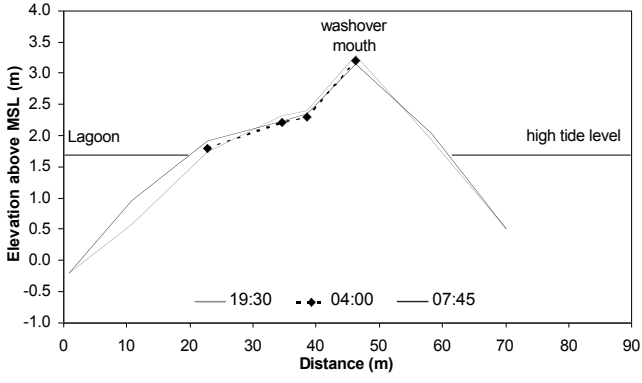

Fig. 4. Morphologic variations during GO.3 fieldwork for the washover lobe central profile.

The transport of the 40 kg of tracer during GO.1 began at 00:43 on February 10th 2001. The FT distribution map of GO.1 point to two main areas of sand transport, one landward of the injection point and another near the SE end of the sampling grid (Figure 5). However, the higher FT counting was next to or at less than 10 m landward from the injection point.

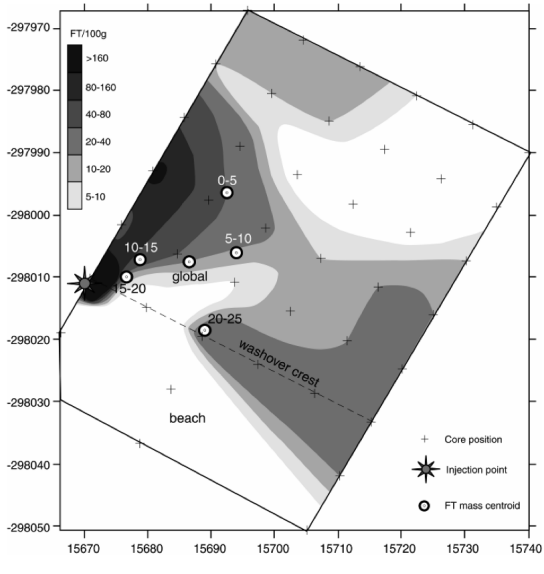

Fig. 5. FT distribution map integrating all sampled layers (0 to 25 cm depth), for GO.1 fieldwork. Mass centroids location is also represented.

About 57% of the FT counted in the laboratory was in the layers 10-15 cm and 15-20 cm, and only about 4% were in the deepest layer (20-25 cm). The mass centroid positions constitute an estimate of the average transport distance for each of the layers. The deepest layer (20-25 cm) shows a displacement in relation to the injection point that is dominated by the longshore downdrift component, yet in the superficial layer (0-5 cm) the average FT transport is dominated by the cross-shore landward component (Figure 5). The remaining percentage of FT on the sampled area after overwash was about 68%.

The FT distribution maps of GO.3 showed a progressive displacement of the FT cloud and mass centroids landward, from the deepest layers (20-25 cm, Figure 6e) to the superficial layer (0-5 cm, Figure 6a). In some layers (0-5 cm and 10-15 cm) there was FT transport to an adjacent eastwards washover; however the highest concentrations were located on the top of the washover fan belonging to the washover lobe (Figure 6). The layer that had the highest count was the deepest (20-25 cm), with the two superficial layers (0-5 cm and 5-10 cm) accounting for only 18% of the count. The remaining percentage of FT on the sampled area after overwash was about 77%.

DISCUSSION

The two fieldwork campaigns recorded non-storm overwash events that resulted from average winter waves ($H_{sb} \approx 1.2$ m) coupled with equinoctial spring tides (tidal level ≈ 1.7 m above MSL). However, the measured overwash flow velocities are in the same magnitude (around 2 m/s) as the ones found in the literature for storm overwash. Leatherman (1977) obtained a mean overwash flow velocity of 1.95 m/s, with an electromagnetic current meter, in Assateague Island (U.S.A); Leatherman and Zaremba (1987) measured 0.5 m/s to 2.0 m/s overwash flow velocities, with an electromagnetic current meter at Nauset Spit-Eastham (U.S.A); mean velocities of 2.0 m/s, measured with a video recording system, were obtained by Holland *et al.* (1991) at the Isles Dernieres (U.S.A.); Bray and Carter (1992) measured by timing wooden floats between markers, overwash flow velocities between 1 and 3 m/s at a barrier in Lake Erie (U.S.A); and a maximum of 1.5 m/s was the overwash flow measured with a flow meter through the Trabucador Bar, Spain (Guillén *et al.* 1994).

The two fieldwork campaigns recorded overwash events under similar oceanographic conditions, therefore the differences in sediment transport were mostly related to the morphologic characteristics of the washovers.

The shape of the washover plain was of a convex featureless surface, gently dipping landward (Figure 3). The washover crest marks the transition between the top of the beach and the washover, and had an asymmetrical cross-sectional profile with a steep side facing seaward (slope of about 0.14) and a gentle slope side facing landward (slope of about 0.03). During the early stages of overwash, when the intrusion was relatively small, the upper beach face and the washover crest were in sedimentary connection. The sediment transport in this stage had an important longshore component (mass centroid of layer 20-25 cm, Figure 5). The washover crest was the most dynamic part (Figure 3),

with accretion taking place as a consequence of the drop in flow capacity as the overwash overcomes the crest and flows over a gently landward dipping surface. Therefore, the convex crest shape was a very significant factor in retarding the flow progression.

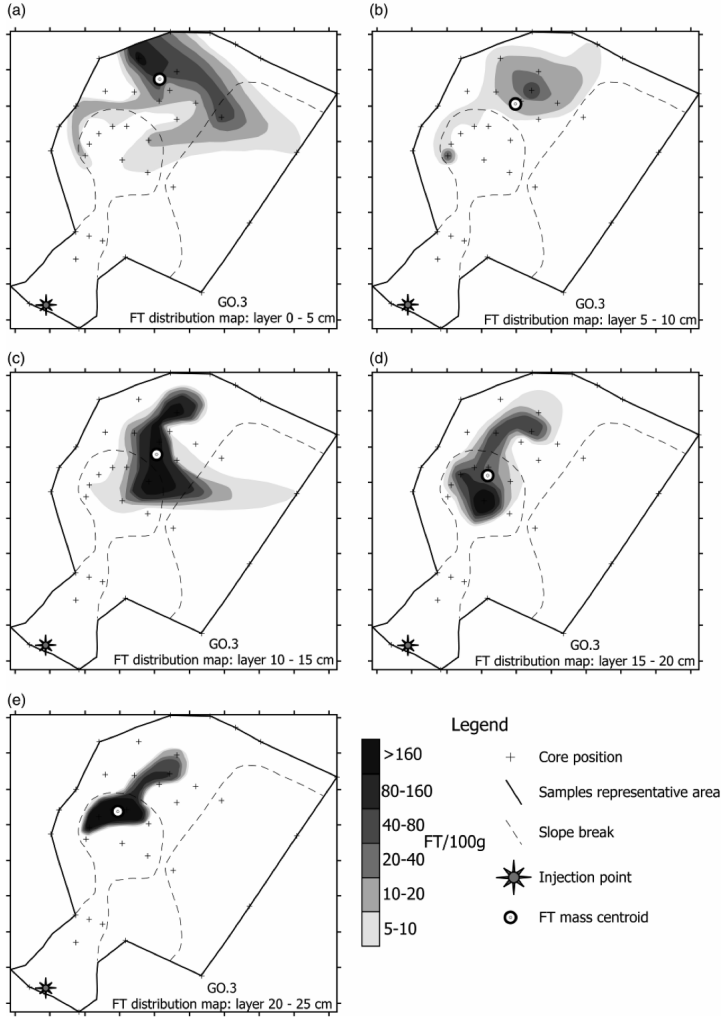

Fig. 6. FT distribution map for all sampled layers, for GO.3 fieldwork: (a) 0-5 cm, (b) 5-10 cm, (c) 10-15 cm, (d) 15-20 cm, and (e) 20-25 cm depth. Mass centroids are also represented.

As overwash frequency increased the onshore sediment transport became more significant. The patterns show that there was very small longshore transport of the tracer, thus suggesting that the overwash flow induced transport was dominantly cross-shore. It was found that the overwash flows on washover plains were constructive, generating a wedge-like layer of sand (Figure 3), denoting a decrease in flow capacity as it progresses through the washover surface. The sediment movement on the washover plain during an overwash event can be divided into three main stages: Stage 1 – Crest Accretion, Stage 2 – Onshore Transport, and Stage 3 – Dynamic Equilibrium. Stage 1 is characterized by the early overwash flows, where the crest is overtopped but the progression of the flow is inhibited by the friction and infiltration on a gentle landward angle crest. Stage 2 corresponds to a higher tidal level that induces an increase in overwash frequency and intrusion, and the occurrence of complete overwash. Once the tide starts to drop Stage 3 begins, inducing almost negligible morphological changes even though overwash continues to occur.

The washover lobe was distinct from the washover plain, not only in plan-view (Figure 2) with a distinct teardrop shape, but also in cross-shore profile (Figure 4). The mouth was very sharp and well defined (Figure 4), marking the transition between the steep beach face (slope of about 0.11) and the steep washover channel (slope of about 0.11). Landward of the channel, the gently dipping slope of the washover fan ended in the prograding steep distal fan. During the overwash event, the cross-shore profile had significant morphological changes, especially erosion of the seaward washover morphologies (mouth and channel) and accretion of the landward morphology (washover fan distal surface, Figure 4). Dune erosion, due to wave-generated run up impingement, caused the deepening and enlargement of the washover mouth. Once the mouth was overwashed, the lateral restriction of the flow in the channel together with the steeper landward slope induced the increase of the flow velocity and subsequent erosion. The bottom friction and infiltration on the surface, together with a lateral spreading due to the absence of dunes on the lagoon side of the barrier, induced a deceleration of the flow and the consequent sand deposition. During the early stages of overwash the deposition was closer to the washover channel (deepest layers, Figures 6d and 6e) and at later stages the deposition was displaced towards the lagoon (superficial layers, Figures 6a and 6b).

CONCLUSION

An innovative set of data was acquired for non-storm overwash occurring on a low barrier island. The overwash flow velocities under these non-storm events had the same order of magnitude as reported by other studies of storm overwash. The same magnitude of waves and similar tidal amplitudes induced different sediment transport patterns according to the washover morphology. Sediment transport inside washover plains and lobes was supported by the sequence of processes that occurred during the overwash events and that were noticeable by the integration of measurements of topography and tracers. The different types of sediment transport stages and patterns were interpreted as a result of distinct interactions between the overwash flow and the three-dimensional morphology of the washovers.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the people that made fieldwork under very difficult and demanding conditions. The work was partially funded by the project PRIMO (POCTI/CTA/39849/2001). Abstract: Pre- and post-storm topography and aerial photography, collected in regions where new washover fans were formed, were studied to determine the extent of morphologic, vegetative and anthropogenic control on washover shape and extent. When overwash is funnelled through a gap in a dune ridge and then spreads laterally on the back barrier, decelerating and depositing sediment, it forms washover fans. Fans were shown to primarily occur at pre-existing gaps in the foredune. During overwash, these gaps, or overwash throats, widened and deepened. The shape and extent of the fan was shown to depend on not only the pre-storm topography, but also the existence of beach tracks, roads and other anthropogenic influences and vegetation. The cross-shore overwash profile change model by Larson et al. (2005) and Donnelly et al. (2005) was modified to include pre-storm throat widths and a lateral spreading angle estimated from the pre-storm topography as inputs and tested using cross-shore profiles through the fan centres. These new inputs make the model more generalised, such that the calibrated model is applicable to a wider range of cross-shore profiles.

INTRODUCTION

Recent increases in frequency and intensity of tropical storms highlight the importance of understanding physical storm phenomena such as overwash. Overwash is the transport of water and sand landward of the beach crest by elevated wave and water levels, sometimes as far as the back barrier bay or lagoon (in the case of barrier island overwash). The sediment deposited by overwash is usually described as washover.

Washover contributes to the sediment budget of barrier islands and is thought to maintain the width of barrier islands as they migrate landward. It can also provide specific habitat for endangered species such as the piping plover. Overwash can also be a hazard, particularly on developed coasts where water and sand intrusion, scour (of coastal roads for example), and even structural damage by debris entrained in the overwashing flow cause problems. The ability to predict the occurrence, magnitude and shape of overwash deposits is therefore of importance to coastal managers, authorities and residents alike. The causes of overwash and overwash processes are well documented (e.g. Hayes 1967, Leatherman 1976, Donnelly et al. 2006), and the ability to predict overwash occurrence (Sallenger et al. 2000) and model beach profile change due to overwash (Wise et al. 1996 , Larson et al. 2005, Donnelly et al. 2005) is just beginning to emerge.

Washover fans are formed when overwash is focused through a local gap in the dune ridge. This gap is known as an overwash throat. Behind the dune ridge the overwashing flow spreads laterally. At the same time the flow decelerates due to the combined effects of lateral spreading, friction and infiltration. Local topography changes may also decelerate (or accelerate) flow. As the flow decelerates, entrained sediment is deposited, forming a washover fan. Such features are commonly identified on the US Gulf and Atlantic coasts following major hurricanes and northeasterly storms.

Data consisting of high resolution, three-dimensional, pre-and post-storm topography collected by lidar, and oblique aerial photography, were collated for several washover fans. The data showed washover fans on Hatteras Island, NC, following Hurricane Isabel, 2003. This high quality data provided the unique opportunity to, for a number of deposits, analyse washover fan shapes and morphologies, measure pre- and post-storm washover throat widths, identify topographical and surface texture restraints on lateral spreading, and in some cases, estimate a potential lateral spreading angle.

Using measurements of the throat width, B_{pre}, and the potential lateral spreading angle, β, an existing algorithm for overwash flow behind the crest of a mainland or barrier beach by Donnelly et al. (2005) and Larson et al. (2005) was tested with these new inputs. Previously these dimensions have been included in the model through coefficients which were calibrated to the post-storm data. The inclusion of these new inputs makes the model more generalised, and hence a calibrated model should be applicable to a wider range of profiles.

DATA EMPLOYED

Hatteras Island is an 80 km long barrier island located in North Carolina, on the Atlantic Coast of the U.S.A. The island has a distinct bend at Cape Hatteras such that the southern portion of the island is facing south-southeast while the northern portion of the island faces east-southeast (Figure 1). The island is relatively undeveloped, with a population of just 4000. A paved road extends parallel to the shore along the island. Hurricane Isabel made landfall as a category 2 hurricane on September 18, 2003 near Cape Hatteras causing numerous washover deposits along the coast. Maximum

sustained winds of 128 km/hr were measured near the cape, and maximum deepwater wave heights were estimated to exceed 15 m offshore of the cape. Along the Hatteras coast, the storm surge exceeded 2m (Fauver 2005).

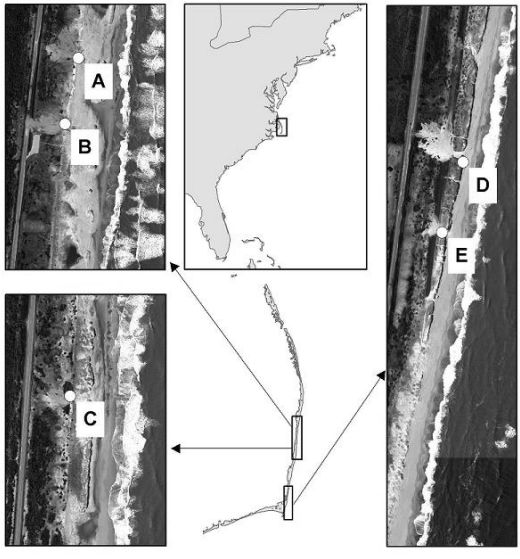

Figure 1. Location map showing U.S. Atlantic Coast, Hatteras Island, and aerial photographs showing locations of the studied fan deposits.

Airborne topographic lidar (light detection and ranging) surveys were used to collect topographical data along the Hatteras Island shoreline immediately prior to and after the landfall of Hurricane Isabel. The pre-storm survey was made September 16, 2003, immediately prior to the first storm wave impacts on the shoreline (Fauver 2005) and the post-storm survey was made on September 21, 2003. The topographic survey data analyzed in this study was collected approximately 45 km northeast of the point of landfall. Oblique and geo-rectified aerial photographs of the Hatteras coastline were also taken on September 21, and these may be compared with pre-storm oblique aerial photographs taken after the previous major storm in 1999.

Lidar surveys allow the rapid collection of large regions of topographic data. Further information about the lidar survey technique and its application in the coastal environment can be found in Brock et al. (2002). In a study statistically comparing data collected using lidar with three traditional ground survey techniques, the accuracy of the individual lidar elevation measurements was deemed to be approximately 15 cm (Sallenger et al. 2003). This level of accuracy is generally suitable for studying changes due to overwash. Large deposit regions with thicknesses of the order of 10-15 cm are observed; however if the measurement error is not systematic, the existence of these

deposits is true, even if the accuracy of the deposit thickness may vary from that measured.

Three regions of pre- and post-storm topographic lidar data in which washover fans occurred were selected (Figure 1). All data is from the section of shoreline north of Cape Hatteras. Each region encompassed a stretch of coastline approximately 650 m long and 250 – 300 m wide from the shoreline landwards. The survey data was linearly triangulated onto a 2 x 2 m grid and plotted on contour maps to evaluate the pre- and post- storm topography. A difference grid, showing the differences in elevation between the pre-storm and the post-storm grids was also calculated and plotted as a contour map, the topography differences map. Cross-sections and alongshore sections were extracted from the grid data for regions of interest.

Hydrodynamic data was also available. A 3-hourly time-series of significant wave-height and peak wave period was extracted from NOAA's WAVEWATCH III model (Tolman 1997, 1999) for a period spanning the pre- and post-storm surveys. The data was extracted at the pre-storm location of the Diamond Shoals wave buoy (41025, depth 54.9 m), which stopped recording some hours prior to storm landfall, hence the use of hindcast wave characteristics. The nearest NOAA tidal gauge, Hatteras Fishing Pier, also failed during the peak of the storm; however, water level data is available from the NOAA Duck Field Research Facility tidal gauge (8651370) which was shown to correlate well with the Hatteras gauge prior to failure (Fauver 2005).

The combination of pre- and post storm topographic data and aerial photography taken immediately prior to and following a hurricane landfall, the sections plotted from the data, and the associated hydrodynamic data, allowed the opportunity to study the morphologic, anthropogenic and surface texture controls on washover fan formation, and model cross-shore profile change caused by overwash using knowledge of these controls.

DATA ANALYSIS

The post-storm changes on the island can be evaluated by examining the topography differences map (the difference between the post-storm and pre-storm elevations) and the post-storm aerial photography. Figure 2 shows an example of a topography differences map (left) beside the pre-storm topography map (right). Positive values of topography difference indicate deposition, and negative values indicate erosion. A general inspection of these maps indicates erosion of the dune face and crest and isolated deposits behind the pre-storm dune location. These are washover fan deposits (dashed outline, Figure 2).

Five distinct washover fans were observed in the three regions. These are labelled *Fan A* to *Fan E* from north to south, as shown in Figure 1. Immediately seaward of the washover fans the rear dune slope is also eroded and a region of higher erosion rates exists through the dune. This is the overwash throat (solid outline, Figure 2). During overwash, overtopping flow is channelled through pre-existing gaps in the foredune and

then spreads laterally behind the dune where the topographical restraints on the flow are more limited. Sheet overwash can occur when the entire dune ridge is overwashed, but this study is limited to confined overwash.

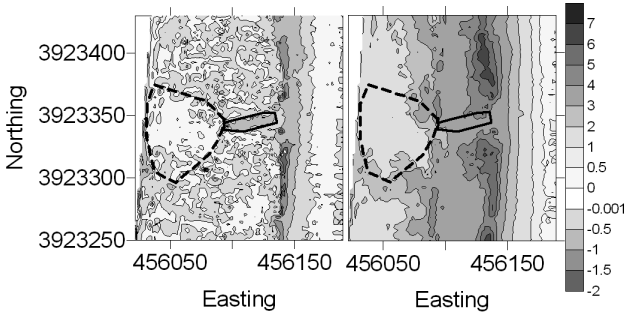

Figure 2 – Pre- and post-storm Topography Differences Map (left) and Pre-storm topography map (right), showing the region of deposition in the washover fan (dotted line) and the region of erosion in the overwash throat (solid line) for Fan C.

Overwash Throats

Comparison of the post-storm throat locations with the pre-storm topography indicates that the location of the overwash throats is primarily determined by pre-existing gaps in the foredune ridge, as can be seen on Figure 2, for Fan C. This has been recognised in overwash literature (e.g. Cleary and Hosier 1979, Dolan and Hayden 1981). The pre-storm photography indicated a pre-existing washover fan at this location.

In the regions where Fans C, D and E occurred, prominent foredune ridges, up to 7 m in height existed. No pre-existing washover fans were observed at the locations of Fans D and E, but the pre-storm topography indicates gaps in the foredune at these locations.

Fans A and B occurred behind a secondary dune ridge. The pre-storm topography does not indicate pre-existing gaps in this dune ridge; however, there were gaps in the foredune ridge directly in front of the fan locations. Additionally, the aerial photography indicates a beach access path passing through the rear dune ridge at the location of Fan B. The pre- and post-storm topography maps for Fan B are shown in Figure 3. The post-storm topography shows that most of the foredune was destroyed. It is suggested that the overwashing flow channelled in the foredune overwash throat had sufficient velocity to overwash the rear-dune, forming an overwash throat through which subsequent overwash was channelled. Along most of this coastal section, the pre-existing foredune throats widened, until eventually they merged. Rapid widening of washover throats was observed in experiments conducted by Donnelly et al. (2005) and Tuan et al. (2006). Sheet overwash of the beach crest would then have been possible. Note that there is some remnant of the foredune remaining directly in front of the rear dune throat, indicating that channelling during the entire storm contributed to the fan formation through the rear dune at this location.

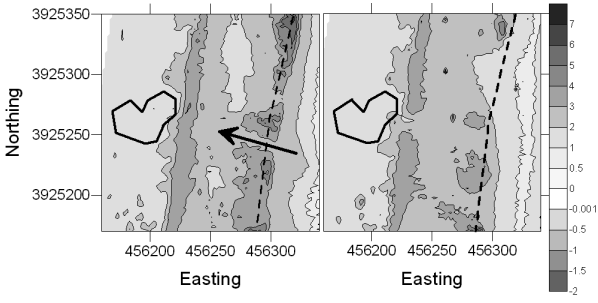

Figure 3 –Pre-storm topography map (left), and Post-storm topography map (right) for Fan B, showing the region of deposition in the washover fan (solid line) and the location of the pre-storm foredune ridge (dashed line).

Alongshore sections taken along the foredune show the deepening and widening of overwash throats during overwash (Figure 4). Pre- and post- storm overwash throat widths were measured from the long sections. The throat width, B, was defined as width at the top of the throat (Fig. 4), because observations during laboratory experiments indicated that during overwash, the sides of the throat collapsed into the channel due to notching, such that the sides of the throat were vertical (Donnelly et al. 2007). Pre and post-storm throat widths are listed in Table 1. Note that in some cases widening is not observed when comparing B_{pre} and B_{post}; however widening is observed at the sides and bottom of the throat. At Fan C, for example, vegetation is observed to hinder the widening of the top of the overwash throat.

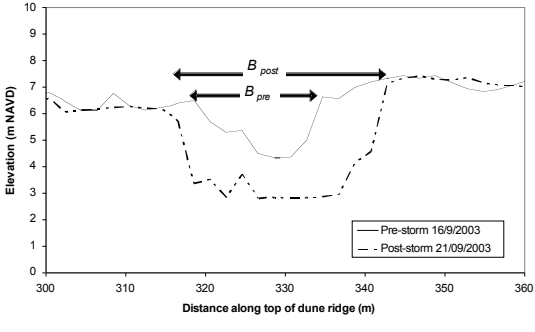

Figure 4- Long-section taken along the foredune at Fan D, defining B_{pre} and B_{post}.

Washover Fans

Table 1 summarises the observed geometry and characteristics of the 5 fans. An outline of the accreted region observed on the topography differences map was compared with the outline of bare sand on the geo-rectified aerial photography taken after the storm

(Figure 5). The outlining of this region was made subjectively due to noise in the data. As expected the two regions are very similar; however, the bare sand region extends seaward through the overwash throat where erosion is observed on the topography differences map. Other small differences in extent are probably due to the resolution of the lidar data. Using the overwash throat and the region of deposited sediment, the lateral spreading angle of the washover throat was measured. In most cases the fans were not symmetrical, so a north, a south, and an average lateral spreading angle was calculated. Additionally, the lengths, *L*, and widths, *W*, of the longest and widest dimensions of the fans were measured, assuming a fan axis parallel to the overwash throat.

Table 1 – Summary of Fan Characteristics

Fan	Shape	β_{north}	β_{south}	β_{ave}	*L* (m)	*W* (m)	*L/W*	B_{pre} (m)	B_{post} (m)
A	Assymetric	64°	14°	39°	67	82	0.8	na**	26
B	Long Diamond	25°	18°	22°	93	42	2.2	28	30
C	Diamond	30°	30°	30°	55	52	1.1	62	66
D	Wide Diamond	25°	42°	33°	28	57	2.0	16	29
E	Wide Triangle	na	45°	na	90	109	0.8	36	34

**There was no pre-existing gap in the rear dune at this location

In the absence of lateral or landward topographic constraints, the overwashing flow is directed landwards, perpendicular to the dune ridge, but spreads laterally as it leaves the confinement of the overwash throat. The fan develops a diamond shape, as velocities are highest in the centre of the fan, thus transporting sediment furthest inland along the fan axis. In reality, topographic constraints, vegetation and anthropogenic development all influence the eventual shape of the fan. Morton (1979) also showed how wind can influence the washover fan shape development. The results shown in Table 1 indicate that the fans can be long and narrow, short and wide or entirely asymmetric. The pre-storm topography and aerial photography were used to examine how the pre-storm morphology and surface texture control the overwash throat and washover fan shape development.

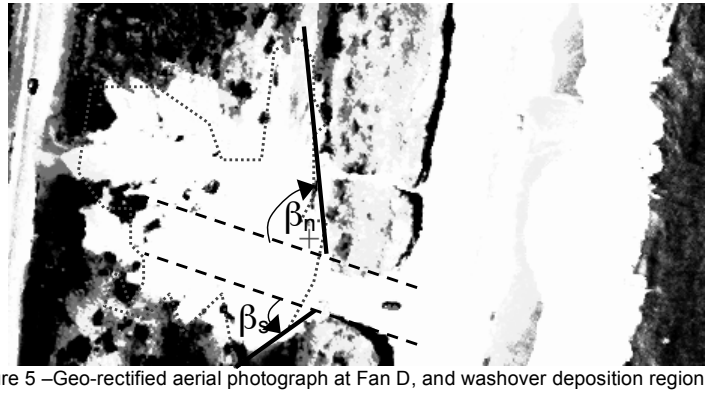

Figure 5 –Geo-rectified aerial photograph at Fan D, and washover deposition region from lidar for Fan D (dotted blue line), and definition of lateral spreading angles, β.

The pre-existing Fan C was extended both landwards and laterally; however, dense vegetation impeded the widening of the overwash throat on the northern side. At Fan C, the lateral spreading angle can be estimated from the pre-storm topography. Lines were drawn from the pre-existing throat to areas of topography at the same elevation as the throat. The angle of these lines to the overwash throat axis, 30^{o}, was similar to that measured on the topography differences maps and geo-rectified photography.

The pre-storm topography indicated that Fans A, B, and D are all relatively unconfined laterally by topography on the back barrier, so it was not possible to use topographical influences to quantitatively predict the fan shape. The fans show a large variation in shape and lateral spreading angle, so factors other than lateral topography must also have a strong influence. Figure 6 shows aerial photographs of Fans A, B, C and E (Fan D is shown in Figure 5).

Fan A is actually two fans merged together. Close inspection of the post-storm photography indicates a smaller throat to the north of the main throat. Additionally, overwashing flow in the main throat appears to have occurred in two directions, perpendicular to the dune ridge and along the northern edge of the dune. There is a small portion of a remnant foredune remaining in front of the overwash throat, and division of flow around this may have lead to two different streams of overwashing flow.

At Fan B, an unpaved beach access track perpendicular to the dune ridge facilitated the development of a long, thin washover fan. Flow along the fan axis, therefore penetrated a lot further landward than would otherwise have been seen. Although not seen in the topography, the track was probably at slightly lower elevation than the surrounding back barrier, and the surrounding barrier is vegetated, indicating less frictional restraint in the track.

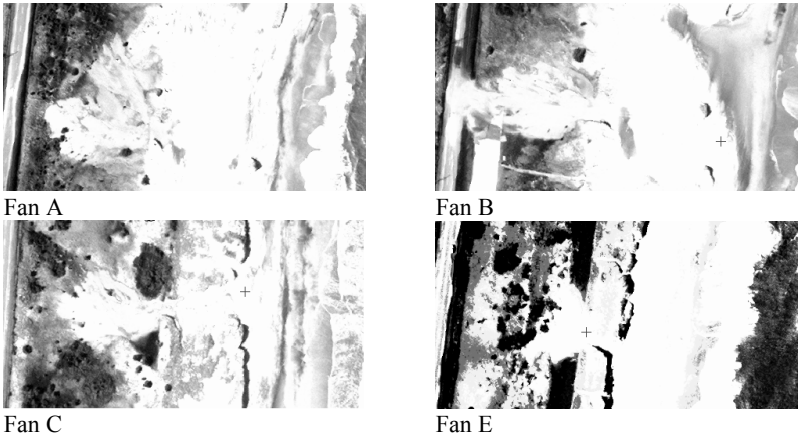

Figure 6 - Post-Storm geo-rectified aerial photography (Fan D is shown in Figure 5)

The shape of Fan D is also affected by an unpaved beach access track perpendicular to the dune ridge, in addition to a paved road located immediately behind and parallel to the foredune ridge. The overwash throat is located 50 m to the south of the track, but the fan extends further inland along the track, and hence is asymmetric. The fan has also extended substantially to the north along the paved road. Finally, Fan E is much wider than it is long due to lateral spreading in both directions along the same paved road and confinement by topography and vegetation on the landward side of the road.

To summarise, washover fans were diamond shaped but varied substantially in length to width ratio. Lateral spreading angles varied from as low as 15^{o} up to 65^{o} but ranged mostly between 20^{o} and 45^{o}. In most cases complicated back barrier topography, dense vegetation, tracks and roads, multiple overwash throats and complicated topography on the foreshore all contributed to the shape development of the washover fans; however, for a simple case, such as at Fan C, topographical confinement alone may be used to quantitatively predict fan shape development. Influences such as tracks and roads can be used to qualitatively predict where overwash will spread. It was seen that overwash flow penetrates further along tracks and roads where friction is reduced.

MODELLING

Larson et al. (2005) and Donnelly et al. (2005) developed an algorithm to calculate beach profile change due to overwash taking into account two different flow regimes over the beach crest, namely runup and inundation overwash, respectively. Ballistics theory was used to calculate the hydrodynamics in the swash zone and the flow rate over the beach crest during runup overwash, whereas weir overflow theory was used to calculate the flow rate over the beach crest during inundation overwash. The concentration of sediment in the overwashing flow was assumed constant following Kobayashi *et al.* (1996). The water flow on the back barrier slope was calculated by considering the continuity of a block of water at steady-state, including lateral spreading and infiltration, and the sediment transport rate was assumed proportional to the velocity cubed. The model was implemented within the SBEACH numerical model for simulating storm-induced beach profile change (Larson and Kraus, 1989).

Donnelly et al. (submitted) calibrated and verified the model for 2-D profiles. Initial overwash throat width, lateral spreading angles and infiltration rates were included together in three overwash coefficients which were calibrated for each location. These coefficients took into account 1) the proportion of sediment in the overtopping flow along with a bore front/weir coefficient for the runup overwash/inundation overwash modules, respectively, (2) the initial throat width and lateral spreading angle, and (3) the infiltration rate. Donnelly et al. (submitted) showed that the model could be verified using calibrated parameters for similarly shaped profiles in the same region, but not for profiles in different regions. This new, 3-D data, allowed the opportunity to input actual overwash throat widths and lateral spreading angles, in order to produce a more generalised cross-shore overwash profile change model. The algorithm was reformulated

such that the initial overwash throat width and a potential lateral spreading angle could be entered. For simplicity, infiltration was assumed to be negligible. A single calibration coefficient remains in the algorithm to represent the proportion of sediment in the overtopping flow along with a bore front/ weir coefficient for the runup overwash /inundation overwash modules, respectively.

Figure 8 shows the results of cross-shore profile modelling at Fans B and C. Initial overwash throat widths, B_{pre}, of 28 m and 62 m were identified for Fans B and C, respectively, using an alongshore section of the dune ridge crest. It is acknowledged that the throat width varies during overwash, but in a predictive mode, the pre-storm throat width is specified. This value is kept constant during the simulation. At Fan C, a potential lateral spreading angle, β_{ave}, of 30° was identified using the pre-storm topography confinement. At Fan B, there was no pre-storm topography confinement and the shape development was affected by anthropogenic influences, so the measured post-storm angle of 17° was used instead to verify the model. In a predictive mode, lateral spreading angles may be derived, where possible, using pre-storm topography confinement, but note that anthropogenic influences and vegetation affect lateral spreading significantly. Where a previous fan exists, the lateral spreading angle of the old fan may provide a good initial estimate. In the absence of a better estimate, an angle of 30 degrees represents the average lateral spreading angle of the measured fans. The model was calibrated at Fan C and verified at Fan B using the overwash coefficient value determined during calibration. The model was run using the aforementioned time-series for wave characteristics and water level during Hurricane Isabel.

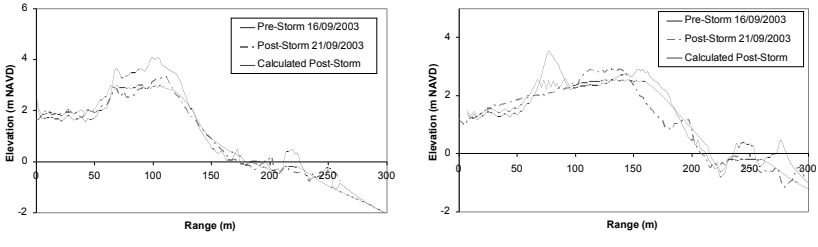

Figure 7 – Cross-shore profiles showing results of overwash model simulations (a) Calibration Run: Fan C, and (b) Verification run: Fan B

The results indicate the model's capability to predict the subaerial barrier evolution, including destruction of dunes, lowering of the beach crest and the landwards deposition of sediment. Optimal root-mean-square (RMS) error values were reached for the same overwash coefficient, indicating the general applicability of the model for similar locations in a predictive mode. The subaerial RMS value for Fan C was 0.231 and for Fan B was 0.397.

CONCLUSIONS

Several washover fans deposited during Hurricane Isabel, 2003, on Hatteras Island, NC, were studied to determine the controls on washover fan development. Fans were shown to typically form at pre-existing gaps in the dune ridge. Two fans were shown to form behind the rear dune ridge, where a gap pre-existed in the fore dune ridge, indicating that flow channelling in the foredune enabled breaching and subsequent overwashing of the rear dune. Overwash throats were shown to both widen and deepen during overwash.

The washover fans were mostly diamond shaped, with landward penetration maximum along the fan axis. Topography, vegetation and anthropogenic influences such as roads and tracks, however, were shown to obstruct this natural fan development and the fans varied substantially in length to width ratio. Lateral spreading angles varied from as low as 15^o up to 65^o but ranged mostly between 20^o and 45^o. It could be seen that washover spread laterally over a wider region where shore parallel roads and tracks existed, and penetrated further inshore along shore perpendicular tracks. Vegetation was seen to impede both throat widening and lateral spreading. Qualitatively, the shape development of a fan can be predicted using these observations. The quantitative lateral spreading angle was able to be predicted for one fan where vegetative and anthropogenic obstructions were negligible and where the pre-storm topography clearly varied in height on the back-barrier.

Initial throat widths and lateral spreading angles (both predicted and measured) were used as inputs to a generalized version of the overwash model by Larson et al. (2005) and Donnelly et al. (2005). The results indicated the model's capability to predict the subaerial barrier evolution. This more generalized cross-shore overwash profile change model can be applied to cross-shore profiles at which overwash is identified as a potential hazard, ie. at pre-existing gaps in the dune ridge using a measured throat width and a potential lateral spreading angle, if a potential lateral spreading can be predicted from the back barrier topography, vegetation, roads or pre-existing fans. It is otherwise suggested that an angle of 30^o be used, as this is near to the average angle for the studied fans.

ACKNOWLEDGMENTS

The study was partly conducted as an activity of the Coastal Morphology Modeling and Management (Cascade) work unit of the System-Wide Water Resources Program (SWWRP) and partly as part of the European Commission research project FLOODsite (Contract Number: GOCE-CT-2004-505420).

Sincere thanks are expressed to Laura Fauver and Karen Morgan, USGS Center for Coastal and Watershed Studies, who took time to help select and extract the lidar data and provide helpful reviews, to Karin Larsson, Lund University GIS Centre for her assistance with Figure 1, and to Magnus Larson for advice regarding modelling and a helpful review of the article.

Abstract: Overwash induced by storm conditions is one mechanism causing coastline change with cross-shore erosion and deposition. Many field studies have been conducted but laboratory experiments are few. This experimental study was conducted for estimation of eroded sand volume by overwash. The experiments were conducted at two different wave heights and four different wave periods in two different slopes of beach face for regular and irregular waves. The experiments were done in a 2D wave tank on mid-scale at Texas A&M University. The measured data from 32 different tests were used to analyze the characteristics of overwash.

INTRODUCTION

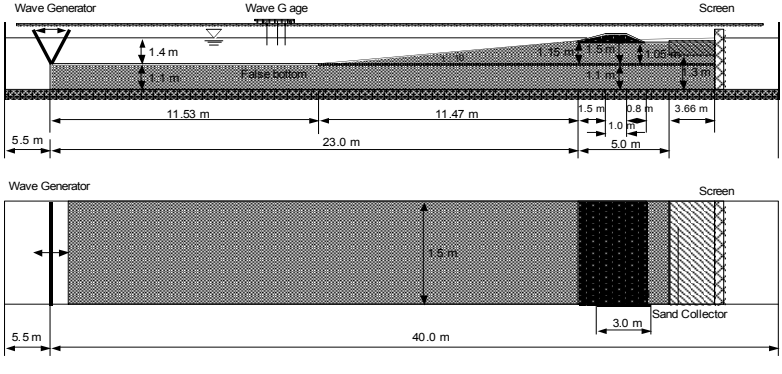
The understanding of interaction between waves and the beach is necessary for understanding erosion caused from severe wave action. Storms accompanied by large waves and sea level rise cause overtopping and overwash over the berm. During an overtopping event, a huge amount of sand is eroded and transported landward by overwash. Available field data are very difficult to obtain during severe weather conditions on the beach, so laboratory data are convenient to analyze overwash. Williams (1978) conducted a small-scale experiment and found that sediment transport of much greater distance was produced from a steep slope beach face than a flatter slope. Hancock (1994) conducted an experiment for simulation of overwash. He measured beach profiles and the amount of eroded sand by overwash for different beach slopes and irregular wave conditions. Kobayashi et at. (1996) developed an

empirical equation for rate of sand overwash and wave reflection based on the work of Hancock (1994).

In this study experiments were conducted with overwash by tropical storm conditions. The offshore slope was 1:10 and two different nearshore beach slopes were used in a two dimensional tank. Different wave heights and wave periods were used for regular and irregular waves at the different slopes of beach faces. The experimental results were used for developing empirical formulas to describe the process for the different conditions tested.

EXPERIMENTAL SETUP

The experiment was conducted in a 2D wave tank that was 28.0 m long, 1.5 m wide, and 3.0 m high as shown in Fig. 1. A flap type of wave generator was located at the end of the channel 1.1 m above the bottom and it generated regular and irregular waves in this experiment. A false bottom was constructed from the bottom of the wave paddle to the toe of the beach slope. This was constructed to prevent energy losses from the wave generator and minimize the amount of sand used to build the artificial beach. A berm was constructed on the top of the structure. Its measured median grain size and specific gravity were 0.15 mm and 2.65, respectively. Each experiment was conducted for 327 seconds and the sampling rate for waves was 50 Hz.



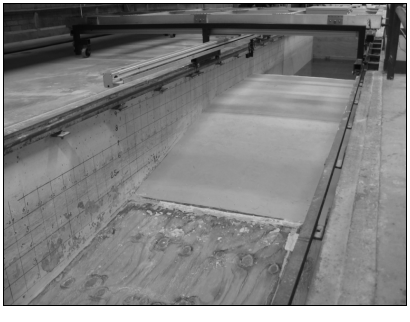


Fig. 1. Side and plan view of experimental facilities.

The experiments were conducted with two wave heights of 0.14 and 0.17 m and four wave periods of 1.4, 1.6, 1.8, 2.0 for regular waves and two H_{mo} of 0.10 and 0.15 m and four peak wave periods (T_p) of 1.4, 1.6, 1.8, 2.0 for irregular waves using TMA spectrum in Table 1. Three wave gages for the separations of incident and reflected waves were installed in the middle of tank and the data were analyzed by the method of three wave gages (Sub et al., 2001). A false bottom was extended on a slope of 1:10 to the beachface and the experiments included two different slopes of beach face (1:4 and 1:5) in the berm. When the slope of beach was milder than 1:5, overwash

could not be generated. About 2.5 m^3 fine sand (d_{50} of 0.15mm) was used to build a laboratory berm on a false bottom and the top of berm was 0.1 m higher than still water level. The initial shape of sand berm is shown in Fig 2.

Table 1. Wave Heights and Periods for Regular and Irregular waves.

Slopes of beach face	Regular waves		Irregular waves	
	Wave Height (m)	Wave Period (sec)	H_{mo} (m)	T_p (sec)
1:4	0.14	1.4	0.10	1.4
		1.6		1.6
		1.8		1.8
		2.0		2.0
	0.17	1.4	0.15	1.4
		1.6		1.6
		1.8		1.8
		2.0		2.0
1:5	0.14	1.4	0.10	1.4
		1.6		1.6
		1.8		1.8
		2.0		2.0
	0.17	1.4	0.15	1.4
		1.6		1.6
		1.8		1.8
		2.0		2.0

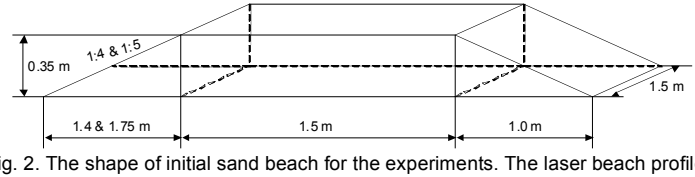

Fig. 2. The shape of initial sand beach for the experiments. The laser beach profiler is installed above the sand berm.

The speed of bores was measured with two wave gages located on the top of berm. The heights of bore proved difficult to measure during overwash events using capacitance wave probes. Typically, it was almost 3 or 4 cm, when it was checked by direct measurement. The speeds of bores were computed by Eq. (1). The speed of bore changed during the experiment with the change of beach profiles. The speeds of bores were measured for first 60 seconds and it was averaged by the number of overwash events. For example, the bore speed was 0.896 m/s, when the wave height was 0.14 m and the wave period was 1.4 sec. The speeds of bores for irregular waves were not measured due to its irregularity.

$$\text{Speed of bore} = \frac{\text{Distance between two gages}}{\text{Time to reach from } 1^{st} \text{ gage to } 2^{nd} \text{ gage}} \quad (1)$$

A laser profiling system was constructed to measure the change of profiles during and after the experiments. It is shown schematically in Fig. 3. The measurements were controlled by a personal computer. The user defined the first and last corner of the measurement field. Then the measurements were conducted automatically. Beach profiles were measured by a laser with 0.5 mm accuracy every 5 mm in x (cross-shore) and 20 mm in y directions. It took about 15 minutes to measure the whole area which was 5.0 m in x and 1.0 m in y directions. Each measurement was conducted at a location 0.25 m away from both walls to eliminate the impact of wall effects. The laser measurement system provided an opportunity to conduct measurements without touching the target. It was also used to measure the beach changes during the experiments. The time series of profile changes were measured within a limited range during the experiments, because the laser beam was reflected by the suspend sediment or foam on the water surface. This laser profiling system improved the accuracy and automation in measurements.

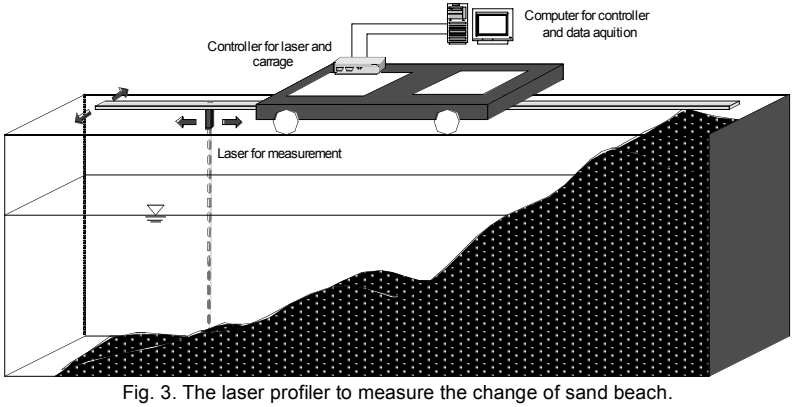

Fig. 3. The laser profiler to measure the change of sand beach.

An example of the measured final beach profile is displayed in Fig. 4. The image was produced by Surfer from the data in x, y and vertical elevation.

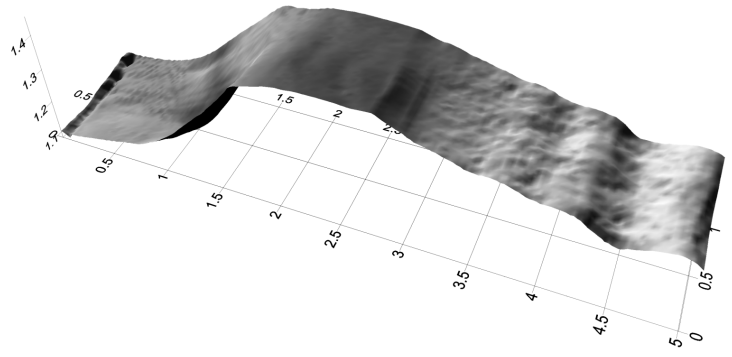

Fig. 4. The plot of sand profile by a laser profile after a beach erosion test.

EXPERIMENTAL RESULTS

The profile data measured every 20 mm in longshore direction were averaged and a representative line from the averaged result was produced in the cross shore direction as shown in Fig. 5. The initial sand profiles were measured at each test. The final beach profiles were measured after running waves for 327 seconds. The measurements of profiles were conducted after all suspended sand was deposited completely and it usually took 10 minutes. Because the maximum range of the laser profiler was 5.0 m in cross-shore direction, the measurements beyond the range were conducted by moving of the laser system. The laser profiler is installed on the top of rails along the wave tank and it can be moved to an interesting location manually.

The creation of a sand bar helped to reduce and stop the impact of overwash by energy dissipation of wave breaking. The larger and longer waves showed more erosion of sand over the berm by overwash. Typical results are shown in Fig. 5 for two wave heights (0.14 and 0.17 m) and four wave periods (1.4, 1.6, 1.8 and 2.0 sec). The sand berm was installed from about 1.0 m to 5.0 m and the bottom outside this area was made by plywood. Therefore there was no erosion below this elevation.

The location of offshore bar was related to the reflection coefficient. The changes of reflection coefficient at each wave period and slope of beach face are shown in Fig. 6. As the reflection coefficient was increased, the bar was located much further offshore. At the longest wave period (2.0 sec), the sediment transport over the berm was increased with lowering of the berm height and the bar moved shoreward. For this wave period, the reflection coefficient also decreased.

The transportation of eroded sand by overwash reduced to nearly zero beyond the 7.0 m mark shown in Fig. 5 for all cases. Sediment transport over the berm was also weak in most of tests for 1.4 and 1.6 sec wave periods. The sediment transport distances landward were not measured in this study but they also correlated with

wave period. Much sand was transported and deposited behind the berm as shown in Fig. 5. The collected volume of sand was almost zero in the test of short wave period and the maximum was 0.0058 m^3 at 0.17 m of wave height and 2.0 sec of wave period. The eroded sand out of this measurement range was collected to calculate the transport rate by the volume.

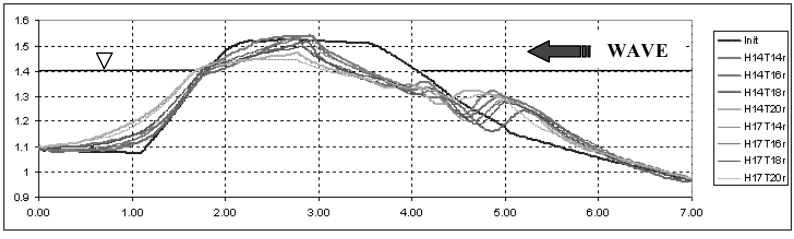

Fig. 5. Beach profiles for regular waves at 1:4 slope of beach. In the legend, Init represents Initial shape of beach and H14T14r means the test result at 1.4 m of wave height, 1.4 sec of wave period and regular waves.

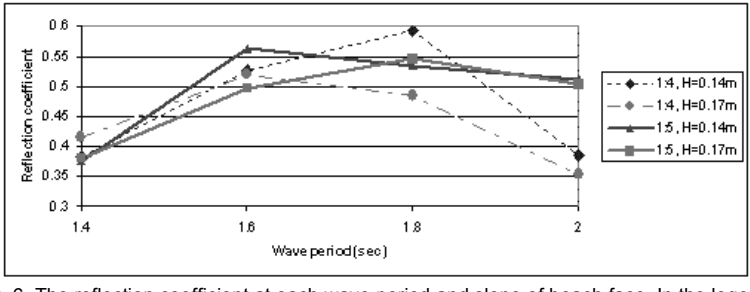

Fig. 6. The reflection coefficient at each wave period and slope of beach face. In the legend, the first and second numbers mean slope of beach face and wave height, respectively.

The experimental results by irregular waves are shown in Fig. 7. The differences between each test were not apparent over 327 seconds. The offshore bars were located at the same location in each test. The test duration (327 seconds) was selected the same as the tests for regular waves for comparison but it was considered that this duration was not enough time to analyze for irregular waves.

Overwash events continued occurring as long as the slope of beach face became steeper than about 1:6 for irregular waves. The erosion rate suddenly reduced after reaching this slope and the beach face retreated while maintaining this slope as shown in Fig. 11. However, erosion and sediment transport behind the berm were different at each wave period for irregular waves in Fig. 7. Longer and higher wave also produced much erosion behind the berm like the results by regular waves. Because irregular waves are composed of different wave heights and periods, their intensity of erosion and transport was weaker than the results by regular waves.

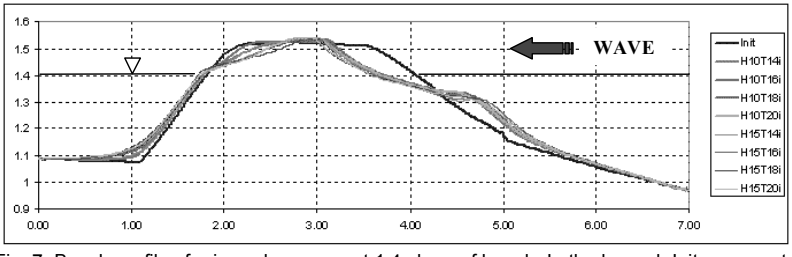

Fig. 7. Beach profiles for irregular waves at 1:4 slope of beach. In the legend, Init represents Initial shape of beach and H14T14i means the test result at 1.4 m of wave height, 1.4 sec of wave period and irregular waves.

The time series of profile changes measured by the laser profiler was used to find the correlation between overwash, erosion rate and time. One of test results is shown in Fig. 8. The time series of profile changes were recorded every 60 seconds. The sand profiles below the water were not measured, because the beam of the laser profiler was reflected on the surface of water with suspend sediment. Most of beach profile changes occurred at the beginning of the experiment and nearly ceased before the end of the test results.

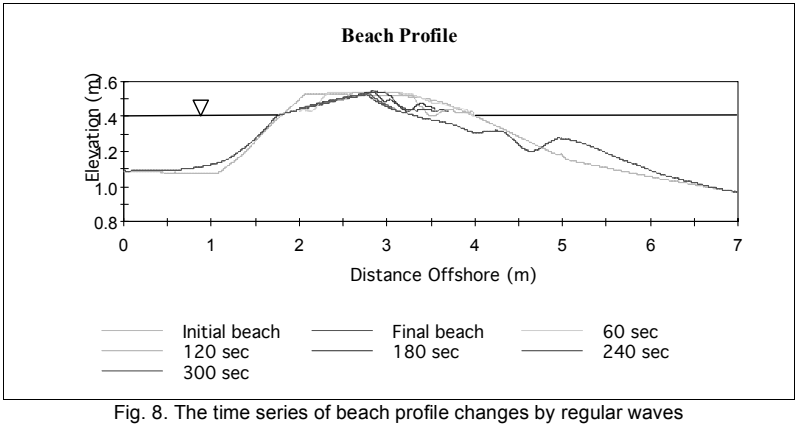

Fig. 8. The time series of beach profile changes by regular waves (height = 0.17 m, period = 1.6 sec, slope = 1:4).

The comparison by different wave height is shown in Fig. 9. Only two different wave heights were used for this study; the higher wave height produced much more erosion as would be expected. It also showed the same results in different slopes of beach face (Fig. 10).

A comparison was made by different beach slopes at the same wave height and period and is shown in Fig. 9 and Fig. 10. Erosion by overwash was much stronger at

a slope of 1:4 than at 1:5 as might be expected. Much sand was transported over the berm and deposited at a steeper slope.

Erosion by overwash was increased according to increasing of wave periods. The differences by different wave heights and periods are shown in Fig. 5. In summary erosion and sand transport were strongest at higher wave height, longer wave period and steeper beach face.

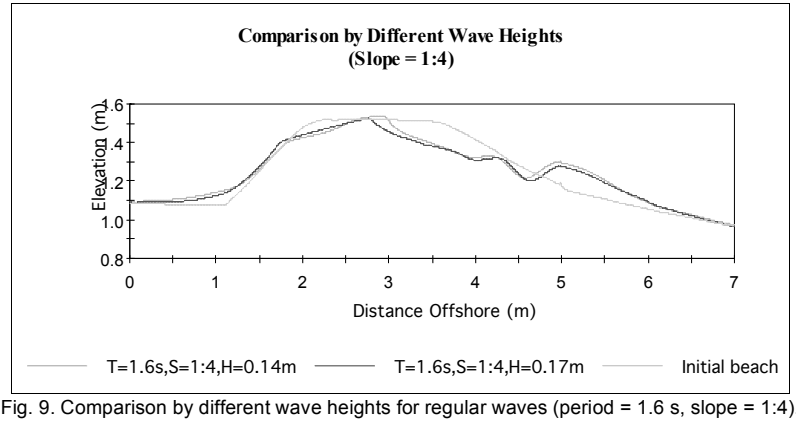

Fig. 9. Comparison by different wave heights for regular waves (period = 1.6 s, slope = 1:4).

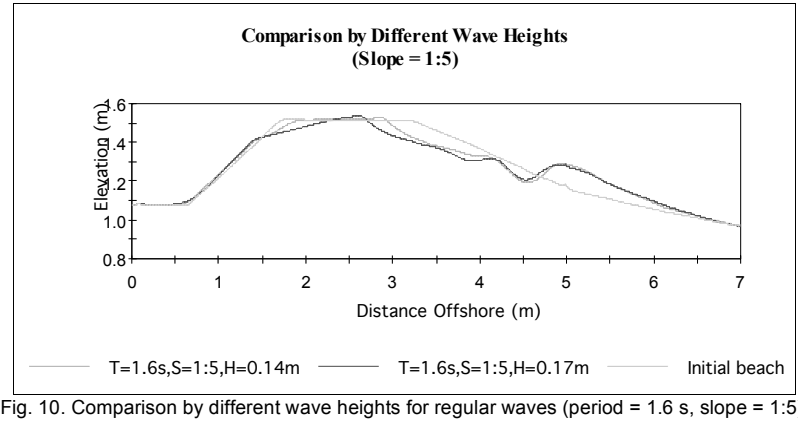

Fig. 10. Comparison by different wave heights for regular waves (period = 1.6 s, slope = 1:5).

The changes of profiles over a longer period are shown in Fig. 11. Each profile was measured at every 327 seconds. The rates of retreat were 51.85 %, 22.22 %, 9.26 %, 9.26 % and 7.41 % at every 327 seconds and it is shown in Fig. 12. The rate of retreat in beach face was reduced and became constant after 981 seconds. About 50 % of retreat was conduct in first 327 seconds.

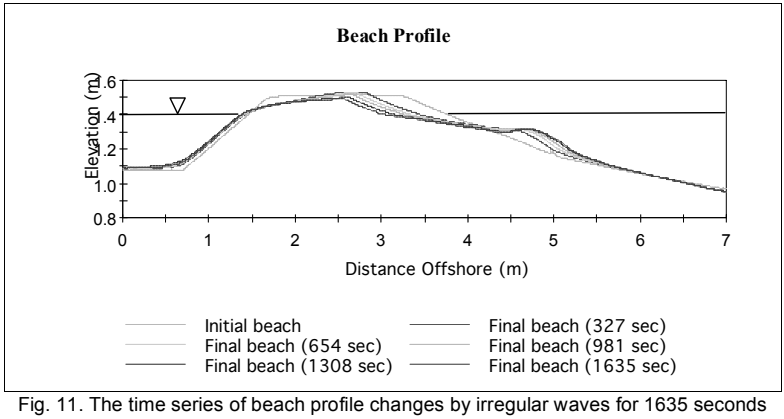

Fig. 11. The time series of beach profile changes by irregular waves for 1635 seconds (H_{mo} = 0.15 m, T_p = 2.0 sec, slope = 1:5). The profiles were measured at every 327 seconds.

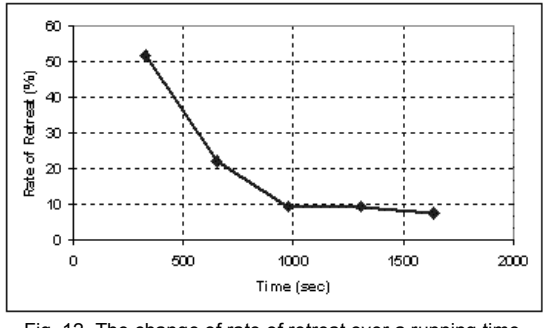

Fig. 12. The change of rate of retreat over a running time.

CONCLUSION

The mid-scale laboratory experiment was designed and conducted to reduce scale effects in this type of laboratory testing of sediment transport. This study presents a set of laboratory experiments by regular and irregular waves for analysis of overwash. The movement and location of the offshore bar has a major effect on the reflection coefficient. The increase of transmission rate by overwash over the berm reduced the eroded sand which was transported offshore. When the wave period was 2.0 sec, othe ffshore bar was generated near to the beach face. The erosion rate was highest at higher wave heights, longer wave periods and steeper beach slopes. About 50 percent of erosion by overwash occurred at the first 327 seconds in the long-term test and the subsequently the erosion rate was decreased and became essentially constant thereafter with time.

These characteristics of overwash by wave height, wave period and slope of beach face had the same trend at each test and they can be used for developing empirical

formulas and analytical methods for continued study of these interesting and important processes.

Abstract: The shoreline changes along the backbarrier of a barrier system are extremely variable and critically dependent upon geographic location and the inherent interaction with hydrodynamic processes. There are only a few studies describing the backbarrier morphodynamic evolution and inherent implications to the entire barrier system. In the present study it is performed the classification of the major evolution and maturation trends observed at Ria Formosa backbarrier, evaluating in particular the role of the complete washover occurrence. Besides the direct influence of inlets displacement, complete overwashes were considered to be one of the main events responsible for sediment availability at the backbarrier, and consequently interfered with the obtained evolution/maturation. Complete washover were assumed to contribute both to immature and mature backbarriers, at different time scales observation.

INTRODUCTION

Beaches identified as low energy occur in a wide range of coastal environments, including those in ocean bays and sounds, gulfs, seas, straits, estuaries, lagoons protected by coastal barriers, amongst others environments (Jackson et al. 2002a).The term low energy has been applied to beaches in environments that range from narrow, shallow lagoons, where onshore winds can generate wave heights <0.10 m on the foreshore (Jackson et al. 2002a), to beaches in the lee of reefs, where significant breaker height is up to 1.0 m (Hegge et al. 1996). Low energy environments are usually fetch-limited and sheltered at the same time and experience a mixture of local and non-local

wave (Jackson et al. 2002b). In fetch-limited environments, like the bayside of barrier islands, wave heights generated by local winds mainly depended on wind conditions and basin dimensions (width, length and depth) and have generally short periods (Nordstrom 1992; Jackson et al. 2002b).

Main controls and shoreline characteristics differ over short distances due to differences in fetch length, exposure to winds, and distance to inlets (Nordstrom 1992). Moreover, beach morphology may also be inherited from overwash events. This type of events is usually related with beach and dune erosion, and can cause major sediment input to the backbarrier area (e.g. Dillon 1970; Leatherman 1976; Dingler et al. 1993). As a consequence, the shorelines occurring along the backside of barrier islands are extremely diverse and variable with respect to morphologies and evolution.

The backbarrier of the Ria Formosa barrier system is an example of a restricted fetch system. The main objective of this paper is to recognize different states of backbarrier evolution and maturation through the application of a Backbarrier Development Classification, evaluating the role of complete washover occurrence in the main evolutionary trends of the backbarrier.

BACKBARRIER DEVELOPMENT CLASSIFICATION

The following sections synthesize the Backbarrier Development Classification, in particular the indexes formulation and it application.

General definitions

The Backbarrier Development Classification is based on the determination of the backbarrier evolution for a giving period of analysis. After performing aerial photograph georectification and interpretation, backbarrier evolution is obtained by the determination of the backbarrier longshore changes through time. The period of analysis must be at least of 10 years, and can be extended to several decades, depending on the available aerial photographs sets.

The longshore evaluation includes the identification and quantification of the longshore extension of the main present morphologies: inner beach next to a barrier (IBB), salt marsh (SM), and inner beach next to inlet (IBI) (Figure 1). The total backbarrier coastline extend (BC) is obtained by the sum of the coastline extend of salt marsh (SMC) and inner beach (TIBC = IBB+IBI coastlines). BC accounts with prominent and embayed parts of the coastline. Longshore changes (in meters) maybe of decreasing or increasing in extend. Longshore analysis also accounts with the measurement of the rectilinear length of each island/peninsula (coastal length - CL) (Figure 1).

Description of the classification

The backbarrier classification is composed of two types of indexes: backbarrier evolution (Bevol) and backbarrier maturation (Bmatur). Bevol gives an overview of the backbarrier evolution and Bmatur indicates the maturation state and observed trend. Bevol is obtained by the relation between backbarrier coastline extend variation (ΔBC)

and the coastal length variation (ΔCL) for a given period (Figure 2A).

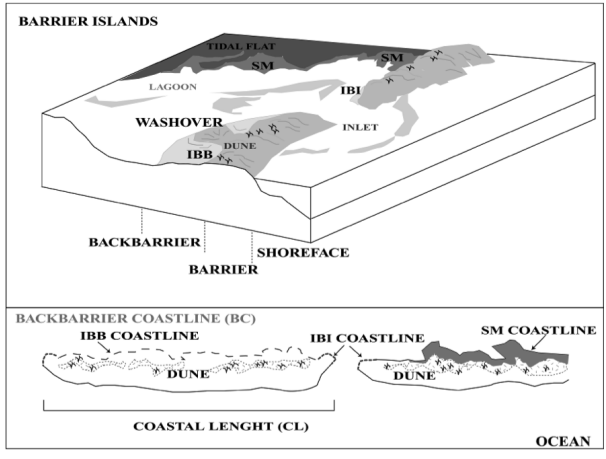

Fig. 1. Schematic representation of the main morphological units existent at backbarriers. IBB, inner beach next to a barrier; SM, salt marsh; and IBI inner beach next to inlet

The backbarrier coastline extend variation (ΔBC) is given by:

$$\triangle BC(\%) = (BCfinal\text{-}BCinitial)*100/(BCinitial) \quad (1)$$

The coastal length variation (ΔCL) is giving by:

$$\triangle CL(\%) = (CLfinal\text{-}CLinitial)*100/(CLinitial) \quad (2)$$

A Backbarrier Growth is defined by a *BC* increase simultaneously to an enlarging of *CL* (Figure 2A). On the contrary, a Backbarrier Reduction exhibits a BC decrease simultaneously to a CL shortening (Figure 2A). Intermediate states, Backbarrier Ramification and Smoothing Backbarrier, represent opposite evolutions of BC and CL (Figure 2A).

Bmatur is given by the relation between the backbarrier maturation state (*Bmat*) and the backbarrier maturation change ($\Delta Bmat$; Figure 2B). Bmat is given by:

$$Bmat = (SMCfinal/TIBCfinal) \quad (3)$$

Higher levels of backbarrier maturation (Bmat) are promoted by higher extension of salt marshes (*SMC*) in relation to sandy beaches (*TIBC*).ΔBmat will give an indication of the maturation process between the initial and final year of analysis:

$$\triangle Bmat = [(SMCfinal/TIBCfinal)/(SMCinitial/(TIBCinitial)] \quad (4)$$

Backbarrier classification using the obtained Δ*Bmat* is related with local hydrodynamic conditions: decrease in hydrodynamic conditions results in salt marsh construction/maintenance (Maturating Backbarrier) and thus ΔBmat>1 (Figure 2B), while increase in hydrodynamic conditions results in salt marsh destruction (Rejuvenating Backbarrier) and thus ΔBmat<1 (Figure 2B).

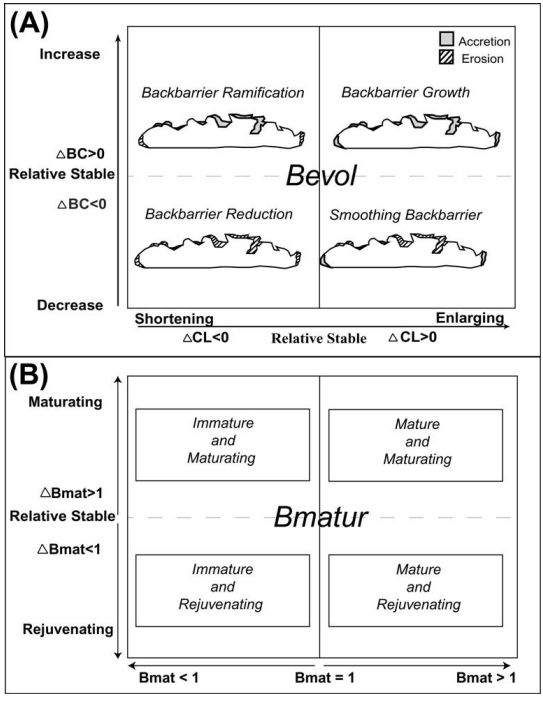

Fig. 2. Conceptual scheme defining the different states of backbarrier classification in terms of evolution (A), and maturation (B)

COMPLETE WASHOVER OCCURRENCE

Complete washover identification is based on the aerial photograph georectification/interpretation, using the same periods of analysis defined for the backbarrier evolution. Implications of complete washover events are inferred by the determination of the number of occurrences and by the quantification of BC affected by complete washovers in a giving period. Therefore, it is possible to quantify the total number of complete washovers and the longshore washover extend (in meters and percentage) for the entire system per period of observation. In addition, cross-shore transects located in complete washover areas are used to quantify its influence in the backbarrier landward/shoreward displacement. The join analysis of the washover parameters and the backbarrier evolution allows the identification of the relative role of

overwashes on the evolution of backbarrier coastlines.

APPLICATION OF THE BACKBARRIER DEVELOPMENT CLASSIFICATION

Study Area

The Ria Formosa is a multi-inlet barrier island system located in southern Portugal (Figure 3). Its present configuration consists of two peninsulas and five islands that extend over 56 km. The entire backbarrier covers an area of 8.4×10^7 m^2 (Andrade 1990), characterized by: i) large salt marsh areas with a high density of shallow meanders, largely composed by silt and fine sand (Bettencourt 1984); ii) large sand flats partially flooded and reworked during spring tides (Pilkey et al. 1989); and iii) a complex net of natural and partially-dredged channels, which narrow and shoal in upper regions of the system (Salles 2001). The inner shoreline, along the backbarrier islands and peninsulas is characterized by low, narrow sandy beaches alternating with portions of salt marsh, and washover plains (Andrade 1998).

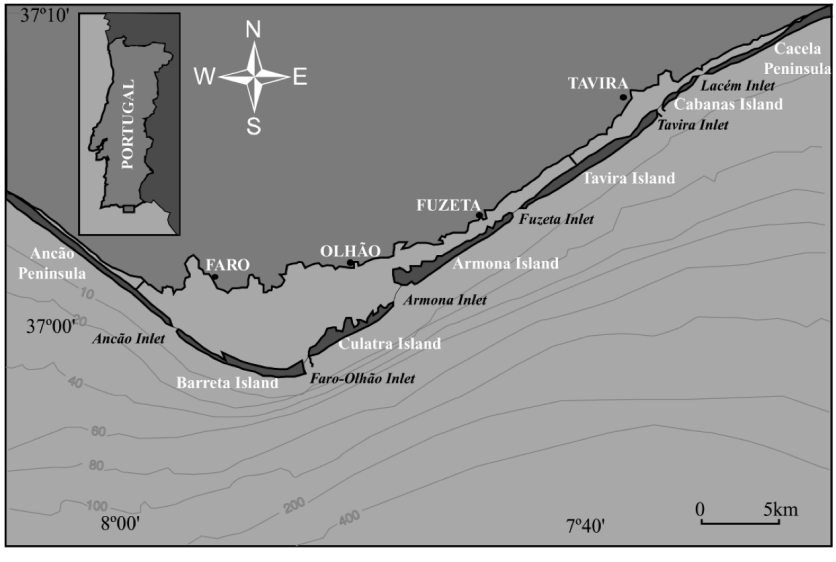

Fig. 3. Study area location

Tides in the area are semi-diurnal, average ranges are 2.8 m for spring tides and 1.3 m during neap tides, however, maximum ranges of 3.5 m can be reached. Wave climate in the area is moderate to high (Ciavola et al. 1997). Incident waves are normally from the W-SW, representing 71% of the total, although SE conditions represent 23% of the total (Costa et al. 2001). The cuspate shape of the Ria Formosa system produces two different areas in terms of exposure to wave action. The west flank is more energetic, being under the direct influence of the dominant wave conditions (W-SW), while the east flank is only directly exposed to the "Levante" conditions (E-SE wind and waves).

Recent evolution of the Ria Formosa barrier system is strongly dominated by physical alterations conduced by inlets position displacement/stabilization (see inlets location at Figure 3). With exception of Armona Inlet, considered to be the only naturally stable inlet of the system (Wheinholtz 1964), the other non-stabilized inlets, Ancão, Fuzeta and Lacém inlets, presents a cyclic easterly migration. Both Ancão and Fuzeta inlets have been relocated in the late 90's into a western position (Vila-Concejo et al. 2002). Faro-Olhão and Tavira inlets are the two stabilized inlets present at the system.

Backbarrier Development Classification

The backbarrier development classification was applied to the Ria Formosa system for the period comprised between 1947 and 2001 (Table 1 and Figure 4). Table 2 presents the main observed characteristics present in the backbarrier of each island/peninsula, as well as a qualitative measure of overwash occurrence and inlets influence, in order to facilitate indexes application discussion.

Table 1. Period of analysis considered for each island/peninsula

Barrier	Period
Ancão Peninsula	1947-2001
Barreta Island	1947-2001
Culatra Island	1947-2001
Armona Island	1969-2001
Tavira Island	1947-2001
Cabanas Island	1989-2001
Cacela Peninsula	1976-2001

In what concerns to the backbarrier evolution (Bevol) barriers are mainly distributed between Backbarrier growth and Backbarrier reduction categories (Figure 4A); an intermediate state was only observed at Armona Island, Smoothing backbarrier. The irregularly in the barriers evolutionary trends, does not allow to define a linear pattern to the overall system, it is however possible to observe a backbarrier reduction trend in the extremes of the system together with a dominant enlarging at the central part.

The backbarrier maturation (Bmatur) was obtained through the determination of ΔBmat for the same period of analysis (Table 1), while Bmat was determined for 2001. Almost all analyzed backbarrier presented ΔBmat>1 (Maturating backbarriers) or stability behavior between 1947 and 2001 (Figure 4B). The western part of the system can be considered as immature but facing maturation; the central part of the system tends to maturation, and the eastern part of the system is formed by two backbarriers subject to opposite levels and trends of maturation (Cabanas Island is mature and under maturation while Cacela Peninsula is immature and rejuvenating).

Table 2. Main characteristics of the Ria Formosa backbarrier, qualitative measure of overwash occurrence and inlets influence.

Barrier	Backbarrier main characteristics	Complete washover occurrence	Inlets influence
Ancão Peninsula	Western: salt marsh Central: with human occupation	Moderate	
	Eastern: sandy beach	Low	Ancão Inlet migration
Barreta Island	Western: sandy beach Eastern: salt marsh	Extreme	Ancão Inlet migration
Culatra Island	Western: human occupation and engineering structures Central: human occupation, salt marsh and sandy beach Eastern: sandy beach as recurved spits	Low	Armona Inlet narrowing
Armona Island	Western: human occupation and salt marsh; Central: salt marsh	Moderate	
	Eastern: sandy beach and salt marsh	Moderate	Fuzeta inlet migration
Tavira Island	Western: sandy beach; Central: salt marsh in the central part Eastern: human occupation and engineering structures		Fuzeta Inlet migration
Cabanas Island	Western: sandy beach and salt marsh and engineering structures	Low	
	Eastern: sandy beach	High	Lacém Inlet migration
Cacela Peninsula	Western: sandy beach Eastern: salt marsh	Moderate	Lacém Inlet migration

Complete washover occurrence

A total of 62 complete washovers were observed at Ria Formosa between 1947 and 2001 (Figure 5). These washovers represented a total longshore extend > 4 000 m for the Ria Formosa backbarrier, 3615 m in the west flank, and >288 m in the east flank (Table 3). The percentage of backbarrier coastline with complete washovers was more significant before 1947 and between 1989 and 1996 due to the washover longshore extent in these periods (Matias 2006). Cabanas Island included the higher number of

occurrences, 21 complete washovers, with major expression between 1976 and 1989. Aerial photograph coverage/quality only allowed quantifying landward/shoreward displacement, as a result of complete washover, at Ancão and Cacela peninsulas and Barreta Island. Results showed a landward displacement of 1myr^{-1} and 2 myr^{-1} at Ancão and Cacela peninsulas, while the western sector at Barreta Island verified a shoreward displacement of 4 myr^{-1}. Table 3 relates the observed maturation trend and the complete washover occurrence between the overall period 1947-2001.

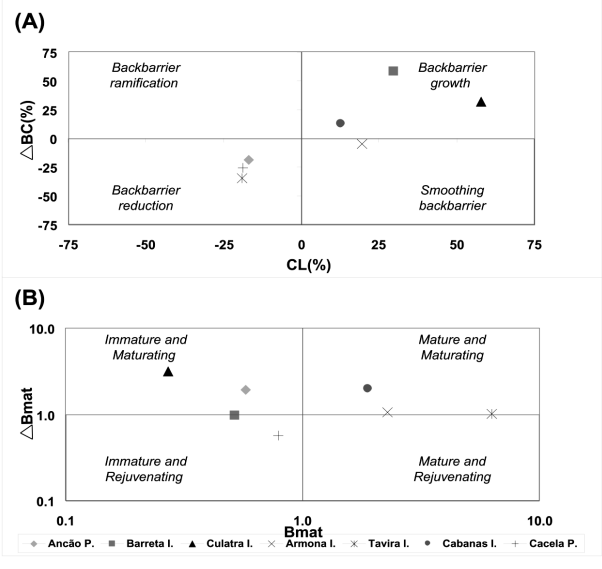

Fig. 4. Classification of the backbarrier development in terms of evolution (A), and in terms of maturation (B)

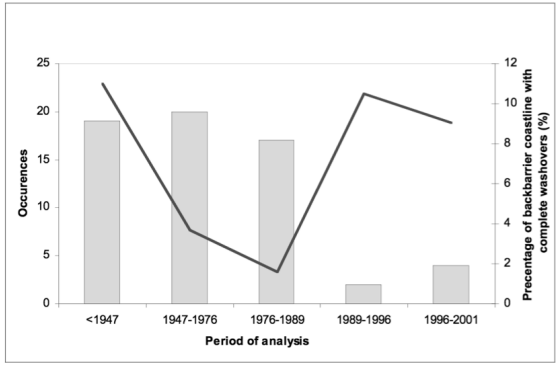

Fig. 5. Occurrences of complete washovers at Ria Formosa in 1947-2001. The number of occurrences is represented by columns and the percentage of BC with washovers by the line

Table 3. Maturation trend and complete overwash occurrence between 1947 and 2001

Barrier	ΔBmat	Nº of complete washovers	Washover longshore extend, m
Ancão Peninsula	Maturating (1.9)	10	368
Barreta Island	Stability (1.0)	11	3247
Culatra Island	Maturating (3.2)	2	44
Armona Island	Stability (1.0)	13	*
Tavira Island	Stability (1.0)	-	-
Cabanas Island	Maturating (2.0)	21	244
Cacela Peninsula	Rejuvenating (0.6)	5	*
Total		62	>4000

* Was not possible to determine washover longshore extend.

DISCUSSION

The definition of different trends of evolution/maturation of backbarriers relies in the application of two types of indexes: Bevol and Bmatur. Bevol provides an overview of the backbarrier evolution through time, while Bmatur provides an overview of the maturation state and its recent evolutionary trend. Both indexes were applied to the Ria Formosa backbarrier. Application of the Bevol showed that most of the barriers are mainly included in the Backbarrier growth and Backbarrier reduction classifications, and presented a maturating/stability trend between 1947 and 2001 (Figure 4A and 4B).

The obtained classification is intrinsically dependent in the recent evolution of the study area. Recent evolution of Ria Formosa barriers is conditioned by several coastal processes, including inlet dynamics (Vila-Concejo et al. 2006) and overwash occurrence (Matias 2006). Changes in inlets position promoted dramatic changes in barriers length and therefore changes in BC and CL, and interfered with local hydrodynamic conditions (Esaguy 1984; 1985; 1986a; 1986b; Andrade 1990; Salles 2001; Vila-Concejo 2003). For instance, Ancão Peninsula and Barreta Island evolutionary classifications are dependent on the chosen period for indexes application and its timings in relation to Ancão Inlet migration cycle (Vila-Concejo et al. 2002). Enlargement of CL and BC in Barreta Island occurred simultaneously to shortening of CL and BC at Ancão Peninsula (backbarrier growth and backbarrier reduction). Likewise, the evolutionary classification (Bevol) of Armona, Tavira, Cabanas and Cacela barriers are also dependent on the respective non-stabilized inlets migration cycle (Table 2).

Besides the influence in Bevol, inlets migration may induce also different backbarrier maturation trends. Alteration in the inlets patterns can promote areas of predominant salt marsh construction by a decrease in hydrodynamic conditions, but can also be responsible by the destruction of salt marsh areas, by an increase in hydrodynamic conditions. For example, the progressive growth of Culatra Island due to Armona Inlet narrowing created areas of lower energy conditions as they became more distant from the inlet channel, which in turn allowed the development of new salt marsh areas (maturating backbarrier). In other cases, for instance Cacela Peninsula, the areas downdrift of the inlet had an increase in hydrodynamic conditions that promoted backbarrier reduction encompassed by a decrease in the salt marsh areas (rejuvenating backbarrier, Figure 4 and Table 2).

Whether overwash plays or not a significant role in a barrier island dynamics depends on numerous factors such as the elevation of islands, presence of vegetation, sediment supply to the beach, and frequency and strength of storms (Leatherman 1976). Increases in BC and variations in Bmatur may be promoted by complete overwash occurrence. The main role of these events to backbarrier sedimentary dynamics is an increase of sand availability. Consequently, complete overwash occurrence is generally associated with cross-shore landward displacement of backbarrier coastline, as observed at Ancão and Cacela peninsulas. In these barriers it was observed after complete washover occurrence a landward displacement of the backbarrier limits ($1myr^{-1}$ and $2\ myr^{-1}$, respectively), by a transference of sediments into the lagoon. The scale of occurrence of complete overwash is thus extremely important when evaluating the medium- long-term barrier evolution. Barreta Island shoreward displacement is mostly justified by the Ancão Inlet migration (Andrade 1990; Vila-Concejo 2003), where overwash events plays a secondary role.

Two different overwash influence can be expected at different time scales: (1) shortly after overwash, the proportion of sandy beach increases (by destruction of SMC or increase of TIBC) and therefore the backbarrier is rejuvenating, and became immature (Figure 6A); and (2) at a later stage, considering that these same complete washovers are not reworked by overwash, salt marsh develop over the washover deposits, therefore the barrier became maturating, and eventually becomes a mature barrier (Figure 6B). Marsh progradation over backbarrier is interpreted as a result of abundant sediment, which permitted marsh expansion (French et al. 1993; Pethick 1998). Example of type 1 influence is the case of Cacela Peninsula that presents a rejuvenating and immature backbarrier (Table 3) in the presence of complete washovers. The classification of the maturity state of a barrier may be related with the timing of overwash. As in the case of Cacela Peninsula, where the overwash influence is relatively recent and therefore its backbarrier is presently immature (Figure 6A), but may in the future turn to a type 2 overwash influence as it maturates. Barreta Island is also an immature backbarrier but in stability, however this barrier is very heterogeneous in terms of backbarrier morphologies (Table 2). The western part is almost permanently overwashed (more than 3 000 m of washover longshore extend) and fully composed of sandy beach, while the eastern part is composed of salt marsh. The classification of stability obtained for this barrier results from an average estimative, but is not representative of any of the two

parts. The Barreta western part is another example of type 1 overwash influence, where a high washover longshore extend (Table 3) was responsible for rejuvenating and immature backbarrier.

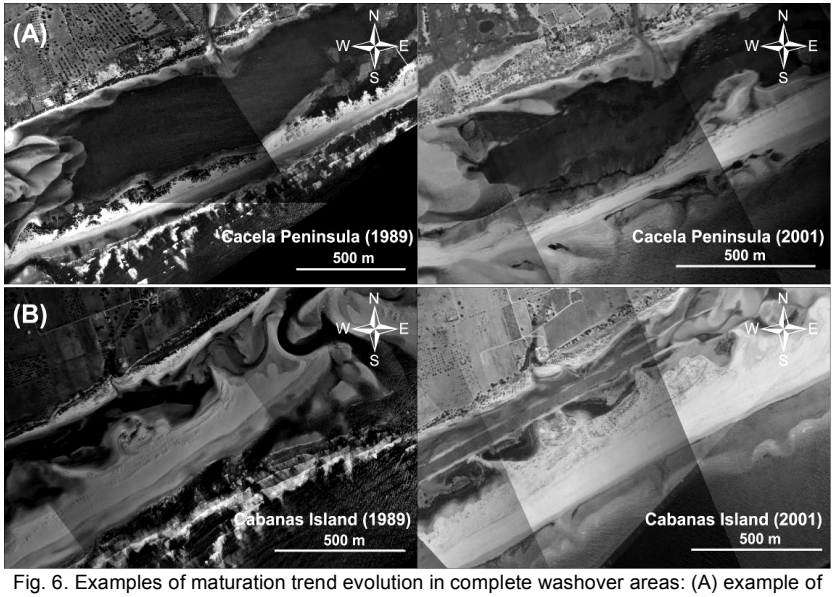

Fig. 6. Examples of maturation trend evolution in complete washover areas: (A) example of type 1 evolution; and (B) example of type 2 evolution

An example of type 2 overwash influence is Cabanas Island (about 240 m of washover longshore extend), that was until recently growing (Table 2) and frequently affected by overwash occurrence (Table 3). This events lead to the existence of a sandy flat that later allowed the development of salt marsh, and consequently a maturating process, which lead to the classification as mature backbarrier (Figure 6B). Armona Island is another example of type 2 overwash influence, providing sediments for salt marsh development (mature backbarrier). Like described for Barreta Island, Armona backbarrier stability resulted from the existence of opposite trends in the backbarrier evolution. The central part of the island was subjected to moderate complete overwash occurrence (Table 2), that afterwards developed salt marsh and initiated a maturating process.

CONCLUSION

The available studies evaluating backbarrier environments evolution are scarce. The main objective of the present study was the application of a Backbarrier Development Classification to the Ria Formosa barrier system, Algarve, Portugal, between 1947 and 2001, and to identify the implications of the complete overwash processes to the definition of such classification and the evolution processes of backbarriers. This classification evaluates the backbarrier evolution and maturation through time.

Results of the evolutionary indexes shows that most of the islands/peninsulas are mainly included in the Backbarrier growth and Backbarrier reduction classifications. In the same analyzed period, most of the barriers presented maturating and stability backbarriers. The obtained classification was shown to be related with the direct influence of inlets displacement, while complete overwashes were also considered to be one of the main events responsible for such classification. Events promoting an increase in sediment availability at the backbarrier, like complete washover, were assumed to have two different influences at the backbarrier evolution according to different time scales: (1) at short-term overwash leads to rejuvenating and immature backbarriers; and (2) at a later stage (medium- to long-term) washover deposits may allow a barrier maturation process.

In cases of backbarrier environments it is extremely important to develop coastal management practices based on predict behaviors of evolution. Application of the Backbarrier Development Classification reveals to be a good approach in the classification of Ria Formosa backbarrier evolutionary trend and likely of being related with the main constrains affecting the system.

Abstract: Ridge-like shoal topography is well developed on the continental shelves of the Mid-Atlantic Bight and the northeastern Gulf of Mexico. In both cases, these linear sand ridges are oriented parallel to the predominant wave approach direction, suggesting common processes for their evolution and maintenance. Along the coasts of tropical islands surrounded by coral reefs, spur-like features are sometimes found. The spurs consist of coral rubble made available by the die-off or destruction of coral through natural processes or anthropogenic factors. The spur features emanate from rubble fields and are aligned parallel to the predominant direction of wave attack. These features, from disparate environmental settings, owe their maintenance and evolution to crossing wave patterns that form through refraction of waves up either side of the shoal or spur features. This paper presents examples of these geomorphic forms in both settings. Existing capabilities for simulating crossing wave processes are discussed.

INTRODUCTION

Improvements to the understanding of physical processes are often driven by the desire and need to explain observations in nature. These observations may consist of direct measurements or the presence and evolution of geomorphic features. The advantage of geomorphic features is that they represent the integrated effects of all forcing functions in the coastal and marine environment over large areas and over long periods of time. This paper investigates the role of crossing waves in the development of two geomorphic forms in very different settings.

Along the continental shelves of the Atlantic and Gulf coasts of the US ridge-like shoal topography is widespread. These linear sand ridges are oriented parallel to the direction

of predominant storm wave attack, suggesting that common wave-related processes are responsible for their evolution and maintenance. The first part of the paper reviews the current state of knowledge on these features and the role of crossing waves in their maintenance.

The second type of geomorphic feature that will be investigated as part of this paper consists of coral rubble spurs that are oriented parallel to the direction of wave attack close to shore at a location in Barbados. Being nearshore features, their orientation is usually close to shore perpendicular. Similar features have been observed along the coast of the Hawaiian Islands. There is clear evidence that these features are created through crossing wave patterns.

Following the review of these two distinct features a general discussion of other examples of the role of crossing waves on the development of geomorphic features is presented. Also, a summary of our ability to predict the hydrodynamic, sediment transport and morphodynamic processes associated with crossing waves is provided.

RIDGE-LIKE SHOALS

The Minerals Management Service (MMS) of the U.S. Department of the Interior is responsible for the management of all mineral resources in federal waters along the Outer Continental Shelf of the US. MMS has the authority to convey, on a noncompetitive basis, the rights to OCS sand, gravel or shell resources for shore protection, beach or wetlands restoration projects, or for use in construction projects funded or authorized by the US Federal Government. One of the key targets of OCS sand are offshore ridge-like shoals. Key questions associated with removing sand from these shoals are: how much can be removed while still maintaining the geomorphic integrity of the features and where is the best location to remove sand to preserve the geomorphic form?

Hayes and Nairn (2004) in an investigation for MMS, completed a literature review of the understanding of the distribution, genesis, maintenance and characteristics of linear ridge and shoal features. Ridge and swale topography is exceptionally well developed on the continental shelves of the Mid-Atlantic Bight (see Figure 1) and the northeastern Gulf of Mexico (see Figure 2). In both cases, these linear ridges are oriented parallel to the predominant wave approach direction, suggesting common processes for their evolution and maintenance. Most researchers have concluded that ridges were derived from shorefaces of barrier islands as they retreated across the shelf in response to rising sea level and that tides or storm-driven currents maintain them.

The widely cited ridge formation theory of Huthnance (1982) developed originally for linear sand banks offshore the Norfolk coast of England requires a sufficient sand source, currents to move the sand, and an irregularity on the sea floor around which the ridges are initiated. Trowbridge (1995) developed a shoal preservation theory for linear shoals located close to the US Atlantic coast that was based on southerly currents created by northeasterly wave attack during storm events. McBride and Moslow (1991) postulated that one of the initial irregularities is a segment of an ebb-tidal delta abandoned by inlet

migration. These theories of origin and initial preservation provide little information on how these features maintain their form once they are detached from the shore yet remain in a zone of active wave attack (i.e. in depths less than 20 m). Snedden et al. (1999) indicate that shoals in water depths less than approximately 20 m are migrating shoreward through the influence of Stokes Drift under fair-weather waves based on the work of McHone (1973). However, this model does not explain the maintenance of the form of linear shoal and ridge features.

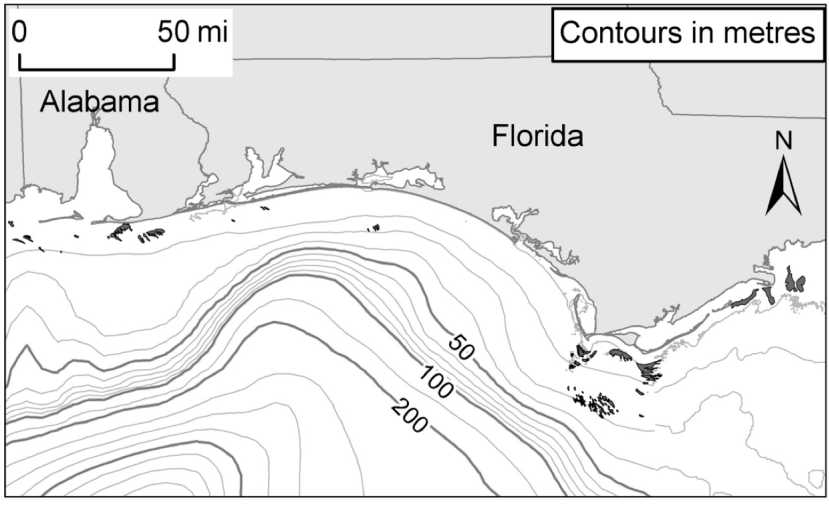

Fig. 2. Map Showing Ridge-Like Shoal Features on the Northeast US Gulf Coast

Hayes and Nairn (2004) present a new conceptual model for the preservation of the linear ridge-like shoal features of the Atlantic and Gulf coasts of the U.S. This model recognizes that the main axis of these shoals is aligned with the dominant direction of storm wave attack. For example, along most of the Atlantic coast of the U.S. the shoals point northeast into the predominant Nor'easters. As an exception, in the lee of Long Island, which provides shelter from the Nor'easters, the shoals have a more east-west orientation. Along the northeast coast of the Gulf of Mexico offshore Alabama the shoals point southeast into the predominant direction of wave attack. The direct influence of wave action on the preservation and evolution of ridge and shoal features has received little attention in the literature on this subject.

A review of the morphology of typical ridge-like features revealed depositional signatures in the form of steep slopes on both the shoreward and seaward side of southerly half of the shoals on the Atlantic coast. This coupled with the observation that these shoals located on the OCS migrate in a southerly or southwesterly direction provide evidence pointing to the importance of wave action and particularly crossing waves. Several articles report on the migration of ridge-like shoal features in the direction of the steep edge of the shoal including Hoogendoorn and Dalrymple (1986) for shoals off Sable Island offshore Nova Scotia, Byrnes et. al. (1999) for shoals offshore Alabama, and Duane et. al. (1972) for shoals offshore Virginia and Delaware. Mariners have often noted the confused sea state over the crest of these offshore shoals, again suggesting wave attack from more than one direction.

Hayes and Nairn (2004) describe the application of a Boussinesq wave model to describe the way in which northeasterly waves interact with a typical group of shoals (Fenwick,

Weaver and Isle of Wight) offshore the Maryland – Delaware border on the OCS (see Figure 3 for the location of these shoals). The MIKE21 Boussinesq Wave (BW) model was applied to simulate waves with a significant wave height of 3 m and a peak period of 16 s from the ENE direction representing a Nor'easter event. A snapshot of an animation of the simulation of wave conditions over the shoals for this condition is shown in Figure 4. The crossing wave pattern over the crest of Fenwick and Weaver Shoals is clearly evident. As waves approach the shoal they split into sets propagating southwest along either side of the shoal and refract towards the crest of the shoal, intersecting or crossing over the crest. The hydrodynamics predicted by the MIKE21 BW model were input to a sediment transport model that considers the influence of non-linear orbital velocity and steady currents based on the work of Dibajnia et. al. (2001). While this approach was able to show there is a convergence of sediment transport over the crest of the shoal (helping to preserve the shape of the shoal against forces tending to flatten and smear the form of the feature), it cannot fully simulate the two components of transport over the crest. Only a single resultant sediment transport vector is predicted (see Figure 5). As explained in the Discussion section of this paper, there are some cases where this will provide a reasonable representation of reality. In general, however, this remains a shortcoming of our capabilities to predict sediment transport under crossing waves.

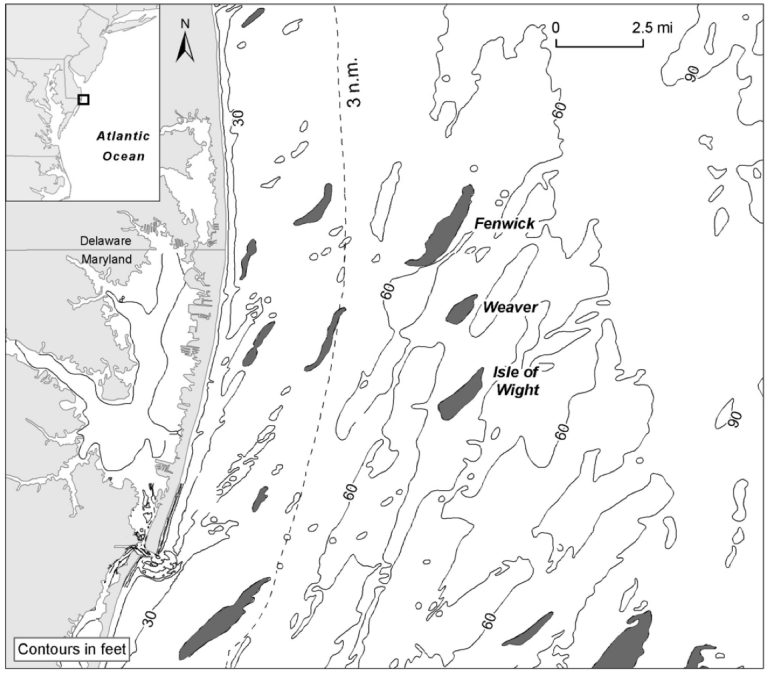

Fig. 3. Location of the Fenwick, Weaver and Isle of Wight Shoals Offshore Maryland/Delaware Border

Based on the wave model, and an interpretation of the sedimentology and geomorphology, a conceptual model of the processes that preserve the form of the ridge-like shoals and cause the features to migrate is shown in the schematic Figure 6. The conceptual model is based on Fenwick Shoal shown in Figures 3 and 4. The steep southeast side of the shoal (bottom right in Figure 6) is the accreting edge of the feature, it is slowly migrating in this direction. From Figures 4 and 5 it is evident that wave heights and associated sediment transport are greater on the northwest side of the feature, perhaps explaining the net deposition and steep slope on the southeast edge. The appearance of crossing sediment transport vectors in Figure 5 is an artifact of the vector lengths representing sediment transport being larger than the model grid spacing. Baird & Associates are currently completing an investigation consisting of field monitoring of waves and currents and numerical modeling to develop a better understanding of the evolution of these features to develop guidelines for dredging shoals for MMS.

CORAL RUBBLE SPUR FEATURES

Baird & Associates recently completed a two-year investigation of the physical and biological processes associated with the beaches, lagoon and reef system at Worthing or Sandy Beach on the south coast of Barbados. The beach at Worthing is anchored by three coral rubble spur features as shown in Figure 7. These spur features have an important role in changes to the beach dynamics at Worthing in addition to the water quality and related coral reef health in the lagoon formed by the central and east spurs. Test pits on the spurs revealed that the spurs are composed of pieces of *Accropora palamata* with diameters ranging from 100 to 300 mm covering a wider range of broken coral sizes mixed with sand.

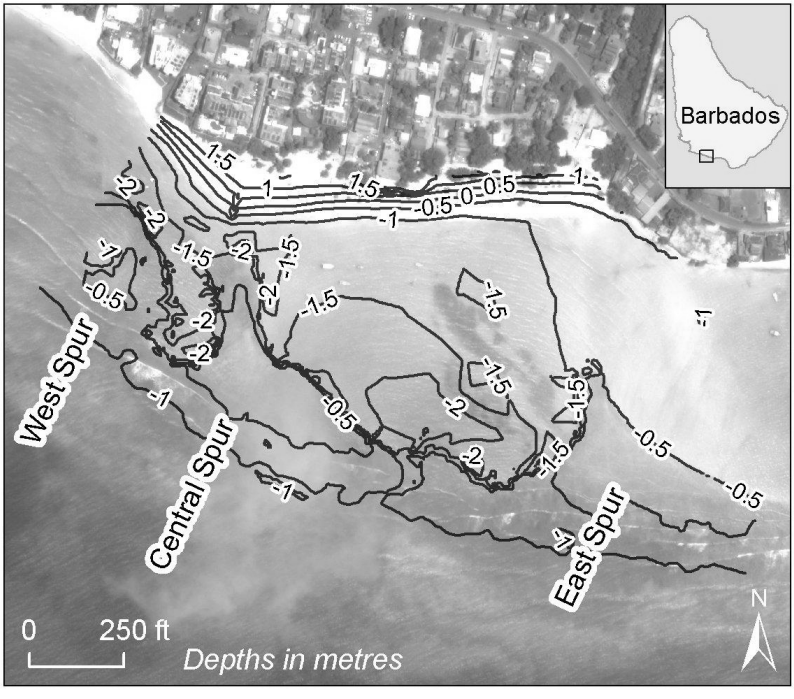

Fig. 7. Three Coral Rubble Spurs Offshore Worthing Beach
on the Southwest Coast of Barbados (on 2005 satellite image)

A historical comparison of the inshore edge of the reef is shown in Figure 8. The three spurs that extend from the reef toward the shoreline are clearly visible. Although there has been little change in the plan form of the east and central spurs, the west spur has extended approximately 55 m toward the shore between 1964 and 2000 with most of the growth occurring between 1973 and 1983. The passage of Hurricane Ivan in September 2004 caused considerable damage to the south coast of Barbados, the most since Hurricane Allen in 1980. The west spur was shifted to the west, the central spur was reduced in length (a crest height reduction) and the east spur was pushed further inshore.

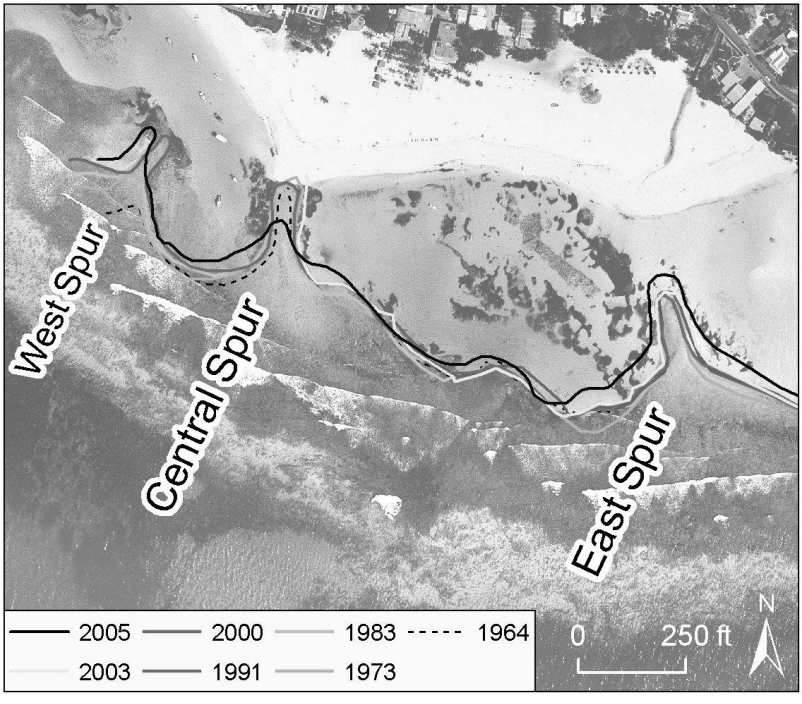

Fig. 8. Historical Change in the Coral Rubble Spur Form at Worthing Based on Air Photo Analysis in GIS (on 2000 air photo)

The predominant wave attack at Worthing is from the south and SSE. The coral rubble spurs have a significant influence on wave transformation which in turn influences the beach stability at Worthing. Also, the waves themselves influence the slow evolution of the spurs. A spectral wave model was applied to describe the wave pattern associated with typical wave attack. The results in the form of wave vectors for the wave condition associated with the 1973 air photo are shown in Figure 9. It is evident from the air photo that both the east and central spurs cause the waves to cross as they propagate inshore on either side of the features refracting towards the crest. Similar to the ridge-like shoal features described in the previous section, this wave transformation process both preserves and develops the form of the spur feature and elongates it slowly in a shoreward direction. The wave direction from the spectral wave model is the result vector direction wherever there are two crossing wave trains – this is particularly evident along the east and central spurs. In the presentation of the vector addition of wave direction from the spectral model, the crossing wave pattern can be inferred from the convergence of wave directions and the abrupt change in direction from one side of the spur to the other. It is possible to output the full 2D directional-frequency spectra from the spectral wave model and this would preserve the two independent waves directions.

The generation and evolution of the coral rubble spurs is initiated by one or more events that lead to the death of coral including: disease, bleaching and hurricane wave attack. At Worthing Beach in Barbados, the initial coral rubble field was created by the death of the *Accropora palmata* likely due to widespread disease in the late 1970's and the damage of Hurricane Allen in 1980. Three rubble spurs were created at Worthing due to the ability of waves to penetrate a relatively long linear and shore-parallel rubble field at two places allowing for three lines of wave convergence – one for each of the three spurs.

Coral rubble spur features are likely created wherever there is an abundant supply of coral rubble generated relatively rapidly due to widespread die off or damage. Another example of coral rubble spurs is shown in Figure 10 located offshore Kihei on Maui in the Pacific Ocean. Several spur features extend from a linear coral rubble field (with breaks between spurs) to shore over a distance of about 100 m. Based on a review of air photos from 1960, 1975, 1988 and 1997 it was determined that the coral rubble field first appeared in 1975 and the spurs have developed in form since that time (personal communication, John Rooney, U. of Hawaii). Rooney postulates the coral rubble was generated through three possible mechanisms: 1) major storms in the 1960s; 2) the tsunami of 1946; or 3) blasting from the combat demolition team in WWII.

DISCUSSION OF CROSSING WAVES AND GEOMORPHIC FEATURES

This paper has reviewed examples of two types of geomorphic forms created by crossing wave patterns. Other common examples where crossing waves contribute to the evolution of geomorphic features include: salients in the lee of breakwaters, small islands and the shoreward limbs of ebb shoals at river or inlet mouths. Crossing waves are also a persistent feature of wave attack at many locations in the world that are exposed to two dominant sources of wave generation. This is often the case at mid-latitude sites that are exposed to open ocean swells at the same time as more locally generated waves from trade winds or extra-tropical storms. At these locations the crossing waves influence entire beaches and not just localized areas such as coral rubble spurs or ridge-like shoals. Regardless, the coastal engineer or scientist is faced with the same problem of how to consider the influence of crossing waves on sand transport and the evolution of geomorphic features.

From the two examples presented, it was evident that the phase-resolving Boussinesq wave model was able to reproduce the crossing wave pattern, while the spectral wave model could not, at least not based on the summary parameters that are typically output (versus the full 2D spectra). The Boussinesq model also predicts the bi-directionality of the orbital velocities at the bed for the example of the offshore shoals. However, to the authors' knowledge there are no commonly available sediment transport predictors or numerical models with such predictors to consider the influence of two crossing wave

trains on sediment transport. So the question arises, is the resultant wave vector and/or orbital velocity speed and direction sufficient to predict the direction and rate of sediment transport under crossing wave conditions?

If two progressive and crossing wave trains with the same period are in phase, the orbital path will be a straight line with its length equal to the orbital amplitude of the combined waves. If the difference in wave approach direction is 90 degrees between two crossing waves with the same period, and the waves are 90 degrees out of phase without any non-linearity due to shoaling, theoretically the orbital path would be circular in plan. Therefore, it is likely that the orbital path for most conditions with crossing waves is somewhere in between and elliptical in planform. Net transport occurs through three possible conditions or mechanisms related to orbital velocity: 1) under non-linear shoaling waves where the onshore velocity under the wave crest is much larger resulting in net shoreward transport; 2) where condition (1) is more pronounced because the offshore component of the orbital velocity is less than the threshold for motion of the sediment grains; and 3) where the peak in suspended sediment concentration is in phase with either the offshore or onshore component of the orbital velocity (either of which may occur under rippled conditions leading to net offshore or onshore transport). Where there is a strong steady current and the waves are only important for entrainment of sediment with the currents being responsible for advection, simply using the resultant vector of crossing waves is likely appropriate. The challenge of considering crossing waves is probably most important under conditions (1) and (2) when there is not a strong current present. Such conditions may also influence the ripple pattern on the sea bed, which in turn could influence the phasing and intensity of sediment re-suspension over ripple crests. While it may not be possible to systematically predict sand transport under crossing wave trains in these conditions, it would be possible to check whether a resultant vector might result in misleading predictions.

CONCLUSIONS

Crossing waves can lead to the development of unique geomorphic forms including offshore shoals, coral rubble spurs and salients under a wide variety of conditions. Crossing waves are also a common feature along coastlines at mid-latitudes exposed to both ocean swell generated at long distances and locally generated sea waves. There are no commonly accepted or standard practices for predicting sand transport and morphologic evolution under crossing waves. In some cases the estimation of the resultant wave condition through the vector addition of two crossing wave trains may be sufficient to predict sediment transport with an acceptable level of accuracy. Nevertheless, this will often not be the case and the validity of using vector addition of either the two wave directions for crossing waves or the associated orbital velocity components should be checked by evaluating the form of the orbital pathway and the speed of water particles along this path together with a consideration of the threshold of motion for the sediment.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. Mike Risk of McMaster University in Canada for his guidance on coral disease and generation of coral rubble, Dr. John Rooney of the University of Hawaii for sharing his air-photo analysis of the coral rubble spurs on Maui, and Bill Curtis and Joan Pope of the US Army Corps of Engineers for the information they provided concerning the coral rubble spurs in Maui. The authors also wish to thank the Coastal Zone Management Unit of Barbados and the US Minerals Management Service for sponsoring Baird's investigations of the coral rubble spurs and offshore ridge-like shoals, respectively.

Abstract: Two events of crescentic bar formation in La Barceloneta beach are analyzed (Mediterranean coast of Spain). They occurred on October 2003 and on December 2005, during Eastern storms with offshore root-mean-square heights between 1.5 m and 2 m, peak periods of about 9 s and angles of incidence relative to shore-normal between 15^o and 30^o. The final alongshore spacings are about 300 m in the first event and about 100-200 m in the second. A nonlinear morphodynamic model is then applied to La Barceloneta conditions to reproduce these two events. The model is able to simulate the final shape of the crescentic bars, reproducing the observed spacings.

INTRODUCTION

Field observations of crescentic bars

Shore-parallel sand bars can display a number of different shapes, the most simple being rectilinear (linear shore-parallel bars). Under certain wave conditions, these bars can develop alongshore inhomogeneities that consist of shallower and deeper areas alternating along the bar (Wright and Short, 1984). When this occurs, a prominent circulation pattern characterized by the presence of rip currents is also established. These strong and narrow offshore-flowing currents are part of a larger circulation cell, which includes an onshore-flowing component as well as feeder currents taking the water alongshore into the rip. The rip currents flow offshore in the channels that breach the bar and the onshore flow takes place over the shoals.

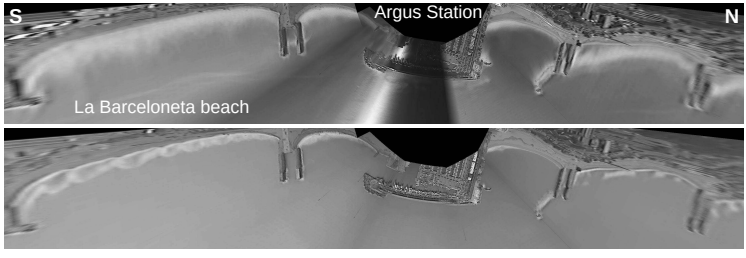

Fig. 1. Planview images of Barcelona city beaches. Upper panel: Linear shore-parallel bar in La Barceloneta on the 10 of December of 2005 at 9h. Lower panel: Well-developed crescentic bar with shoreline attachments (megacusps) on the 13 of December of 2005 at 8h.

This results in a wavy shape of the bar in planview, thus called crescentic bar (see the lower panel of Fig. 1). These alongshore undulations and the corresponding circulation cells frequently occur at regular or quasi-regular intervals. Crescentic bars have been observed on many beaches (up to 33 references are listed in Table 1 of van Enckevort et al., 2004) but systematic field studies are scarce, especially in the case of embayed beaches.

Most of the knowledge of mid-term dynamics of crescentic bars relates to bar state models (Wright and Short, 1984). During the peak of a storm, a shore-parallel bar is developed or enlarged and migrates offshore (longshore bar and trough state). Under the subsequent lower energetic conditions, the bar becomes crescentic and migrates slowly onshore (rhythmic bar and beach state) until the horns occasionally weld to the shore (transverse bar and rip state). The following stormy period destroys the rhythmicity and rebuilds the shore-parallel bar.

Previous modeling of crescentic bars

Although the formation of crescentic bars has been often attributed to the hydrodynamic forcing by infragravity edge waves, it is nowadays well accepted that the most plausible cause is a positive feedback between breaking waves, currents and the evolving morphology (self-organization processes). Small random perturbations are always present in the bottom of any alongshore-uniform beach. The existence of such bottom perturbations will cause changes in both the currents and the wave properties (such as their height and angle of incidence). Their joint interaction will produce small perturbations in the net sediment transport that in turn will modify the bottom of the beach. If there is a positive feedback between a certain developing perturbation (like a crescentic bar) and the associated sediment transport, the former will grow and dominate the beach bathymetry.

The existing modeling studies based on self-organization describe the generating mechanism and predict the order of magnitude of the wavelength and the migration rate (Deigaard et al., 1999; Falqués et al., 2000; Caballeria et al., 2002;

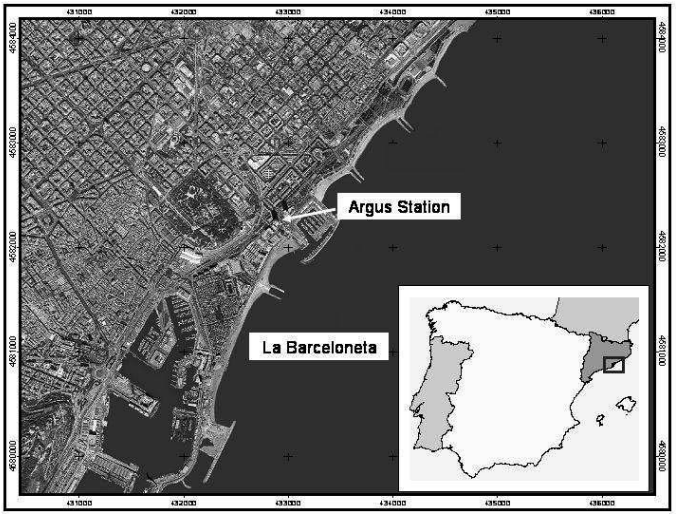

Fig. 2. Study region including the location of the Argus video station.

Damgaard et al., 2002; Reniers et al., 2004; Calvete et al., 2005). However, a serious limitation of our present knowledge on crescentic bars is the lack of quantitative comparisons between field observations and model results. A pioneer study is that of van Enckevort et al. (2004), where observations of crescentic bars in four open beaches were qualitatively compared with existing model results.

Present study

The embayed beaches on the waterfront of Barcelona have been monitored with an Argus video system since November 2001 (Ojeda and Guillén, 2006). In one of these beaches, La Barceloneta, a single shore-parallel bar is usually present, which often exhibits a crescentic shape (see Fig. 1). This system is therefore an ideal lab to test models for crescentic bar formation. The aim of the present research is to investigate the formation and evolution of crescentic bars in La Barceloneta, comparing field observations with the predictions of the nonlinear morphodynamic model proposed by Garnier et al. (2006).

The field site is presented in the next section and two events of crescentic bar formation observed in La Barceloneta are reported in the third section. The model, presented in the fourth section, is then applied to La Barceloneta conditions and the corresponding results are described in the subsequent section. The sixth section contains a discussion of the model results and a comparison with the observations.

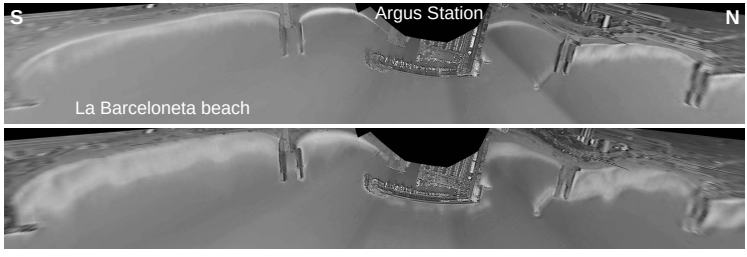

Fig. 3. Planviews of Barcelona city beaches. Upper panel: Linear bar in La Barceloneta on the 15 of October of 2003 at 8h. Lower panel: Crescentic bar on the 18 of October of 2003 at 16h.

FIELD SITE

The field site is located in La Barceloneta beach, at the seafront of Barcelona city (Spain). This artificial beach has an orientation N18^{o}E, a length of 1100 m and it is confined between two groins, the southern one showing an L-shape (see Fig. 2). In the nearshore domain (water depth <5 m), the sediment has a mean grain size of 0.40 mm and the mean slope is 0.033.

Being a microtidal region (water level fluctuations <0.20 m), the winter storms are the major hydrodynamic forcing in Barcelona city beaches. Due to the shoreline orientation, the most important ones are those coming from the East, which are frequently associated to the cyclonic activity in the Western Mediterranean Sea. Their typical duration is of a few days and their main occurrence is from October to April. The significant wave height, H_s, can increase up to 6 m during winter storms but the mean annual H_s is lower than 1 m. Before 2004, only one virtual buoy was providing directional wave information every three hours (WANA2066051 point). These data are computed by the Spanish National Institute of Meteorology using the numerical models HIRLAM and WAM. Since 2004, direct hourly measurements of a directional buoy located at 69 m depth are also available (COST-BARCELONA buoy). Bathymetries of La Barceloneta beach collected on the 6 of October of 2003, the 5 of November of 2003 and the 26 of October of 2005 revealed the existence of two types of profiles: constant sloping beaches during summer (before the arrival of winter storms) and profiles with one bar after the occurrence of significant storms.

An Argus video system (Holman and Stanley, 2006), composed of five full color cameras, was located on November 2001 atop a building close to the Olympic Marina, at 142 m high (see Fig. 2). They span a 180^o view and allow full coverage of the four beaches surrounding the marina (Ojeda and Guillén, 2006). Nearshore bars are seen as white stripes (high intensity values) in the time exposure images (averaged over 10 minutes). These images from the five cameras are rectified and merged to a single planview image (see Fig. 1).

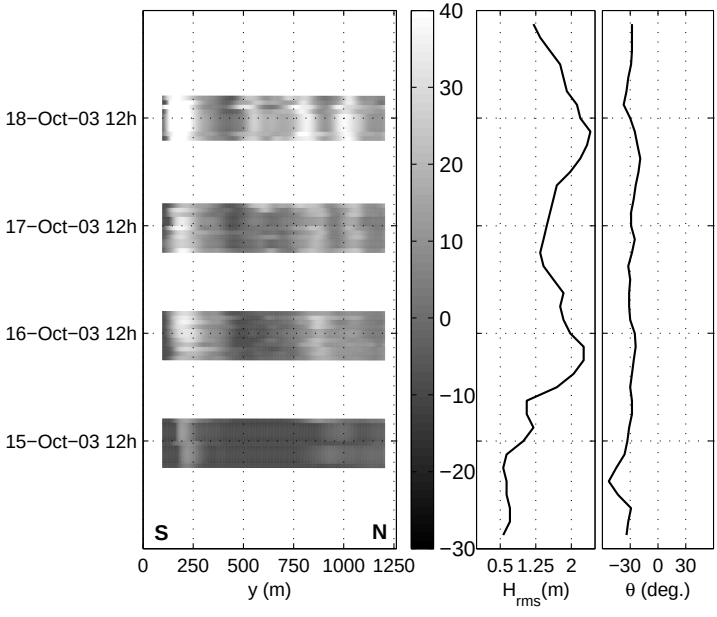

Fig. 4. Crescentic bar event in La Barceloneta during October 2003. Time series of (from left to right) the bar crest lines, $\hat{x}(t, y)$, the root-mean-square wave height, H_{rms}, and the angle of wave incidence, θ, relative to shore-normal. In the first panel, $y{=}0$ corresponds to the southern edge of the beach. Wave conditions were obtained from the WANA2066051 point.

FIELD OBSERVATIONS

Methodology

The characteristics and dynamics of the nearshore bar in La Barceloneta beach have been studied using the planview images obtained from the Argus station. A detailed description of the methodology can be found in van Enckevort et al. (2004) and Ojeda et al. (2007). Bar detection capability of this system is restricted to a range of wave conditions ($0.9 < H_s < 3.5$ m), when wave breaking patterns can be identified. The lines of maximum intensity are extracted from the images using the BLIM program developed by the University of Utrecht. Three preprocessing steps are then applied in order to remove (1) the pixel induced noise, (2) the large-scale shoreline curvature and (3) the bar crest obliquity. The obtained quantity, $\hat{x}(t, y)$, is assumed to be representative of the perturbations of the bar crests with respect to an averaged position. The overall behavior of the bar crest lines from November 2001 to December 2004 was described in Ojeda et al. (2007), including their response to storms and the coupling with the shoreline dynamics. The present contribution focuses on the two most clear events of crescentic bars formation found from November 2001 to December 2005.

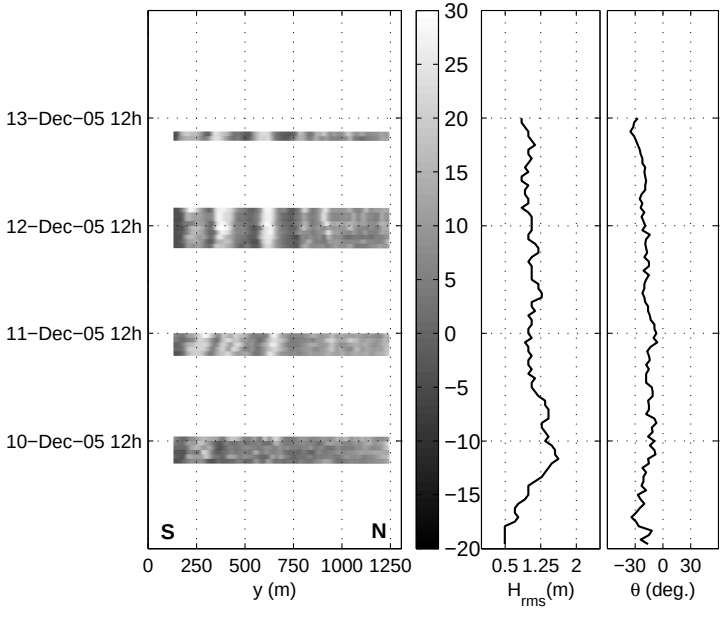

Fig. 5. Crescentic bar event in La Barceloneta during December 2005. Graph description can be found in the caption of Fig. 4. Wave conditions were obtained from the COST-BARCELONA buoy at 69 m depth.

Detected crescentic bar events

The first event of crescentic bar formation of the studied period occurred during a major Eastern storm in October 2003. A crescentic bar emerged (see the lower panel of Fig. 3) and prevailed during the entire 2004 (Ojeda et al., 2007). A space-time diagram (timestack) of the bar line perturbations $\hat{x}(t, y)$ corresponding to this event is shown in Fig. 4, together with the wave conditions. In the first panel, $y = 0$ m corresponds to the southern edge of the beach. Only one seaward perturbation around $y = 250$ m was present on October 15th. As described in Ojeda et al. (2007), this seaward perturbation was present near the southern tip of La Barceloneta from November 2001 to December 2004, probably formed during a period of extreme wave conditions in October 2001. On October 18th, the last day of the storm, four perturbations could be detected along the 1100 m alongshore length, giving an alongshore spacing of about 300 m. The averaged offshore wave conditions during the storm were a root-mean-square height of $H_{rms} = 1.9$ m, a peak period of $T_p = 9.9$ s and an angle of wave incidence of $\theta = 28^o$, relative to shore-normal. The averages were taken from October 16th at 3h to October 19th at 3h ($H_{rms} > 1.25$ m), using the data from the WANA2066051 point.

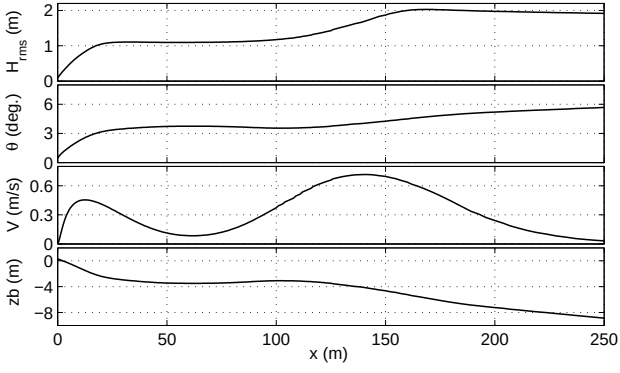

Fig. 6. Initial reference state used in the simulation of the first event of crescentic bar formation in La Barceloneta. The cross-shore distribution of (from top to bottom) wave height, angle of wave incidence, longshore current and beach profile are shown. The x-axis is the cross-shore direction. The profile is taken from a bathymetry measured on the 5 of November of 2003.

The second event of formation of a crescentic bar in La Barceloneta occurred during a less energetic Eastern storm in December 2005. The planviews corresponding to this event have been shown in Fig. 1. A well-developed crescentic bar with at least six undulations is visible on December 13th at 8h, displayed in the lower panel. This can also be seen in the corresponding timestack, shown in Fig. 5. Only the seaward perturbation at $y = 250$ m was detected on December 10th, whereas six seaward perturbations were visible on December 13th. They were spaced every 200 m in the southern half of the beach and every 100 m in the northern half. The storm-averaged offshore wave conditions corresponding to this event were $H_{rms} = 1.1$ m, $T_p = 8.7$ s and $\theta = 17^o$. The averages were taken from December 10th at 4h to December 13th at 12h ($H_{rms} > 0.75$ m), using the data of the COST-BARCELONA buoy.

MODEL FORMULATION

A nonlinear 2DH morphodynamic model (Garnier et al., 2006) is used to describe the initial formation and further evolution of crescentic bars in La Barceloneta. The model describes the feedbacks between depth-averaged mean currents, waves and an erodible bed in a nearshore zone bounded by a straight and infinite coastline (no groin effects are included). The hydrodynamics is modeled with the wave- and depth-averaged shallow water equations for water momentum balance, water mass conservation and wave energy and phase conservation. Waves are assumed to have a narrow spectrum in frequency and wave vector whilst their heights are assumed to be random and to follow the Rayleigh distribution, characterized by H_{rms}. Bed level evolution is described with a sediment mass conservation equation, where the sediment transport is modeled with the Soulsby/van Rijn formula (Soulsby, 1997).

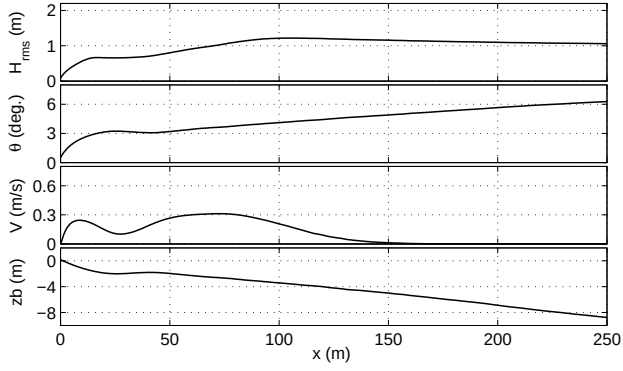

Fig. 7. Initial reference state used in the simulation of the second event of crescentic bar formation in La Barceloneta. Graph description can be found in the caption of Fig. 6. The profile is taken from a bathymetry measured on the 26 of October of 2005.

The model solves the full set of nonlinear equations and provides information about the mid-term behavior of the system O(weeks). The solution procedure starts by selecting an initial alongshore uniform reference state that is in equilibrium (i.e. steady). In this study, the chosen reference profiles $z_b^o(x)$ are obtained from the available bathymetries measured in La Barceloneta (on the 5 of November of 2003 for the first event and on the 26 of October of 2005 for the second). Then, the offshore wave conditions are imposed at 69 m depth and the cross-shore distribution of the equilibrium hydrodynamic quantities is computed: H_{rms}, θ, the longshore current, V, and the elevation of the mean free surface, z_s. Figures 6 and 7 show the initial reference state used in events 1 and 2, respectively. The lower panels display the reference beach profiles, $z_b^o(x)$. As can be seen, on the bathymetry measured on the 5 of November of 2003, the bar was located at about 100 m from the shoreline, whereas this distance was approximately 40 m in the bathymetry of the 26 of October of 2005. Table 1 summarizes the parameter setting used to simulate the two events, including the wave conditions imposed at 69 m depth. The reason why the angle of wave incidence used is smaller than the measured ones (described in the third section) will be explained in the next section.

Once the reference state has been solved, small random perturbations O(cm) are superimposed to it and direct numerical time-integration of the full set of equations (including bed evolution) is performed. The computational domain is a rectangle of 250 m in the cross-shore direction and 2000 m in the alongshore direction. The solution is assumed to be periodic in the lateral boundaries and constant wave conditions are imposed on the offshore boundary. This latter assumption is in agreement with the measured wave conditions leading to crescentic bar formation in La Barceloneta (see Figs. 4 and 5).

Table 1. Parameter setting used in the model of this study.

Wave conditions event 1			Wave conditions event 2			Other parameters	
$H_{rms}(m)$	T_p (s)	θ	$H_{rms}(m)$	T_p (s)	θ	d_{50} (mm)	z_0 (m)
1.9	9.9	10^o	1.1	8.7	10^o	0.4	0.01

MODEL RESULTS

Model runs were performed to simulate the two events of crescentic bar formation of La Barceloneta in October 2003 and December 2005. The existing literature shows that formation of crescentic bars is favored by shore-normal wave incidence (for instance, see Calvete et al., 2005) and this was also verified in La Barceloneta. When running the model with the angle of wave incidence measured in the offshore buoys (28^o in event 1 and 17^o in event 2), unreasonably large values for the growth times and the wavelengths were obtained. The offshore wave angle had to be reduced to 10^o to obtain more realistic results. The results presented in the rest of this paper are those corresponding to $\theta = 10^o$ and the measured values of H_{rms} and T_p. They are shown in Table 1, together with the values used for the grain size, d_{50}, and the roughness length, z_0).

Figure 8 shows the result of the model for the conditions of the first event. The upper panel is a time series of the bottom perturbation with respect to the initial beach for a longshore transect located at $x = 50$ m. During the first four days the bathymetry developed what would be the final dominant wavelength, with a spacing between channels of about 400 m. This is best shown in the lower panel of Fig. 8, which displays the Fourier transform of the signal shown in the upper panel. During the subsequent two days the crescentic topography evolved without changing the dominant spacing, the pattern growing in amplitude with nearly no migration. During the seventh day of numerical evolution, before growth saturation had been reached, the model blew up.

Figure 9 displays a planview of the topographic and hydrodynamic results obtained on day 7 (just before the model blew up). Three undulations can be detected in the alongshore length of 1200 m that is shown, corresponding to the dominant wavelength of 400 m. Resembling the observed systems of crescentic bars and rip currents in natural beaches, the shape of the undulations is alongshore variable. The flow field has two main components: the initial longshore current flowing from left to right (waves arrive from the bottom left corner of the planview) and a rip-current system with the alternation of offshore and onshore flowing. This results in a meandering of the longshore current with some strong rips (for instance at $y = 1250$ m).

The results obtained when using the conditions corresponding to the second event are shown in Figs. 10 and 11. The planview with the topographic and hydrody-

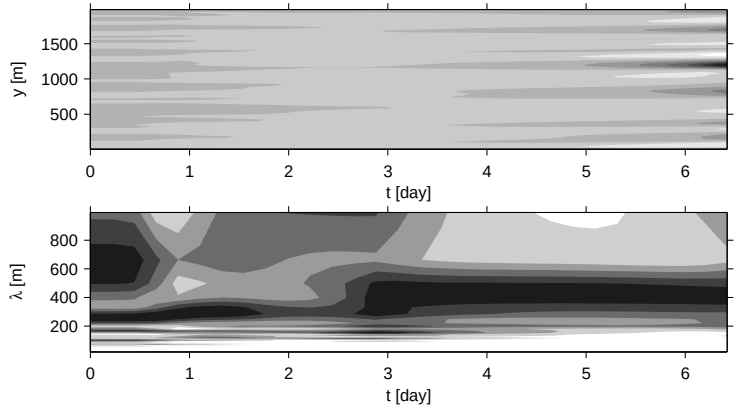

Fig. 8. Model simulation of the first event of crescentic bar formation in La Barceloneta beach. Time series of the bottom perturbation with respect to the initial beach for the longshore transect located at $x=50$ m (upper panel) and the corresponding Fourier transform (lower panel), which is indicative of the dominant wavelengths. In the upper panel, light (dark) gray corresponds to shallow (deeper) sections. In the lower panel, dark gray indicates larger spectral density.

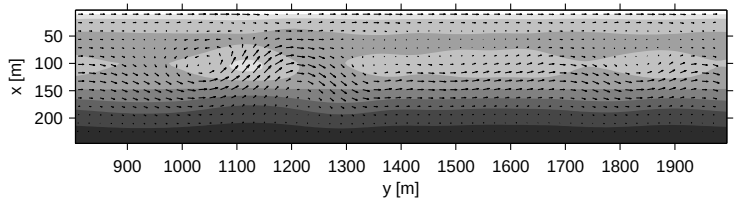

Fig. 9. Planview of the final state obtained for the first event. Colors represent the bottom level (deeper sections are darker) and the small arrows correspond to the 2DH flow field coupled with the emerging morphology. The x-axis is the cross-shore direction ($x=0$ being the shoreline) and the y-axis stands for the longshore direction (an alongshore length of 1200 m is shown).

namic results obtained by the model before it blew up shows similarities with that of event 1. It consists of a crescentic bar with alongshore variable undulations and the longshore current is meandering due to the presence of rip currents. The most significant difference is a reduction of the length scales by a factor of 2, the dominant wavelength being now 200 m (three undulations in an alongshore length of 600 m). The time series of Fig. 11 shows that the model needed about four days to reach the final dominant wavelength of 200 m. However, in this case there was another detectable (but weaker) wavelength of 100 m. During the subsequent five days the crescentic feature grew in amplitude with nearly no migration, until the model blew up at the end of the eighth day, before saturation had been reached.

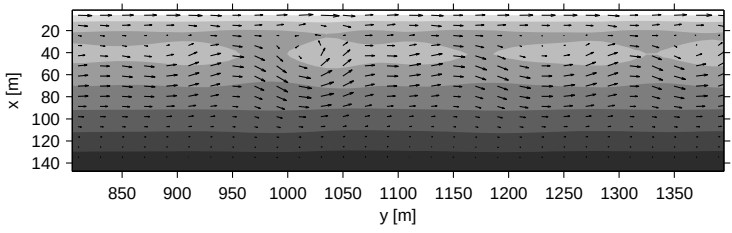

Fig. 10. Planview of the final state obtained for the second event. Graph description can be found in the caption of Fig. 9, but the scaling of the axis is different in the present figure (an alongshore length of 600 m is shown).

DISCUSSION AND MODEL-DATA COMPARISON

The crescentic bars observed in La Barceloneta beach showed a wavelength of about 300 m in October 2003 and of 100-200 m in December 2005. Previous models have predicted that the wavelength of crescentic bars increases roughly linearly with the distance from the shoreline to the crest of the initial bar (Deigaard et al., 1999; Damgaard et al., 2002; Calvete et al., 2005). This is consistent with our observations, the bar being further offshore in the first event, as can be seen in the corresponding planviews (lower panels of Figs. 1 and 3). This is also confirmed by the available bathymetries, the 5 of November of 2003 the bar was located at 100 m from the shore whilst the 26 of October of 2005 the distance was 40 m (see Figs. 6 and 7). In qualitative agreement with what was observed in La Barceloneta, the model used in the present contribution predicted a wavelength of 400 m in the first event and a combination of 200 m and 100 m in the second event. Therefore, the physical processes responsible for crescentic bar formation that are included in the model by Garnier et al. (2006) could explain some of the properties of the bars detected in La Barceloneta.

However, the model was not able to describe appropriately some other characteristics of the detected crescentic bar events. In particular the angles of wave incidence used in the simulations were smaller than those that were measured in the field. It should be pointed out that the existing models (including the one by Garnier et al., 2006) have some properties that limit the comparison of their results with the field observations in La Barceloneta. Firstly, the geometry used in the models is highly idealized: a rectilinear shoreline with periodic boundary conditions (rather than groin simulation) and initial alongshore uniform conditions in the bathymetry. The geometry of La Barceloneta beach is significantly different, since it is limited by groins, it has a curvilinear shoreline and it displays significant alongshore inhomogeneities in all the available bathymetries.

Future work should include the development of the model, prioritizing the description of groin effects. Moreover, events of crescentic bar formation in other

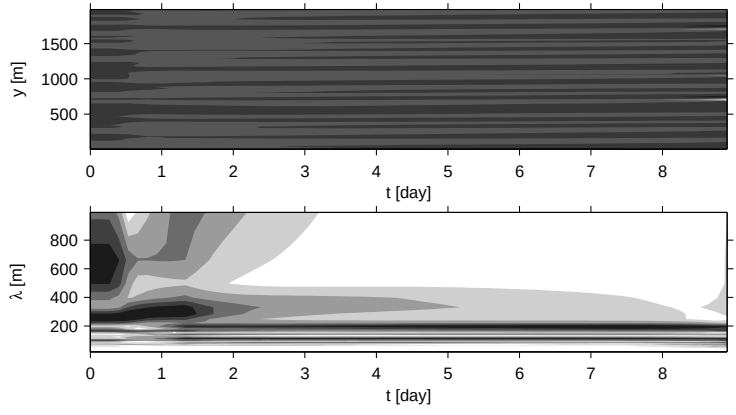

Fig. 11. Model simulation of the second event of crescentic bar formation in La Barceloneta beach. Graph description can be found in the caption of Fig. 8.

beaches should be analyzed to better fit with model results in case of θ larger that 15^o. Finally, the model blew up before saturation of the growth of crescentic bars was reached. This is the case in all the nonlinear models for crescentic bar formation that are available (e.g., Caballeria et al., 2002; Damgaard et al., 2002; Reniers et al., 2004). However, the model used in the present study was able to reproduce the growth and saturation of transverse/oblique shore-attached bars in initially plane beaches (Garnier et al., 2006). More research is needed to obtain growth saturation of crescentic bars in initially barred beaches.

CONCLUSIONS

The characteristic wave conditions leading to formation of crescentic bars in La Barceloneta beach, on the Spanish Mediterranean coast, have been determined. Crescentic bars emerge during Eastern storms with offshore root-mean-square heights between 1.5 and 2 m, peak periods of 9 s and angles of incidence between 15^o and 30^o, relative to shore-normal. The observations are coherent with the theoretical prediction that the wavelength of crescentic features increases when the distance from the bar crest to the shoreline is larger.

Two events of crescentic bar formation detected in La Barceloneta have been reasonably reproduced with a nonlinear morphodynamic model, the predicted and the detected wavelengths being in qualitative agreement (from 100 m to 400 m). Future improvements of the model should be to include groin effects and to consider larger angles of wave incidence for crescentic bar formation.

Abstract: The aim of this study is to compare long-term (30 yr) bar migration characteristics at two field sites on the Danish North Sea coast. One site displays systematically onshore migrating bars (Skallingen) while the bar migration at the other site (Vejers) is systematically offshore. Using cross-shore profile data and a sediment transport model, the paper discusses the mechanisms that cause divergent longshore bar behaviour at the two sites. The main reason for the difference appears to be larger undertow speeds at Vejers, caused by a steeper outer shoreface and a larger bar relief, leading to breaking wave reformation between bars.

INTRODUCTION

With the emergence of data sets on long-term profile change in e.g. the Netherlands and on the East coast of the US, it has been realized that multiple bar systems often display a tendency towards a systematic offshore migration of individual bars. Observations of such systematic seaward bar displacements were reported by Kroon (1990) and Wijnberg and Terwindt (1995) off the Dutch coast. Similar offshore migration tendencies were observed at Duck, N.C. (Plant et al., 1999) and in New Zealand (Shand and Bailey, 1999). The characteristics of the offshore bar migration cycle are similar at most sites. Longshore bars are formed close to the shoreline, they oscillate back and forth in the inner surf zone for a few years and then they begin to migrate consistently offshore. In water depths of 4-7 m, the migration cycle slows down and stops, subsequent to which the bars decay and eventually disappear. The return period for the bar migration cycle ranges between 1-13 years for the different study sites (Ruessink and Terwindt, 2000; Ruessink et al., 2003).

The onset of offshore bar migration is probably related to the decay of the outermost bar in the system. When the outer bar decays, larger wave heights are allowed further into the surf zone. This causes increased speeds of the undertow under breaking waves across the inner bars and hence increased rates of offshore sediment transport on those bars.

However, the reasons for the offshore bar decay are not known and the relationships between the bar migration cycle and coastal sediment budgets are poorly understood. The offshore bar migration cycle should lead to a sediment loss from the beach and an erosion of the shoreline. This does not appear to be the case. Consequently, it has been suggested that there may be a recycling of the sediment within the bar system such that the sand from the outermost decaying bar is transported landward during the decay process (Ruessink and Terwindt, 2000). Alternatively, the bar migration may be only a translation of the form with no sediment transport involved.

Not all multiple bar systems display a net offshore migration. Net onshore migrating bars were observed within a multiple-barred system at Skallingen, Denmark (Aagaard et al., 2004a). At this site, longhore bars originate in water depths of 3.5-4 m, migrate onshore through the surf zone and finally weld with the beach face. The onshore bar migration is consistent with measurements of sediment transport which is onshore directed across the bars during storm conditions (Aagaard et al., 2002).

A short distance north of Skallingen, at Vejers on the exposed Danish North Sea coast, the longshore bars migrate offshore in the long term. The aim of this paper is to conduct a comparative study of the two sites at Skallingen and Vejers using long-term profile data and a recently proposed sediment transport model (Aagaard et al., 2002) in order to analyze the mechanisms that cause divergent longshore bar behaviour at the two sites. Additionally, the relationships between the bar migration cycles and the sediment budget at the two sites will be addressed.

FIELD SITES

The two sites are both located on the Danish North Sea coast at either side of the submerged shoal of Horns Rev which is a Saalian terminal moraine and the two sites are separated by a distance of approximately 25 km (Figure 1). Horns Rev is attached to the cuspate foreland of Blaavands Huk which acts as a natural groyne to the southerly littoral drift along the North Sea coast.

The Horns Rev shoal significantly affects the two sites. Vejers is located updrift of the shoal and there is a large influx of sand from more northerly sources through the southerly directed littoral drift. According to the Danish Coastal Authority (DCA, 2001), the annual supply of sand to the beaches around Vejers is on the order of 2.3 million cubic meters per year (Table 1) due to a negative littoral drift gradient north of the shoal. Even though there is no doubt that the cuspate foreland at Blaavands Huk has been built up by the littoral drift, the shoreline at Vejers is currently almost stable. In contrast, Skallingen is located to the south of the shoal with a positive littoral drift gradient and the shoreline is receding by about 4-5.5 m/yr on average.

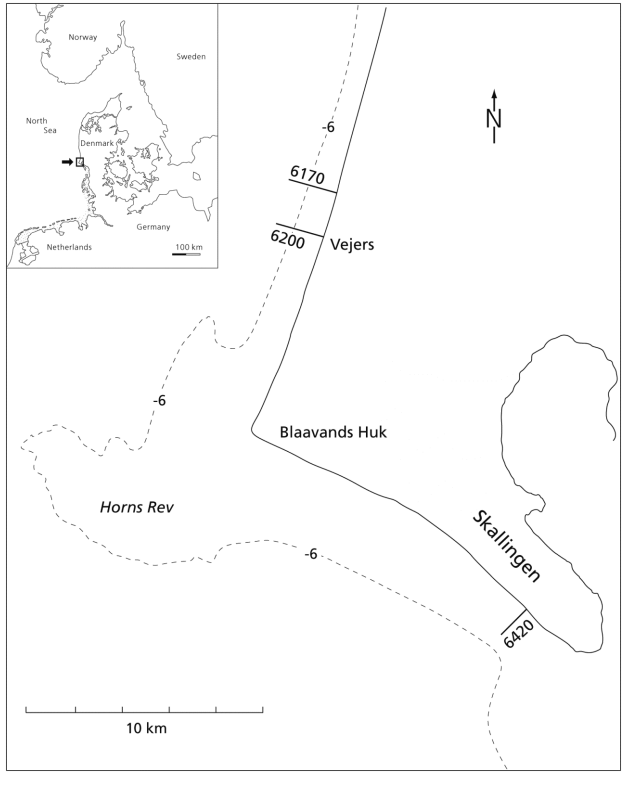

Figure 1. Map of the study area at the Danish North Sea coast. The two field sites at Vejers and Skallingen are separated by the submerged shoal of Horns Rev.

The annual (southerly directed) net littoral drift at the southern end of Skallingen has been estimated at about 0.6 million cubic meters per year, which is approximately similar to the annual sediment loss from the barrier (Table 1). There is no or very little sediment moving across the Horns Rev (DHI, 2002) because the shoal acts as a wave guide.

Because of the shoreline exposure and the location of the shoal, the two sites are also exposed to different hydrodynamic boundary conditions. The mean annual significant offshore wave height is 1.2 m at Vejers, and 1.0 m at Skallingen and the mean spring tidal range is 1.2 and 1.8 m, respectively (Table 1). Low swell frequently occurs at Vejers whereas that is not the case at Skallingen.

Table 1. Environmental boundary conditions and morphological characteristics at Vejers and Skallingen

	Vejers	Skallingen
Mean annual H_s, m	1.2	1.0
Mean spring tidal range, m	1.2	1.8
Net annual littoral drift*, $m^3 \times 10^6$	2.3	0.6
Mean slope, upper shoreface	0.006	0.006
Modal beach state	Intermediate	Dissipative

*The net littoral drift is directed towards the south. Numbers are based on DCA (2001) for Vejers and Aagaard et al. (2004b) for Skallingen.

As Skallingen is located at the head of the bight formed by Horns Rev and the Wadden Sea barriers further south, it often experiences severe storm surges during which the mean water level may reach approximately 4 m DNN (Danish Ordnance Datum). Surges at the more exposed site at Vejers are considerably smaller.

Figure 2 illustrates the cross-shore profiles and mean sediment grain sizes at the two sites. Both profiles are typically triple-barred. The mean grain size on the upper shoreface at Vejers is about 180 microns with sediments at bar crests being slightly coarser. The mean grain size is finer at the lower shoreface, about 110 microns. At the crest at the outermost bar, at $x \approx 1200$ m, the grain size is much coarser, 520 microns, suggesting a local winnowing of the sediment. Similar grain sizes occur at Skallingen even though bar crest sediments are slightly finer than at Vejers and there is no evidence of winnowing. As a result, the mean upper shoreface slope is similar at both sites, $\beta = 0.006$ and the seaward slopes of the bars are also similar, $\beta \approx 0.025$. However, the bars are much larger at Vejers where the bar relief is often up to 3 m whereas it is < 1 m at Skallingen. As a consequence of the deeper troughs at Vejers, waves tend to break through plunging at bars and reform between the bars and the modal beach state is intermediate, while it is dissipative at Skallingen where continuously spilling breakers tend to occur across a wide surf zone.

LONGSHORE BAR BEHAVIOUR

Figure 3 illustrates the profile evolution at DCA Line 6170 at Vejers during the period 2002-2006. Four bars appear in the profile: A small inner bar very close to the shoreline, a larger middle bar at $x = 1400$-1500 m, a very large outer bar at $x = 1700$-1800 m and a broad, low-relief fourth bar in a water depth of about 5 m. In the course of one year (2005-2006), the middle and outer bars both migrated about 60 m offshore and increased in size whereas the fourth bar decreased in size as the crest and landward slope eroded.

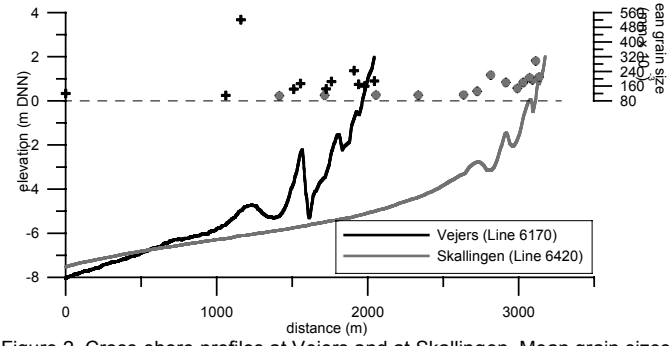

Figure 2. Cross-shore profiles at Vejers and at Skallingen. Mean grain sizes across the shoreface are plotted.

It is likely that this bar had entered the state of decay which is consistent with the indication of winnowing of the sediment (Figure 2).

A similar plot for DCA Line 6420 at Skallingen is shown in Figure 4 for the years 1994, 1995 and 1996. In 1994, the shoreface was double-barred with longshore bars at $x = 150$ m and $x = 300$ m. Within the following year, a trough was eroded at $x = 400$ m with a new bar forming further seaward. The two existing bars remained stable in position. During the period 1995 to 1996, all three bars migrated between 50-100 m onshore.

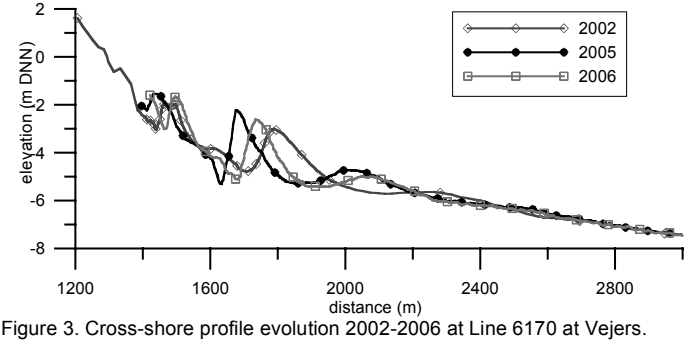

Figure 3. Cross-shore profile evolution 2002-2006 at Line 6170 at Vejers.

To provide a longer-term perspective, bar crest positions in Lines 6200 and 6420 are plotted in Figure 5 for the periods 1969-2002 and 1969-1998, respectively. At Vejers, the bars originate at the shoreline and subsequently migrate offshore at average speeds of 45-55 m/yr and they decay approximately 800-900 m from the shoreline in water depths of 5.5-6 m. In 2006, the outermost bar in the profile (Figure 3) had almost reached this position. The duration of the bar migration cycle is in the order of 15 years. If the

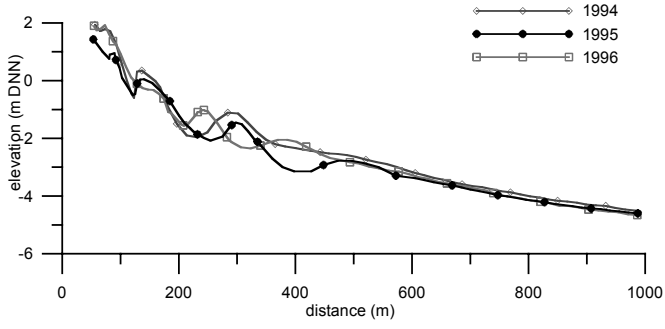

Figure 4. Cross-shore profile evolution 1994-1996 at Line 6420 at Skallingen.

seaward migration of the bars at Vejers involves a net cross-shore transport of sediment, the bar size and the migration speed correspond to a mean annual loss of about 50 m^3/m from the beach. However, the surveys indicate that the shoreline and the dunes are weakly accreting by about 6-7 m^3/m/yr and the 8 m depth contour, representing the limit of the outer shoreface is moving slightly landward, ≈ 3 m/yr (Figure 5). Thus, there is no evidence for any significant sediment loss from the beach to the shoreface.

At Skallingen, longshore bars originate in water depths of 3-4 m and they migrate onshore with speeds of 20-30 m/yr (Figure 5). When the bars enter the intertidal zone, they become dissected by rip channels which initiate cell circulations with onshore directed mean currents across the bars and rip currents in the channels (Aagaard et al., 2004a). This circulation forces the bars further onshore and they finally weld to the beach face. The bar cycle return period is in the order of 8 years, corresponding to a net onshore directed sediment supply of 6-7.5 m^3/m/yr. The 5 m depth contour is translating landward at an average rate of 8-17 m/yr, probably in response to a loss of sand from the

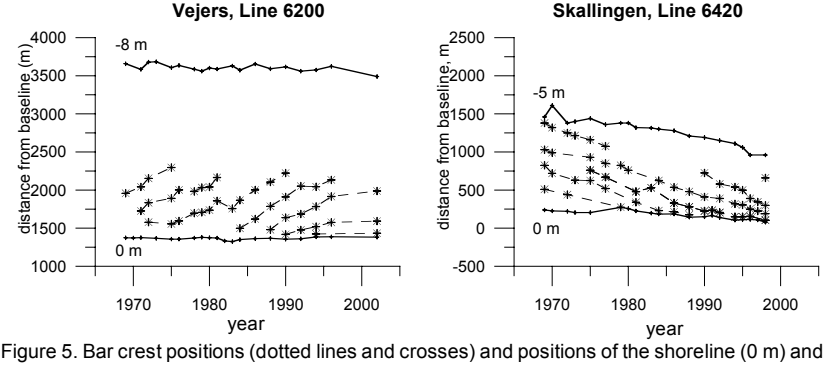

Figure 5. Bar crest positions (dotted lines and crosses) and positions of the shoreline (0 m) and upper/lower shoreface boundary at DCA Lines 6200 and 6420. Distances are given relative to the DCA baseline.

shoreface, associated with the onshore migrating bar forms. However, there is again a mismatch between the inferred direction of sediment transport and the movement of the shoreline. The mean rate of shoreline recession is 4-5.5 m/yr with brief interruptions to the long-term trend when longshore bars are welding (Figure 5). The main reason for the shoreline recession is the longshore sediment loss which currently far exceeds the onshore supply of sand (Aagaard et al., 2004b).

WAVES, CURRENTS AND SEDIMENT TRANSPORT

The causes for the different profile response were investigated by running a wave transformation model across representative shoreface profiles at the two sites. The model selected is the well-validated Battjes-Janssen model (Battjes and Janssen, 1978) which was recently assessed in detail for field conditions by Grasmeijer and Ruessink (2003). The selected profiles are depicted in Figure 2: Line 6170 in 2005 at Vejers, and Line 6420 in 1995 at Skallingen. The model is run for two representative (high energy) wave conditions; a westerly storm and a northwesterly gale.

The storm event was large but not extreme and it occurred on January 8-9, 2005. The mean significant wave height in deep water was 3.5 m and 3.3 m at Vejers and Skallingen, respectively and zero-crossing wave periods were 7.3 s and 7.6 s. The angle of deep-water wave incidence was 18^0 and 28^0, respectively. Mean surge heights were 0.5 m at Vejers and 1.5 m at Skallingen.

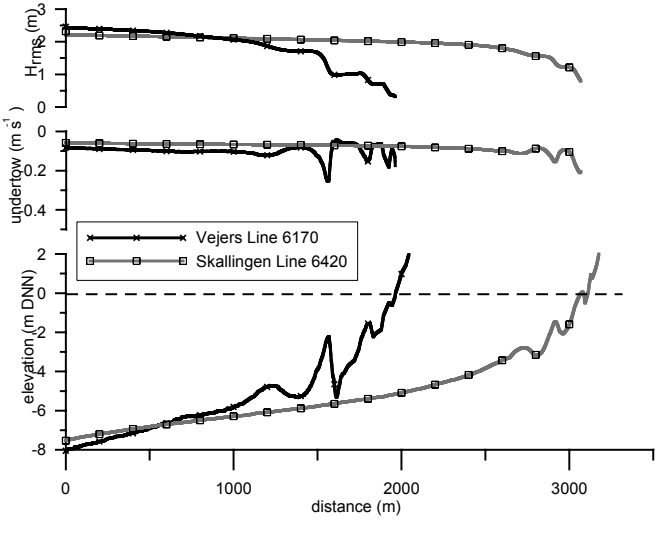

Figure 6. Wave height transformation and undertow speeds across the shoreface at Vejers and Skallingen during storm events..

Model outputs of rms wave height and undertow speed across the shoreface are plotted in Figure 6. Due to the steeper outer shoreface at Vejers, wave energy dissipation across the bars is more intense, particularly across the large outer bar. The wave transformation model predicts reformation of the breaking waves between bars. At Skallingen, the gently sloping outer shoreface results in much more gradual wave height decay and the waves lose energy across a wide surf zone with no reformation between bars, in accordance with visual observations.

The different patterns of wave transformation result in different speeds of the offshore directed mean currents at the two sites. The predicted undertow is up to −0.25 m s^{-1} on the upper shoreface at Vejers (at the outer bar) whereas maximum undertow speeds on the shoreface at Skallingen are only up to −0.15 m s^{-1} at the inner (intertidal) bar. In addition, it is unlikely that an undertow does occur at the inner bar at Skallingen as cell circulations tend to dominate in the shallow water depths at this position.

Figure 7 depicts the model predictions from more moderate wave conditions. The event selected occurred on November 12-13, 2004. The offshore H_s was 2.1 and 1.6 m at Vejers and Skallingen and wave periods were 5.8 and 5.0 s. The angle of wave incidence was close to zero at Vejers and 44^0 at Skallingen. Mean surge heights were 0 and 0.5 m.

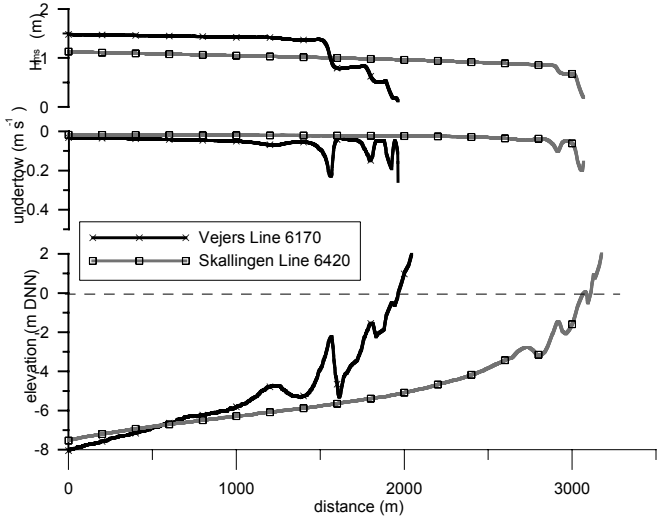

Figure 7. Wave height transformation and undertow speeds across the shoreface at Vejers and Skallingen during gale events.

The predicted wave height and mean current characteristics are qualitatively similar to the storm case. Wave dissipation is strong across the large bars at Vejers and much more gradual at Skallingen. Waves reform between the bars at Vejers whereas that is not the

case at Skallingen. Maximum undertow speeds are almost identical to those occurring during storms conditions.

Most numerical models for cross-shore sediment transport predict net offshore transport under breaking waves (e.g. Gallagher et al., 1998; van Rijn et al., 2003) and therefore they cannot be used to assess the differences in sediment transport characteristics at these two sites, because the transport and the bar movement is onshore under breaking waves at Skallingen. Instead, the empirical sediment transport model proposed by Aagaard et al. (2002) is used to evaluate the processes that result in seaward bar migration at Vejers and landward migration at Skallingen. In this model, a non-dimensional sediment transport index, Q_d, takes the values between −1 and +1 such that landward sediment transport occurs for positive values of Q_d and seaward transport occurs for negative values. If $Q_d = +1$, the suspended sediment transport is completely dominated by the incident waves and hence directed onshore; if $Q_d = -1$, the transport is accomplished completely by the undertow. Q_d does not predict the magnitude of the transport, only the directional tendencies of this transport.

Q_d depends on the non-dimensional parameter, D:

$$D = \frac{psu_{rms}}{|U|} \tag{1}$$

(Aagaard et al., 2002) where p is the cross correlation between instantaneous (cross-shore) velocity and sediment concentration, s is (cross-shore) velocity skewness, u_{rms} is orbital velocity magnitude and U is the mean cross-shore current (undertow) speed. As s and particularly p currently cannot be predicted from any numerical model, D was reformulated in terms of more easily predictable parameters and is denoted Γ:

$$\Gamma = \frac{\theta_{\max}(H_s / h_b)u_{rms}}{\gamma_s^{\,2} \tan\beta} \tag{2}$$

where θ_{max} is the wave-current Shields parameter, computed according to Soulsby (1997), H_s is the local (significant) wave height, h_b is the depth of initial wave breaking, γ is the local relative wave height (H_s/h) and β is the local slope. Based on field observations the empirical relationship

$$Q_d = 0.026\Gamma - 0.752 \tag{3}$$

was obtained (Aagaard et al., 2002). Eq.(2) contains parameters which are all predicted from the wave transformation model, or that can be obtained from the beach profile. Consequently, Eqs.(2) and (3) were calculated across the profiles at Vejers and Skallingen. The model is only applicable for locally breaking waves ($\gamma_s > 0.40$) and positive (*i.e.* seaward facing) slopes. For the computation of the Shields-parameter, a

grain size of 200 microns has been used for Vejers, which represents the average grain size on the three bar crests, whereas 180 microns has been used at Skallingen.

Outputs from the sediment transport model for storm conditions are illustrated in Figure 8. The model predicts $Q_d < 0$ across all bars (except at the outermost decaying bar) and hence offshore migrating bar forms at Vejers, whereas $Q_d > 0$ consistently for Skallingen, except for the innermost intertidal bar where cell circulation tends to replace undertow. Hence, the model is in qualitative agreement with longshore bar migration tendencies at both locations.

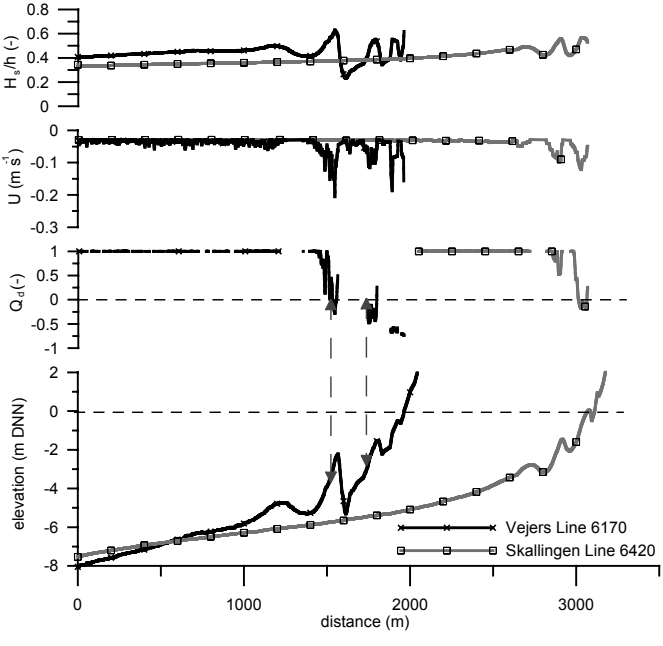

Figure 8. Model predictions of non-dimensional sediment transport (Q_d), undertow speed (U) and relative wave height across the shoreface at Vejers and Skallingen during storm events.

The model predicts two zones of sediment transport convergence at Vejers (at $x \sim 1500$ m and 1730 m), both located 65-70 m seaward of the existing bar crests. These convergence zones correspond to positions towards which bar crests should tend to migrate. No sediment transport convergence zones are predicted for Skallingen (except in the intertidal zone) and the bars are predicted to migrate consistently onshore during storms, in agreement with observations.

The reason for the different (predicted) behaviour at the two sites during storms is mainly due to larger undertow speeds at Vejers (Figure 8). Model predicted undertow speeds are slightly smaller than predictions from the Battjes-Janssen model (Figure 6), $U = -0.21$ m s^{-1} at Vejers and $U \sim -0.10$ m s^{-1} across the bar crests at Skallingen. Undertow speeds are larger at Vejers because of larger relative wave heights across bars, which are caused by 1) the smaller energy dissipation across the relatively steep outer shoreface, and 2) the reformation of breaking waves in troughs between bars.

Figure 9 depicts the model predictions for the moderate gale case. The sediment transport tendencies are identical to the storm case, but the zone of active wave breaking has narrowed and the model is applicable only to the inner parts of the profiles. The predicted points of sediment transport convergence on the bars at Vejers have moved slightly onshore because of the smaller wave heights but they are still located on the seaward slopes of the bars and the bars should still tend to migrate offshore at this site.

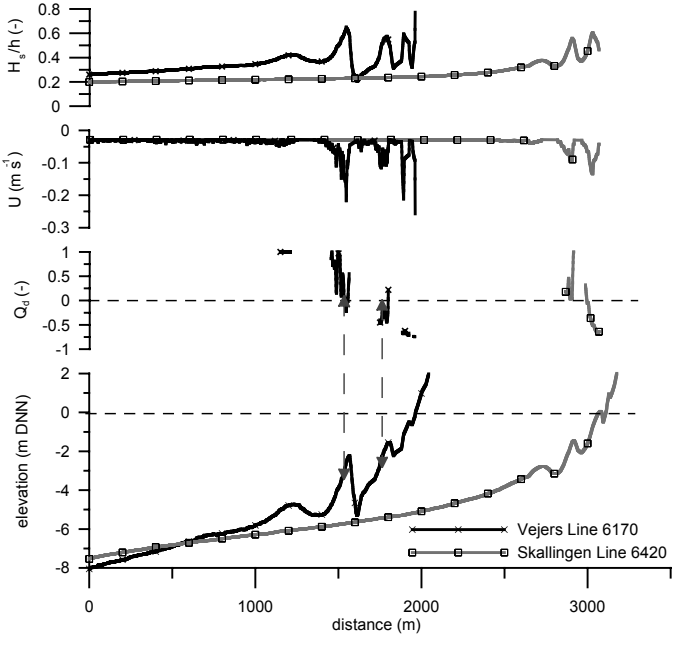

Figure 9. Model predictions of non-dimensional sediment transport (Q_d), undertow speed (U) and relative wave height across the shoreface at Vejers and Skallingen during gale events.

DISCUSSION AND CONCLUSIONS

The long-term behaviour of longshore bars is very different at Vejers and Skallingen. At Vejers, longshore bars move offshore in the long term, whereas the opposite is the case

at Skallingen where longshore bars move onshore under breaking waves. The empirical sediment transport model used here suggests that the main reason for this difference is the larger undertow speeds at Vejers during breaking wave conditions. During storms, the offshore sediment transport caused by the undertow exceeds the onshore sediment transport due to incident wave skewness while the reverse situation occurs at Skallingen.

The larger undertow speeds at Vejers occur because a): The lower shoreface is steeper which allows larger waves to reach the upper shoreface and, in particular, b): The bars are much higher and larger at the intermediate beach at Vejers than they are at the dissipative site at Skallingen. This causes significantly larger wave energy and hence radiation stress gradients across the bars at Vejers, as well as larger relative wave heights due to delayed wave breaking.

The reasons for the larger bar relief at Vejers so far remain speculative because sediment grain sizes are approximately identical at the two sites. There are two factors that are likely to contribute. One is the difference in tidal range. Tidal ranges are larger at Skallingen and tides tend to smear the morphology, producing smaller bars, because of the divergent sediment transport directions within the surf zone over a tidal cycle (Aagaard, 2002). The other likely explanation is the effect of the littoral drift. Vejers receives a large longshore supply of sediment due to the negative littoral drift gradient updrift of the Horns Rev. Longshore sediment transport occurs primarily on bars which then intuitively should accrete as a consequence of the sediment deposition. At Skallingen, the situation is the opposite. Because of the positive littoral drift gradient south of the Horns Rev, the beach erodes and the bars are starved of sediment, leading to smaller-relief features.

The littoral drift gradients are also the likely explanation for the mismatch between the cross-shore sediment transport direction and the long-term profile behaviour at the two sites. The beach at Skallingen recedes even though longshore bar migration (and sediment transport during storms) is landward directed. This is because the longshore loss of sediment far exceeds the onshore supply through the onshore migrating bars (Aagaard et al., 2004b). At Vejers, the beach and dunes are accreting even though bar migration is offshore. It is likely that the longshore supply of sand is an essential factor in this behaviour.

The sediment transport model predicts onshore directed transport across the outermost decaying bar at Vejers (Figure 8) and the lower shoreface is not accreting (Figure 5). Hence, it does not appear that the sand supplied through the offshore migrating bar forms is permanently deposited in the profile at Vejers. Research is ongoing in order to close the sediment budget and to ascertain whether the offshore bar migration at Vejers indeed does involve a net transport of sand.

Abstract: A methodology is presented to identify possible rip current embayments from lidar-derived shorelines along the U.S. Oregon coast. Analyses of these features include their location and their representative length scales in an effort to determine a desired orientation of the features. A total of 99 embayments were analyzed having an average length and amplitude of 575 meters and 17 meters. During the major El Niño event of 1997/1998 there is an increase in size; however, the total number of embayments remained unchanged. The locations of rip embayments in the respective surveys does not show any significant correlation and appears to be random.

INTRODUCTION

Natural shoreline morphologies are complex and often exhibit various types of cuspate and rhythmic features at both small and large scales. Recent advances in rapid, large scale surveying technologies such as lidar have provided the comprehensive topographic data necessary to quantify the occurrence and evolution of these shoreline features. Rip embayments are spatially localized areas of erosion, sometimes called an erosional "hotspot" (Komar 1998; Kraus and Galgano 2001), and are an example of a cuspate-type feature that is common on the winter shorelines of the Pacific Northwest. These embayments can occur as either rhythmic or independent forms and they generally have a longshore length scale on the order of hundreds of meters, similar to sand waves, arrhythmic giant cusps, or rhythmic giant cusps (Dolan 1971). Their cross-shore length

scale (amplitude) can be as large as 50 meters and essentially represents their erosional impact. Rip embayments, as their name implies, are generally assumed to be the result of the hydrodynamics associated with rip currents. However, as with beach cusps and many other shoreline features, their hydrodynamic origin is not always certain.

The presence of rip embayments creates vulnerability within the natural beach defense system. Storm waves will preferentially attack the beach through the deeper areas along the rip channels leading to the embayments. This means they are also better able to reach backing dunes and cliffs, which are the last defense for most coastal developments. Extreme events such as these have been well documented in Oregon, at times accounting for up to 30 meters of dune erosion in 3 weeks and causing houses and property to succumb to the ocean (Komar and Rea 1976).

Observations have established that a rip current that persists and is reasonably stationary will carve out a channel along the main flow axis where the currents are the strongest. The rip current or "rip cell" is supplied by longshore feeder currents and the net result is often a net offshore transport of sand. As sand along the beachface is removed by these currents, a localized erosional feature termed a rip embayment is created (Komar 1971). Swash processes also play a role in the erosion leading to the formation of embayments; however, their exact contribution is not well understood. Nonetheless, much of the sediment is likely carried offshore within the rip current and can often be seen as a large plume of suspended sediment extending beyond the break point (Shepard et al 1941).

Field observations of rip current embayments are limited and mainly derived from the shorelines of the Pacific Northwest (e.g. Komar and Rea 1976; Komar et al 1989; Revell et al 2002). The frequent, long period swell found here is conducive to rip generation and hence, is the likely culprit. However, rip embayments have been noted in California (Shepard et al, 1941), the East coast of the United States (Dolan 1971; List et al 2006), New Zealand (Stephens et al. 1999; Shand et al, 2004) and Australia (Wright and Short 1984; Short and Hesp 1982). Though, it should be noted that those were mainly qualitative measurements that focused on the amount of dune erosion, while detailed measurements of the rip embayment morphologies were not undertaken. The observed length scales ranged from 300-800 meters and their amplitude was described in terms of the associated dune erosion (O(10) meters).

In the following sections we present a methodology for identifying rip embayments (or at least features with the characteristics of rip embayments, though their actual origin remains unknown). The developed methodology is then applied to a representative shoreline contour, in this case the Mean High Water (MHW) contour extracted from lidar surveys undertaken along Oregon coast in 1997, 1998, and 2002. From these data we examine the morphological and spatial characteristics of rip embayments and their frequency of

occurrence on the Oregon coast. The analysis will also consider whether embayments form at preferential locations and whether the 1997-1998 El Niño played a role in increasing the frequency of embayments or contributed to their migration.

STUDY SITE

The Oregon coast can be divided into approximately 18 "pocket beach" littoral cells that are headland bounded. These cells can further be subdivided into sub-cells by the presence of inlets, jetties, and rocky promontories. In the present work we identify populations of shoreline features that are characteristic of rip current embayments from lidar surveys of four separate sub-cells. However, to be clear, we are unable to definitively establish the physics of embayment formation. Nevertheless, henceforth we will refer to them as rip current embayments and quantify their physical scales.

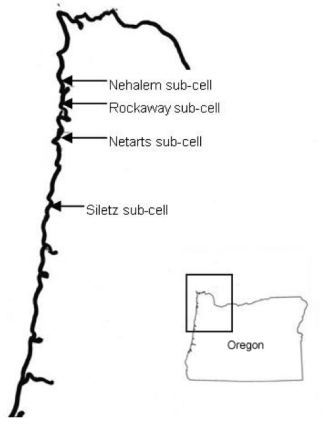

Figure 1 – Locations of the sub-cells used in this study.

The lidar data utilized herein are from portions of the Netarts, Siltetz, Nehalem, and Rockaway littoral cells. The Netarts sub-cell encompasses Cape Lookout State Park and extends ~9 km north to the Netarts Bay inlet. The Siletz sub-cell extends ~10 km from Government Point north to the inlet to Siletz Bay. The Rockaway sub-cell extends ~9 km north from the Tillamook Bay to Nehalem Bay, while the Nehalem sub-cell extends ~8 km north of Nehalem Bay to Neahkahnie Mountain. The morphodynamic characteristics of three of the sub-cells, Netarts, Rockaway, and Netarts, are similar and typified by wide, gently sloping (~2.3°) fine sand beaches, making them fully dissipative in the

morphodynamic classification of Wright and Short (1984). In contrast, beaches along the Siletz littoral cell are characterized by coarse sand, and steeper beach slopes so they are classified as intermediate to reflective.

Wave conditions on the central to northern Oregon coast are much the same. During the winter, the wave regime is characterized by long period high energy waves (~3 meters wave height, ~12 second wave period) from the southwest accompanied with elevated water levels. The summer months have relatively calmer conditions with waves (~1 meter height and 8 second period) arriving from the northwest on lower water levels (Ruggiero et al, 2005). Rip embayments are thought to be less prevalent in the summer months (Komar et al 1989), whether they remain throughout the year has not been documented.

DATA

Anticipating the 1997-1998 El Niño event, the USGS conducted lidar surveys along the Washington, Oregon and California coastline in the fall of 1997 and again in the spring of 1998 (Revell et al 2002). Specific flights within our area of interest were carried out on 17 October, 1997 and on 28 April, 1998. Lidar data from a flight on 20 September 2002 are also examined as part of this study.

The most prevalent source of error in lidar data arises from reflections off the water surface, which creates a noisy topographic signal. These points are eliminated by establishing the tidal elevation during the flight time and removing data points taken from areas below this elevation (Stockton et al 2002). To establish the water elevation, data from nearby tide gages during the approximate times of the lidar flights were used.

As noted by Revell et al (2002), the 1997 surveys were conducted during mid-tide. This tidal elevation is less than a meter from our desired datum, which caused noise similar to that found in Stockdon et al (2002). Due to this effect only the shoreline from the Netarts sub-cell was resolved. The 1998 and 2002 surveys were flown during low tide where tidal elevations were at least a meter below our shoreline datum. Thus a shoreline was able to be extracted from all locations.

The presence of rip current embayments (as with most morphologic features) is dependant in some fashion on the antecedent wave conditions. As context for the lidar determined shorelines from 1997, 1998, and 2002, the antecedent wave conditions for Oregon are shown in Figure 2. Continuous wave height and period data were collected from the National Data Buoy Center station 46002 located 275NM West of Coos Bay, OR. As can be seen in Figure 2, the October 1997 LIDAR was preceded by two major storms, characterized by significant wave heights that exceed 8 m with the capability of transporting large quantities of sediment. A period of nearly five months of low energy conditions preceded the September 2002 survey.

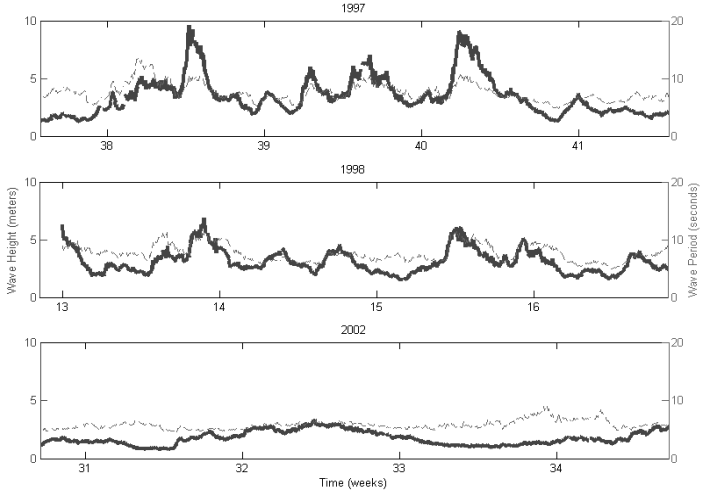

Figure 2 – Antecedent wave conditions prior to lidar surveys, wave height (solid blue line), wave period (dotted green line), x-axis represents weeks (lidar surveys took place at the end of each respective record).

METHODOLOGY

As a representative shoreline contour, we utilize the MHW level. Using a datum based shoreline provides unbiased repeatability whereas proxy shorelines based on visual cues are highly subjective. The study sites have a constant value for MHW that has been established at 2.1 meters NGVD88 (Weber et al 2005).

The raw lidar data was obtained from the NOAA Coastal Services Center (http://maps.csc.noaa.gov/TCM/). In post-processing NOAA has modified the data into a 5 meter grid within the Oregon State Plane North projection oriented in Northings and Eastings. This provides a series of beach profiles along the Eastings and with a profile located every 5 meters in the Northings direction. On average, the beaches were oriented with a six degree offset from true north and thus an Easting cross-shore profile closely resembled a true profile oriented normal to shore. For each profile, the cross-shore location of the most seaward MHW elevation is found through simple interpolation. Through these cross shore profiles a beach face slope is calculated for the portion within on meter of the MHW elevation. Once the location of MHW is found for each profile the MHW shoreline contour can be determined.

In order to establish the rip embayment locations we must identify local areas of erosion relative to the overall mean shoreline (baseline). The baseline is established by lowpass filtering the raw MHW contour. This filter consists of a running average filter applied twice with a window size of 1500 m and then demeaning the signal. Applying the filter twice results in a sharp cutoff, whereby only features with length scales larger than 1500 m remain. A second signal is then created with short scale features such as beach cusps (and remnant noise), removed from the raw shoreline by another lowpass filtering operation (100 m window size, applied twice) and again demeaned. The first signal is subtracted from the second, resulting in a bandpassed signal with bandpass limits of 100 m and 1500 m. An example of the bandpassed MHW shoreline contour that results from this method is shown in the middle of Figure 3 (bold line) where positive values are indicative of erosion.

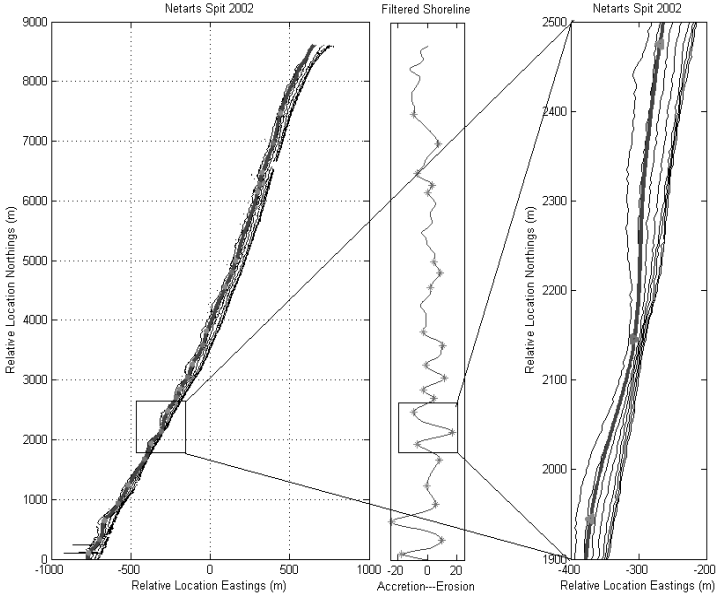

Figure 3 – (left panel) Elevation contours from lidar data, filtered MHW shoreline shown in bold, contour interval is 0.5 meters; (middle panel) filtered MHW shoreline (right panel) expanded view of a single rip embayment. In all panels, stars represent the locations of embayments and horns.

Individual embayments and horns are identified by applying a local maximum-minimum method (Koptenko 2003) on the bandpassed shoreline with a threshold that ignores small scale features less than 100 meters in length and less than 5 meters in amplitude (marked in the center panel of figure 3).

Using a datum based shoreline allows consistent and repeatable measurements of the features. A simple diagram of the scale definitions we have employed for rip embayments is shown in Figure 4. The length of the embayment is measured as the linear distance between adjacent horns located on the bandpassed shoreline (bold line in right and left panel figure 3. The amplitude of the embayment is the perpendicular distance from the maximum point of erosion within the embayment to the line of length.

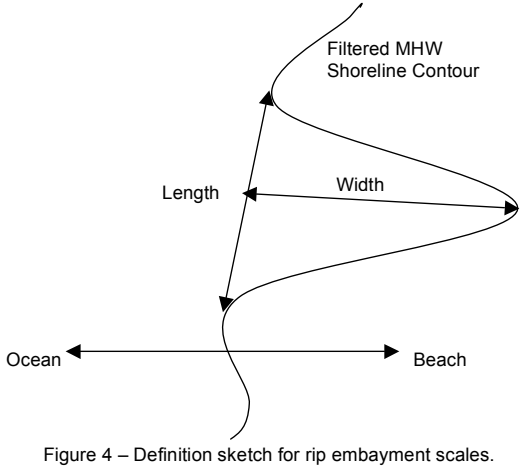

Figure 4 – Definition sketch for rip embayment scales.

Measurements of the rip embayments are dependant upon the chosen datum used for the analysis. As an example, a more complete topographic survey of a rip embayment, obtained from a land-based technique May 2005 (see e.g. http://www.oregongeology.com/sub/Nanoos1/index.htm) is shown in Figure 5. This feature was surveyed using a Trimble 5700/5800 RTK-DGPS surveying system mounted on an ATV and extends further offshore than the lidar survey. This feature remained through July 2005 but was erased by October 2005. It is evident from Figure 5 the survey that estimated embayment amplitudes would effectively increase if lower contours were used for the analysis, and at the upper levels of the beach face there is very little signal of the embayment. However, the longshore scale of the embayment appears less dependent on the chosen contour. The filtering process applied

to the lidar data also inherently reduces the amplitude of the embayments. However, for comparison, using the MHW contour for the data in Figure 5, the observed embayment is approximately 450 meters in length with an amplitude of about 25 meters, which compares favorably with the scales estimated from the lidar data in this sub-cell.

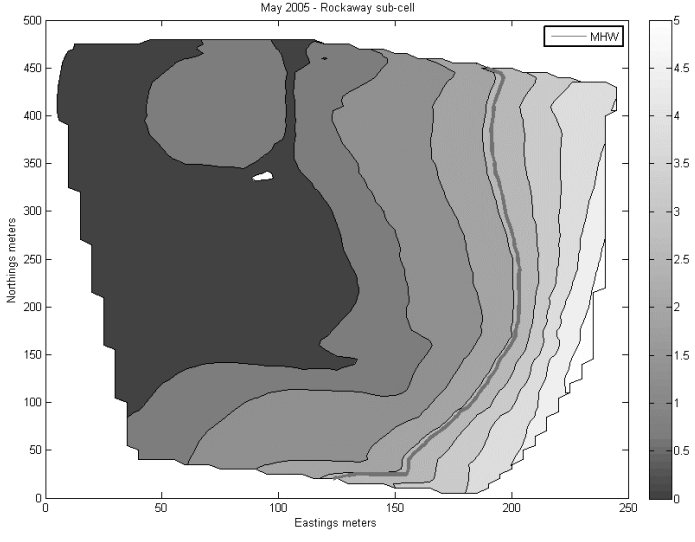

Figure 5 – Land-based survey of rip current embayment, located at 2231500 X 224910 Y in Oregon State Plane North.

RESULTS

Following the method described above plausible rip current embayment length, amplitude, slope, and spatial location were analyzed for four sections of coast for the three years in which lidar data is available. A summary of all features is first provided, followed by an examination of the temporal relationships and particularly the response pf the embayments to the 1997-1998 El Niño in the Netarts sub-cell.

A total of 99 rip current embayments were detected and measured along sandy shorelines totaling approximately 90 km, with an average of eleven embayments per year, per study site. Table 1 provides a summary of the results for each sub-cell throughout the study period. As defined, the embayments exhibit a mean length and amplitude of 575 meters and 17 meters respectively. These values are located near the center of the expected range;

however, the scales have a large standard deviation. Nonetheless, the majority of the features had a length and amplitude less than 1000 meters and 30 meters.

The center of erosion of the embayments in not often located equidistant from its horns. For each study period there is no predisposition to be skewed to the north or the south. This asymmetric nature may be the result of some form of minor migration of the embayment. Another possibility is that the rip current channel is directed at an oblique angle to the shoreline causing a preferred side of erosion.

Examining the embayments from a given site, it is evident that under the same offshore wave conditions individual embayment response was not consistent. Some embayments were characterized by an increase in both their length and amplitude, while other embayments exhibited a decrease in their morphological dimensions; still others experienced an increase in their length and a decrease in amplitude.

Table 1 – Numerical summary of rip current embayment measurements

	Embayment Count	Mean Length [m]	Std Length [m]	Mean Amplitude [m]	Std Amplitude [m]	Mean Space [m]	Std Space [m]
Netarts Spit							
1997	10	556	112	9	5	662	334
1998	10	641	207	14	6	814	438
2002	10	557	195	15	7	738	367
Siletz Spit							
1998	14	542	195	21	16	533	202
2002	10	467	135	16	7	686	393
Nehalem Spit							
1998	10	564	121	18	8	667	336
2002	12	621	257	22	12	651	289
Rockaway Beach							
1998	11	596	254	20	16	745	300
2002	12	630	203	22	15	654	226

It is expected that rip current size scales with rip current strength and, correspondingly, rip embayment amplitude would scale with length. Indeed, there is an apparent linear relationship between the length and amplitude of the embayments as shown in Figure 6. At the Siletz sub-cell, the embayments are relatively shorter than those at other sites (or equivalently, the Siletz embayments are of larger amplitude). It is possible this is due to the coarser grained sediments and steeper beach face found at this site

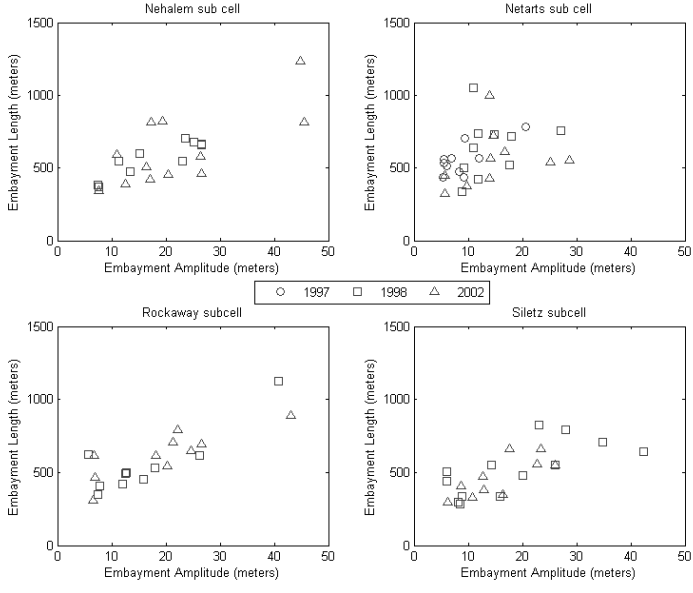

Figure 6 – Summary of Observed Embayments

Although the number of embayments at each site did not vary significantly between the different years, there was some change in the characteristic dimensions of the features. For example, in the Netarts sub-cell data that spans the major 1997-98 El Niño, there is a general increase in the spatial scale of the embayments. The embayment length scale increased 15% and the amplitude of the embayments increased by 55%.

The data also indicate a correlation between beach slope and the location of the rip embayments. Figure 7 shows the bandpassed MHW shorelines along with the local cross-shore beach slope at the MHW contour. It is evident from the figure that within most of the embayments the slope increases to a maximum at the center of the embayment. This appears to be a characteristic of rip embayments, and may possibly be used as an additional criterion for distinguishing erosive embayment features from other shoreline variability.

The spacing and location of embayments on a given shoreline is shown in Figure 8 and appears to be random. A few embayments are found directly adjacent to one another

creating localized rhythmic behavior, while at other locations a single embayment is isolated in a long stretch of straight beach. Due to the differences in the locations of the embayments from year to year, it is likely that embayments are not preferentially occurring at a given location. Even in the 1998 survey, which took place only 6 months after the 1997, there does not appear to be any correlation with the embayment locations from the 1997 survey. It is likely that the largest storms that occurred that winter wiped clean the shoreline embayment signals. Although there may be evidence of preferential dune erosion at the site of rip embayments that remains in the 1998 data. As yet, we have not examined this hypothesis.

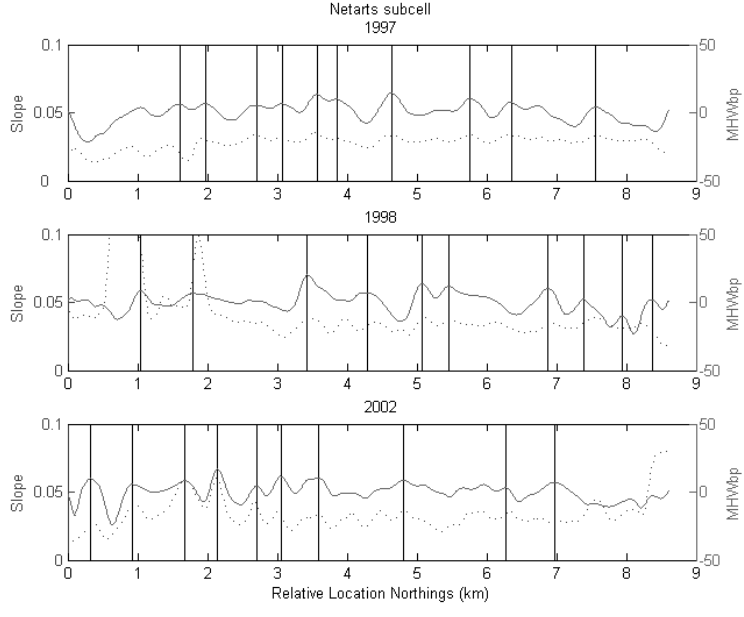

Figure 7 – Correlation between embayments and slope. The solid line represents the filtered MHW shoreline. The dotted line represents the slope. The vertical lines represent the center of the embayments.

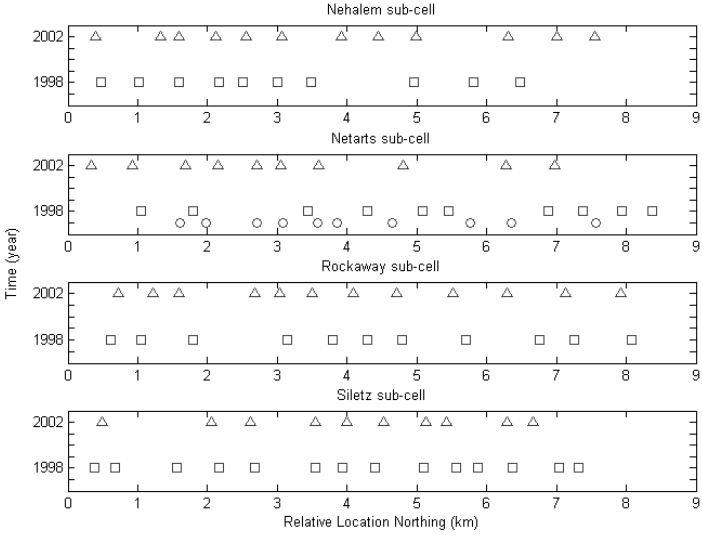

Figure 8 – Locations of embayment center versus survey time.

It is not clear yet if the antecedent wave conditions (Figure 2) for each survey has played a significant role in the embayment results. The wave data show that prior to the October 1997 survey there were two significant storm events with offshore wave heights of nearly 10 meters. Prior to the April 1998 survey there were two moderate storm events with wave heights around 5 meters. Prior to the September 2002 survey wave conditions there were five months of low energy conditions. Given these differences in the antecedent wave conditions, the only significant difference we have discerned in the rip embayments is the aforementioned general increase in embayment scales at the Netarts site for the 1998 data. Clearly further work is necessary to better understand the link between the wave conditions and the creation of rip embayments.

CONCLUSIONS

Using a bandpass filtered, datum based shoreline, morphologic features characteristic of rip current embayments with longshore length scales in the range of 100—1500 meters were extracted and analyzed. These erosional features are fairly common along the Oregon coast. In total, 99 embayments were found in shoreline data from four sites and three different years (9 shorelines total, ~90 km of sandy coastline). Consistent measurements of embayment length and amplitude made along the filtered shoreline had a mean length and

amplitude of 500-700 meters and 10-20 meters respectively. The features appear to be distributed randomly along the coastline with no correlation in the locations from year to year. However, there does appear to be a correlation between the location of the embayments and the local slope in the cross-shore profile, with the slope tending to reach a maximum at the centers of the embayments.

FUTURE WORK

In order to better establish the hydrodynamic origin of rip embayments and their relationship to the prevailing wave conditions, our plan is to simulate the hydrodynamics of these morphologies with a sophisticated wave-driven circulation model. However, a prerequisite to this modeling effort will be to first obtain comprehensive bathymetric surveys (full surf zone coverage) of representative rip current embayments. We are presently developing a bathymetric survey system based on a personal watercraft in order to achieve this. Once obtained, the nearshore circulation field induced by these representative embayments will be simulated numerically. Finally, we will establish which wave conditions are necessary for rip circulations to develop.

Abstract: The inner continental shelf off northern South Carolina is a sediment-limited environment characterized by extensive hardground areas, where coastal plain strata and ancient channel-fill deposits are exposed at the sea floor. Holocene sand is concentrated in large shoals associated with active tidal inlets, an isolated shore-detached sand body, and a widespread series of low-relief sand ridges. The regional geologic framework is a strong control on the production, movement and deposition of sediment. High-resolution geologic mapping of the sea floor supports conceptual models indicative of net southwestward sediment transport along the coast.

INTRODUCTION

The U.S. Geological Survey is working in cooperation with the state of South Carolina, the National Oceanic and Atmospheric Administration's South Carolina Sea Grant Consortium, several universities, and the U.S. Army Corps of Engineers to better understand the factors that control beach erosion, marine habitat distribution, and vulnerability of coastal communities to storms and sea-level rise. The primary objective is to determine the influence of the regional geologic framework on coastal evolution through the interpretation of high-resolution geophysical data and bottom samples. This report is largely based on the work of Baldwin et al. (2004, 2006), Putney et al. (2004) and Denny et al. (2006) which used geologic mapping to provide insight into the processes that have shaped the South Carolina coast and inner shelf.

GEOLOGIC SETTING

The study area is located on the inner continental shelf of Long Bay along the northeastern coast of South Carolina (Figure 1). This area lies on the passive, trailing-edge, U.S. Atlantic continental margin. Although the region experiences little tectonic activity today, its long-term evolution has been heavily influenced by crustal deformation that occurred during the early rifting stages of the Atlantic Ocean (Klitgord et al., 1988). The most prominent structural component underlying the coast is the Carolina Platform, a broad area of crust that is slightly uplifted relative to the flanking marginal basins and embayments. Together, these features form an undulating, subsurface paleotopography that has heavily influenced regional patterns of deposition and erosion since the Cretaceous (Gohn, 1988; Riggs and Belknap, 1988). Repetitive sea-level fluctuations during the Tertiary and Quaternary periods interacted with this underlying paleotopography to further modify the morphology of the coastal plain and inner shelf.

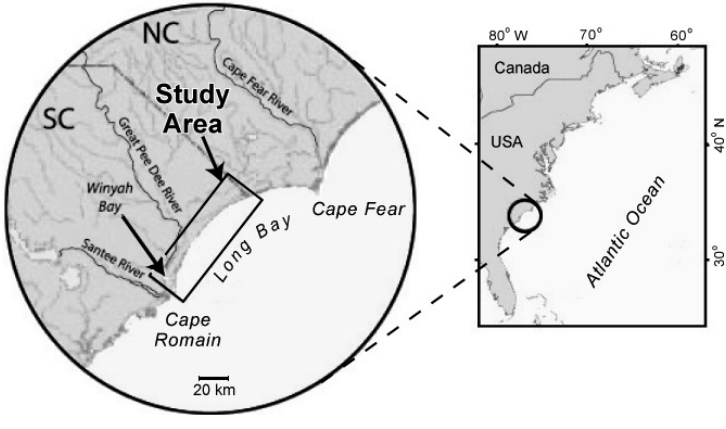

Figure 1. Map showing the location of the study area. The black rectangle indicates the extent of maps in Figures 2 and 7.

The Grand Strand coast consists of a nearly continuous series of sandy beaches that extend about 100 km (62 mi) along the central and southern portions of Long Bay between Little River Inlet and the tidal estuary of Winyah Bay (Figure 2). This arcuate stretch of coast encompasses a central, mainland-attached beach that is bounded by two sets of barrier islands and spits at the northern and southern ends of the littoral cell. Shoreline-change studies show that the coastline has remained relatively stable ($< \pm 1$ m/yr) since 1872, except near tidal inlets (Morton and Miller, 2005). The Grand Strand lies in the transition zone between the wave-dominated, microtidal barrier islands of North Carolina and the tide-dominated, mesotidal barrier islands of the Georgia Bight (Hayes, 1994). The region is periodically impacted by hurricanes and northeasters, causing extensive erosion and damage to coastal infrastructure. Sediment supply is limited by the lack of major rivers entering the central part of Grand Strand coast. Most sediment carried by the Pee Dee River

system, which reaches the coast at the southern margin of the littoral cell, is trapped behind dams or in the estuarine section of Winyah Bay (Patchineelam et al., 1999).

GEOLOGIC FRAMEWORK OF THE INNER SHELF

The inner shelf of Long Bay is low relief and gently slopes from the shoreface to the seaward extent of the study area about 10 km offshore. Water depths in the survey area range from 4-14 m (Figure 2A). Six geophysical surveys were conducted from 1999-2003 to map the geologic framework of the inner shelf and shoreface. Approximately 700 km² of the inner shelf were mapped using interferometric sonar (swath bathymetry), sidescan sonar, high-resolution seismic-reflection profiles, cores and grab samples. Full descriptions of the data acquisition and processing are presented in Baldwin et al. (2004) and Denny et al. (2006).

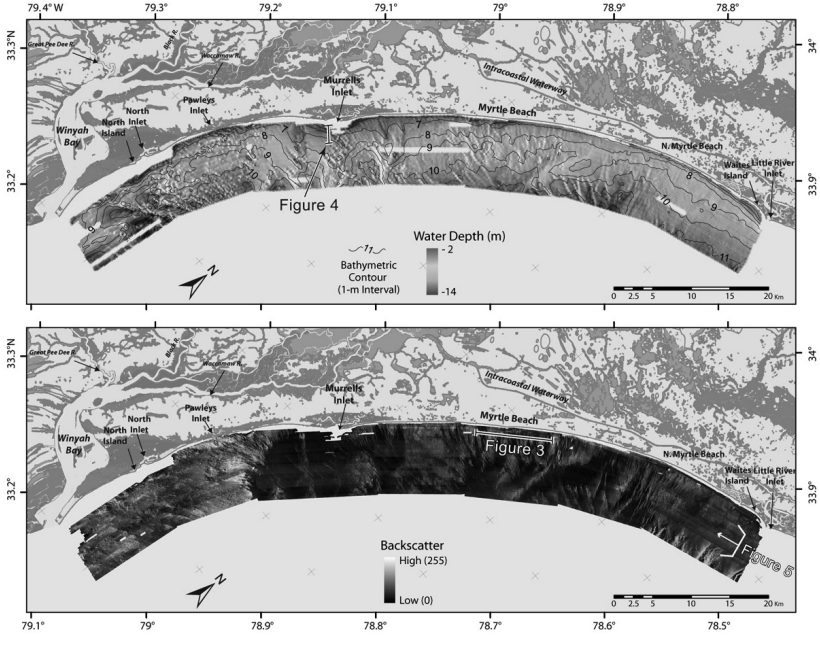

Figure 2. TOP: Map of bathymetry on the Long Bay inner shelf. BOTTOM: Sidescan-sonar image of the Long Bay inner shelf. High backscatter is represented by light tones; low-backscatter is represented by dark tones. *Modified from Denny et al. (2006)*.

The geologic framework of the Long Bay inner shelf consists of four primary components: 1) Cretaceous and Tertiary sedimentary rocks, 2) incised paleochannel deposits, 3) a regional transgressive unconformity, and 4) Holocene inner shelf sand bodies The following sections provide a summary of each component and examine their significance in the context of a dynamic, evolving coast.

Sedimentary Rocks

The sandy mudstones and siltstones underlying the Grand Strand coastal system range in age from Cretaceous to Tertiary. These coastal plain strata were originally deposited in shelf environments similar to what exists today off South Carolina (Colquhoun et al., 1991; Gohn, 1988). The stratigraphic section representing this time is thin due to its location on the flank of the relatively uplifted Mid-Carolina Platform High, or Cape Fear Arch (Snyder et al., 1982; Riggs and Belknap, 1988). Younger units are generally absent along the axis of this subsurface structural high due to erosion or non-deposition resulting from repeated shoreline transgression/regression.

Exposures of coastal plain strata on the inner shelf are represented by high-backscatter within the sidescan-sonar imagery (Figure 2B). The sedimentary rocks are slightly deformed and gently dip down towards the south-southeast, away from the Mid-Carolina Platform High. Erosion has truncated the dipping beds and exposed layers of different composition and physical competence. More resistant units locally crop out on the sea floor, forming low-relief ledges and hardgrounds that are important habitat for benthic-dwelling organisms (Figure 3; Ojeda et al., 2004). When eroded by waves and currents, the older sedimentary rocks supply much-needed new sediment to the coastal system (Riggs et al., 1995; Gayes et al., 2003). Differential erosion of the tilted, coastal plain strata has also influenced the location of river systems, as evidenced by a complex network of incised paleochannels that record relict drainage across the region (Baldwin et al., 2006).

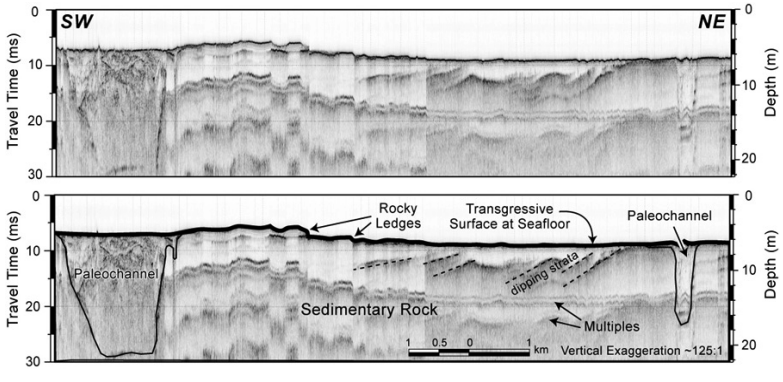

Figure 3. Subbottom profile and interpreted section showing paleochannel deposits incised into sedimentary rock. Both are commonly exposed at the sea floor as hardgrounds. Holocene sediment is thin to absent and the transgressive unconformity is at the sea floor. See Figure 2 for location. *Modified from Baldwin et al. (2004).*

Paleochannel Deposits

A review of previously published studies and interpretation of seismic-reflection profiles and boreholes indicate that the mouth of the Pee Dee River has migrated in a southerly direction over approximately the last 2 million years (Baldwin et al., 2006). Seven groups of sediment-filled channels cross beneath the lower coastal plain and

inner shelf of the Grand Strand. The paleochannels are incised 6-24 m deep into the underlying sedimentary rocks and range in width from 1-12 km. During Pleistocene highstands of sea level, the formation of barrier islands on the lower coastal plain caused the river to progressively shift southward from the center of Long Bay near the NC/SC border to its present position at Winyah Bay.

Erosion during multiple episodes of Quaternary sea-level change has heavily truncated the paleochannel deposits on the inner shelf. Their eroded upper surfaces are typically exposed at the sea floor as high-backscatter hardgrounds, except locally where they are buried by thin, discontinuous deposits of relatively low-backscatter Holocene sediment**.** Subbottom profiles across the paleochannels exhibit seismic signatures that range from transparent, homogeneous fill to intricate cut-and-fill geometries that represent multiple episodes of incision and deposition (Figure 3). Evidence from boreholes collected onshore confirms that the channel-fill sediments were deposited within fluvial, estuarine, open-bay, back-barrier, and nearshore-marine settings.

Transgressive Unconformity

A regional surface of erosion is deeply etched into the coastal plain strata and paleochannel deposits that underlie the shelf. This transgressive unconformity is a major bounding surface that formed in part during the most recent marine transgression (Baldwin et al., 2004, 2006). The unconformity probably represents a much longer period of geologic history, including successive phases of sea-level change during the glacial-interglacial periods of the Pleistocene epoch.

The transgressive unconformity is a low-relief surface that dips gently seaward at very low slopes (< 1°). It separates underlying, geologically older strata from overlying, Holocene sedimentary deposits. In many areas that lack Holocene sediment cover, the transgressive unconformity is exposed at the sea floor as rocky ledges and high-backscatter hardgrounds (Figure 3).

Holocene Sand Bodies

Deposits of Holocene sand lie above the low-relief transgressive unconformity and are expressed as minor bathymetric highs. Denny et al. (2006) identified three principal types of sand bodies that occur in the study area: 1] shoals associated with tidal inlets, 2] an isolated, shore-detached shoal, and 3] small-scale, low-relief ridges.

Inlet-associated shoals contain the largest accumulations of sediment on the inner shelf. The thickest deposits (> 4 m) are within low to moderate backscatter, shore-normal ridges that extend offshore from modern tidal inlets. These deposits generally thin in a seaward direction (Figure 4) and extend seaward beyond the boundary of the study area. Well-defined sand ridges are superimposed on the inlet shoals in the southern part of the littoral cell and are oriented at angles of 35-50° to the coast. The largest ridges near Winyah Bay measure 2-6 m high from crest to trough; smaller features along Pawleys and Debidue islands are 1-2 m high. Older sedimentary rock

and paleochannel deposits are commonly exposed in the troughs, creating complex patterns of high- and low-backscatter within the sidescan-sonar imagery (Figure 2).

Subbottom profiles across the shoal offshore of Murrells Inlet revealed several small, shallow channels lying *above* the transgressive unconformity (Figure 4). These channels are much younger than the large paleochannels that incise the coastal plain strata (Baldwin et al., 2006), and measure less than 100-m wide and 2-m deep in cross section. A second unconformity within the Holocene section truncates the top of the small channels, which are discontinuous in a cross-shelf direction. The channels probably represent a former drainage system, such as tidal creeks and/or local swashes that developed early in the ongoing transgression, when sea-level was lower than present.

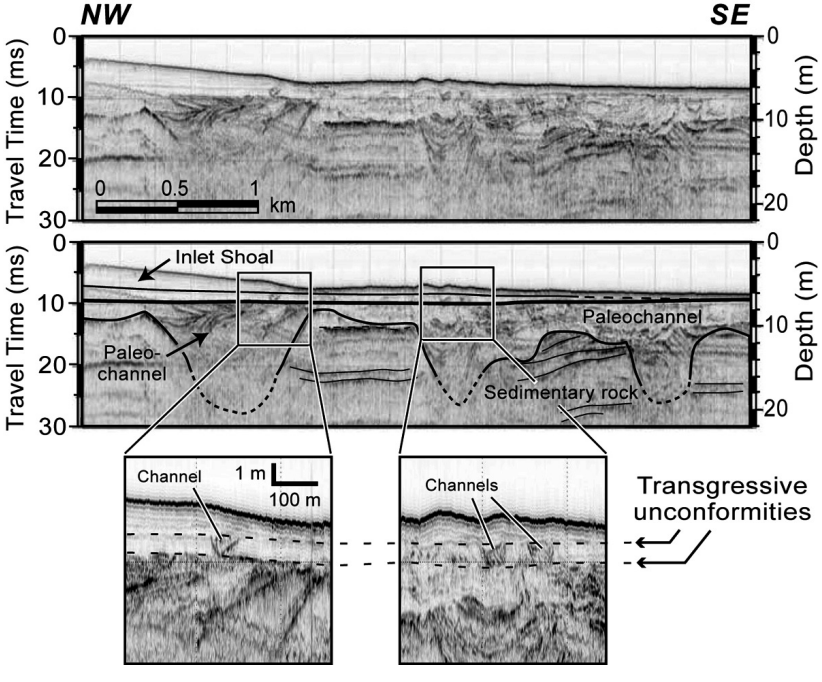

Figure 4. Subbottom profile and interpreted section showing seaward-thinning deposits of the inlet-associated shoal off Murrells Inlet and two transgressive unconformities. See Figure 2 for location. *Modified from Baldwin et al. (2004)*.

The isolated, shore-detached sand shoal that lies 3 km off Myrtle Beach is anomalous because it is not associated with an active tidal inlet. This lobate deposit extends from the shoreface to the offshore margin of the study area in water depths of approximately 7-12 m (Figure 5). The shoal measures about 3-km wide and 11-km along its NE-SW trending axis, and is about 2-m high where it rises above the

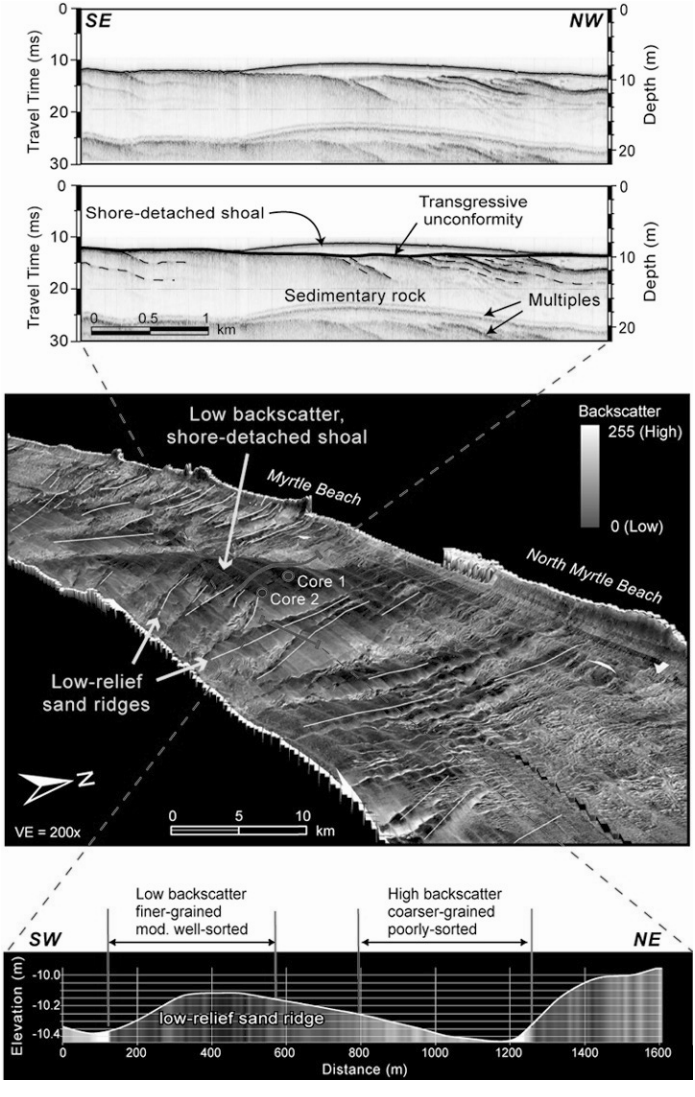

Figure 5. TOP: Subbottom profile across shore-detached shoal off Myrtle Beach. MIDDLE: Perspective view of sidescan-sonar imagery draped over bathymetry, looking toward the southwest. High backscatter is represented by light tones; low-backscatter by dark tones. BOTTOM: Bathymetric profile across a low-relief sand ridge showing asymmetry with steeper slope facing to the southwest. High-backscatter, coarser-grained sediment covers the trough and NE-facing side of the ridge. Low backscatter, finer-grained sediment covers the crest and SW-facing side. See Figure 2 for location. *Modified from Denny et al. (2006)*.

otherwise flat sea floor. It contains an estimated volume of 26 million m^3 of sediment, largely consisting of medium-grained quartz sand with a gravelly lag at the base that coincides with the transgressive surface. In cross section, the feature exhibits no asymmetry that would indicate a direction of net sediment transport.

No internal stratification was observed in subbottom profiles across the shoal, suggesting that the sediment is generally uniform. Cores through the shoal contained up to 1.5 m of fine-medium, shelly sand overlying an erosional surface at the base (Figure 6). The maximum age of the sand body is constrained by two radiocarbon-

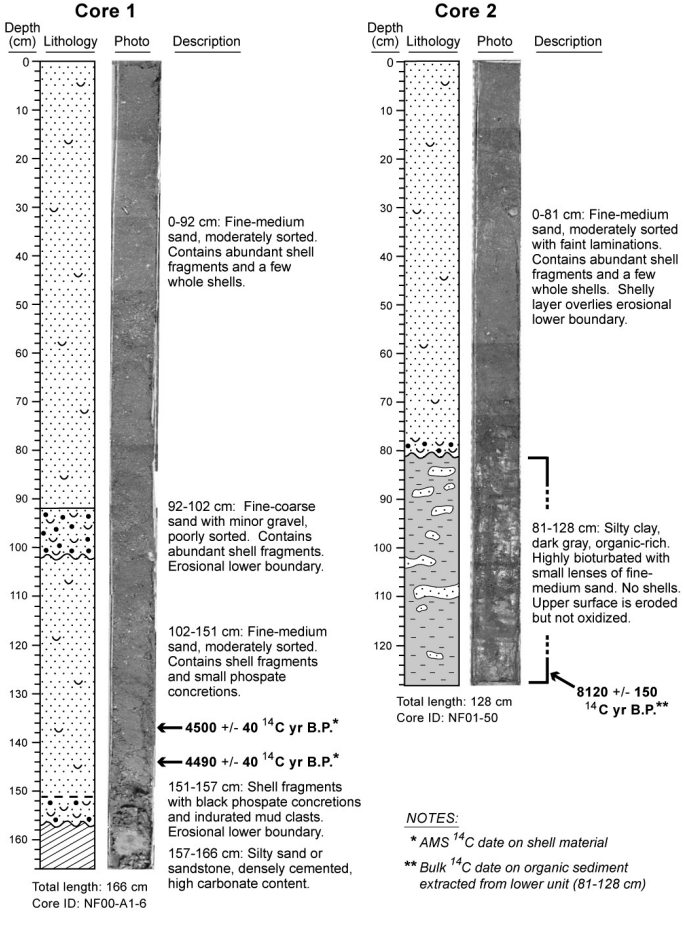

Figure 6. Descriptive logs and photographs of cores collected from the shore-detached shoal off Myrtle Beach. See Figure 5 for locations. *Descriptions by E. Karabanov (pers. comm., 2001).*

dated shells that returned ages of 4810-4540 cal. yr BP. An organic-rich sample from muddy deposits at the base of the sand body, at or just above the transgressive surface, returned an age of 9470-8600 cal. yr BP. Small channel-fill deposits of Holocene age (i.e., overlying the transgressive unconformity) were imaged beneath the shoreface just inshore of the shoal.

Low-relief sand ridges occur over large areas from the shoreface to the offshore edge of the study area, and are present within or adjacent to the inlet shoal complexes. These subtle features are generally less than 1-m high, about 1-km wide, and up to 3-km long. The ridge crests are roughly linear, vary in orientation from shore-perpendicular to shore-oblique, and are covered with low-backscatter, fine sand (Figure 5). In cross section, the sand ridges are slightly asymmetric with a steeper slope generally facing toward the southwest.

IMPLICATIONS FOR COASTAL EVOLUTION

Geological framework studies reveal the sediment-limited nature of the Grand Strand coastal system. A general, structurally-driven lack of accommodation space and long-term reduction in sediment supply are the major factors responsible for sediment limitation. The region's central position on the Mid-Carolina Platform restricts space for sediment to accumulate and exposes very old Cretaceous and Tertiary strata at or near the sea floor. The relatively gentle slope of the shallow margin also maximizes the potential for erosion across a broad area.

Large sand shoals on the Long Bay shelf experienced modification during marine transgression, and were partially preserved as sea level rose to the present-day position. Waves and currents continue to rework the Holocene deposits, as evidenced by the low-relief ridges within and adjacent to the shoal deposits. Except for locally thick shoal deposits, sediment cover is thin and discontinuous over the majority of the Long Bay inner shelf (Figure 7). The relative lack of mobile sediment suggests that

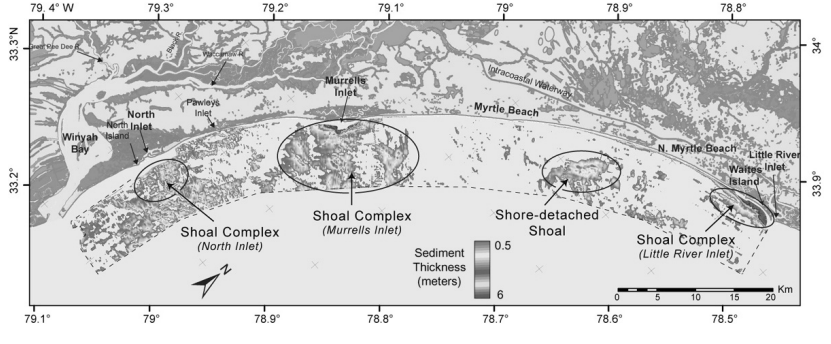

Figure 7. Isopach map showing the thickness of modern sediment accumulation above the transgressive unconformity. Extensive areas of the inner shelf lack modern sediment that is thicker than approximately 0.5 m. *Modified from Denny et al. (2006).*

the ongoing transgression has been very efficient in recycling sediment and conserving it as the coast has migrated landward. Preservation is generally low for coastal deposits that existed on the inner shelf during earlier parts of the transgression. However, deposits of early-middle Holocene age are preserved in at least two locations: the inlet-shoal complex off Murrells Inlet and the shore-detached shoal off Myrtle Beach.

The inlet-shoal complex off Murrells Inlet contains buried channel-fill deposits of probable estuarine or backbarrier origin (Figure 4). The preserved section is 1-2 m thick and bounded above and below by a pair of flat-lying transgressive unconformities. The lower surface is interpreted as the *tidal ravinement unconformity*, an erosional surface that formed relatively early in the transgression at the base of tidal inlets or channels (Allen and Posamentier, 1993). Preservation of this unconformity is low; it is generally destroyed by passage of the shoreface as the transgression proceeds. The upper surface is interpreted as the *shoreface ravinement unconformity*, a major erosional surface that formed beneath the transgressive shoreface (Swift, 1968). This wave-cut surface generates a strong, flat reflection that truncates older sedimentary rock and paleochannel deposits in most parts of the study area. The two surfaces merge offshore in water depths of 6-8 m. In an alternative interpretation, the younger channels could represent tidal distributaries that built out during a slight stillstand of sea level; thus the upper unconformity would be a *flooding surface*. Coring and dating of these surfaces is required to determine their origins and place them in the correct sequence-stratigraphic context.

The shore-detached shoal off Myrtle Beach does not resemble the inlet-shoal complex described above and is not associated with an active tidal inlet. The origin of the shoal is uncertain, but radiocarbon-dated shells from just above the transgressive unconformity constrain its maximum age to the middle Holocene (Figure 6). Muddy deposits at the base of the shoal might represent "freshwater lagoon deposits" that accumulated in the early Holocene (E. Karabanov, personal communication, 2001). Although subbottom profiles show no evidence of small Holocene channels within the shoal itself, several of these younger channels are preserved above the transgressive unconformity in areas located just inshore of the shoal. Based on overall sand-body geometry and setting, the shore-detached shoal is interpreted as a reworked inlet deposit. The shoal is probably the remnant of a tidal delta or a large sand body that was originally confined to the throat of a former inlet. The small channels above the transgressive unconformity probably represent tidal channels or swashes that existed landward of the inlet throat. Similar deposits were described from transitional inlets along the flank of the Georgia Bight (Hubbard et al., 1979; see their figure 10). In this transition zone, which includes the Grand Strand, the shape and orientation of sand bodies reflect the relatively equal importance of wave and tidal action. Geomorphic evidence onshore also suggests that the shoal originated as an inlet deposit. A series of small lakes and swashes on the mainland, possibly remnants of a larger lagoon, line up with the margins of the proposed inlet. Lennon et al. (1996, p. 79) suggested that the lakes "... mark a back-barrier lagoon that filled in when a barrier island welded onto the mainland." As the

barrier migrated landward in this hypothetical scenario, a relatively high topographic gradient onshore prevented the landward expansion of the lagoon. The lagoon decreased in area and presumably the inlet closed due to loss of tidal prism.

Geologic mapping supports conceptual models of sediment generally moving from northeast to southwest along the coast. Baldwin et al. (2004, 2006) showed that the Pee Dee River has migrated in a southerly direction for millions of years, thereby shifting the major supply of fluvial sediment away from the center of the Grand Strand. Consequently, the central and northern parts of the Grand Strand now depend primarily on the reworking of relict shoreline and inner shelf deposits to provide new sediment. This long-term reduction in sediment supply and the interaction of coastal processes with the underlying geologic structure has produced extensive hardbottom areas. Over shorter time scales (i.e., the late Holocene), the southerly direction of net sediment transport is inferred from bedform asymmetry and textural variations observed on the inner shelf (Figure 5, bottom panel). These characteristic patterns are indicative of sediment-transport pathways and are being used to guide process-oriented studies.

After the geologic mapping was completed, a series of instruments were deployed on and near the shore-detached shoal to measure winds, currents, wave characteristics, and suspended sediment concentrations. Data were collected at eight sites from October, 2003 to April, 2004 (Sullivan et al., 2005). Preliminary results show that different storm systems influence the direction and magnitude of net sediment transport over the shoal (Sullivan et al., 2006). Cold fronts and warm fronts generally drive sediment transport toward the northeast; tropical storms and hurricanes generally drive it to the southwest. If transport is roughly equal in each direction, it provides a potential mechanism for partially preserving the shore-detached shoal off Myrtle Beach. Over the last 5000 years or so since the shoal was formed, storm waves have shifted sediment back and forth across the shelf rather than fully eroding the deposit.

ACKNOWLEDGEMENTS

A cooperative partnership between the U.S. Geological Survey and the South Carolina Sea Grant Consortium provided funding for this study. The success of this project depended on the hard work of many people, including William Danforth, Tom O'Brien, Dave Nichols, Charles Worley, Barry Irwin, Shawn Dadisman, Jenna Hill, Ilya Buynevich, Paul Byham, Richard Goldberg, Elizabeth Johnston, Neil Gielstra, German Ojeda, and Jamie Phillips. Excellent ship support was provided by the captains and crews of the *R/V Atlantic Surveyor*, *R/V Megan Miller*, and the *R/V Coastal II*. We thank Jeff List and Larry Poppe for thorough reviews of this manuscript.

Abstract: A sand wave field in the eastern flood channel of Moriches Inlet was monitored for eight weeks during the summer of 2005. Bathymetric data show sand waves which are 15 m long and 39 cm tall with shallow slip faces. These sand waves remained stationary over the eight week study. Analysis based on work by van Rijn (1984) and Yalin (1964) suggests that these sand waves were created when the current velocity reaches 80 cm/s. However, the peak current speeds recorded during this study are less than 60 cm/s. Infrequent, high-energy events are believed to have created these sand waves. A hypothetical event creating these sand waves is described based on a linear analysis of tidal range and peak tidal currents. Water level data from Sandy Hook, NJ and Shinnecock Inlet, NY are used to identify this event. This study demonstrates that episodic events may control sand wave morphology and that once emplaced the sand waves become autonomous.

INTRODUCTION

Sand waves are potential hazards in navigation channels. As they develop within the channel or migrate into the channel from adjacent areas, they reduce the project depth. In the Panama City Entrance Channel and in the Columbia River sand waves reduce the navigation depth by half. In addition to causing channel shoaling, sand waves also decrease the depth-averaged flow velocity and increase turbulence. To efficiently manage tidal navigation channels and model sediment transport it is necessary to understand and predict the geometry, distribution, and migration rates of sand waves.

The conditions under which sand waves develop have been well defined through flume experiments. Under these controlled conditions variations in grain size, water depth, and flow velocity create predictable changes in bedform morphology. However, these

predictive relationships are less reliable to natural settings, especially in tidal channels. Complications arise because:

1. water depth, flow velocity, and grain size are not independent of one another,
2. channel morphology and flow conditions typically are not in equilibrium,
3. sand supply may be limited, and
4. wave-current interaction may change flow conditions.

Moriches Inlet, which is located along the South Shore of Long Island, New York, USA, is a wave-dominated, micro-tidal inlet (Figure 1). It is a sand rich-inlet that connects Moriches Bay directly to the Atlantic Ocean. The focus of this study is the sand wave field in the eastern flood channel (2-4 m) of Moriches Bay. The sand wave field is on a shallow bank (~2-3 m deep) between two relatively deep channels; the west is ebb dominated and the east is flood dominated. Data collected at the inlet include eight weekly bathymetric surveys, sediment samples (d_{50}=0.43 mm), current measurements (peak tidal currents 60 cm/s), and water level data (spring range=1 m, neap range=60 cm). The field study was designed to measure the geometry of the sand waves, document any morphological change, track sand wave migration, and record the hydraulic conditions.

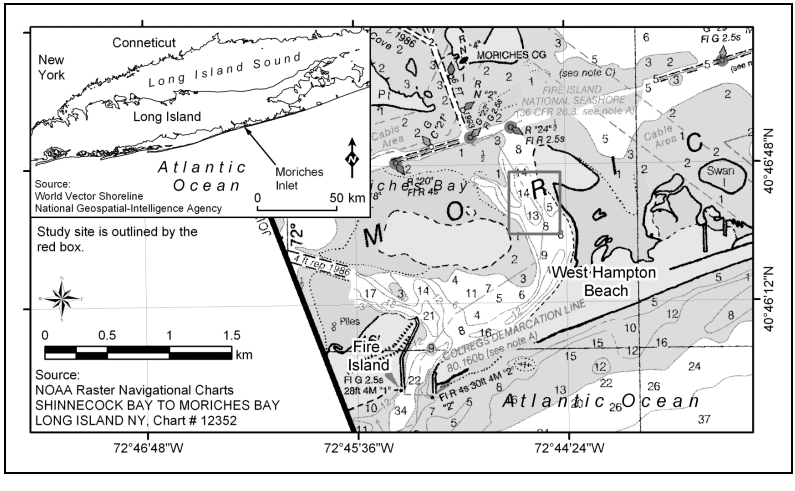

Figure 1. Location of the study area within Moriches Bay. Study site is delineated by the red box.

SAND WAVE MOPHOLOGY

Weekly bathymetric surveys were collected using an Innerspace Model 455 single-beam depth sounder (200 kHz and 8°). The location of the boat was tracked with a Trimble AgGPS 132 GPS (sub-meter accuracy). Two surveys were taken over the first 24 hours to capture sand wave response to a spring tide. Thereafter, the surveys were collected

weekly (29 July, 5 August, 12 August, 19 August, 26 August, and 2 September). Sand waves in this area can generally be divided into two groups- well-defined, flood-orientated sand waves on the bank and smaller, ebb-orientated sand waves in the ebb channel.

Bathymetric surfaces were modeled using ArcGIS ™. A Triangulated Irregular Network (TIN) was created from the individual soundings for each survey. The TINs were converted to grids in order to run more efficiently in ArcMap™ (Figure 2). The error of the bathymetric interpolation is ±12 cm. The sand wave location, height, wavelength, and orientation were identified on each of the eight surveys. Cross-sectional profiles were extracted from the bathymetric grid along each of the survey lines running northwest-southeast and then imported into MatLab for analysis with a script written by the author. The crests and troughs of the sand waves were identified by calculating the approximate derivative of each cross section (Figure 3). The wavelength, height, and slope of the sand waves calculated from the crests and troughs. This information was then imported back into ArcMap™. In ArcMap™, the sand wave crests were delineated along those crests points imported from MatLab.

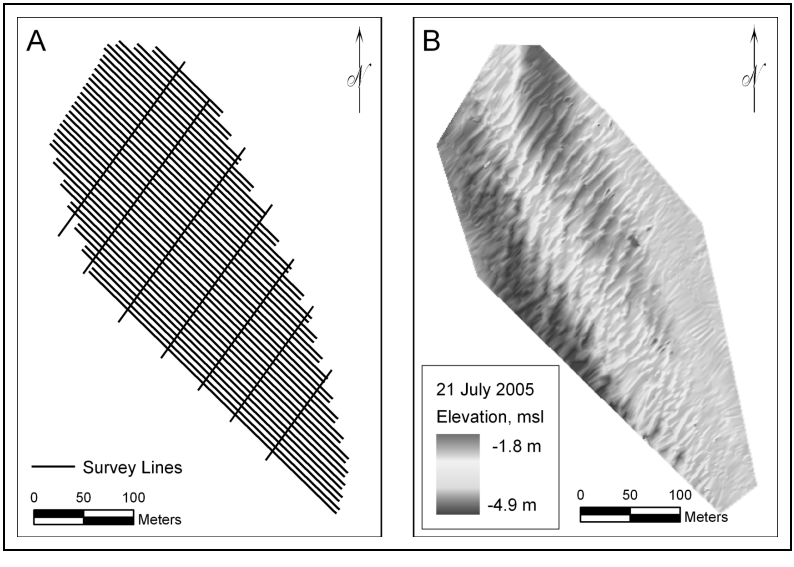

Figure 2. a) Survey track lines along which bathymetric data were collected. b) Bathymetric map of the study area on 21 July 2005. The map is a one meter grid.

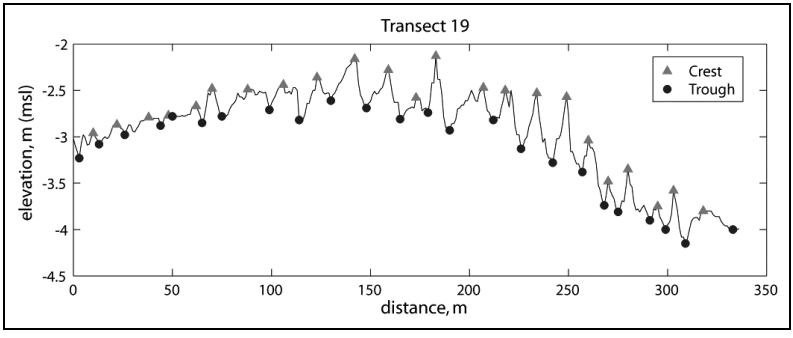

Figure 3. Cross Section from transect 19 which runs through the center of the study area. Crests are shown as triangles and the troughs are shown as circles.

Bathymetric surveys within the 0.07 km^2 study area show two unique morphologies. There are larger, better-defined flood-dominate sand waves on the shallow bank, and smaller ebb-dominate sand waves in the ebb channel. The mean height was 39 cm and the wave length was 15 m over the entire study area. The average spacing of the ebb- and flood-orientated sand waves was the same, but their heights varied. The ebb-orientated sand wave height was 23 cm compared to the larger flood-orientated sand wave height which was 46 cm. The slip face slopes are shallow. The slopes are sub-horizontal, varying from 3.6˚ to 4.4˚. There was little variation in these dimensions during the study period. Morphological changes between the spring and neap tide cycles were not documented.

The location of the sand wave crests were tracked over the seven week study period (Figure 4). Considering the horizontal uncertainty of the depth soundings (±1 m), an uncertainty of ±2 m should be assumed when comparing surveys. These data indicate a lack of systematic migration of the sand waves over the study period. Realignment, flexing, and some bifurcation of the crests occurred. However, bifurcating crests usually returned to their previous continuous configuration, and therefore, may be the result of variations in interpolation due differences in the location of the soundings between surveys rather than changes in the morphology.

PREDICTED SAND WAVE HEIGHT

Laboratory studies (Southard 1971; Southard, et al. 1990) and field studies (Aliotta, et al. 1987; Boothroyd, et al. 1975; Dalrymple, et al. 1978; Dalrymple, et al. 1995; Gabel 1993; Mazumder 2003; McCave 1971; Yalin 1964; Zarillo 1982) have demonstrated that bedform morphology is a function of flow depth, grain size, and flow velocity or shear stress. Yalin (1964) and van Rijn (1984) have estimated the dimensions (height and spacing) of sand waves based on the shear stress. Yalin's derivation for sand wave spacing begins with non-dimensional parameters for the "relative roughness" and "grain-size Reynolds number," i.e., the particle Reynolds number. The Reynolds number

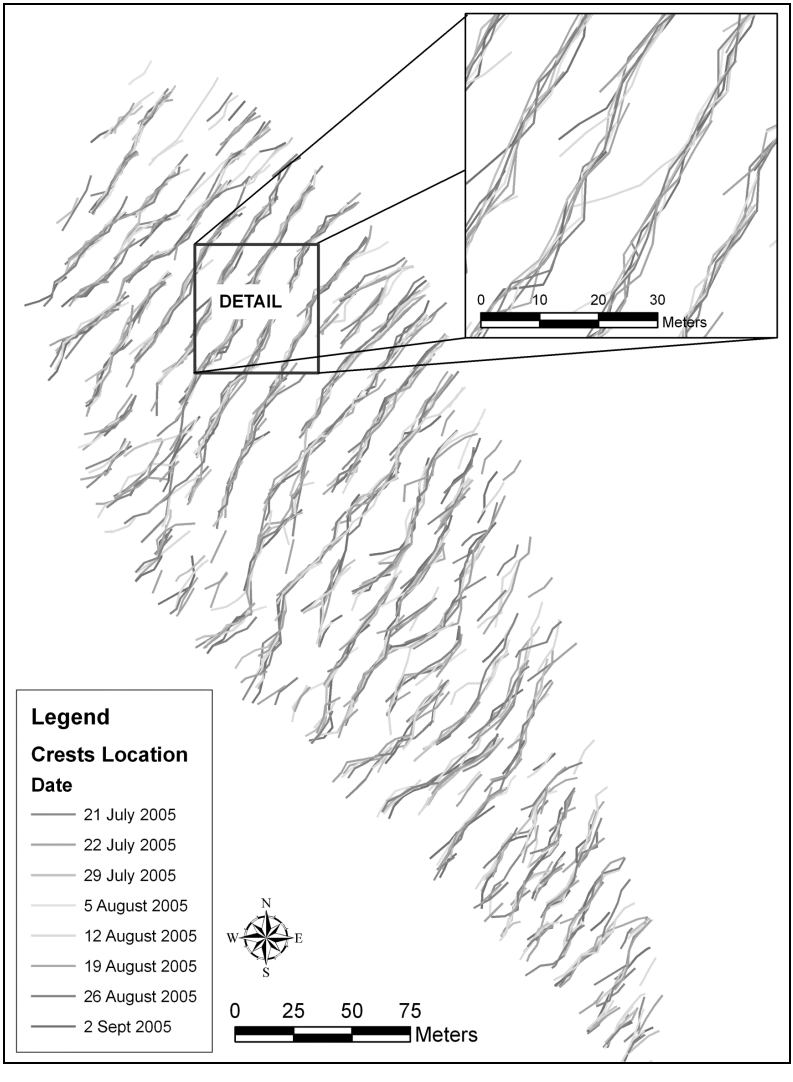

Figure 4. Lines show location of sand wave crests from 21 July to 2 September 2005. There is some movement due to reworking of the sand waves and uncertainty in the surveys but there is no systematic movement of the sand waves indicating migration.

incorporates viscosity, grain size, water depth, and flow velocity. The relative roughness is flow depth over the grain size. Assuming the sand waves develop under rough flow conditions, where the turbulence is not related to the grain size, the equation simplifies, and the wavelength remains dependant only on the flow depth. Yalin goes on to support his equations empirically. Yalin's prediction of sand wave height is based on shear stress, which implicitly includes viscosity, flow density, grain size, and flow velocity. The equation for height is also derived empirically from flume and river data.
Yalin's relationships are:

$$\eta = 0 \qquad \tau < \tau_{cr} \qquad \text{Equation 1}$$

$$\eta = \frac{h}{6}\left(1 - \frac{\tau_{cr}}{\tau}\right) \qquad \tau_{cr} < \tau < 17.6\tau_{cr} \qquad \text{Equation 2}$$

$$\eta = 0 \qquad \tau \geq 17.6\tau_{cr} \qquad \text{Equation 3}$$

$$\lambda = 2\pi h \qquad \text{Equation 4}$$

where η is the sand wave height, τ is the shear stress, τ_{cr} is the critical shear stress, λ is the sand wave spacing, and h is the water depth. Van Rijn's sand wave height prediction also incorporates grain size, but his wavelength equation is still based only on water depth. Van Rijn's relationships are:

$$\eta = 0 \qquad \tau < \tau_{cr} \qquad \text{Equation 5}$$

$$\eta = 0.11h\left(\frac{d_{50}}{h}\right)^{0.3}\left(1 - e^{-0.5T_s}\right)\left(25 - T_s\right) \qquad \tau_{cr} < \tau < 26\tau_{cr} \qquad \text{Equation 6}$$

$$\eta = 0 \qquad \tau \geq 26\tau_{cr} \qquad \text{Equation 7}$$

$$\lambda = 7.3h \qquad \text{Equation 8}$$

$$\text{where } T_s = \frac{\tau - \tau_{cr}}{\tau_{cr}} \qquad \text{Equation 9}$$

and d_{50} is the median grain size. Both models predict no transport if the shear stress is less than the critical value, $\tau < \tau_{cr}$, and, therefore, no sand waves are predicted to develop if that condition is met. They also acknowledge a maximum shear stress beyond which bedforms are 'washed out.' Using values representative of the Moriches Inlet field site (d_{50}=0.48 mm and h=3 m) the height and length of the sand waves can be estimated. The shear stress was evaluated for a current velocity of 0.4 m/s, 0.5 m/s, and 0.6 m/s, and the associated shear stress values were 0.28 N/m^2, 0.43 N/m^2, and 0.62 N/m^2, respectively. The wavelength predictions are larger than observations, 19-22 m compared to an observed average wavelength of 15 m (Table 1). The standard deviation of the observed wave lengths is 4 m, so the prediction and observations agree. Sand wave height is consistently under-predicted, 2-29 cm compared to observations of 39 cm. The standard deviation of the sand wave heights measured at Moriches Inlet is 13 cm. Again, the predicted and observed values agree, albeit ~~just~~ barely.

Table 1. Predicted Sand Wave Heights and Wavelength

	$\overline{U}$ = 0.4 m/s	$\overline{U}$ = 0.5 m/s	$\overline{U}$ = 0.6 m/s
Yalin Height (m)	0.04	0.20	0.29
Yalin Wavelength (m)		19	
van Rijn Height (m)	0.02	0.17	0.29
van Rijn Wavelength (m)		22	

$\overline{U}$ is the depth-averaged velocity

MOBILIZATION OF THE SAND WAVE FIELD

The sand wave field at Moriches Inlet is a persistent feature which has been observed on aerial photographs from 2001 and 2004, and bathymetric surveys from 2004 and 2005, however, the conditions responsible for creating them was not observed during this study. Predictions of sand wave height based on flow velocity measured at Moriches Inlet (Yalin, Equation 2; van Rijn, Equation 6) under predict the height of the sand waves, suggesting that a stronger current velocity was responsible for building these features. Assuming these predictions are accurate, the flow conditions responsible for creating these features were likely not observed during this study.

Evidence for sand wave development under conditions different than those seen during this study is also evident in the slope of the slip face and the steepness of the sand waves. The sand waves display an asymmetrical profile, but the slip face is gently sloped and does not approach the angle of repose. This indicated that the sand waves are not actively migrating. These sand waves were likely actively migrating during their developing phase, but are now stationary because the net sediment transport is not sufficient to cause migration. The weak current and negligible sediment transport have modified the morphology of the sand waves but not erode them or reversed their orientation.

Given the reasons described above, it is concluded that the sand wave field at Moriches Inlet developed when flow conditions where stronger than those observed during this study, possibly during a storm surge or other meteorological event that increased the tidal current velocity. Since then, the typical flow conditions have gently reworked the sand waves, relocating the crests to a more central location, and flattening the slip face while the sand waves remain stationary.

The hypothetical event creating the sand waves can be reconstructed using the empirical equations for sand wave height published by van Rijn (1984) and Yalin (1964) and the physical relationship between tidal range and current speed. The observed sand wave height is 39 cm. To achieve this height, according to the relationships published by Yalin (1964) and van Rijn (1984), the current speed should reach 80 cm/s. Therefore, it can be assumed that the event creating these sand waves caused current velocity in the study area to increase to 80 cm/s.

The velocity of the tidal current is a function of the tidal prism. Because the tidal period remains constant, as the tidal prism increases, the water must flow faster in order to accommodate the larger flux. As long as the area of the bay is constant as the water level rises, tidal range is a valid proxy for tidal prism. In a bay with steep sides and few tidal flats, such as Moriches Bay, the area of the bay remains fairly constant throughout the tidal cycle and, therefore, the relation between tidal prism and current speed can be extrapolated to tidal range and current speed. The current data collected during this study also suggests the bay area remains constant as the water elevation nears high tide. The velocity gradually decreases near high tide; if there were large changes in the bay area as the tide rose, the velocity record would show an acceleration near high tide but it does not.

An increase in tidal range will increase the current speed. Changes in the tidal range are generally periodic and caused by lunar and solar forcing. However, there is also a stochastic component to the tides which is forced by metrological conditions such as wind and/or barometric pressure. For example, during a storm, low barometric pressure, wave setup, and wind forcing may increase or decrease the elevation of the water's surface. This change may increase the tidal range and, therefore, the current velocity.

The water level and current data collected at Moriches Inlet were used to calculate the tidal range and the peak current speeds so that a relationship between these two parameters could be defined. The linear regression between peak current speed and tidal range was calculated for four records. Other current records were disregarded because of the poor data quality (high signal-to-noise ratio or invalid velocities because the meter tipped over) or the length of the record (at least four days of measurements were needed). In addition to being a function of tidal prism, current velocity also depends on the bathymetry; therefore, the relationship between peak tidal current and tidal range is spatially dependent. Because of the spatial dependence, each record was analyzed separately (each record was collected from a slightly different location within the study area). These data were further separated by flow direction. In areas with an asymmetrical tidal signal, the relationship between the peak flood velocity and the tidal range is different than relation between the peak ebb velocity and the tidal range. The study area is generally flood-dominate, so the flood and ebb velocities were analyzed separately. The flood velocities were stronger and showed a better correlation to tidal range than did the ebb velocities. After the analysis was completed, one additional record was disregarded because it had a strong diurnal inequality which resulted in a poor correlation between the current velocity and the tidal range. The R-squared values for the individual stations were 0.73, 0.94, and 0.94. An overall relation between tide range and peak current velocity for the study area was obtained for these three stations (Figure 5):

$$U_{peak} = 0.12 + 0.41(\text{Tidal Range}) \qquad \text{Equation 10}$$

where U_{peak} is the peak tidal current in m/s. For this equation, the R-squared value dropped to 0.51, but the inclusion of all the data makes it a more robust predictor for the

general study area. Based on the regression, the peak current velocity will be 80 cm/s when the tidal range is 1.66 m.

Water level data from Sandy Hook, NJ[1] and Shinnecock Bay[2] were used to evaluate the frequency of events with a tidal range exceeding 1.66 m. Shinnecock Inlet is 30 km east of Moriches Inlet, and the tide gauge was just inside the inlet (Figure 6). Sandy Hook is the National Oceanic and Atmospheric Administration (NOAA) reference station for Moriches Inlet. The correction for low water is 0.60, and the correction for high water is 0.62. These corrections were applied to the observed water levels measured at Sandy Hook to approximate the tidal range at Moriches Inlet (Figure 7). Between May 1998 and December 2005, the tidal range exceeded 1.66 m only once, on 12 December 2000. This tidal range could have increased the tidal velocity and created the sand wave field at Moriches Inlet. This large tidal range was caused by strong winds and a drop in atmospheric pressure. During that day, the wind velocity increased from 2 m/s to 19 m/s, and the wind turned from the north (Figure 8). In addition, the barometric pressure dropped below 1,000 pHa. The drop in atmospheric pressure raised the elevation of the high tide and wind amplified the ebb flow out of the bay and created an extra low low-tide. The result was an extremely large tidal range of 1.95 m.

CONCLUSION

The sand waves at Moriches were compared to predictive models of sand wave height presented by Yalin (1964) and van Rijn (1984). Both models are based on shear stress. Yalin's and van Rijn's equations under predicted the sand wave height by 10 cm. Their model both predict a sand wave height of 29 cm compared to 39 cm as measured at Moriches. Although the sand waves are asymmetrical, the slip face angle is very shallow. The average slope ranges from 3.8˚ to 4.7˚. The steepest slip faces are 5.9˚-6.2˚.

It is unlikely that the observed flow conditions are responsible for the development of this sand wave field. According to Yalin's and van Rijn's predictions, the current velocities are too weak to build these features. Episodic storms events could increase the tidal currents, which could produce these features. After the passage of the storm the typical tidal currents continue to rework the sand waves. Slowly the sand wave crest is eroded and the slip face angle is flattened. Typical current conditions do not completely erode the sand wave but active migration is not observed during these conditions.

The observation of this moribund, or relic sand wave field at Moriches Inlet suggests that sand waves may persist long after the conditions responsible for their development have subsided. Once sand waves are present on the seabed, the bathymetric irregularities caused by these features help maintain the sand waves during extended periods of low flow conditions. During typical hydrodynamic conditions sand waves become autonomous or self maintaining. This conclusion suggests that infrequent high-energy flow events should be taken into account when trying to predict the development of sand waves.

ACKNOWLEDGEMENTS

The authors would like to thank the following organizations and individuals for their financial and technical support of this study:

- Office of Naval Research for graduate funding through the National Defense Sciences and Engineering Fellowship.
- Coastal Inlets Research Program, U.S. Army Corps of Engineers for their financial support of the field work.
- Geological Society of America for financial support of the field work through their Graduate Student Research Grant.
- Steven Borgeld, from Humboldt State University, for supplying the grain size data for the Humboldt Entrance Channel.

Abstract: Bed forms in alluvial systems are three dimensional. The most common bed forms are: ripples, dunes and bars. Under certain flows, different bed forms may be superimposed on each other, e.g. dunes superimposed on bars or ripples superimposed on dunes. The irregularity in the bed of alluvial streams caused by the existence of bed forms produces additional flow resistance, which affects the hydrodynamics and sediment transport properties of the system. The geometry of bed forms in large alluvial rivers such as the Lower Mississippi River exhibits both coherent and random characteristics. Average wave lengths and heights alone cannot adequately describe these bed forms. A spectral approach was used in this study to capture the periodicity and frequency distributions of the observed bed forms along a study reach in the Lower Mississippi River extending from river mile zero (Head of Passes) to river mile 234 (near Baton Rouge, LA).

INTRODUCTION

An alluvial river like the Mississippi River is defined as a stream that transports gravel, sands or/and clays. Alluvial rivers normally have an aspect ratio (width to depth) of 10 or greater (Yalin and da Silva, 2001).

One of the major characteristics of alluvial rivers is that their channel geometry is not only affected by the magnitude of the discharge, but also by the amount of sediment being transported. The river discharge causes a change in the river sediment transport and in turn, the channel bed geometry responds to this change. This causes a change in the water level elevation and thus another change in the sediment transport. The resulting bed forms appear in two flow regimes, lower-flow regime and upper-flow regime.

Bed forms in the lower-flow regimes, with Froude number ($Fr = \frac{U}{\sqrt{gh}}$, where U is the mean velocity; g is the acceleration of gravity; h is the mean flow depth) generally less than 1, are as follows: ripples, dunes, washed out dunes (also called transition dunes). With higher velocities, the lower-flow regime transitions into the upper flow regime (Froude number near or greater than 1), which has the following bed forms: plane bed, antidunes, and chutes and pools (Simons and Richardson, 1966).

Once bed forms appear, streamlines near the bed may not conform to the bed surface, especially in the case of ripples and dunes where the flow separates at the crest of the bed form so that there is a pressure gradient between the downstream and upstream faces of the bed form. The net force thus produced is the form resistance of the bed form. As a major component of resistance, form resistance changes as the flow conditions change. Hence, the effective 'friction' factor in an alluvial river varies with flow conditions.

During the transformation of a sand bed from a flat bed to ripples, and subsequently to dunes, the resistance to flow tends to increase. Then resistance decreases as the dunes are washed out at higher discharges. At even higher velocities, nearly symmetrical sand waves (antidunes) form with little or no flow separation at the crests. Therefore, the form resistance is smaller than that for dunes. The energy loss is more than that for a plane bed, because the breaking of the sand waves generates a strong local turbulence that dissipates part of the flow energy. Energy must also be expended to transport the increased bed material load.

The geometric characteristics of bed forms are irregular and random in nature and therefore the notion of average bed form wave length and average bed form wave amplitude is not sufficient to describe the geometry of the bed forms; alternative statistical indicators are introduced in this study.

PROBLEM DEFINITION

Extensive research has been conducted on the flow and sediment transport over bed forms in alluvial rivers (e.g. mean flow field, turbulence, shear partitioning, bed load transport, bed form geometry). Much of this work was either laboratory studies or small scale field investigations. Recently (1990s) advances in technology have improved the way data are collected and analyzed, e.g. flow data, velocity data and detailed bathymetric information providing greater knowledge about the bed form geometry.

Kennedy and Karim (1990) stated the following *"this finding suggests that models that are significantly more accurate than those that have already been developed, including those presented herein, likely will not be forthcoming until more accurate and more comprehensive field and laboratory data are available"*.

American Society of Civil Engineers (ASCE) Task Committee on Flow and Transport over Dunes (2002) reported the following conclusions "*Field studies with detailed measurements of not only dune characteristics but also flow and transport are valuable and daunting for the same reason: they indicate the complexity of the real problem, which together with practical constrains on field measurements, make more difficult the analysis and interpretation of the data"*.

Recent technological advances in river bottom mapping and data collection devices such as multi-dimensional surveys of the riverbed (also called Multibeam Bathymetric Surveys) represent an opportunity for researchers to overcome some of these hurdles, as they can provide information that could have never been acquired with older technology.

Bathymetry surveys use sound navigation and ranging (sonar) systems to collect depth information. Single-beam sounders collect discrete data points along survey track lines, while multibeam sounders collect continuous high-resolution bathymetry data with complete overlap throughout the survey area. This study uses bathymetry from Multibeam Surveys to characterize the bed forms in the Lower Mississippi River.

METHODOLOGY

The approach in this study was to apply spectral analysis to multibeam bathymetric survey data of the Lower Mississippi River to examine the periodicity in the bed form sequences. Spectral analysis belongs to a family of time series analytic techniques whose aim is to uncover trends or patterns in a sequence of data over time. By extending the temporal methods and substituting space for time, one dimensional spatial data can also be analyzed by these techniques (Granger, 1969; Bennet 1979; Richards, 1981).

Examples of this application are the determination of objective wavelengths in meanders (Speight, 1965, 1967; Chang and Toebes, 1970; Ferguson, 1975; Hokke, 1984), pools and riffles (Richards, 1976), bed forms (Naden 1987, Nordin 1971), and pools caused by coarse woody debris (Nakamura and Swanson, 1996). These successful applications suggest that spectral analysis may be a useful tool for detecting the periodicity in bed forms in the Lower Mississippi River.

Spectral analysis partitions the variation in a time (or spatial) series into components according to the duration or length of the intervals within which the variation occurs (Rayner, 1971). Spectral analysis was applied in this study to the Multibeam bathymetric survey data collected by the Army Corps of Engineer in the Lower

Mississippi River during the period from June 2003 to August 2003. These data were provided to the authors as a part of a hydrodynamic and ecological modeling study of the lower Mississippi River. Meselhe et al (2005) presents more detailed explanation of the study. Multibeam data were collected from River Mile (RM) Zero (Head of Passes) up to RM 234 (near the city of Baton Rouge). Figure 1 shows the extent of the reach where of the Multibeam data were collected.

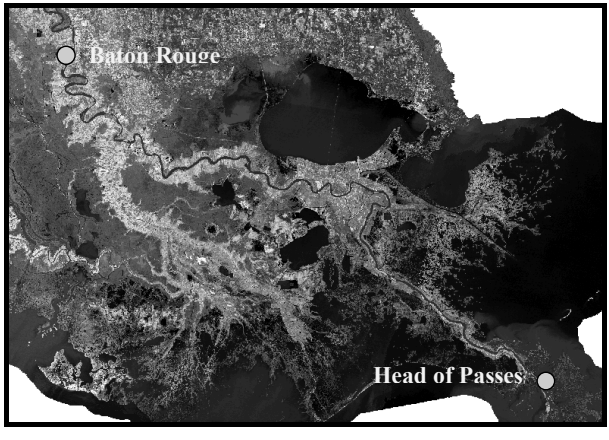

Figure 1: Range of Multibeam bathymetric data collected by USACE

A sample three dimensional view of a Multibeam dataset collected at RM 223 is shown in Figure 2.

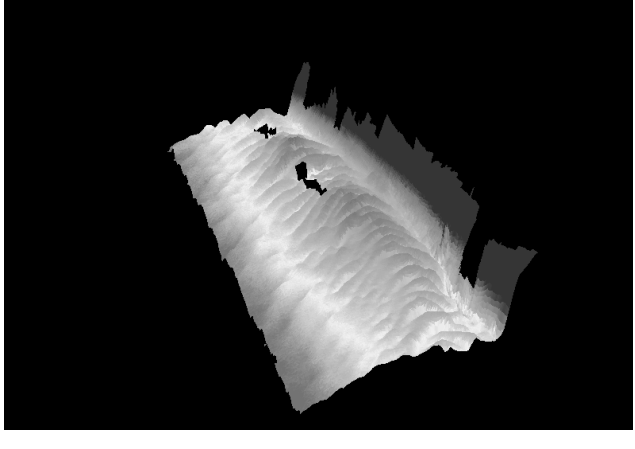

Figure 2: 3D view of a Multibeam data collected in RM 223

A total of 31 Multibeam datasets were acquired and several longitudinal profiles were extracted from each data set. The profile locations were selected such that they cover

the total width of each dataset. To ensure the capture of the bed forms variation in size, sections both parallel and perpendicular to the main flow direction were extracted. Spectral analysis was then applied to the extracted profiles.

RESULTS

A sample extracted profile from Multibeam dataset at RM 223 (Figure 3) is shown in Figure 4, while spectral analysis results of the same profile is shown in Figure 5.

Figure 3: Plan view of Multibeam dataset at RM 223

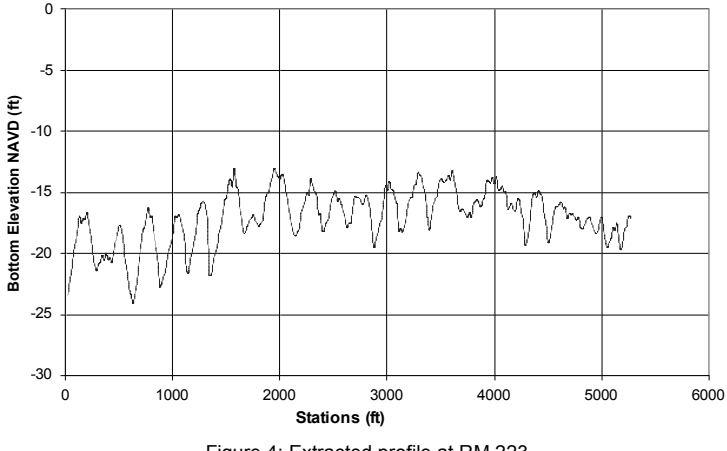

Figure 4: Extracted profile at RM 223

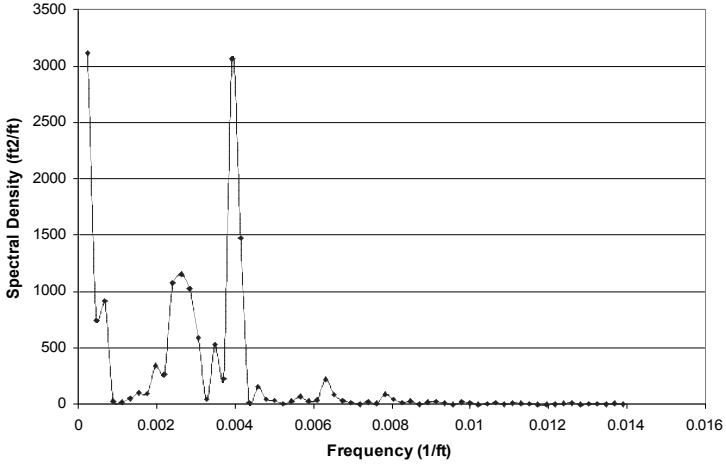

Figure 5: Spectral analysis results at RM 223

Results of the spectral analysis show a distinct periodic character in the longitudinal bed profiles in the sampled datasets. Statistically significant spectral peaks were detected in almost all of the datasets; several reaches exhibit more than one significant peak as shown in Figure 5. At least three significant peaks were noted for each profile and then the corresponding bed form wave lengths, heights and steepness (height/wavelength) were calculated. The calculated wave lengths, heights and steepness for the entire length of the studied reach are shown in Figure 6, 7 and 8.

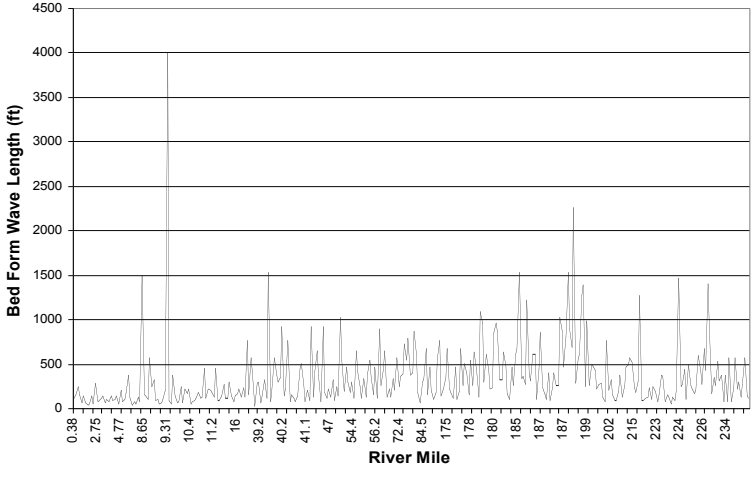

Figure 6: Time series of bed form wave length

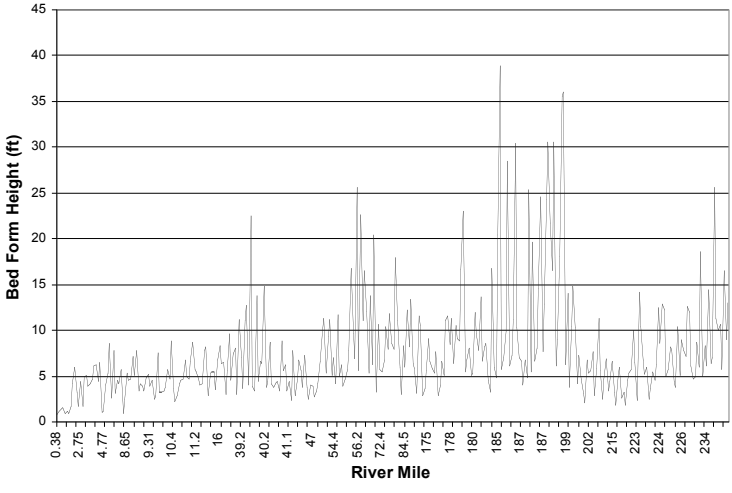

Figure 7: Time series of bed form height

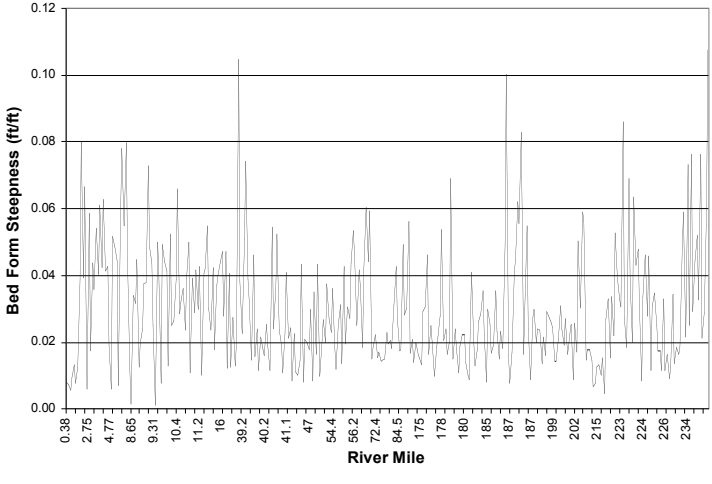

Figure 8: Time series of bed form steepness

Figure 6 shows that the dominant bed form wave lengths on average ranged from 50ft to 500ft in the upstream section of the studied reach while an increase in the wave length was observed in the downstream section of the reach where the bed form wave length on average ranged from 250 – 1000ft. The same pattern was also observed in the bed form height (Figure 7) where the heights on average ranged from 1ft to 7ft in the upstream reaches of the River, while in the downstream reaches they ranged from 4ft to 15ft. Although figures 6 to 8 reveal some valuable information about the bed

form geometry in the studied reach of the Lower Mississippi River, they also clearly show that presenting the spectral results only as spatial series plots is not adequate to represent the results. Table 1 summarizes additional statistical analysis performed on the spectral results obtained from the survey.

Table 1 One variable summary of the spectral results

One Variable Summary			
	Bed form length (ft)	**Bed form Height (ft)**	**Steepness (ft/ft)**
Mean	354.58	7.717	0.03011
Variance	135659.49	34.134	0.00033
Std. Dev.	368.32	5.842	0.01821
Median	242.71	6.000	0.02520
Minimum	29.44	0.850	0.00100
Maximum	4026.00	38.860	0.10742
Range	3970.56	38.010	0.10642

The statistical measures summarized in Table 1 reveal the high variability present in this natural system; the bed form standard deviation is the same order of magnitude as the mean suggesting that the bed form data are following a skewed probability density function. To quantify the degree of skewenesses present in the bed form data, frequency histograms for the bed form wave lengths, heights and steepness were constructed (Figure 9, 10 and 11). These frequency plots list the numbers of observation of each variable (length, height and steepness) in different classes.

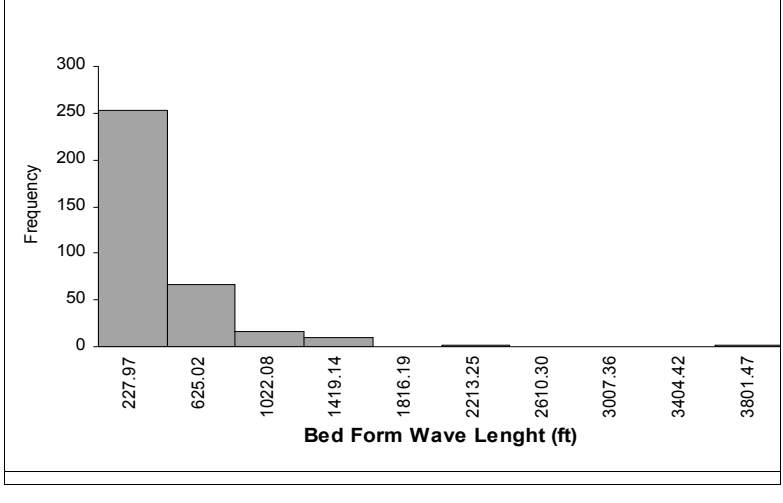

Figure 9 Histogram of the bed form wave length

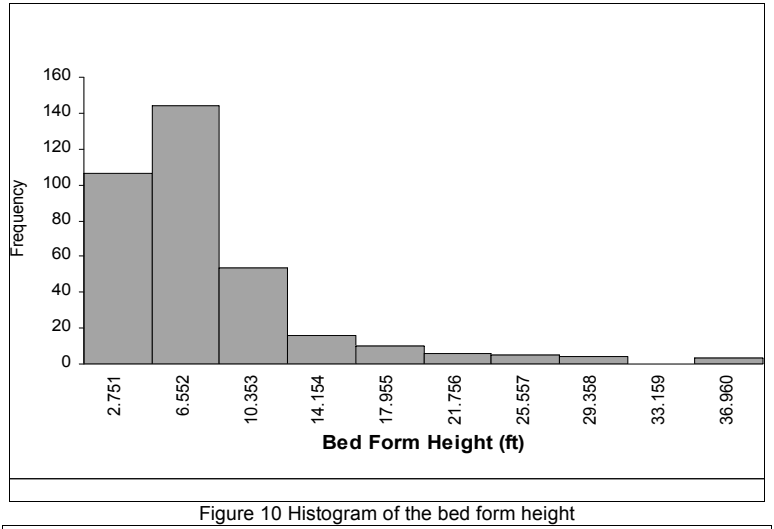

Figure 10 Histogram of the bed form height

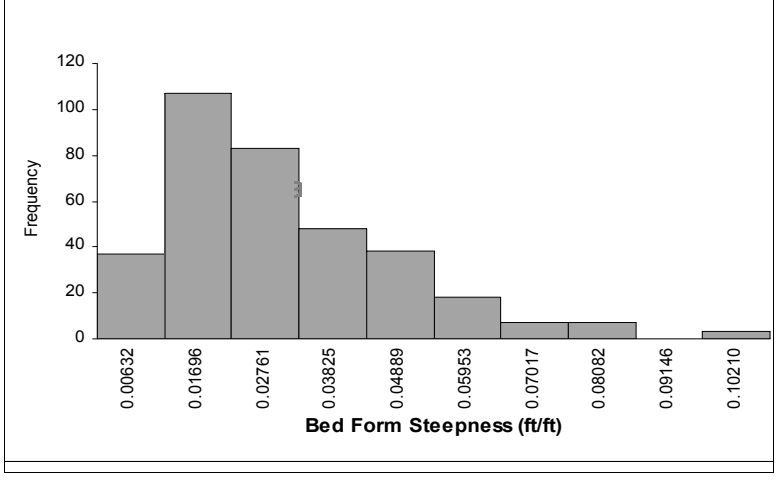

Figure 11 Histogram of the bed form steepness

The histogram shapes confirm the skeweness observed in the one variable summary presented in Table 1. The histograms plots showed skeweness to the right with a single peak. For bed form wave lengths (Figure 9), the majority of the calculated wave lengths are in the 250 -500ft range, while for bed form height (Figure 10), the majority of the values are in the range of 6 - 8 ft; the steepness was in the range of 0.01 to 0.03.

FLOW- RESISTANCE RELATION

The bed form statistical geometry findings presented above were then correlated with some hydrodynamic features that resulted from an undergoing hydrodynamic modeling study of the Lower Mississippi River described in Meselhe et al (2005). This process is ongoing; however, a sample of the preliminary results is presented here.

Hydrodynamic model results for the period between June 2003 and August 2003 (same period when the multibeam data were collected) were obtained from a calibrated one-dimensional model for the Lower Mississippi River, the model extends from Tarbert Landing RM 306, MS to the Head of Passes RM Zero, LA (Meselhe et al 2005). Model data that were used included: Average velocity (U), Total Average Hydraulic Radius (R_h), Energy Slope (S) values at several points along the study reach and utilized to calculate the bed form shear stress as follows:

$$\tau''_0 = \frac{1}{2}\rho C_d \frac{H_d}{\lambda} U^2 \tag{2}$$

where τ_0" is the bed form shear stress; ρ is the density; C_d is the drag coefficient = 0.25; H_d is the bed form height; λ is the bed form wave length; U is the average cross sectional velocity.

Different values for C_d have been obtained from the literature ranging from 0.21 (Smith and McLean, 1977) to 0.23 (Wilberg and Nelson, 1992) to 0.25 (Nelson and others, 1993). The value of C_d was found to have a direct effect on the shear computations.

The bed form shear velocity (u_*") was then calculated as follows:

$$u_*'' = \sqrt{\frac{\tau_0''}{\rho}} \tag{3}$$

The flow parameter ψ_{35} was then calculated as follows:

$$\psi_{35} = \frac{\rho_s - \rho}{\rho} x \frac{d_{35}}{R'_h S} \tag{4}$$

where ρ_s is the bed material density, d_{35} is the sieve size in the bed material of which 35 percent is finer (ranged from 0.2 to 0.3 mm in the studies reach with a trend to gets finer in the downstream direction), and plotted versus U/ u_*" as shown in Figure 12.

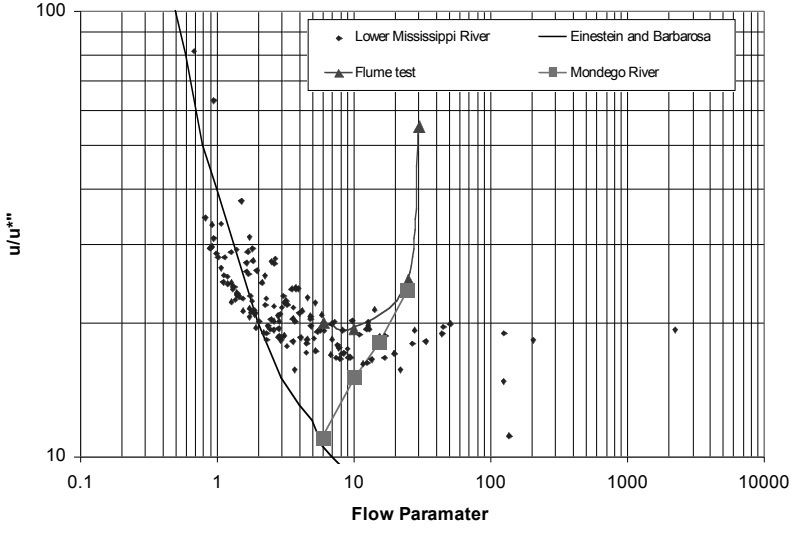

Figure 12 Preliminary Bed Form Resistance versus flow parameter for the Lower Mississippi River

The results shown in Figure 12 follow the general trend established by Einstein and Barbarossa (1952); however the data in the lower section of the plot are in better agreement with a curve based on later flume tests by Einstein and another curve for the Mondego River in Portugal by Cunha (1967). However both of these experiments included coarser sand (coarser than 0.6 mm) than that in this study (0.2 to 0.3 mm).

Previous research on bed forms was primarily laboratory studies or small scale field investigations. This study extends the range of bed form dimensions beyond those that have been considered in the current literature. Future analysis and ongoing acquisition of more detailed sediment size distribution of the Lower Mississippi River will help improve the accuracy of Figure 12.

SUMMARY AND CONCLUSIONS

Spectral analysis process was performed to 31 Multibeam datasets covering approximately 234 miles of the Lower Mississippi River for the purpose of quantifying the periodicity of bed form geometry in the river. The spectral results indicated that the dominant wave lengths varied from 50 to 500 ft at the downstream part of the study reach and 250 to 1000 ft in the upper part of the study reach. Similarly the bed forms heights increased in the upstream direction from 1 – 7 ft to 4 -15 ft. These changes were consistent with an increase in the bed shear stress in the upstream direction. Statistical characterization of the results was also performed for the purpose of testing the variability in the data. Results from histogram plots and

spatial series plots indicated the existence of wide variability in the data and the existence of a strong right skeweness phenomenon in the data.

Preliminary correlations between the resulted bed form geometry and some hydrodynamic features of the river were also performed. The results show a distinct relation between the bed form resistance and the flow characteristics. The wide range of bed form dimensions presented in this study produced a wider range of bed form resistance than has been previously included in the published literature.

All the analysis presented in this study was based on data extracted from a large alluvial river (Lower Mississippi River), with a very low energy gradient (less than 0.002 %), covered with a fine sediment bed (0.2 – 0.3 mm) and carrying a wash load in the range of 100-200 mg/L and should not be generalized to different natural river systems.

There has been much theoretical research and applications of bed form mechanics. Bed forms are primary contributors to resistance in alluvial rivers; their varying dimensions and migration from one regime to another (e.g., flat to dune to antidune) produce continuing change in the energy gradient. The work presented in this study was aimed at developing resistance relationships based on field data and computational procedures. Ultimately this research is intended to provide a better representation of flow resistance in hydrodynamic and sediment transport modeling codes.

Abstract: Laboratory experiments were conducted in a large wave flume to study the effects transient wave conditions on ripple geometry. Two primary experiments of nine hours each were performed in which the order of two wave conditions (4m and 6m waves) was altered. Bed measurements over the region were acquired using acoustic equipment, and results of ripple equilibrium characteristics were compared.

INTRODUCTION

Sand ripples play a vital role in a variety of coastal engineering topics such as bottom boundary layer flow, sediment transport, friction factor estimates for wave attenuation, and, a relatively new area, acoustic interaction with sonar signals. It is no wonder, that ripples have long held the interest of numerous researchers worldwide, throughout the years. A great amount of investigation has been conducted on the mechanism of ripple formation and equilibrium ripple characteristics under constant oscillatory flow conditions. Studies have lead to numerous equilibrium ripple predictors under constant forcing with the current most widely accepted by Wiberg and Harris (1994). However, in coastal environments, flow conditions seldom remain constant. Therefore, it becomes critical to investigate the resulting ripple geometries under these transient conditions. Only recently have laboratory studies begun to focus on this area. However, most experiments utilized small oscillatory sediment trays (i.e. Smith and Sleath 2005) or oscillatory flow tunnels (i.e Doucette and O'Donoghue 2006) in which many researchers

always tend to question the validity of results when extrapolating towards ripples generated in the field environment. With this in mind, it is the aim of this study to provide results on ripple formation under transient wave conditions within a large-scale wave flume in which flow conditions are thought to be more representative of the natural coastal region, and to serve in expanding the knowledge base from other wave flumes experiments such as Faraci and Foti (2001) and Testik et al. (2005).

EXPERIMENTAL SETUP

Experiments were conducted in the large tilting wave flume (49m long x 1.83m wide x 1.20m high) located in the Ven Te Chow Hydrosystems Laboratory.

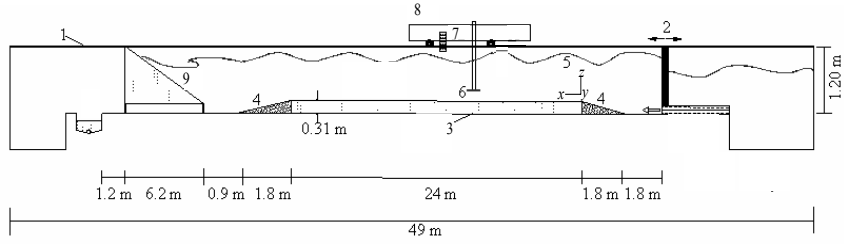

Figure 1: Schematic of Experimental Facility: 1. wave flume; 2. wavemaker paddle; 3. sand bed; 4. wooden ramp; 5. waves; 6. Seatek sensors; 7. water surface acoustic sensor; 8. movable carriage 9. beach; (Modified from Cataño 2005)

The sidewalls of the flume were composed of 1.22m (4ft) long sections of plexiglas to allow for optical visualizations and measurements, while the floor was composed of steel plating. A sand bed (approximately 30cm thick) composed of 0.25mm mean grain size diameter was located over the entire lateral span of the middle 24m of the flume. Two wooden ramps were present at either end of the bed to provide a gradual transition and retain the sand. Waves were generated in water depth of 60cm over the sand bed by a piston-type wavemaker located 3.6m from the beginning of the sand bed. Bathymetric measurements were obtained from a 32 element SeaTek sensor array (accuracy of ± 2mm in the vertical) having 4cm sensor offsets oriented about the centerline of the tank spanning the lateral dimension of the flume. A STI acoustic probe (model SU7110) was used to measure the wave amplitude at various positions along the tank (vertical accuracy of ±0.8mm). Sampling rates of the water surface probe were adjusted to ensure an integer number of waves were measured to reduce the energy leakage when performing FFT analysis on the wave data. Sensors were affixed to a wheeled frame containing an internal moveable cart controlled by linear-screw drives which allowed for the accurate positioning of the sensors over a 130cm length section, while the wheeled frame allowed for the movement/repositioning along the entire length of the tank. Wave reflection was minimized by implementing a specially modified beach composed of fibrous horse-hair matted material at a 1 on 6 slope, which resulted in approximately less than 5% reflection depending on the wave characteristics. Thus, for all practical purposes, the waves in theses experiments were considered to be progressive waves. Lastly, a Logitech 1.3 mega-pixel camera was used to provide a visual record of the ripple evolution.

EXPERIMENTAL PROCEDURE

In order to perform preliminary study on the transition of ripples under progressive waves, two exemplary experiments, experiment "A" and experiment "B", were conducted. Each experiment was run with a specified wave condition for an initial 3-hour block which was sufficient for the ripples to reach two-dimensional (2-D) quasi-equilibrium state. For the subsequent 3-hour block, the wave conditions were changed and the rippled bed was allowed to respond to the newly induced wave forcing. In order to ensure ripples had reached their ultimate 2-D quasi-equilibrium due to the second wave forcing, an additional 3-hour block was conducted. Thus, each experiment consisted of a total of nine hours composed of three 3-hour intermittent blocks, with a specific wave condition for the first 3-hours and different condition for the remaining six hours. Experiment "A" was initialized with a wave of 5.1cm amplitude and 2.63sec period for the first 3-hour block and then changed to a shorter 1.87sec wave of 5.9cm amplitude for the remaining two 3-hour blocks. Oppositely, experiment "B" was started with a 1.87sec wave then switched to the 2.63sec wave. Wave periods, *T,* of 2.63sec and 1.87sec were selected in order to achieve integer number wavelengths of 6m and 4m, respectively, with the 60cm water depth used in the experiments (based on dispersion relationship). Wave amplitudes, *a,* of 5.9cm and 5.1cm were selected to provide comparable estimates of the Shields stress parameters of 0.8 and 0.6 respectively, based on computations assuming linear water waves.

Prior to each experiment, the sand bed was smoothed and initiator ripples were created across the width of the bed at 1.22m intervals along the length of the entire sand bed, to provide uniform perturbations from which ripples can readily generate (providing the condition for incipient motion is meet) (Rosengaus 1987). The influence of tank-end effects and variations in wave conditions were minimized by studying only the middle 6m of the flume. During the initial hour of each 3-hour block, wave measurements were conducted at 0.5m intervals over the 6m span. Immediately after each 3-hour block, waves were stopped and bathymetric measured were performed at 1cm intervals along the longitudinal direction over the 6m region. Ripple wavelength and height were computed for each sensor array along the 6m region by averaging ripple crest to crest and crest to trough distances around each ripple crest, respectively. Finally, since the implementation of the SeaTek in these experiments was limited to providing a detailed three-dimensional "snapshot" of the bed at every 3-hour interval, a 1.3 mega-pixel camera was setup to view the 1064cm to 1186cm region from the wavemaker and record pictures at 2-minute intervals to qualitatively capture the transition of the sand bed, due to the change in wave forcing.

EXPERIMENTAL RESULTS & ANALYSIS

Resulting data from the experiments "A" and "B" can be seen in figures 2 and 3, respectively. In each figure, the results for the first 3-hour block are shown in the left column while the results for the subsequent 3-hour block are presented in the right column of the figure. Subplots 1a) and 1b) in each figure depict the resolved first and second harmonic water wave amplitudes which were present over the test region for that 3-hour duration. Based on the first harmonics, reflection coefficients were computed to

be about 4.5% (essentially progressive waves, as previously mentioned). However, it is important to note that the long scale variation in the second harmonic amplitudes are due to the presence of a free second harmonic in the tank as discussed in Madsen (1971).

Subplots 2(a&b) and 3(a&b) illustrate the ensemble of the ripple wavelengths and heights from each SeaTek sensor array along the 6m region, respectively. Due to minor small scale variations in the rippled bed, there exists some scatter in the results; however the dominant characteristics can be seen. After the initial 3-hours, both experiment "A" and "B" exhibited variations in the ripple wavelength which where out of phase with the first harmonic of the water wave which is as expected from wave theory. One would anticipate a similar trend in the ripple heights; however the data appears too scattered to distinguish an unmistakable coherent pattern.

In the subsequent 3-hour block (3 to 6 hours) the newly imposed wave forcing clearly resulted in modified ripple wavelengths and heights. In the case of experiment "A", ripple wavelengths decreased (on average) from ~10.5cm to ~8cm, while ripple heights experienced a slighter decrease from ~1.75cm to ~1.25cm. Experiment "B" resulted in a similar change with ripple wavelengths and heights increasing from ~8cm to ~10.5cm and ~1.25cm to ~1.75cm, respectively. As a result of the transition, data scatter is increased, which is to be expected as the bed evolves from a previously rippled state to a new equilibrium state. However, despite the scatter, the prevalent results of the subsequent 3-hour blocks of one experiment are consistent with the initial 3-hour block results of the other experiment. Thus, it seems that despite the bed being previously rippled, 3 hours seems to be an adequate amount of time for the bed to display dominant ripple characteristics of that wave forcing. It should be noted that experiment data agreed well with the current ripple predictor by Wiberg and Harris (1994). Extending the experiments an additional 3 hours (6 to 9 hours) resulted in similar ripple characteristics to that of the previous time block (3 to 6 hours).

Results from the camera were utilized to achieve greater qualitative temporal resolution of the bed transition. Select camera images can be seen in figure 4. Within the first 3 hours of the experiments the bed resulted in nice uniform 2-D ripples. After approximately 40 minutes into the new waves conditions (time=3:40), experiment "A" (having the 1.87sec waves) had exhibited a rapid response in ripple lengths nearly approaching the new equilibrium ripple length. Since the water wavelength in experiment "B" was increased, the bed underwent a more gradual transition in which existing ripple lengths slowly increased toward new equilibrium, instead of the more abrupt change of new ripple forming between existing ripples as predominate in experiment "A". By the 6hr and 9hr marks, the bed appeared to lack the 2-D uniformity as was present at the initial 3hr time of the experiments. However, the newly resulting bed was two-dimensional enough to exhibit the general associated ripple equilibrium characteristics.

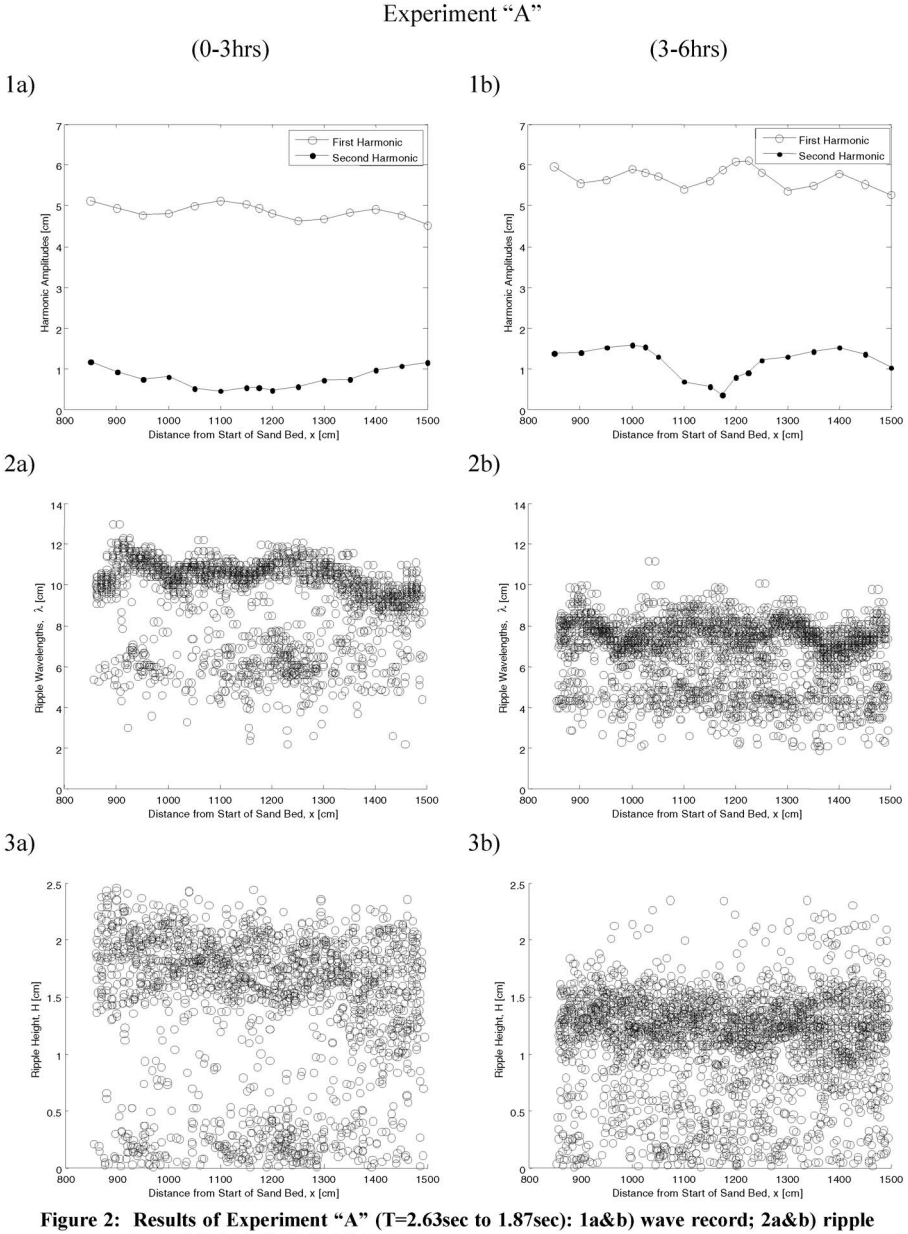

Figure 2: Results of Experiment "A" (T=2.63sec to 1.87sec): 1a&b) wave record; 2a&b) ripple wavelengths; and 3a&b) ripple height.

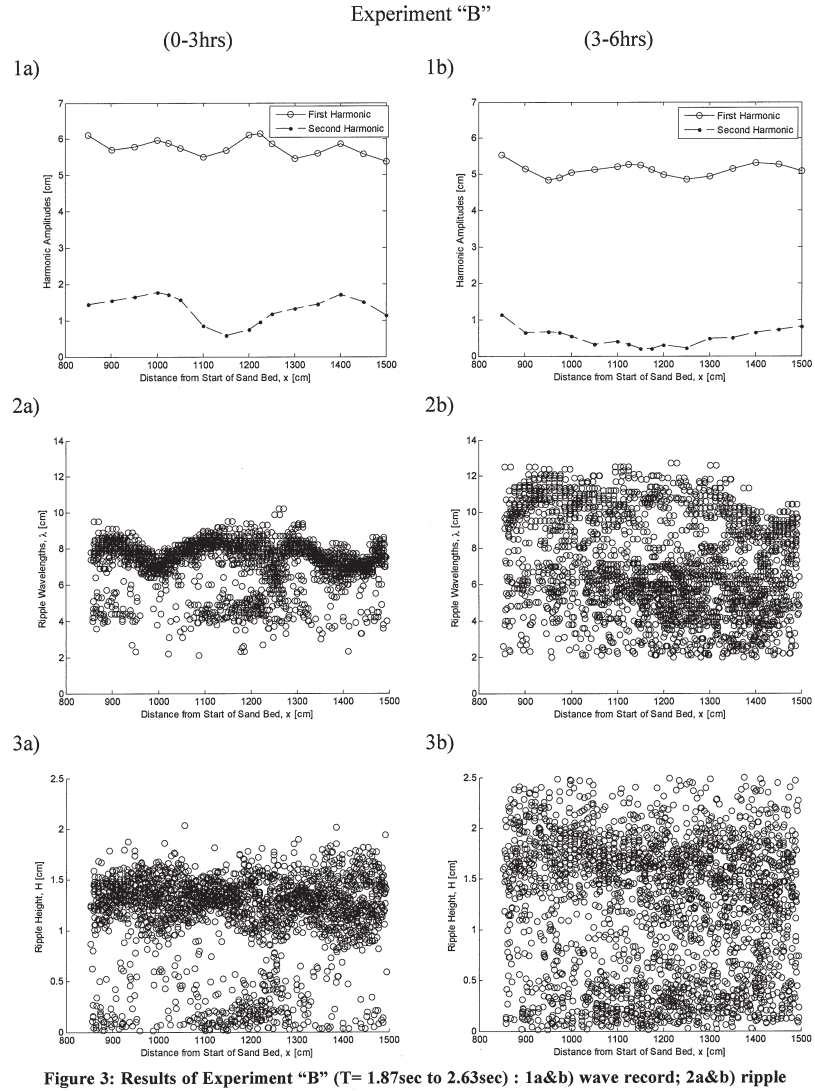

Figure 3: Results of Experiment "B" (T= 1.87sec to 2.63sec) : 1a&b) wave record; 2a&b) ripple wavelengths; and 3a&b) ripple height..

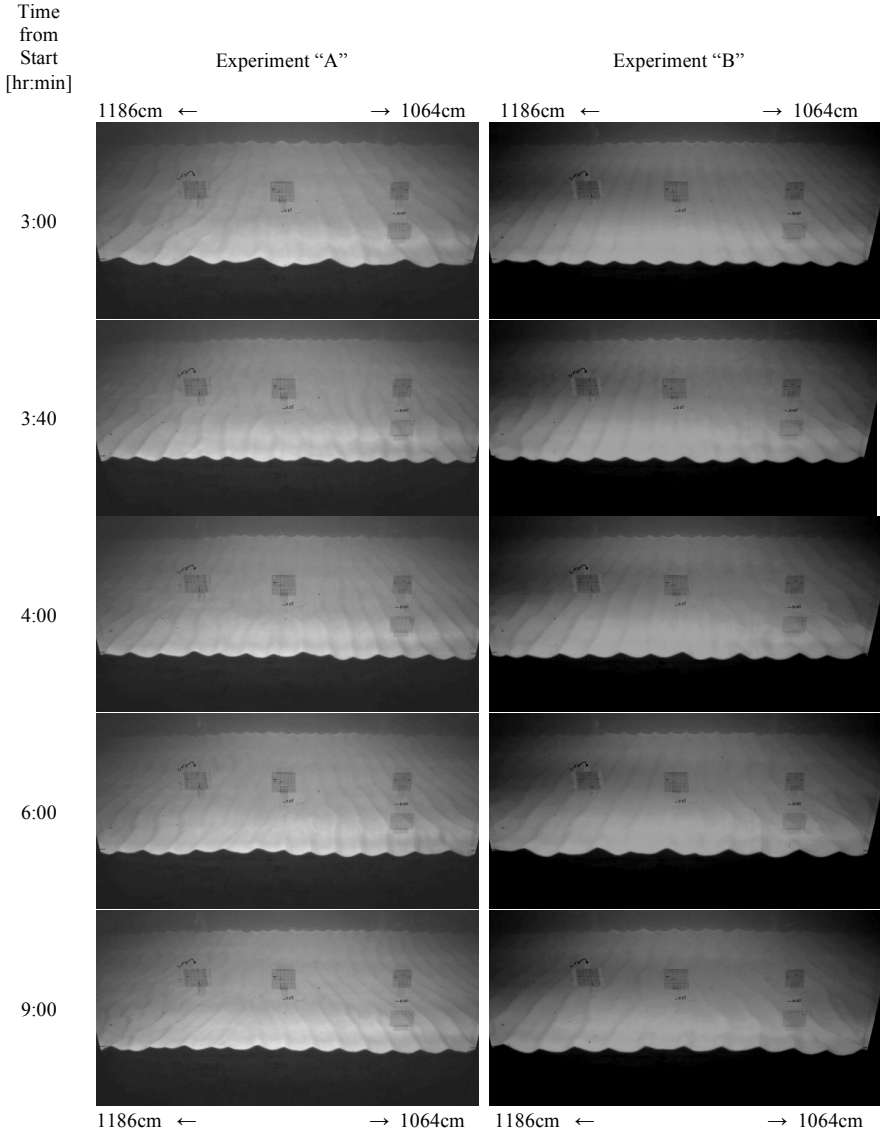

Figure 4: Sample results from the camera positioned over 1064cm to 1186cm from start of sand bed. (note: hr – hours and min – minutes)

CONCLUSIONS

The ripple measurements presented herein show that ripples under transient wave conditions achieve the ripple equilibrium for that specified wave condition provided there is adequate forcing time. For the wave conditions used in this study, 3 hours was ample time to reach the equilibrium conditions from an initially flat bed (with initiator ripples). The subsequent 3-hour block under the new wave forcing resulted in a sand bed which was not entirely uniformly 2-D; however dominant ripple equilibrium characteristics were apparent. The slight variations in 2-D ripples persisted even after an additional 3 hours.

FUTURE WORK

Future research will involve canceling the second harmonic using the method discussed by Madsen (1971). In order to allow total control of the waves, the wavemaker will be controlled via a personal computer rather than the current built-in function generator. Also, the internal screw drive on cart will be automated to allow the SeaTek to rapidly scan the bed, enabling additional three-dimensional scans at much shorter time intervals.

ACKNOWLEDGEMENTS

The authors wish to thank the US Office of Naval Research for financial support under Grant N00014-05-1-0083. Also, we wish to thank Francisco Pedocchi and other laboratory researchers for many valuable discussions. Finally, we would like to acknowledge Brett Zitny for his help with our laboratory experiments.

Abstract: Complex empirical orthogonal function (CEOF) analysis is applied to investigate the medium-term morphologic evolution of the ebb shoal at Sebastian Inlet, using a high resolution decadal dataset of hydrographic surveys. Results indicate that most of the variance (98.2%) is found in the first complex function (SM-1) interpreted as the average bathymetry, showing no significant time-dependent fluctuation. The second function (SM-2) accounts for 0.8% of the total variance and is dominated by a cross-shore transfer between the shoreward and leeward flanks of the shoal, as well as deposition from the ebb-jet and natural bypassing around the shoal. The temporal dependence (TM-2) showed large random changes that may correspond to bypassing activities in the inlet vicinity. The CEOF technique is successful in reproducing propagating sedimentation patterns not recognized by regular EOF, such as bypassing around the leeward flanks of the shoal, and cross-shore transfer around the terminal lobe and availability for bypassing.

INTRODUCTION

The long-term prediction of sediment transport and inlet/beach morphological changes is a difficult task since there is insufficient knowledge of the governing processes and how these processes are described in equation form (Larson *et al.*, 2003). Coupled with this limitation are nonlinear processes found within coastal systems that create chaotic behavior and restrict the effectiveness of physically based models. The alternative is modeling based directly on analysis of the sampled data for a particular study area such that one might capture the essential properties of beach morphology in time and space. The strength of data-based models is the replication of morphologic behavior without requiring insights into the physical processes. Although this causes concern when applying a model to different study areas, this can be alleviated by continuing efforts to link data-analysis results with knowledge of physical forcing (Larson *et al*., 2003).

As a first step toward data-based modeling, the application of principal components analysis (PCA) is utilized whereby the data are examined to identify and quantify (1) dominant patterns as they evolve in time and space and (2) how these patterns relate to one another. The added benefit of PCA in reducing large data sets to a few basic patterns is the ability to separate the signal (long-term morphological processes) from the noise (smaller scale processes and inaccuracies in measurement) within the data.

One particular form of PCA is Empirical Orthogonal Function (EOF) analysis, which projects the observed data onto a set of shape functions (the spatial EOFs) that are derived from the data itself. These functions are empirical in that they are defined by the covariant nature of the measured, long-term data set. They are orthogonal in that no two functions describe the same variance. The limitation of traditional EOF analysis to detect standing oscillations only, makes it difficult to accurately represent patterns that propagate with time. In order to determine characteristics of wave-like motions within the data (e.g. wavelength and wave speed of bedforms), complex EOF (CEOF) analysis must be performed where the phase information is retained for comparison to the amplitude. A few studies to date have been performed that employ CEOF analysis. Since CEOF captures both amplitude and phase information, the analysis performed by Liang and Seymour (1991) on nearshore bathymetric data efficiently described the fast moving sand wave and other propagating features in their study area.

Sebastian Inlet (Figure 1) is well documented in terms of wave climate and morphologic evolution. Hydrographic surveys of the inlet system and surrounding beaches were conducted on a semiannual basis since 1991. Although the data coverage (Figure 1) includes the entire inlet system (ebb shoal, throat, sand trap and flood shoal), and the adjacent beaches to the north and to the south, the present study focuses only on the ebb shoal complex. Volumetric analysis of the ebb shoal by Zarillo, *et al.* (2003) have shown that the inlet is in state of quasi-equilibrium, with impoundment of sand on the north beaches and the ebb shoal and a sand deficit on the beach immediately to the south of the inlet

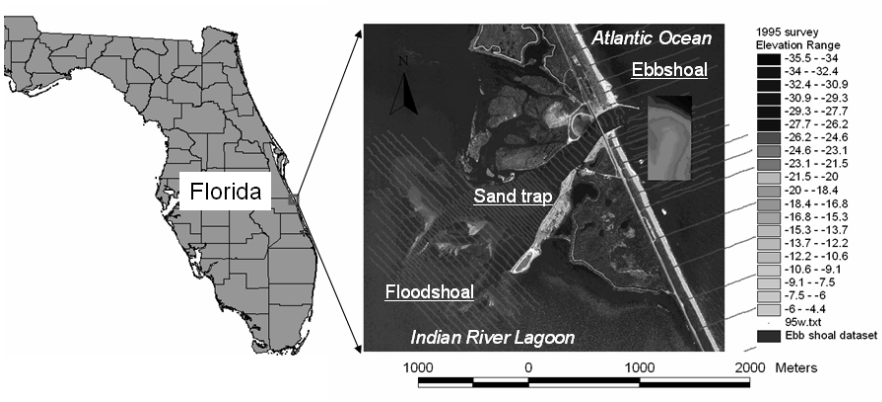

Figure 1 Study area. A TIN created from a mask to delineate the ebb shoal and generate different elevations on the grid from data (xyz) imported into ArcView® GIS.

Management strategies for sand budgets have included dredging, bypassing from an interior sand trap at the edge of inlet channel, and beach nourishment on the downdrift beaches. Net longshore sediment transport rates are directed southerly and estimates range from 120,000 to 230,000 m^3 per year (Dombrowski, 1993). This is mostly due to Northeasters occurring in the winter months creating strong southerly drifts, whereas tropical systems from the south tend to reverse longshore sediment transport to the north. In recent years, due fewer winter extratropical storms, the net drift has been from south to north therefore reducing the rate of ebb shoal growth and enhancing accretion of the south fillet. A previous study of inlet morphodynamics conducted by Goshow (2000) using regular EOF analysis determined standing sedimentation patterns and suggested a relationship with wave climate and engineering activities in the inlet vicinity.

The present study is the first attempt to apply CEOF analysis at a stabilized inlet to investigate ebb shoal morphodynamics and gain insight into the natural bypassing mechanisms. The study aimed at 1) identifying the main sedimentation patterns represented by each complex eigenmode, 2) determining possible seasonal variation in the patterns, and 3) evaluating the use of the complex EOF technique versus regular EOF technique in capturing the propagating sedimentation patterns of a very dynamic morphologic feature.

COMPLEX EMPIRICAL ORTHOGONAL FUNCTIONS

Preprocessing of data for CEOF analysis begins with obtaining a complex time series after applying a Hilbert transform on the scalar variable of interest. This approach, described in Equation (1), allows the amplitudes obtained to remain unchanged and extract information about the temporal phase of each component. In other words, the real part of this new complex time series retains the original data array information $z(x,t)$ whereas the imaginary part $\tilde{z}(x,t)$ (described as the Hilbert transform of the

original data set) provides the corresponding temporal phase information within the set.

$$Z(x,t) = z(x,t) + i\tilde{z}(x,t) \qquad (1)$$

The next step in the preprocessing of data for the CEOF method is to compute the complex covariance matrix of the newly formed complex bathymetry data set. Normally, the equation form of this step can be written as:

$$C = \frac{1}{N_x N_t} \sum_{n=1}^{N_x} Z_{jn}^* Z_{kn} \qquad (2)$$

That is, Equation (2) expresses the covariance relationship between the complex bathymetry matrix and its complex conjugate for the j^{th} and k^{th} terms for the total of surveyed points N_x and the surveyed times N_t.

It is from the complex covariance matrix (C) that the eigenfunctions (eigenvectors (ϕ_n) and eigenvalues (λ_n)) are determined. Since the complex covariance matrix (C) is Hermitian combining the eigenvalues and the trace of the matrix will provide a direct measure of the variance (σ_n^2) that is comprised in each function (or mode) according to:

$$\sigma_n^2 = \frac{\lambda_n}{T_r(C)} \qquad (3)$$

The determination of the variance allows to establish which are the principal eigenfunctions that can be used to reduce (or compress) the information in the original data into fewer modes. Usually, most of the variance is expressed in three or five modes and therefore considered sufficient to reconstruct the original data. In this study only the first four modes are of interest.

Different approaches in the reconstruction of data from the CEOF modes exist and result from variations in the weights used in the computation of the complex empirical orthogonal functions. Although more rigorous approaches to the determination of the temporal and spatial weights exist the technique employed here yields similar results in a mathematically simpler and straightforward method.

The temporal modes (φ_n) are obtained from an equation of the form:

$$\varphi_n = \tilde{z}(x,t) - \bar{\tilde{z}}_x(x,t) \qquad (4)$$

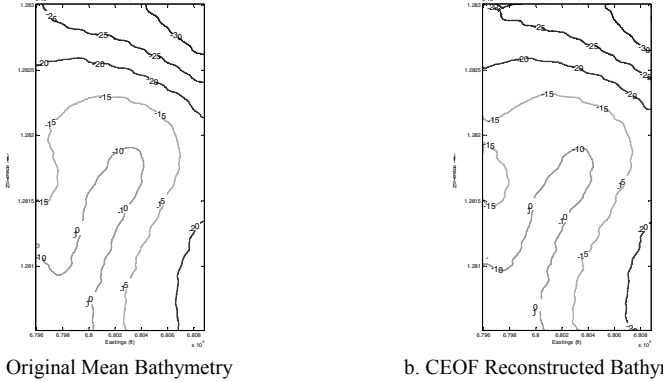
The complex empirical orthogonal functions that describe the general shape of the data variability are termed spatial modes. To obtain these spatial modes (A_n),

$$A_n = \varphi_n \times \phi_n \qquad (5)$$

Usually, the first spatial mode describes the mean bathymetry featured in the data, the second and subsequent spatial modes describe the changes that occur to the mean bathymetry during the time span of the data series.

In order to have a better understanding of the magnitude in which the spatial and temporal modes affect the interpretation, scaling is performed on each of the temporal

and the spatial components. When using a covariance matrix, as was done in this analysis, every temporal function is scaled by the average of its absolute values. For the spatial functions, each is normalized by multiplying its temporal scale factor. With this procedure, every spatial function is then considered to represent average change (Goshow, 2000).



When reconstructing the bathymetry data from the selected principal modes, only the real part can be considered and it can be expressed in the form:

$$z(x,t) = \left[\sum_{n} real\left\{ A_n(x) \cdot \phi_n(t)' \right\} \right] + real\left\{ \overline{\tilde{z}}_x(x,t) \right\} \quad (6)$$

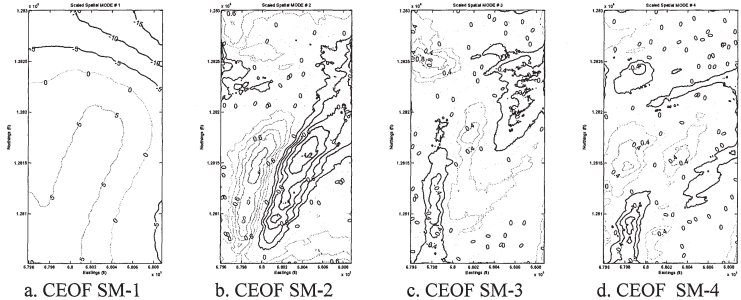
As previously discussed, the advantage of EOF and CEOF analysis is that most all of the variance is described by the first few modes allowing for data reduction. It is the analysis of these first few spatial modes that provides insight about the behavior of the physical processes captured within the data sets. When combined with the information described by the temporal weights (*i.e.* the temporal modes), a better understanding of the evolution of the bathymetric features can be obtained and their connection to natural and anthropogenic effects can be facilitated.

MEAN AND RECONSTRUCTED BATHYMETRIES

The mean bathymetry of the entire time series is shown in Figure 2-a. The bathymetry contours range from z = -10ft. at the top of the bypass bar (shallow region) to approximately z = -18ft. at the outer edge of the bar. There is a sharp drop in the elevation (z = -28ft.) to the NE of the bypass bar. The orientation of the bypass bar is clearly shown as being 45^{o} to the shoreline and attaches to the downdrift beach as an attachment bar (SW corner of Figure 2-a).

a. Original Mean Bathymetry b. CEOF Reconstructed Bathymetry

Figure 2. The mean bathymetry values of the original data set (a) and reconstructed bathymetry (b). Units are in feet for depth values and coordinates (Eastings and Northings).



As shown in Table 1, CEOF analysis on the morphological evolution of the bypass bar reveals that most of the variance is comprised into mode 1 (98.2%) which

represents the mean bathymetry. The subsequent modes reflect the other dynamic variations within the data and are interpreted according to the physical processes of the particular study area. In order to reconstruct the original data of any time series, the inclusion of at least the four most dominant modes is considered standard practice. The inclusion of these four modes represents 99.4% of the total variance.

Table 1. Percentage of variance represented by each mode.

MODE #	% of Total Variance	MODE #	% of Total Variance
1	98.153	11	0.032176
2	0.80106	12	0.026667
3	0.27903	13	0.021687
4	0.17225	14	0.020218
5	0.12497	15	0.016627
6	0.10314	16	0.013964
7	0.066099	17	0.011502
8	0.053469	18	0.010531
9	0.044016	19	0.0088727

In order to interpret the results correctly, values associated with the first complex eigenmode were directly added to the corresponding mean bathymetry in that year, whereas for higher eigenmodes these values were subtracted from the mean bathymetry. This allows for a more realistic description of the dynamics occurring at the study area. Thus, notice that in Figures 3-b to 3-d and Figure 4 lighter gray contour lines indicate erosion patterns, whereas darker gray contour lines correspond to accretion patterns.

a. CEOF SM-1 b. CEOF SM-2 c. CEOF SM-3 d. CEOF SM-4

Figure 3. CEOF Spatial Modes 1-4. Gray indicate positive values (erosion); Black indicate negative values (deposition) except for SM-1 where the sign indicates deviations from the mean.

First Complex Eigenmode

The 10:1 ratio in scaling of spatial mode 1 (SM-1) versus the other three modes (Figure 3-a) reflects the predominance of the pseudo-mean bathymetry of the bypass bar. It is termed "pseudo-" because it is a result of the CEOF analysis and is called "-

mean" because the contours resemble the original data. Further, the variability in the first temporal mode shows no time-dependent fluctuation (Figure 4-a), which is in agreement with the minimal time-dependence characteristics of the mean-beach function. The temporal mode 1 (TM-1) showed an increasing trend until 1995, then decreased until late 1998, and increased again until 2000. This is in agreement with the phase shifts observed in late 1994 and late 1998. Positive jumps in the amplitude were observed in 1993, 1994, 1997 and 1999 and may correspond to sand inputs from mechanical bypassing projects. The amplitude and phase curves follow the same trend over the time period.

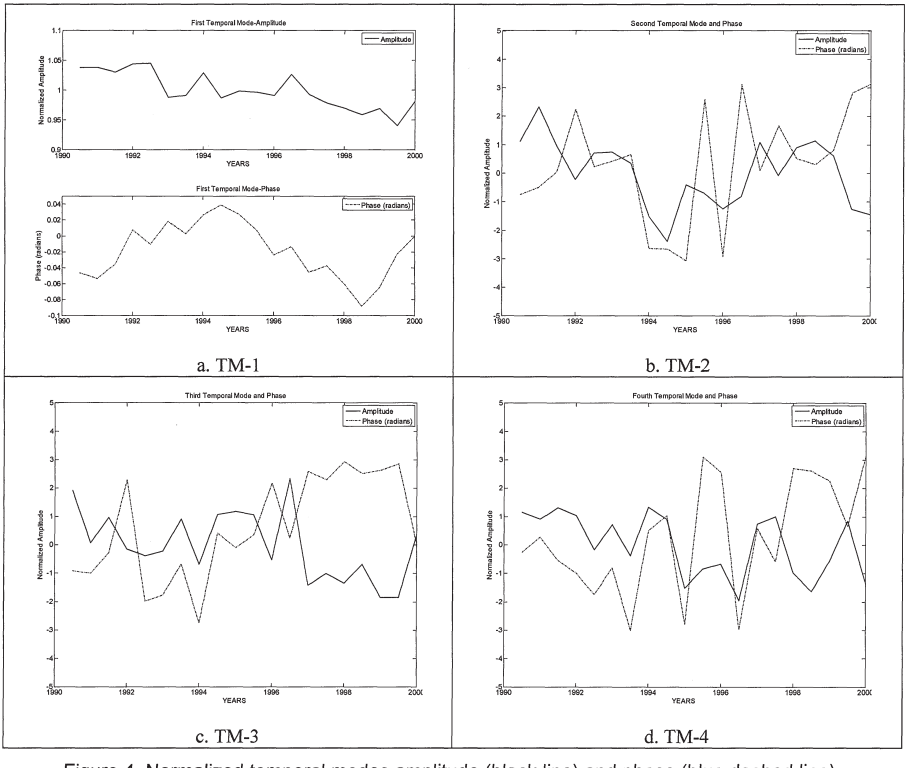


Figure 4. Normalized temporal modes amplitude (black line) and phase (blue dashed line).

Second Complex Eigenmode

Contour results for the second spatial function (SM-2) are presented in Figure 3-b. A significant cross-shore exchange of sediment is observed between the leeward and shoreward edge of the shoal. Maximum values of positive contours reach 0.6 ft, whereas negative contours attain values of -1.2 feet. Negative contours represent the tendency to decrease in depth therefore representing deposition. Further, the patterns

of the negative contours were found to extend much more to the Northeast of the study site, following the bathymetric contours. This would suggest an input from natural bypassing and a longshore component in the dominant patterns as well. Even though the majority of changes occur in the southern part of the domain, a smaller area with deposition pattern (negative contours) is observed in the NW corner of the contour plot, with values around -0.5 ft. This area corresponds to the terminal lobe of the ebb shoal, at the edge of the ebb jet.

To further investigate the evolution of the sedimentation patterns and the propagation of geomorphic features of the ebb shoal, a sequential representation of the fluctuating second, third and fourth complex eigenmodes is presented in Figure 5. The spatial evolution of mode 2 indicated two main patterns corresponding to a shift in the shoal's ridge position (Figure 5-a). During the first three years of the study, patterns were dominated by the erosion of the shoreward flanks of the shoal and deposition on the leeward flanks. At the same time, a deposition area was observed on the ebb shoal. From Fall/Winter 1994 to Spring/Summer 1997, a shift in the patterns was observed, with accretion on the shoreward flanks while the leeward flanks were eroding. At the same time, the deposition area from the ebb-jet was less pronounced, exhibiting no appreciable change tending to erode at a now reduced area closer to the inlet mouth. Finally, patterns were reversed again until the end of the study period. Changes in these patterns were represented by sharp reversals rather than smooth shift from erosion to accretion. To some degree, it appears as if the patterns of leeward accretion/shoreward erosion occurred right after the bypassing projects.

The second temporal mode (TM-2) of the ebb shoal presented in (Figures 4-b) showed large random changes, with no noticeable seasonal patterns. However, shorter trends within the time period consisted in a decrease in the normalized amplitude from summer 1991 to summer 1994, increasing again until 1999, toward equilibrium. A longer trend of approximately 20 months is revealed in the occurrence of consecutive positive as well as negative peak values. Although no explanation for this apparent cycle is offered, further investigation of this oscillation will be later explored. A closer look at the curves of normalized amplitude and phase revealed that they follow pretty much the same trends over the time period, with a positive peak in winter 1991 and negative peak in summer 1994. The positive jumps in TM-2 occurred subsequent to bypassing activities with a lag time of approximately a year. The noticeable peak in winter of 1991 occurs before the extreme storm season affecting the area, responsible for the subsequent decreasing trend in the amplitude. Events like the Halloween Storm of 1991, with wave heights of over 3m and periods of 20 seconds, lasted for several days later in Fall is therefore responsible for creating that major drop observable in the temporal amplitude of mode 2. The 3 year cycle was found to last until 1994 and was related to an active season for storms. The same area was nourished in 1992-93, but with half the volume and is associated with the peak at this time being less pronounced (Figure 4-b). Another major peak in the temporal variability of mode 2 occurred during the 1998-99 mechanical bypass project.

Third Complex Eigenmode

As indicated by Table 1, the third complex eigenfunction accounts for 0.27 % of the total variance, which is about three times less than the second eigenfunction. Spatial pattern fluctuations for the third complex eigenmode (SM-3) are shown in Figure 5-c. Unlike the SM-2, cross-shore patterns for SM-3 in the southwest part of the area were found to be reversed. Negative contours corresponding to sand deposition were identified on the shoreward flank of the shoal and positive (erosion) on the leeward flank. The linear shape of the contours was interpreted to describe a pattern of seasonal bar migration. In addition, the deposition area to the northwest corner of the domain previously identified for the SM-2 as a deposition zone, it is now related to erosion patterns for the SM-3.

Deposition was also observed farther offshore on the terminal lobe, suggesting a cross-shore exchange between the ebb shoal and terminal lobe. The spatial propagation patterns recognized in the third eigenmode showed a linked trend between the terminal lobe in northeast part of shoal to the shoreward flanks to the southwest, as well as a link between the leeward flank (southeast part) and the ebb shoal (northwest part), suggesting a complex transverse sediment flux involving several morphologic features.

The response of the third temporal eigenmode (TM-3) presented in Figure 4-c was found to exhibit a slightly decreasing trend over the time period, as well as an increased seasonality in the signal. Positive jumps in the normalized amplitude were observed mostly in summer; this is further discussed in the seasonal variability section. A noticeable phase shift was observed in Fall/Winter 1992 dataset, as well as in Fall/Winter of 1994. The amplitude and phase curves follow the same trends, with a slight phase lag until 1995 and then become out of phase, especially from 1996 to 2000.

Fourth Complex Eigenmode

The fourth complex eigenmode accounted for less than 0.2% of the total variance and the spatial patterns are represented in Figure 3-d. Patterns consisted of patches of deposition/erosion on the shoreward flanks of the shoal, as well as deposition around the outer area. There appears to be scouring at the edge of the main ebb channel from the ebb jet and at the reef rock outcrops (black, Figure 5-d). Again, cross-shore fluxes along the banks of the bypass bar are evident in the fourth spatial eigenmode (SM-4). A noticeable erosion area is located in the middle of the shoreward flank of the shoal. The temporal function (TM-4, in Figure 4-d) continues to emphasize the seasonality of the changes as discussed for mode 3. Clearly, these more variable patterns (mode 3 and 4) were associated with summer and winter changes in the physical forcing and seasonal comparison in the spatial patterns was performed between these modes to recognize any characteristics pattern of each season.

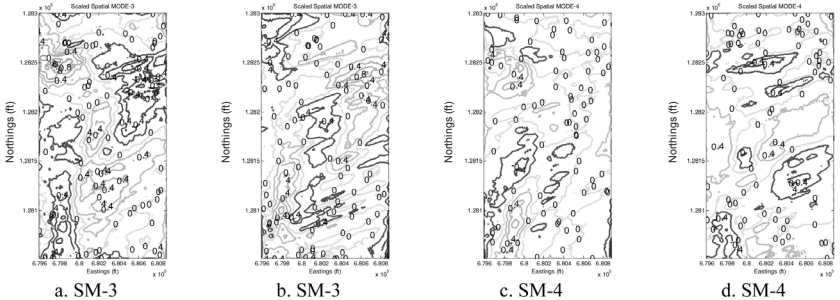

Figure 5. Spatial Modes 2 to 4. Lighter grays indicate positive values (accretion). Dark grays to black indicate negative values (erosion). White indicates zero change.

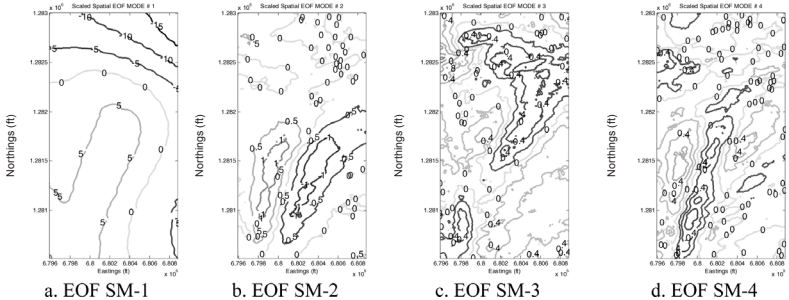
Seasonal variations in spatial eigenmodes

The CEOF analysis was performed on Spring/Summer and Fall/Winter data sets independently and contour plots for the third and fourth mode are presented in Figure 6. The two first modes are not shown since no significant seasonal differences in the



patterns were observed. However, significant changes in patterns were observed in the third and fourth modes, especially reversals in cross shore shoal motion. For the spatial mode 3 (SM-3 in Figure 6-a and 6-d), extended deposition along the shoreward flanks of the shoal (Figure 6-a southwest region) was observed during the Spring/Summer months whereas the opposite occurred during the Fall/Winter, including deposition on leeward side of the shoal. The deposition basin which corresponds to the other significant exchange feature is located father off the inlet mouth in Spring/Summer.

a. SM-3 Spring/Summer | b. SM-3 Fall/Winter | c. SM-4 Spring/Summer | d. SM-4 Fall/Winter

Figure 6. Spatial Modes for Spring/Summer (a, c) and Fall/Winter (b, d). Lighter grays indicate erosion; Darker grays indicate deposition.

This last observation could be related to seasonal differences in wave climate. Winter months are usually dominated by Nor'easters, and more deposition could be expected toward the inlet mouth and channel since sediment is being pushed by waves into that region. In summer, gentler wave climate and fewer high energy events occur so that the ebb jet extends the shoals farther offshore on to the terminal edge so that sand is available for bypassing to the south beaches in winter. The sand bar formation in the

Figure 7. Spatial Modes from regular EOF analysis. Grays are positive values (erosion); dark grays to black are negative values (deposition).

third eigenmode, in the south-west part of the area was located shoreward and had a very linear shape. However, patterns for Fall/Winter indicated a more discontinuous bar, located farther offshore and characterized by significant erosion towards the shoreward flanks of the bar as indicated by the light grey contour lines.

In addition to the CEOF analysis, regular EOF was performed on the same data sets for comparison of resulting patterns (Figure 7). Differences were notable in each of the higher order modes (SM-2, SM-3, and SM-4). For the second eigenmode (SM-2), the main difference is in the shape of the negative contours. It also seems that the second and fourth regular EOF modes (EOF SM-2 and SM-4) are described by the second complex eigenmode (CEOF SM-2), indicating that regular EOF is not as effective as CEOF in separating higher order modes. The elongated form of the pattern was not fully described by the regular EOF technique. Under Complex EOF analysis, sediment bypassing is more evident and clearly reproduced whereas the regular EOF technique did not fully recognized the propagating pattern.

SUMMARY AND DISCUSSION

The ebb shoal at Sebastian Inlet has a complex bathymetry, and the area experiences complex waves refraction patterns that create unique sedimentation patterns. In addition, these complex wave interactions may create localized reversals in the drift direction, meaning that under storm conditions (Northeasters) sediment pathways would be to the north, filling in the South fillet and inlet channel.

Several reversals in the patterns were observed in the second eigenmode (SM-2), and northward transport and channel infilling and impoundment of the south jetty seemed to occur when the shoreward flanks of the shoal are accreting. This very dynamic area often experiences a return of the longshore current that has been interrupted by jetties, wave induced currents, and by the rip currents that are enhanced by the reef outcrops. The predominance of the cross ridge exchange on ebb shoal morphodynamics suggested by Mode 2 may also be related to wave breaking and induced currents, suggesting that the bypass bar shares the morphodynamic characteristics of a shoreface rather than a shoal. The elongated shape of the deposition patterns of the second eigenmode (SM-2) also suggested the natural bypassing mechanisms and sand transfer from updrift to downdrift beaches, as well as from the swash bars and terminal lobe (from ebb-jet) to the bypassing and attachment bars. The deposition area at the mouth of the inlet is located farther offshore in Spring/Summer, which is consistent with the gentler wave climate in summer and dominance of ebb-jet sedimentation pattern rather than wave reshaping. This observation agrees with previous studies on natural bypassing at inlets which found that under normal or non-storm conditions, sand in the channel was moved in a net seaward direction and deposited on the terminal lobe (FitzGerald et al., 2000). The deposition area observed in Mode 2 at the end of the inlet mouth corresponds to the deposition basin of the ebb shoal, where sand is being deposited and available for being moved toward the terminal lobe and bypassed. This includes sediment being transferred directly from the updrift beach to the ebb shoal/bypass bar complex and from the main ebb channel.

The observation of the spatial evolution in the second and third eigenmodes also indicated that an important transfer mechanism was occurring between the ebb shoal deposition basin at the edge of the main ebb channel and the terminal lobe. The longshore influence is not evident and appears more clearly in Modes 3 and 4. The third and higher modes were associated with increased variability (chaos) of the area. Spatially this was represented by alternating patterns of accretion/erosion along the shoreward flanks of the shoal. The formation of a consequent sand bar suggested by the third eigenmode (SM-3) may be interpreted as the classic mean bar function. The bar was found to be more linear bar and located more shoreward in summer compared to a discontinuous bar located farther offshore in winter. This resembles the seasonal bar formation and beach profile evolution along the seasons.

CONCLUSIONS AND RECOMMENDATIONS

The morphologic evolution of the ebb shoal at Sebastian Inlet was analyzed using Complex EOF technique, from 1990 to 2000. The technique successfully identified the dominant sedimentation patterns and bypassing mechanisms occurring on the ebb shoal of a stabilized inlet. Patterns recognized by the second complex eigenmode included a cross-ridge sand transfer between the leeward and shoreward flanks of the shoal, deposition along the bypass bar and on the ebb shoal at the end of the main ebb channel. Reversals in the patterns were observed and temporal patterns indicated that the morphologic evolution of the shoal is a function of bypassing activities and irregular forcing mechanisms such as the number and intensity of storms, as well as changes in the drift direction. The third complex eigenmode represented the sand bar position and shape in the southwest area, as well as deposition on the terminal lobe. The seasonal comparison for the third and fourth complex eigenmodes was primarily a function of the wave climate. The ebb shoal morphodynamics in summer were controlled by tidally driven currents of the ebb-jet feature whereas wave induced transport dominates in winter.

The CEOF is a powerful technique which recognized more sedimentation patterns in each mode than the regular EOF, emphasizing the bypassing component identified in the second eigenmode, the deposition on the terminal lobe. CEOF was also more effective in describing the seasonal migration pattern of the bar in SM-3, as well as the propagating behavior of the terminal lobe which was being pushed away from the inlet mouth and made available for bypassing to the south beaches.

Although, the temporal modes are useful in relating the spatial patterns to possible forcings or management activities, some of the drastic changes accompanied with opposing temporal phase trends make it difficult to properly characterize the processes acting on the study area. Therefore, care must be taken in the interpretation of the data without prior knowledge of the basic dynamics of the study area.

This type of analysis can be useful in supporting the calibration of numerical models for morphology change. That is, considering that enough data is available, shorter model runs can be completed and still “catch” all the pattern changes described in the eigenfunctions of the hydrodynamic regime.

Additional accompanying analysis techniques and further investigation are required to provide a wholistic view of the dynamics around the Sebastian Inlet ebb shoal. It is suggested that a Canonical Correlation Analysis (CCA) should be performed to complement the CEOF analysis and to detect the possible correlations between morphological changes and the wave forcings. Although CCA is a powerful analytical tool in explaining the correlation between two different sets of data, the results are often difficult to interpret because of the multiple sets of new variables generated as its product. An effort to apply CCA to the present study data will be attempted by implementing the technique to a smaller (resampled) bathymetry data set. It is expected that this approach will yield faster computational times, but information on the higher order variability will be lost. It is therefore recommended that other techniques be attempted such as 3-Way EOF or Non-Linear EOF.

ACKNOWLEDGEMENTS

The authors would like to thank the Sebastian Inlet Tax District for providing the data. In addition we acknowledge Pamela J. Christian for her feedback and Dr. Eric Thosteson for his insight on coding CEOF and for instilling the motivation to publish the findings of what started as a class project.

Abstract: Deep draft ships transiting through confined channels can significantly alter surrounding hydrodynamic conditions. The Burlington Shipping Channel is a confined channel on Lake Ontario which has experienced significant scour due to ship drawdown. A range of investigations including the development of an *SGH* model of the Burlington Channel have been undertaken to understand the processes leading to scouring near the channel walls. It is proposed the direction of ship motion is fundamental to the depth of scour observed at the entrances to the channel. The *SGH* model achieved a good level of hydrodynamic calibration and an assessment of modeled scour based on spatial variation in critical sediment size is consistent with observed scour patterns. The critical sediment diameter along the channel is an order of magnitude greater than the native bed material. In the mid-sections of the channel, scour potential is generally independent of direction of ship motion and consecutive ship movements in opposite directions appear to cause minimal net sediment transport. The development of design criteria curves for channel protection using the *SGH* model is presented.

INTRODUCTION

Deep draft ships transiting through confined, shallow water bodies can significantly alter the ambient hydrodynamic conditions. These impacts are observed through two main processes; wake and drawdown. Wake is the term given to the stern and bow waves generated by a moving ship. The waves propagate away from the ship and generally have periods of less than 10s. The character of wake waves is influenced by the vessel profile and ship speed.

Drawdown is the observed decrease in water level surrounding the ship as it moves through the channel and is primarily caused by the ship's displacement of the channel cross-section (Herbich and Schiller 1984). A feature of drawdown is the long period nature of the waveform in shallow, confined water bodies (surge wave). Although the amplitude of the surge wave may not be large, the period of this wave can be between 30 to 100 seconds. The orbital motion associated with the drawdown wave is relatively uniform through the water column and current speeds near the sea bed can be large. The surge wave generated by drawdown in confined channels is a function of ship speed, depth under the ship, drawdown height and blockage ratio (Maynord 2004). The blockage ratio is the wetted cross-section of the ship relative to the channel.

Wake and drawdown can interact with the surrounding shoreline and bed material, and shoreline erosion and bed scour due to ship movements has been observed at numerous sites.

BURLINGTON SHIPPING CHANNEL

Hamilton Harbour is a 2,150 ha protected body of water located on the western shoreline of Lake Ontario. It is located approximately 60 km southwest of Toronto and is a major industrial centre of Canada. Hamilton Harbour is the busiest Canadian Port on the Great Lakes. It handles over 700 ship passages and 12 million tonnes of cargo each year. The port is situated in a naturally enclosed basin separated from Lake Ontario by a narrow channel, the Burlington Shipping Channel. Recent studies have shown that sections of the Burlington Shipping Channel have been significantly scoured. In response, a series of data collection, engineering and numerical modeling investigations have been undertaken to investigate; the causes of scour, magnitude and spatial variation in the physical forcing causing scour and potential stabilization techniques.

Hamilton Harbour evolved with Lake Ontario during the glacial retreat approximately 9,500 to 12,500 years ago (Gilbert, 1994). Prior to 1823, a sand spit separated Hamilton Harbour and Lake Ontario with a shallow channel to the north of the present channel (O'Connor, 2002). The Burlington Shipping Channel was constructed in 1823 and is 88m wide with a design depth of approximately 9.5m to chart datum (CD). The channel is constructed with vertical sheet piles. The bed material within the channel and surrounding areas is generally a medium grain sand. Figure 1 is an aerial photo of the Burlington Channel.

A variety of different bulk carrier ships frequent Hamilton Harbor. The size of ships in the Great Lakes is limited by the capacity of the structures which facilitate vessel movement between the lakes and the Atlantic Ocean. In general, the ship specifications are relatively uniform due to the size constraints of the St Lawrence Seaway.

Fig. 1. Aerial view of the Burlington Shipping Channel

The most common ship type is the SeawayMax class which is the maximum sized vessel allowed in the St Lawrence Seaway. The maximum dimensions of ships in the St Lawrence Seaway are:-

- Length: 225.5m,
- Beam: 23.7m, and
- Draft: 8.1m.

Certain sections of the seaway can accommodate larger ships however these ships are unable to pass into the Atlantic Ocean. Depending on water levels, ships can move through some inner sections of the Great Lakes (including Hamilton Harbour) with a draft up to 9.5m.

SHIP DRAWDOWN IN CONFINED CHANNELS

Drawdown caused by deep draft ships in confined channels has been widely observed and studied. Schif (1949) developed the concept of the limiting speed in confined channels. This concept results in a self-propelled ship not being able to exceed a speed where the flow velocity (ship speed plus return flow speed under the ship) is equal to the celerity of a gravity wave.

A number of analytical methods have been developed from the initial work of Schif (1949) to estimate peak long period currents due to ship movements including PIANC (1987) and Maynord (1996). These methods have been shown to provide reasonable estimates of velocities and drawdown height away from the ship when applied to channels with simple cross-sections, for example rectangles or trapeziums. In these cases, the decay of the surge wave can be neglected. The analytical methods are unable to evaluate ship effects near channel transitions (Maynord, 2004)

In recent years, considerable efforts have been applied to develop numerical tools to investigate ship effects on spatial scale. Stockstill and Berger (1999) documented an extension of the finite element model HIVEL2D to investigate ship effects. The 2D

shallow water equations were modified to include the ship hull as a pressure source. The depth-averaged approximation can be made because the wavelength of the surge wave is in the same order of magnitude as the ship length, which is much greater than the depth in most navigation channels. The HIVEL2D drawdown model has been shown to produce good estimates of current speeds and surge wave heights in a number of studies (Stockstill and Berger 1999; Stockstill and Berger 2001; Maynord 2004).

STUDY APPROACH

A number of investigations were undertaken in 2005 and 2006 to study ship hydrodynamics and associated scour along the Burlington Shipping Channel. Those relevant to this study are briefly described below.

Site Data Collection

Bathymetric and hydrodynamic data was collected to examine the extent of scour and the physical forcing contributing to it. Figure 2 is produced from bathymetric survey conducted in May, 2005. Areas in dark blue indicate depths up to 14mCD, which is significantly greater than the design depth of the channel. The areas of scour are most pronounced across the eastern (Lake Ontario) entrance to the channel. There is also a smaller extent of scour observed surrounding the western (Hamilton Harbor) entrance and along the channel centerline.

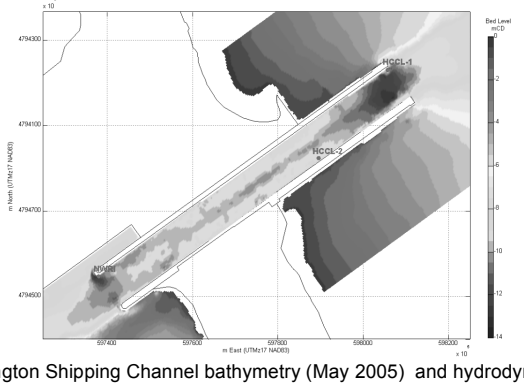

Fig. 2. Burlington Shipping Channel bathymetry (May 2005) and hydrodynamic data collection sites (scour areas are shown in dark blue).

In response to the scour observed in Figure 2, a field data collection exercise was undertaken in August to September 2005, to collect hydrodynamic data from a series of three locations in the channel during the transit of deep draft ships (HCCL, 2005). Acoustic Doppler Current Profiler (ADCP) instruments were deployed at a total of three locations for seven ship movements. The locations are indicated on Figure 2 (HCCL-1, HCCL-2 and NWRI). The ADCP instruments were configured to record currents in 0.3m bins through the water column every 0.5s. Ensembles were averaged every 5s. The dimensions (length, beam and draft) and approximate transit velocity were recorded for each ship movement.

Numerical Model Investigations – *SGH*

Following the field data and desktop engineering studies, an applied research study was undertaken to investigate the ship induced hydrodynamics and scour along the whole channel. The field data provided snapshot information on ship induced forces at particular locations. A suitability calibrated numerical model is able to investigate these forces along the whole channel.

SGH (Ship-Generated Hydrodynamics) is a sophisticated ship wake and drawdown model which is capable of efficiently investigating ship induced hydrodynamics over a large model domain with complex bathymetry. It is a 2D depth-averaged, finite difference model which can simultaneously simulate wake and drawdown processes due to deep draft ships. The motivation behind its development was the need to investigate the combined impacts of drawdown and wake along the St Lawrence River. *SGH* is a proprietary software product of Pacific International Engineering and was developed as part of the sediment transport software SedSim (Davies and Macdonald, 2001). The investigations at Burlington Channel have applied the drawdown module of *SGH* only. Wake is of only secondary importance at the Burlington Channel due to the sheet pile edge treatment of the channel.

SGH uses the same technique as the US Army Corp of Engineers' model HIVEL2D to model a vessel as a moving pressure field (Stockstill and Berger 1999). A spatial representation of the vessel hull is specified. *SGH* consists of two computational domains. The first is a temporally varying domain which propagates along with the ship. This domain features high resolution to resolve the steep gradients around the vessel. The results from this grid are superimposed on the overall model domain and all parameters are solved at each location on the grid.

Open or closed boundaries can be specified, and ambient hydrodynamic conditions, for example currents, can be specified along model boundaries. Energy absorption can be specified within the model to minimize reflections along boundaries. The model is sensitive to the shape of the vessel hull.

A full description of the development of *SGH* including model source terms is contained in Macdonald (2003).

RESULTS

Hydrodynamic Data

A full discussion of the hydrodynamic data collected at the Burlington Channel is contained in Taylor *et al* (2007). Maximum near-bed currents recorded during the ship movements were:-

- HCCL-1: 1.6m/s
- HCCL-2: 1.1m/s
- NWRI: 0.8m/s

Figure 3 is a plot of the current profile through the water column at Location HCCl-1 during a ship movement. Bin 1 refers to near-bed current speeds and Bin 48 near the water surface. The current profile is relatively uniform.

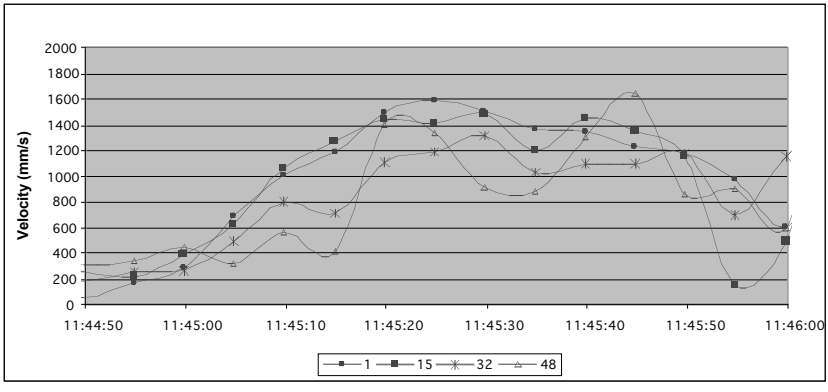

Fig. 3. Vertical velocity profile at Location HCCL-1 during an east bound ship movement.

Conceptual Scour Model

Based on the observed hydrodynamic conditions described in Taylor *et al* (2007) and the bathymetric survey of the channel, a conceptual scour model of the Burlington Channel has been developed.

A number of studies have been undertaken into the properties of the surge wave generated by large ships in confined channels including Herbich and Schiller (1984). In general, ships passing through a confined channel generally causes a significant drop in initial water level in front of the ship, and a resulting surge as the ship proceeds along the channel. The surge wave propagates in the opposite direction to ship motion.

The ADCP current data collected at Burlington Channel was found to be consistent with Herbich and Schiller (1984). In all cases, the direction of the peak near-bed current was in the opposite direction to the motion of the ship. The direction of ship motion is significant on the magnitude of observed currents near the entrances. At Location NWRI, largest currents were observed during the west bound movement of ships, and at Location HCCL-1 the largest currents were observed during east bound ship movements. At Location HCCL-2, a large difference in current magnitude between east and west bound ships was not observed.

Following the initial review of the field data and available literature, two key outcomes were evident; sediment transport potentially occurs along the whole channel, not only at

the entrances, and that the scour pattern observed at the entrance is similar in nature to that observed at channel constrictions.

Of the scour areas identified in Figure 2, the most significant are near the channel walls at the western and eastern entrances. There is evidence of scour in the order of 0.5m up to 300m east of the western entrance (Fig. 2). The scouring of the channel centerline is a result of the jet induced by the ship propellers and does not impact on any of the surrounding structures. The conceptual sediment transport model focuses on the physical processes that lead to the scour at each entrance and along the channel piers.

The observed currents in the mid-section of the Burlington Channel are large enough to initiate motion of medium grain sand material. Therefore sediment transport is expected to occur along most of the Burlington Channel. The absence of scour in the middle sections of the channel is the result of no net sediment transport occurring over a longer period of time. Ships have to enter and leave Hamilton Harbor through the Burlington Channel. As a result there is an equal number of ship movements in each direction. In the mid-sections of the channel the sediment transport induced by a ship moving in a particular direction is counteracted by ship movement in the opposite direction. As a result, over the long term little net sediment transport occurs.

The Burlington Channel acts as a flow constriction to ship induced flow at both the Hamilton Harbor (western) entrance and the Lake Ontario (eastern) entrance. Investigations undertaken by Gill (1981) illustrate the general scour processes near a confined channel. Importantly, the scour at the entrance to the confinement is significantly larger than in downstream sections of the channel. The physics behind this outcome can be explained by the behavior of shear stress surrounding an obstruction. Investigations undertaken by Molinas *et al* (1998) quantified the shear stress concentrations surrounding a vertical wall obstruction in a channel. This work showed that bed shear stress concentrates near the upstream toe of an obstruction.

A consequence of this constriction effect is that bed shear stresses are highest when flow is being directed towards the entrances of the Burlington Channel from outside the channel. The field data indicated that current speeds at both entrances were highest when the ship induced flow was heading into the channel. The larger currents and scour observed at the eastern entrance is the result of a larger confinement ratio between the channel and adjoining water body. Bed shear stress investigations by Gill (1981) indicated that the bed shear stress near a contraction was a function of the confinement ratio between the upstream and downstream sections of the constriction. At the Burlington Channel, the confinement ratio at the eastern entrance which adjoins Lake Ontario is significantly larger than for the western entrance. As a result the scour magnitude and extent is larger at the eastern entrance. It is proposed that the scour pattern observed at the entrances to the channel are an imprint of the bed shear stress during ship movements causing flow into the channel. That is, east bound ship movements cause the greatest scour at the eastern entrance when currents caused by the

drawdown are directed into the channel, and similarly west bound ships produce the greatest scour at the western entrance.

Numerical Model Investigations – *SGH*

Model Calibration

Simulations were undertaken for each of the seven observed ship movements. Figure 4 is a time series plot of model (solid red) and measured (dashed blue) current speed, current direction and water level during the west-bound movement of a SeawayMax vessel (*Canadian Transport*) at Location HCCL-2 (mid-channel). Calibration in the mid sections of the channel was better than at the entrances where three-dimensional processes associated with the flow acceleration are more significant (Taylor *et al*, 2007).

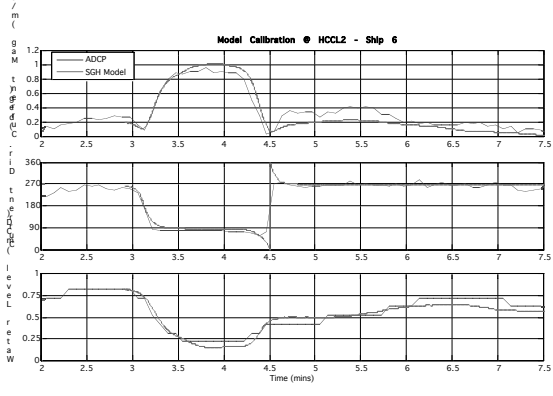

Fig. 4. Calibration of the *SGH* model at Location HCCL-2.

Overall the model calibrated well to the available field data; however, it must be noted that due to the two-dimensional assumption of the model, the magnitude of currents in the immediate vicinity of the western entrance, and to a larger extent the eastern entrance, will generally be underestimated within the model. In the application at the Burlington Channel, 'slip' boundary conditions were employed along the channel walls to achieve a good level of calibration. A full description of the calibration of the *SGH* model of Burlington Channel is described in Taylor *et al* (2007).

Critical Sediment Diameter and Scour Potential

A general formula to estimate potential scour due to ship induced scour (due to drawdown) in and near confined channels is not available. In order to investigate the potential spatial variation in scour depths along the Burlington Channel, the spatial variation in critical sediment diameters has been determined from the peak currents determined by the *SGH* model during a theoretical ship movement. As highlighted in Figure 3, the velocity profile through the water column during the peak of the surge

wave does not observe a logarithmic profile. Therefore, instead of using Shields formula to estimate critical sediment diameter of bed material in the channel, the Isbash formula was adopted. This method does not assume a velocity profile and the calculated peak velocity from the *SGH* model (depth-averaged) was adopted as the near-bed velocity. The form of the Isbash equation used in this study is shown in Equation 1.

$$D = b\frac{v^2}{2g\Delta} \tag{1}$$

where D = sediment diameter (critical), v = peak velocity (near-bed), g = acceleration due to gravity ($9.81 m^2/s$), Δ = relative density (1.65), and b = turbulence coefficient. A value of 0.7 was adopted for b which is typical of normal turbulent flow.

SeawayMax ship specifications and a speed of 3.5m/s were adopted for these investigations. East and west bound ship movements were simulated to quantify the influence of ship direction on forcing contributing to the observed scour. As the *SGH* model is not designed to resolve the hydrodynamics within the immediate vicinity of the ship and under the ship, areas within 10m of the ship path have been neglected from this study.

Figures 5 and 6 present the critical sediment diameter (mm) for east and west bound ships respectively. Comparing the two results, at the western end of the channel, the model predicts significantly larger critical sediment diameters in the western section during east bound ship movements. This is consistent with the observed scour pattern (Fig. 2) where some degree of scour occurs up to 200m east of the western entrance. At the western entrance itself, the model predicts larger critical sediment diameters during west bound ship movements.

At the eastern entrance, east bound ships produce larger critical sediment diameters. The model predicts the largest critical sediment diameters approximately 250 to 350m from the western entrance along the northern pier. However, the magnitude of the critical sediment diameter in this region is generally similar for east and west bound ships. As the direction of sediment transport varies with ship direction, assuming equal numbers of ship movements in each direction the model is consistent with the observation of minimal net scour over time in this region (Fig.2). Overall, along the channel piers the model predicts critical sediment diameters in the order of 30mm to 60mm.

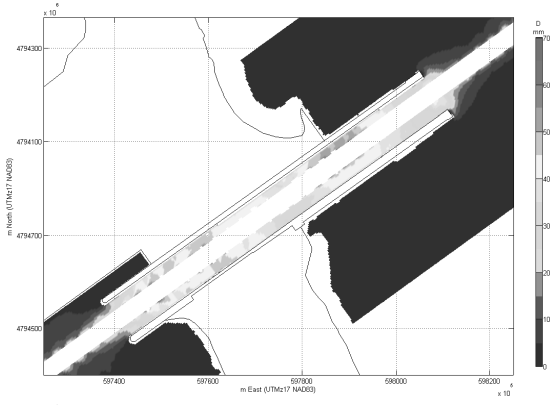

Fig. 5. Critical sediment diameter (m) during east bound movement.

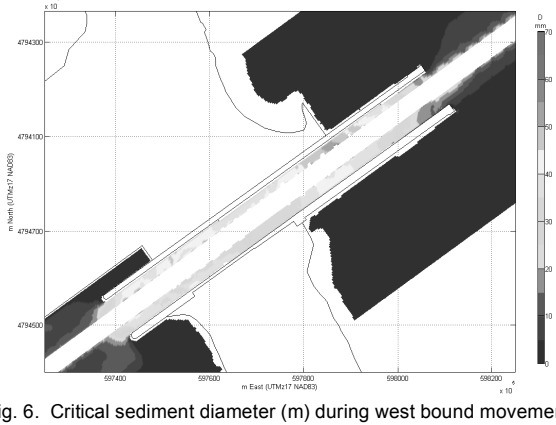

Fig. 6. Critical sediment diameter (m) during west bound movement.

DISCUSSION

The *SGH* model of the Burlington Channel demonstrated a good degree of hydrodynamic calibration, particularly in the mid-sections of the channel. At the channel entrances, the two-dimensional assumption of the model appears to underestimate potential currents near the entrances (Taylor *et al* 2007). Investigations into critical sediment sizes throughout the channel using the *SGH* model indicate that net scour is concentrated at the channel entrances. There is significant variation in scour potential at each entrance depending on the direction of ship motion. Greater scour is observed at the eastern entrance due to the larger confinement ratio.

Investigating potential scour within the channel using the variation in critical sediment size between east and west bound ship movements is a simplified approach. Scour within the Burlington Channel and near the entrances will be influenced by a range of

additional factors including the upstream (relative to the current direction) supply of sediment. Figure 7 presents a relative comparison of observed scour (left) and modeled potential scour (right). Areas in red indicate scour areas. It is evident that the model is consistent with the observation that bed levels within the mid-sections of the channel over time are relatively stable despite the hydrodynamic forces being sufficient to move the native bed material. Over time, the equal numbers of ship movements in the each direction appear to cancel out potential scour. Overall, the extent of scoured areas near the entrances is smaller for the model compared to the observed extent.

Fig. 7. Measured (left) and modeled scour areas (right)

Numerical models such as *SGH* are particularly suited to engineering applications. Theoretical design criteria for peak current speed and wave height associated with the surge wave have been determined throughout the Burlington Channel to further investigate the physical processes which cause scour. A series of simulations with a range of ship draft and speed combinations have been undertaken to determine design criteria curves for bed protection at the locations in Figure 8. The following parameters have been adopted for these simulations:-

- Ship speeds: 2m/s, 2.7m/s, 3.5m/s and 4.0m/s
- Ship draft: 7.75m, 8.5m and 9.25m

These parameters encompass the full range of ship speed and draft specifications which may be expected. SeawayMax specifications for ship length and beam were adopted. A water level of 0.5mCD (74.7mIGLD85) was adopted and this value is reflective of the mean water level in Lake Ontario.

The peak current speed, current direction and surge wave magnitude for each location have been obtained from each simulation. Design plots for surge wave amplitude and peak current speed based on ship speed and draft have been prepared. The plots are presented in a dimensionless form.

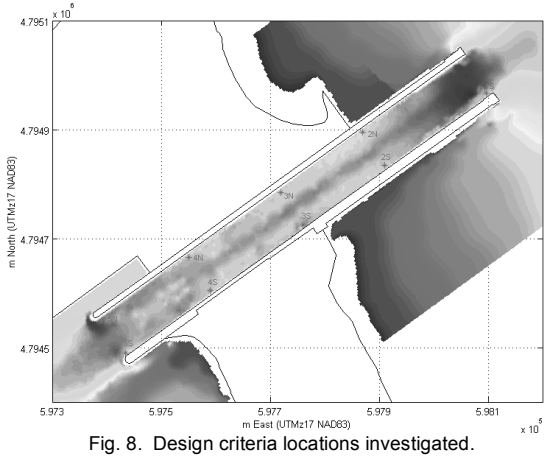

Fig. 8. Design criteria locations investigated.

The x-axis quantity is the ship Froude number as described by Herbich and Schiller (1984). The ship Froude number is described by Equation 2.

$$Fr_{ship} = \frac{v_{ship}}{\sqrt{gd}} \tag{2}$$

where v_{ship} is the ship velocity and d is the ship draft.

The surge wave plots have a y-axis of described by Equation 3.

$$\frac{H_{surge}}{d} \tag{3}$$

where H_{surge} is the amplitude of the surge wave and d is the ship draft.

The peak current speed plots have a modified Froude number for the y-axis described by Equation 4.

$$Fr_{Upeak} = \frac{u_{peak}}{\sqrt{gd}} \tag{4}$$

where u_{peak} is the peak current speed of the surge wave and d is the ship draft.

Figures 9 to 13 present dimensionless design criteria plots for peak current speed and surge wave height at Locations 1N, 2N, 3N, 4N and 5N respectively. The plots for the corresponding locations along the southern wall have been omitted because they show the same general trend as the northern locations. In these plots, west bound ship

conditions are shown in red and east bound ship conditions are shown in blue. Least squares fitted quadratic curves are shown in solid lines and 95% confidence intervals are enclosed by the dashed lines.

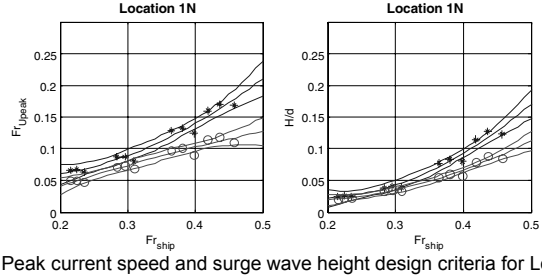

Fig. 9. Peak current speed and surge wave height design criteria for Location 1N (West bound (o), East bound (*))

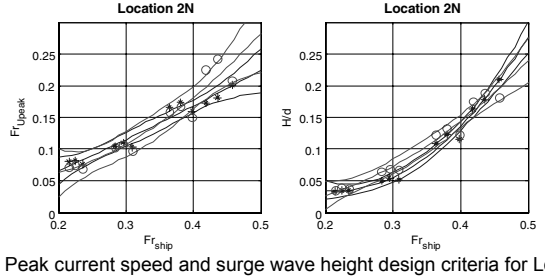

Fig. 10. Peak current speed and surge wave height design criteria for Location 2N (West bound (o), East bound (*))

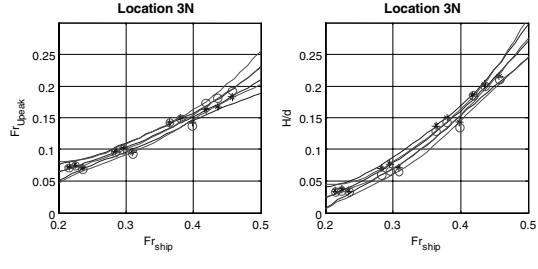

Fig. 11. Peak current speed and surge wave height design criteria for Location 3N (West bound (o), East bound (*))

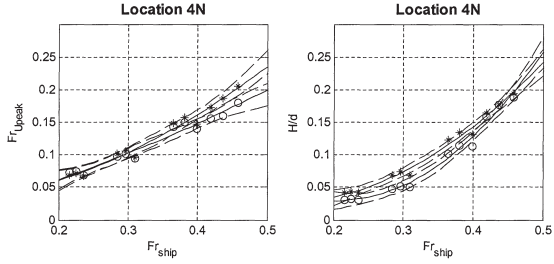

Fig. 12. Peak current speed and surge wave height design criteria for Location 4N (West bound (o), East bound (*))

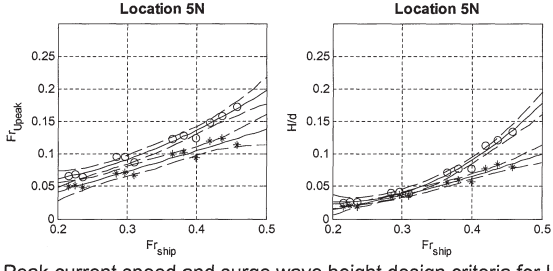

Fig. 13. Peak current speed and surge wave height design criteria for Location 5N (West bound (o), East bound (*))

East bound ship movements produce critical design conditions at Location 1N and west bound movements produce critical design conditions at Location 1S. This is consistent with observed conditions at Burlington Channel and the conceptual scour model where east-bound ship movements produce peak currents which are directed into the channel. Similarly, at Location 5N, west bound ship produce the critical design conditions. In the middle section of the channel east and west bound ship movements produce similar design conditions.

CONCLUSIONS

Investigations into ship induced scour in a confined channel, the Burlington Shipping Channel, have been undertaken. Measured hydrodynamic data together with bed survey data highlighted the significance of contracting flow at the channel entrance on observed scour patterns. An *SGH* numerical model used to simulate the surge wave generated by ships moving through the Burlington Channel has been developed. This model achieved a good degree of hydrodynamic calibration, particularly in the mid-sections of the channel. The model generally underestimated potential current speeds near the eastern entrance channel where the confinement induced by the channel causes significant flow acceleration.

The critical sediment size investigations with the *SGH* model indicate that the model can identify areas with significant scour potential. The model has been used to produce theoretical design criteria relationships for bed protection along the channel. Models such as *SGH* can provide significant value to engineering investigations associated with channel scour. Ship induced scour investigations near major hydraulic controls, for example strongly confined entrances, require comprehensive hydrodynamic data collected at the site.

ACKNOWLEDGEMENTS

The authors wish to thank Riggs Engineering and HCCL, Canada for allowing their data to be utilized in these investigations. Pacific International Engineering, Ottawa generously provided *SGH* and technical assistance for this project. The work at Queen's University was made possible through funding by Cardno Lawson Treloar, Sydney.

EVOLUTION OF GRAIN-SIZE DISTRIBUTION ON BOGUE BANKS: IMPLICATIONS FOR SELECTION OF BORROW MATERIAL

Timothy W Kana

Coastal Science & Engineering, PO Box 8056, Columbia, SC 29202-8056 USA. tkana@coastalscience.com

Abstract: Bogue Banks, North Carolina is 40 kilometers (km) long and has received 6.6 million cubic meters of nourishment in the past five years. Six borrow areas of varying quality have been used ranging from fine, muddy sand in a federal dredge disposal area to coarse, shelly sand in an offshore borrow area. Composite sediment samples representing the native beach (foredune to low-tide terrace) were sampled before nourishment in June 1999 and after nourishment in November 2006. Profiles have been surveyed along the beach and combined by reach to form composite sections before and after nourishment. This paper provides representative pre/postnourishment grain-size distributions (GSDs) and composite profiles to illustrate similarities and (mostly subtle) differences between the native and nourished beaches. Despite some wide differences in GSDs, the nourished beaches and inshore morphology were generally maintained in the postnourishment profile. Additional sediment sampling and profiling are being conducted to quantify differences among the Bogue Banks projects.

INTRODUCTION

A widely accepted tenet of beach nourishment design is that the borrow source should attempt to match the native grain-size distribution (NRC 1995). It is presumed that if the nourishment material is similar to the native beach sediment, the project will perform as a natural beach (ie, erode at approximately the same rate), and environmental impacts will be minimized. Because discrete sediment samples tend to have a unique size distribution, common practice is to pool results of many samples in such a way as to define a composite size distribution both for the native beach and for a prospective borrow area. These composite grain-size distributions can then be compared to judge how closely the borrow source matches the beach. The analysis is even further reduced when applying accepted sediment compatibility models, such as the James (1975) overfill factor (R_A), which require only four measures: mean size and sorting parameter of the native and borrow sediment.

Using data from North and South Carolina nourishment projects, we find that traditional compatibility analyses work acceptably where there is little variation in sediment size distribution over the littoral profile (eg, South Carolina fine-sand beaches). Composite native size distributions in these cases tend to consist of well-sorted (poorly graded) sediments with a distinctive mode and an easily computed mean (cf, Kana and Mohan 1998). South Carolina beaches tend to maintain simple profiles with a narrow dry beach, wide wet beach, and little offshore topography. Given the relative homogeneity of sediments across most South Carolina beaches, finding and identifying matching sediments for nourishment is fairly straightforward.

Many North Carolina beaches, by contrast, consist of poorly sorted sediments (in the composite). Large variations in grain size occur across the profile, which in turn, probably accounts for the complexity of topography and persistence of an offshore bar. Commonly, North Carolina beaches have relatively wide, dry-sand berms, narrow wet-sand beach faces, and a nearshore platform on which a breakpoint bar forms. Mean grain size tends to go from fine sand in the dunes to coarse sand in the inner surf zone, then back to fine sand over the bar. This multi-modal size distribution does not lend itself to simple classification based on a single mean grain size. Selection of borrow sources, in these cases, should seek the broadest range of sizes possible. If the full spectrum of sizes is placed on the beach via hydraulic fills, the presumption is that waves will sort the sediments and better reproduce the cross-profile grain-size variations observed on the natural beach.

Bogue Banks, North Carolina (Fig 1), provides an example of a beach that has received multiple nourishments in the past five years in discrete segments using six borrow sources. This paper compares the prenourishment and postnourishment beach in terms of the changes (or similarity) of sediment grain-size distribution and profile development. Sediment comparisons are limited to the visible beach (dune to low-tide terrace), because that zone served as the initial baseline condition for selection of borrow areas for the majority of the shoreline (CSE–Stroud 2001).

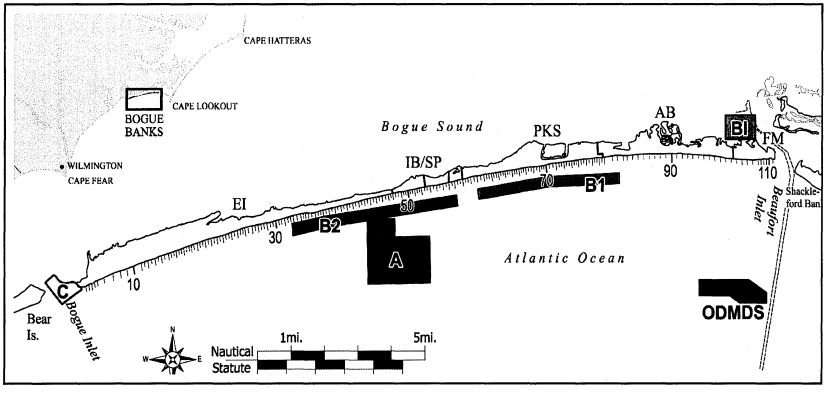

Fig 1. Bogue Banks, North Carolina. Communities: AB – Atlantic Beach; PKS – Pine Knoll Shores; IBSP – Indian Beach/Salter Path; EI – Emerald Isle. Borrow areas utilized for nourishment 2002–2005.

SETTING

Bogue Banks is a 40-kilometer-long (25 miles) barrier island trending east-west and bounded by large tidal inlets: Beaufort Inlet to the east and Bogue Inlet to the west. Situated about 25 km from Cape Lookout, Bogue Banks is sheltered from northeast storm waves but exposed to seas and swell from the southeast and southwest. Tide range is approximately 1.1 meters (m) (3.6 feet), average significant wave height is of the order 1.2 m (3.9 ft) (Roessler 1998) and **net** sediment transport is indeterminate based on available hindcast data and erosion rate information, but is likely to be of the order 50,000 cubic meters per year (m^3/yr) or less (CSE–Stroud 2001). Beach sediments typically vary across the profile with fine sand (~0.25 mm diameter) in the foredune, medium to coarse sand on the berm (0.35-0.6 mm), and fine sand on the outer bar (~0.2 mm diameter). Estimated profile closure depth in this setting is in the depth range –15 to –20 ft mean sea level (Bodge et al 2006, CSE 2006).

Four municipalities and one state park form the political boundaries along the island (east to west): Fort Macon State Park, Atlantic Beach (AB), Pine Knoll Shores (PKS), Indian Beach/Salter Path (IBSP), Emerald Isle (EI).

The beach has been relatively stable over the past 50 years with erosion rates averaging ~0.6 meters per year (m/yr) (2 ft/yr) (NCDENR 2004 – http://dcm2.enr.state.nc.us/Maps/ER_1998/SB_Factor.htm). The island contains well-developed dunes with over 5 m (16.5 ft) relief in the foredune (typical). Serious erosion first impacted Atlantic Beach in 1954 (Hurricane *Hazel*), because it was the center of development along the island. Seawalls built in response to storms and erosion eliminated much of the dry beach in this locality by the 1970s (Pilkey et al 1975).

NOURISHMENT PROJECTS

Prior to 1999 only Atlantic Beach and Fort Macon State Park had been nourished. These are sites of federal dredge-disposal projects with large inputs in 1986 and 1994 (USACE 1993). Much of this material was obtained from a US Army Corps of Engineers dredge disposal area – Brandt Island (Fig 1, labeled BI). Maintenance dredging of the Beaufort Inlet navigation channel and Morehead City Harbor uses Brandt Island for disposal. This diked containment area is periodically pumped out to Atlantic Beach so it can be reused. Anecdotal information indicates the 1986 and 1994 pump-outs introduced large quantities of fine sand and mud with much of the material moving offshore. The sediments remaining on Atlantic Beach by 1999 were well-sorted fine sand (CSE–Stroud 2001).

Several hurricanes impacted Bogue Banks in quick succession between 1996 and 1999 with *Floyd* (September 1999) causing extensive property damage along PKS, IBSP, and EI. Atlantic Beach sustained almost no dune recession and served as a model for other communities considering nourishment. By 2001, the remaining towns along Bogue Banks had initiated nourishment projects using several different sand sources.

Between 2001 and 2005, 6.6 million cubic meters (8.6 million cubic yards) were added to the beach, advancing the shoreline an average of ~23 m (75 ft). Virtually the entire length of Bogue Banks received new sand during this period (Fig 2). Of the total volume placed since 2001, 70 percent has been retained between the base of the foredune and the outer bar [measured to –11 ft NGVD 1929 vertical datum which approximates –3 m (–10 ft) mean sea level]. The remainder is accounted for between the outer bar and depths of –6 m (–20 ft) (CSE 2006). The principal storm events since nourishment were Hurricane *Isabel* (September 2003) and *Ophelia* (September 2005), both of which made landfall as Category 1 storms in this locality. Hurricane *Ophelia* caused upward of 1.2 million cubic meters of erosion (~17 percent of the nourishment volume) along the subaerial beach to the outer bar and accounts for much of the visible sand losses and profile adjustment.

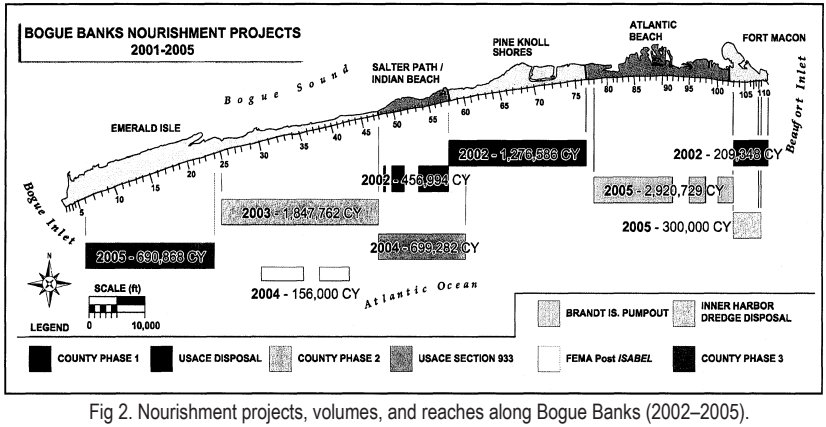

Fig 2. Nourishment projects, volumes, and reaches along Bogue Banks (2002–2005).

BORROW SOURCES

Six sand sources have been used for nourishment along Bogue Banks with estimated percentages of the aggregate volume placed.

BI – Brandt Island (33 percent) – Federal dredge spoil containment basin which was pumped out and deposited along Atlantic Beach and Fort Macon State Park in 1986, 1994, and winter 2005.

Offshore Area A and B1 (20 percent) – Used for PKS and IBSP in 2002.

Offshore Area A and B2 (23 percent) – Used for EI in 2003.

ODMDS (10 percent) (Ocean Dredge Material Disposal Site) – Utilized for federal Section 933 projects to IB/SP and eastern EI in 2004 (Fig 2).

Bogue Inlet (Area C) (8 percent) – used for western EI in 2005.

Outer Harbor Channel (6 percent) – Beaufort Inlet used for Fort Macon State Park in 2002 and 2005.

Geotechnical studies by CSE–Stroud (2001) sampled the native beach (subaerial portion to the low-tide terrace), Brandt Island, Bogue Inlet, and offshore areas A, B1, and B2. Later sampling was performed in the ODMDS. Composite samples (pooling groups of beach samples and groups of offshore borings) were used to determine sediment compatibility of potential borrow sources. The beach was resampled in 2006 at the same localities for comparison after nourishment and profile adjustment. In some localities, the fill has had four years to adjust while in most areas there has only been 1–2 years of adjustment. All localities were impacted by Hurricane *Ophelia* after nourishment, but before the 2006 samples were collected.

PRENOURISHMENT TO POSTNOURISHMENT SEDIMENT GRAIN SIZES

Figures 3–7 show representative composite grain-size distributions for prenourishment conditions (June 1999), postnourishment (November 2006), and the respective borrow area used. (Note: Where more than one area has been used, the dominant one is compared.)

Atlantic Beach (Fig 3) is the only section of Bogue Banks with fine sand. It was nourished in 1986 and 1994 using Brandt Island spoil sediments, so the "native" grain-size distribution (GSD) differed from the rest of the island. Its 2005 nourishment also utilized Brandt Island. Borrow material tested finer (mean = 0.203 mm), but the postnourishment result on the subaerial beach is incrementally coarser than the prenourishment condition (mean before = 0.237 mm, mean after = 0.256 mm). (Note the near-uniformity of the 1999 and 2006 size frequency curves.) CSE (2006) estimated ~0.8 million cubic meters (~35 percent) of the nourishment volume were eroded during placement and shifted seaward of the outer bar. The portion lost and

portion retained within the subaerial beach are reflected in the difference between borrow frequency curve and the native beach. The fine fraction in this case shifted offshore, leaving the coarser fractions along the berm and swash zone where all sampling took place.

Pine Knoll Shores and Indian Beach/Salter Path were nourished in 2002 (Phase 1 of a three-phase project), and eastern Emerald Isle was nourished in 2003 (Phase 2) using sand from offshore Area A (~50 percent), Area B1 (~25 percent), and B2 (~25 percent). Figure 4 shows pre/postnourishment composite GSDs (1999 versus 2006). Figure 5 compares the offshore borrow areas with the 2006 composite, and Figure 6 compares the ODMDS (used for a limited reach) with the 2006 beach. In this case, two offshore borrow areas (B1 mean = 0.276 mm, and B2 mean = 0.313 mm) had a significant fine-sand fraction, but they also contained an admixture of coarser sediments making the deposits poorly sorted and strongly coarse-skewed (CSE–Stroud 2001). Borrow Area A (mean = 0.525 mm) was the coarsest of the three offshore sites with the flattest GSD frequency curves.

These deposits were selected for use in the Phase 1 and Phase 2 projects because of their proximity to nourishment areas and their lower overfill ratios. The coarse material consisted largely of crushed shell which became controversial in this jurisdiction. Prenourishment shell content on the subaerial beach averaged ~15 percent, whereas borrow Areas A, B1, and B2 averaged ~40 percent. The result after profile adjustment shows a good match of the modal grain size (~0.30 mm) but retention of a significant coarse fraction in the gravel range (>2 mm diameter). Retention of coarse material is believed to account for reduced sand losses compared with Atlantic Beach (CSE–Stroud 2001). By 2006, the percent shell ($CaCO_3$) had reduced to ~21 percent along the Phase 1 and Phase 2 reaches.

Western Emerald Isle (Phase 3) was nourished using sediment from Bogue Inlet (Area C mean = 0.313 mm). The pre/postnourishment composites (Fig 7) yield an excellent match with the borrow composite (prenourishment mean = 0.341 mm, postnourishment mean = 0.332 mm). In this case, the means, modes, and shape of the frequency curves are nearly identical after 1.5 years of fill adjustment.

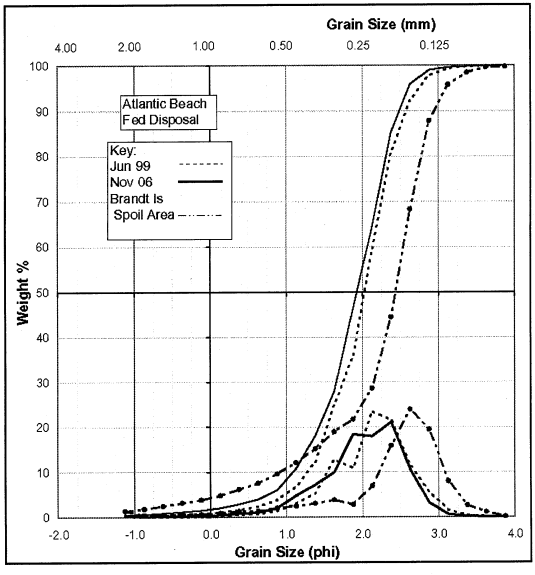

Fig 3. Atlantic Beach composite sediment GSD: Toe of Dune to Low Tide Terrace, before and after nourishment. Brandt Island (BI) was the borrow area.

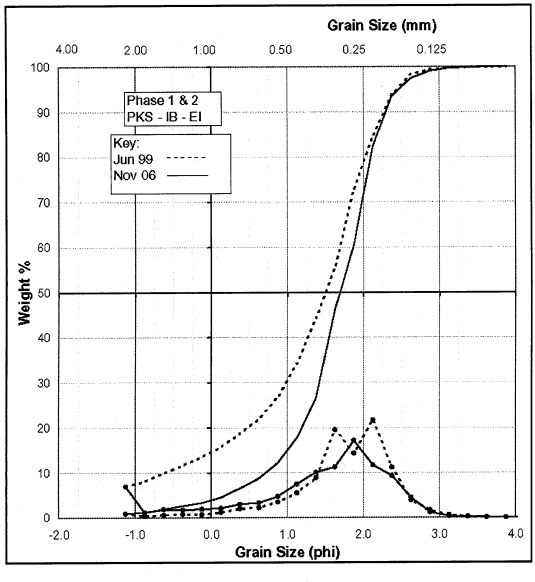

Fig 4. Phases 1 and 2 (PKS, IBSP, and eastern EI) composite sediment GSD before and after nourishment.

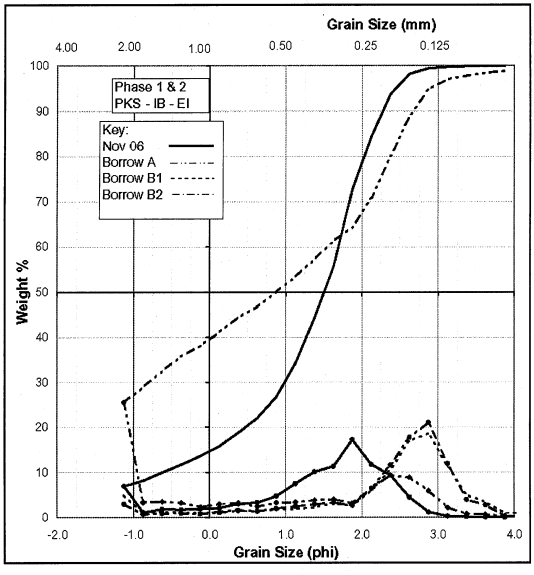

Fig 5. Phases 1 & 2 composite GSD for PKS, IBSP, and eastern EI after nourishment versus offshore borrow Areas A, B1, and B2 used for ~85 percent of the nourishment along this reach.

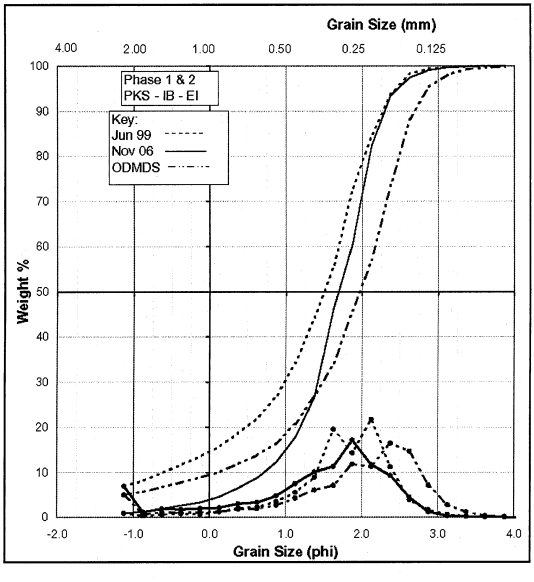

Fig 6. Phases 1 & 2 composite GSD for PKS, IBSP, and eastern EI versus the ODMDS borrow area used for ~15 percent of the nourishment along three communities.

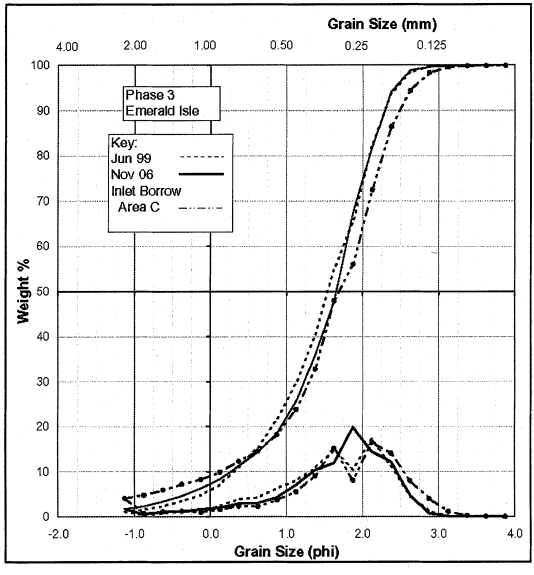

Fig 7. Phase 3 (western EI) composite sediment GSD before and after nourishment. Bogue Inlet Area C was the borrow area.

PROFILE EVOLUTION

Island-wide surveys are available for several years between 1999 and 2006. Figures 8 and 9 illustrate the typical evolution of the profile for portions of Atlantic Beach and Indian Beach/Salter Path since nourishment [see CSE (2006) for a comprehensive data set]. The profiles before and after nourishment have been matched at the mean high water contour to illustrate changes or similarities in shape and position of the active surf zone.

Profile shape in the surf zone reflects the mixing and sorting of nourishment sediments. The degree of similarity of shapes, therefore, reflects the match of borrow and native sediments on the beach. In both examples, the postnourishment shape closely matches the prenourishment shape in the principal breaker/swash zone [+5 ft to –7 ft NGVD; equals (~)+1.2 m to –2.5 m MSL]. The Atlantic Beach profile generally lacked a distinctive offshore bar prior to nourishment—instead demonstrating a series of inflections in the offshore profile. The general morphology was retained after nourishment, although the underwater inflection points varied. Note how closely the beach face slopes match (average is 0.032 between the +5 and –7 ft NGVD contour).

Indian Beach was nourished with much coarser sediment (similar to its native). The postnourishment profile retains the steeper inshore slope (~0.042) and topography of the offshore bar. Relief of the trough-bar system is greater, but the width of the trough and height of the outer bar are similar to prenourishment conditions.

One might expect such similarities in profile shape if the nourishment (section) volumes were small. But in both examples, the nourishment was substantial, displacing the shoreline 20–40 m. As a result, the native sediments remain largely buried under the nourishment sands.

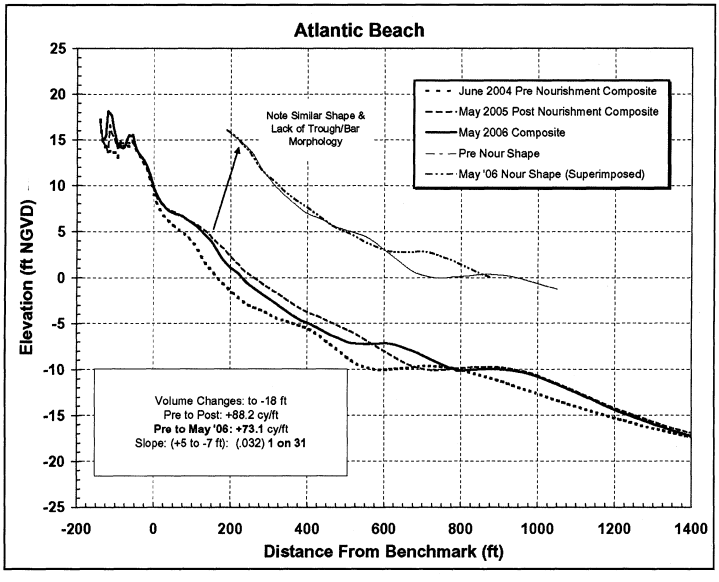

Fig 8. Pre/postnourishment profiles (composites) for Atlantic Beach. Surf zone to outer bar section has been displaced and overlain to illustrate similarity of postnourishment shape and slope.

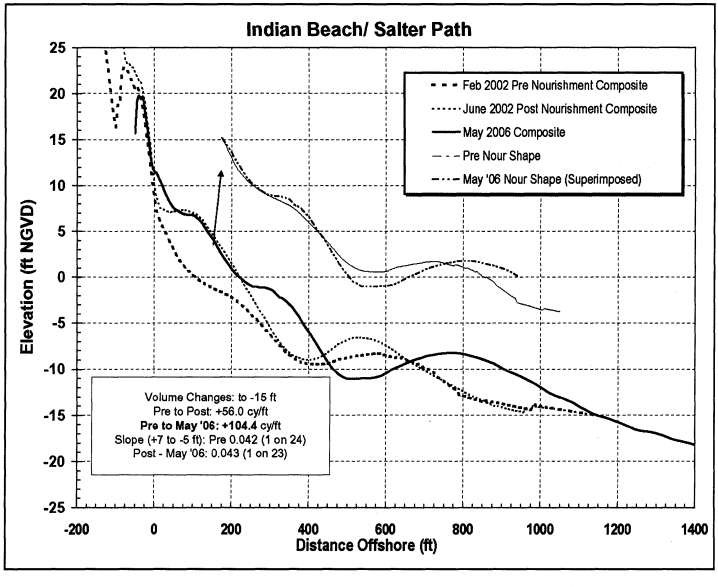

Fig 9. Pre/post nourishment profiles for IBSP. Note retention of shape, morphology, and general dimensions.

IMPLICATION FOR DESIGN

These preliminary results suggest that the inner surf zone and profile of a nourished beach can adopt a similar slope and morphology as the native beach if the borrow area matches the native beach closely (ie, Bogue Inlet – Area C), or if the mean grain size of a poorly sorted deposit matches the native beach (ie, Phases 1 and 2 areas using offshore Areas A, B1, and B2). The result for Atlantic Beach suggested that the sediments in the Brandt Island borrow area would not have produced a similar profile as native along PKS, IBSP, and EI because they were much finer. The resulting beach-face slope for AB was ~1 on 32 versus ~1 on 24 along the Phase 1 and Phase 2 communities. AB's borrow material resulted in a good match with that native beach segment largely because it had been nourished previously in 1986 and 1994 using similar fine-grained sediment.

The NC Coastal Resources Commission has recently adopted sediment grain-size standards for the state to insure that excess fines or excess gravel and shell are not placed on state beaches by nourishment projects (cf, http://www.nccoastalmanagement.net/sediment.htm). While such regulations are a step forward, mean sediment grain size should also be matched wherever possible to avoid changes in beach slopes and morphology. Placing 0.2-mm sediment along all of Bogue Banks, in effect, would flatten the beach face slope and reduce or eliminate bar-trough morphology. Conversely, placing much coarser material on the beach may result in a persistent lag deposit and produce steeper-than-native slopes. Additional sampling is needed to quantify these effects.

ACKNOWLEDGMENTS

This work was conducted as part of the design services contracts between the towns of Emerald Isle, Pine Knoll Shores, and Indian Beach (NC) and the author's company. Philip McKee, Trey Hair, Diana Sangster, and Kim Baker assisted with data collection, laboratory testing, and preparation of the manuscript.

Abstract: One of the key elements in predicting beach fill performance is the evaluation of the "compatibility" of beach sands. Several formulations have been proposed to estimate the "compatibility" or "overfill" ratio. Most of them assume that both native and borrow sand has a log-normal grain size distribution. Log-normal distribution has long been accepted as the most adequate distribution for characterizing marine sediment samples. Furthermore, Galofre and Medina (2000) showed that for specific conditions of the marine dynamics a log-normal grain size distribution is achieved as the final equilibrium distribution of a sediment deposit. However other distributions, such as weibull or hyperbolic distributions, have also been proposed to represent sediment samples. In this paper, new field data are analyzed in order to further explore Galofre and Medina (2000) equilibrium grain size distribution hypothesis and to identify those situations in which sediment samples do not fit a log-normal distribution.

INTRODUCTION

The equilibrium beach profile concept suggests that beaches respond to wave forcing by adjusting their form to an equilibrium or constant shape attributable to a given type of incident waves. Since profile shape is just a consequence of sediment reallocation, the equilibrium concept should be also valid for cross-shore grain size distribution. The existence of an equilibrium grain size distribution was theoretically showed by Galofre

and Medina (2000). These authors showed that for specific conditions of the acting dynamics and of the sediment characteristics, a log-normal grain size distribution is achieved as the final equilibrium distribution. Furthermore, some relation between the wave dynamics characteristics and the grain size distribution was also found (Galofre and Medina 2000; Galofre and Medina 2001)

Several authors had previously suggested that log-normal distribution can be used as a good estimation of the grain size distribution, (e.g. Krumbein 1938; Inman 1953; Moutzouris 1988; Moutzouris 1991; Medina et al 1994). However, other authors had suggested that log-normal is not the most appropriate distribution to characterize the grain size distribution. These authors claim that in some cases, log-normal distribution doesn't provide an adequate adjustment of extreme points of distribution. Furthermore, other authors have showed that bimodal samples can be fit using overlapping log-normal distributions.

Log-hyperbolic distribution has also been used on sediment grain size distribution characterization as an option to traditional log-normal. Log-hyperbolic distribution is defined by four parameters and is shown in log-normal scale like a hyperbola. The parameters can be related to mean, standard deviation, symmetry, and kurtosis. The domain variation in the last two parameters are a triangle, hyperbolic triangle shape, in those can be found the samples according the distribution shape, hyperbolic or other limit shape (Normal or Gaussian) and they are related to erosion or accretion. The comparison between log-normal and log-hyperbolic distributions (Wyrwoll and Smith 1985) has been made in desert dunes. The log-normal distribution can be seen as the limit case of a log-hyperbolic distribution.

Fredlund et al. (2000), developed an equation defined by five parameters for one-modal samples that fits better in well graded samples than log-normal with two parameters, specifically in mud and clay materials. The obtained values for R^2 were of 0.999, a reasonable number considering that many parameters were used to ensure a better adjustment. Other authors used Weibull's distribution functions in order to fit multi-modal samples. This author concluded that log-normal distribution performs equal or better for fluvial or lake sediment samples while Weibull distribution fits better for multi-modal samples.

From the above paragraphs it can be concluded that a general consensus on the distribution to be used or the reason why one distribution fits better or which distribution should be used in a particular marine environment, does not exist.

It is worth noting that the analytical method proposed by Galofre and Medina (2000) stated that if a turbulent dynamic acts on a sediment deposit no matter what grain size distribution, the eroded material has a log-normal distribution. The non eroded sediment deposit will have the initial distribution minus the log-normal eroded part. Note that the sediment deposit that is found at a particular time in a specific marine location could be the eroded part or the non-eroded part of a previous sediment deposit. For instance, the

beach bar is the eroded sediment part during the bar formation (eroded from the berm) and it is the non-eroded part during the beach recovering stage.

The above mentioned statement is illustrated in figure 1. In this example, an initial uniform distribution, P_0, is forced by 20 events of turbulent dynamics. After these 20 events, the initial volume, (V_0) is partially eroded and becomes (V_N), as some volume (V_E) has been eroded. V_E has a log-normal grain size distribution.

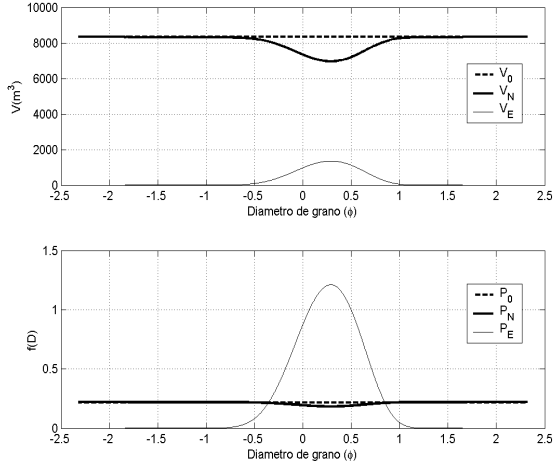

Fig. 1. An initially uniform grain size distribution generates a log-normal grain size distribution. Upper panel in volume, lower panel in probability density function.

The eroded volume will become a sediment deposit somewhere. If this new deposit, that now has a log-normal distribution, is then subjected to 20 new turbulent events, it will be further eroded. The eroded part of the deposit will have a log-normal distribution while the remaining sediment will have a log-normal minus a log-normal distribution (bi-modal). See example in figures 2 and 3.

Beach restoration and periodic nourishment maintenance is probably the most attractive method of beach erosion control. It is one of the most direct methods for maintaining and improving recreational benefits in shore protection projects and it is also used for emergency storm protection. One of the key elements in predicting beach fill performance is the evaluation of the "compatibility" of beach sands, that is, the determination of the amount of required borrow material needed to yield one unit that is consistent with the native material.

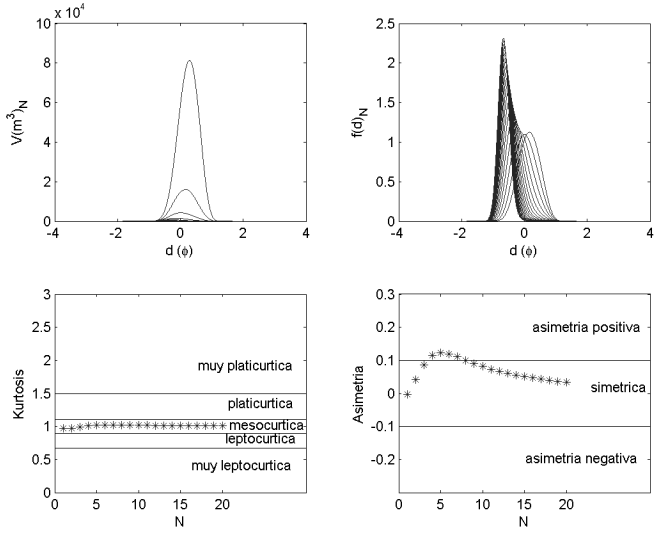

Fig. 2. Initial log-normal distribution. Upper left graphic in volume, upper right graphic in probability density functions, lower panel shows asymmetry and kurtosis.

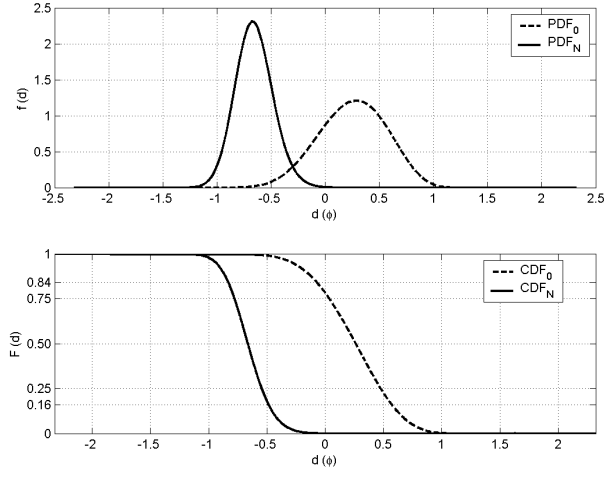

Fig. 3. Final log-normal distribution, after N=20 actions, from initial log-normal distribution. Upper panel in volume, lower panel in probability density function.

Taking advantage of the log-normal equilibrium distribution, Galofre and Medina (2001) and Galofre (2001) developed a simple method for estimating the relative compatibility of borrow material. However, several circumstances may invalidate the hypothesis of a log-normal native and borrow sand, namely:

- Wave climate that changes in time (seasonally, periodically, and randomly) and induces temporal variation of turbulent dynamics.
- Borrow sand sources with non log-normal distribution.
- Morphological changes that may affect sediment characterization and local wave climate.

In this paper, new field data are analyzed in order to further explore Galofre and Medina (2000) equilibrium grain size distribution hypothesis and to identify those situations in which sediment samples do not fit a log-normal distribution.

NEW DATA BASE ANALYSIS

More than 5.000 samples have been used to further explore Galofre and Medina (2000) equilibrium grain size distribution hypothesis. The samples were collected in 31 Spanish beaches. These beaches are classified into three groups: Cantabric Sea (13), South Atlantic (11), and Mediterranean Sea (7).

All the samples were best fitted to a log-normal distribution. The statistical parameters evaluated were: mean (first momentum) and standard deviation (second momentum), using phi units ($\phi = -\log_2 d$, d in mm.), avoiding the extreme values from the distribution as follow:

$$\bar{\phi} = \frac{\phi_{75} + \phi_{50} + \phi_{25}}{3} \tag{1}$$

$$\sigma_{\phi_{7525}} = 0.75 \cdot \left(\phi_{75} - \phi_{25}\right) \tag{2}$$

where $\bar{\phi}$ is the mean grain diameter in phi units, ϕ_n represents the sieve diameter in phi units that retains n percent of granulometric sediment sample weight, and $\sigma_{\phi_{7525}}$ is the standard deviation using percentages 75 y 25.

In a log-normal distribution, the Standard deviation ($\sigma_{\phi_{7525}}$) is evaluated using the percentages 16 y 84, $\sigma_{\phi_{8416}}$, as a result of taking into account all the data, σ_ϕ,

$$\sigma_\phi = \sigma_{\phi_{8416}} = \sigma_{\phi_{7525}} \tag{3}$$

evaluated from,

$$\sigma_{\phi_{8416}} = 0.5 \cdot (\phi_{84} - \phi_{16}) \tag{4}$$

$$\sigma_{\phi} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n} p_i (\phi_i - \bar{\phi})^2}, \quad \bar{\phi} = \sum p_i \phi_i \tag{5}$$

p_i is the probability of occurrence of ϕ_i, diameter on phi units of grain size *i*.

The asymmetry (third momentum) and kurtosis (fourth momentum) are the parameters that can show information about whether the analysed grain size samples are log-normal or not. These parameters are evaluated in phi units.

$$\text{Asymmetry} = \frac{(\phi_{84} - \phi_{50})}{(\phi_{84} - \phi_{16})} - \frac{(\phi_{50} - \phi_{10})}{(\phi_{90} - \phi_{10})} \tag{6}$$

$$\text{Kurtosis} = \frac{(\phi_{90} - \phi_{10})}{1.9 \cdot (\phi_{75} - \phi_{25})} \tag{7}$$

Negative asymmetry means that the finest grain sizes have been washed by the waves. On the other hand, positive asymmetry shows accumulation of fine sand compared with log-normal distribution. This parameter can be used to fix the limits of which fractions of the samples can be considered log-normal.

Some plots comparing the different ways of calculating standard deviation are presented in figure 4 for the Cantabrian Sea case. If the distribution were a perfect log-normal, results obtained from the three different procedures would be the same. The correlation coefficient shows the similarity of the computed values. The samples that show a greatest disagreement are those collected at El Puntal beach.

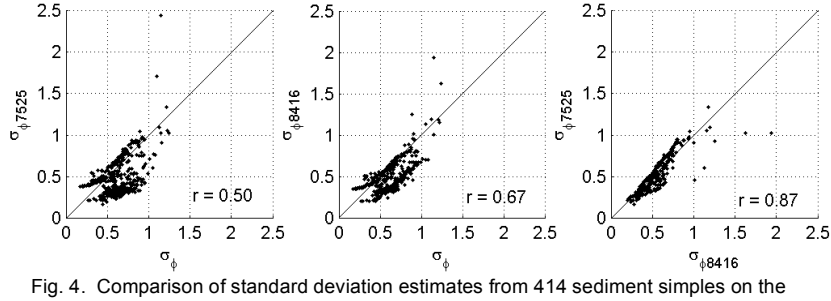

Fig. 4. Comparison of standard deviation estimates from 414 sediment simples on the Cantabrian Coast.

An example of the ability of the log-normal grain size distribution to fit the most non-log-normal sediment samples of El Puntal Beach is shown, figure 5. Note that the larger

disagreements between data and log-normal distribution always appear in the coarser fraction of the sample. The larger disagreements are encountered in the sediment samples located around the bar location (-5 m.) that usually appear on this beach.

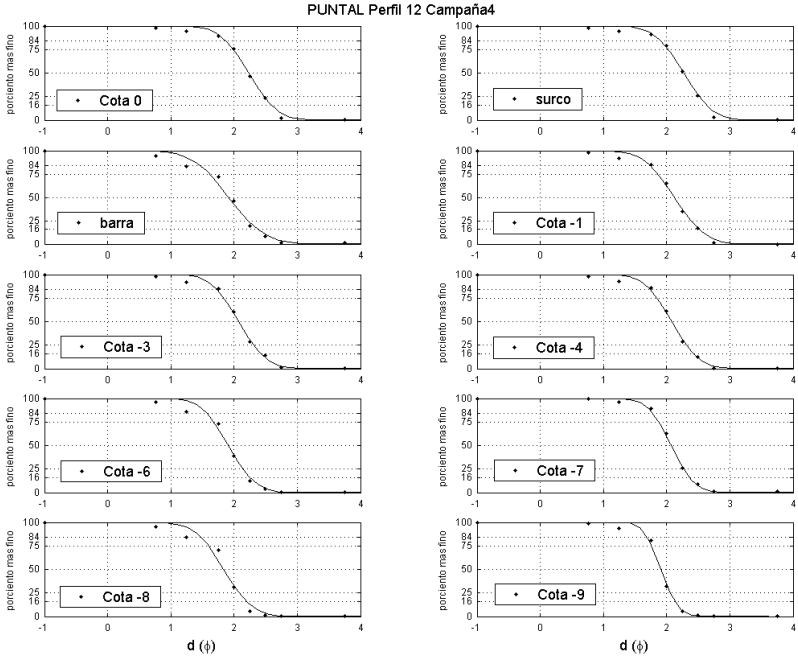

Fig. 5. Log-normal best fit distributions for El Puntal sediment samples.

The agreement between log-normal distribution and field data is also represented in figure 6. From this figure it can be concluded, that samples with negative asymmetry shows a lower R^2 than those with null asymmetry. Likewise, when the standard deviation is greater and when the distribution is leptokurtics, R^2 decreases.

Note that the worst fit corresponds to the negative asymmetry, in other words, to those places in which the fine sediment has eroded. These samples are located mainly on the bar during the accreting period of the beach. It is also worth noting that even though the discrepancy from the log-normal distribution is significant in the coarse fractions, it is negligible from the volume point of view since it only affects less than 10% of the sample.

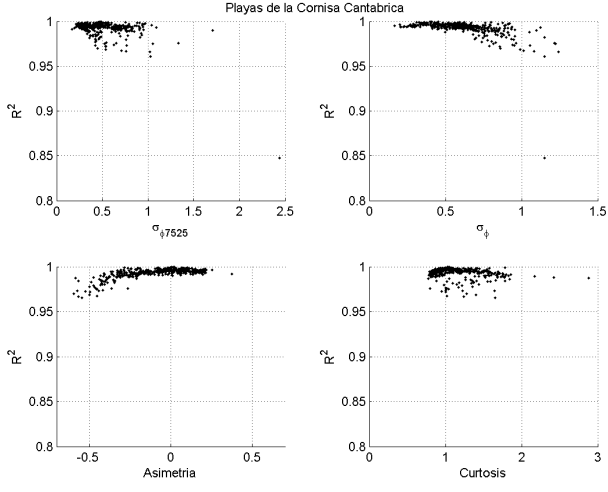

Fig. 6. Correlation coefficient, R, for sediment simples of the Cantabrian coast.

LOG-NORMAL APPLICATIONS

According to Galofre and Medina (2000) and Galofre and Medina (2001), log-normal distribution is the equilibrium grain size distribution of a sediment deposit generated by the accumulation of sediment eroded from an existing sediment source.

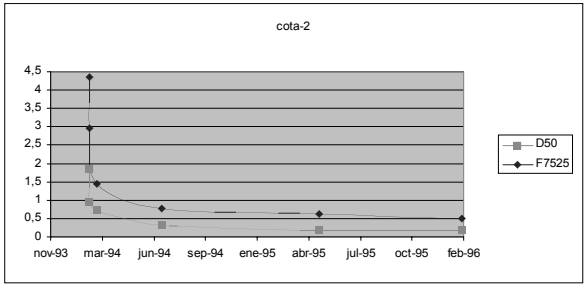

Fig. 7. Altafulla, Tarragona, profile 3. D_{50} and F_{7525} temporal evolution.

If this equilibrium distribution is changed, for example by nourishment works, the new material will not be in equilibrium with the existing dynamics, and a new equilibrium gain size distribution will be reached. Figure 7 shows the results from a monitoring survey after a beach nourishment project at Altafulla. We can see that the sediment grain size distribution reached the log-normal equilibrium distribution one year after the

nourishment works. The log-normal grain size distribution parameters are the mean and standard deviation. Mean is represented by D_{50}, and standard deviation, σ, by $F_{7525} = (\phi_{75} - \phi_{25})/2$. ϕ_x represents the sieve size, in units $\phi = -\log_2 d(mm)$, that retains x% of material.

It seems reasonable to acknowledge that there is a relationship between some parameter of wave climate and the grain size distribution. Galofre and Medina (2000), Galofre and Medina (2001) and Galofre (2001) found a relationship between H_{S12}, significant wave height that exceeded 12 hours a year, and F_{7525}. The relation between a wave parameter, H_{S12}, and log-normal grain size distribution parameter, F_{7525}, is shown in figure 8.

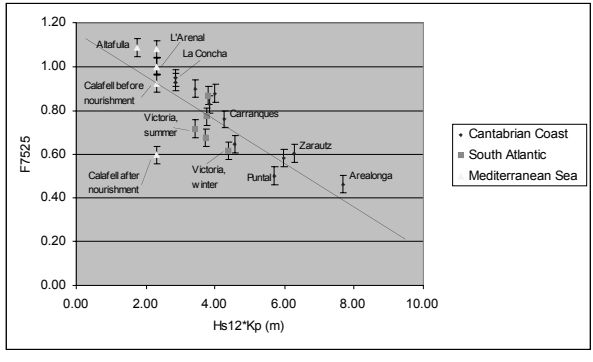

Fig. 8.- Relation between H_{S12} and F_{7525}

$$F_{7525} = -0{,}1.\ H_{S12}(buoy).K_p + 1{,}16 = -0{,}1.\ H_{S12}(local).K_p + 1{,}16 \qquad (8)$$

The overfilling ratio in beach nourishment works is necessary in order to predict beach fill effectiveness. Overfilling ratio measures the amount of required borrow sand needed to yield one unit that is consistent with the native material. Several attempts have been made to develop a procedure for evaluating the compatibility of borrow material compared to the native material (Krumbein and James 1965; Dean 1974; Guillen and Hoekstra 1996). Their basic assumption is that the borrow material will reach a final log-normal grain size distribution and that the mean and standard deviation of this final distribution $N(\phi_{50n}, \sigma_{\phi n})$ are related to those of the native distribution $N(\phi_{50n}, \sigma_{\phi n})$, where sub-index 'n' and 'b' are related to native and borrow sand.

An exhaustive analysis based on the compatibility of grain size distribution samples from borrow sand to equilibrium distribution was made using the principles shown in figure 9. New overfilling factors, R_A and S, were proposed (Galofre and Medina 2001; Galofre 2001).

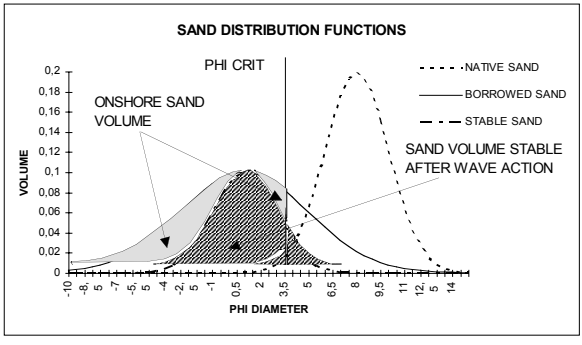

Fig. 9. Native, borrow and stable sand distribution functions in nourishment works.

This method assumes that native, borrow and final equilibrium grain size distribution are log-normal. This is useful for obtaining analytical expressions of overfilling ratios. It can be evaluated also by assuming that grain size distribution of native and final equilibrium sand are log-normal.

For analytical analysis one must assume that all grain size distribution is log-normal. In this method, the part of borrow sand that has a log-normal distribution is considered to be stable with the mean of borrow material and the standard deviation of native sand, $N(\phi_{50b}, \sigma_{\phi n})$.

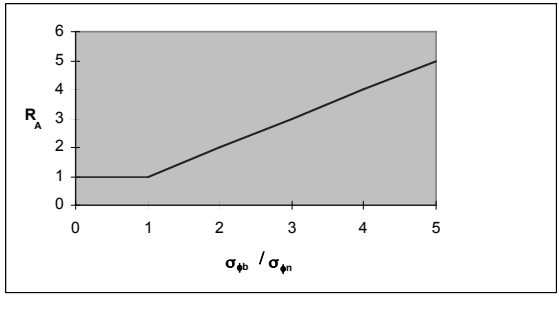

Fig. 10. Evolution of R_A versus $\sigma_{\phi b}/\sigma_{\phi n}$.

According to these assumptions, R_A, overfilling ratio of the stable sand, can be calculated based on the principles exposed previously:

a) If $\sigma_{\phi b} < \sigma_{\phi n}$, then $R_A = 1$

b) If $\sigma_{\phi b} > \sigma_{\phi n}$, then $R_A = \sigma_{\phi b}/\sigma_{\phi n}$ .In this case $R_A > 1$

Figure 10 shows the evolution of R_A with $\sigma_{\phi a}/ \sigma_{\phi n}$. R_A is related to the quotient $\sigma_{\phi b}/ \sigma_{\phi n}$. Therefore, this parameter provides the following information: if $\sigma_{\phi b} < \sigma_{\phi n}$ all borrow material is stable and if $\sigma_{\phi b} > \sigma_{\phi n}$ only the material which has a D_{50} of the borrow sand and a σ of the native or equilibrium material is stable.

The remaining sand is not only made up of stable sand, but also of 'coarse' material, still present in the nourished area. ϕ critical, ϕ_{crit}, is defined as that which differentiates the material remaining on the beach from that which has been washed away. ϕ_{crit} is defined by a parameter, Dalrymple (1992), dividuing the material that goes onshore from that which goes offshore. According to this principle, S can be calculated. the overfilling ratio of remaining sand, as the addition of stable and coarse material:

a) If $\sigma_{\phi b} < \sigma_{\phi n}$, then $S = R_A$.
b) If $\sigma_{\phi n} < \sigma_{\phi b}$, then $S = R_A/(1+\alpha.R_A)$, where α is a factor depending on native and borrow sand parameters. In this case, as a result, $S < R_A$.

From this analysis some conclusions were found:

a) If borrow material is well sorted, than the native equilibrium sand has a distribution with standard deviation of borrow sand. If it is assumed log-normal, grain size distribution after nourishment works will be $N(\phi_{50b}, \sigma_{\phi b})$.
b) If coarser material remains in the filled area, the grain size distribution is not log-normal. It is a distribution divided into stable sand, log-normal, and the coarser material.
c) Poorly sorted material is heavily resistant to wave action.
d) All existing methods for calculating overfilling ratio assume that native, borrow and equilibrium or stable sand have a log-normal distribution.

CONCLUSION

The log-normal distribution function adjusts the granulometric beach samples. The analytical method suggested by Galofre and Medina (2000) and the field data (Galofre and Medina 2001; Galofre 2001) show that any granulometric sample subjected to a turbulent action reaches a log-normal distribution. Over time, this distribution will reach equilibrium.

When the beach sample is subjected to turbulence dynamic and the process is slow, the parameters of the log-normal distribution D_{50} and σ are respectively related to the source of the sediment and the marine dynamics.

Taking into account that the equilibrium distribution is log-normal in the beach nourishment cases, and assuming that the borrow sand is log-normal, a new formula to calculate the over-fill factors R_A and S is presented.

Abstract: The Louisiana Department of Natural Resources (LDNR), along with the other Coastal Wetlands Planning, Protection, and Restoration Act (Public Law 101-646, Title III)(CWPPRA) agencies, authorized a team led by DMJM Harris to design the restoration of the West Flank of Whiskey Island. Significant among the overall project objectives are:

- Demonstrate the feasibility of using Ship Shoal sands for restoration projects.
- Restoring the integrity of the West Flank of Whiskey Island.
- Adding offshore sediment to Whiskey Island to increase sediment supply.

A key design factor was the determination of the overfill requirements, which would determine how much material had to be removed from Ship Shoal to achieve the appropriate quantity and quality of material on the West Flank of Whiskey Island after the project had been completed and conditions stabilized. There are two primary approaches to determining the overfill factor, which are described in the United States Army Corps of Engineers (USACE) 2002 Coastal Engineering Manual (CEM), (USACE, 2002). This manuscript discusses the design analysis, the decision on which approach to use, and associated results on the overfill factor chosen for this project.

INTRODUCTION

The Isles Dernieres barrier island chain, which includes Whiskey Island, is considered one of the most rapidly deteriorating barrier shorelines in the United States. The islands are not rolling over and preserving area as would be predicted by conventional coastal engineering theory. Higher retreats and loss rates are observed in the middle of the island chain including Whiskey and Trinity Islands, as compared to the ends of the chain system, which includes Raccoon and East Islands. This would indicate that the two interior islands are acting as feeders for the two exterior islands in this chain. The Isles Dernieres chain is losing its structural integrity and the capability to perform its function in the coastal and estuarine ecosystem. Chief among these is the chain's storm buffering capacity and the protection it provides to population centers, oil and gas infrastructure, inland bays, estuaries, and wetlands.

To address the potential loss of Whiskey Island, the Coastal Wetlands Planning, Protection, and Restoration Act (Public Law 101-646, Title III) (CWPPRA) authorized the Ship Shoal-Whiskey Island West Flank Restoration Project (TE-47) for funding. The federal sponsor, the Environmental Protection Agency – Region 6 and the local sponsor, the Louisiana Department of Natural Resources (LDNR), authorized a team led by DMJM Harris to design the restoration of the West Flank of Whiskey Island. The Ship Shoal-Whiskey Island West Flank Restoration Project (TE-47) is located on the West Flank of Whiskey Island 17.5 miles southwest from Cocodrie, Louisiana in Terrebonne Parish. It is bounded by Coupe Colin and Raccoon Island to the west, Whiskey Pass and Trinity Island to the east, Lake Pelto to the northeast, Caillou Boco to the north, Caillou Bay to the northwest, and the Gulf of Mexico to the south. The proposed borrow site is located entirely within Block 88 of Ship Shoal approximately 10.1 miles south-southwest of Whiskey Island in the Gulf of Mexico. The project site and the proposed borrow site are shown in Figure 1.

Significant among the overall project objectives are to:

- demonstrate the feasibility of using Ship Shoal sands for restoration projects.
- restore the integrity of the West Flank of Whiskey Island
- add offshore sediment to Whiskey Island to increase sediment supply.

This paper is a summary of the design efforts that resulted in the DMJM Harris Final Design Report (DMJM Harris, 2005) which includes the Moffatt & Nichol Final Coastal Engineering & Modeling Report (Moffatt & Nichol, 2004a), Moffatt & Nichol Sediment Suitability Assessment (Moffat & Nichol, 2004b), Soil Testing Engineers Report of Sampling Investigation, Whiskey Island (Soil Testing Engineers, 2004a), Soil Testing Engineers Report of Sampling Investigation, Ship Shoal-Block 88 (Soil Testing Engineers, 2004b).

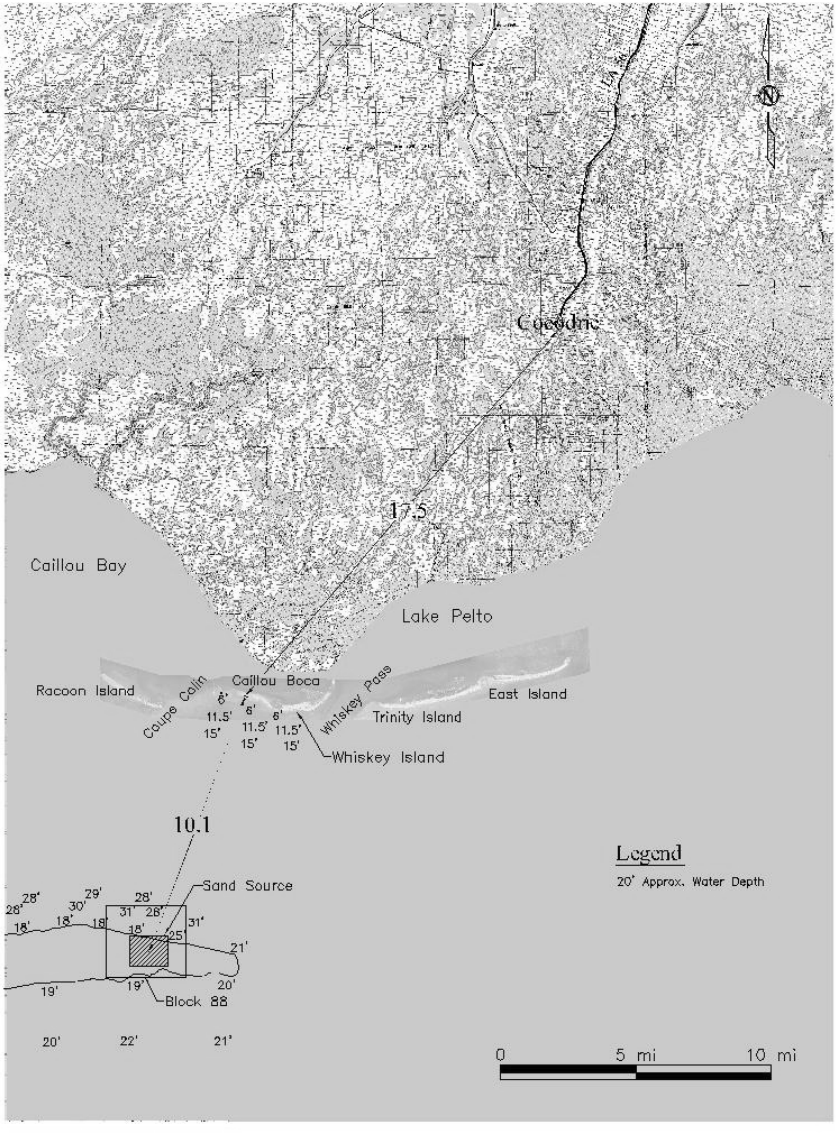

Figure 1: Whiskey Island and Ship Shoal Location

SEDIMENT INVESTIGATIONS

The Project Team concluded, based on the data presented in C&C Technologies, 2003 and Kulp et al., 2001, that the most suitable sand materials for island replenishment with Block 88 appeared to exist near the middle to southern half of the block. The Project Team developed a sediment investigation plan based on this data provided by LDNR after producing the requisite *Quality Assurance Project Plan***.** They conducted the investigation on Ship Shoal and Whiskey Island and prepared *Sand Source Maps* of potential Ship Shoal Borrow Areas showing viable sand thicknesses.

The proposed borrow site is entirely within Minerals Management Service's (MMS) designated Block 88 of Ship Shoal. In order to develop detailed information on the borrow site surroundings and soil characteristics a geophysical survey of the proposed borrow site was performed in August of 2003. The geophysical survey including 35 vibracores was completed to depths of approximately 15 to 20 feet below the mudline. The potential borrow area within Block 88 is approximately 30 million square feet in size. The hydrographic conditions across most of the borrow area site are relatively flat, with the controlling depths at approximately minus 18-feet mean lower low water (MLLW) datum. Based on the vibracores performed as part of the geophysical survey, the top nine to fifteen feet of the borrow area were determined to be a fine-grained sand, which is similar to the sand on Whiskey Island.

On Whiskey Island, the Team used intertidal and subaerial beach samples to characterize the beach and nearshore environment. Although USACE recommends a composite containing the mean high water, mid-tide, and mean low water to give the best representation of the foreshore beach, the Team determined to use samples at or above MLW and samples along the shallow crest of the West Flank to develop composite values for a more appropriate comparison of native beach materials with the Ship Shoal borrow area materials. Analysis of the Whiskey Island samples resulted in a determination that it was a moderately sorted fine sand not radically different from the Ship Shoal sand.

In performing the Ship Shoal Sediment Investigation the Project Team also determined there were no known active pipelines, fixed platforms, caissons, wellheads, or other structures within the proposed borrow area in Block 88. A sonar survey of the site did pick up eleven sonar contacts, which were mostly debris. Many additional unidentified magnetic anomalies were located by the sonar survey, all of which were assumed to be debris.

Various Grain Size Diameters

Different statistical measures are used in various models and designs to describe the sand grain distribution on barrier islands. It is useful to review the differences between

reported average median and average mean values along with what sediment data was used to compute or determine these values.

The ***mean grain size diameter*** for a sediment sample is the value estimated using the three sediment size diameters of $\mathbf{D_{16}}$, $\mathbf{D_{50}}$, and $\mathbf{D_{84}}$. The ***average mean grain size diameter*** $\boldsymbol{D_{50}}$ is computed based on the average of the mean grain size diameters for all the samples included in the sample set.

The ***median grain size diameter*** is the value in the sediment sample that has an equal number of values above and below this median value. The ***average median grain size diameter*** would be computed based on the average of the median grain size diameters for all the samples included in the sample set.

The Team developed models using the Delft3D computer modeling system for the project. Delft3D computer modeling for sediment transport and morphology requires an ***average median grain size diameter*** for the project area including supratidal and subtidal sediment characteristics. The average median grain size diameter for Whiskey Island was computed to be $D_{50} = 0.15$ mm.

DETERMINATION OF OVERFILL REQUIREMENTS

Ideally, the borrow sediment used in restoration projects should be texturally similar to the native sediment of the coastal area to be restored (Louisiana Gulf Shoreline Restoration Report, 2003). While the average mean and average median grain sizes of the Whiskey Island and Ship Shoal borrow material are close, of course, the grain size distribution of the borrow material does not exactly match the grain size distribution of the native material at Whiskey Island. Therefore, an analysis was required to assess the compatibility of the two materials from a functional perspective. Borrow material placed on the beach will undergo sorting as a result of the coastal processes; and given enough time, will approach the native grain-size distribution. The portion of borrow material that does not match the native sediment grain-size distribution is assumed to be lost to the offshore.

Included in the design were a ***Sediment Suitability Assessment*** and ***Basis of Design Determination***. The Project Team sampled sediment on Whiskey Island and Block 88 of Ship Shoal and developed composite statistics for the beach material at Whiskey Island and compared them to composite statistics for each potential borrow area to assess the materials' compatibility.

A key design factor was the determination of the overfill requirements, which would determine how much material had to be removed from Ship Shoal to achieve the appropriate quantity and quality of material on the West Flank of Whiskey Island after the project had been completed and conditions had stabilized. The CEM describes two primary approaches to determining the overfill factor (USACE, 2002).

One method is based on the equilibrium beach profile concept, an assessment of storm-induced erosion, and an assessment of wave-driven longshore transport losses. The equilibrium beach profile concept is based on a single grain size parameter, the ***average median grain size diameter*** and does not consider the natural variations in grain size that occur in natural and nourished beaches.

The other method, which we will call the CEM method for computing the overfill requirement, consists of calculating relationships between the mean and standard deviations of the φ (phi)-scale grain size distributions of the native beach and the borrow site and then computing an overfill factor. Borrow material placed on the beach will undergo sorting as a result of the coastal processes and, with time, approach the native grain-size distribution. The portion of borrow material that does not match the native sediment grain-size distribution is assumed to be lost to the offshore (USACE, 2002). The CEM has adopted this concept and recommends the use of an overfill factor (R_A) as "*the volume of borrow material required to produce a stable unit of usable fill material with the same grain size characteristics as the native beach sand.*" Conceptually the overfill material is the estimated quantity of material that does not fit the native beach and will be washed away.

The overfill factor is a way of computing the fill volume when the borrow and native sediments have different gradation characteristics. The overfill factor method is based on the assumption that sorting processes will selectively remove borrow material from the various size classes until a stable grain size distribution results. The closer the overfill factor is to 1.0, the more appropriate is the borrow site selected.

It should be noted that the overfill factor is different from the cut-to-fill factor, which accounts for losses in the dredging and placement process, not for differences in the grain-size distribution of the material. The cut-to-fill factor was considered in the design process to determine the volume of materials required to be removed from the borrow area. Most beach fill projects assume that dredging payment will be based on gross fill volumes as opposed to measured cut volume at the borrow site. Dredging contractors typically estimate this and other dredging process inefficiencies and account for them in their cost estimates and bids. A conservative cut-to-fill ratio factor of 1.7 was considered in the design process for sizing and permitting the limits of the borrow area. The Sand Source Borrow Area was delineated to use those portions of the borrow material that would yield lower overfill factors.

The total dredgeable material available within the specificed limits of the Sand Source Borrow Area is 6.61 million cubic yards. The estimated quantity to be placed on the project site for bidding purposes is 3.85 million cubic yards.

Design Results

Sediment compatibility was analyzed between sediment from Ship Shoal to be placed on Whiskey Island and the native material of Whiskey Island. The Project Team analyzed

the sediment compatibility using the two methods to determine sediment compatibility and the overfill factor for the design of the project fill volume.

The first method, the equilibrium beach profile concept, compares the ***average median grain size diameter*** for the samples at or above Mean Low Water (MLW) with samples taken along the shallow crest of the present West Flank of Whiskey Island to the average median grain size diameter of the sand from Ship Shoal. The average median grain size diameter for the West Flank of Whiskey Island is a D_{50}= 0.20 mm. The average median grain size diameter from the proposed borrow area of Ship Shoal is a D_{50}= 0.20 mm. Using this method the overfill requirement would be equal 1.0. This methodology suggests that additional borrow material would not be required and no additional overfill would be placed on the island during construction.

The second method for determining the overfill factor, the CEM Method correlates the ***average mean grain size diameter*** for Whiskey Island (a D_{50} = 0.19mm) with the ***average mean grain size diameter*** from all the vibracore locations in the investigated borrow area on Ship Shoal.

Overfill factors were computed using data from each of the borrow area vibracores. For each vibracore, composite characteristics in phi (φ) units including the mean (M_φ) and standard deviation (σ_φ) were developed for the upper sand layer within the Ship Shoal borrow area. These characteristics were used as input to the Coastal Engineering Design and Analysis System (CEDAS) software package developed by the USACE to compute the overfill factors for each vibracore. The values are presented in Table 1.

This method produced an average overfill factor of **1.2** to be used for the design of the project fill volume required. This average overfill factor provided 1.2 units of borrow material to create 1.0 units of stable native Whiskey Island material

Since the first methodology is based on a single grain size parameter and produced a placement factor of 1.0 and the CEM Method considered the distribution of grain sizes spread around the mean and produced a more conservative overfill factor, the Project Team determined that the CEM method was the more prudent method for this project. The entire design process underwent detailed reviews by LDNR that included a thorough vetting with concerned state and Federal agencies.

The methodologies are based on variable data. The 35 vibracores on Ship Shoal on an individual basis yielded overfill factors from 1.00 to 1.50. The average overfill factor of 1.2 will be used for the project. Several poorly sorted (well graded) samples with relatively coarse mean grain sizes have overfill factors near or equal to 1.0. All samples had overfill factors less than 1.53, with the majority close to the average value of 1.2.

This means that there will be variability in the performance of the fill over time as dredged material differs depending on the specific location within the source area. The Project Team used this information to design the borrow area so as to remove the most

consistent material first and increase the probability of the long term volume retention of the material placed on Whiskey Island and improve the degree of successful restoration.

The mean sediment diameters (M_φ) and standard deviations (σ_φ) for the native (*n*) and borrow materials (*b*), were computed as follows:

$$M_\phi = \left(\frac{\phi_{16} + \phi_{50} + \phi_{84}}{3} \right) \quad (1)$$

and

$$\sigma_\phi = \left[\left(\frac{\phi_{84} - \phi_{16}}{4} \right) + \left(\frac{\phi_{95} - \phi_5}{6} \right) \right] \quad (2)$$

where:

$\sigma_{\varphi n}$ = standard deviation or measure of sorting for native material.
$\sigma_{\varphi b}$ = standard deviation or measure of sorting for borrow material.
$M_{\varphi n}$ = mean sediment diameter for native material.
$M_{\varphi b}$ = mean sediment diameter for borrow material.

CONCLUSION:

It is feasible to use Ship Shoal sands for restoration projects in the Isles Dernieres. Projects using the sediments available on Ship Shoal can be used in barrier island restoration with the proper design. In this case, the project will restore the integrity of Whiskey Island in the near-term. Replacing lost sediment without changing the regional hydrogeomorphology probably means the island will erode again over the long-term. On the other hand, adding approximately 4 million CY of offshore sediment to Whiskey Island will increase the overall sediment supply in the coastal zone of the Isles Dernieres.

In reviewing the two methods to determine the appropriate volume to be placed on Whiskey Island, the Design Team recommended that the method that provided an overfill factor of 1.2 be used. LDNR has approved this design recommendation, which will increase the probability of the long-term volume retention of the material placed on Whiskey Island and improve the degree of successful restoration.

The project specifications require that pre and post topographic and bathymetric surveys will be taken along the Plan transects. These surveys will be used to calculate the volume of fill placed on the project site.

It is also recommended that periodic continued topographic and bathymetric surveys be conducted in order to measure the movement and performance of the island. These subsequent surveys could be used to also estimate the rate at which material is lost from the island during its post restoration life and verify the accuracy of the overfill factor, which was selected.

ACKNOWLEDGEMENTS

The authors appreciate the cooperation of LDNR and the other CWPPRA agencies for their efforts that encouraged the whole design process to undergo their thorough review. The authors acknowledge and thank all the design team members for their design contributions especially Moffatt & Nichol Engineers. Finally the authors thank DMJM Harris for their permission to present this manuscript.

Abstract: Broward County relies on its beaches to attract tourists but 21 of the 24 miles of Broward beaches are defined as critically eroded. The Broward County Office of Waste and Recycling Services processed approximately 15,000 tons of glass each year and is searching for beneficial use of this material. The Broward County Beach Demonstration Project is investigating the feasibility of using recycled glass to augment the shore protection program needs, specifically in areas of higher relative erosion (hotspots). The addition of glass cullet as emergency beach fill may extend the life of the shore protection project by nourishing these areas with smaller volumes of fill. This paper details investigations performed to date including a literature review, geotechnical investigation, biological analyses, public perception research, and abiotic testing and shows that glass cullet is a viable beach compatible material.

INTRODUCTION

Broward County has conducted numerous beach nourishment programs since the early 1960's because its beaches are in a chronic state of erosion. Significantly, 21 of the 24 miles of Broward beaches are defined as critically eroded (Florida Department of Environmental Protection, 2000). Broward County has several potential sources of beach compatible sand including offshore inter-reef sedimentary infills, upland dune, inland sources, and aragonite sand from the Bahama Banks to provide fill for these

projects. However, the Broward County Office of Waste and Recycling Services processed 15,840 tons of glass in 2004 at cost of $145,000 (Austin, 2004) and is searching for a beneficial use of this material. Broward County is implementing a demonstration project to determine the feasibility of using recycled glass as beach-compatible material. This material could supply, on an emergency basis, some of the volumetric needs of the County's shore protection program while providing another market for recycled glass.

It is proposed to use glass cullet as a potential alternative source material for beach fill. Glass cullet has physical properties similar to natural silica sands, making it a viable alternative beach fill material along critically eroded shorelines (Finkl and Kerwin, 1997; Kerwin, 1997). Recycled glass cullet has many advantages as a potential alternative beach fill material including:

1. The ability to mechanically select grain sizes comparable to the native beach characteristics;
2. Chemical, mechanical, geologic, and engineering properties of appropriately sized glass cullet are similar to natural sand;
3. The ability to utilize a readily available recycled product;
4. Proactive implementation of a comprehensive recycling program;
5. Utilization of an environmentally safe, inert material.

Despite the potential advantages of glass cullet, additional investigations were necessary prior to placing this material on the beach. The Broward County Beach Demonstration Project has completed a literature review (Thomson *et al.*, 2004a), geotechnical investigation (Thomson *et al.*, 2004b), public perception research (MARS Research, 2004), biological analyses (Makowski *et al*., 2005), and abiotic testing (Makowski *et al*., 2006). This paper outlines the findings from these investigations.

LITERATURE REVIEW

Due to the limited secondary materials market and increasing cost of recycling glass, the Broward County Commission, Office of Waste and Recycling Services conducted a pre-feasibility study on using recycled glass as beach fill material (Malcolm Pirnie, 2003). This study concluded that using glass cullet as beach fill material was a viable concept and recommended that further studies be conducted. A feasibility study for Moonlight Beach, California, conducted by Woodward-Clyde (1993), also showed that glass cullet was a viable beach compatible material.

Studies conducted at Texas A&M University compared the performance characteristics of recycled glass to natural sand (Edge, 2002) in physical model experiments where a 3-D wave tank generated regular waves. The tank was divided into two channels: one for a glass beach and the other for native beach sand. Six tests measured beach profile change due to wave action in the tank. At the end of the test, glass cullet and native beach sands were found to have the same performance characteristics for the conditions tested. The wave reflection coefficient for glass cullet was less than native beach sand, suggesting that glass cullet absorbs energy better than sand.

Also investigated was the rate of abrasion and loss of mass through abrasion (Edge, 2002). A tumbler machine was used to simulate wave action, current, and wind. This experiment measured mass loss for two samples: one was glass only and the other was a mixture of glass plus sand. The latter combination was an attempt to simulate real world effects where the glass cullet and sand are mixed. The glass and sand/glass samples were placed in the tumbler machine with water. After several days of tumbling, the samples were sieved and dried. Grain sizes less than sieve #200 were removed from the sample. Masses were measured after 7, 14, and 36 days of tumbling. These tests showed that the glass-only sample had a very high initial rate of abrasion, but the rate eventually stabilized and was comparable to the glass/sand mixture.

Glass cullet has been placed on two beaches on the Caribbean island of Curaçao, at the Hilton Hotel on Piscadera Bay (southern coast near downtown Willemstad) and at Zanzibar Park (also on the southern coast). Grain sizes of the cullet placed on these beaches ranged from 0.20 mm to 0.60 mm (Paardekooper, 2004).

The volume of glass cullet placed at the Hilton Hotel is unknown, but approximately 110 cubic yards of glass cullet was mixed with native beach sand in a 1,000 square foot area at Zanzibar Park (Paardekooper, 2004) along with a control section of 100% cullet. According to Paardekooper (2004), beachgoers preferred the beach sand - glass cullet mixture compared to the control plot with only glass cullet. This study noted, however, that visitors did not distinguish between sections of the beach that had varying ratios of natural sand to glass cullet. Turtle nesting occurred at both sites but there is no official data available from the local government agency regarding nesting or hatching success (Paardekooper, 2004).

A glass cullet beach was also constructed in the Town of Lake Hood, New Zealand. The Town created a beach using recycled glass cullet to encourage recycling and to increase environmental awareness (Temple, 2004). The lake is man-made, and WasteBusters Trust Canterbury constructed a beach for a festival in January 2003. The "Crystal Beach," composed entirely of glass cullet, is reported to look and feel like natural sand (WasteBusters, 2004).

Literature on two other "glass beaches" was also found. The one in Fort Bragg, California was the site of an old dumpsite. This practice was halted and large items such as cars and refrigerators were removed. Eventually, wave action washed out many of the paper products leaving glass that has become rounded over time. Near the Town of Port Allen on the island of Kauai, Hawaii, there is a beach composed of winnowed glass fragments. The site was a former dumping ground for glass bottles. Reworked by wave action, the glass has been comminuted and reduced to pebble size. However, neither of these beaches is representative of the type of material that is proposed for use on Broward County's beaches.

GEOTECHNICAL INVESTIGATIONS

Geotechnical investigations were conducted to determine grain-size distribution, Munsell color, carbonate content, grain angularity, and chemical analyses for potential contaminants in beach sand and glass cullet. Six samples of beach sand were collected from a back dune area at the southern end of the broad walk on Hollywood Beach, City of Hollywood Beach, Broward County, Florida (following the Broward County Segment III Shore Protection Project). Beach samples, collected as part of the Broward County Shore Protection Project General Reevaluation Report (Coastal Planning & Engineering / Olsen Associates Joint Venture, 2003) were also included in the comparison. Samples of glass cullet were obtained from three manufacturers including: Andela Products Ltd., Richfield Springs, NY; Glass Aggregate Systems, Faribault, MN; Recycle America Alliance, New Haven, CT.

The manufacturers were requested to provide pulverized glass samples that were similar to the grain size distribution of the natural sand along the Hollywood, Florida beaches. The results of the grain size analysis are summarized in the Table 1 below.

Table 1. Summary of Grain Size Analyses.

Sample	Mean Grain Size (mm)	Sorting	Percent Fines [2]
Beach Samples			
Sample #1 (surface)	0.50	0.74	1.7
Sample #2 (-1.5 ft)	0.47	0.76	1.1
Sample #3 (-3ft)	0.46	0.86	0.7

1. CPE/Olsen J-V, 2003
2. Percent material passing the #230 sieve.

Table 1 shows that there was a range of mean grain sizes produced by the glass cullet manufacturers that bracketed the grain size values observed for the beach samples. Equally important is that the percent fines was low. The Florida Department of Environmental Protection (FDEP) requires that beach fill sediments contain no more than 5% fines (silt plus clay).

Public perception and FDEP requirements require that glass cullet looks like beach sand. A Munsell Color analysis was performed and the results are summarized in Table 2.

Table 2. Summary of Munsell Color Analysis.

Sample	Munsell Color Value		Munsell Color Description	
	Dry	Wet	Dry	Wet
Beach Samples				
Sample #1 (surface)	10YR 7/1	10YR 6/2	Light gray	Light brownish gray
Sample #2 (1.5 ft)	10YR 7/2	10YR 6/3	Light gray	Pale brown
Sample #3 (3ft)	10YR 7/2	10YR 6/3	Light gray	Pale brown
Sample #4 (surface)	10YR 7/1	10YR 6/2	Light gray	Light brownish gray
Sample #5 (1.5ft)	10YR 7/2	10YR 6/2	Light gray	Light brownish gray
Sample #6 (3ft)	10YR 7/2	10YR 6/3	Light gray	Pale brown
Glass Cullet Samples

Glass Aggregate Systems	2.5Y 8/3	5Y 6/4	Pale yellow	Pale olive
Recycle America Alliance	10Y 8/1	5Y 6/3	Light greenish gray	Pale olive

Beach sands can be broadly categorized by their chemical composition into either carbonate beaches ($CaCO_3$) or siliciclastic/quartz (SiO_2) beaches. The beaches in Broward County are a mixture of bioclastic carbonate sands (coquina shell fragments, reef fragments, and skeletal fragments of marine organisms) and silica sands in the form of quartz (Coastal Planning & Engineering / Olsen Associates Joint Venture, 2003). The carbonate content is important because carbonate sands perform differently than silica sands due to different intraparticle porosities, density, bulk density, and structural integrity of carbonate grains (Halley, 2000). In Miami-Dade County, weathering of carbonate sands produces sediments with higher concentrations of silt and clay sized material, which results in elevated turbidity levels in the nearshore zone (USFWS, 2002). Glass cullet avoids these issues because it is composed primarily of silica-based compounds and fines can be controlled prior to placement on the beach.

The average carbonate content of the beach samples was 70%, but ranged from 61% to 84%. The glass cullet samples were not tested for carbonate content because they are chemically 100% silica.

The angularity, or roundness, of individual grains affects sediment settling and motion initiation. It can also be important as a public perception issue. Sample grains of the beach sand and glass cullet were placed under a microscope and visually examined to determine grain angularity using Power's visual classification (Powers, 1953). The existing beach sand is rounded to sub-angular with both high and low sphericity values while the glass cullet was very angular with low sphericity. Edge (2002) showed that glass cullet abrades but that the rate of abrasion decreases and stabilizes with time. Therefore, the angularity of the glass cullet can be expected to decrease over time. Angularity is not expected to have a significant impact on the performance of the glass cullet as beach fill.

FDEP requires that for fill material to be considered beach-compatible that it must not contain toxic material, as specified in Section 62B-41.007 (2)(j)(4) of the Florida Administrative Code. Glass cullet and beach sands were tested for contaminants as part of the geotechnical investigations. Beach sands were used as a control or guide to general background contaminant levels to which the glass cullet would be compared. Tests were performed to detect the presence of lead (Pb), mercury (Hg), total coliform, fecal coliform, enterococci bacteria, 85 semi volatile organics (8270C test), petroleum hydrocarbons (FL-PRO test), and total salt content. Only 5 of the semi-volatile organics registered and these were all below the FDEP (2001) level for direct residential exposure.

PUBLIC PERCEPTION

A public perception investigation was performed by MARS Research (2004) to determine whether the concept of using glass cullet would be accepted by the public. The analysis was broken into three parts: a focus group meeting with beach professionals; a focus group meeting with tourism representatives; and a random phone survey of over 400 Broward County representatives.

The beach professionals were most skeptical about the concept. Most of their concerns did not appear to be with the concept of using recycled glass but of the likelihood that it could be permitted. Interestingly, once the beach professionals were shown a sample of the glass cullet, they adopted a more positive attitude. The beach professionals had several questions regarding the performance of the glass cullet that could not be answered at the time, as most of the investigations presented in this report had not been performed yet. These questions included the similarity of glass cullet to natural beach sand with respect to abiotic and environmental factors.

Overall, the tourism professional focus group was supportive of the concept. Their primary concern was erosion of the beaches, which is obviously one of the key reasons that tourist visit Broward County.

The phone surveys showed that there was support from the public with 89% approving of the concept (45% completely approved, 35% somewhat approved, while 9% disapproved). Overall, the findings were that using glass cullet for beach nourishment is appealing, interesting, and relevant to the public.

BIOLOGICAL ANALYSES

In response to a directive from the Florida Fish and Wildlife Conservation Commission (FFWCC) and FDEP, the CPE team developed a phased scientific investigative program to evaluate material effects on invertebrate and vertebrate (fish) biotic community assemblage. Other studies have demonstrated that experimental bioassays can accurately detect either adverse or benign effects on marine organisms (Peters *et al.*, 2002; Ringwood and Keppler, 2002). In addition, State resource protection agency representatives have suggested that the habitation and colonization of lower invertebrates may serve as a good indicator of the effect recycled glass cullet will have on higher vertebrates. These investigations were undertaken to validate the hypothesis that recycled glass cullet is a viable beach fill alternative to more traditional sand sources. A complete record of this study and the data found are presented in Makowski & Rusenko (in press).

The objective of the biological investigation was to monitor the colonization and survivability of lower invertebrates and fish, through experimental bioassays, in various cullet mixtures. A saltwater flow system was utilized to simulate natural beach conditions within each test matrix. Direct observations and supplemental chemical analyses were conducted to determine whether recycled glass cullet has an affect on biological communities.

Five combinations of glass cullet and beach sand were investigated: 100% beach sand, 75% beach sand/25% glass cullet, 50% beach sand/50% glass cullet, 25% beach sand/ 75% glass cullet, and 100% glass cullet. Saltwater, obtained through the Gumbo Limbo Nature Center oceanic intake system, was delivered through a network of PVC pipes to each test container and provided a constant supply of fresh saltwater (approximately nine water changes over a 24 hr period) to the marine organisms and sediments. Each combination of sand/cullet had three replicate containers. Photo 1 shows three of the containers used to perform the bioassays.

Species introduced into each test matrix were collected or supplied by the Gumbo Limbo Nature Center of Boca Raton, Florida, and included local representative microfauna (i.e., copepods, ostracods, nematodes) and macrofauna organisms (i.e., crustaceans, mollusks, fish). All testing and recorded observations were conducted from May to July, 2005, at the Gumbo Limbo Nature Center.

Macrofaunal organisms were allowed a 24-hour acclimation period before monitoring was initiated. Live marine shrimp were added weekly as a source of food, and uneaten material was not allowed to accumulate in the containers. Biological monitoring of macrofaunal test organisms were conducted through direct visual observations performed at least twice per week for the duration of the study. Macrofauna success rate was calculated by taking the proportion of survived individuals over the total number of individuals introduced to a specific sediment matrix. A complete census of all individuals was taken on a weekly basis.

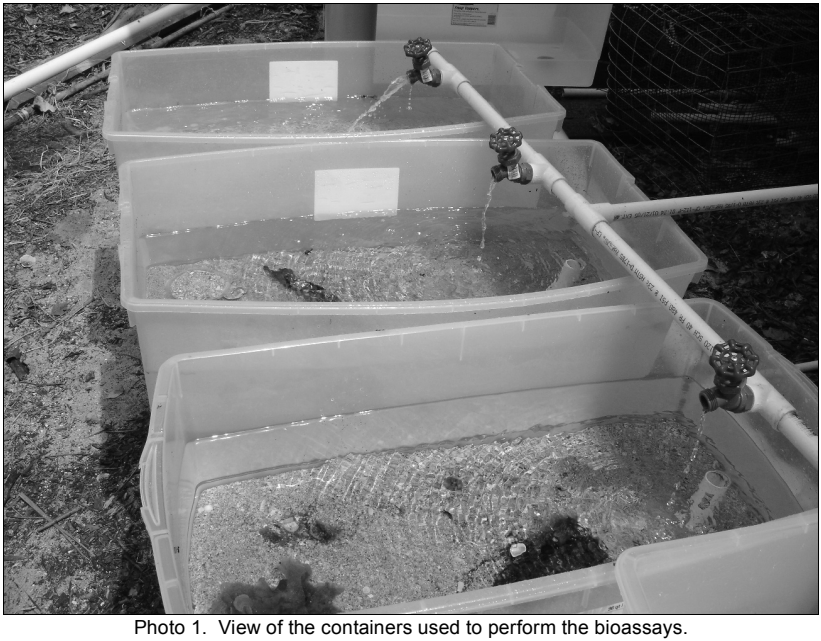

Photo 1. View of the containers used to perform the bioassays.

Microfauna organisms were introduced to each test container by taking a five pound sample of 'live' sand from established (nitrogen cycled) reef display tanks located at the Gumbo Limbo Nature Center. A one-week acclimation and colonization period was allowed before monitoring was initiated.

Biological monitoring of microfauna test organisms was conducted through interstitial core analysis. A 50.1 g interstitial core sample was extracted from each test matrix using a 0.5m long piece of ½ inch PVC pipe and a stopcock. Core samples were taken on a weekly basis and analyzed for the presence/absence of microfauna under a trinocular video microscopy system at a total magnification of 400x. Identification of microorganisms was through external characterization, and active status of individuals was digitally documented.

An important and unexpected observation during the study was the formation of a blackish film that began to develop on the different cullet sediment mixtures after three weeks of testing, first starting on the 100% cullet and then appearing on all the other experimental series, including the controls near the end of the testing period. Further analysis determined that the black film was a precipitation of hydrogen sulfide. This anaerobic sulfide-reducing process has been documented in stagnant coastal waterway systems that lack influential wave action (Carlson *et al.*, 1994). However, when

sediments containing the cullet were mixed and allowed to aerate by directing water movement into the substrate (wave simulation), the visible hydrogen sulfide accumulations disappeared, and no microbial zonation was detected. Hydrogen sulfide test readings also showed that levels were decreased after the wave simulation and aeration was initiated.

After a two-month exposure to glass cullet sediments, it was determined that the artificial cullet substrate did not adversely affect macro-organism habitation or micro-organism colonization. This was evident with the uniform lack of mortality observed in the introduced individuals and the active presence of interstitial microfauna.

Individuals displayed normal active behavior within the cullet matrices and showed no adverse signs of physical stress. Of particular note, was the use of the cullet as defensive camouflage by the test crustaceans and mollusks. In order to shield themselves from predators or direct UV light, the sargassum and blue crabs would thrust their carapaces backward into the cullet until they were completely covered. This behavior was shown repeatedly over the testing period with no harm to the crabs. Similarly, whelks would burrow deep into the cullet as a protective measure, and would do so with no observed injury to their foot or mantle.

Microscopic analyses revealed that colonization of interstitial microorganisms were successful within the cullet mixtures. All the same classes of microorganisms were observed in the control as well as the experimental replicates. Interstitial movements were documented and showed that microorganisms were able to actively transport without adverse effects. Uniform colonization of the sediment mixtures was also reaffirmed by the consistent organic content readings in all the test series.

ABIOTIC ANALYSES

Supplemental testing of abiotic factors was deemed necessary by the FFWCC and FDEP to document the acceptability of glass cullet as an alternative beach fill material. The abiotic factors of temperature, humidity, and gas exchange are considered the most important abiotic variables affecting the survival of reptilian embryos (Ackerman, 1980, 1991; Miller, 1985; Packard and Packard, 1988; Maloney *et al.*, 1990; Mortimer, 1990). In this case, sea turtles were identified as the species of concern. Florida serves as one of the most important nesting environments for sea turtles in the United States, with more than 50,000 nests annually. When an alternative sediment type is introduced to the system, the main concern is that a foreign incubation environment may be produced. Sand acts as a barrier through which water vapor, carbon dioxide (CO_2), and oxygen (O_2) diffuse and dissipate heat. For incubation to be successful and produce hatchlings onto the beach surface, the nest environment must facilitate embryonic development (Georges *et al.*, 1993). Minute differences in temperature, moisture, and gas exchange have the potential of dramatically affecting the sex ratios and survivability of sea turtles during their developmental stages (Mrosovsky and Yntema, 1980; Standora and Spotila, 1985; Mrosovsky, 1988).

The purpose of this *in situ* study was to determine if glass cullet mixtures exhibit the same abiotic characteristics (temperature, moisture content, and respiratory gas exchange) when compared to the current beach sediments. Within the glass cullet, the synergism between moisture, temperature, and gas exchange must be similar to natural beach conditions in order to avoid impacts to the development of embryos during incubation. A complete record of this study and the data found are presented in Makowski *et al.* (in review).

A test plot was constructed on a beach in the City of Hollywood Beach, Broward County, Florida in March 2006. The test plot was 12 m (40 feet) long, 3 m (10 feet) wide, and 1 m (3 feet) deep. Sixteen individual test sections (4 sections for each of the 4 natural beach/glass cullet mixtures) were constructed within the test plot. Each section was 1.5 m (5 feet) by 1.5 m square and 1 m (3 feet) deep. The four natural beach/glass cullet mixtures tested were 100% beach sand, 75% beach sand/25% glass cullet, 50% beach sand/50% glass cullet, and 25% beach sand/75% glass cullet. Photo 2 shows the test plot with each individual section roped and labeled.

Photo 2. A view of the test plot with the rope demarking varying mixture sections.

Using three programmed data loggers placed in each of 16 simulated nests within the native sand/glass cullet matrix, measurements are obtained at the bottom, center, and near the top of each monitoring section. The data loggers collected specific

measurements on temperature and relative humidity every half hour. In addition to the temperature and humidity measurements, gas probe samples are analyzed weekly for O_2 partial pressures (gas exchange) using an oxygen gas analyzer.

After a 171 day testing period (March to August 2006), it was determined that all glass cullet test sections offered a suitable nesting environment for incubating sea turtle embryos based on the measured abiotic factors . Temperature in the glass cullet sections was found to be insignificantly different from the native beach sand controls. All sections, experimental glass cullet and control, logged similar dew point temperatures and relative humidity readings that would allow sea turtle eggs the necessary moisture during incubation. And gas probe samples taken from all the experimental cullet test section recorded high concentrations of oxygen, with no significant variations from the beach sand controls.

UPCOMING WORK

The next step of the project is to place glass cullet along the beach and determine how it performs. A proposal to place and monitor approximately 765 m^3 (1,000 cubic yards) along the beach in The City of Hollywood, Broward County is currently being reviewed by Regulatory Agencies.

CONCLUSION

The analyses conducted to date show that glass cullet is a viable, beach compatible, fill material. The geotechnical analyses suggest that the grain size, color, percent fines, and angularity of glass cullet are sufficient to characterize the material as beach compatible. Contaminant analyses show that the material is clean. The public perception research suggested that the public is amenable to the concept of using glass cullet as a source of beach fill. Biological and abiotic testing both suggest that there will be no impact to microfauna or macrofauna communities, and that sea turtle embryo development will not be impacted due to the use of this material upon the beach.

ACKNOWLEDGEMENTS

We would like to acknowledge the Broward County Commission Office of Waste and Recycling Services and the Florida Department of Environmental Protection for their funding and support of this project. The Broward County Environmental Protection Department has provided valuable assistance in the development of the program and technical contributions. We would also like to acknowledge Malcolm Pirnie, Inc for leading this project. Gumbo Limbo Nature Center has provided facilities to conduct several of these investigations and Dr. Kirt Rusenko has provided time and insight into the biological aspects of the work.

Abstract: This paper presents the analysis of the evolution of the Cancun Beach Nourishment, in Quintana Roo, México. The nourishment project was based on the analysis of four beach profile sets (1985, 1989, 2000, and 11/2005, after hurricane Wilma), high resolution satellite images, wave data and native sediment samples from Cancun Beach. After Wilma the remaining sand volume was approximately 0.5x106 m3, with beachwidth of only 10 to 17 m. Although the nourishment sediment volume ($2.7x10^6$ m^3) was limited by the available federal budget, the design dry beach width was estimated to be between 22 and 28 meters. After nourishment, three beach profile sets were analyzed (April, August and November 2006), as well as the associated morphodynamic state. At present, the beach profile tends to a pre-Wilma natural slope. This process is however decreasing the dry beach width to find a stable state along the beachface.

INTRODUCTION

The beach of Cancún as most of the Mexican beaches are dominated by erosion processes, associated with world climate change, form of the beachface, sediment characteristics and the occasional but not less important the effects of strong hurricanes striking the region like Gilbert in 1988 and Wilma in .2005.

Previous studies have determined that under normal wave conditions Cancún beach is dissipative, according to the morphodynamic state classification proposed by Wright and

Short (1984). This morphodynamic state changes when a meteorological extreme event like a cold front or hurricane occurs. The beach response to these events is strong but not uniform. In fact, the erosion is stronger in the Northern zone of Cancún beach, near Punta Cancún, than in the south near to Punta Nizuc (see Fig. 5). This erosion process, translates in the sediment being transported toward the lower areas of beach profile (offshore) forming longshore bars wich in turn play an important role protecting the beachface and keeping the sand within the closure depth. These events change the beach from "dissipative" to a "dissipative and lonsghore bar-trough". See Fig. 1 and Fig. 2.

Fig. 1 Cancún Beach before nourishment

Fig. 2 Cancún Beach after Nourishment

During the storm, waves are larger and the closure depth shifts offshore to deeper areas. After the storm, the longshore bar-trough state evolves to the initial state (dissipative), and the original closure depth is also reestablished. However, these are inevitably some loss of sand because one part of the material was transported beyond this original closure depth during the storm.

This process has been observed through the last 20 years. During this period the two most important hurricanes on record ocurred: Gilbert in 1988 and Wilma in 2005. Both hurricanes were classified as category five in the Saffir-Simpson scale. Particularly, after Wilma in October 2005, the beachface (from Punta Cancun to Punta Nizuc, a 12 km long) lost approximately 5.5 millions m^3 of sand with zones showing only with a 10 to 17 meters dry beach widths (Fig. 3). and zones without dry beach, as shown in Fig. 4.

Fig. 3 Cancún Beachface with a 17 meters of Dry Beach. After Wilma

Fig. 4 Beachface without Dry Beach. After Wilma

Due to the beach condition after hurricane Wilma, and the importance of this resort to México (the most important tourist destination), an emergency project of nourishment was implemented. The objective was to rehabilitate the beach profile with to produce a dry beach width between 22 and 28 meters along to the coastal front from Punta Cancun to Punta Nizuc. The final project and supervision contract was assigned to CFE ("Comisión Federal de Electricidad"). CFE gathered and analyzed beach morphodynamics studies during the last 20 years, as well as the most recent bathymetric surveys, to evaluate the dynamics of the processes responsible of the beach behavior and its response to an extreme wave climate occurrence. Furthermore, the aim of the project

surveys, to evaluate the dynamics of the processes responsible of the beach behavior and its response to an extreme wave climate occurrence. Furthermore, the aim of the project was to identify the evolution of the morphodynamic states by means of Benedet´s (2004) procedure implementation to identify boundary conditions which characterize the beach in terms of these morphodynamic states. Finally, the observation and analysis of the beach profiles, contributed to determine the morphodynamic evolution after the nourishment works and to find possible long-term solutions to the erosion problem.

STUDY AREA

Cancún beach is located in the Mexican southeastern state of Quintana Roo, and it belongs to the Municipio Benito Juarez (Fig. 5). It is a headland beach, confined to the North by Punta Cancun (21°,07',08''N, 86°,44',25''W) and to the South by Punta Nizuc (21°,02',07N, 86°,46',38''W). It is bounded to the North by Bahia de Mujeres, to the East by the Caribean Sea and to the West by Nichupté Lagoon.

The study zone is a littoral barrier beach, and it has a 12 kilometer beachface. Its native beach sediment is mainly of biogenic origin, with mean grain size between 0.22 and 0.55 mm. Due to the erosion processes, the beachface is not in dynamic equilibrium. Historically, several hurricanes have hit the project area, accelerating the erosion processes considerably, such as Hurricanes Gilbert in 1988 and Wilma in 2005.

Before Hurricane Gilbert Punta Nizuc Punta Nizuc showed a 57 meters beach width with a sand volume of 10.5×10^6 m^3 (CFE, 2006), as shown in Fig. 6. After hurricane Gilbert occurrence the mean beachwidth decreased to 35 meters, with a sand volume of 6.0×10^6 m^3 (i.e., 4.5×10^6 m^3 were lost). Seventeen years later Hurricane Wilma hit Cancun beach again increasing considerably the erosion problem along the project area, so the sand loss was estimated in additional 5.5×10^6 m^3, therefore the remaining sand volume in the beachfront was approximately 0.5×10^6 m^3. The mean grain diameter (d_{50}) was 0.24 to 0.32 mm.

Fig. 6 Punta Nizuc in 1985, before Hurricane Gilbert.

Preliminary Studies (Coast Line Evolution)

The erosion process caused by hurricane Wilma along the project area was analyzed by CFE using high resolution satellite images. In Fig. 7 to 12 the red line shows the coastline before hurricane Wilma and the blue one shows the coastline after Wilma. Fig. 7 to 12 show the beach width loss which varies between 7 (South zone) and 32 m (central zone). Table 1 summarizes the beach width loss with 21.68 m as a mean value.

Emergency Beach Nourishment Project

The emergency beach nourishment project was performed by the CFE Oceanography Department. The main objective was to restore the beach profile along the 11.6 kilometers of Cancún Beach. According to CFE's preliminary design and the first bathymetric survey after Wilma, the design width was estimated to be between 22 and 28 meters, with a construction width of 60 meters.

The sand volume estimate for the Cancun beach nourishment was the result of assessing the sediment transport rate by waves and currents, as well the native and fill sediment characteristics. The nourishment volume of sediment was unfortunately restricted by the available federal budget (U.S. $ 20 Million) which corresponded to only $2.7x10^6$ m^3 of sand. The borrow area was located 30 kilometer NE of the project area with a 30 m mean depth.

Post Construction Monitoring Cancun Beach

For the nourishment Project CFE analyzed the coastline evolution from bathymetries surveyed in 1985, 1989, 2000 and 2005. In addition three more detailed bathymetries were performed by CFE on April, August and November 2006, after the nourishment.

The detailed beach profile analysis was made every 100 m, with a starting point on 0+600 m and a final point on 12+100 m, on Punta Nizuc. In order to save space 6 beach profiles were selected to show the applied methodology, and they are shown in Fig. 13.

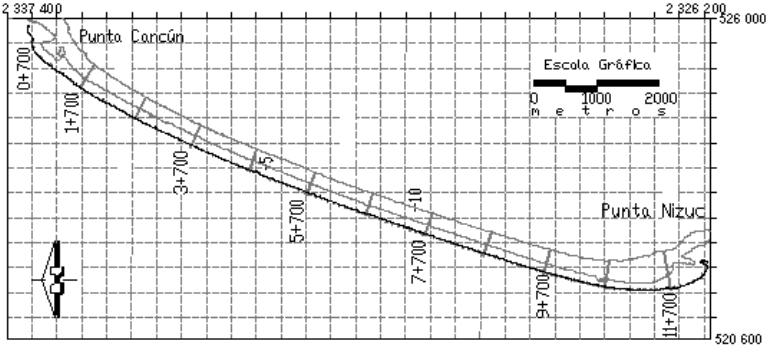

Fig. 13 Selected beach profiles.

The wave climate was determined by jeans of a wave-current-temperature measurement instrument (InterOcean S4) deployed at 20 m depth in front of Punta Cancún. The measurement period presented here starts on January 25th and ends on August 17th, 2006.

Fig. 14 shows the wave rose, observing that during the measurement period the dominant direction comes from the range 100 to 135° (SE). The wave heights vary from 0.27 to 2.2 m.

Table 2 shows the statistical treatment to the whole sample. The mean value for the wave height varies from 0.6 to 1.2 m, meanwhile the wave periods vary from 5 to 6.5 seconds.

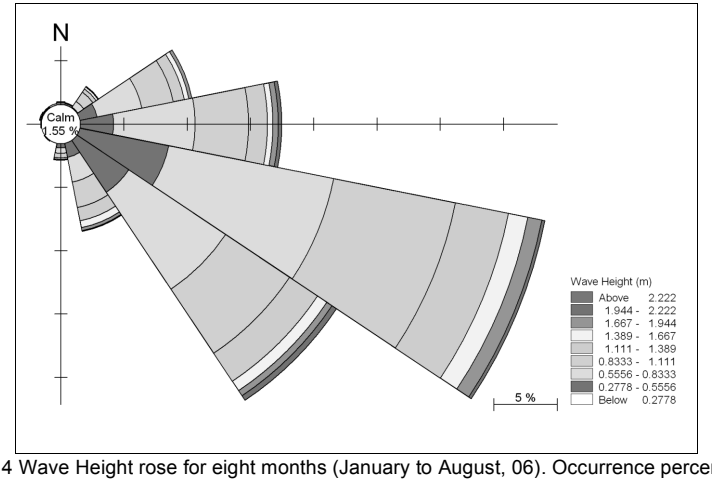

Fig. 14 Wave Height rose for eight months (January to August, 06). Occurrence percentage to wave height and its direction.

Table 2 Wave Climate Statistics, January to August 2006, Cancún Beach.

Wave Climate	Time Period	Wave Height	Wave Period
		m	s
1	January 25 -March 25	0.8-1.2	6-6.5
2	March 26 - May 25	0.6-0.8	5-5.5
3	May 26 - July 25	0.4-0.6	6-6.5
4	July 26 - August 17	0.6-0.8	6-6.5

The fill sediment characterization along the 11.6 km was determined through the analysis of 100 sand samples evenly spaced distribution. The results indicate that the grain size distribution varies between 0.27 and 0.53 mm. The mean grain size for the nourishment sand was 0.39 mm, meanwhile the mean grain size for the native sand is 0.32 mm

BACKGROUND

The morphodynamic state of a beach can be represented by Wright & Short's classification (1984) which is based on the dimensionless fall velocity (Ω) given by

$$\Omega = H_b / \omega T \tag{1}$$

where H is the breaker wave height, T the period and ω the fall velocity. Based on experiments and observations Wright and Short (1984) found that the dimensionless fall velocity is a prediction equation which helps to identify the beach state according to the wave characteristics and the beach grain size. When $\Omega > 6$ the beach tends to be dissipative, and when $\Omega < 1$ it tends to be a reflective. The intermediate beaches have values of dimensionless fall velocity between 1 and 6.

Bennedet, et. al., 2004, proposed the calculation of boundary conditions, via. mean grain size of a beach fill that will generate mostly dissipative or reflective beach conditions, given by

$$\Omega = K d_f^{-b} \tag{2}$$

where K is a specific value function of the H_b / T and df^{-b} is the fill composite sand grain size. Finally, with the fitted of Ω the morphodynamic boundary conditions can be obtained.

ANALYSIS RESULTS

Previous studies have determinates that close to Punta Cancun Northern zone, the beach profiles are more vulnerable than the Southern one. As a result of that behavior three-dimensional post-storm longshore bars form to protect the beachface from Punta Cancún to the section 7+700 (Morán, et. al., 2006).

During the hurricane occurrence, three-dimensional post-storm longshore bars formed as far as the 7+700 section (Fig. 13), and their geometric characteristics and position along to the profile are linked to the degree erosion on that area.

From the post-Wilma profiles we can see that the distance from shoreline to the shoreward side of bar is smaller in the sections where larger dry beach erosion occurred (Table 1). This suggests that the sand lost during hurricanes is able to return to the active profile (dry beach), depending to the wave climate conditions.

Besides, from the 7+800 profile to Punta Nizuc it a soft longshore sand bar is observed, given the stabilization of zone. As the zone is more stable than Punta Cancún, the lost of sand is so much smaller that the natural cover can be possible.

In turn, from the post beach fill profiles we can see that the profile evolution obeys a tendency to recover a pre-Wilma equilibrium state. In all of cases it is observed that changes in the low profile (between the oceanward end of the bar and closure depth) are small, suggesting a state close to equilibrium in that zone of the profile.

On section 1+700 we can see that after nourishment the sand fill and the longshore bar migrated first offshore, and later the bar redistributed along the active profile, suggesting in turn a tendency to reach the equilibrium slope.

On section 3+700 the longshore bar also migrated offshore and disappeared, but apparently in this area it did not redistribute along the profile, suggesting the deposited san volume was sufficient to reach an equilibrium state.

The behavior on sections 5+700 and 7+700 is similar. In both sections the longshore bar evolution is slightly shoreward (26 to 30 m.). The longshore bar indeed returned to its pre-Wilma position.

For section 9+700 the erosion effects only were significant in the first 100 meters, favoring a relatively small dry beach loss of only 10 meters, as well as faster profile stabilization.

Finally, the large loss of dry beach (27m) in section 11+700 was caused by the presence of protection structures close to the section (11+800 and 11+900).

On another hand, Fig. 15 show the coast line evolution in the area corresponding to the same profiles observed before. The black line is the coast line position before nourishment, the red line represents the coastline position on August 2006 (soon after the end of the fill process) and the green line represents the coastline position on November 2006. It can be seen first that the beach profile changes is companied by important changes in the coastline. For instance, sections 3+700 to 5+700 present a coastline retreat of 8-11 m, which, as shown before, is related to the development of a new equilibrium profile. It is important to keep in mind that volume fill is not enough to the beachface reach the stability state.

Finally, Fig. 16 shows the morphodynamic state of the beach as a function of the sand

fill and the wave climate reported on the Table 2. For all wave climate conditions the state of the beach is intermediate with dimensionless fall velocity varying from 5.7 to 1.47. Also fitting curves for morphodynamic bounded conditions area presented. The grain size necessary to reach dissipative states varies from 0.155 to 0.265 mm. For the Cancún beach to represent a state close to reflective the wave climate has to be similar to "wave climate 3" (Table 2), with grain size of 0.58 mm. Although the rest of the wave climate states also decrease as the grain size increases, they do not reach the reflective state for the grain size encountered in the area.

CONCLUSION

The beach profiles analysis presented here suggest that the beach, after nourishment, is evolving towards a new equilibrium state beach. The coastline is retreating, but this is not necessarily associated with instability. Instead, it should be regarded as the evolution to a new equilibrium condition, in which unfortunately the sand fill volume was not sufficient.

This study also shows that the main damage of hurricane Wilma was not on the dry beach, but on the low and offshore part of profile. After the hurricane, the upper part of the profile eroded in order to provide sand to the lower and (through the formation and migraton of a longshore bar), and thus reach the equilibrium slope and profile. The Cancún beach tends today to be a stable system again, until the impact of another hurricane.

Abstract: This paper describes a series of geomorphic investigations conducted to establish a long-term sediment budget and quantify sources and sinks of sediment contributing to the growth of fillet beaches and erosion of adjacent shorelines at the St. Joseph Harbor area on southeast Lake Michigan. Long-term bluff recession and lakebed erosion rates are determined for the study area. The impact of the harbor and its operations on the sediment budget are discussed.

INTRODUCTION

The city of St. Joseph is located on southeast Lake Michigan (Figure 1). The jetties of St. Joseph Harbor were initially constructed between 1837 and 1839. There were several extensions to the north and south jetties. The final extensions to the present day length were completed in 1903. The north jetty is approximately 2,740 ft (835 m) long; the south jetty is about 175 ft (53 m) shorter than the north jetty. Figure 2 summarizes the history of St. Joseph Harbor construction. Following the construction, sand was trapped in the fillet beaches, which grew on both sides of the harbor, and later in the navigation channel. The loss of sand from the littoral system is likely to have exacerbated the natural erosion over some time periods at certain locations south of the harbor. Starting in 1970, the US Army Corps of Engineers (USACE) has placed a quantity of sand approximately equal to the amount of sand intercepted by and dredged from the outer navigation channel back into the littoral system on the south side of the harbor. Prior to 1970, the dredged material was dumped offshore.

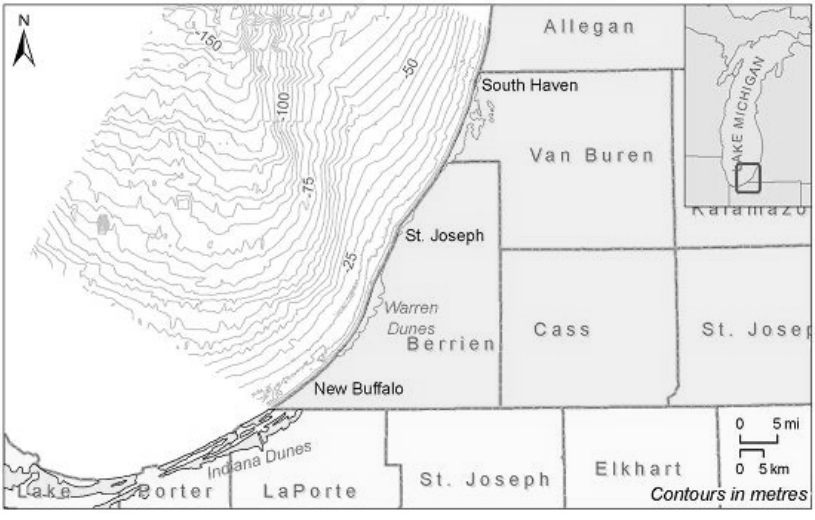

Fig. 1. Southeast Lake Michigan and the study area

Fig. 2. Harbor construction history

The present study was to evaluate the environmental, topographic/hydrographic and geologic conditions of an area extending from approximately 10 miles (16 km) north of the St. Joseph Harbor to 10 miles (16 km) south of the harbor and quantify sources and sinks of sediment to establish a long-term sediment budget. Morphological developments resulting from construction of the harbor and related activities will be discussed.

GEOLOGIC SETTING

The Indiana Dunes complex at the south end of Lake Michigan and the Grand Mere and Warren Dunes deposits south of the harbor (see Figure 1) have formed through the deposition of sand carried along the shore from the north over the last several thousand years, as described by Thompson and Baedke (1995). Thompson and Baedke (1995), Baedke and Thompson (2000) and Baedke et al. (2004) used the successive depositional ridges in the Indiana Dunes complex and found that a beach ridge is formed approximately once every 33 years in response to quasi-periodic high lake levels. The continuous record of deposition of these ridges up to the early 1800's indicates that the supply of sand has remained relatively constant through the last 100's of years (Thompson et al. 2004). The sand that is deposited in the Indiana Dunes may be conclusively related to littoral transport from the northeast (due to the form of the ridges) through natural erosion of the southeast shores of Lake Michigan (Thompson and Baedke, 1995). The end moraines that formed at the toe of glacial ice lobes moving south down the long axis of Lake Michigan (Larson, 2006) have been eroded over the last several thousand years, most likely by wave action as there were no subsequent glacial advances (Larson and Schaetzl 2001; Larson 2006), and supplied the sand to create the dunes in the Grand Mere Lakes (Tague, 1942) and Warren Dunes area and the Indiana Dunes to the south.

The geology around St. Joseph Harbor varies from glacially consolidated bluffs (with 10 to 80% clay/silt content) to sand dune deposits. This variability in geology distinguishes the erosion processes along these shorelines from the well-studied fully sandy coasts. Larson (2006) has produced a map view of the surficial geology together with stratigraphic sections for the study area north and south of the harbor based on information collected and interpreted over the past 20 years (see Figure 3). Below is a description of the geology south of the harbor where shoreline erosion has been an ongoing concern.

There is a 3 miles (5 kilometers) long reach immediately south of the harbor that consists of three primary stratigraphic units; lacustrine sand, sandwiched between an upper till at the surface and a lower till at and below the lake level. The bluff height is about 90 ft (27 m) through most of this reach, but diminishes to 70 ft (21 m) towards the south end. With the exception of the south fillet beach, this is a cohesive shore zone with exposed till in the nearshore zone.

Further to the south there is a zone of about 2.3 miles (3.7 km) long where the upper till layer no longer exists and the lower till layer initially is discontinuous and then

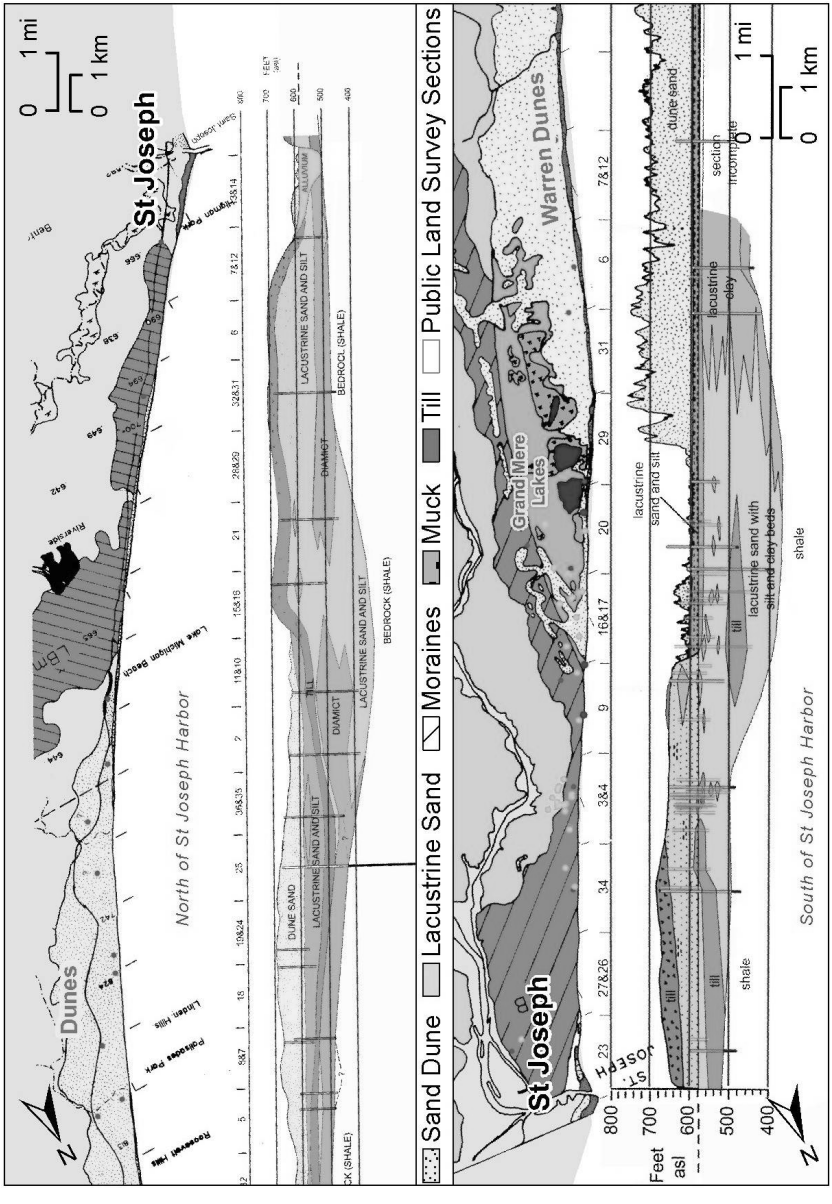

Fig. 3. Geology of the study area

disappears entirely and only lenses of clay appear below lake level within a "Lacustrine Sand" body. The cohesive shore gradually changes to a sandy shore over this zone. The average bluff height is about 60 ft (18 m). Most of the sediment eroded from this area is lacustrine sand. The Lacustrine Sand unit both north and south of St. Joseph is a mix of stratified sand, silt, and clay with some thin gravel layers (Larson, 2006). The dominant lithology, however, is sand (sand proportion varies along the shore from locations with almost 100% sand to places with only 50% sand).

South of the above zone there is a "Lacustrine Sand and Silt" layer with less pronounced bluffs. This layer consists chiefly of fine-to-coarse sand, which likely was deposited in an open near-shore environment in less than about 30 ft (9 m) of water during transgression of the Nipissing I high lake level (Larson 2006). This zone extends for about 2.5 miles (4 km) followed by Grand Mere dunes and then Warren dunes. Grand Mere dunes range from 20 to 40 ft (6 to 12 m) in height and sit over top of the lacustrine sand and silt unit. In summary, the shoreline south of the harbor changes from dominantly cohesive to dominantly sandy from a location about 3 miles (5 km) south of the harbor over a short section of shoreline.

BLUFF RECESSION AND LAKEBED EROSION (SEDIMENT SOURCES)

Historic erosion rates of the shorelines and bluffs, both north and south of the harbor, were determined through comparisons of snapshots of the shoreline and bluff conditions from maps, air photos and a satellite image. The primary reference years were based on:

- Michigan General Land Office (GLO) mapping from 1829/1830;
- Map of the bathymetry of the harbor area from 1871;
- Air photographs from 1938, 1960, and 2002.

All the images and historic charts were georegistered in GIS and both the shorelines and top of bluff lines were digitized. A recession analysis was then completed for both shorelines and top of bluff lines using a tool that measures transects between a historic and recent line at 20 m intervals. The Average Annual Recession Rate (AARR) was determined by taking the mean of all transects over the area of interest and then dividing by the number of years in the comparison period. This result is the Average Annual Recession Rate for that particular time period.

Bluff Recession Rates

Bluff recession rates were calculated for the periods in between four pairs of snapshots from the years: 1830, 1871, 1938, 1960 and 2002. Figures 4 and shows sample results of bluff line comparison from 1830 to 1871. From this figure, it is evident that between 1830 and 1871 the natural (pre-harbor) erosion increased over a 3 mile (4.8 km) reach south of the harbor. Bluff recession rates in this zone ranged between 2.5 to 9.0 ft/yr (0.75 and 2.7 m/yr) with an average of 5.2 ft/yr (1.6 m/yr). Further to the south of this zone of harbor influence, however, the bluff recession rates in Zone 2 were in the range of 0.7 to 2.6 ft/yr (0.2 to 0.8 m/yr) with an average of 1.7 ft/yr (0.5 m/yr). This rate may be considered to be the natural background erosion rate for this zone, at least for the wave conditions and water levels associated with this period.

North of the harbor in Benton Harbor Township, the two maps provided a limited comparison of bluff lines, resulting in an average recession rate of 0.75 ft/yr (0.2 m/yr), which may be considered as the natural background erosion rate for north of the harbor again, for the conditions of this period. The explanation of the difference in background AARR is attributed to an increase in wave energy south of the harbor due to existence of a rise in the lakebed centered on a point directly northwest of the harbor. Numerical modeling of wave transformation using spectral wave models showed that this lakebed high (Figure 1) acts as a lens to focus waves from the north and northwest, thus creating a high wave energy zone over an approximately 10-mile (16 km) long reach south of the harbor. The average bluff recession rate in Zone 3 for the 1830-1871 period was 1.08 ft/yr (0.3 m/yr). Moving from Zone 2 to Zone 3, the geological composition changes from a mixture of cohesive and sandy bluffs to a sandier environment, and the bluff/dune height decreases, while the percentage of sand content increases. Zone 4 consists mostly of sand dunes, and a bluff/dune line was difficult to define. Similarly, bluff recession rates were defined for 1871-1938, 1938-1960 and 1960-2002 as shown in Table 1.

Table 1. Bluff Recession Rates (m/yr)

	North of the harbor	Zone 1	Zone 2	Zone 3
1830 to 1871	0.23 (0.16)	1.60 (0.71)*	0.53 (0.28)	0.33 (0.18)
1871 to 1938	0.40 (0.15)	0.45 (0.16)	0.71 (0.16)	0.53 (0.21)
1938 to 1960	0.28 (0.23)	0.34 (0.22)	0.59 (0.36)	0.26 (0.17)
1960 to 2002	0.23 (0.02)	0.23 (0.24)	0.82 (0.46)	0.35 (0.20)

* Values inside the parentheses show the standard deviation associated with the spatial averaging of the estimates of recession rate made every 20 m within each zone.

The period from 1871 and 1938 includes gradual extension of the jetties until 1903 to their present length. In this period the erosion in Zone 1 was reduced to an average of 1.5 ft/yr (0.45 m/yr). This reduction in recession rate is mostly due to the implementation of shore protection (along the coastal railway and highway) toward the end of this period. The area of highest erosion shifted to Zone 2, which had an average recession of 2.33 ft/yr (0.7 m/yr). The recession rate in Zone 3 also increased to 1.7 ft/yr (0.5 m/yr). The 1938 to 1960 period corresponds to the introduction of even more shore protection structures in Zone 1. Recession rate in Zone 1 was further reduced to 1.1 ft/yr (0.3 m/yr) as a result of shore protection measures. Spatially averaged erosion rates for Zones 2 and 3 were 0.85 and 1.9 ft/yr (0.25 and 0.6 m/yr), respectively. The area of highest recession was again found in Zone 2 for this period. Between 1920 and 1938, lake levels were well below average, resulting in creation of wide beaches that could have protected the bluffs during early 1938-1960 period. The average bluff recession rate north of the harbor for this period was 0.92 ft/yr (0.3 m/yr).

Construction of shore protection structures continued in the most recent period of 1960 to 2002. Although historic low lake levels were recorded in 1965, lake levels were well above average during the 1970's, 1980's, and 1990's, resulting in extensive bluff erosion. The average recession rate in Zone 1 was reduced further to 0.75 ft/yr (0.23 m/yr), probably as a result of shore protection measures. Average erosion rates in Zones 2 and 3 were 2.7 ft/yr (0.83 m/yr) and 1.1 ft/yr (0.35 m/yr), respectively. The area of peak erosion remained within Zone 2 during this period.

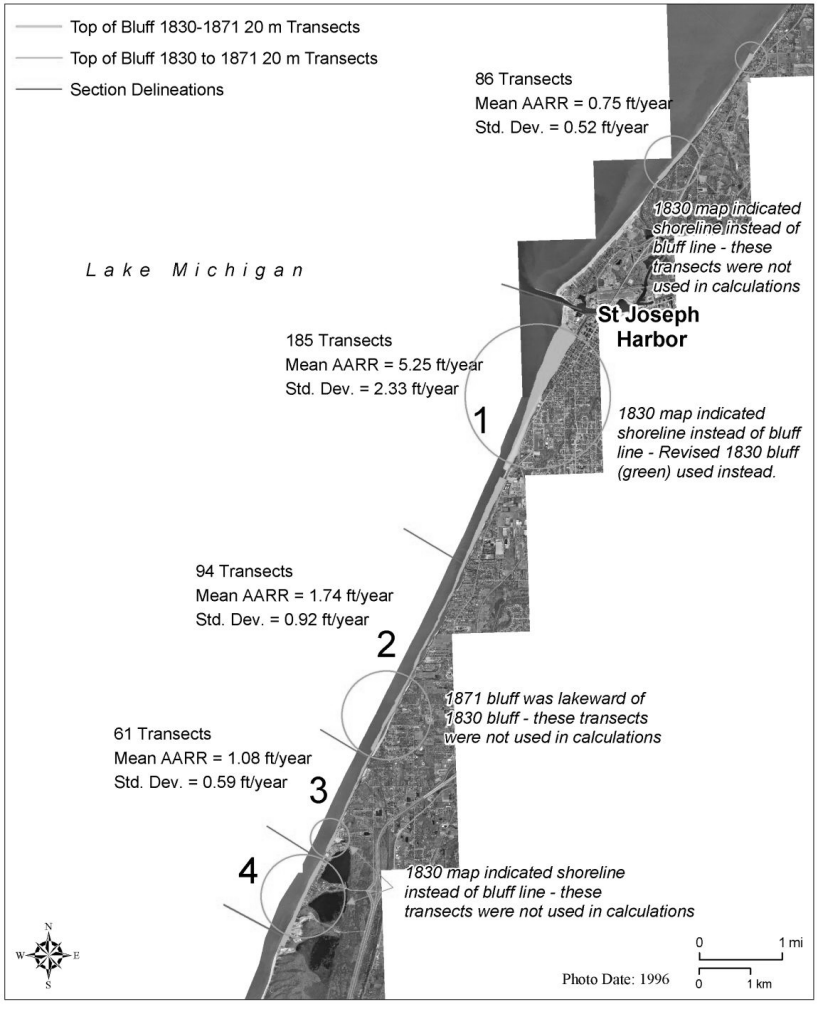

Fig. 4. AARR summary for 1830-1871 period

Lakebed Erosion

Lakebed erosion volumes south of the harbor were determined through comparisons of marine-based hydrographic surveys of 1871, 1954, 1965, and the airborne Light Detection and Ranging (LIDAR) survey of 1999. The 1954 and 1965 charts together provided a complete coverage of the full study area. Figure 5 shows the bathymetry comparison between 1871 and 1954/65. Lakebed erosion is observed in Zones 1, 2, 3, and part of Zone 4. Most of Zone 4, however, experienced accretion in this period. Accretion is also observed along the deeper part of Zone 1 that corresponds to establishment of a bypassing shoal. The average erosion rate in Zones 1, 2 and 3 was relatively uniform; ranging from 0.016 $yd^3/yd^2/yr$ (0.015 $m^3/m^2/yr$) in Zone 1 near the harbor to 0.015 $yd^3/yd^2/yr$ (0.014 $m^3/m^2/yr$) in Zone 3. The unit $yd^3/yd^2/yr$ may be considered as an average rate of lakebed lowering in yards per year or yd/yr. Erosion and accretion volumes in Zone 4 are almost equivalent.

Similar bathymetry comparison between 1954/65 and 1999 showed that erosion rate in Zone 1 increased to 0.041 $yd^3/yd^2/yr$ (0.038 $m^3/m^2/yr$) as a result of construction of more shore protection structures. Zone 4 also experienced erosion in this period. Compared to the earlier period, the average erosion rate was 0.01 $yd^3/yd^2/yr$ (0.001 $m^3/m^2/yr$) at the southern end of Zone 1 and in Zone 2. The erosion rate reduced to 0.013 $yd^3/yd^2/yr$ (0.012 $m^3/m^2/yr$) in Zone 2 and 0.012 $yd^3/yd^2/yr$ (0.011 $m^3/m^2/yr$) in Zone 3. The reduction in lakebed erosion during this period compared to the previous period may be attributed to the USACE nourishment activities that started in 1970.

Combined Bluff and Lake Bed Erosion Rates

Based on the bluff recession rates and the lakebed erosion rates discussed above, total erosion quantities (i.e. including lakebed and bluff components) were calculated for four snapshots between 1871, 1938, 1960, and 2002. Also, using the percentage sand content information, the corresponding sand volumes eroded from the bluffs and lakebed were estimated. In addition, the eroded sand volume prior to the construction of the jetties before 1836 was estimated by removing the distinctive harbor erosion influence (Zone 1 in Figure 5). The total (lakebed and bluff) average annual sand volume eroded from the area for different periods was thus estimated as follows:

Before 1836: 131,000 yd^3/yr (100,000 m^3/yr)
1871 to 1938: 191,000 yd^3/yr (146,000 m^3/yr)
1938 to 1960: 209,000 yd^3/yr (159,800 m^3/yr)
1960 to 2002: 216,000 yd^3/yr (165,100 m^3/yr)

It may be seen that the erosion volume has increased over the time. It should be noted, however, that the above values are long-term averaged numbers and actual erosion volumes during shorter periods may considerably deviate from these numbers depending on the supply rate from updrift, river and nourishment activities as well as the outgoing longshore transport rate that are discussed below.

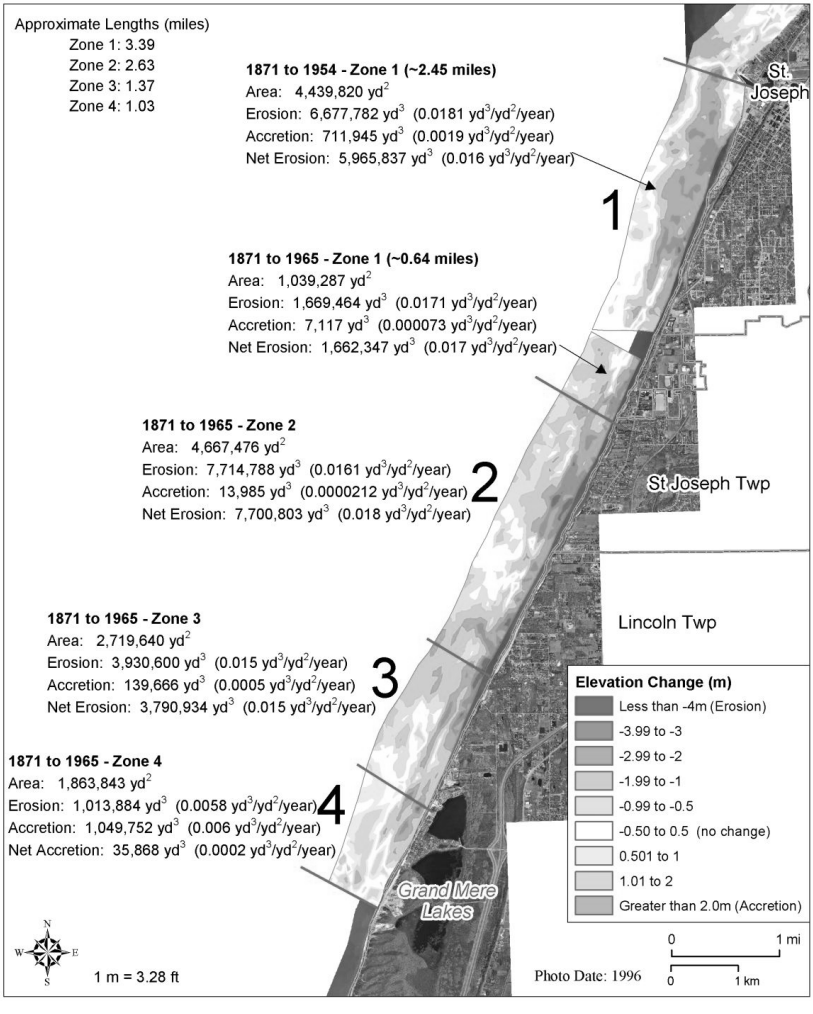

Fig. 5. 1871 to 1954/65 lakebed comparison

HARBOR INFLUENCE (SEDIMENT SINKS)

There are three key forms of sinks to the littoral sediment budget associated with harbors:

1. Accumulation of sediment in fillet beaches;
2. Dredging and disposal of sediment dredged from navigation channels;
3. Loss of sediment to the creation of bypass shoals.

Each of these three possible sinks is evaluated in this section.

Fillet Beach Accumulation

The jetties at St. Joseph Harbor started to trap sand since their construction until they reached their trapping capacity. The history of the growth of the north fillet beach area derived from historic shorelines since 1834 is shown in Figure 7. The variability in fillet beach size is related to natural factors and in particular to changing water levels. The water level effect was therefore removed by adjusting the fillet beach area based on the difference between the water level at the time of the survey and a common reference level. The solid lines represent an estimate of fillet beach area growth with the water level effect removed. The lines represent two different beach/nearshore slopes required for the adjustment (representative of the range of average beach slopes at the site). It may be seen that the north fillet beach has three periods of response: 1) Between 1836 when the jetties were first constructed and around 1870 when they were first extended, 2) Between 1870 and 1893 to 1903, when the last lengthening of the jetties was completed in a series of stepwise extensions as shown in Figure 2, and 3) The period from 1903 to the present. The three periods feature an asymptotic trend that is consistent with rapid initial growth followed by increasingly slower growth toward the end of each period (i.e. as more sand moves past the fillet beach into the navigation channel). In particular, the north fillet beach has had a slow growth over the last 30 to 40 years, indicating that the fillet beach area is no longer expanding.

Sand was similarly lost into the south fillet beach; however, the south fillet is much smaller because the north waves, being larger than south waves, are able to remove much more sand from the south side of the south jetty (Dibajnia et al. 2004). Comparison of pre-harbor and post-harbor charts also suggests that the south fillet was mostly formed by redistribution of the sediment that once formed the old river mouth bar prior to construction of the jetties. The St. Joseph south fillet beach grew between 1836 and 1938 and has been relatively stable since then.

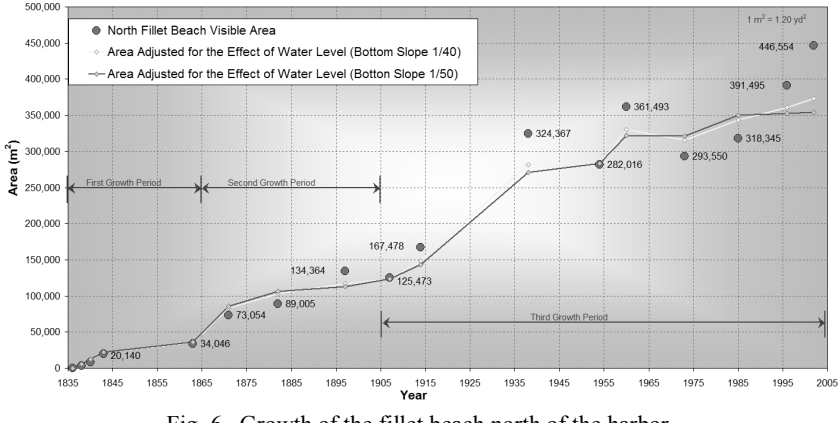

Fig. 6. Growth of the fillet beach north of the harbor

Dredging

For St. Joseph Harbor, deposition in the navigation channel is generally divided into two areas: the inner and outer channels. Deposition in the outer channel is mostly related to littoral sand transport, whereas sediment deposited in the inner channel is mostly derived from the river and watershed. There is likely some amount of deposition in the outer channel related to sediment supplied by the river. The inner channel often includes a significant quantity of fine sediment (i.e. grain size less than about 0.125 mm) that would not remain in the littoral zone even if it were to make it to the lake. Dredging records dating back to 1879 were obtained and reviewed to determine the amount of maintenance dredging associated with the inner and outer channel areas, and this information is presented in Figure 7. The red dots represent the total maintenance dredging and, where sufficient information is provided, the inner and outer channel components are indicated (blue squares and green diamonds respectively). There is considerable variability in year-to-year dredging due to inter-annual variability in trapping or sediment deposition in channels, as well as decisions on when to dredge due to economic and other factors (the navigation channel depth has varied through time as shown in Figure 7). The total maintenance dredging reached a peak in the mid-1900's, and is now decreasing. There has been a trend for increasing outer channel dredging between 1900 and the present. This corresponds to the slowing of fillet beach growth as it approaches maturity and the corresponding increase in transport of sand past the fillet beach and into the navigation channel. The entrance channel depth is now supposed to be maintained to 24 ft (7.3 m) below low water datum, across a width of 300 ft (90 m) or more. It is clear that a limited amount of sediment is able to bypass this channel without being deposited in it. From the data available since about 1960, the rate of outer channel dredging has averaged about 30,000 yd^3/yr (22,900 m^3/yr).

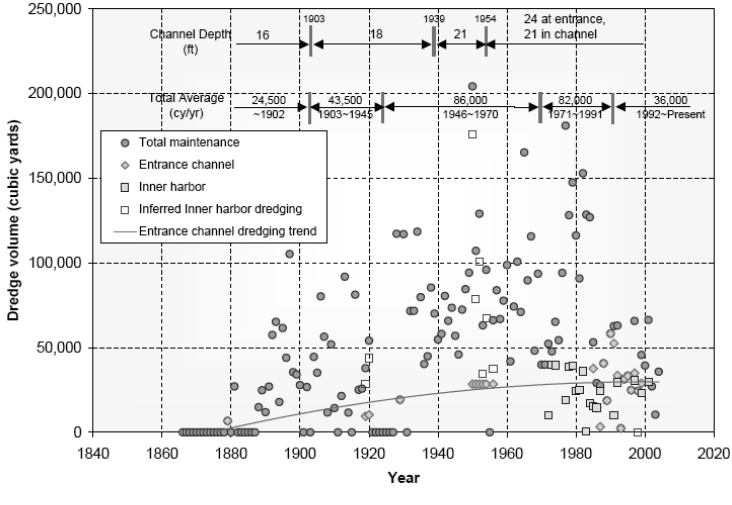

Fig. 7. Dredging History at St. Joseph Harbor (from USACE Detroit District)

The inner channel dredging would appear to have been responsible for the peak in total maintenance dredging in the 1950's and 1960's, and this peak is consistent with observations by others that this period corresponded to the highest erosion of agricultural land (due to extensive agriculture and poor soil conservation practices; see Trimble and Crosson 2000). More recently, it is believed that loads were reduced through urbanization of previously agricultural land and through improved agricultural practices relating to soil conservation. Similarly, prior to European settlement (i.e. prior to logging and then agriculture), there would have been little sediment delivered from the river and watershed. This topic of watershed sediment will be discussed in a separate paper.

Deposition in Bypassing Shoals

As fillet beaches approach maturity in terms of growth, bypassing of the harbor commences, whereby sand moves around the harbor. Sand transported along the shore by waves and wave-driven currents will attempt to reinstate the net rate of longshore transport by creating a bypassing shoal. As the bypass shoal builds, inevitably it disrupts the main purpose of the jetties by providing the pathway for sand to fill in the navigation channel and results in the need to dredge.

An assessment of possible bypassing shoals has been completed through lakebed surface comparisons to describe areas of net erosion/sedimentation between 1907, 1954, and 2001 (these data represent snapshots when the required data was available). The results for the 1907-1954 period are shown in Figure 8. This figure shows three zones of deposition (most apparent in Figure 10). Starting from offshore, Zone 3 is a large zone stretching across the length of both fillet beaches and generally extends between water depths of 12 and 16 m (40 and 50 ft); Zone 2 consists of two lobes (2a and 2b) of sediment that appear to emanate from the outer navigation channel towards the north and south in depths of 6 to 11 m (20 to 36 ft); and Zone 1 corresponds to the underwater part of the north and south fillet beaches (and was accounted for under the discussion of the fillet beach accumulation).

The deposition rate in Zone 3 was approximately 39,000 yd^3/yr (29,800 m^3/yr) (including both clay/silt and sand fractions) prior to 1954 and 37,000 yd^3/yr (28,200 m^3/yr) between 1954 and 2001, and 109,000 yd^3/yr (83,300 m^3/yr) up to 1970 (considering that offshore dumping was stopped in 1970). Based on the numerical modeling results (completed for the river flows with and without the influence of wave action), and location data of offshore dumping, it appears that most of the deposition in Zone 3 must have been a result of offshore dumping.

The volume of sediment accumulation in Zone 2 corresponds to annualized deposition rates of approximately 65,000 and 3,900 yd^3/yr (49,700 and 3,000 m^3/yr) of sand for the periods 1907-1954 and 1954-2001, respectively. Since approximately 1970, there has been some minor erosion of the Zone 2a deposits, and accumulation has recently occurred in Zone 2b only, which indicates that part of the updrift supply is also deposited in Zone 2b (i.e. between the 6 and 11 m contours below low water datum). From the numerical model results it was found that when south and north waves interact with river

flows, sediment is carried and, in some instances deposited in the two Zone 2 lobes. One reason for the reduction in the growth of the Zone 2 shoals is the increase in the navigation channel depth over the 1900's (see Figure 9 for the change in channel depth). Also, it should be considered that the Zone 2 lobes effectively represent a bypass shoal for river sediment to make its way back to the shore. It took many years for the bypass shoals to build and now they have effectively reached maturity. The Zone 2 shoals likely consist of a mix of sandy and silty sediments owing to the important role of river sediments in building these deposits.

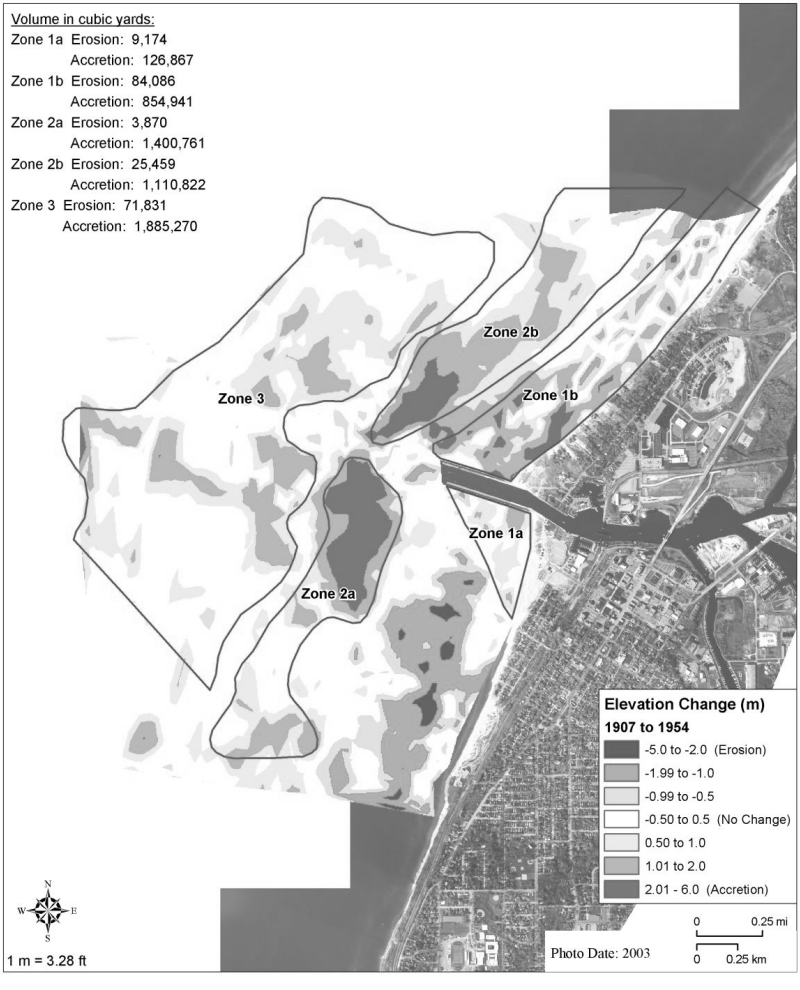

Fig. 8. Lakebed change between 1907 and 1954 around the harbor

Numerical modeling of sediment bypassing showed that presently about 45,000 yd^3/yr (34,400 m^3/yr) can bypass the north jetty of which more than 35,000 yd^3/yr (26,700 m^3/yr) is trapped by the navigation channel, and there is minimal bypassing (less than 10,000 yd^3/yr (7,600 m^3/yr) of the harbor mouth for longshore sand transport on an annual basis to south downdrift of the harbor (i.e. almost all the sand is trapped in the navigation channel). Sand is transported from the south into the navigation channel on a very infrequent basis. Details of the numerical modeling work will be presented in a future paper.

CONCLUSION

Factors contributing to the long-term sediment budget at St. Joseph Harbor were quantified. These were divided into sediment source factors including bluff recession and lakebed erosion rates as well as river sediment load, and sediment sink factors including accumulation in fillet beaches and bypassing shoals and dredging from the navigation channel.

Abstract: Headland Control is a unique shoreline management technique whereby existing geomorphic features (*i.e.* headlands) are enhanced with large stone breakwaters and/or the breakwaters are strategically placed alongshore to create headlands. These enhanced or created shore headlands are widely spaced for economy, and the adjacent coasts are allowed to continue to erode toward an equilibrium shore position where a wide, stable, and protective sand beach becomes vegetated and forms a low dune. The final equilibrium planform is a large pocket beach whose dimensions will depend on the amount of sand that will come to reside in the evolving embayment. Headland Control is applicable to long reaches of agricultural or unmanaged shore land since protecting the entire property is very expensive per linear foot. Three sites where this method of shore management was implemented are discussed in terms of shore planform prediction, overall shore change, and storm response.

INTRODUCTION

Headland Control is a unique shoreline management technique whereby existing geomorphic features (*i.e.* headlands) are enhanced with large stone breakwaters and/or large stone breakwaters are strategically place alongshore to create headlands. These enhanced or created shore headlands are widely spaced for economy, and the adjacent coasts erode toward an equilibrium shore position or planform. The final equilibrium planform is a large pocket beach whose dimensions will depend on the amount of sand that will come to reside in the evolving embayment. Sand is usually only placed directly behind the created headland during construction, and vegetation is planted along the backshore to assist in the dune creation process. Headland control generally is applied to long reaches of agricultural or unmanaged shore land

to begin the process of shore stabilization by pocket beach creation.

This paper discusses three headland control sites, two of which are located along the Potomac River in Virginia and one on the St. Mary's River in Maryland (Figure 1). They include: 1) Summerille/Staples, Northumberland County, Virginia, 2) Murphy, Westmoreland County, Virginia, and 3) St. Inigoes Neck, St. Mary's County, Maryland. The Summerille/Staples project was initially installed in 1978 while Murphy (installed in 1997) and St. Inigoes (installed in 2001) are newer installations. All three of these sites are included in the Chesapeake Bay Breakwater Database currently being developed by the Virginia Institute of Marine Science (VIMS) for the U.S. Army Corps of Engineers, Section 227 Program. In predicting the final shore planform, we utilized the Static Equilibrium Bay (SEB) formula by Hsu and Silvester (1989) and Silvester and Hsu (1993). The net direction of wave approach was ascertained from an analysis of historical shoreline change using aerial imagery as well as wind/wave modeling.

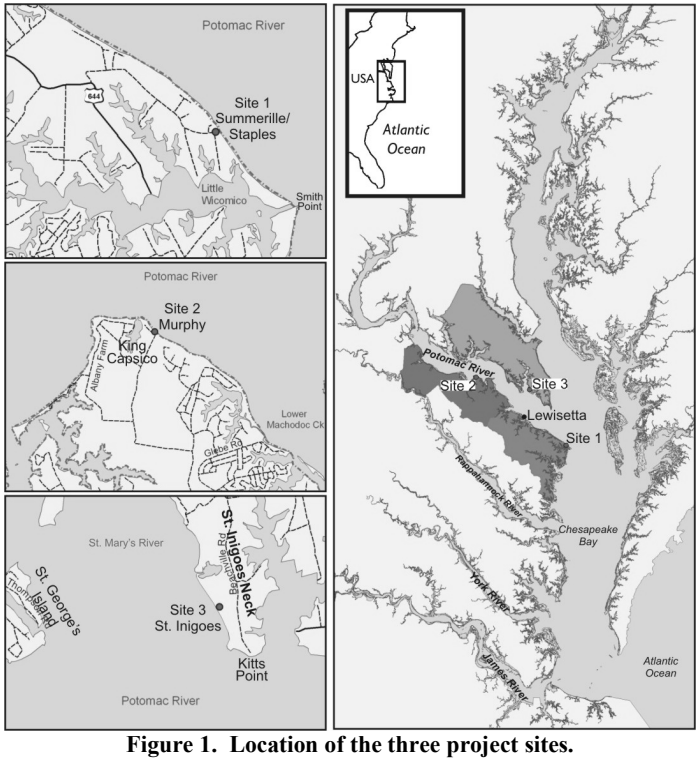

Figure 1. Location of the three project sites.

EQUILIBRIUM

Determining the shape or shore planform of crenulate/spiral and pocket beaches or embayments has been the subject of numerous research efforts. This procedure was first developed by Silvester (1970) and later refined by Hsu *et al*. (1989) and Silvester and Hsu (1993). The method is referred to as the Static Equilibrium Bay (SEB) method (Figure 2). This is an empirical model developed by analyzing hundreds of pocket and embayed beaches around the world. Hardaway *et al.* (1991) introduced this to Chesapeake Bay in order to better design headland breakwater systems for shore protection. Since then, many headland breakwater sites have been installed, analyzed, and reported on (Hardaway and Gunn 1991; Hardaway *et al*. 1993; Hardaway *et al*. 1995; Hardaway and Gunn 1999a; Hardaway and Gunn 1999b; Hardaway and Gunn 2000; and Hardaway and Gunn 2003). These reports often utilized a combination of RCPWAVE, a wave refraction computer model, and SMB, a wind/wave generation computer model, to characterize the impinging wave climate on headland breakwater sites.

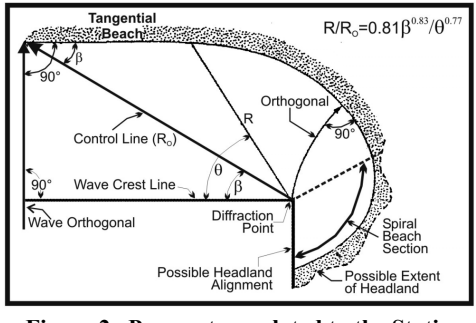

Figure 2. Parameters related to the Static Equilibrium Bay Model (Hsu *et al.* 1989).

The SEB method was initially developed along open ocean coasts for "natural" coastal embayments. A certain degree of common sense is required to utilize the model since it was originally developed to assess if a given embayment is in "equilibrium". Therefore, one needs a bay to apply the SEB model. If sand is moving along an embayed coast, it may be considered in "dynamic equilibrium" until such time as sand supply is cut off and the shore planform further evolves to a more static condition. This is the condition often found along sand starved Bay coasts.

Determining both the direction of wave approach and the control line (Ro) are important. The updrift headland is usually easy to define in a natural setting, but the downcoast headland can cause complications especially if it protrudes into the bay (Silvester and Hsu 1993) (Figure 3). In Chesapeake Bay, this is usually the case for headland breakwater design, and therefore the transition point occurs at the water line or contour which will be used for the bay shape calculations, usually mean high water (MHW). It is not an exact calculation, and the method should be used only to get a good approximation of bay shape. The tangential section turns into the impinging

wave climate, and then the spiral section adjusts to it.

Ultimately, the embayed beach is the primary element for shore protection. The design of the embayed or pocket beach's shore planform must account for sand supply and wave climate. Along open coasts, a dominant direction of wave approach with only minor short-lived reversals is assumed. In Chesapeake Bay, this may or not be the case. Many shore reaches will have an annual and storm direction of wind/wave approach from different directions. The more oblique the impinging wave crest to the coast (*i.e.* as β becomes bigger), the deeper or more indented the pocket bay. Headland Control requires allowing the shoreline between breakwater units to erode. Storms, Hurricane Isabel in particular, have hastened and more clearly defined the future of this shoreline management strategy.

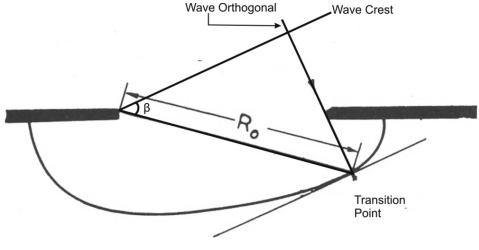

Figure 3. Diffraction due to protruding downcoast headland (Sylvester and Hsu 1993).

SHORE EVOLUTION

Shore change assessment is a very useful tool in understanding how a given reach of coast has evolved over time, particularly around the fetch-limited and depth-limited sheltered coasts of Chesapeake Bay. The use of orthorectified historical aerial imagery provides information not only on the position of the shoreline but also types of land use, infrastructure, shoreline structures and offshore bar systems that exist in a moment in time. Aerial archive data sets are not very complete so a certain amount of interpolation and interpretation is necessary. The open coasts of the Bay and rivers have undergone some dramatic changes and understanding shore evolution is necessary when assessing the hydrodynamic forces acting on the coast.

Most of the Bay shoreline is receding as a result of rising sea level and the local impinging wave climate. The wave climate is a function of wind-driven waves often in combination with tidal currents. The greatest wave energy is generated during storm events. In the Bay region, this is during northeasters and the occasional hurricane where elevated water levels (storm surge) and large wind-driven waves combine to impact the Bay shores at higher than normal elevations, cutting into upland banks, and producing large quantities of bank sediments for the littoral system. Shore erosion, particularly along the upland banks, is greatest during storm events which must be accounted for in developing shoreline protection strategies for a given shore reach.

Shore evolution is the response to the process. The longer the temporal record, the more hydrodynamic forcing has occurred. The geomorphic evolution of the upland banks provides insight into how larger storms have formed that coastal reach over time. Movement of sand features such as spits also provide evidence of the direction of wave attack and, consequently, sediment transport. One can ascertain net sediment movement and if it is somewhat balanced or bidirectional. Assessing the sand supply also is critical to beach development in pocket bay evaluations.

Hurricane Isabel impacted the Chesapeake Bay on September 18, 2003 with record high storm surge and high winds. Virtually all shorelines were impacted to one degree or another especially those with open fetch exposures to the north, northeast, east, southeast and south as Isabel's winds rotated north to south through her passage. Hundreds, if not thousands, of shore protection systems were damaged or destroyed. Many open shorelines with no protection incurred erosion rates of 10 to 30 ft (3 to 9 m) depending on location to the storm surge and wind/wave climate. Sites with headland control systems experienced varying degrees of shoreline recession as they eroded toward equilibrium.

In the fall of 2006, three coastal storms, including Tropical Storm Ernesto, impacted the Bay coast of Virginia and Maryland. Although water levels were less than Isabel, they had high water and winds that significantly impacted the estuarine shorelines. Of the three sites, Murphy was most impacted by these storms.

Table 1. Recent storm statistics for Lewisetta, Virginia on the Potomac River.

Storm	Maximum Tide Level Relative to MLLW (feet)	(meters)	Maximum Sustained Winds (mph)	(m/s)	Peak Gust (mph)	(m/s)	Max Wind Direction (°TN)
Hurricane Isabel	6.5	2.0	52	23	69	31	95
Hurricane Ernesto	5.6	1.7	43	19	63	28	90
Northeast Storm 10-6-2006	3.1	0.9	38	17	46	21	85
Northeast Storm 11-2-2006	2.5	0.8	21	9	29	13	2

HEADLAND SITES

Site 1: Summerille/Staples, Northumberland County, Virginia

Site 1 is located along the Potomac River near Smith Point (Figure 1). The shoreline is oriented northwest/southeast with fetch exposures to the north, northeast, and east of 25 n.m., 16 n.m., and 13 n.m. (46 km, 30 km, 24 km), respectively. Until 1937, the shoreline was relatively straight with a continuous beach along most of the reach. Alongshore transport was mostly uninterrupted except for areas of overwash into small coastal ponds on either side of the Site 1 shore (Figure 4). The upland banks along the Site 1 are about +12 ft MLW (+3.6 m MLW) and composed of fine sands. Bank geology varies along the Potomac River coasts and as the banks erode they provide the sediments for the shore and nearshore regions. The sand and gravel

fractions accumulate on the beach and offshore bars while the silts and clays tend to be carried offshore into deeper waters of the River and Bay.

A crenulate embayment was created at Site 1 due to the Summerille groinfield and the shore hardening that defines the downriver boundary of that embayment. The upriver tidal pond embayment also had become well developed. This area had been known as the Summerille site and was the subject of scrutiny in the 1978. The downriver offset created by the Summerille groinfield increased steadily since its installation in the 1960s. By 1978, the shore at the site had eroded more than 100 ft (30 m). The solution was to install a spur to abate the immediate problem (Anderson *et al*. 1983) (Figure 4). Since then, the spur has been lengthened and additional spurs were added to the downriver revetment in the late 1990s that clearly defined the boundaries of the Site 1 embayment (Figure 4). The embayment had taken on the classic log spiral/crenulate shape.

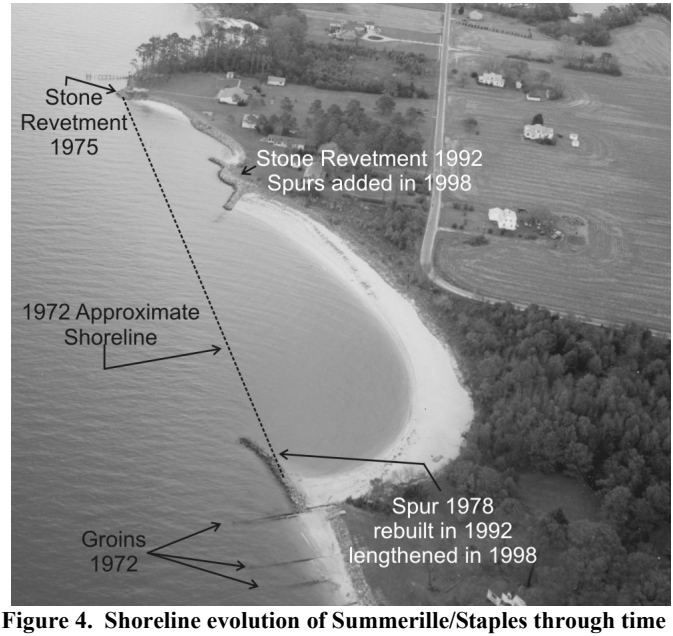

Figure 4. Shoreline evolution of Summerille/Staples through time shown on a post-Hurricane Isabel photo (2003).

The upland banks within the embayment continued to erode and evolve toward an equilibrium planform as seen in 1994. The tangential section of the bay was used to portray the net direction of wave approach. Using this reverse method to establish the incident wave condition, the SEB model was applied during a 1991 VIMS study

to predict where the spiral section of the bay would evolve. This study predicted the resulting line *i.e*. whether it was the shoreline, the base of bank or top of bank (Hardaway *et al*. 1991). Figure 5 shows the predicted bay shape on 1994 imagery.

The 2002 imagery shows a shore advance as result of the added spur on the downriver boundary which perched the tangential section thereby helping the bay to equilibrate. It is important to understand that this is a sand rich system and the input of sand into the bay was essential to beach expansion. Once the sand reached the limit of the downriver boundary it began to bypass. The spiral section of the bay finally eroded/evolved to where the beach as wide enough to attenuate storm waves against the adjacent upland banks. The average beach width is 65 ft (20 m) from MLW to the base of the bank, and the elevation is +6 ft MHW (+1.8 m) at the base of the bank.

Hurricane Isabel brought a large amount of sand into the embayment to the point that the established dune grasses along the backshore were almost completely covered. Recent northeast storm events brought even more sand into the bay. The bay is now in dynamic equilibrium.

Site 2: Tayloe Murphy, Westmoreland County, Virginia

Site 2 resides further up the Potomac River at King Capsico (Figure 1). The Site 2 shoreline occurs on the downriver side of King Capsico Point and faces northeast with fetch exposures to the north, northeast, and east of 9 n.m., 5 n.m., and 6 n.m. (17 km, 9 km, and 11 km), respectively. In 1937, the shorelines adjacent to and including Site 2 had beaches along the coast. The land use was almost all agricultural. The eroding banks were +15 to +20 ft MLW (+4.5 to +6 m MLW) and composed of a variety of sands and gravels.

By 1969, significant shore development had occurred on King Capsico Point with subsequent shore hardening and installation of groins. The Site 2 shore was still mostly undeveloped except for the main Murphy house on the point. Two large spits resided in front of the Murphy home at that time. The nearshore was paved with cobble eroded from the adjacent bank which reinforced the base of bank such that a natural headland was created. This headland eroded much slower than the adjacent downriver coast. In 1987, two large groins were installed in front of the Murphy home, further enhancing that point. The downriver reach shore continued to erode, and, by 1994, had become a concern of Mr. Murphy. A revetment was installed along the north shore to protect the house but the downriver reach continued to recede. The offset had evolved into an open ended embayment pinned on the upriver end by the point.

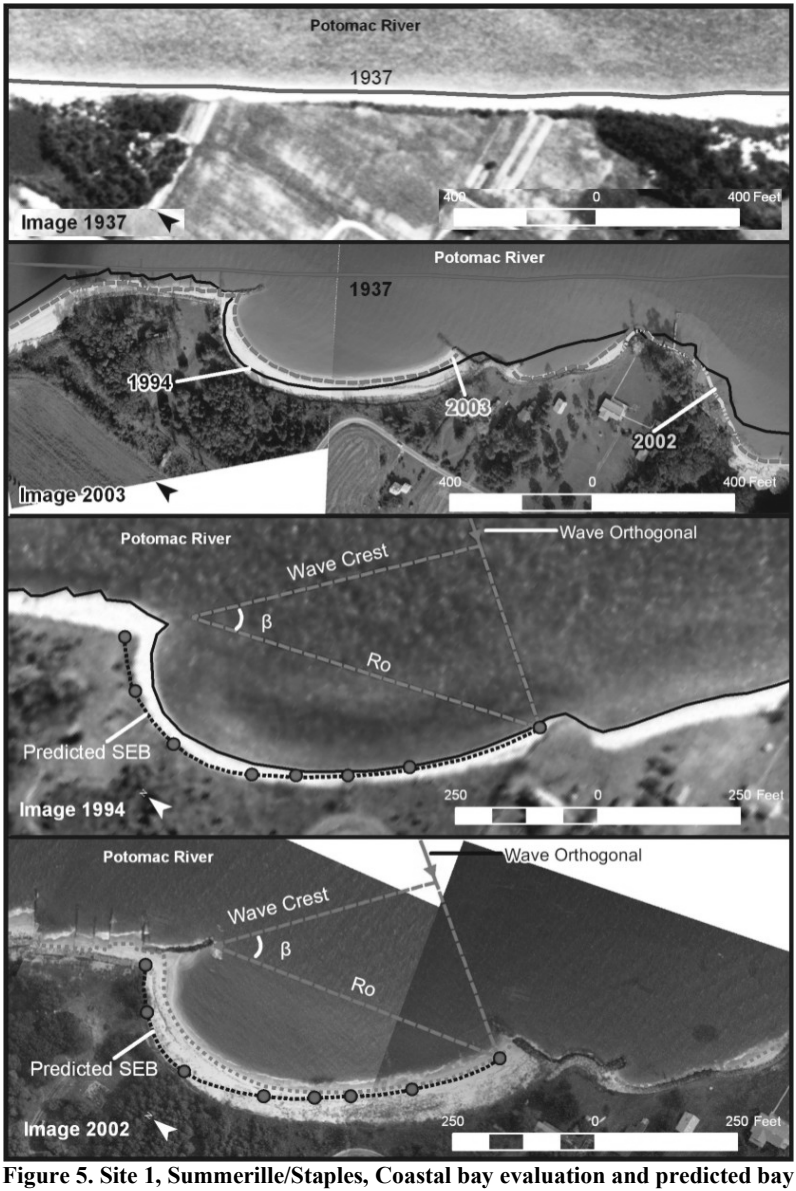

Figure 5. Site 1, Summerille/Staples, Coastal bay evaluation and predicted bay shoreline using SEB. Dots are values of R for a given θ (see Figure 2).

Mr. Murphy contacted Coastal Design and Construction, Inc., and it was decided that

a series of widely spaced headland breakwaters could be cost effectively installed along the embayed coast and allow the adjacent shorelines to evolve toward equilibrium (Figure 6). If this became unacceptable then additional breakwaters or a revetment could be installed. A wave climate analysis indicated the net direction of impinging waves for annual northerly conditions and the occasional northeast storm attack.

The result was the installation of a large headland spur and three headland breakwaters with beach fill to create the tombolos in 1997 (Figure 6). The design was based partly on the impinging wave climate, shore morphology, and cost. The spur, which is BW1, is about 200 ft (60 m) long and shelters the embayment from the northwest. Breakwaters 2 and 3 are 150 ft (45 m) each at +4 ft MLW (+1.2 m MLW) while breakwater 4 is shorter and lower to allow a smoother transition onto the adjacent unprotected shore (Hardaway *et al*. 1993). A bulkhead further downriver acts as a boundary for the embayment.

Figure 6 shows the site in 1999 with Bay B still actively eroding. A change in the geology of the bank sediments occurred over time. Initially, a relatively thick 5 to 8 ft (1.5 to 2.4 m) sand layer existed along the base which would "feed" the embayments with sand even as the banks between structures continued to erode. However, with time the strata facies changed to a siltier substrate. Hurricane Isabel caused a significant retreat of the unprotected banks (Figure 6). However, the headland breakwaters and tombolos remained intact. Recent northeasters have continued the erosion, and although "equilibrium" is not far off, Mr. Murphy opted for a revetment along the backshore. The low, stone revetment is small and is perched at the back of a wide beach berm.

Site 3: St. Inigoes, St. Mary's County, Maryland

Site 3 occurs on the west shore of St. Inigoes Neck in St. Mary's County, Maryland (Figure 1). The land is very low with little or no sand in the banks which were eroding at an average of -4 ft/yr (-1.2 m/yr) with the greatest erosion occurring adjacent to the south headland at over -6 ft/yr (-1.8 m/yr) (Figure 7). The land use is agricultural such that Headland Control seemed an appropriate, cost-effective strategy for this coast.

The project site is over 4,800 ft (1,460 m) long and is defined by a headland on the south boundary that has been hardened with a stone revetment which runs along the south shore of Kitts Point and turns north up the St. Mary's river. The north boundary is defined by a small tidal pond (Sage Pond), marsh and inlet complex which has been a headland feature since 1853 (and before) and defines the south boundary of another embayed coast up the St. Mary's River. The upland bank along the project site is about +5 ft to +8 ft MLW (+1.5 m to 2.5 m MLW) and composed of silts and fine sands. The nearshore is shallow tidal flats, and a very narrow beach existed along the pre-project coast.

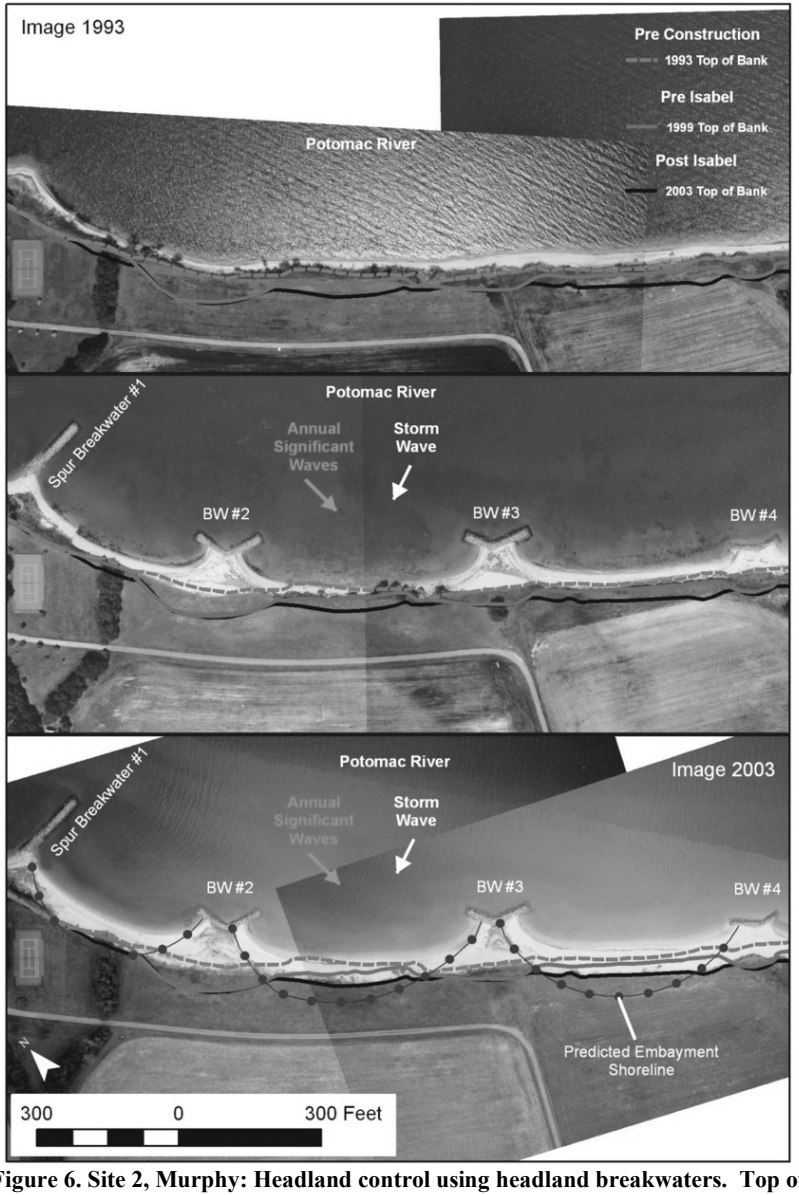

Figure 6. Site 2, Murphy: Headland control using headland breakwaters. Top of bank in the embayments eroded over 7 m during H. Isabel. A revetment has been installed along the base of bank and a wide beach resides in the bays.

Fetch exposures to the northwest, west, and southwest are 3 n.m., 2.5 n.m., and 7

n.m.(3 km, 2.5 km, and 7 km), respectively. Evidence of a "Bay" wave, which can travel up the St. Mary's River from the south and southeast, exists. This long-period swell was observed on one site visit and might be injurious to the shore over time. The evolution and shape of the natural embayments along Site 3 indicates the dominate direction of wave approach is from the south and southwest. Although northwesters can be furious during the winter months, the shorter fetch and nearshore flats reduce their influence on this coast. However, some wave energy can turn up the St. Mary's River around St. George's Island from the northwest wind/wave train coming down the Potomac River. This wave approaches the project coast from the southwest but dissipates as it goes north up the St. Mary's.

The project design began where the worst erosion occurred along the southern part of the site, the spiral section of the larger bay. The first breakwater (BW1) was placed near the end of the revetment while BW2 and BW3 were placed in front of a farm road where a tree line intersected the shore. These three units are closer together so equilibrium might be attained sooner to minimize land loss. Other subtle features included a small patch of trees for BW5, a small point for BW6, a drainage ditch for BW7, and on the south side of the inlet to Sage Pond for BW8, the terminal structure. BW4 was sited at the upriver limit of construction for the southern four units. This left a relatively wide gap between BW4 and BW5 which the landowner understood might require an additional structure.

Nearby borrow pit sands were used to build the tombolos and provide construction access. Each unit is 180 ft (55 m) along its crest and the center inflection point is approximately about 80 ft (24 m) from MLW with the ends of each unit about 100 ft (30 m) from MLW. These structures were built relatively close to shore with large tombolos to insure long-term headland attachment. The embayed coasts began adjusting soon after installation. Although the approximate net direction of wave approach was gleaned from the pattern of shore change, once the tombolos were set then the equilibrium bay could more easily be plotted. Hurricane Isabel revealed the true nature on the impinging wave climate as the spiral section of each bay eroded significantly and the tangent sections were set. The "equilibrium" shore planform is plotted in white and represents approximate MHW (Figure 8). Like Site 2, the long-term options were to add sand and/or breakwaters as funds and conditions dictate.

After Hurricane Isabel additional sands were placed in Bay B, C and D. Each received about 1000 cubic yards (765 cubic meters) each to supplement the bay beaches. It is evident that additional sands are needed to enhance the bay beaches, but the bay coasts needed to evolve to a point where the sands would reside more comfortably in the bay spiral or pocket. Bay E, the widest, will receive an additional breakwater unit with sand tombolo.

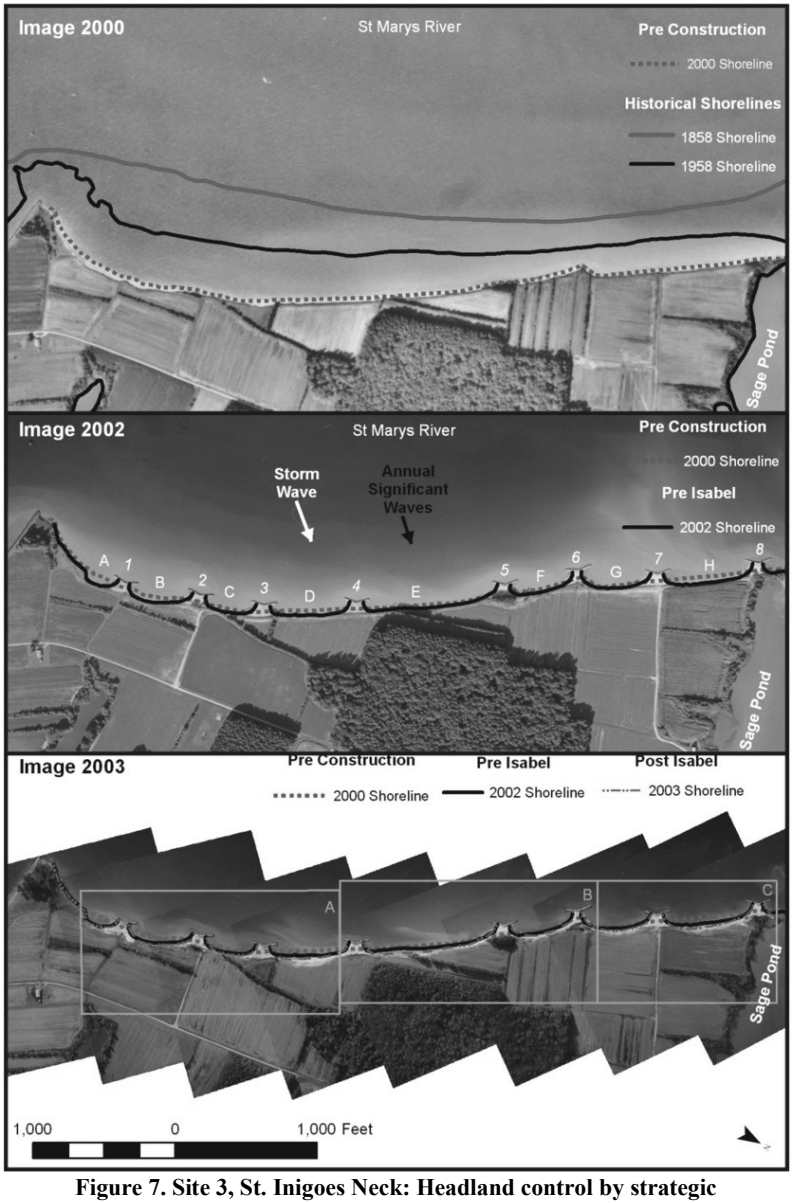

Figure 7. Site 3, St. Inigoes Neck: Headland control by strategic placement of headland breakwaters.

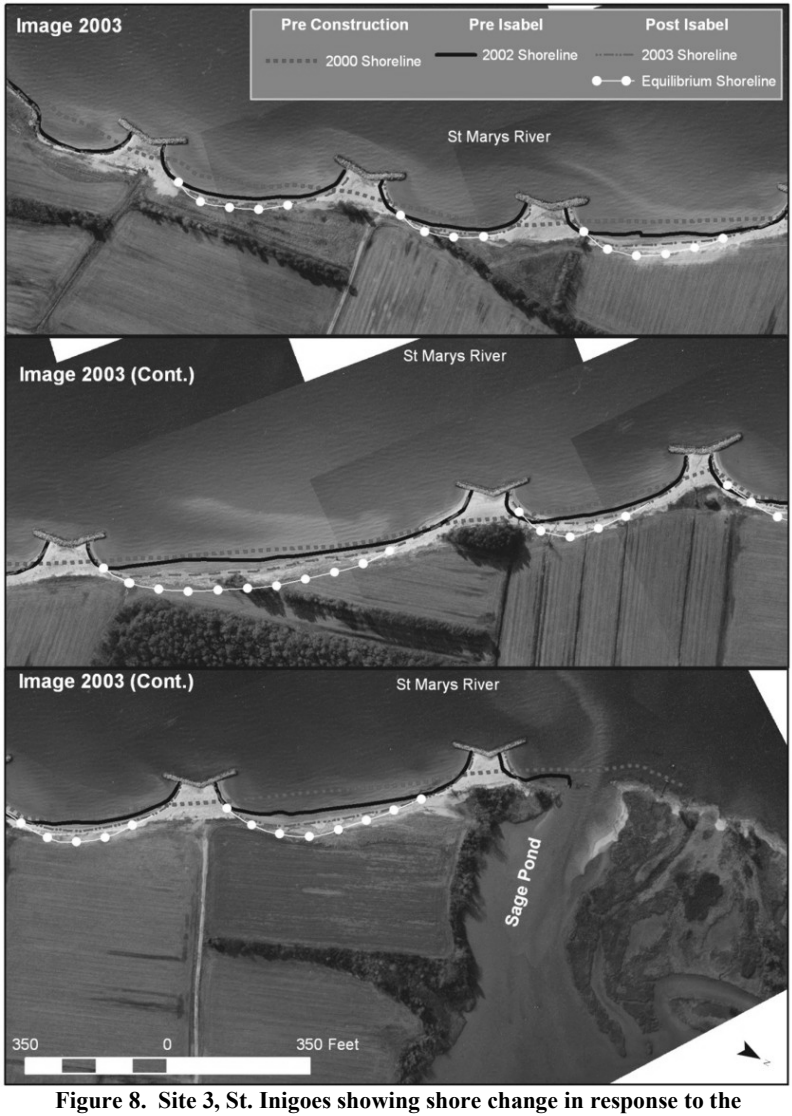

Figure 8. Site 3, St. Inigoes showing shore change in response to the breakwaters. Beach erosion in the predicted bay shape still requires additional sand for a protective beach.

CONCLUSION

The use of Headland Control can be a cost-effective method of reach management. This is done by placing widely spaced breakwaters and/or enhancing existing shore features and allowing the adjacent embankments to erode and evolve into equilibrium embayments. The "final" equilibrium planform is dependent on the impinging wave climate and the amount of sand in the system.

The three sites discussed in the paper have different physical settings and relative amounts of sand in the littoral system. It is important that the property owner understands potential issues when Headland Control is recommended for shoreline managment; these include 1) time, 2) added sand, 3) added structures and 4) cost. The SEB model helps predict ultimate equilibrium but not necessarily how long it will take. Projected erosion rates based on the shore history is probably the most reasonable, but, as we have seen, severe storms may hasten issues 2 and 3. Costs are always an issue, and sand sources can be the most critical in terms of availability and proximity to the site.

Severe storms may be good for headland control systems. They erode the unprotected upland banks in the embayments toward the design planform. Equilibrium is reached with a wide, stable and protective sand beach that becomes vegetated and forms a low dune. Along many undeveloped reaches of Chesapeake Bay, shore erosion is significant and protecting the entire property is very expensive per linear foot. However, by establishing headlands, the shoreline will eventually reach equilibrium. Since initial cost is only for the headlands and a small volume of sand for construction access, the cost per linear foot is greatly reduced. Ongoing monitoring is required in order to determine when another structure or sand is needed.

ACKNOWLEDGEMENTS

The authors would like to thank Donna Milligan for her help in revising, editing and formatting this paper as well as creating some of the figures. Thanks to George Thomas for obtaining the low-level aerial photography. Christine Wilcox did an excellent job rectifying the historic and recent images in GIS as well creating the figures. Finally, thanks to Kevin O'Brien for his help in summarizing storm data as well as reviewing the report.

COASTAL PROTECTION AGAINST WIND-WAVE INDUCED EROSION USING SOFT AND POROUS STRUCTURES: A CASE STUDY AT LAKE BIEL, SWITZERLAND

Selim M. Sayah[1] and Stephan Mai[2]

2. University of Hannover, now at German Federal Institute of Hydrology, Koblenz, Germany, mai@bafg.de

Abstract: At the southern shore of Lake Biel in Mörigen, Switzerland, the sandy beach covered with reed plantations suffers strong erosion although a protection project was realized in the late 20th century. The design of this protection project included the construction of segmented porous structures (brushwood fences) parallel to the shoreline. Their purpose was to damp the incoming energy of wind-generated waves and to protect the shoreline against additional erosion. In order to enhance the shoreline protection, an additional study, based on in situ analysis of wind, waves and bathymetric evolution and numerical modeling of wave field and nearshore wave generated current responsible of sediment transport on the other hand, was carried out. The results revealed that by an adaptation of the existing system an enhancement can be achieved in order to thwart any further erosion and to promote sediment deposition at the leeside of the fences.

INTRODUCTION

Brushwood fences (see Fig. 1a-b) are most commonly used in lakes to provide reliable, soft, and cheap shore protection (Sayah et al. 2004). They are especially effective in shallow regions where hydrodynamic forces, generated by wind and currents, are not very significant. The fences are mainly composed of two elements (see Fig. 1b). The first one, related to the structural stability, is composed of two parallel rows of wooden piles (average spacing of piles equals 0.6 m). Between the two rows, wooden branches, often called "fascines", are inserted in a cylindrical bundled manner. This porous middle

element is responsible for the dissipation of incident waves. The average porosity of fascines varies between 10% and 80%.

Fig. 1. (a) Brushwood fences in Lake Biel (Switzerland) used to protect reed plantation; (b) Typical design concept of the brushwood fences

The site selected for the case study where multiple brushwood fences are constructed is located at the South-Eastern shore of Lake Biel (see Fig. 2) at almost 6 km South of Biel city. The location is called Mörigen. The selection of this site was based on three main reasons:

1. Many field surveys were carried out in this site: wind, waves, and bathymetric measurements
2. This site is located almost at the middle of the shore side of Lake Biel where erosion is most active
3. More than ten brushwood fences segments are located at this site used for wave damping

(a) (b)

Fig. 2. (a) Lake Biel in Switzerland and localities where in situ measurements are undertaken; (b) Wind rose based on statistical analysis at Payerne wind station situated at 30km south-west of Lake Biel (MeteoSuisse 1990)

The segmented brushwood fences in Mörigen are shown in Fig. 3. Each extremity of a single structure was located using GPS technique that provided the Swiss coordinates X

and Y. The altitude Z for each segment was measured locally. In addition to the positions of brushwood fences, wind velocities over water are measured at almost 2 m above the water level together with wave characteristics and the transmission coefficient of one single segment of brushwood fences at the upper part.

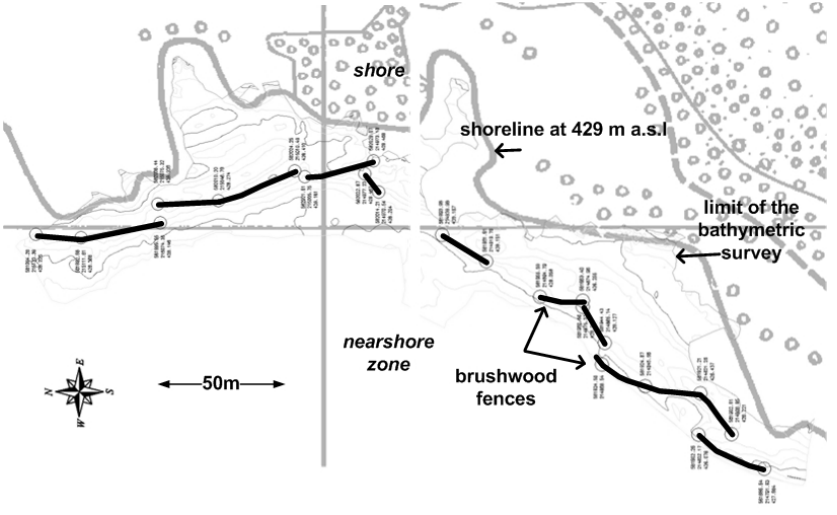

Fig. 3. Segmented brushwood fences at Mörigen in Lake Biel

FIELD MEASUREMENTS OF WIND AT MORIGEN

In situ wind measurements at Lake Biel have been realized in several other localities. However, the measurements of wind at the site of Mörigen selected for the present case study, show substantial results concerning wind velocities for the two major regimes over Lake Biel (see Fig. 1b). Instant over water wind velocities U_W and directions are measured during 6 months period (from first of October 2004 until the end of March 2005) with a Young anemometer Velocities and directions are averaged at 10 minutes intervals. Furthermore, the wind is measured at Payerne ANETZ wind station (wind over land) for the same period of time (wind rose of the fixed wind station is at Fig. 1b).

The comparison of over water and over land wind speeds and events shows relevant similarities. The events are selected when wind speed is significantly higher than 2.5 m/s and lasting at least 1 hour. The events at Payerne occur at the same period and almost for the same direction trends as at Mörigen. However, the measured wind speeds are at both station shows little discrepancy.

Fig. 4 highlights the effect of wind speed variation due to transition from land to water. The data shown corresponds to wind speeds for the South-western wind events during the period [Dec. 2004 - Mar 2005]. It includes measurement during more than 10 wind

events. Thus, wind speed tends to increase after a transition from a land surface. However, due to the behavior of water roughness as a function of wind speed, the ratio of over water wind speed at a fixed level to over land wind speeds (U_W/U_L) is not constant, but varies nonlinearly. Fig. 4 provides the trend for the form of such variation. The exact magnitude and characteristics of the transition depend on the roughness properties of the terrain and vegetation on one hand, and on the stability of the air flow on the other hand. Resio and Vincent (1982) presented a simple approximation of this wind speed variation based on a logarithmic fitting curve to the asymptotic over land and over water wind speed values.

Furthermore, trends in Fig. 4 indicate, as expected, that wind speeds over water follow a power law. The ratio (U_W/U_L) tends to infinity when U_L tends to zero and to almost 1 when U_L tends to infinity. The latter fitting depends mostly on the location of on water measurement station and on the wind regime. For "mean" wind speeds (roughly varies between 6 and 10 m/s in Switzerland), corresponding to recurrent wind events, such fitting provides a rough ratio of (U_W/U_L) equal to 1.35. Thus, wind over water is 35% stronger than wind over land for average wind events. This rough estimation strongly depends on the nature of vegetation beside the lake and the local topographic conditions. Therefore it could be not used for general applications.

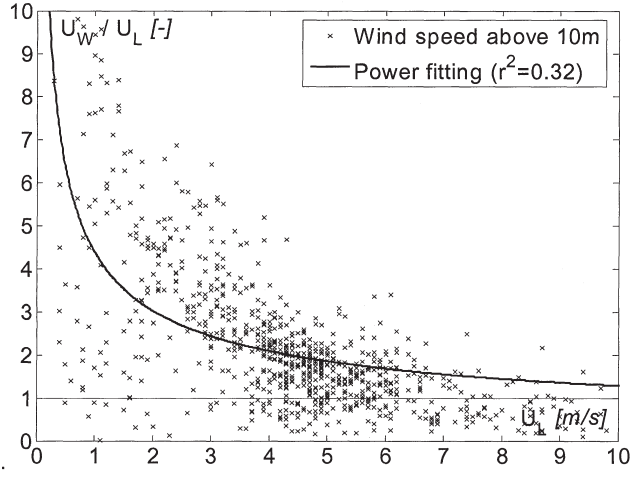

Fig. 4. Ratio of wind speed over water U_W at Mörigen to wind speed over land U_L at Neuchâtel according to U_L for a wind sector [210°-240°] during [Dec. 2004 - Mar 2005]

IN SITU WAVE TRANSMISSION

The field measurements of waves were carried out at the upper part of the brushwood fences field in Mörigen. Waves were measured before and behind a typical segment of brushwood fences during the same period as the wind measurements. The waves selected for the analysis correspond to significant waves heights H_s greater than 0.15 m.

Results of K_T according to the dimensionless freeboard R_c/H_s are provided in Fig. 5. During field measurements, the lake water level was always lower than the top of the brushwood fences. Therefore, the structure was always emerging and the transmission coefficient calculated is considered as average. The mean K_T value could be estimated during such conditions is equal to $K_{T,mean}$=0.32.

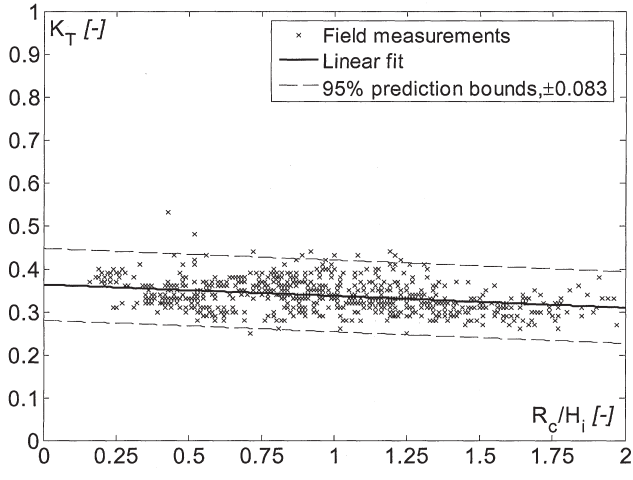

Fig. 5. Transmission coefficient K_T of typical brushwood fences at Mörigen according the relative freeboard R_c/H_s for a structure height h=1.12 m

ANEMOMETRIC AND LIMNIMETRIC BOUNDARY CONDITIONS

For the present case study, it is proposed to calculate incoming wave in the region of Mörigen using the numerical analysis by Swan model (Booij et al. 1996) .Since the duration of wave measurements in the nearshore region of Mörigen is too short, a long term analysis of incoming waves could not be carried out. Therefore, it was proposed to calculated wind-waves based of the statistics of wind measured off shore (at Payerne) after applying on wind velocities the correction coefficient as described before in order to obtain calibrated data.

Three main wind regimes are considered for Mörigen as following:

1. South-Western wind (sector [210°-240°]) "Le Vent": fetch=7000 m
2. North-Eastern wind (sector [30°-60°]) "La Bise": fetch=4500 m
3. North-Western wind (sector [300°-330°]) "Le Joran": fetch=3500 m

By using the long term statistical analysis for the three regimes, a calculation of wind velocities for every wind sector and return period could be made. Afterwards, the calculation of waves is carried out in Swan, using as input wind velocities and

directions. Since waves are refracting near Mörigen, incoming wave directions are different than wind directions. Therefore special attention should be given to wave direction used afterwards when calculating wave field in the brushwood fences location.

By calculating wave heights, periods and directions in Swan, it is possible to introduce these values as boundary conditions for the modeling of the wave field at Mörigen. Fig. 6 provides an example of wave characteristics for the stronger and more frequent wind regime (le Vent). The wind duration does not play a major role since the condition for the selection of wind velocities is defined when the duration is long enough to produce a fetch limited condition (Kamphuis 2000) Furthermore, the wind speed depends mainly on the selected return period T_r.

The return periods of waves are the same as the return periods of winds. Only three return periods are selected as follows: T_r= 1, 5, and 20 years. For each return period, three water levels of the Lake Biel are selected: MHWL= 429.60 m, MWL=429.20 and MLWL=428.8 m.

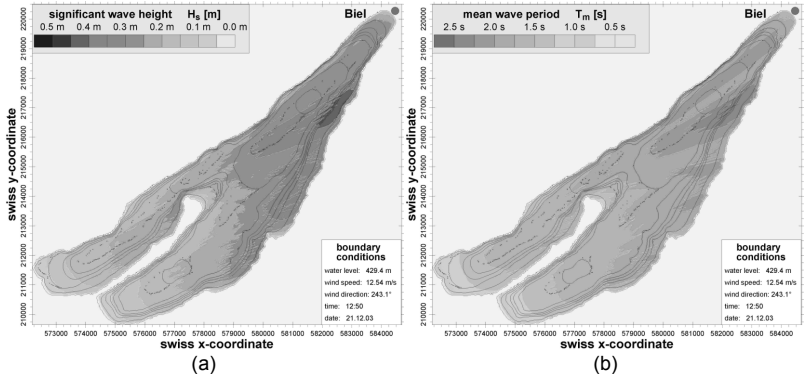

Fig. 6. Wave field in Lake Biel during a South-Eastern wind regime for the MHWL: (a) significant wave heights; (b) mean wave periods

EFFECT OF THE LAKE WATER LEVEL VARIATION

This section highlights the effect of the present nearshore brushwood fences field at Mörigen on the incoming waves when the lake water level changes. They are based on numerical modeling carried out by an elliptic mild slope solver as described by Madsen and Larsen (1987). It was proposed to calculate first the wave field without introducing any structures. In a next step, the wave field is calculated with the presence of the protection system as described before. This allows an accurate description of the effect of the protection system on the nearshore hydrodynamics and constitutes the basis of any protection enhancement proposals.

The variation of the water level influences significantly the shoreline position (see Fig. 7). Therefore, for the MHWL the shoreline moves in the landward direction and for MLWL, it moves in the seaward direction. At some shallow places, for a water level variation of 0.80 m, the shoreline displacement could reach 25 m. Furthermore, for shallower regions the shoreline displacement is almost 75 m. Such high values bring out the effect of the distance of brushwood fences from the shoreline. This distance should be long enough in order to enable a good performance of the structure during low water regimes. The results show that this criterion is practically fulfilled in almost all the cases. Even for the MLWL, all brushwood fences structures are still in water and able to damp efficiently the incoming waves.

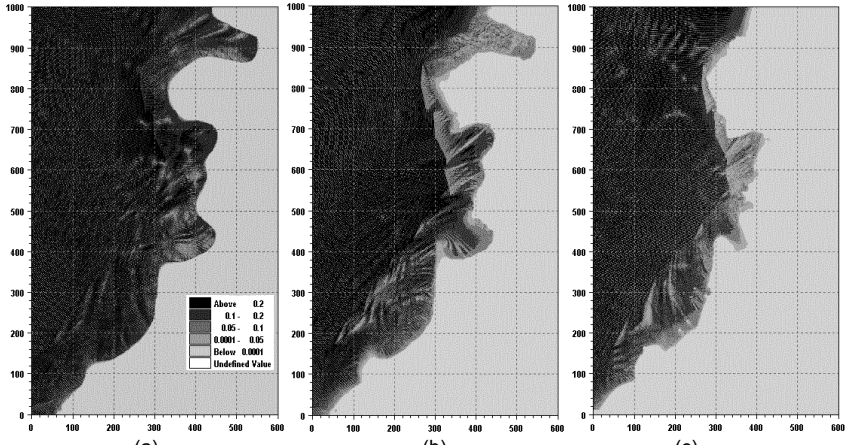

Fig. 7. Wave heights at Mörigen during a Western wind regime with the presence of the protection structures and T_r= 5 years (a) MHWL (B) MWL (c) MLWL

Additionally, the wave damping effect decreases significantly for all the modeled wind regimes when the water level is high. Therefore, when comparing in wave heights behind the brushwood fences field for the three modeled water levels of the lake, it is apparent that during a MHWL period, the incoming waves are almost equal before and behind the protection structures. It has to be noted that during this water level regime, the structures are totally submerged.

For the MWL, waves in the protected area at the leeside of the brushwood fences are much smaller than waves corresponding to the MHWL. However, when compared to waves during the MLWL, they do not appear to be much higher, although the water level variation is the same. This is probably due to the fact that for both water level regimes, the structure in emerging. For this condition, its efficiency is almost constant. Concerning the wave field width at the leeside of the protection structure, the results

show that for MWL, the protected region is much wider than the one corresponding to MLWL.

EFFECT OF THE WIND REGIME VARIATION

The wind regime has a clear effect on the nearshore wave field at Mörigen. When comparing results in Fig. 8 it appears that waves tend to be higher for the South-Western regime. This could be clearly seen for the return period T_r= 5 years. Such high waves are essentially due to the fact that the fetch of this wind regime is almost twice as large as the fetches of the two other main wind regimes. Moreover, wind speeds for South-Western wind are the highest.

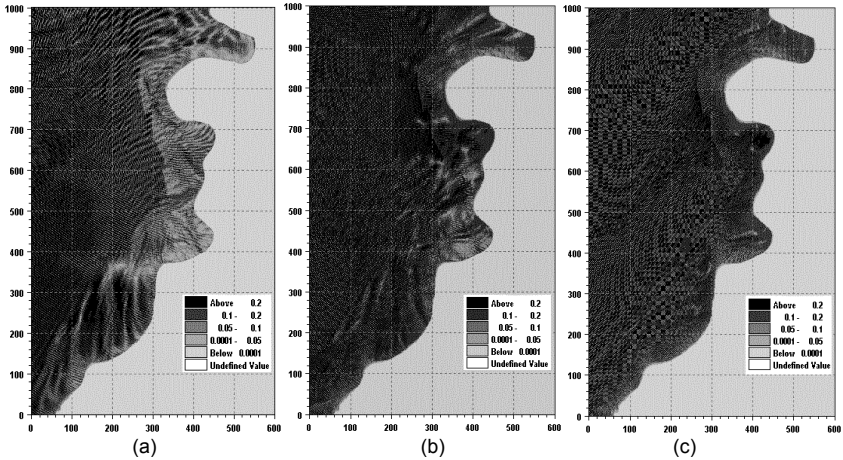

Fig. 8. Wave heights at Mörigen during a three different wind regimes with the presence of the protection structures at the MHWL and T_r= 5 years (a) South-Western (b) Western (c) North-Eastern

With the presence of the brushwood fences (see Fig. 8), wind regimes influences significantly the wave field at the leeside of the protection structures. Therefore, when comparing wave fields for MHWL, it appears clearly that for both North-Eastern and Western wind regimes, waves reach more easily the shore by diffraction through the wide gaps in the brushwood fences field. However, during a South-Western wind regime, although waves are higher, it seems that the present geometrical disposition of the structures protects the shoreline very efficiently.

Furthermore, the efficacy of the brushwood fences geometrical disposition during a South-Western wind regime is clearly shown for the MHWL. When comparing the wave field in Fig. 8, it appears that the average wave heights in the lee of the structures are almost twice smaller for the South-Western wind.

NEARSHORE CURRENT GENERATION

For the most significant cases, radiation stresses (Copeland 1985) were calculated in order to generate current maps in the nearshore region of Mörigen. This has been carried out using a hydrodynamic model.

The main conclusions of current simulations were as follows (see Fig. 9):

1. The nearshore wave generated bed currents are significantly reduced for the MHWL. However, for the MLWL, strong currents are more frequent and could easily reach values up to 0.5 m/s.
2. Without the presence of the protection structures, the currents could be easily "canalized" parallel to the shore. Their presence enhances current disturbance and damping.

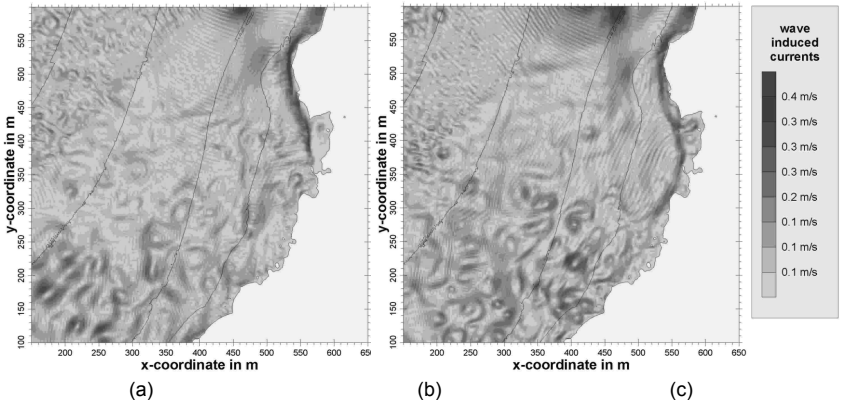

Fig. 9. Wave generated currents based on the calculation of the radiation stresses for the MWL and T_r= 5 years (a) with the protection system (b) without the protection system

CONCLUSIONS AND RECOMMENDATIONS

The brushwood fences field at Mörigen in Lake Biel has been modeled using the elliptic mild slope equation. The wave field at the leeside of the fences is obtained for the three main lake water levels, and for the three main wind regimes. The statistical analysis of in-situ over-land wind measurements permitted the identification of three main wind directions, North-East, North-West and South-West. After adjustment of wind velocities based on the ratio of over-water and over-land wind speeds (equal to 1.35), waves statistics for each regime were determined using the numerical model of the entire lake based on Swan application. In average, for a wind return period of T_r= 20 years, corresponding to an average wind velocity of 12 m/s , the waves at Mörigen are almost 0.4 m height and 2.2 s period. The introduction of the transmission values of the brushwood fences and bottom characteristics into the numerical model of the nearshore

region of Mörigen are provided through in-situ measurements and depend on water level variation.

For each wind regime, eighteen cases have been investigated. In order to evaluate the effectiveness of the brushwood fences field related mainly to their geometrical distributions, nine cases are considered without the presence of the structures and nine cases with the presence of the structures. They correspond to the three selected return periods, T_r= 1, 5 and 20 years, for each, three selected water levels, MHWL,MWL and MLWL are considered.

The comparison of the results permitted the following conclusions:

1. When the water level of the lake is MHWL, the effectiveness of the brushwood fences field is very low. The transmission of the incoming waves is almost 100%
2. Although during the South-Western wind regime, incoming waves reaches their highest values, they are efficiently damped by the particularly adapted geometrical configuration of the brushwood fences field. For the two other wind regimes, waves are able to reach the shore through wide gaps between the fences

The present study demonstrated the effectiveness of the use of elliptic mild slope equation to model real cases, where porous structures are built. The input of the results obtained by the Swan model for wind-wave data appeared to be very relevant and adequate. Further detailed numerical analysis of currents and bedload sediment transport is crucial, and should reveal significant nearshore phenomenon that contributes to a better understanding of the hydrodynamics of the brushwood fences field in order to suggest resolute enhancement of the protection system.

Abstract: Goldsmith Inlet is a small semi-natural and non-navigable inlet located on the northeast shore of Long Island, NY, and it connects Goldsmith Pond to Long Island Sound. The coast is gravelly, waves relatively small because of limited fetch, and tide range relatively large at 2 m as compared to the south shore of Long Island. The inlet has been in existence since at least the 1700's, but is apparently prone to closure in recent times. Field data collection, GIS analysis of morphology, and numerical modeling of the inlet current were performed. The inlet is found to be highly flood dominant, with two natural sills restricting ebb flow. As a result, gravel remains at the inlet mouth, with the flood shoal composed of fine sand. No ebb shoal is found, probably a result of the limited ebb-tidal discharge. It is concluded that an easterly orientation promotes channel stability and is to be preferred to re-alignment of the inlet to run straight out to Long Island Sound.

INTRODUCTION

Goldsmith Inlet (Fig.1 and Fig. 2) is a small, semi-natural inlet located on the northeast shore of Long Island, NY, and connects Goldsmith Pond to Long Island Sound (Leatherman et al. 1997). The inlet is not navigable, and it is protected on the up-drift side by a structure called a jetty that should be considered as a groin in retaining sand on its up-drift (west) side. Goldsmith Inlet is of interest in that it is a gravelly inlet, migrates down drift, has no ebb shoal, is strongly flood dominant, and is relatively stable. This paper abstracts information contained in a comprehensive study by Morgan et al. (2005).

In contrast to the south shore of Long Island, inlets on the north shore have received little study. Many are small and serve small and isolated water bodies. North shore inlets appear to be more stable in location than the south shore inlets. The sediment along the south shore consists predominantly of fine to medium sand, with a median grain size of 0.3 mm being typical. In contrast to the sandy beaches backed by dunes found along the south shore, high bluffs and a wide range in grain size characterize the north shore of Long Island. The tide range along the north shore is about double that of the south shore and the waves along the north shore are smaller and steeper. Longshore sediment transport is an order of magnitude less on the north shore as compared to the south shore.

This paper discusses coastal processes at Goldsmith Inlet. Field data collection conducted in Oct 2002, during a spring tide, included surveys of the adjacent nearshore, inlet, and Goldsmith Pond; measurements of water level in Long Island Sound and in the pond; short-term measurement of the current; and sediment sampling. Available aerial photographs were obtained, starting in 1938, and aerial photographs of the study area were taken on 15 Apr 2003 and 16 Apr 2004. A GIS analysis of inlet morphology and morphology change was conducted. A tidal inlet hydrodynamics model DYNLET (Amein and Kraus 1991) was established to calculate the inlet current and water level.

Fig. 1. Goldsmith Inlet, 16 Apr 2003

Goldsmith Inlet has been in existence since at least the 1700s. Historically, a strong tidal current at Goldsmith Inlet is indicated by the presence of a tidal mill on Goldsmith Pond from about 1840 to the early 1890s. The sediment on the neighboring beaches is coarse sand to gravel, and the sediment in the inlet is primarily gravel and cobble.

Goldsmith Inlet has a depth of 0.3-0.6 m, and inlet width ranges from about 3 to 30 m. The mean width is about 15 m (Fig. 2), and it is approximately 360 m long. Goldsmith Pond has a mean depth of 0.5 m and a surface area of approximately 88,000 sq m. The

tide range in this area is about 2 m, and spring tide range is 2.3 m. The tidal prism of Goldsmith Inlet and Goldsmith Pond is calculated to be 8.5×10^4 m^3, based on measured bay area and half the spring tide range.

Fig. 2. Goldsmith Inlet entrance with view of east beach, 28 Mar 2003

Construction of the jetty was completed in 1964. Since 1964, the jetty has gradually deteriorated. Degradation and complete impoundment of sediment on the jetty's west side have led to greater sediment intrusion. The inlet has been occasionally dredged as a source of sand and gravel for upland activities and to provide sediment for renourishment of Kenneys Road Beach, located east and down drift of the inlet. More recently, Goldsmith Inlet has been dredged on an emergency basis, when the inlet has experienced closure, with the dredged material placed on the adjacent down-drift beach. Since the bathymetric survey of Oct 2002, the mouth of Goldsmith Inlet migrated to the east. In the winter of 2003-2004, a west-oriented spit accreted at the inlet mouth, redirecting the mouth slightly toward the west. The presence of ice directly east of the inlet may have been partially responsible for buildup of this west-oriented spit as well as the redirecting of the inlet mouth to the west. The Town of Southold has discussed the future of Goldsmith Inlet and the Goldsmith Inlet jetty. Beyond the creation of a deeper channel, an option being considered is shortening of the jetty, which may mitigate erosion east of the jetty yet still preserve a portion of the beach fillet west of it.

DATA COLLECTION

A bathymetric survey of the offshore adjacent to Goldsmith Inlet was conducted by boat on 6-8 Oct 2002. Goldsmith Inlet and Pond, the beaches adjacent to the inlet, and the area from the shoreline to wading depth were surveyed with a total survey station and surveying rod. The survey of Goldsmith Inlet and Goldsmith Pond was conducted on 8 Oct 2002. A water level gauge was deployed from 19 Sep to 8 Oct 2002. Flood current velocity was measured in the inlet from 1323 to 1643 GMT, 8 Oct 2002 by

means of a hand-held current meter mounted on a pole that was sunk into the bed. Sediment samples were also taken.

Bathymetry

The coast west of Goldsmith Inlet is characterized by a relatively uniform shoreline and a large number of glacial erratics. The shoreline east of Goldsmith Inlet is less uniform. The area offshore on both sides of Goldsmith Inlet has a steep gradient, with a slope of approximately 1:10 from the beach to a depth of approximately 6 m NAVD88. A depression that is oriented parallel to the shoreline is located from 200 to 600 m offshore, where the depth reaches 7 m NAVD88. The entrance to Goldsmith Inlet is narrow and shallow. Depths range between 0.3 and 1.3 m NAVD88, and a large in-channel bar formation in the center of the channel becomes exposed during low tide. The channel has been observed to contain running water at all times during numerous field visits. At the time of the 6-8 Oct 2002 survey, the channel was 4 m wide at the entrance to the Long Island Sound and expanded to 35 m at the entrance to Goldsmith Pond.

An interesting finding of the survey is that Goldsmith Inlet lacks an ebb shoal. To the west of the inlet, an elevated formation (shoal) is located 300 to 600 m offshore. Because of this distance, this formation is not considered a consequence of either the modern or the historic inlet. Although the maximum ebb-current velocity at Goldsmith Inlet exceeds 1 m/sec and is comparable to that at other inlets that have formed ebb-tidal shoals, the volume of water flow or discharge is evidently too small to construct an ebb shoal. Sediment transported by the ebb current to the mouth of Goldsmith Inlet is transported from the entrance by waves and the wave-induced longshore current. This conclusion implies that bypassing from west to east occurs around the jetty, onto the spit, and back to the shore on the east side along a bypassing bar.

In contrast to lack of an ebb shoal, Goldsmith Inlet possesses a well-developed flood shoal consisting of three lobes. The lobes are located on the east bank, center channel, and west bank, where Goldsmith Inlet enters Goldsmith Pond (Fig. 3). Because of the mild elevation relief in the pond, the east and west lobes of the flood shoal are exposed during low water. The west lobe of the flood shoal is located approximately 250 m into the inlet. Sediment entering the inlet during flood tide is inferred to have formed this feature. This attachment on the west bank may redirect the ebb and flood tidal current and decrease the flushing capacity of the inlet. Sediment also approaches the inlet entrance from the spit that forms adjacent to the jetty. The entrance channel tends to align to the east, a characteristic that has become more pronounced with growth of the attachment shoal and the build-up of sediment along the jetty.

Water level

A tide gauge was placed near the southern bank of Goldsmith Pond and secured to the pond bottom. Water level at Goldsmith Pond is plotted in Fig. 4, together with that in Long Island Sound measured at the nearby Mattituck Inlet jetty (a Federal inlet located 8.4 km west of Goldsmith Inlet). In Goldsmith Pond, the average water level of the record was 0.28 m above NAVD88. This means that the pond does not completely empty to mean sea level (MSL), because the water flow is retarded by a sill in the area of

the flood shoal, as indicated in Fig. 6 and, to a lesser extent, by a sill in the inlet located near the shoreline.

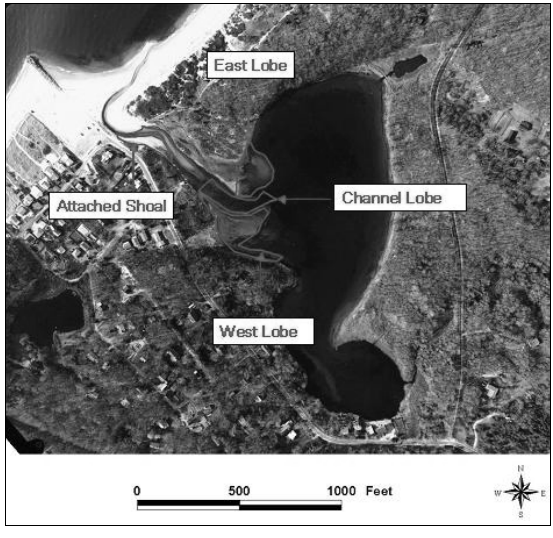

Fig. 3. Goldsmith Pond flood shoal. 16 Apr 2003

The measured tidal range within Goldsmith Pond varied from 0.37 to 1 m NAVD88. The mean tidal range for the deployment was calculated to be 0.66 m, with a spring tidal range of approximately 0.9 m for the period of record. The reduction in tide at Goldsmith Pond is, therefore, about 1 m or half the tidal range in Long Island Sound. Fig. 4 plots water level at Mattituck Inlet and Goldsmith Inlet for 5–7 Oct 2002. Because the tidal wave travels from east to west in Long Island Sound, the phase of the tide at Goldsmith Inlet will slightly lead that outside of Mattituck Inlet.

The bottom of the mouth of Goldsmith Inlet is located approximately at the elevation of the NAVD88 datum, near the visually observed mean shoreline position. Therefore, flow into the inlet and pond can only occur when the water level in the Sound is above MSL. The relation between NAVD88 and MSL at the mouth of the inlet is not known with confidence. Flow into the inlet and pond can only occur if the water level in the Sound is above the NAVD88 or MSL datums, according to the modeling results. When high tide is reached in the Sound, high tide in the pond occurs about 29 min later (median lag) and is 0.8 m lower. In contrast, the median phase lag for the low waters is 195 min (3.24 hr).

The long-term average water level in Goldsmith Pond is expected to be constant. The time duration of the high water is much shorter than the duration of the low water about the mean water level. Because the same amount of water must enter on flood as leaves at ebb to maintain the average water level in the pond, but in a shorter time, the average of the inlet channel cross-sectional current velocity on flood must be much greater than on

ebb. Such an inlet is called flood dominant, referring to the greater magnitude, but shorter duration of the flood tide.

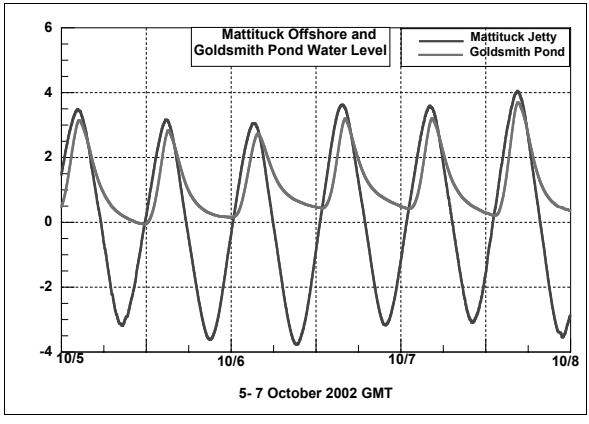

Fig. 4. Goldsmith Inlet water level, 5–7 Oct 2002

Current

The flood current velocity at mid depth and flood tide reached 1.3m/sec, after which the meter had to be removed because of concerns over the rising water level and strong current on. Corresponding to discussion of water level, there must be a strong asymmetry in current velocity at Goldsmith Inlet, with flood current being significantly stronger than ebb current. Sediment transport is proportional to a power of water velocity, typically the third power. Therefore, the flood-dominance will tend to transport sediment into Goldsmith Pond.

Sediment

Fourteen sediment grab samples were collected from Goldsmith Inlet on 8 Oct 2002, supplemented by 17 samples collected on 31 Jul 2003. The surficial sediment at the inlet entrance is predominantly composed of gravel (-6 to -2 ϕ). A transitional area is located around the shoal attached to the west bank where smaller gravel (-4 to -2 ϕ) dominates sand. The area of the inlet south of this region, which includes the flood shoal and the bottom of the pond is composed primarily of fine gravel and very coarse to coarse sand (-1 to 1 ϕ).

Figure 5 is a plan-view distribution of sediment grain size at Goldsmith Inlet. The plan view clearly shows fining of sediment with distance into the inlet and pond from the entrance. Current velocity magnitude plays a major role in determining the distribution of grain size within an inlet, resulting in a graded deposit and sorting within the channel. The greater velocity magnitude at the inlet mouth entrains and transports increasingly larger grain sizes. As the current velocity magnitude decreases, the larger grain size fractions are deposited, whereas finer sediments are transported further into the inlet.

Fig. 5 Goldsmith Inlet median grain size distribution of surface samples

CALCULATION OF CURRENT

Water-surface elevation and current velocity at Goldsmith Inlet and Goldsmith Pond were calculated with the DYNLET model. DYNLET is a 1-D plus model in that it solves for current velocity at specified stations along each cross section. Water level at the nodes and velocity at the stations are calculated, with the velocity apportioned at the stations according to the bottom friction or conveyance of the channel. A uniform rectilinear bathymetry grid for Goldsmith Inlet and Goldsmith Pond was created by importing the Oct 2002 bathymetry survey data into DYNLET. Thirty-one nodes with cross sections of varying length were then generated (Fig. 6).

The model was forced at Node 1 with water level measurements adapted from the Mattituck Inlet jetty gauge, and a no-discharge boundary condition (current velocity of zero) was specified at Node 31 located at the back of the pond. The distance between nodes was determined so as to represent significant changes in morphology through consideration of channel or pond width, depth, and roughness of the bottom. The DYNLET grid of Goldsmith Inlet originates approximately 200 m offshore. The distance between nodes within the channel and pond is approximately 20 m.

Water level measurements obtained offshore of Mattituck Inlet from 19 Sep to 8 Oct 2002 drove the model. The relation between MSL and NAVD88 at Goldsmith Inlet and Pond is not known. It was found by numerical experimentation that raising the water surface elevation by 0.25 m produced a successful model simulation that accurately

represented the tidal signature recorded at Goldsmith Pond, while not drying the channel. The authors have never observed the inlet channel to dry, even during low tide. A shift upward in the driving water level is functionally equivalent to shifting the entire bathymetry grid down by the same amount.

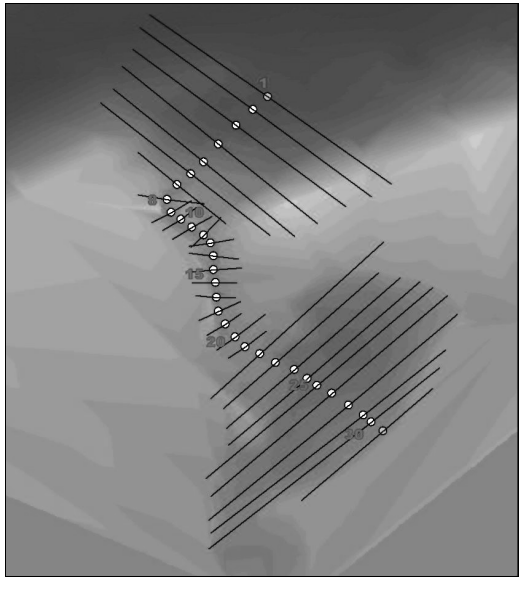

Fig. 6. DYNLET grid of Goldsmith Inlet, with nodes and extents of nodal cross-sections

DYNLET was calibrated by specifying larger values of the bottom friction coefficient in the Goldsmith Inlet channel, where small rocks are present and can protrude above the water surface, some of which may be remnants from jetty construction. The default value of Mannings n of 0.025 m/sec$^{1/3}$ was maintained at most nodes, but in the channel where rocks and roiling water are observed, the value was increased to 0.03 to 0.04. The time step in the model was set as 30 sec. The tidal record offshore of Mattituck Inlet was therefore adjusted forward 36 min to account for the time of tidal wave travel. This adjustment implies that the tidal wave moves westward at about 0.23 m/sec along the shallow water of this portion of the north shore of Long Island.

Figure 7 compares measured and calculated water level for 5-8 Oct 2002, a period of spring tide. Current velocity measurements taken for a short interval on 8 Oct 2002 are compared to corresponding DYNLET current velocity calculations (Nodes 13 and 14) in Fig. 8. The calculations well reproduce the limited length of the measurements. The current velocity is strong, exceeding 1 m/sec, and the calculated current is flood dominant.

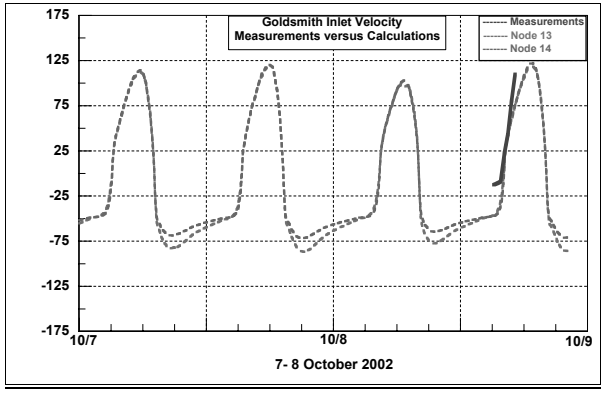

Fig. 8. Measured and calculated current velocity at Nodes 13 and 14, 7-8 Oct 2002

MORPHOLOGY CHANGE AND CHANNEL MIGRATION

Our analysis indicates that the greatest rates of erosion on the down-drift beach occurred between 1972 and 1978. Effective natural sediment bypassing was not established until the spit directly east of the jetty had reached a certain volume and areal extent. The impoundment fillet directly west of the jetty was the apparent primary sediment sink in this area prior to 1972. After this, the formation of the spit directly east of the jetty became the primary sediment sink for the local sand-sharing system. This period may have also been characterized by greater rates of sediment intrusion within the inlet.

Construction of the jetty apparently stabilized the inlet for 17 years by blocking eastward-moving material, because the first dredging of record occurred in 1977. Goldsmith Inlet was dredged seven times until 1990, and several times in the early 1990s. The inlet apparently maintained a degree of stability from the mid 1990s to 2002. The relatively large tidal range and large sediment grain size contribute to inlet stability. The instability observed in recent times may owe to continued degradation of the jetty, which allows sediment to enter the inlet.

Because Goldsmith Inlet is free to migrate to the east and away from the jetty, the location of its entrance channel is dynamic. The orientation of the channel, sediment impoundment west of the jetty, and the formation of a fillet east of the jetty were analyzed for times available from aerial photographs. The reorientation indicates that the inlet is presently an ephemeral inlet, in contrast to the preceding century when it was apparently more stable and open.

Figure 9 shows selected orientations of the inlet entrance from 1993 to 2004. Change in location and morphology of the Goldsmith Inlet channel entrance between 6-8 Oct 2002 and 16 Apr 2003 is substantial. Sediment accumulation extended the beach 18-25 m for the 150 m directly east of the jetty, and the entrance channel mouth migrated 107 m to the east. The effective greater length of the channel reduces the ebb flow and contributes to closure. The acute angle of the inlet relative to the shoreline however allows for more effective sediment bypassing.

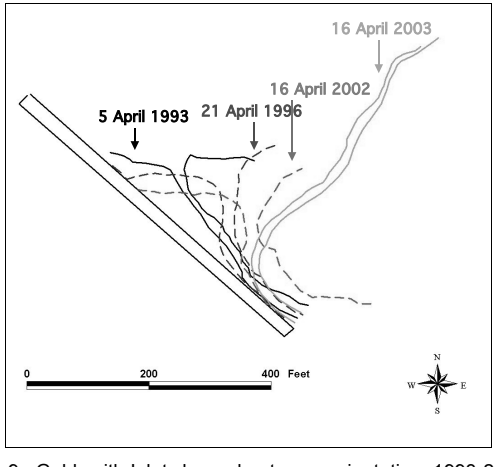

Fig. 9. Goldsmith Inlet channel entrance orientation, 1993-2003

TIDAL ASYMMETRY

The times series of water level in Goldsmith Pond exhibits three remarkable properties: (1) low tide usually does not reach 0 NAVD88, which is approximately MSL at the site, (2) the tide range in the pond is less than half that in Long Island Sound, and (3) water

level rises much more rapidly than it falls, and the duration of ebb is much longer than flood. Properties (1) and (2) are related. In Goldsmith Pond, the duration of the average ebb tide (peak to trough) of record was 8 hr, 56 min, and the duration of the average flood tide (trough to peak) was 3 hr, 28 min.

Tidal asymmetry of coastal inlets has been well studied and is summarized by Walton (2002). For example, shoaling channels truncate the lowest portion of the tide, resulting in a longer falling tide and weaker ebb current as compared to the flood current. Such a truncation is a hypsometric effect, the control of water surface elevation by the geometry of the bathymetry or depths. At the inlet, the elevation of the entrance is near MSL. At the lower water levels of ebb tide, the sills at the flood shoal and shoreline become more effective in retarding flow. In addition, water enters the fringing marsh of Goldsmith Pond on flood tide more rapidly than when it exits on ebb. The effective friction of the marsh, creating storage capacity, will release water slowly as compared to its entrance at flood tide.

The tidal water levels calculated in DYNLET levels exhibit strong asymmetric behavior for Goldsmith Inlet. Figure 10 plots water level at selected nodes along the inlet channel for 5-8 Oct 2002. At nodes located near the forcing in Long Island Sound, the water level signal is sinusoidal. With distance into the inlet, the water level signal becomes more asymmetric, achieving a greater maximum on flood than on ebb, and with a shorter time of flood than ebb. There are three possible causes for the asymmetry. The first and likely dominant cause is the presence of sills in the inlet. The higher water of flood can enter the inlet rapidly, because the tide wave celerity is given by the square root of the product of gravitational acceleration and depth. On the lower water of ebb, the depth has decreased, and the water that can ebb slows. Connected with this hypsometric change in wave speed, bottom friction will retard flow more strongly for shallower water.

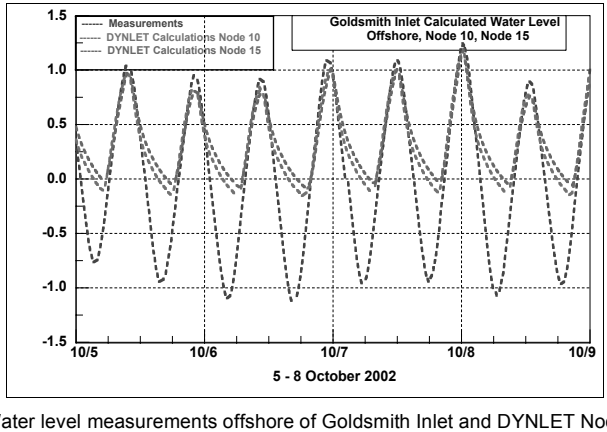

Fig. 10. Water level measurements offshore of Goldsmith Inlet and DYNLET Nodes 15 and 20 calculations, 5-8 October 2002

A second cause for the asymmetry in water level and current signals in the inlet and pond is the preferential drainage in the wetland surrounding Goldsmith Pond. It is expected that flooding water will enter the wetland more rapidly than the draining water on ebb. A third reason for the asymmetry is the non-linear interactions of flow components introduced by the bottom friction terms and advective terms in the equations of motion.

Figure 11 plots the maximum calculated velocity at each node for a spring flood tide and the subsequent ebb tide on 7 Oct 2002, together with the bottom elevation. The flood current had maximum velocity of 1.43 m/sec for this time interval. Strong flood-tidal currents persist to the exit of the channel into Goldsmith Pond. The ebb current at the mouth exceeds 1 m/sec.

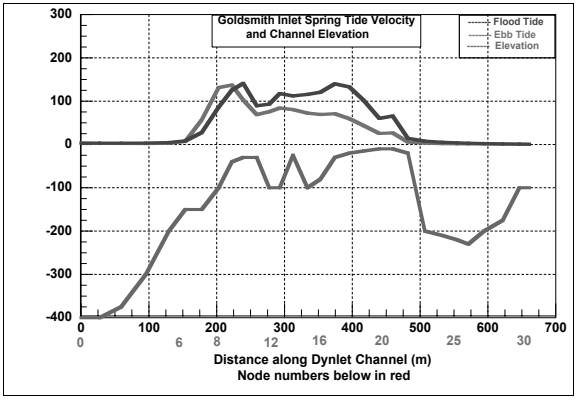

Fig. 11. Maximum calculated flood and ebb spring tide current speed and water elevation 7 Oct 2002

Figures12 and 13 display composite surfaces of maximum calculated flood and ebb velocity within the channel for hours 400 to 450 of the model run. A strong flood current persists over the entire channel and into the pond, whereas the ebb current is weak over much of the channel and pond, except at the mouth of the inlet. Such behavior would tend to transport sediment, particular sand, toward Goldsmith Pond, promoting flood shoal development and growth. The strong ebb current at the entrance would tend to maintain the inlet by sweeping finer sediments away from the mouth. However, sediment brought into the inlet on flood will not be flushed on ebb, promoting closure by constriction inside the inlet and not necessarily at the mouth.

CONCLUDING DISCUSSION

The presence of a tidal mill at Goldsmith Inlet in the 18th and 19th centuries indicates stability of the channel and strong tidal flow prior to the partial modifications of 1963-1964. The construction of the west jetty and the new-work dredging (1964) promoted stability of the inlet by substantially interrupting longshore transport of sediment to the east for approximately 14 years. In 1978, the jetty at Goldsmith Inlet appears to have

reached impoundment capacity. Thereafter, sediment intrusion into the Inlet increased, promoting dynamic morphological evolution within Goldsmith Inlet, partially mitigated by dredging. The increased rates of sediment intrusion resulted in the creation of an attachment fillet directly east of the inlet, the eventual maturation of the flood shoal, and a subsequent increase in the rate of channel infilling.

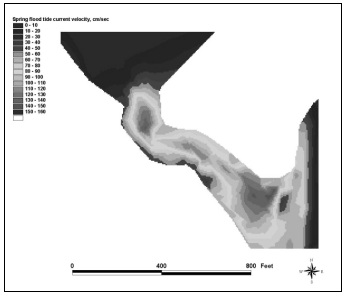

Fig. 12. Goldsmith Inlet spring flood tide maximum current velocity, inlet channel

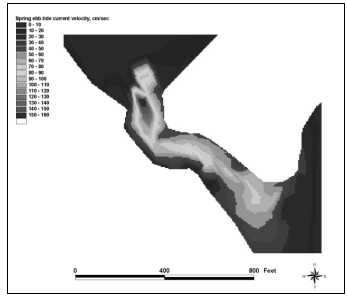

Fig. 13. Goldsmith Inlet spring ebb tide maximum current velocity, inlet channel

Re-establishment of an effective natural longshore sediment bypassing system appears to have taken place sometime in the early 1980s, when an attached fillet located directly east of the jetty reached an areal extent that promotes bypassing. Partial dredging from 1980 to 2000 apparently mitigated the continued growth and maturation of this attached fillet, and the eastward migration of the inlet entrance. The lack of dredging in recent years (in addition to continued degradation of the jetty) has allowed for rapid growth of this feature and resulting eastward migration of the inlet entrance (2001-2002). Re-establishment of a natural system of sediment bypassing has occurred, where sediment is transferred from this attached fillet via a bypassing bar located near the swash zone and eventually to the beach east of Goldsmith Inlet.

The current through Goldsmith Inlet is strongly flood dominant, determined in main part by the shallow sills in the channel. Because sediment transport is proportional to a power of water velocity, net sediment transport is directed into Goldsmith Pond. The greater velocity magnitude at the inlet mouth entrains and transports larger grain sizes. As the current velocity magnitude decreases with distance into the inlet, gradational deposition occurs, with the larger grain size fractions deposited and finer sediments transported further into the inlet.

The elevation of the entrance to Goldsmith Inlet is located near MSL. At the lower water levels of ebb tide, the sills at the flood shoal and shore become more effective in retarding flow. In addition, water enters the fringing marsh of Goldsmith Pond on flood tide more rapidly than when it exits on ebb. The effective friction of the marsh, creating storage capacity, releases water slowly as compared to its entrance at flood tide.

The mouth of Goldsmith Inlet appears to be at or near locational and cross-sectional equilibrium if it is oriented to the east, as shown in Fig. 1. Past dredging practice has realigned the channel parallel to the jetty. It is concluded that an orientation with the mouth directed to the east is the optimum for sediment bypassing and maintenance of inlet stability. The accretion fillet to the east, between the jetty and the inlet mouth, now functions to bypass sediment via transport by wave-induced current in the swash zone and by the ebb current issuing from an easterly orientation. If the accretion fillet to the west were mined substantially, impoundment at the jetty would reduce the sediment bypassing volume, turning back the processes in time.

ACKNOWLEDGEMENTS

Field data collection led by Mr. William Grosskopf of OCTI, East Coast, and discussions with Mr. William Seabergh of the Coastal and Hydraulics Laboratory, U.S. Army Engineer Research and Development Center (ERDC) are appreciated. This study was supported by the Coastal Inlets Research Program conducted at the ERDC, Vicksburg, MS. Permission was granted by Headquarters, U.S. Army Corps of Engineers, to publish this information.

Abstract: The Port of Barranquilla is one of the two main Colombian Ports on the Caribbean coast. Shoaling in the Port's access channel from the mouth of the Magdalena River to the terminal of the Regional Port Society of Barranquilla has historically restricted navigation for vessels with drafts as shallow as 30 feet. The existing harbor facilities in Barranquilla will require a 40-foot deep access channel in order to allow permanent access for larger ships without navigation restrictions. A feasibility study proposed several flow training structures to scour the channel and maintain navigable access to the Port. In this study, a hydrodynamic and morphological model was constructed using the Delft3D system to test the validity of the solution defined in the feasibility study. The model was further applied to improve that solution in order to guarantee a stable navigation channel with a depth of 40 feet and a width of 150 feet as required for safe navigation. The model prediction suggests that the improved solution will create and maintain the design navigation channel within 3-4 years after construction.

INTRODUCTION

The Port of Barranquilla is one of the two main Colombian Ports on the Caribbean coast. The Port's access channel from the mouth of the Magdalena River to the terminal of the Regional Port Society of Barranquilla has historically presented navigation restrictions

even for 30-foot draft ships. The Ministry of Transportation of Colombia has contracted a number of technical studies over the last decade with the goal of developing a plan that could ensure the required channel depth in the last 22 kilometers of the Magdalena River that guarantees access to the main terminals of the Port of Barranquilla from the mouth of the River. These studies concluded that the depth of the channel constitutes the limiting factor in increasing the competitiveness of the Port. The existing harbor facilities in Barranquilla will require a 40-foot deep access channel in order to allow permanent access for ships of 35000 TPM without restriction. An initial feasibility study (Universidad del Norte, 1999) identified two critical shoaling locations, near the river mouth and at Isla 1972 (see Figure 1), which is in a straight sector of the river situated between two bends. These areas have required a significant amount of dredging in the past.

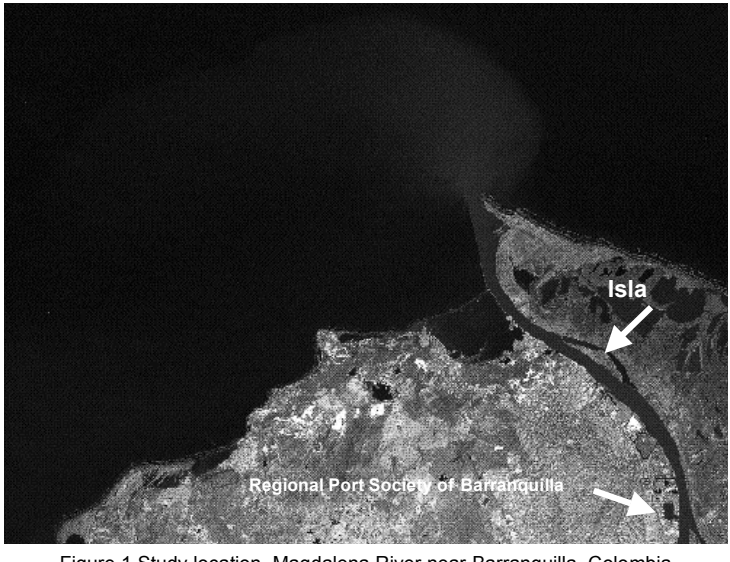

Figure 1 Study location. Magdalena River near Barranquilla, Colombia

To permanently improve the navigation conditions the feasibility study proposed a solution that consisted of a number of groin-type structures to create contractions of the river's cross section. It is predicted that the contractions would increase flow velocity and thereby scour the river bottom to the depth required for safe navigation.

This paper presents the development and application of a 3D morphological model of the last 22 kilometers of the Magdalena River to study the performance of the proposed solution and to define an alternative solution if the proposed one fails to ensure safe navigation. The following paragraphs describe the model development, model predictions and the final solution which is under construction at this time.

MORPHOLOGICAL MODEL SETUP

The morphological model was developed using the Delft3D modeling system (WL | Delft Hydraulics, 2006). The orthogonal curvilinear grid extends 20 km upstream of the river mouth to approximately 2 km offshore from the tip of the existing breakwaters. Grid resolution is approximately 100 m along the river and 30 m across. This grid resolution was selected to accurately simulate the hydrodynamics along the main navigation channel and the morphological changes generated by the groin-like structures while keeping the simulation time required for long term morphological simulations within manageable limits. The selected grid resolution does not allow for an accurate simulation of the flow patterns at the tips of the structures and therefore local scour for the design of the structures was calculated analytically.

.

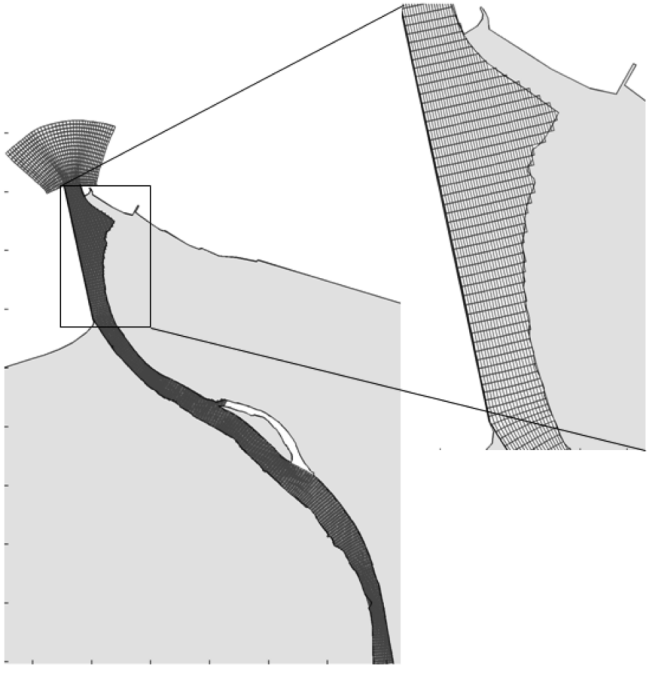

Figure 2 Numerical Model Grid

Where the river mouth opens to Caribbean Sea, the depth abruptly changes to 60 meters from the 12 to 14 meters typical of the navigation channel. This is a persistent feature observed in all available historical bathymetries. Figure 3 presents the bathymetry of the study area in November 2005 where the two critical shoaling locations can be observed near the river mouth and at Isla 1972. These areas have required a significant amount of dredging in the past and are the sections of the river where the flow training structures should have the largest impact.

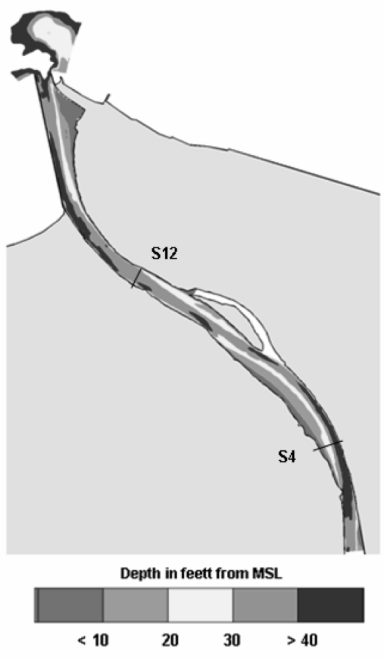

Figure 3 Model Bathymetry for November 2005 conditions. Depths are in feet in order to show areas below 40 feet, which is the require depth for the design channel.

Since the river mouth is one of the areas where sedimentation in the navigation channel is regularly observed, a three-dimensional model was used to simulate the interaction between the river fresh water and the denser water of the Caribbean Sea at the mouth. The vertical grid was defined using sigma coordinates which are bottom fitted with a free surface. The model has a total of 7 vertical layers. In addition the model also used the κ-ε turbulence closure scheme. Model boundary conditions were prescribed at the upstream and downstream boundaries. Since the tidal variability was not included in the model, the downstream boundary water level was constant and equal to the mean sea level, independently of the river discharge. The upstream boundary is a discharge boundary and has been defined using available rating curves from records since 1967 to present. In every simulation a salinity boundary condition of 30 ppt was used at the offshore boundary and 0 ppt at the upstream boundary.

The hydrodynamic model was calibrated to historical and recently measured data. In particular, the hydrodynamic model was calibrated to reproduce the observed variation in water levels in the last 20 kilometers of the river and also the observed averaged velocities under different flow conditions. Most of the data used for calibration were

provided by the Las Flores Hydraulic Engineering Laboratory of Universidad del Norte, in Barranquilla, Colombia.

Three flow conditions were considered for calibration: 9,800 m^3/s, 8,000 m^3/s and 3,900 m^3/s. These conditions are representative of high, average and low flow conditions, respectively, in the Magdalena River. Figure 4 presents the simulated water levels for these three discharges versus the observed range of levels.

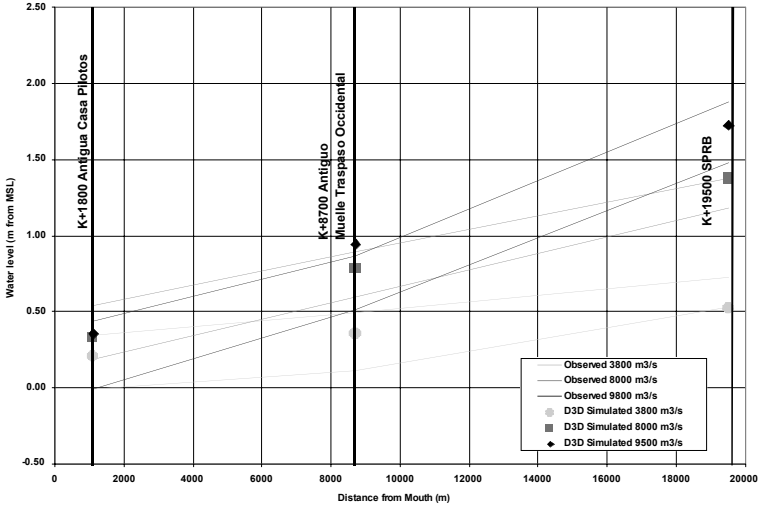

Figure 4 Simulated and observed range of water levels along the last 20 kilometers of the river for three different flows (after Universidad del Norte, 2005).

Velocities were also compared to observations at two sections of the river corresponding to kilometers 17 (S4) and 8 (S12) from the river mouth (see Figure 3). Simulated depth average velocity values across the section for a discharge of 9,500 m^3/s are 1.42 and 1.49 m/s for S4 and S12 respectively, which are very similar to the observed values at the same sections (1.42 and 1.49 m/s respectively). In addition Figure 5 shows the simulated distribution of velocities in cross sections S4 and S12. The distribution of velocities across the channel and in the vertical in these two sections is comparable to those observed in the field.

During the calibration phase it was observed that the model was able to reproduce the secondary flow at the river bends, simulating surface and bottom transversal currents in opposite directions; however, a quantitative comparison could not be made since data was not available for this purpose. Figure 6 presents simulated salinity and velocities in a vertical profile along the navigation channel for the last 2 kilometers of the river and offshore of the river mouth. Results are shown for a simulation with average river discharge. The model simulates the flow of the river fresh water above the denser ocean

water. It has been observed in the field that due to high river discharge, the penetration of the denser saline water layer upstream is limited to the first couple of kilometers from the river mouth.

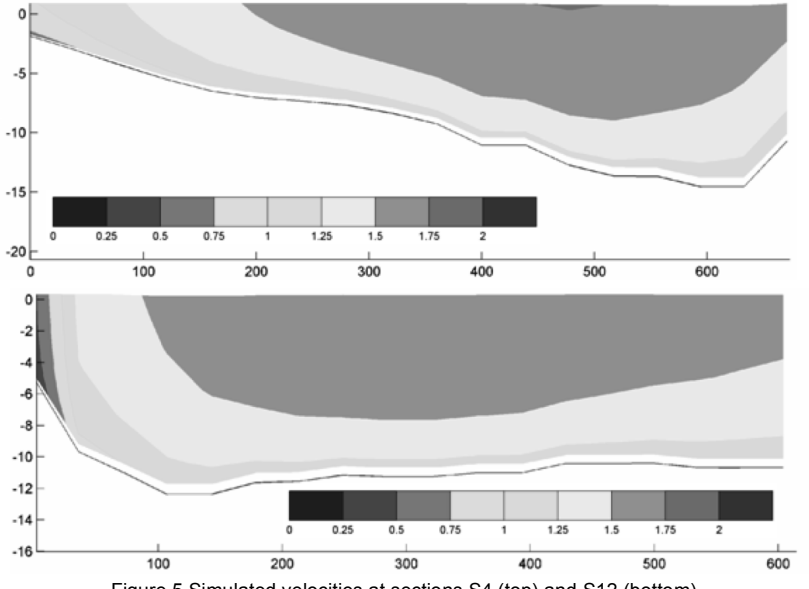

Figure 5 Simulated velocities at sections S4 (top) and S12 (bottom)

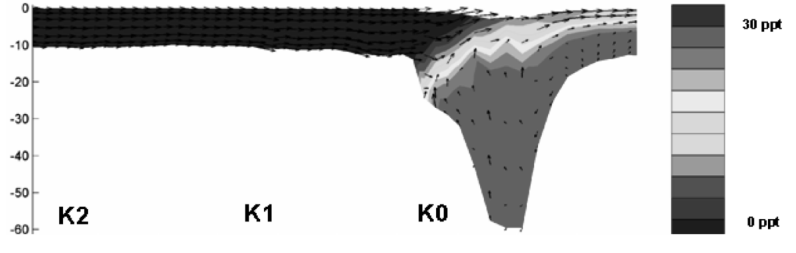

Figure 6 Simulated salinity distribution at the river mouth. Depths are in m from MSL. K0, K1 and K2 are kilometric points from the river mouth.

The river carries a large amount of suspended sediment most of which is in the form of washload consisting of very fine sand and mud. Bottom sediment samples were collected throughout the study area and it was observed that very fine sand and mud only accumulate in a few locations near the river banks. The D50 value for the non-cohesive sediment in suspension has a value between 0.08 and 0.09 mm, and D90 between 0.1 and 0.125 mm. This material is more fine than that found on the river bottom. The navigation channel river bottom consists of fine sand with a D50 in the order of 0.2 mm. Since the washload is carried by the river offshore, mud transport has not been simulated in the numerical model. Bed load and suspended load was simulated for sand with a D50 of 0.2 mm. Upstream sediment transport model boundary conditions use the equilibrium profile concentration. The equilibrium profile is computed by the model so that the suspended sediment load entering the model through the upstream boundary is adapted to the local flow conditions.

The Delft3D morphological model applied in this study follows Lesser and Roelvink (2004) with the sediment transport formulation of Van Rijn (1984) which considers separately bed load and suspended transport and is well suited to simulate sediment transport in rivers. Morphological changes in the study area that are calculated at one hydrodynamic model time step tend to be very small. Therefore, it is possible to apply a morphological multiplication factor since the model simulates quasi-steady state conditions based on the prescribed flow at the upstream boundary condition and does not consider the effect of waves and tides,. This factor speeds up the morphological changes in such a way that those calculated from a specific period of time will be equivalent to that period multiply by the morphological factor. Results from a sensitivity study indicated that for this particular model setup a morphological factor of up to 365 produce very similar results to a simulation using a factor of 1. A factor of 365 was used in this study, and therefore changes obtained during a one day of hydrodynamic simulation represent morphological changes during one year.

There are some limitations regarding data availability and simplifications made in the model setup that could have an effect on the results and the calibration of the morphological model: the model does not simulate the erosion of the banks which could have an influence in long term changes; the model does not consider flood plains which inundate during periods of high flow; the model does not consider dredging events in the navigation channel that take place regularly; and the available bathymetric data are not complete from bank to bank.

MORPHOLOGICAL MODEL CALIBRATION

The model was calibrated for the periods 1998-2003 and 2003-2004 and then validated for April 2004 to November 2005. Figure 7 shows the initial cross sections in April 2004 and the simulated and observed cross sections in November 2005 at the two standard sections S4 and S12. As it can be observed the model reproduces the deepening of the channel that was generally observed in the two control sections. In addition Figure 8 shows the measured and simulated deepest value at each kilometer for the last 13 kilometers, which is the river segment to be primarily affected by the river training

structures. The model predicts the general morphological trends in the navigation channel during this period and in particular replicates the erosion of the navigation channel between kilometers 2 and 4 and the accumulation between kilometers 11 and 13. The latter is an area of concern and requires regular maintenance dredging.

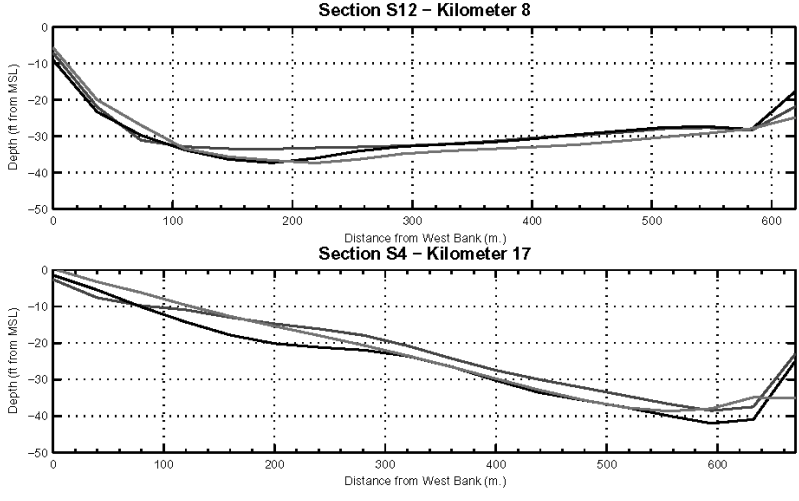

Figure 7 Measured cross sections in April 2004 (Blue) and November 2005 (Black) and model simulated for November 2005 (Red).

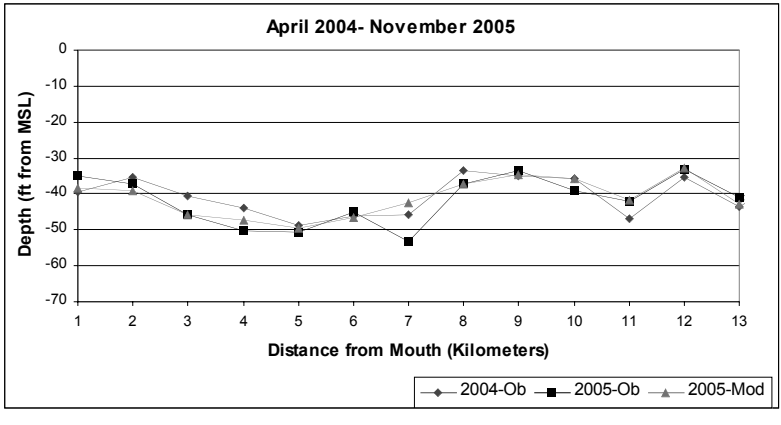

Figure 8 Maximum cross section depth measured in April 2004 (Blue) and November 2005 (Black) and model simulated for November 2005 (Red).

MORPHOLOGICAL FLOW

Daily river flows have been estimated for the 1967-2005 period from existing rating curves. In order to compute the sediment transport associated to a river flow, the average velocity associated to this flow has to be known. Available velocity data was used to develop a relation between average velocity in the project area and the river flow. Daily sediment transport for the 1967-2005 period was calculated using the estimated average velocities, at a depth of 12 m (average existing navigation channel depth) using the sediment transport formulation of Van Rijn 1984. The flow representative of the average sediment transport, or morphological flow, for the 1967-2005 period, is approximately 7,500 m^3/s, while the average flow is in the order of 6,400 m^3/s. Figure 9 shows the annual average sediment transport as a percentage of the sediment transport associated to the morphological flow. Years represented in blue indicate years in which the annual sediment transport was higher than the one associted to the morphological flow while years in red represents years with an average flow lower than the morphological flow. It has to be noted that there is a strong relation between the annual river flows in the Magdalena River and the occurrence of El Niño or La Niña events in the Tropical Pacific. Figure 9 shows the strong signature of the last El Niño event of the 20th Century in 1997-98.

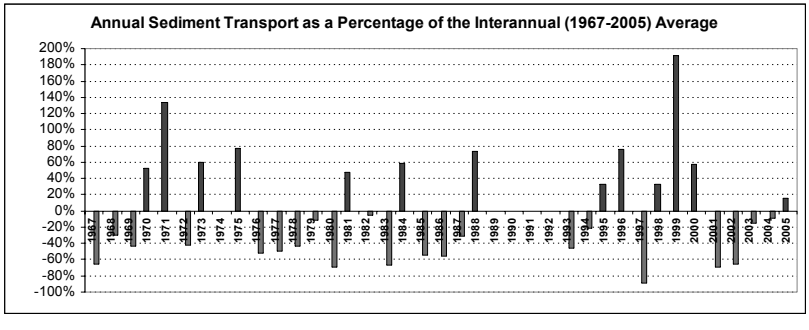

Figure 9 Annual sediment transport as a percentage of the sediment transport associated to the morphological flow

MORPHOLOGICAL MODEL APPLICATION

The morphological model was used to predict morphological changes up to 6 years after the construction of the training works. The previously defined morphological flow was applied at the upstream boundary for all the simulation period. Sensitivity tests were performed to confirm that considering monthly or seasonal variability in the morphological flow produced similar long term results to using an average annual value. The model was initially used to test the validity of the alternative defined in the feasibility study (Universidad del Norte, 1999). Results from this alternative did not produce a navigation channel with a depth of 40 feet and a width of 150 feet to allow navigation of the design vessel continuously from the river mouth to the port terminals.

The length, number and location of each groin (called espolones in Spanish) were modified for each defined alternative and simulated with the morphological model in order to optimize the solution. Nearly 20 plans were simulated in order to reach to the final alternative presented in Figure 10. This final solution included some modification of the structures defined in the feasibility study and the inclusion of three new short groins. Groin 0 was added to extent the influence of the structures further upstream particularly in the area near kilometer 12 where dredging is regularly required under existing conditions. Additionally, groins 5 and 7 were added to the external curve to provided continuity to the navigation channel during the first years after construction. Simulations predicted that without these groins the stable channel at the external curve will be disrupted by the sediment eroded from the channel in the upstream sections. The model also predicts that the channel will tend to form again in the same location within 4 to 5 years after construction.

Figure 11 shows the evolution of the navigation channel width as predicted by the model every year up to 4 years after construction of the final selected alternative. It can be observed that the model predicts an uninterrupted 40 ft channel wider than 150 meters along the area influenced by the structures, between the river mouth and kilometer 12.

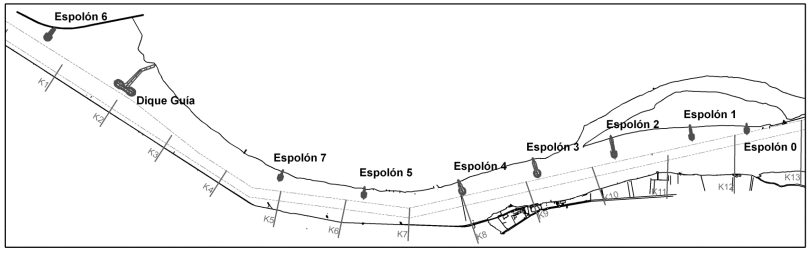

Figure 10 Final alternative

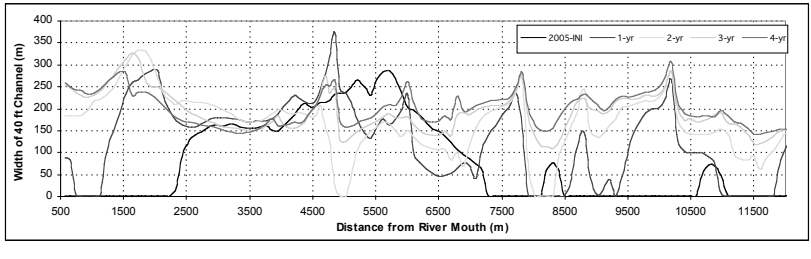

Figure 11 Simulated evolution of the width of a 40 ft deep navigation channel in the area of influence of the structures. (Required with is 150 m)

Figure 12 shows the initial bathymetry and the simulated bathymetry after 5 years in three sections of the river for the final alternative. It can be observed from the Figure how the navigation channel is completely formed and stable after 5 years.

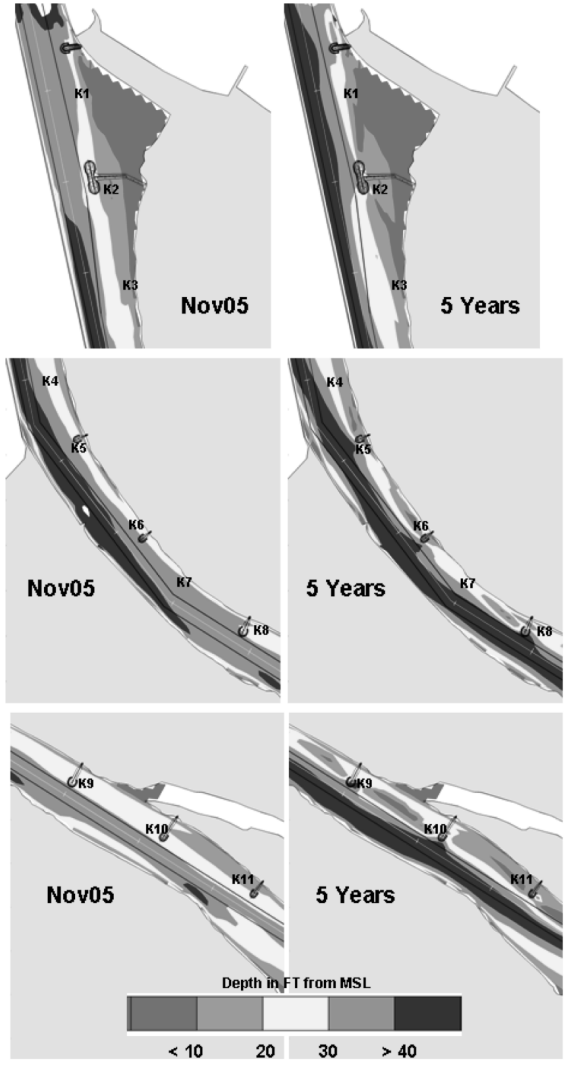

Figure 12 Model initial and 5-year simulated bathymetries for the final alternative

Figure 13 presents the maximum depth average velocities along the navigation channel under pre and post-constructions conditions. The structures could produce an increase on the maximum velocities in the channel in the order of 0.2-0.3 m/s. These results were used to study the effect that this increase on velocities will have on navigability along the channel.

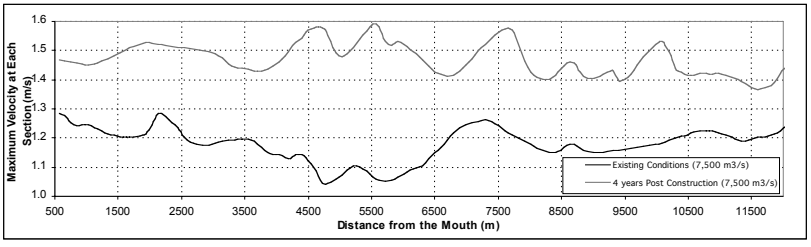

Figure 13 Simulated maximum depth average velocities along the navigation channel for pre and post-contruction conditions

CONCLUSION

A state of the art morphological model has been applied in Barranquilla, Colombia to design navigation channel deepening works. A hydrodynamic and morphological model was calibrated and validated to available recent and historical data. The model was able to reproduce the primary historical morphological trends observed in the study area.

The calibrated model was then used as a tool to test several deepening works alternatives with goal of producing a navigation channel 150 meters wide and 40 feet deep. Although not explicitly discussed here, model predictions have also been used as inputs to a navigation model to study the navigation conditions for the design vessel in the predicted channel.

Construction of the final alternative is under way. Figure 14 shows a picture of groin 1 (Espolón 1) after construction. Recent post-construction surveys indicate that the constructed structures are already deepening the navigation channel as predicted by the model. Comparison of model predictions and observed post-constructions bathymetries will be considered in future studies in order to asses the prediction capabilities of this type of morphological model.

Abstract: The offset configuration of Tauranga tidal inlet delta system, in combination with the dredged entrance channel, hinders sediment supply to the down-drift beaches. Maintenance dredging of the entrance channel provides suitable sediment to be deposited as a nearshore berm, downdrift of the entrance channel, as a means to artificially bypass the tidal inlet and renourish the beaches of Mt Maunganui. During April and May of 2004, ~112,000 m³ of dredged medium sand was deposited between two nearshore dump grounds (Sites B and C), under the assumption that onshore transport would occur and act to renourish the beaches shoreward of these sites. Bathymetric and side-scan sonar monitoring showed erosion of the mounds at both sites and significant onshore dispersal at Site B clearly evident after disposal. Sub-aerial beach profile monitoring from 1999 to 2005 shows continued accretion of the sub-aerial beach from 2001 to 2005, partially in response to ongoing beach nourishment. This suggests that any reduction in sediment supply to the down-drift beaches is being successfully alleviated.

INTRODUCTION

Capital and maintenance dredging of Tauranga Harbour entrance channel has been undertaken since 1968, with the spoil mainly used for reclamation projects (Sulphur Point), deposited in approved dump grounds (Healy *et al.,* 1998), or used for commercial purposes. However, the dredged entrance channel acts as a sink for the littoral drift, partially cutting off sediment supply to the downdrift beaches of Mount Maunganui. To remedy any possible sediment deficit, the Port of Tauranga Ltd uses the dredged sediment from the tidal inlet delta system to renourish the adjacent downdrift beaches.

Previous studies of an inner shelf dump ground in 8 m water depth off Mt Maunganui beach have been carried out by Foster (1991), and reported in Foster *et al.* (1994, 1996). That disposal campaign was carried out in 1991-1992, where some 80,000 m³ of coarse sandy sediment from the entrance channel was deposited in ~8 m water depth off Mt Maunganui Beach (Site A, Figure 1). This material was subsequently monitored for 16 months and, as predicted, shoreward migration was observed (Foster *et al.,* 1994, 1996).

From the beginning of April through to the 24th of May 2004, maintenance dredging of the entrance channel to Tauranga Harbour was undertaken using the trailer suction dredge *Pelican*. To mitigate any potential reduction in sediment supply to the downdrift beaches, 112,000 m³ of the dredge spoil was deposited ~3.5 km east of the entrance channel, in ~4-17 m water depth (Sites B and C, Figure 1). The dredge spoil was deposited under the assumption that onshore sediment movement would occur and act to renourish the beach. Of the 112,000 m³ deposited at Sites B and C, 83,225 m³ of sediment was deposited at Site B and 28,696 m³ at Site C.

To date no investigations of dredge spoil dispersal have been carried out at Sites B or C (Figure 1).

The aims of this paper are to characterize the natural dump ground sediment facies and identify any changes resulting from the subsequent dredge spoil disposal; and investigate the fate of, and account for, the material dumped in disposal sites B and C.

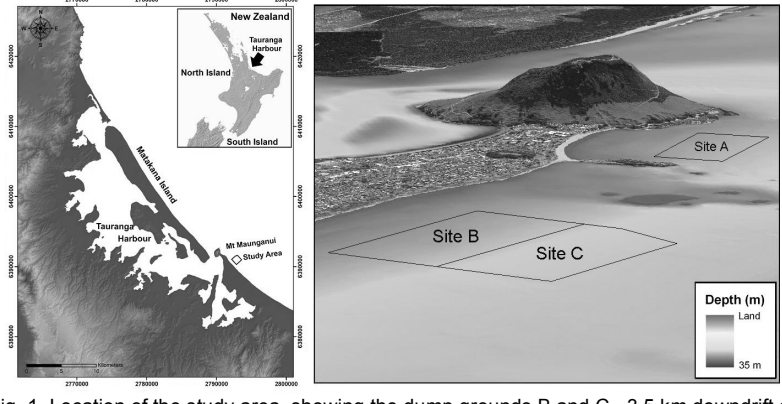

Fig. 1. Location of the study area, showing the dump grounds B and C ~3.5 km downdrift of the entrance channel.

STUDY SITE

Tauranga Harbour is a mesotidal estuarine lagoon (851 km^2) located on the northeastern coast of New Zealand (Figure 1)(de Lange and Healy, 1990; Healy, Cole and de Lange, 1996). The Port of Tauranga maintains ~8.2 km of navigation channels (Healy *et al.*, 1998), including the dredged entrance channel, which is maintained at 14.1 m (C.D).

Hume and Herdendorf (1992) categorise the Bay of Plenty coastline (which includes the disposal ground on the beach adjacent to Tauranga Harbour) as a wave exposed, open sediment system, comprising sandy beaches developed by the littoral drift. Healy *et al.* (1977) suggests that the orientation of Tauranga entrance and the depth of the tidal gorge act as a partial barrier to the net southeasterly directed littoral drift. This can lead to accretion at Matakana (updrift) and erosion at Mt Maunganui (downdrift) (Healy *et al.,* 1977). The limited bypassing of the littoral drift is further exacerbated through deepening the entrance channel by dredging (Healy, 1980).

DATA COLLECTION AND ANALYSIS

Side-Scan Sonar Surveys

In order to assess any changes to the nature of the dump ground sediments and bedforms after dredge spoil disposal, a series of side-scan sonar surveys were undertaken for Sites B and C. These comprised one pre-disposal survey (April-04) and three post disposal surveys (June-04, October-04 and January-05). All of the surveys (aside from October-04) were undertaken in conjunction with surficial sediment sampling, providing ground truthing to aid in the sonograph interpretation. Side-scan sonar surveys were carried out using a dual frequency Klein 595 side-scan system. The surveys consisted of 8 run lines from 3-18 m depth, overlapped to gain full coverage of the dump ground area. A swath width of ~150 m was used. To allow better reflection of wave generated bedforms, survey lines were carried out parallel to the shore, similar to those conducted at Mt Maunganui by Harms (1989) and Foster (1991), and at Mangawhai-Parkiri by Healy *et al.,* (1996). A geo-referenced mosaic of the survey data (processed to 0.5 m resolution) was generated in post-processing, and overlaid on aerial photographs.

Sediment Sample Collection and Analysis

In order to provide ground truthing for the side-scan sonar surveys, two cross-shore transects were created through the dump grounds. Samples were collected at 100 m intervals along each transect using a Van Veen sediment grab sampler. All samples were collected on the same day as the side-scan surveys were undertaken. Sediment textural analyses were then carried out using the University of Waikato Rapid Sediment Analyser (RSA). The RSA is a fall tube apparatus which is thoroughly discussed in Darlan (1991).

Bathymetric Surveys

In order to identify and to monitor the dispersal of the deposited sediments within the active nearshore profile, repeated singlebeam and multibeam bathymetric surveys of the dump grounds were undertaken. Surveys were carried out on 4 occasions, viz., November 2003 (pre-disposal), 9th June (~17-20 days after disposal), August 2004 and April 2005.

The November-03 and June-04 surveys were undertaken by the Port of Tauranga Ltd, using a 200 kHz Knudsen singlebeam echosounder. Positional information was recorded by Real Time Kinematic GPS accurate to ±0.05 m (Owen Maynard, pers.comm.). The surveys consisted of 24 runlines, spaced at 50 m intervals, perpendicular to the shore. The August 2004 and April 2005 dump ground soundings were acquired with an

EM3000 shallow water multibeam system. The surveys consisted of shore parallel run lines which were overlapped to obtained full ensonification. The surveys encompassed the entire dump ground areas and an area ~200 m shoreward of the dump ground. All depth measurements are relative to local chart datum.

Data from each survey was gridded in SURFER®. Volumetric and morphological variation due to dredge spoil dumping and dispersal was obtained by subtracting the gridded surface of each survey from the preceding one. However volumetric comparisons between the multibeam survey (undertaken on August 2004 and obtaining close to full coverage) and the interpolated grid of the single beam survey (June 2004), must be viewed with caution, taking into account the obvious limitations when comparing an interpolated surface with an actual surface.

Sub-Aerial Beach Surveys

To assess the possible changes to the sub-aerial and inter tidal beaches (shoreward of Sites B and C) as a result of dredge spoil dispersal, 6 shore normal survey lines were established. Surveys were conducted every 2-3 months (April-04 to May-05) at low tide, using standard staff and level techniques. The survey lines were spaced at 100-150 m intervals. The accuracy of this type of survey method and those similar to it i.e. the "Emery method" is suggested to be in the order of ±0.01-0.05 m (Gable and Wanetick, 1984).

To quantify the temporal and spatial change between surveys, the raw profile data was converted to XYZ coordinates and gridded. This allowed estimates of volume change between each survey to be undertaken. Volumetric calculations based on grids where the data is widely spaced are unable resolve any variations that occur between any two survey lines; thus they only provide an estimate of the change in volume.

RESULTS AND DISCUSSION

Side-Scan Sonar and Textural Analysis

The pre dumping sonograph for both sites B and C demonstrates that the dump grounds are primarily dominated by the fine featureless sonograph facies (FFS). Textural analyses from this study and previous studies by Foster (1991) suggest that this featureless pattern coincides with moderately to moderately well sorted fine sands. Two areas, ~ 90 x 90 m of the medium to coarse grained, rippled sediments (termed CGR's) are observed in the middle of Site B (Figure 2). Some confined patches of coarse grained ripples (CGR's) are also distributed through Site C. Comparisons with the side-scan sonar surveys undertaken in the same area in 2002 suggest that these areas may be residual deposits of coarse sediments corresponding to previous dredge spoil disposal campaigns.

The first post dumping side-scan survey (June-04) is again dominated by the FFS sonograph facies at Site B (Figure 2). A number of small areas of CGR's can be identified through the middle of Site B. These areas correspond to the primary disposal areas at this site and thus may represent areas where the finer proportion of the dredge sediments has been selectively removed, leaving a concentration of the coarser dredge

spoil. Alternatively, as CGR facies were also apparent in these areas prior to dumping, it may indicate that higher turbulence over these areas inhibits the deposition of fine sediments (Green *et al.,* 2004). Although the area corresponding to spoil disposal also appears to exhibit a slightly darker return (higher acoustic response) on the sonograph than the April-04 survey, surficial sediment samples show no significant change in grain size and only a slight increase in shell content. The October-04 and January-05 surveys exhibit a similar pattern to the June-04, whereby the Site B dump ground is dominated by FFS sonograph facies (Figure 2). The small areas of CGR facies are still present, but have reduced in size. Overall at Site B little obvious change as a result of dredge spoil disposal can be identified.

Contrary to Site B, at Site C the areas of dredge spoil deposition are clearly identifiable (Figures 2 and 3). One month after disposal (June-04) the dump mounds (~10-14 m water depth) are distinguished by areas of the CGR's facies, characterized by dark coloured and rough textured sonograph facies (Healy 1985, Harms, 1989, Bradshaw *et al.,* 1994). Surficial sediment samples from these areas consist of medium to coarse sediments with a high shell content. These areas are dominated by rippled bedforms, aligned parallel to the shore, with wave-lengths of 0.7-1 m. Surrounding these areas are the combined CGR/FFS facies (coarse grained ripples with sand dunes and "ribbons" of fine sediment overlayed). The formation of concentrated areas of CGR on dredge spoil mounds has previously been reported by Dahm and Healy (1980). They conclude that the reworking of the dredge spoil by wave focusing leads to the selective removal of the fine constituent of the spoil, resulting in the formation of this facies (CGR), which is also typically observed to occur naturally on the inner shelf (cf. Spiers, 2005).

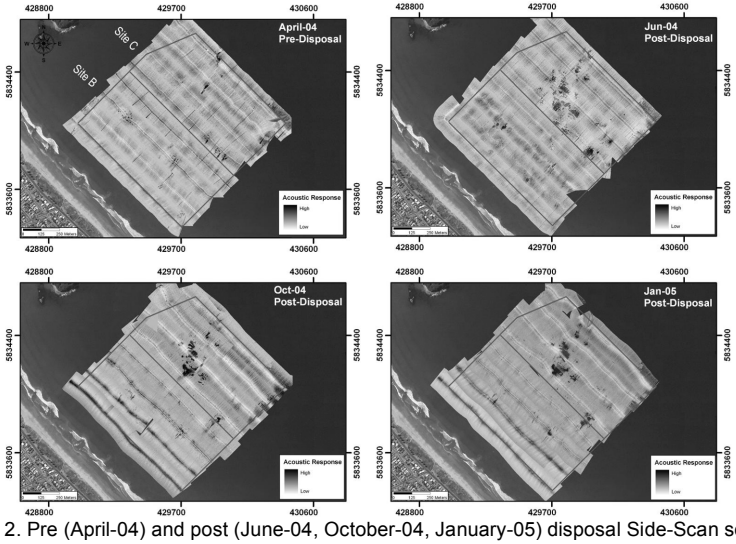

Fig. 2. Pre (April-04) and post (June-04, October-04, January-05) disposal Side-Scan sonar mosaics for dump grounds at Sites B and C. Photograph courtesy of the Eastern Bay of Plenty Regional Council.

The October-04 and January-05 surveys display a reduction (since June-04) of the area of CGR's at Site C. The two largest areas of CGR's are still evident and are generally unchanged between June-04 to January-05. However, the smaller areas have been replaced by the combination facies CGR/FFS or, in many cases have been completely enveloped by fine featureless sand (FFS). Interestingly, the most significant change at Site C is the reduction in the CGR/FFS facies between June-04 and January-05. The pronounced 'ribbons' of fine sand (Bradshaw *et al.,* 1994) transgressing the underlying coarse dredged sediments are only found in close proximity to the large CGR's facies, being replaced by the FFS over the rest of the dump ground. Aside from the large areas of CGR's, the rest of the dump ground appears to have rapidly reverted back to its pre-disposal state. As suggested by the significant reduction in the size of the coarse lag deposits between 2002 and 2004, it is anticipated that the large areas of CGR's will degrade and revert to FFS over time.

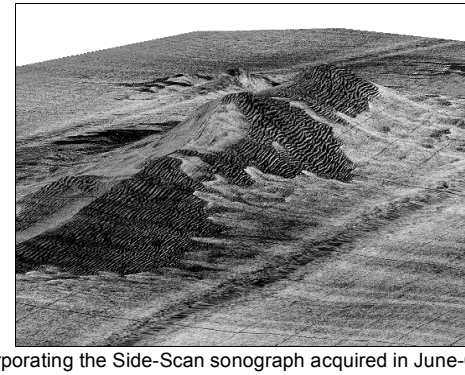

Fig. 3. Image incorporating the Side-Scan sonograph acquired in June-04 with dump ground bathymetry from the same time to allow a 3D view of the sonograph. This figure represents a view of the seaward side of the main Site C dump mound from a side-on perspective (from the east). Dump mound relief has been vertically exaggerated to emphasize the main features.

Dump Mound Formation and Nearshore Dispersal

The residual difference between the Nov-03 (pre-dumping) and Jun-04 (1st post dumping) surveys reveals the extent of the deposited dredge spoil (Figure 4). Dredge spoil appears to have been deposited in a line through the centre of Site B at ~5-8 m water depth (relative to chart datum). The line of spoil is characterized by three dominant mound features, with peaks of up to ~0.7 m and cross-shore widths ranging from 50-250 m. Volume calculations suggest that sediment accretion of ~52,500 m³ has occurred at Site B since the pre-dumping survey, the majority of which is clearly attributed to the 83,000 m³ of spoil deposited at this site.

The volume of sediment accounted for at Site B is ~30,500 m³ less than the dredge recorded volume deposited at this site. The timing of the pre- and post-disposal surveys may provide one explanation for the observed difference. As the pre-disposal survey was undertaken 4 months prior to the start of disposal, any changes occurring over this

time period (i.e. erosion and accretion) are also incorporated into the volume calculations between the pre and post disposal surveys. Therefore, any reduction in bed level occurring prior to disposal, but corresponding to the disposal areas, would lead to a reduction in the volume of sediment accounted for. Spiers (2005) reports that natural variation in the nearshore is commonly observed along Mt Maunganui beach and can result in large volume changes over short periods of time (3-4.5 months). Also, as the post-disposal survey was not undertaken until ~17-20 days after all of the dredge spoil had been deposited (and ~3 months since dumping began), it could be postulated that the dredge spoil had already undergone significant migration out of the dump ground by this time. This idea seems plausible given the likely influence of shoreward mass transport in this area (Harms, 1989; Healy *et al.,* 1991) and frequency of time that sediment is entrained at these depths (80 % of the time in 8 m depth, Spiers (2005)).

The main area of deposition at Site C occurs as one primary mound feature, located slightly seaward of the boundary between Sites B and C (Figure 4). This area contains peaks of up to ~0.85 m and occurs between the 10 and 14 m contours. The main mound has an extent of 450 m in the alongshore direction and 270 m in the cross-shore direction. A number of smaller mounds can be observed surrounding this area and slightly seaward of the main mound area. Volume computations show deposition of ~32,000 m³ at Site C between Nov-03 and Jun-04. Unlike Site B, the 28,700 m³ of dredge spoil deposited at Site C can be completely accounted for, indicating that little or no dispersal of the deposited sediments has taken place by the post-disposal survey (~17-20 days after disposal). This is likely to be a result of the slower dispersive nature of this site (Healy *et al.,* 1998) and the lower incidence of sediment entrainment with increased depth.

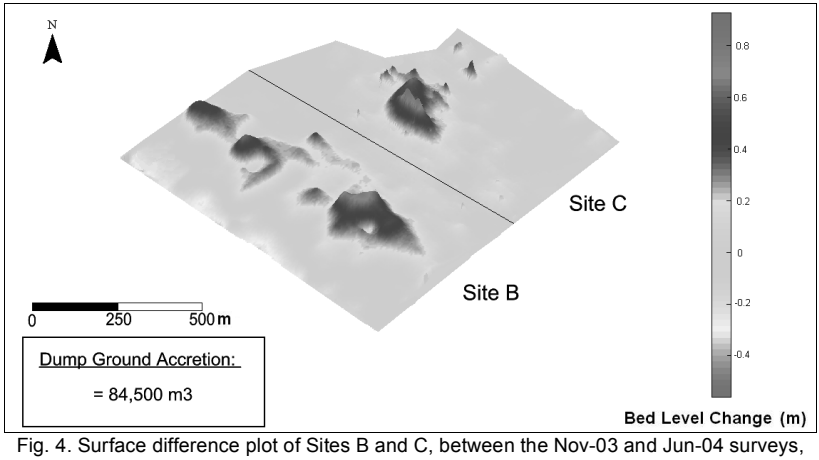

Fig. 4. Surface difference plot of Sites B and C, between the Nov-03 and Jun-04 surveys, revealing the areas of dredge spoil disposal.

In order to monitor any dispersal from the dump mounds since disposal, the Jun-04, Aug-04 and April-05 surveys have been compared. Residual differences between the Jun-04 and Aug-04 (Figure 5a) surveys indicate that the primary areas of erosion within the dump grounds occur around the peaks of the main spoil mounds. At Site B erosion of the dump mounds is primarily in the range of 0.1-0.2 m with a maximum bed level reduction of 0.4 m from the highest peaks. This suggests a significant reduction in the height of the main dump mounds (> 50% in places), which initially showed elevations of up to 0.7 m in the Jun-04 survey. Other isolated pockets of erosion are also observed at various regions throughout the dump ground, where erosion is generally between 0-0.15 m. Volume computations show that ~14,200 m³ of sediment has eroded at Site B between Jun-04 and Aug-04. Most of this eroded volume appears to be a result of dredge spoil dispersal from the 3 or 4 main dump mounds (Figure 5a).

The main area of accretion observed at Site B, from Jun-04 to Aug-04, forms an elongated trail on the western side of the dump ground and is located directly shoreward of the eroded dump mounds (Figure 5a). This elongated trail of accretion has a cross shore length of ~250 m, with a maximum alongshore width of ~100 m and a vertical extent of up to ~0.2 m. Clearly this feature is indicative of onshore diabathic transport from the nearby eroded dump mounds. Further to the west of this elongated trail are a number of other areas of accretion which appear to result from onshore migration of the deposited dredge spoil. These areas have also accreted by up to 0.2m and extend 30-60 m shoreward of the eroded dump mounds. A number of smaller more localized areas of accretion are also observed throughout Site B. Between Jun-04 and Aug-04 approximately 9,500 m³ of accretion is identified at Site B, of which a considerable proportion can be attributed to the shoreward dispersal of sediment from the eroded dump mounds. A "cut and fill" comparison (the accreted volume minus eroded volume) indicates a loss of 4,700 m³ of sediment from Site B. The elongated areas of accretion, identified shoreward of the eroded dump mounds, provide evidence to suggest that this loss has occurred as a result of onshore transport of the deposited dredge spoil.

As observed for Site B, between Jun-04 and Aug-04 the main areas of erosion at Site C correspond to the peaks and inner areas of the main spoil mounds (Figure 5a). The dump mounds appear to have eroded by up to 0.5 m in places, which corresponds to > 50% of the observed height as at Jun-04 (~0.85 m). A number of other areas of erosion, generally ranging from 0.1-0.3 m are also observed throughout the dump ground area. Volume computations suggest that ~8,900 m³ of sediment has eroded at Site C, a large proportion of which can be attributed to erosion of the deposited dredge spoil.

As anticipated, the slower dispersive nature of Site C (due to the deeper water depth and lower incidence of sediment entrainment) confined the primary areas of accretion to a small radius around the main mound areas. The observed accretion occurs mainly within small areas of 30-50 m in both the cross and alongshore extent and up to 0.3 m in the vertical. The areas of accretion tend to be distributed both shoreward and seaward of the main spoil mounds and in some areas occur between the main peaks of the mound, which may indicate transport of sediment from the main peaks into these areas.

However, it must be noted that a number of the observed accretional areas are located between the run lines of the June singlebeam survey. It is possible that some of these areas may correspond to areas of dredge spoil disposal that were not resolved by this survey, possibly leading to a false indication of accretion between the Jun-04 and Aug-04 surveys. Therefore the volumetric computations for Site C, between Jun-04 and Aug-04, should be viewed with caution. Volume computations suggest that ~10,000 m^3 of accretion occurred at Site C (Jun-04 to Aug-04), indicating a net gain of ~1,100 m^3 of sediment at this site. As expected, this value suggests that most of sediment eroded from the spoil mounds is likely to have been redistributed within the dump ground area. The 1,100 m^3 gain may be a result of either diabathic or parabathic transport into this site or potentially represents areas of accretion that were under-sampled by the June singlebeam survey.

The residual contour plot for the period Aug-04 to April-05 indicates that Sites B and C have accreted significantly over this 7 month period (Figure 5b). Accretion at Site B dominates the majority of the site and is characterized by an increase in bed level of ~0.2-0.4 m. Erosion occurring at Site B between Aug-04 and April-05 is confined to a small number of areas, corresponding to the original dump mound locations. These areas are small in extent (maximum of 40 m) and show a reduction in bed level of 0.1-0.4 m. A "cut and fill" comparison for Site B indicates that 69,450 m^3 of accretion and 1000 m^3 of erosion have occurred between Aug-04 and April-05. This equates to a residual gain of 68,450 m^3 over Site B. The volume of sediment entering the site makes any dispersal of the deposited sediments impossible to detect.

Accretion at Site C between Aug-04 and April-05 appears to encompass the majority of the site (Figure 5b). The average bed level change at this site ranges from 0.3-0.4 m. By April-05, the areas of observable erosion at Site C are limited to two small patches (maximum of 15 m in width) which correspond to the position of the main dump mound (as at Jun-04). Volume computations indicate that Site C showed accretion of ~100,000 m^3 and erosion of ~160 m^3 between Aug-04 and April-05. This corresponds to a net gain of ~99,840 m^3 over the dump ground or +0.2 m of vertical change (accretion) per m^2 of the surveyed area. As with Site B, due to the large increase in the volume of sediment entering the site, it is not possible to detect dredge spoil dispersal.

The area shoreward of the dump ground has also accreted considerably between the two surveys (Figure 5b). By April-05 the formation of longshore bar system with a vertical extent of up to 1.6 m is clearly apparent. Two areas of erosion (up to 1m) are observed directly shoreward of the bar, indicating a well developed trough and bar system. These features may have formed in response to erosion of the berm and beach face area, after periods of high storm activity (Komar, 1998). This would seem logical, given the high levels of accretion observed throughout the rest of the dump ground area at this time.

The findings from the residual contour plot indicate that any dredge spoil dispersal that has taken place between Aug and April is concealed by a significant amount of natural variation in the nearshore and therefore can not be detected. As the total net gain over

Sites B and C (~169,300 m³) between Aug-04 and April-05 is larger than the volume of dredge spoil deposited, its dispersal is increasingly difficult to separate or even detect from the natural variation.

The morphological variation observed between the surveys is likely to result from sediment exchange between the dune-beach-nearshore components of the beach system in response to short term and seasonal variations in wave climate (Healy *et al.,* 1977), in particular by the number of storms events occurring over that period. During calmer periods or those dominated by long period swell waves and offshore winds (Spiers, 2005), the sediment deposited in the nearshore tends to migrate shoreward, accreting the beach and building out the berm (Healy *et al.,* 1977).

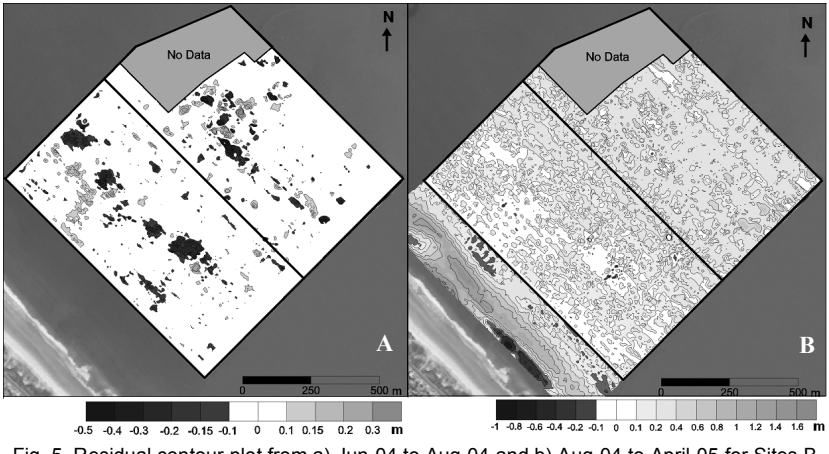

Fig. 5. Residual contour plot from a) Jun-04 to Aug-04 and b) Aug-04 to April-05 for Sites B and C.

Sub Aerial Beach Surveys

A comparison between the April-04 and Jun-04 beach profiles indicates that the beach shoreward of Sites B and C had accreted by ~9,000 m³ (Figure 6). This equates to ~0.14 m of accretion per m² of beach. Accretion was widespread over most of the beach and especially notable at the eastern extent of the surveyed area, with an increase in beach level ranging from 0.05 to 0.6 m. The April-04 survey was completed directly after a large erosive event, which suggests that the accretion observed at this site is likely to be indicative of the post storm recovery phase i.e. sediment is redistributed from the nearshore to build up the sub-aerial beach. Bathymetric analysis from the nearshore zone between Nov-03 and Jun-04 (1st post disposal survey) indicates that > 30,500 m³ of dredge spoil could not be accounted for. Several possible explanations for this have been presented in the preceeding sections, including the suggestion that significant migration of the deposited dredge spoil had already occurred prior to the June-04 survey. The

accretion noted between Apr-04 and Jun-04 further supports the idea that a proportion of the material accreting onto the beach by Jun-04, may have resulted from shoreward dispersal of the dredge spoil.

By September-04 further progradation is apparent, with ~5,600 m³ (0.087 m/m^2 of beach) of sediment accumulating on the beach (Figure 6). It is suggested that the observed accretion is partially due to the onshore dispersal of the deposited dredge spoil. This is consistent with nearshore bathymetric analysis undertaken between Jun-04 and Aug-04, where it was established that shoreward migration of the dredge spoil deposited at Site B had occurred.

Between Dec-04 and Feb-05 the beach shoreward of Sites B and C had undergone considerable erosion of ~12,800 m³ (-0.198 m/m^2 of beach). The observed erosion appears to have been caused by a large storm event (associated with strong onshore winds) several days prior to surveying. As previously mentioned, it is likely that a storm such as this would result in a significant amount of deposition in the nearshore, similar to that noted in the April-05 bathymetric surveys (Figure 5b). Between Feb-05 and May-05 the beach had accreted by 21,630 m³ (0.33 m/m^2 of beach), with approximately one third more sediment accreted than had been eroded by the Feb-04 storm. During the May-05 survey it was evident that the beach had noticeably accreted just prior to surveying. Sizable amounts of pumice (likely originating from the inner shelf) and large accumulations of the Gastropod whelk *Struthiolaria papulosa* were evident at the high tide mark throughout survey site. Accumulations of *Struthiolaria papulosa* are often observed after large wave events which coincide with offshore winds and are suggestive of diabathic transport (Healy pers.comm).

Volumetric computations from the entire period April-04 to May-05 indicate that the beach has accreted by ~24,200 m³ (0.37 m/m^2 of beach). As explained in the preceding section, the residual volume gain or loss over the entire survey period appears to be dependant on which phase of the cut and fill cycle is occurring at each survey time. The April-04 survey was undertaken after a large erosive event, whereas the May-05 survey occurred during a period of recovery, albeit apparently rapid recovery; therefore the gain between these two surveys was as anticipated.

Historical beach profile data for this site, dating back to 1999 (Figure 7), indicates that the sub-aerial beach and inter-tidal zones have continually accreted from 2001 to 2005. The ENSO signal is evident in the data, with erosion of the beach from 1999 to 2001 attributed to a La Nina period. The June-05 profile represents the most seaward position of the upper beach face and berm between Oct-99 and 2005. This suggests that potential for the entrance channel to reduce sediment supply to the downdrift beaches has been countered by dredge spoil disposal or by natural processes.

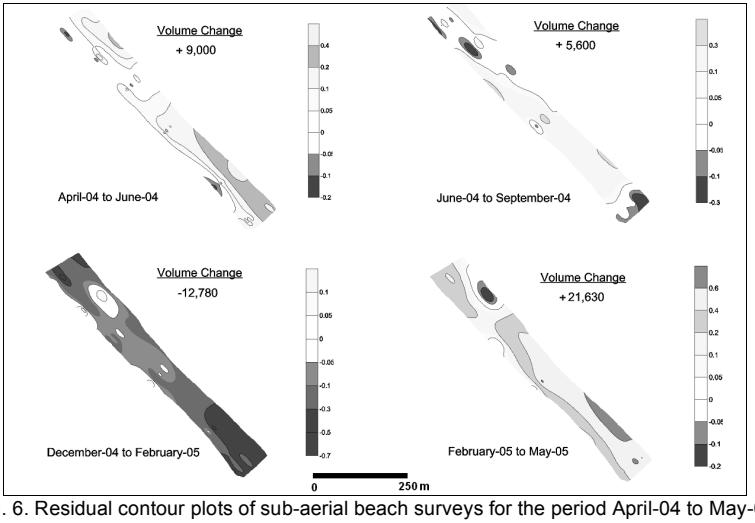

Fig. 6. Residual contour plots of sub-aerial beach surveys for the period April-04 to May-05 for Sites B and C.

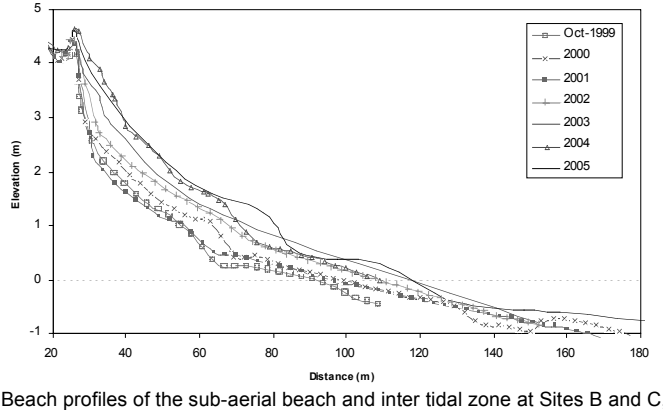

Fig. 7. Beach profiles of the sub-aerial beach and inter tidal zone at Sites B and C, for the period Oct-1999 to June-2005. Note that all profiles are taken from the month of June or July unless otherwise stated in the legend (data supplied by Environment Bay of Plenty).

CONCLUSIONS

Side-Scan sonar surveys of Site C confirm the presence of coarse grained ripples surrounded by ribbons of fine featureless sonograph facies, which correspond to the areas of dredge spoil dumping (as indicated by textural analysis). However, the extent of these areas (the combination facies CGR/FFS in particular) is significantly reduced over the monitoring period, suggesting that the dump ground is reverting back to its pre-

disposal state. Conversely, at Site B there is little variation in pre and post disposal surveys, which is consistent with textural analysis results.

Repeat bathymetric surveys (multibeam hydrographic and single beam echosounding) and beach profiles, were used to account for and investigate the fate of the deposited dredge spoil. The deposited dump mounds were clearly identified by the Jun-04 survey. Erosion of the dump mounds was evident at all sites and significant shoreward migration clearly identifiable at Site B. Dispersal at Site C was also evident, however only in a localized radius around the main dump mound, consistent with the findings of Healy *et al.* (1998), who argued that dispersal from this site would occur at a slower rate. However, analysis of the surveys conducted between August-04 and April-05 indicates that natural variation over the dump ground can be significant, making dispersal difficult to detect.

Changes to the sub-aerial beach and inter-tidal zones were dominated by a cycle of rapid storm-induced "cut", followed by persistent recovery (fill). Post storm progradation of the sub-aerial beaches and inter-tidal zone was exhibited at between Apr-04 and Dec-04. Observed shoreward dispersal from the dump mounds (Site B) during this period, suggests that this accretion can be partially attributed to the shoreward migration of the deposited dredge spoil. Over the monitoring period, the sub-aerial beach and inter-tidal zones showed an estimated volume gain of ~24,200 m^3 at Sites B and C. The observed gain is related to inputs into the system (i.e. beach nourishment induced from dredge spoil disposal) and the phase of the "cut" and "fill" cycle that the profiles were in when compared.

Historical beach profiles indicate that any reduction in sediment supply to the downdrift beaches of Mt Maunganui (as a result of the entrance channel) is being successfully mitigated. However, the effects of the ENSO cycle are evident, and clearly play an important role in the determining the beach state over time. Progradation of the sub-aerial beaches, which is partially attributed to ongoing beach renourishment, is construed as a "positive impact", enhancing the amenity value of the beach and providing stability against erosive events.

Abstract: Estimates of maintenance dredging quantities were needed for a proposed widening and deepening of a navigation channel. However, detailed numerical modeling of sediment transport was not desired at the time. Channel sedimentation rates were estimated based on a new semi-empirical methodology. The methodology is based on a simplification of the sediment deposition equations (Krone 1962 and DuBoys 1879). Basic inputs to these equations include water velocities, total suspended sediment concentration (TSS), critical bottom shear stresses for erosion and deposition, Manning friction coefficient, bulk density of settled muds, and settling velocity for sediment particles (flocs). These equations are solved at discrete locations along the channel and integrated over time to give an overall sedimentation rate. The desktop methodology is applied to the Matagorda Ship Channel (Texas) widening and deepening project. The methodology offers a relatively simple way to estimate changes in maintenance dredging quantities for modifications to existing projects.

INTRODUCTION

The Matagorda Ship Channel (MSC) is a deep-draft navigation channel on the central Texas coast which serves the Calhoun County Navigation District's Port of Port Lavaca-Point Comfort. The channel transits from the open Gulf of Mexico through Matagorda and Lavaca Bays, both shallow estuaries. A map of the area is shown in Figure 1.

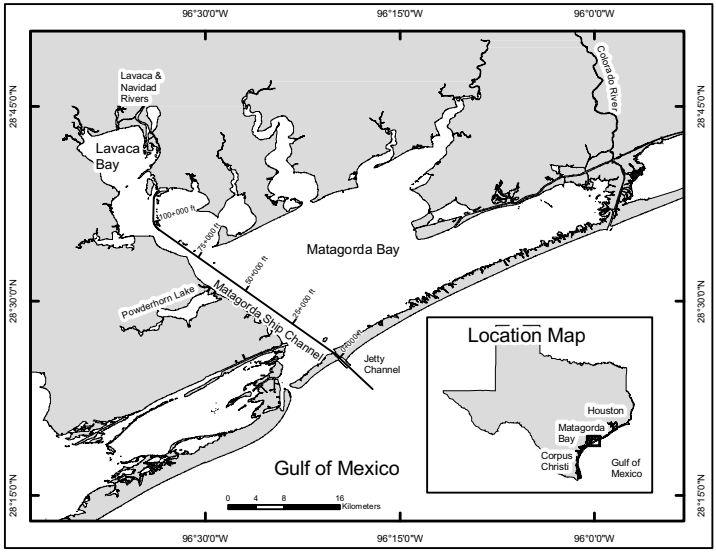

Fig. 1. Area Map

Presently, the channel has a depth of 36 ft mean low tide (MLT) with a 200 ft toe-to-toe width inside of Matagorda Bay. (MLT is a local tidal datum used by the U.S. Army Corps of Engineers Galveston District and is roughly equivalent to an annual low tide event.) Proposed improvements to the channel include widening the channel to a width of 400 ft toe-to-toe and deepening the channel to 44 ft MLT in the Matagorda and Lavaca Bay segments. The deepening would also include 2 ft of advanced maintenance and 2 ft of allowable overdepth dredging for a total depth of up to 48 ft MLT. The offshore portion of the channel would also be widened and deepened; however, it is not treated in this paper. A separate, but related, project would also widen the jetty channel at the entrance to Matagorda Bay.

As with many Gulf Coast navigation channels, the MSC has relatively high rates of sedimentation. Based on 40 years of dredging records the present vertical accumulation rates for the channel are approximately 1.3 ft/yr in the Matagorda Bay segment and 2.1 ft/yr in the Lavaca Bay segment. Sedimentation rates have been very consistent over time for much of the channel, with the exception of the upper channel near the port where there has been a notable trend toward increased sedimentation. The majority of material settling in the channel is clay and silt, with only minor portions of sand in most areas. The source of sediment shoaling in the channel is believed to be primarily from sediments suspended in the water column that settle out in the channel. The sources of suspended sediment include riverine input through the Colorado River, Lavaca River,

Navidad River, and several other smaller river inputs to the Bays (although the navigation channel is not a riverine channel) along with sediments resuspended from the shallow bay surrounding the channel by waves and currents and sediment eroded from the clay bluffs which surround much of the Bays.

For planning and cost estimating purposes, estimates of maintenance dredging quantities were needed for the proposed widening and deepening. However, detailed numerical modeling of sediment transport was not desired at the time. The existing methods of estimation of maintenance dredging quantities are generally based on gross geometric assumptions or extrapolation of trends from past widening and deepening project (Trawle, 1981). In the case of the Matagorda Ship Channel no prior widening and deepening projects have been performed making extrapolation of such trends impossible.

Therefore a simplified semi-empirical methodology was developed for estimation of changes in maintenance dredging quantities for the new project geometry. The methodology is based on historic dredging records and can be based on either numerical model output of water velocities in the channel or simple assumptions on the changes in water velocities due to the modifications. Since a hydrodynamic and salinity model was created for assessment of salinity impacts in the estuary, the results of the numerical model were available for use.

SEDIMENTATION ESTIMATE METHODOLOGY

The methodology is based on a simplification of sediment deposition equations with a few basic assumptions. The primary process of sedimentation considered is due to the suspended sediment transport, and does not include bedload or fluid mud processes. The rate of change in bed elevation due to deposition is proportional to the sediment flux near the bottom surface

$$\frac{dh}{dt} = \frac{1}{\rho_f} p W_s C \tag{1}$$

where h is the local water depth, ρ_f is the bulk density of sediments, p is the probability of deposition, W_s is the sediment settling velocity, and C is the representative mass concentration of suspended sediments.

The probability of deposition can be approximated as (Krone, 1962)

$$p = \begin{cases} 1 - \dfrac{\tau}{\tau_s}, & \tau < \tau_s \\ 0, & \tau \geq \tau_s \end{cases} \tag{2}$$

where τ_s is the critical shear stress for deposition, and τ is the bed shear stress. Using DuBoys' approximation (1879), the bottom shear stress can be determined as

$$\tau = \gamma R S \tag{3}$$

where γ is the unit weight of water equal to water density multiplied by the gravity, R is the hydraulic radius of the channel, S is the slope of water surface relative to the channel bottom. The hydraulic radius is found as a ratio of the cross-section area (A) and the wet perimeter (P), which are determined from geometry of the channel.

According to Manning's equation, the velocity in the channel can be approximated as

$$u = \frac{1}{n} S^{\frac{1}{2}} R^{\frac{2}{3}} \tag{4}$$

where n is the Manning's roughness coefficient.

Finally, the relationship between the shear stress and current velocity becomes

$$\tau = \gamma\, n^2 u^2 R^{-\frac{1}{3}} \tag{5}$$

If time series of velocity data is available for a period of time (T) then the average accumulation rates (r) can be found by integrating of equation (1) such as

$$r(x) = \frac{1}{\rho_f} \overline{p}(x) W_s(x) C(x) \text{ with } \overline{p}(x) = \frac{1}{T} \int_0^T p(\tau, x) d\tau \tag{6}$$

in which the probability p is a function of time, while other variables are assumed to be constant with time and only vary with location along the channel (x).

Representative suspended sediment concentration can be found by inversion of equation (6) with some expected values for settling velocity and bulk density of sediments. Assuming no change in concentration for the modified channel, the new accumulation rates then can be calculated if the change in velocities is somehow known or can be estimated.

The primary sources for suspended sediments are river inflows and redistribution of sediment within the bay by action of waves and currents. Resuspension of sediments within the channel is assumed to be a minor source. By changing configuration of the channel, it is assumed that the primary sources are not affected and, therefore, the representative concentration is assumed to remain constant.

The methodology does not include the effects of local erosion and redeposition in the channel. When erosion occurs it resuspends some of the recently deposited sediments; thus, the calculated representative suspended sediment concentration may be lower than the actual concentrations within the channel. When deposition is the prevailing condition the difference between the representative suspended sediment concentration and actual measured long-term average concentration (if available) would represent the

amount of material resuspended. Explicit inclusion of erosion would necessitate solving the time varying mass balance equations for sediment transport in and near the channel.

By increasing channel dimensions (width and depth) changes in all major hydraulic parameters can be expected. Due to increase in hydraulic radius, resistance of the channel decreases. This may result in increase of total flow through the channel. However, since the channel is not restricted from sides, slope of water surface will not necessarily remain the same. Therefore, combined changes in slope and hydraulic radius may result in either increase or decrease of flow velocity.

With a deeper channel, intensity of density currents is expected to increase as they depend on a cube of water depth (Ward et al, 1980). A deeper channel is expected to be more vertically stratified with larger volumes of sea water entering the bay during each tidal cycle. Presence of the density currents can increase flood and decrease ebb tidal currents within the channel. The effects of density currents with proposed changes to the channel geometry were not explicitly integrated into the sedimentation model; however, the model simulations from which the velocities were extracted account for such density currents.

It is also assumed that density of settled sediments and critical shear stress for deposition remain constant and water column salinity and changes in salinity do not affect sedimentation rates.

APPLICATION TO MATAGORDA SHIP CHANNEL WIDENING AND DEEPENING

For application to the MSC, dredging records for the period of 1963–1998 were analyzed to find long-term average sedimentation rates for each 5,000 ft channel segment. (Note that all distances for the MSC are given as along channel distance north of the Gulf entrance.) The velocities in the existing and modified channel were estimated with a three-dimensional numerical model (Moffatt & Nichol, 2006), and available as a time series for a six month period (April through September, 2003). In general, velocities for the proposed channel are on average approximately 20% higher in the lower channel and approximately 10% lower in the upper channel (see Figure 2) primarily as a result of the widened jetties (Moffatt & Nichol, 2006). The widened jetty channel decreases friction losses through the entrance to the bay and results in an increased tidal prism. The settling velocities were assumed to be a constant value along upper part of the channel and linearly increasing closer to the channel entrance. The increase in settling velocity is due to increasing content of fine sand in suspension.

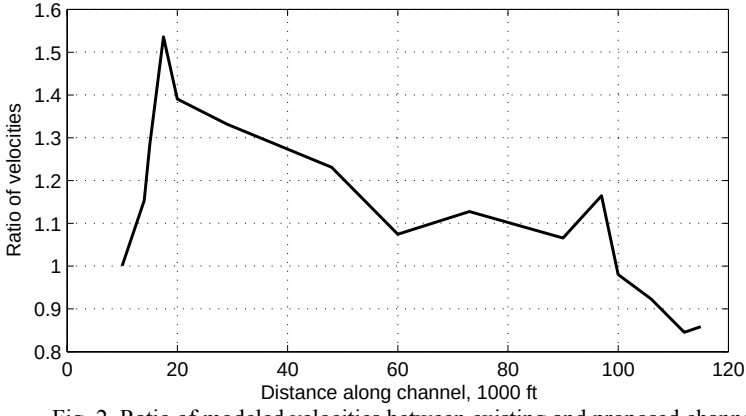

Fig. 2. Ratio of modeled velocities between existing and proposed channel

Values for critical shear stresses were taken from laboratory measurement and were estimated to be: for deposition—0.03 Pa; for erosion—0.10 Pa (ALCOA, 1998). The accumulation rates were calculated neglecting erosion. This approximation seems to be valid because for the most part of the channel the applied shear stress exceeds the critical stress for erosion during less than 40% of time (see Figure 3). And even though erosion can occur at some stages of tidal cycle the eroded sediments are assumed to remain within the channel. Therefore, one of the underlying assumptions of this model is deemed reasonable for a desktop analysis. Since velocities are, in general, increased, the assumption of neglecting erosion also leads to more conservative (i.e., larger volume) results.

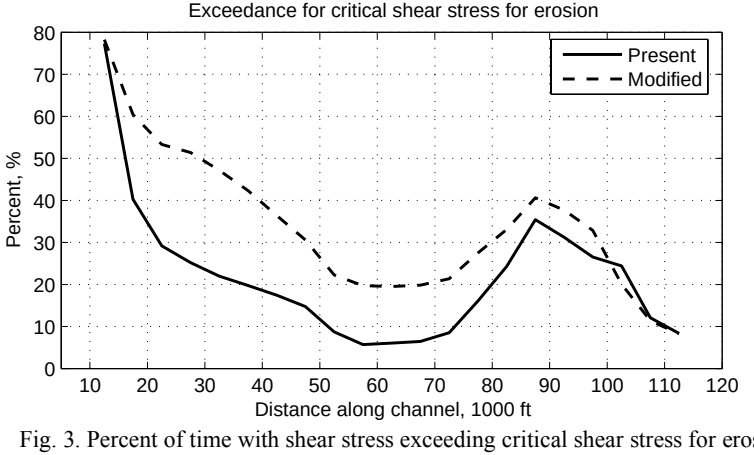

Fig. 3. Percent of time with shear stress exceeding critical shear stress for erosion

Long-term averages of suspended sediment concentrations vary along the channel. Data from the Texas Commission on Environmental Quality's (TCEQ's) water quality database are shown in Figure 4. The average concentrations were interpolated along the channel according to distance from the monitoring stations. It is noted that the various sample locations had different numbers of samples collected at different time periods; however, the average for each station was used for the analysis without further analysis of data spread, seasonality, or other factors. Average measured TSS was 40 mg/l. TSS levels estimated from historic dredging records are shown in Figure 4 along with the average and range of measured data and were used in the model as a calibration parameter. There is a good agreement with measured TSS data; however, the concentrations were underestimated in the lower portion of the channel mainly due to increasing erosion which is neglected in the model.

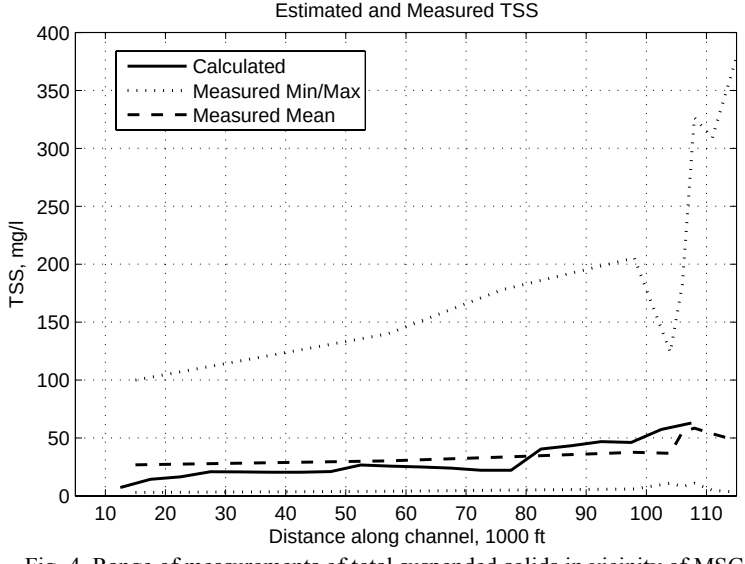

Fig. 4. Range of measurements of total suspended solids in vicinity of MSC with estimated TSS levels within the channel

Assuming that the suspended sediment concentrations do not change after the channel modification, average dredging volumes were estimated. Results of the calculations are presented in Figures 5 through 7. The total vertical accumulation rates are presented in Figure 8. The sedimentation rates (ft/year) were based on the approximate top width of the channel where the dredge cut intersects the natural bay bottom as this was is the effective width for sediment trapping. Table 1 gives an overview of the total sedimentation rates. It can be seen that the increase in channel dimensions has the largest effect on the total volumes. The sedimentation rate increases 67% due to the change in channel geometry. The effect of changes in hydrodynamics is much smaller.

It results in an approximately 5% overall decrease in vertical accumulation rate. However, there is a shift in areas of sedimentation with higher vertical accumulation rates after project expected in the upper channel.

Table 1. Total dredged volumes calculated

Case	Total dredged volume, yd3/year	Ratio	Change in vertical accumulation rate, %
Present configuration	2,353,150	–	–
Due to increased dimensions	3,933,802	1.67	–
Combined effect of increased dimensions and accumulation rate	3,811,360	1.62	–5%

CONCLUSION

A methodology for estimating sedimentation for navigation channel widening and deepening was developed. The methodology is relatively simple and is suitable for desktop type analysis where a full, detailed numerical sedimentation model is not desired or feasible. The methodology is based on a simplification of the sediment deposition equations (Krone 1962 and DuBoys 1879). Basic inputs to these equations include water velocities, critical bottom shear stresses for deposition, Manning friction coefficient, bulk density of settled mud, and settling velocity for sediment particles (flocs) with total suspended sediment concentration (TSS) used as a calibration parameter. These equations are solved at discrete locations along the channel and integrated over time to give an overall sedimentation rate. The equations can be solved either based on assumed changes in velocities or using velocities from a numerical model.

The methodology was applied to the MSC widening and deepening to develop estimates of future maintenance dredging needs. Existing sedimentation rates based on long-term dredging records were used to estimate TSS as a calibration parameter. The TSS values calculated agree reasonably well with measurements in the vicinity. For the proposed channel modifications, including widening of the jetty channel which allows for a greater

tidal prism, the velocities in the channel were found to generally increase except in the upper end of the channel. This in turn leads to estimation of slightly decreased vertical accumulation rates for most of the channel, but with increased vertical accumulation rates in the upper channel. Overall the sedimentation rates are estimated to increase approximately 62% over present sedimentation rates, mostly due to the increased channel plan area.

ACKNOWLEDGEMENTS

Work described in this paper was done under contract for the Calhoun County Navigation District. Review and input on the work was received from URS Corporation staff including Chris Reed and U.S. Army Corps of Engineer staff including Ishaq Syed at the Galveston District and Nick Kraus and Lihwa Lin at the Engineer Research and Development Center.

Abstract: A mass-balance, control-volume approach is presented for estimating vertical sediment fluxes and mass-averaged settling velocities in dredge plumes. The method requires detailed measurements of velocity and suspended sediment concentration along the control volume boundaries. An example application is presented in which horizontal fluxes at the control volume boundaries are derived from Acoustic Doppler Current Profiler data. Results of the analysis demonstrate good qualitative agreement with the general understanding of sediments at the site. The control-volume method is suitable for application to other types of dredge plumes and general sediment transport research related to vertical fluxes and settling of suspended sediments.

INTRODUCTION

Navigation dredging is a vital activity for national economic security, enabling access to ports by commercial, deep-draft, ocean-going vessels (USACE, 1983). During dredging operations, sediments are removed from the channel bottom and transported by pipeline or vessel to approved dredged material placement sites. However, a portion of the sediments removed from the bed are suspended into the water column, transported from the dredging and placement sites by ambient currents, and returned to the bed through particle settling and deposition. The transport and fate of sediments suspended by dredging operations is a primary concern due to potential impacts to natural resources (USACE, 1983; Wilber and Clarke, 2001).

Elevated suspended sediment concentration (SSC) and turbidity may impose a range of environmental impacts such as gill abrasion and clogging; increased light attenuation and reduced photic depth (impacts to micro-algae, macro-algae, and submerged aquatic vegetation); burial, smothering, and abrasion of demersal eggs; reduced growth rate of larval and juvenile organisms (leading to increased mortality and reduced recruitment); blockage of fish migration routes; degradation of spawning habitat; and dispersion of sediment-adsorbed contaminants (Newcombe and Jensen, 1996; Wilber and Clarke, 2001). Newcombe and Jensen (1996) propose that impacts to fish are a function of SSC, duration of exposure, species, and life stage. In the United States, natural resource agencies (state departments of environmental quality; state, regional, and federal fisheries agencies; and federal environmental protection) require dredging proponents (such as port authorities and the U.S. Army Corps of Engineers) to demonstrate that proposed dredging activities meet regulatory requirements established by under Section 404 of the Clean Water Act, Section 103 of the Marine Protection, Research, and Sanctuaries Act, National Environmental Policy Act of 1969, and state water quality standards.

Numerical models are among the primary tools through which dredging proponents demonstrate that proposed dredging activities are likely to meet regulatory requirements. These models represent the processes of sediment suspension, advection, diffusion, settling, and deposition through a collection of both empirical- and physics-based equations to predict transport and fate of sediments suspended by dredging operations (Koh and Chang, 1973; Johnson, 1990; Johnson et al. 2000). Wide variations in dredging equipment and sediment characteristics and limited knowledge of the rates of suspension and characteristics of suspended material lead to large uncertainties in model estimates of sediment transport and fate (Germano and Cary, 2005). Milligan and Hill (1998) suggest that time-variant flocculation effects must be included in sediment transport models for assessing environmental impacts in the coastal zone. Similarly, advancement of the predictive capabilities of dredged material transport, fate, and impacts are not expected until better understanding is gained of the influences of dredge and sediment types on sediment suspension and sediment dynamics.

To present, limited progress has been made in quantifying the rate of sediment suspension from various dredge types and even less progress has been made in describing suspended sediment characteristics and settling processes in dredge plumes. Limitations in present knowledge of suspension and settling in dredge plumes are largely attributable to past limitations in sampling technology. Until the early 1990s, field measurements were limited to physical pump and bottle samples analyzed for total suspended solids (McLellan et al. 1989). Limited spatial and temporal resolution available with physical sampling in dredge plumes characterized by high spatial and temporal gradients made quantifying suspension rates and settling extremely challenging. Advances in the fields of optical, acoustic, and photographic instrumentation permit corresponding advances in the ability to collect information about dredge plume dynamics (Puckette, 1998; Tubman and Corson, 2000; Reine et al., 2002). These recent advances in suspended sediment sampling technologies have opened new possibilities in research directed toward understanding of suspended sediment characteristics and settling dynamics in dredge plumes. Better understanding of settling dynamics in dredge plumes will lead to improved predictive methods, better informed dredging operation planning, reduced impacts to natural resources, and increased efficiency of dredged material management.

The purpose of this paper is to describe a method developed for estimating vertical flux and mass-averaged settling velocities within dredge plumes. The method presented is dependent upon high-resolution velocity and suspended sediment measurements within dredge plumes. Recent advances in Acoustic Doppler Current Profiler (ADCP) technology permit both velocities and concentrations to be quantified from a moving platform.

CONTROL VOLUME APPROACH

For a dredge plume, a control volume of size $\Delta x \times \Delta y \times \Delta z$ can be defined (Figure 1) such that time variations of the mean suspended sediment concentration within the control volume are given by differences in spatially averaged sediment fluxes across the bounding surfaces as follows:

$$\frac{\Delta C}{\Delta t}\Delta x\,\Delta y\,\Delta z = \Delta y\Delta z\left(F_{x1} - F_{x2}\right) + \Delta x\Delta z\left(F_{y1} - F_{y2}\right) + \Delta x\Delta y\left(F_{z1} - F_{z2}\right) \qquad (1)$$

where C = suspended sediment concentration (M L^{-3}), t = time, x,y,z = Cartesian coordinates, F = suspended sediment flux (M L^{-2} T^{-1}) averaged over each boundary.

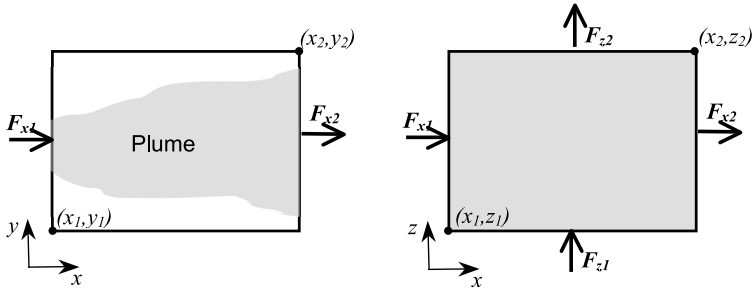

Fig. 1. Control volume for flux balance of dredge plumes.

Assuming that the plume traveling through the control volume has reached steady state (dC/dt = 0), that the lateral control-volume boundaries are outside the plume ($F_{y1} = F_{y2} = 0$), and that there is no sediment flux through the top of the control volume at the water surface ($F_{z2} = 0$), the spatially averaged vertical flux across the bottom surface of the control volume reduces to:

$$F_{z1} = \frac{\left(F_{x2} - F_{x1}\right)\Delta z}{\Delta x} \qquad (2)$$

To estimate vertical flux to the seabed within the defined control volume, measurements of cross-sectionally averaged horizontal fluxes at *x1* and *x2* are required. Neglecting horizontal turbulent diffusion, sediment flux at a point on the boundary is given by $F=uC$, where u = boundary-orthogonal velocity component. ADCPs are capable of providing both velocity and suspended sediment concentration (SSC) necessary to compute sediment flux across control volume boundaries. Acoustic backscatter has been shown to

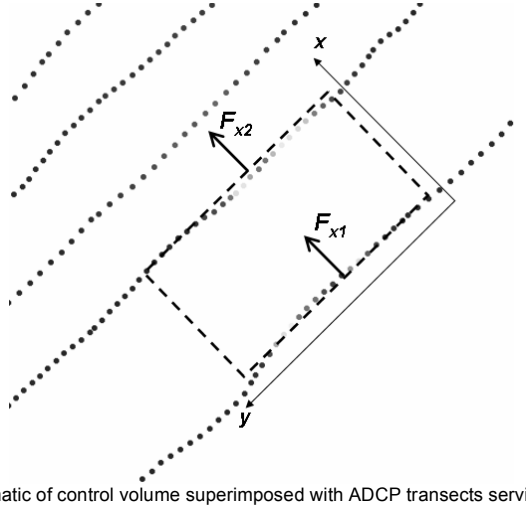

Fig. 2. Schematic of control volume superimposed with ADCP transects serving as control-volume boundaries in the *x* direction.

be a reliable, unobtrusive estimator of SSC (Thorne et al., 1991; Land and Bray, 2000), including measurements of dredge plumes (Battisto and Friedrichs, 2003; Reine et al. 2002; Clarke, et al. 2005). Figure 2 presents ADCP transects taken orthogonal to the prevailing current through a dredge plume. These transect lines define control-volume boundaries, with the velocity and SSC data providing basis for horizontal suspended sediment fluxes. Neglecting horizontal turbulent diffusion, the cross-sectionally averaged horizontal fluxes at *x1* and *x2* can each be calculated from a subsection of the ADCP transect data that includes the suspended sediment plume as follows:

$$\overline{F_x} = \frac{\sum_{i=1}^{NY}\sum_{k=1}^{NZ} u_{i,k} C_{i,k} \Delta z_k \Delta y_i}{\sum_{i=1}^{NY}\sum_{k=1}^{NZ} \Delta z_k \Delta y_i} \tag{3}$$

where the *i.k*, subscripts associated with $u_{i,k}$, $C_{i,k}$, Δy_i and Δz_k in Eq. 3 refer to ADCP bins, not the control volume.

Assuming mean vertical fluid velocities to be negligible, there are two contributions to the average vertical flux at the base of the control volume, namely gravitational settling and vertical turbulent diffusion:

$$F_{z1} = w_s C_1 - K_{z1} \frac{dC_1}{dz} \tag{4}$$

where the vertical eddy diffusivity, K_z, sediment concentration, and vertical concentration gradient are all evaluated at the height of the base of the control volume, z_1, and are all

averaged across the width of the control volume, Δy. By rearranging the terms, an expression for the settling velocity at height z_1 is obtained:

$$w_s = \frac{F_{z1} + K_{z1}\dfrac{dC_1}{dz}}{C_1} \tag{5}$$

which requires estimation of vertical flux, vertical diffusion, and vertical concentration distribution. Note that in Eq. 5, w_s and F_{z1} are expected to be negative with the adopted positive upward convention. In the typical situation of negative vertical concentration gradient, gradient diffusion (represented by $K_z\ dC/dz$) hinders settling by exchanging lower-concentration sediment-water mixture from above with higher-concentration mixture from below. For constant vertical flux and near-bed concentration, if gradient diffusion increases, still-water settling velocity must also increase.

MEASUREMENTS

The U.S. Army Engineer Research and Development Center, Environmental Laboratory (ERDC-EL) conducted vessel-mounted ADCP surveys near a hydraulic dredging outfall to monitor dredged material plumes in the vicinity of seagrass beds in St. Andrew Bay near Panama City, Florida (Figure 3). A hydraulic cutterhead dredge removed sediments classified as predominantly fine sand from Port Panama City and transported the slurry through a pipeline to a spill barge (located at the "S" in "Spill Barge" in Figure 3) within the permitted placement area. The end of the pipeline was directed vertically downward, 3 m beneath the water surface in 12-m depth. During the study, numerous surveys were

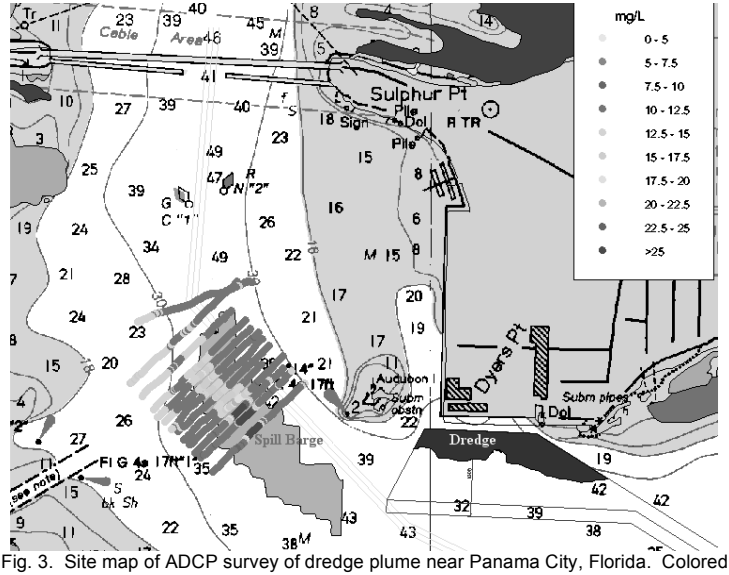

Fig. 3. Site map of ADCP survey of dredge plume near Panama City, Florida. Colored shading along transect lines indicates depth-averaged concentration.

conducted during various stages of the tidal cycle, each consisting of 10 or more transects oriented perpendicular to the tidal current. The data presented in this paper are from a survey conducted during flood tide immediately down current of the placement location as shown by the transect lines in Figure 3. Spacing between transects ranges from 30 to 80 m, with median spacing of 40 m, and spacing between individual soundings along each transect averages 4-5 m.. Each transect took less than 5 minutes to complete, and the 10 transects used in this analysis were completed in less than 45 minutes, ensuring a relatively small change in the tidal hydrodynamics. Velocity and SSC data were collected with a 600 kHz ADCP. Data collection and calibration methods were performed in accordance with Land and Bray (2000) and Reine et al. (2002).

Examples of concentration and velocity data from Transect 2 (the 2nd transect north-west of the spill barge) are presented in Figure 4. The concentration data indicate rational trends of variation associated with the high-concentration plume down current of the discharge point. However, the velocity signal is dominated by random noise. (Mean velocity perpendicular to Transect 2 is 0.08 m s^{-1}, but the standard deviation is 0.34 m s^{-1}.) Because the investigators collecting these data were interested primarily in monitoring suspended sediment concentrations, bin spacing of the ADCP was set at 0.25 m to maximize resolution of the suspended sediment plume at the expense of velocity data quality. For a study dedicated to assessing settling dynamics of a dredge plume, bin spacing must be optimized to provide adequate vertical resolution of SSC while maintaining good quality velocity data.

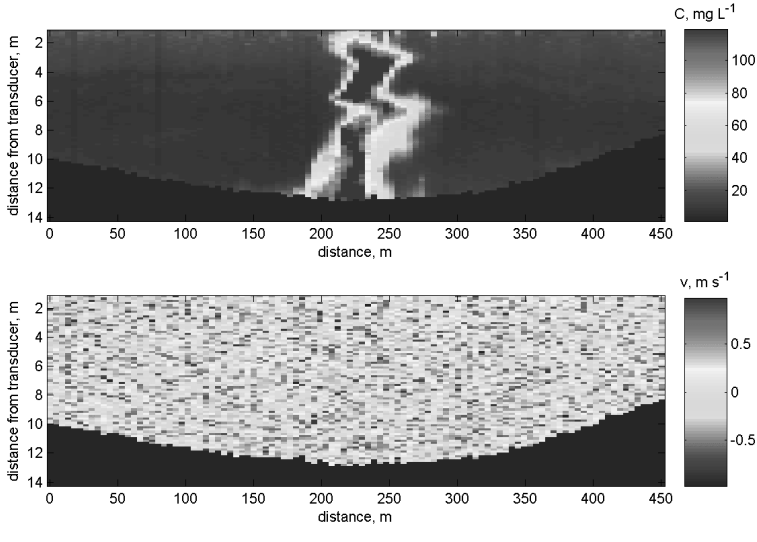

Fig. 4. Raw concentration and velocity data from Transect 2. Velocity data represent magnitude perpendicular to the transect. (+u = NW, -u = SE).

A significant observation from the concentration data is the distinct signature of sediment settling from the plume with distance from the discharge point as shown in Figure 5. Sediment concentrations within the plume at Transect 1 are large, but progressively decrease to near-ambient levels at Transect 5. Transect 1 passes within 10 meters of the spill barge, through the high-concentration effluent of the discharge pipe. Common slurry content of hydraulic dredge effluent is approximately 15-20 percent (by volume) or 400-500 g L^{-1}. At these large concentrations, significant acoustic energy is absorbed by suspended sediment (Thorne et al., 1991; Wren et al. 2000), resulting in lower acoustic backscatter and consequently lower inferred SSC. This effect of high sediment concentration on acoustic backscatter is shown as a zone of lower inferred concentration within the plume between 6-10 m below the transducer in Transect 1. As SSC is likely underestimated within this region, Transect 1 is omitted from later analysis.

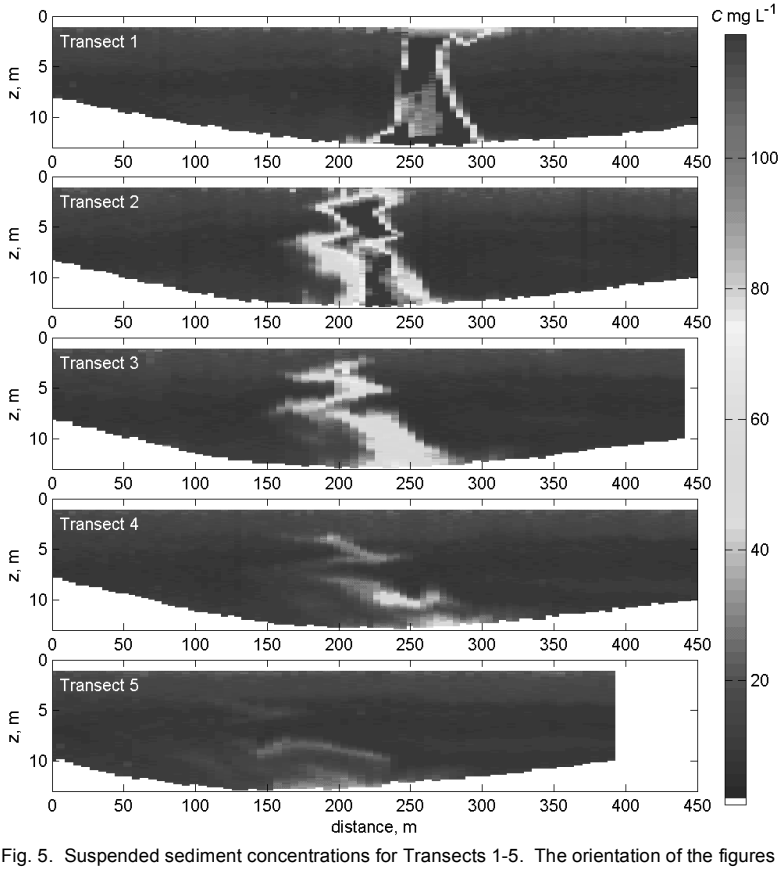

Fig. 5. Suspended sediment concentrations for Transects 1-5. The orientation of the figures is such that flow is into the page.

RESULTS

Horizontal suspended sediment flux is estimated from the data collected along Transects 2 through 6. Transect 1 was omitted as previously explained due to assumed acoustic attenuation in the concentration signal resulting from large SSC. At and beyond Transect 6, the dredge plume is barely distinguished from ambient sediment concentrations. The lateral range of data used to compute horizontal fluxes was determined visually and limited to the portion of data clearly identified as a plume. As discussed previously, quality of velocity data was poor due to the small bin height selected for data collection. Due to the noisy signal, average velocities were determined for each transect and applied to the horizontal flux calculations of Eqn. 3 which are presented in Figure 6. Note that the cross-sectionally averaged horizontal fluxes decrease from 3 to 1.3 g m^{-2} s^{-1} over a 120 m distance, with the horizontal flux gradient decreasing with distance from the pipeline outfall.

Vertical flux for each control volume is estimated by Eq. 2 from the computed horizontal fluxes at each transect, distance between transects, Δx, and mean water depth (substituted for Δz), with the width of each control volume limited to the maximum width of the two bounding transects containing the dredge plume. Mean vertical sediment fluxes are plotted in Figure 6 at the central position of each of the four control volumes. Mean vertical flux magnitude is greatest between Transects 2 and 3 at -0.4 g m^{-2} s^{-1} and decreases by roughly an order of magnitude to -0.03 g m^{-2} s^{-1} 100 m away between Transects 5 and 6. The marked reduction in horizontal and vertical fluxes within such a short distance from the pipeline outfall suggests that much of the suspended sediment in the dredge plume deposits near the placement site.

With estimates of vertical sediment flux, near-bed sediment concentration, near-bed vertical concentration gradient, and an estimate of vertical diffusivity, Eq. 5 permits an

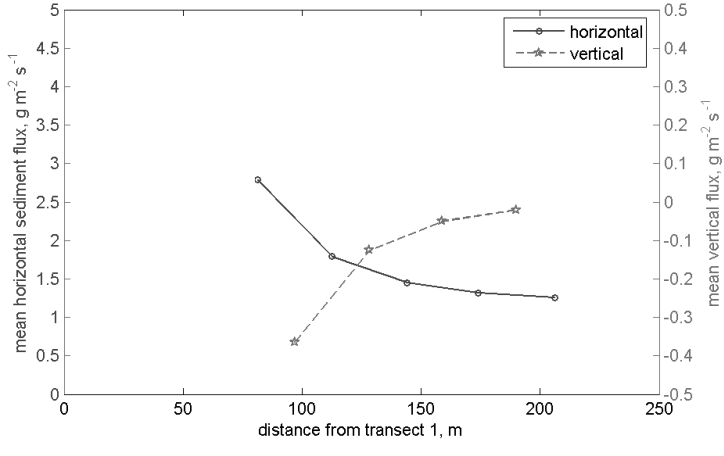

Fig. 6. Cross-sectionally averaged horizontal and vertical fluxes for Transects 2-6.

estimate of mass-averaged sediment settling velocity. For this application, mean suspended sediment concentration and vertical concentration gradient were averaged for bins within 3 m of the bed and between the bounding transects. Velocity measurements were not of acceptable quality to directly estimate K_z from the vertical velocity profile, so an alternate, first-order approximation was estimated assuming logarithmic distribution of velocities in the benthic boundary layer, parabolic distribution of vertical eddy diffusivity, sandy bed with hydraulic roughness, $z_0 = 0.006$ m, and the transect-averaged velocity. Average value of K_z for the four control volumes is 0.005 m^2s^{-1}. The resulting estimates of settling velocity for the four control volumes is presented in Figure 7. The first two control volumes, for which horizontal fluxes rapidly decrease have an estimated settling velocity on the order of 0.02 m s^{-1}, and settling velocity decreases to 0.012 and 0.005 m s^{-1} in the final two control volumes.

As the dredged material in this example is predominantly fine sand and settling velocities estimated in Figure 7 fall in the range of expected fall velocities of fine sand, an estimate of the equivalent sand diameters can be made using an empirical estimate of sand settling velocity (Soulsby 1997):

$$w_s = \frac{\nu}{d}\left[\left(10.36^2 + 1.049D_*^3\right)^{1/2} - 10.36\right] \tag{6}$$

where ν = kinematic viscosity of water, d = sediment diameter, $D_* = \left[\frac{g(s-1)}{\nu^2}\right]^{1/3} d$, $s = \frac{\rho_p}{\rho}$, ρ = water density, and ρ_p = particle density. Given settling velocity and water properties, Eq. 6 is solved for d. Estimated equivalent sand diameters are presented in Figure 7. The trends in d follow those of w_s, decreasing with distance from the plume

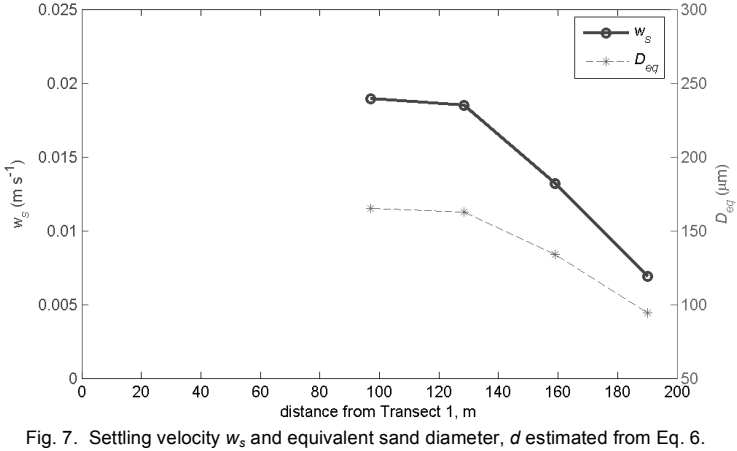

Fig. 7. Settling velocity w_s and equivalent sand diameter, d estimated from Eq. 6.

source, ranging from 160 μm for the first control volume down to approximately 100 μm for the last control volume. The equivalent diameters are not verifiable from the data collected for this example, but are consistent with the general classification of sediments from the dredging site. Decreasing settling velocities and inferred equivalent diameters with distance from the plume source suggest that coarser sediments deposit near the pipeline outfall and progressively finer sediments remain in suspension longer to be transported and deposited farther from the source.

Given the relatively weak currents at the site and the relatively large settling velocities of the suspended fine sand, gradient diffusion plays a minor role in opposing settling and deposition of the plume sediments. Comparing the relative strength of the settling flux ($w_s C$) to the gradient diffusion flux ($K_z \, dC/dz$) indicates that the magnitude of the diffusive flux is between 5 to 15 percent of the settling flux.

DISCUSSION

The control-volume approach is shown to provide reasonable results in estimating vertical fluxes to the seabed in dredging plumes, with ADCP data (velocity and concentration) providing the necessary data to estimate horizontal fluxes across longitudinal control volume surfaces. Additionally, if details of near-bed vertical diffusion and concentrations are available, a mass-averaged settling velocity estimate is possible.

Significant attention must be given to instrument configuration and experimental procedures for reliable estimates from the analysis. ADCP bin spacing must be optimized to produce good resolution of suspended sediment concentration without degrading the quality of Doppler-estimated velocities. For the example application presented in this paper (which was performed to estimate SSC only), the ADCP was configured to provide maximum resolution of SSC which caused significant errors in the velocity record. Even with the problems in the velocity data, the method was shown to provide reasonable estimates of vertical flux and settling velocity. The robustness of the method for the example application is attributed to the strong settling signature of the sandy sediments in suspension. For applications involving sediments with smaller settling velocities (such as clay and silt), the method is likely to be less forgiving regarding quality of the velocity data.

One of the founding assumptions in the method presented is steady-state nature of the plume. While plumes resulting from hydraulic pipeline placement (such as shown in the example) are characteristically steady state, other dredging operations are not. For instance, mechanical dredging with a clamshell, backhoe, or bucket dredge is characterized by discrete pulses of suspended sediment. For this case, transects should be conducted repeatedly at fixed distances from the dredging operation to obtain mean fluxes across the control volume boundaries. Data collection becomes even more complicated for hopper dredges, in which transect lines must be run relative to a moving source. In this case, two ADCP systems transecting the dredge plume at fixed relative distances must operate in tandem.

While the control volume approach presented here has been developed with dredging applications in mind, the method is suitable for other suspended sediment research topics in a wide range of environments. Research of vertical sediment flux and deposition at river mouths, estuaries, and the inner shelf could apply the control-volume approach with sediment flux defined by ADCP transects. As with dredging applications, careful attention to spatial and temporal scales of variation in fluxes, assumptions of the analysis method, and limits in instrumentation and data collection would need to be considered.

CONCLUSION

A mass-balance control volume approach to horizontal sediment fluxes in dredge plumes is shown to provide reasonable estimates of vertical flux and mass-averaged settling velocity. The method relies on ADCP or similar instrumentation to provide suspended sediment flux at the control volume boundaries. Estimating vertical flux within the control volume requires estimates of velocity and SSC along the control volume boundaries. Further analysis of near-bed concentrations, vertical concentration gradients, and near-bed vertical diffusion allows estimation of mass-averaged settling velocity. The method presented is applicable to non-steady dredging plumes or other sources of suspended sediment with appropriate modification to data collection methods.

ACKNOWLEDGEMENTS

Funding for this work was provided by the U.S. Army Corps of Engineers Dredging Operations and Environmental Research (DOER) Program. Program Manager for DOER is Dr. Todd Bridges. Permission was granted by the Chief of Engineers to publish this information. Data for the example application were provided to the authors by Dr. Douglas Clarke, Kevin Reine, and Chuck Dickerson (U.S. Army Engineer Research and Development Center – Environmental Laboratory). The development and presentation of the control volume technique benefited from discussions with Dr. Courtney Harris (Virginia Institute of Marine Science) and Dr. Larry Sanford (University of Maryland, Horn Point Laboratory).

WHAT DOES "PHYSICAL REGENERATION" OF MARINE AGGREGATE DREDGING SITES MEAN?

Markus Diesing[1, 2]

Abstract: The impact of dredging and the physical regeneration of a sand-dredging site were monitored over a period of almost seven years with side-scan sonar and multi-beam echo sounder. The seabed physically regenerated from the dredging impact within a few years, except for a limited area where multiple dredging caused a pronounced impact and the seabed remained in an altered state. Based on the observed results, questions arise regarding the meaning of the term "physical regeneration". Here I intend to propose working definitions of physical regeneration, which are dependant on the nature of the particular of investigation.

INTRODUCTION

In recent years, marine aggregates (sand and gravel) have evolved as an important resource for the construction industry and for coastal protection issues. In the near future, demand is expected to grow due to an increasing urbanization of the coastal zone and large-scale construction projects. Furthermore, a large percentage of the global coastlines are receding. This problem might become even more important due to a rising sea level, caused by global warming (Church et al. 2001). Preferred "soft" coastal protection schemes will therefore possibly cause an increasing demand for marine sand. Despite several advantages of marine aggregates, when compared to those of terrestrial origin, including quality, availability and ease of transport, possible negative impacts have to be considered:

1. **Coastal engineering-related impacts**: Marine aggregate dredging often causes significant changes in seabed elevation, which in turn may alter inner shelf and shoreface wave and current fields, thereby indirectly affecting sediment transport patterns. Direct negative impacts on coastal sediment budgets and finally coastal erosion are expected, when aggregates are extracted within the active beach-shoreface sediment system (Demir et al. 2003).

2. **Benthic biology-related impacts**: Mining of marine sand and gravel directly leads to degradation or even destruction of benthic biotopes (ICES 2001). A major pre-requisite for the recovery of benthic biotopes is the naturally induced physical regeneration of the seabed. The natural regeneration of such areas following cessation of dredging is dependant on several factors such as the hydrodynamic conditions, the type of the extracted resources, the benthic life within the dredging site and the intensity and depth of dredging.

Here I present results from repeated seabed surveys performed at a dredging site in the western Baltic Sea, a practically non-tidal epicontinental shelf sea in northern Europe. The site is located approximately 2 nautical miles west of the village Wustrow, Germany off the coast of the Fischland peninsula (Fig. 1) in water depths between 10 and 12 m below mean sea level (msl). This stretch of coastline can be described as wave-dominated according to the classification of Davis and Hayes (1984).

The dredging site Wustrow II is 1,100,000 m^2 in size. According to the map of Tauber and Lemke (1995), the upper layer of the seabed is composed of moderately sorted fine sands. The mean grain size of surface sediments ranges from 210 to 250 µm, while the average thickness of the deposit amounts to 1.9 m.

In autumn 1997, approximately 320,000 m^3 of sand were extracted by trailer-suction hopper dredging (Krause 2002). This method normally leads to the production of shallow linear or curved furrows on the seabed (Fig. 2A). The extracted sands were used for a beach replenishment scheme at a nearby coastal strip of the Fischland peninsula. The morphological evolution of the site was monitored during the following seven years. The obtained results raise questions, which lead to working definitions of physical regeneration. A second extraction took place some time between May 2000 and March 2005 (according to the gathered data), but this has not been considered in the frame of this study.

METHODS

Data from side-scan sonar surveys were collected in March 1998, September 1998, May 2000, October 2004 and March 2005. The equipment consisted of a towed Klein 595 dual-frequency (100/384 kHz) side-scan sonar during the first four surveys and a towed EG&G 272TD dual-frequency (105/390 kHz) side-scan sonar during the last survey. Data acquisition was performed in digital format from May 2000 onwards (with Isis Sonar, Triton-Elics), while during the initial two surveys paper printouts were produced. During the last survey, the dredging site was also surveyed with an L3-Communications/Elac Nautik Seabeam 1185 multi-beam echo sounder with a working

frequency of 180 kHz. Data were digitally recorded with the software Hydrostar (L3-Communications/Elac Nautik Seabeam 1185).

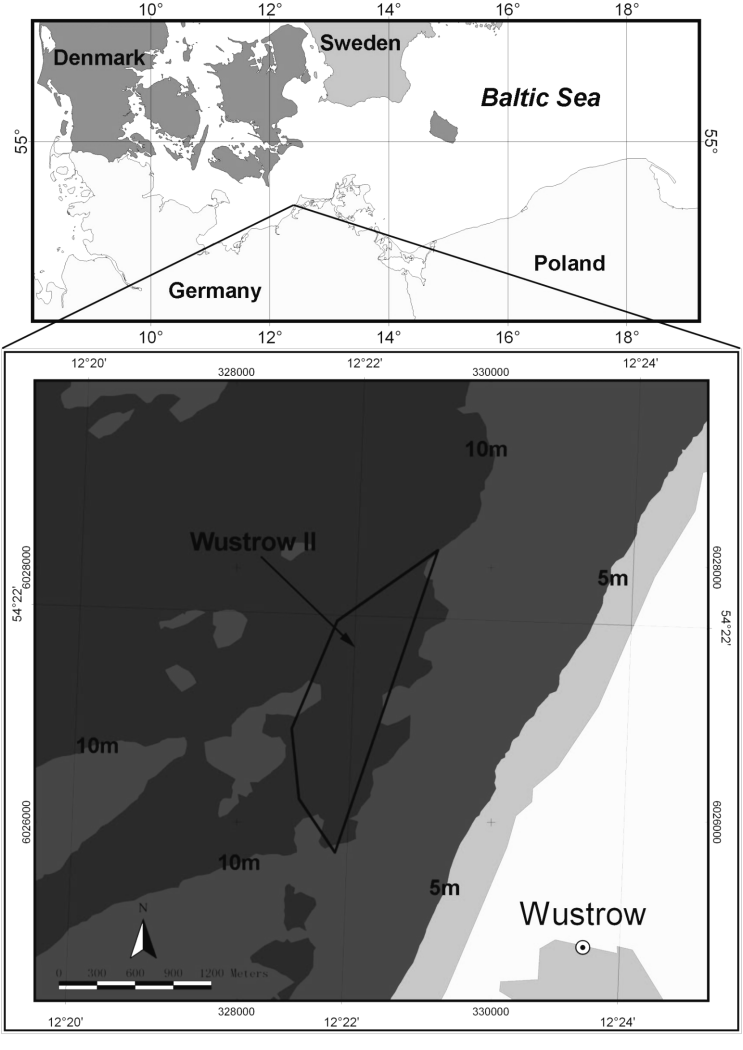

Fig. 1. Location of the dredging site "Wustrow II" in the western Baltic Sea.

During all surveys, the ship's track lines were chosen to allow full coverage of the seabed. Positioning was achieved by differential GPS, providing an accuracy of the vessel's

(and therefore also of the multi-beam's) position better than 5 m. The side-scan sonar was towed behind the vessel with about 10 m of cable out. This offset was accounted for by a constant value for each profile, when calculating the position of the tow-fish. The positioning error of the side-scan sonar is thus greater compared to the multi-beam.

The digital side-scan sonar data were processed and geo-referenced using the Isis Sonar and Delphmap software packages (Triton-Elics) in order to create mosaics of the study area. The analog data were digitized and geo-referenced according to a procedure outlined in Kubicki and Diesing (2006), which was successfully applied by Diesing et al. (2006). The geo-referenced side-scan sonar data were projected in Universal Transverse Mercator (UTM) projection and displayed in a geographical information system. Blocks of 100 m by 100 m size were defined according to the UTM grid. The number of identifiable tracks per block was visually counted for each survey. As a result, maps displaying the number of dredge tracks per 100 m by 100 m block were created. Tracks produced during a second extraction were not taken into consideration. The post-processing of the raw multi-beam data was conducted using the software packages HDPpost and HDPedit (L3-Communication/Elac Nautik).

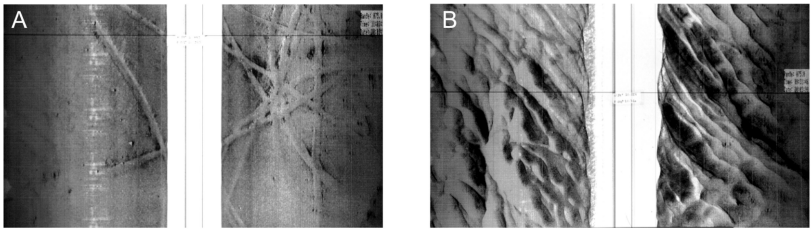

Fig. 2. Impact of dredging four months post-dredging using side-scan sonar: A – Individual dredge tracks; B – Multiple dredge tracks causing a significant depression on the seabed.

RESULTS

An initial survey four months post-dredging revealed that vast areas of the dredging site were affected by approximately 2 m wide and 0.5 m deep dredging furrows caused by trailer-suction hopper dredging (Figs. 2A, 3A). The highest impact was recorded in the southwest of the dredging site, where multiple dredge tracks created a depression of more than 5 meters below the surrounding seabed (Figs. 2B, 3A). Six months later (September 1998), the less intense impacted areas showed a reduction in the number of dredge tracks, but the impact in the heavily dredged site was still clearly visible (Fig. 3B). In May 2000 (30 months post-dredging) the situation was significantly different (Fig. 3C): Detectable dredge tracks were limited to the high-impact site and had a weathered appearance. The number of tracks had decreased significantly. Instead tracks had gained in width, thus indicating a merging of individual dredge tracks. During the two final surveys in October 2004 (82 months post-dredging) and March 2005 (87 months post-dredging), only a few heavily weathered dredge tracks were discernable in the high-impact site (Fig. 3D).

The side-scan sonar data indicated that the dredging site appeared to be completely re-generated outside the high-impact area, as no dredge tracks were recognizable. In the high-impact area, backscatter was slightly lower indicating the presence of finer or less compacted sediments or a combination of both. Additionally, the multi-beam bathymetric survey from March 2005 showed the presence of a depression with a size of 450 m in length, 130 m in width and up to 4 m in depth below the surrounding seabed in the high-impact site (Fig. 4).

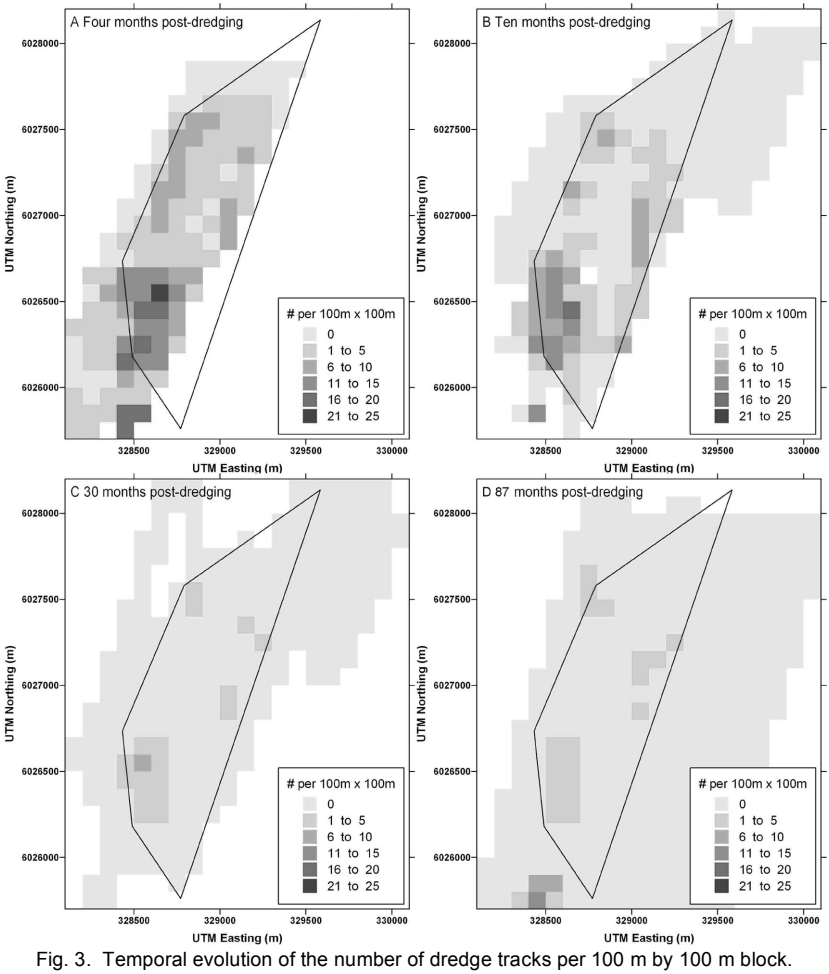

Fig. 3. Temporal evolution of the number of dredge tracks per 100 m by 100 m block.

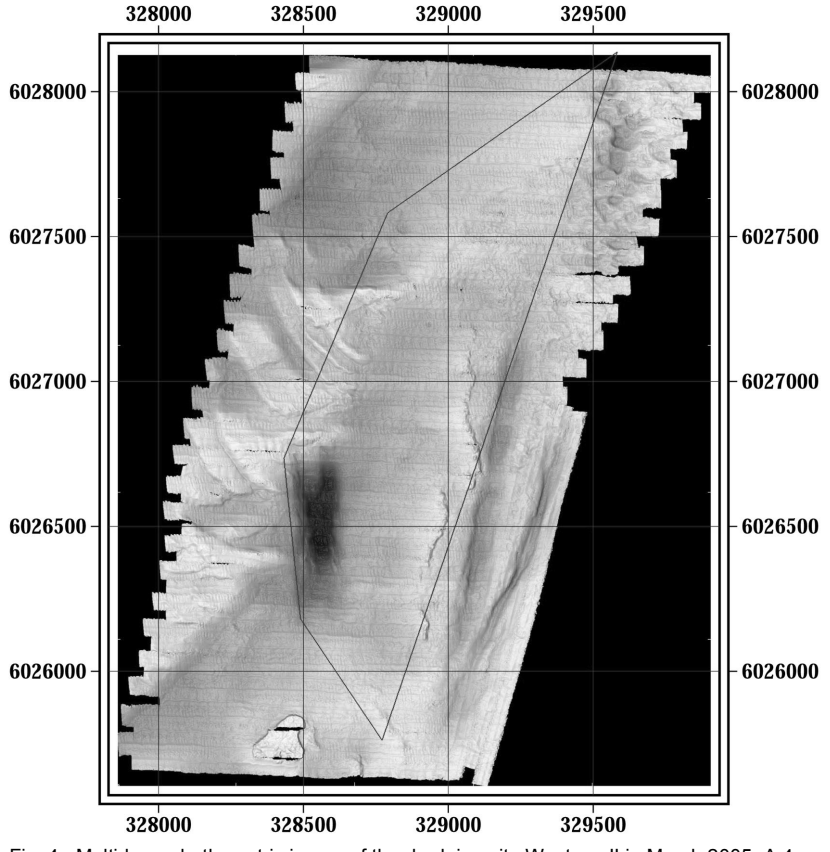

Fig. 4. Multi-beam bathymetric image of the dredging site Wustrow II in March 2005. A 4 m deep depression in the high-impact site is clearly visible.

DISCUSSION

When do we consider a dredging site to be physically regenerated? And how do we measure this regeneration? These are questions, which arise from the above-mentioned observations. As outlined below, the definition of "physical regeneration" depends on the aims of the study and whether it is dealing with coastal engineering-related or benthic biology-related impacts of dredging.

Although the pre-dredging status of the dredging site Wustrow II is unknown, which prevents the calculation of volume change, it is fairly clear that the sediment budget is far from being balanced. In this sense, the dredging site cannot be judged as being physically regenerated. The remaining depression on the seabed might therefore have an impact on wave and current fields and ultimately on sediment transport patterns. It is,

however, unlikely that direct negative effects, such as infilling from beach sediments (Demir et al. 2003), arise from the dredging impact, as the depression lies beyond the active zone of the shoreface-beach profile, which is located in approximately 10 m below msl (Dette et al. 2001).

In the high-impact area, lower backscatter values indicate different sediment properties when compared to the surrounding areas. In fact, Krause et al. (in review) show that during the initial ten months post-dredging, fine sands enriched in organic carbon content replaced the medium sands of low organic carbon content, which were present prior to dredging. However, this area is relatively limited in size when compared to the whole dredging site. Moreover, dredge tracks were practically not discernable using side-scan sonar outside the high-impact area, which indicates that the small-scale morphology induced by dredging is leveled out and the seabed sediments in this area do not significantly differ from the non-impacted surrounding seabed. Such conditions might be sufficient for the initiation of the biological recovery of the seabed, which can be defined as the establishment of a benthic community that is statistically indistinguishable from surrounding non-impacted sites, assuming the surrounding sites were similar to the dredged area prior to dredging (Cooper et al. 2005).

The definition of physical regeneration is therefore dependant on the nature of the particular investigation: If we are interested in sediment budgets and the alteration of sediment transport patterns than a dredging site might be considered to be physically regenerated when the sediment balance is zero. This is a very robust and quantitative definition, however, it does not account for alterations in the quality of sediments, e.g. grain-size, sorting, compaction, etc., which have a profound influence on the benthic communities they support. On the other hand, if we are investigating the physical regeneration as a major pre-requisite for the biological recovery of the seabed and the restoration of benthic biotopes, than it might be sufficient that the small-scale topography induced by dredging is leveled out and the physical properties of the seabed sediments are comparable to the status prior to dredging even if the sediment balance is still (slightly) negative. Such investigations can be best performed with high-resolution side-scan sonar, while the determination of the sediment budget implies the utilization of multi-beam echo sounders.

CONCLUSION

The definition of the term “physical regeneration” is dependant on the studied subject and the nature of the particular investigation. In this contribution, definitions are given for coastal engineering purposes and investigations dealing with the recovery of benthic biotopes after dredging. Other definitions are likely to emerge, depending on the aim of the study. It is therefore recommended that for every study the term “physical regeneration” should be clarified before using it.

ACKNOWLEDGEMENTS

The fieldwork was assisted by the Captain and crew of R/V Littorina of the Leibniz Institute of Marine Science at Kiel University. My colleagues Dave Limpenny and Keith

Cooper (both Cefas, Burnham) critically reviewed the draft document. Jochen Krause (German Federal Agency of Nature Conservation, Isle of Vilm) helped me to understand the biological aspects of recovery. I would like to thank all persons and institutions mentioned above.

Abstract: Over the past decade, the City of Norfolk, USA has financed design and construction of multiple nearshore breakwater fields and numerous beach fill projects. In 2005, an assessment of historical shoreline conditions was performed to evaluate the need for an extension of an existing breakwater field in conjunction with periodic nourishment. Based on the shoreline assessment, it was recommended that the breakwater field be extended.

Three additional breakwaters at East Ocean View were designed and constructed in June 2006. Since construction, salients have formed under the local wave climate and have been maintained since construction. Periodic monitoring surveys are used to evaluate shoreline response in the vicinity of the structures and along East Ocean View beach. Monitoring will serve as the basis of design guidelines for future detached breakwater and fill placement design.

INTRODUCTION

Detached breakwaters have been used in low energy environments to increase the longevity of beach nourishment at several sites within the Chesapeake Bay. Over the past decade, the City of Norfolk, Virginia, USA has financed design and construction of multiple nearshore breakwater fields and numerous beach fill projects.

The City of Norfolk's shoreline is located on the Chesapeake Bay. The shoreline extends approximately 7.3 miles, from Little Creek Inlet to Willoughby Spit (Figure 1). East Ocean View Beach section of the Norfolk shoreline extends from Little Creek approximately 5300 feet northwest towards Willoughby Spit.

East Ocean View Beach has historically experienced long-term shoreline recession since stabilization of the inlet at Little Creek in 1929. In the past 10 years, northeast storms (noreasters) and hurricanes have significantly impacted this shoreline, resulting in erosion and loss of the frontal dune system, increasing the risk of damage to beachfront properties. The East Ocean View Beach area is experiencing residential and commercial development. It has become an increasing concern to maintaining adequate protection of existing and proposed structures and improving the quality of the shoreline.

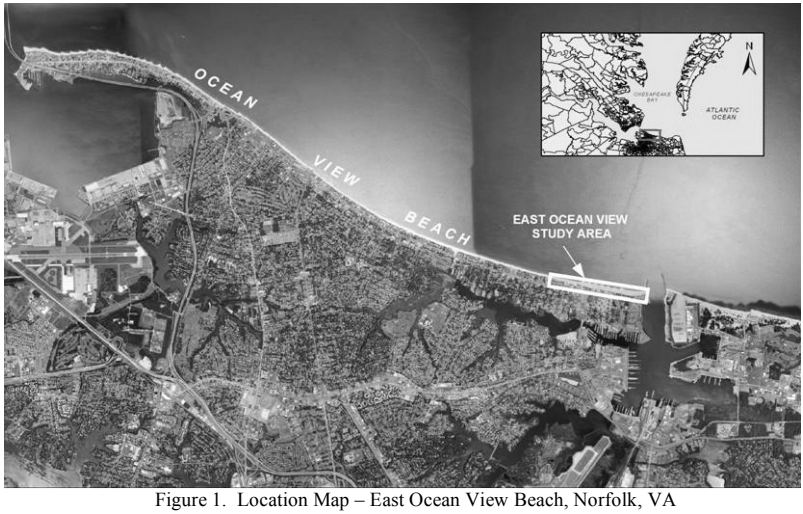

Figure 1. Location Map – East Ocean View Beach, Norfolk, VA

In an effort to mitigate erosion along the East Ocean View Beach shoreline, numerous beach nourishment projects have been undertaken during the past fifty years (1953, 1960, 1984, 1989, and 2003). The source, quality and performance of the sand fill material have varied. In addition to the beach nourishment efforts, concrete rubble has been placed by the City as an emergency measure in an effort to stabilize the shoreline at sites with severe erosion.

A study conducted in 1995 for the City of Norfolk by Andrews Miller & Assoc. (1993), designated the shoreline along East Ocean from 17th Street to the west jetty at Little Creek inlet as a critically eroding area and recommended construction of a nearshore breakwater field. In an effort to increase the longevity of the sand fill, seven nearshore breakwaters along East View shoreline were constructed in August 2000 and November 2001. A beach nourishment project was subsequently completed in December 2003.

In 2005, an assessment of historical shoreline conditions was performed to evaluate the need for an extension of the existing breakwater field in conjunction with periodic nourishment. Based on the historical assessment, it was recommended that the breakwater field be extended.

Three additional breakwaters at East Ocean View were designed and constructed to meet project objectives. Project construction of the new breakwaters was completed in January 2006. Periodic monitoring surveys were used to evaluate shoreline response in the vicinity of the structures and along Ocean View beach.

The objectives of this paper are to: (a) summarize the historical shoreline analysis performed in 2005, (b) present an overview of the breakwater design and (c) document shoreline response along East Ocean View.

HISTORICAL SHORELINE ASSESSMENT

An evaluation of shoreline change within the project area was performed using historical shoreline data available from 1929 to 2004 and recent beach and nearshore profiles surveyed in 2003 and 2005.

Shoreline Change 1929 to 2004

Shoreline data was derived from a combination of sources. Several data sets were compiled as part of the shoreline analysis completed for the City of Norfolk (Beach Consultants, January 2004). Shorelines were digitized and placed in an AutoCAD format. A baseline for measuring shoreline positions was digitized approximately along Ocean View Avenue at East Ocean View Beach. Transects running perpendicular to the baseline were placed every 180 feet across the shoreline. The distance from the baseline to the shoreline was measured along each transect. In the event that digital aerial photography was not georectified, the hard-copy aerial photographs were scanned and georeferenced using ArcGIS software tools and other available georeferenced images for the study area.

Shoreline change is estimated for three distinct reaches (Figure 2):

(1) Western portion of the study area (Station 50+35 to 37+33)
(2) Nearshore breakwater field – (Breakwaters #1 through 7) which were constructed in August 2000 and November 2001 (Station 12+55 to 37+33)
(3) Planned nearshore breakwater zone (Breakwaters #8, 9, 10) (Station 0 to 12+55)

Table 1 summarizes the historical shoreline change within East Ocean View project area from 1929 to 2004. Table 2 identifies the engineering activity along the East Ocean View Shoreline since stabilization at Little Creek Inlet.

From 1929 to 1942, Reaches 2 and 3 experienced a shoreline erosion rate of 9 to 10 feet/year. Shoreline instability within the project area may in part be attributable to stabilization of the inlet. Net longshore transport of sediment in the project area is from east to the west. Therefore, the inlet may act as a sediment sink, interrupting the natural bypassing of sediment to Reach 1 at East Ocean View.

Table 1. Average Historical Shoreline Change Statistics (ft) at East Ocean View, Norfolk, VA

Location	Stat	1929-1942	1942-1970	1970-1980	1980-1995	1995-1999	1999-2002	2002-2004

Jan-06	Breakwater Construction - 8,9,10

In an effort to mitigate erosion, beneficial use of dredged material was initiated at Ocean View as early as 1953. During the past 53 years (from 1953 to present) a total of 3.6 million cubic yards (Mcy) of sand has been placed on the East Ocean View shoreline. The placement of sand on the beach accounts for the shoreline advancement during the period from 1942 to 1970.

There are few periods within the past 50 years during which the shoreline change rate was not directly influenced by nourishment. The periods from 1929 to 1942, 1970 to 1980 and 1995 to 1999 provide an indication of shoreline change, without direct sand placement. The average rates of shoreline change during 1970 to 1980 and 1995 to 1999, within Reach 3, were -4.6 ft/year and -9.7 ft/year respectively. During the period from 1995 to 1999 (prior to breakwater construction), the rate of erosion along the shoreline at Reach 2 was estimated to be -9.9 ft/year.

Nearshore Breakwaters & Beach Fill

Most recent efforts to stabilize the shoreline at East Ocean View include construction of seven nearshore breakwaters (Reach 2) and placement of beach fill (Reach 1,2,3) undertaken in December of 2003 (Figure 2). The nearshore breakwaters were constructed during August 2000 and November 2001. Each structure extends an average length (Ls) of 240 feet, with a distance between breakwaters (Lg) of 120 feet.

The December 2003 beach nourishment project consisted of a placement of a total of 366,000 cy of material along East Ocean View shoreline, an average of approximately 66 cy/linear foot. The median sediment grain size by profile ranged from 0.4 to 0.5 mm (Moffatt & Nichol, 2004).

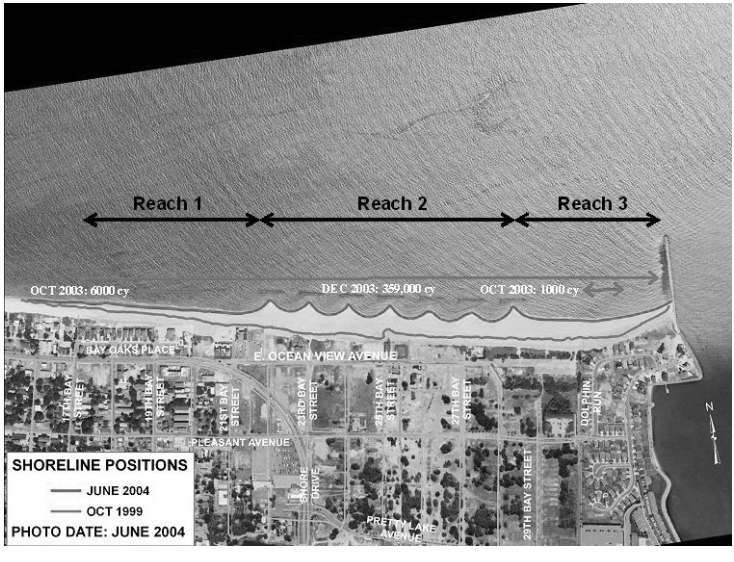

Figure 2. Shoreline Response to Nearshore Breakwater Construction & Beach Fill

Comparison of the post construction December 2003 to the September 2005 beach fill profiles was performed. Table 3 summarizes the shoreline change by Reach. Figures 3 and 4 illustrate the shoreline response and volumetric change to a depth of -10 ft NAVD.

Table 3. Average Shoreline Change from December 2003 to September 2005

Location	Shoreline Change (ft)	Volumetric Change (cy/ft)	Total Volumetric Change (cy)
Reach 1	-60.6	-28.8	-55,646
Reach 2	-24	-8.1	-20,364
Reach 3	-72	-17.1	-19,609

Shoreline response at East Ocean View is influenced by a multitude of factors including: (a) magnitude and direction of wave energy, (b) sediment characteristics of the beach fill material, (c) beach fill placement template, (d) presence of hard structures including nearshore breakwaters and west jetty at Little Creek Inlet and (e) relative location within the regional littoral cell.

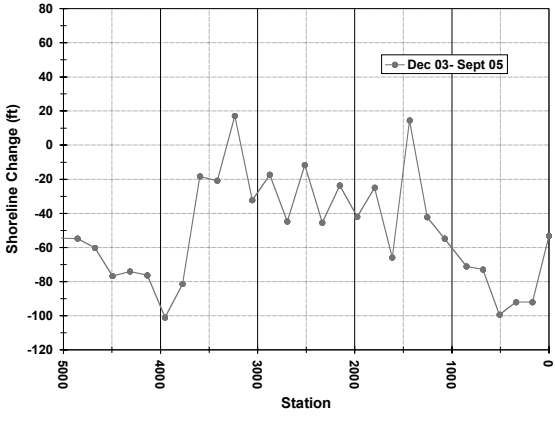

Figure 3. Shoreline Change December 2003 to September 2005

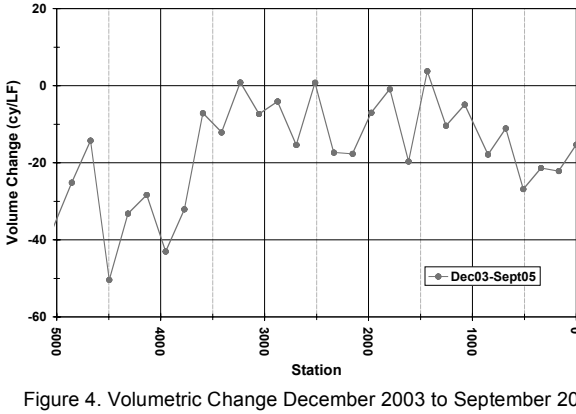

Figure 4. Volumetric Change December 2003 to September 2005

Since construction of the beach fill project in 2003, salients have formed in the landward of the nearshore breakwaters (Figure 3). During the period from December 2003 to September 2005, within Reach 2 there was an average shoreline recession of -24 ft, eroding at an average rate of -8 cubic yards/linear foot (cy/lf). Comparing the rate of shoreline change to the adjacent areas (Reaches 1 and 3), the breakwaters appear to have

been effective at reducing local erosion of the shoreline. Performance of the breakwaters indirectly has an effect on the rate of erosion at the downdrift beach; the downdrift shoreline (Reach 1) had eroded at a rate of -28.8 cy/lf.

During the 21 month period, the average shoreline recession over Reach 3 was -72 ft, eroding at -17 cy/lf. The cumulative erosion along Reach 3 was approximately 19,600 cy. Although, adjustment of the shoreline was anticipated after placement of beach fill, the shoreline is exhibiting an accelerated rate of erosion compared to Reach 2. Given the rate of erosion and risk of property damage along Reach 3, the City elected to pursue extension of the breakwater field in this region

NEASHORE BREAKWATER DESIGN

Breakwaters are designed to reduce wave energy by protecting the shoreline from wave attack and transforming incoming waves. When a wave interacts with a permeable structure, a portion of the energy is (a) dissipated on the structure, (b) reflected (depending on the geometry of the structure), (c) diffracted through the gaps, (d) transmitted through the structure and (e) transmitted over the structure (depending on the elevation of the structure).

Design considerations for the extension of the nearshore breakwaters at East Ocean View are discussed below.

Planform Geometry

Detached breakwaters have been used in low energy environments to increase the longevity of beach nourishment at several sites within the Chesapeake Bay, Gulf of Mexico and in the Great Lakes. Although detailed performance assessments are not available, general observations regarding the shoreline response have been used to develop guidelines.

Empirical relationships have been developed that predict the nearshore response based on three dimensionless ratios, Y/ds, Ls/Lg and Ls/Y. Where: (Y) Distance of breakwater from nourished shoreline; (Ls) Length of breakwater structure; (Lg) Gap distance between adjacent breakwater segments; (Ds) Depth (average) at breakwater structure below mean water level.

The ratio Ls/Y is most commonly used as an indicator of shoreline response. Several references cite tombolo formation under conditions where Ls/Y is greater than 1.5 (USACE, draft 2002). Ahrens and Cox (1990) assessment of nearshore breakwaters in the Chesapeake Bay documents salient formation at L_S/Y of 1.5 and subdued salient formation where Ls/Y = 0.8 to 1.5.

Salients are most likely to form in environments where breakwaters are sufficiently offshore, short relative to incident wavelength, and transmissible either by being low

crested or having large gaps between structures.

Existing breakwaters at Ocean View beach serve as a design analog. The seven existing breakwaters along Ocean View from 21st Bay Street to Little Creek Inlet extend an average length (Ls) of 240 feet, with a distance between breakwaters (Lg) of approximately 120 feet. Distance from the pre-nourished shoreline to breakwater (Y) varies from approximately 180 to 220 feet. The resulting Ls/Y is estimated to be 1.09 to 1.33, within the limits identified for salient formation. The ratio Ls/Lg for the existing breakwaters is 2.0 with the ratio Y/ds ranging from 23 to 32.

Figure 5 depicts the response of the shoreline landward of the existing structures. Salients have formed under the local wave climate and have been maintained since construction of the nourishment project in 2003. Based on initial observations since construction, all else being equal, the ratio of Ls/Y used for the initial breakwater design is appropriate to create salient formation for the local conditions.

Figure 5. Salient formation along existing breakwaters at East Ocean View (Photo taken in September 2005)

Three additional breakwaters at East Ocean View were designed with Ls = 260 ft and Lg =130 ft (Ls/Lg = 2). Although the jetties at Little Creek Inlet create a shadowing effect that causes reduction in incident wave energy along the shoreline, the proposed additional breakwaters were conservatively sited to within a 150 ft distance of the west jetty. The orientation of the breakwater closest to the Little Creek Inlet is set approximately parallel to the 6 ft contour, normal to predominant incident wave energy. Based on the pre-nourishment surveys, the ratio Ls/Y was estimated to be 1.2 to 1.3 and Yavg/ds = 33 to 37.

Physical Design Parameters

Design procedures were employed to evaluate the integrity of existing breakwaters and

design additional breakwaters. Methods were used to evaluate the cross-sectional geometry of the breakwater, sizing the armor stone and the performance of the breakwaters in terms of wave transmission.

Table 4 identifies the tidal range at the NOAA gage data at the Chesapeake Bridge.

Table 4. Water levels at the Chesapeake Bridge - NOAA gage 8638863

Datum/Event	ft NAVD	m NAVD
Mean High High Water (MHHW)	1.29	0.39
Mean High Water (MHW)	0.98	0.30
Mean Low Water (MLW)	-1.57	-0.48
Mean Low Low Water (MLLW)	-1.61	-0.49
Historical High occurring 2/5/98	4.97	1.51
Historical Low occurring 1/11/78	-4.54	-1.38

A range of storm surge and significant wave height design conditions were considered. Design storm surge elevations were characterized based on available data and prior investigations by the Virginia Institute of Marine Sciences (VIMS) in Boon et. al. (1978). Breakwaters were designed for a range of surge elevations up to 4 ft NAVD (approximately a 10-year recurrence interval event) and a design breaking wave height under a maximum surge of 7.5 feet.

General guidelines for the sizing of armor stone of nearshore breakwaters do not exist. Methods developed for sizing stone of conventional offshore breakwaters was applied, with consideration of the basis of empirical methods. Cross-section geometry and stone size were evaluated using empirical methods identified in the CEM. Selection of an appropriate armor stone for design storm conditions was performed using Hudson's formula and Van De Meer's approach. The crest elevation of the breakwaters was established at +2 ft NAVD, approximately 1 ft above MHW (+0.98 ft NAVD).

Figure 6 illustrates the design cross-section for the nearshore breakwaters.

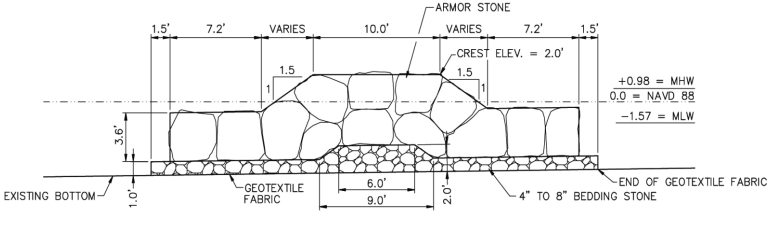

Figure 6. Nearshore breakwater design cross-section

An empirical method developed by Ahrens (2001) was employed for estimating the total

wave transmission for nearshore breakwaters. The breakwater was determined effective in reducing the transmission of wave energy during frequent storm conditions. With the surge elevation at 0.0 ft NAVD and wave heights ranging from 2 ft to 4 ft, the wave height was estimated to be reduced by an average of 23%. During low frequency events with surge elevation at 3.8 ft NAVD and wave heights ranging from 5 to 6 ft, the incident wave energy was estimated to be reduced by 10%.

MONITORING NEARSHORE BREAKWATER FIELD AND BEACH FILL (SEPTEMBER 2005 TO OCTOBER 2006)

Wave Climate

As identified above, shoreline response at East Ocean View is directly influenced by magnitude and direction of wave energy. In March 2006 a wave gage was installed as part of the City of Norfolk comprehensive shoreline management program. The wave gage was placed in 23 feet of water approximately 6400 ft offshore of the beach at Norfolk; it is located approximately 2000 ft west of the project area. Summary statistics for the period from March 2006 through August 2006 are identified in Table 5.

Table 5. Summary statistics for the period from March 2006 to August 2006

Wave Statistic	Mar	Apr	May	Jun	Jul	Aug
Average Significant Wave Height, H_s (ft)	1.3	1.3	1.2	1.0	0.8	1.0
Average Wave Period, T_m (s)	2.5	2.6	2.5	2.5	2.4	2.4
Average Peak Wave Period, T_p (s)	5	5.4	4.8	5.9	5.6	5
Max Observed Significant Wave (ft)	3.9	4.6	5.2	4.4	2.2	4.4
Maximum Observed Height, H_{max} (ft)	6.2	8.3	8.4	7.3	3.8	6.6

The largest wave heights recorded were during tropical storm Ernesto. During this storm on September 1, 2006, maximum wave heights of 13 feet were recorded and significant wave heights of up to 7.7 feet. Based on the NOAA gage 8638160, the maximum recorded surge elevation was +3.87 ft NAVD, approximately 2.9 ft above MHW. Figure 7 illustrates the growth in wave height during the Ernesto.

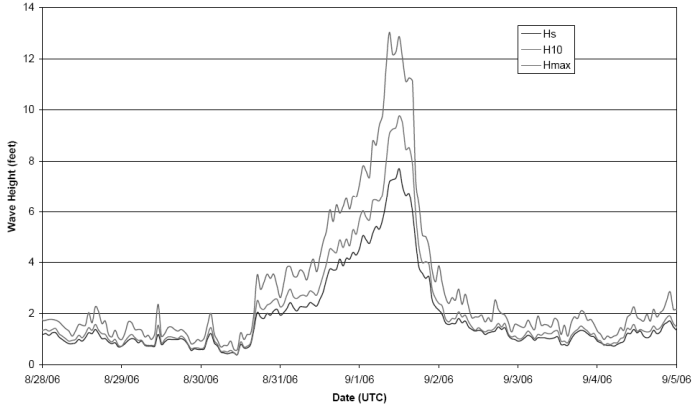

Figure 7. Wave Height recorded during Tropical Storm Ernesto

Performance of Breakwater Field & Beach Fill

Project construction of the three additional breakwaters was completed in January 2006. Periodic monitoring surveys (September 2005, March 2006 and October 2006) were used to evaluate shoreline response in the vicinity of the structures and along Ocean View beach shoreline. Figure 8 illustrates the post-construction monitoring conditions and shoreline change between 2004 and 2006.

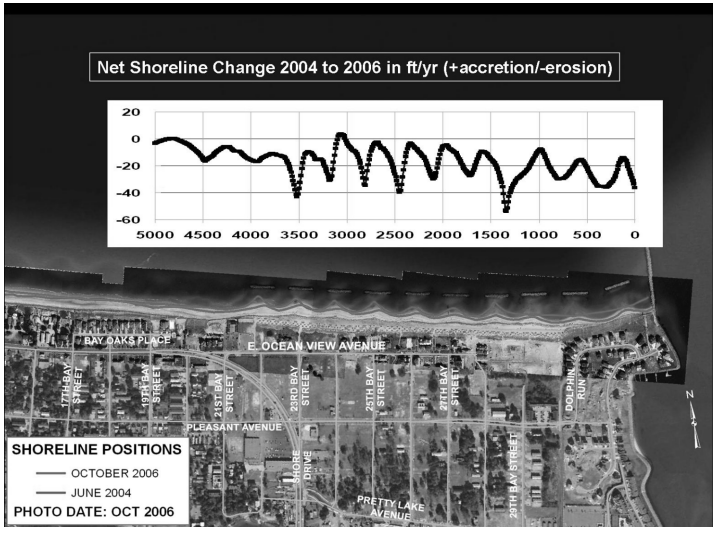

Figure 8. Shoreline Change from June 2004 to October 2006

During the period from June 2004 to October 2006 the majority of shoreline experienced recession (Figure 8). Salients formed behind the constructed nearshore breakwaters within Reach 3; along the existing breakwater field salients are less pronounced than they were during the prior shoreline characterization in June 2004.

A summary of shoreline change based on beach and nearshore profiles is compiled in Tables 6, 7 and 8.

Table 6. Average Shoreline Change at MHW (ft)

Location	Sept 05-Oct 06 (ft)	March 06-Oct 06 (ft)
Reach 1	-9.4	-4.6
Reach 2	-20.5	-27.0
Reach 3	-20.0	-24.0
Total	-16.8	-19.0

Table 7. Average Volumetric Change Rate March 2006 - October 2006

Location	Above 0 ft NAVD (cy/lf)	Above -15 ft NAVD (cy/lf)
Reach 1	-4.57	-9.55
Reach 2	-3.47	-4.83
Reach 3	-3.18	-3.28
Total	-3.76	-6.00

Table 8. Cumulative Volumetric Change March 2006 - October 2006 (cy)

Location	Above 0 ft NAVD	Above -15 ft NAVD
Reach 1	-8,169	-18,100
Reach 2	-8,739	-12,157
Reach 3	-2,847	-2,874
Total	-19,755	-33,131

During the period from September 2005 to March 2006 there was an average accretion of approximately 2.9 cy/lf/period along Reach 1; cumulative volume change over this reach was approximately 8,000 cy of material. From September 2005 to March 2006, the average volumetric change (above -15 ft NAVD) for Reach 2 and 3 was estimated to be +1 cy/lf/period and -1 cy/lf/period, respectively.

The Reach 1 shoreline at MHW, during the period from March 2006 to October 2006, realized an average rate of recession of less than 5 ft/year. Although there was little change in the shoreline at MHW, the total erosion (above -15 ft NAVD) was -9.6 cy/lf. This reach experienced an average erosion rate of -4.6 cy/lf above 0.0 ft NAVD from March 2006 to October 2006 (Figure 9).

Reaches 2 and 3 experienced similar trends during the monitoring period from March 2006 to October 2006. The average shoreline recession at MHW along Reaches 2 and 3

was estimated to be -24 ft/year and -27 ft/year. Average erosion (above -15 ft NAVD) was estimated to be -4.8 cy/lf and -3.3 cy/lf for Reach 2 and 3, respectively. As illustrated in Figure 9, the majority of the net erosion along both Reaches 2 and 3 appeared to be above 0.0 ft NAVD. The portion of erosion occurring above 0.0 ft NAVD is estimated to account for greater than 70% of the total erosion occurring at Reaches 2 and approximately 95% of the net total erosion occurring at Reach 3; this is most likely attributable to Ernesto.

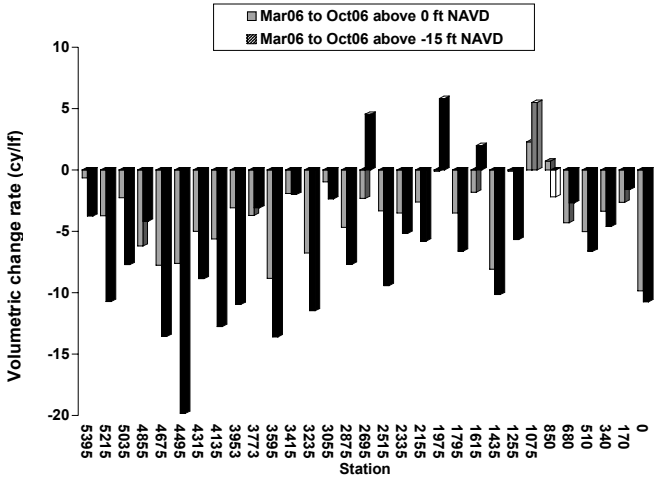

Figure 9. Volumetric Change March 2006 to October 2006 in cy/lf/period

Figure 10 illustrates the cross-section profile change that occurred from December 2003 to October 2006 at the gaps between breakwaters. Station 510 is located in the gap between breakwaters 9 and 10. Erosion of the beach fill material placed in December of 2003 is evident. From March 2006 to October 2006, there was continued erosion of the dune (-5.7 cy/ft/period). Below the MHW water level, the profile experienced accretion at some locations with a net change of -1.6 cy/lf/period.

An example of a cross-section adjacent to a breakwater is illustrated in Figure 11. Station 340 is located at the midpoint of the eastern most breakwater (adjacent to the west jetty at Little Creek Inlet). From March 2006 to October 2006, the shoreline was relatively stable; the salient feature is evident in the cross-section surveys.

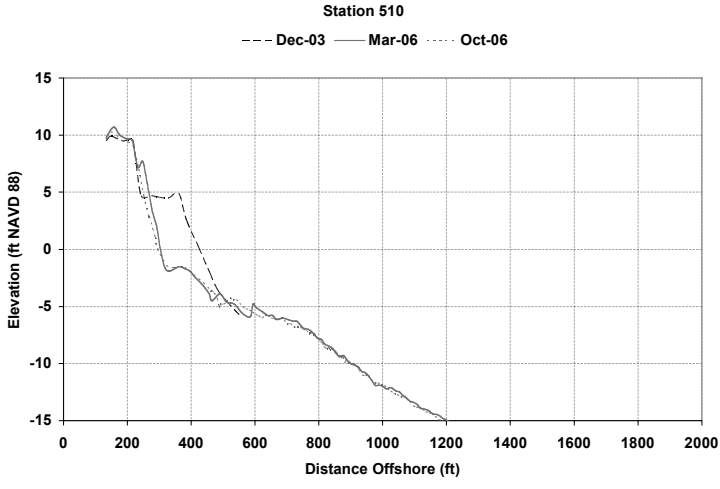

Figure 10. Monitoring beach profiles at Station 510

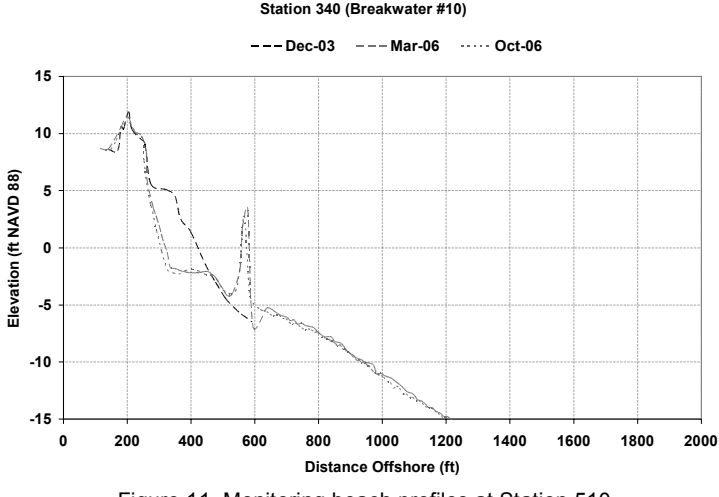

Figure 11. Monitoring beach profiles at Station 510

CONCLUSION

During the monitoring period, the East Ocean View shoreline experienced a maximum storm surge of (+3.9 ft NAVD) and significant wave height (7.7 feet). Although the shoreline realized extensive dune and berm erosion at several locations, there was no

evidence of structural damage to the breakwaters. The shoreline landward of the breakwater field has responded in plan form as designed. Salients have formed in landward of the constructed breakwaters; no tombolos have been established.

The nearshore breakwater field has reduced the relative rate of beach erosion along the landward shoreline and indirectly affected the downdrift beaches. Based on monitoring from December 2003 to September 2005, of the approximately 66 cy/lf of beach fill, an average of 8 cy/lf of material eroded landward of the breakwater field during the initial 21 months. The downdrift shoreline eroded at an average rate of -28.8 cy/lf.

Trends in shoreline change from March 2006 to October 2006, provide additional indication of the effectiveness of the nearshore breakwaters. The average berm and dune erosion landward of the breakwater field was estimated to be on average approximately 33% less than that calculated for downdrift beaches. The total rate of erosion experienced along the shorefront landward of the breakwater field was approximately 45% of that calculated for the downdrift shoreline.

As part of a comprehensive monitoring program the City of Norfolk plans to continue to collect data including: wave gage measurements, beach and nearshore profiles, and aerial photographs. Additional data will allow for further assessment of the performance of nearshore breakwaters and will aid in the cost effective design and planning.

ASSESSING BEACH FILL COMPATIBILITY THROUGH PROJECT PERFORMANCE EVALUATION

Donald K. Stauble[1]

1. U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA. Donald.K.Stauble@erdc.usace.army.mil.

Abstract: Part of the design processes in beach nourishment projects is to determine the suitability of the borrow material for placement on the native beach. Ideally the sediment would be of similar grain size distribution, shape and color. Often the borrow source is a different environment and therefore a different size distribution and predicting the amount of borrow that will remain on the profile once it is placed is problematic. Case studies on past projects indicate that fill compatibility is complex and not well predicted by using the standard suitability methods. Use of the entire grain size distribution is needed to better predict performance. Borrow material similar to the native sediment will return to a native distribution within one year, while finer or coarser distributions take longer to equilibrate. Coarser borrow material seems to provide a more stable fill. Fill volume is also important along with grain size in project success.

INTRODUCTION

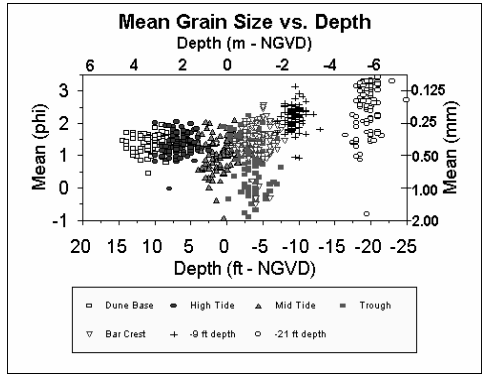
The correct analysis of sediment data is important to the design engineer and regulatory official in obtaining the following information about a beach nourishment project:

1) The suitability of borrow area sand for erosion control projects
2) The volume of sand needed to obtain the desired level of storm protection
3) Assessment of long-term sediment characteristics, fill stability and the timing of renourishment.

Two basic approaches are commonly used that apply grain size parameters to characterize the native (pre-nourished beach) and borrow area sediment: 1) calculation of the overfill ratio and 2) application of the equilibrium beach profile in determining needed fill volumes (CEM 2003). These methods are used in design of almost every

nourishment project to assess fill suitability, but little follow up has been reported on how well these methods have predict actual project performance. Both methods use the basic sediment statistics of mean and sorting to characterize the native beach and borrow area. These simple statistics are limited in characterizing the beach and do not do well in predicting actual behavior of the fill over time. A method that uses the entire grain size distribution is needed to better cover the resorting of borrow material placed on a beach. The evolution of the entire grain size distribution on the case study beaches have shown that the sediment response is complex and further research is needed to come up with a more reliable method to predict fill suitability and renourishment requirements. Long-term monitoring is also needed on select projects to evaluate fill evolution and relate that to project performance. Case Studies are used here to examine actual project sediment behavior from initial beach and borrow area characterization to post-fill long-term redistribution.

SEDIMENT CHARACTERIZATION



Sediment distributions are three dimensional both on the beach and in the borrow area. A good sampling scheme is required to document the variability in both the cross-shore and alongshore direction on the native beach and in the horizontal and vertical limits of the borrow area.

Native Beach

Spatial variations may be present due to variations in the underlying geology, transient morphology (i.e. beach cusps, bar features), influences of shore protection structures (i.e. groins, breakwaters, jetties) and hot spots (areas of increased erosion). Characterization of the native beach can be divided into two interrelated tasks on collection and analysis of: 1) the native beach grain size distribution and 2) the beach profile morphology (Stauble 1991a; 1991b). Beaches are made up of a variety of mineral components and contain a wide range of grain sizes that vary in both the cross-shore and alongshore directions. While the main component of most beach nourishment project sediment is quartz sand, many beaches may contain components such as carbonate material (i.e. shell, coral fragments, aragonite), rock fragments (i.e. volcanic basalts, plagioclase, chert), and heavy minerals. The grain size distribution at any given point on the beach is a function of the energy of the cumulative coastal processes (i.e. wind, waves and currents) and mineralogy of the available sediment. In addition, color, shape and roundness, and sediment bulk density also play a roll in the choice of borrow sediment makeup and aesthetics of beach fill material.

Differences in the cross-shore grain size distribution have been documented on natural beaches, with the coarsest grains found in an area between the backwash/surf interaction zone and the highly turbulent shore break plunge point (Bascom 1959; Zarillo, et al 1985; Stauble 1992). The berm crest area also contains significant coarse material due to runup sediment transport dynamics. Finer, better-sorted material is found in the dune area owing to predominantly wind transport processes. Seaward of the surf zone, sediments become consistently finer and better sorted, at least out to depth of closure. A long-term sediment study of the Ocean City, MD beach fill project (Stauble and Bass

1999) also exhibited this cross-shore sediment distribution. The pattern was found in the native pre-fill beach; within six months after fill placement and in the long-term (ten year) fill resorting. A typical adequate cross-shore sample scheme will collect sediment at the dune base, berm crest, mid tide, low tide terrace (trough) and several samples in the nearshore from bar crest out to closure. A plot of mean grain size versus cross-shore location of all profiles at the Ocean City MD beach fill project shows a consistent distribution of coarsest sediment in the low tide/trough area, with fining in the inshore and offshore direction based on a ten year span of sediment data (Figure 1).

Composite Samples

To reduce variability in the cross-shore grain size distributions, composite samples are usually constructed combining several samples into a new single distribution, where either the sieve classes are mathematically averaged or the samples are mixing together before sieving. Several types of composite samples were examined (Stauble and Hoel 1986) to determine which combination of beach samples eliminated spatial variability and provided the best comparison of actual behavior over time from various beach fill projects. Two basic types of composites were chosen after an examination of various combinations of samples available from each project:

1) The typical method uses a ***profile composite*** of all the samples collected across a profile to approximately the depth of closure. This composite was usually skewed to the finer grain sizes due to the more uniform nearshore samples, which often exhibited a good match to finer borrow material but over time more fill loss was measured on these projects.
2) The ***intertidal composite*** uses samples from the intertidal zone (between mean high water and mean low water). This composite gave the best representation of the beach-fill behavior over time since this is the location of typical fill placement and of subsequent fill reworking on most projects. Intertidal composites were usually coarser by excluding the finer nearshore samples. This resulted in a higher overfill ratio, but long-term project performance was more favorable.

Based on the comparison of composite samples and analysis of project fill behavior over at least one year, the intertidal composite is recommended as it better represent the native beach and provide more accurate input to the overfill calculations. The resulting higher overfill factors required more fill volume to be placed but in general, those projects retained more fill volume within the first year than projects that used the profile composite (Stauble and Hoel 1986).

Borrow Area Samples

Borrow area sediments need to be adequately characterized to determine suitability. To characterize the variation in sediment distribution in the borrow area, several representative surface samples and cores are needed to adequately describe the three-dimensional nature of most borrow sources. Sediment samples are collected from representative sediment layers within each core. *Core composite samples* are made by combining sample data from within each core and *borrow area composite* samples are made by combining sample data from cores collected over the entire borrow area.

Fill material for beach nourishment can come from a variety of sources, such as upland stock piles, inlet ebb and flood shoal mining, navigation channel dredging, sand trap mining or sand bypassing, estuarine sands and nearshore shelf sands (Stauble and Hoel, 1986).. Because the environment of deposition of a borrow area can be different from the beach, variations in the makeup of borrow sands cause design challenges for determining what is stable fill material and what is environmentally suitable for placement.

PROJECT PERFORMANCE EVALUATION

To evaluate how well the borrow material performed; a review of several projects was done to measure the performance of fill sand over time. The overfill factor is defined as the volume of borrow material required to produce a unit volume of stable fill material (CEM 2003). Thus a overfill factor of 2 means that ½ of the borrow material is unstable and twice the design volume of borrow area sediment would have to be placed on the beach to provide the desired protection. A review of the three overfill calculation methods are given in Stauble (2005). A few beach nourishment projects had well designed monitoring programs that collected adequate samples of the native beach, the pre-dredge borrow area and a systematic set of post-fill placement samples ranging from one to up to ten years of project life. Analysis of the sediment grain size data has allowed an assessment of the pre-placement native beach and borrow sediment by applying the overfill and equilibrium profile methods. This process was used to identify suitability of borrow material, based on the existing models. It also allowed for evaluation of how grain distributions of fill material actually behaved over a given periods of project life. Sediment samples and profiles collected on a quarterly, semi-annual and annual bases allow for long term study of fill resorting and change due to seasonal, storm and renourishment cycles. Many beach nourishment projects exhibit hot spots of higher erosion (Stauble and Gravens 2004). The combination of sediment and profile response at hot spots relative to the background project response has provided insight into causes and possible remedial actions. Use of coarser grain size fills and extra fill volume placed specifically in hot spot areas can reduce overall renourishment requirements in the long term life of the project.

To assess how well suitability predictions work on actual projects, four projects are presented to evaluate sediment grain size distributions and volumes retained over at least one year after fill placement. Two of the example projects cover a post placement period

of one year, with one covering an eight year period and one covering a ten year period. The investigation examines the pre-fill native beach, a representative sample of the borrow area and the distribution of the post-fill sediment on the four projects. The percentage of fill volume lost over time was measured from profile change. A comparison of what actually happened to the fill with what the model predicted provided an idea of how the models actually worked.

The Ocean City, New Jersey beach fill project is located on a barrier island along the southern New Jersey coast, where 918,000 cu m was placed along a 3.6 km section of beach south of Great Egg Harbor Inlet in 1982 (Figure 2). Sediment samples from the Ocean City, NJ project consisted of intertidal samples only collected at the high tide (HT), mid tide (MT) and low tide (LT) areas of the profile (Stauble and Hoel 1986). The native-borrow comparison (Figure 3a), shows that both the native and borrow had similar distributions of very well sorted sands with the borrow material having a slightly lower percentage in the 0.177 to 0.125 mm (2.5 to 3.0 phi) range and excess sand in the 0.105 to 0.044 mm (3.25 to 4.5 phi) range. The slightly finer fill material was due to its Great Egg Harbor Inlet flood shoal origin which was placed on the ocean beach by pipeline dredge. The native mean was 0.171 mm (2.55 phi) and a sorting of 0.58 phi as compared to the borrow mean of 0.149 mm (2.75 phi) and sorting of 0.50 phi. Some of this excess fine material was immediately transported offshore during placement by hydraulic dredge. The fill factor was calculated at 1.75. One year later the fill material had returned to a native-like grain size distribution as shown by the grain size distribution curve in Figure 3b. Some fine

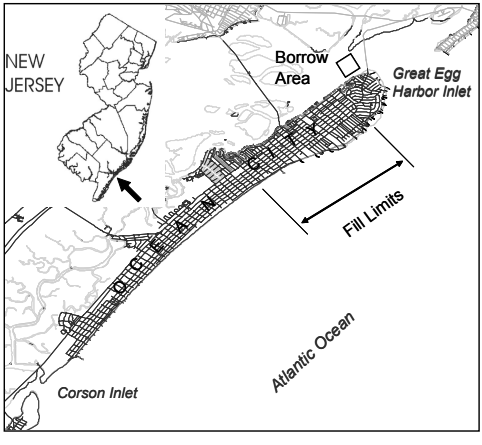


Figure 2. Location of Ocean City NJ project.

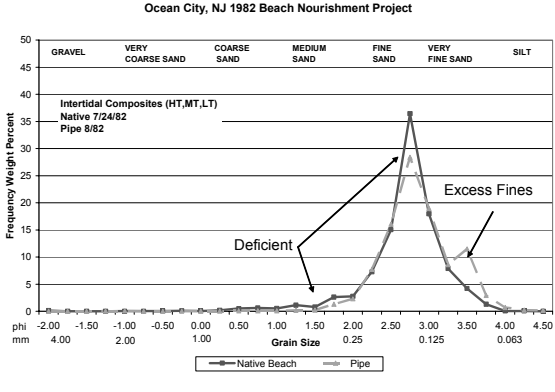

Figure 3a. Pre and Borrow grain size distributions at 1982 Ocean City, NJ. project.

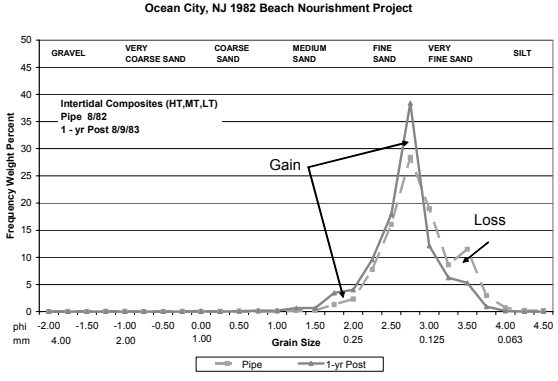

Figure 3b. Borrow and 1-yr post fill grain size distributions at 1982 Ocean City, NJ. project.

material was lost from the intertidal area and a small amount of coarser grain material was deposited on this flat slopping beach. An estimate of 69% of the fine grained fill was remaining after one year but the profiles did not reach to closure (Stauble and Hoel 1986)

The Indialantic/ Melbourne Beach Florida beach nourishment project is located along a 3.38 km stretch of barrier island in the central Atlantic coast of Florida (Figure 4). In 1981, 195,000 cu m of sand was trucked to the site from an upland stockpile created after dredging of the Port Canaveral navigation channel and turning basin. Borrow material for the project contained excess coarse shell material (4.0 to 0.5 mm, -2.0 to 1.0 phi), excess fine-grained material (0.18 to 0.04 mm, 2.5 to 4.5 phi) but was deficient in the 0.5 to 0.18 mm (1.0 to 2.5 phi) medium sand range found on the native beach (Stauble and Hoel 1986). Figure 5a compares the intertidal composite (HT, MT, LT) with the borrow material showing the coarser more poorly sorted borrow as compared with the native sand. The native mean was 0.32 mm (1.62 phi) and exhibited a sorting of 0.72 phi, while the borrow mean was 0.33 mm (1.59 phi) with a sorting of 1.61 phi. Though the mean grain-size was similar, the borrow material was more poorly sorted with a fill factor of 1.38. This example emphasizes the importance of looking at the entire grain size distribution when determining the suitability of a borrow material for a beach, and not just using the mean and sorting values alone. One year later, the fill had mixed with the underlying native sands and had resorted itself back to close to the native distribution with a loss of the fine material and a slight loss of coarse shell hash (Figure 5b). Only 45% of the fill remained within the study area after one year but the profiles did not reach closure depth so volume could not be adequately

measured (Stauble and Hoel 1986).

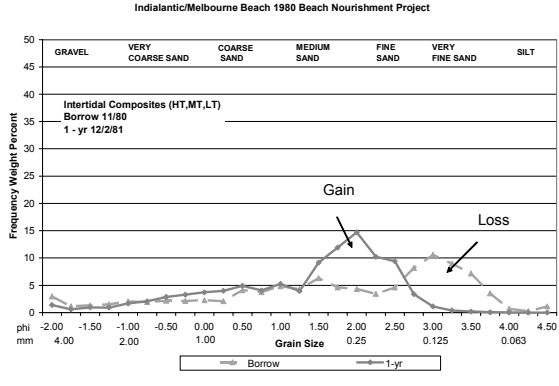

Figure 5b. Borrow and 1-year post fill grain size distributions at the 1980 Indialantic/Melbourne Beach project

Delray Beach, Florida is located on the southeast Florida Atlantic coast. At this particular fill event a volume of 1.25 mill cu m was pumped from an offshore source and placed along 3.05 km of barrier island shoreline (Figure 6). The Delray Beach fill project of 1974 was a example of placement of much finer offshore borrow material on a relatively coarse native beach (a somewhat worst case scenario of incompatibility of borrow material). The offshore borrow source area sediment contained a large excess of fine-grained material 0.25 to 0.044 mm (2.0 to 4.5 phi) and is deficient in the larger sand-sized fractions 2.0 to 0.25 mm (-1.0 to 2.0 phi). The native beach (profile composite only data available) had a mean and sorting of 0.49 mm (1.02 phi) and 0.57 phi respectively. The borrow material had a mean and sorting of 0.21 mm (2.27 phi) and 0.67 phi respectively. This is an extremely large difference in mean grain-size, but the sorting was similar (Figure 7a). The fill factor was greater than 10. Large losses of the fine-grained sediments were seen initially and eight years later the sediment was still finer than the native beach (Figure 7b). This project is an example of the borrow area sediment distribution permanently changing the distribution of the beach after placement with the long-term (8-year) grain size distribution falling in between the original native and finer borrow. Limited profile and sediment data on this project made detailed analysis difficult, but there was some indication of large loss of this fine fill material from the beach, with much of the material residing in the nearshore. A second fill was placed in 1978 and the only available post-

placement data was in 1980. A rough estimate of 26% of fill remaining in the profiles within the 8 year study period suggests that the fine material was not adequate for the project (Stauble and Hoel 1986).

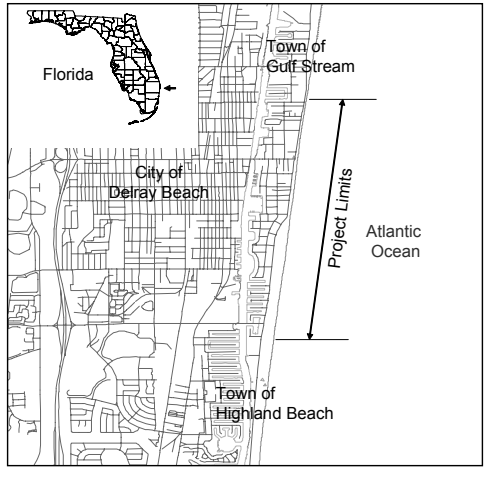

Figure 6. Location of the Delray Beach, FL 1973 Project.

Ocean City, Maryland is located on Fenwick Island, a barrier Island in the middle of the Delaware-Maryland-Virginia (Delmarva) Peninsula (Figure 8). The beach fill project covers 14.7 km of open Atlantic beachfront and was constructed in two phases. Phase I started in 1988 with a State of Maryland sponsored recreational fill that placed 2.0 mill cu m of sand. The Federal Fill added an additional 2.8 mill cu m of sand for hurricane and storm protection in 1989-90. Due to high storm activity the project added an additional 1.2 million cu m in 1992 and 917,520 cu m in 1994. Sand was pumped from several offshore borrow sites over the 5 year period. Native sediment data was collected just prior to Phase I placement in July 1988 and after the project was completely constructed from May 1995 to April 1998, just before the first renourishment (Stauble and Bass 1999). It was difficult to assess the borrow sediment makeup, due to the multiple offshore sites used over the multiple placements from 1988 to 1994. The first sediment collected after project completion in May 1994 was used as a proxy to represent a mixture of all the borrow areas used. This project also had several hot spots where the erosion exceeded the average project wide erosion (most related to shore-attached shoals). As a corollary, there were also cold spots where accretion was above the amount of fill placed, indicating the three-dimensional nature of sediment transport and profile readjustment on this project. Analysis of

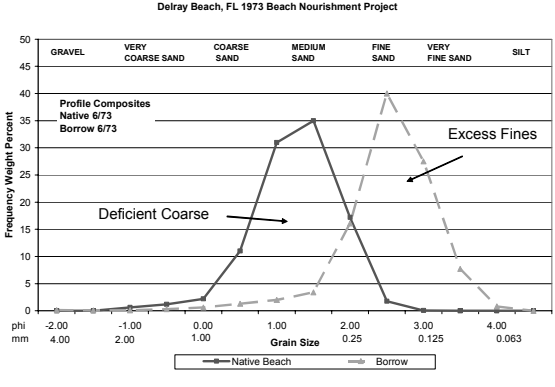

Figure 7a. Native and borrow grain size distributions at the Delray Beach, FL project

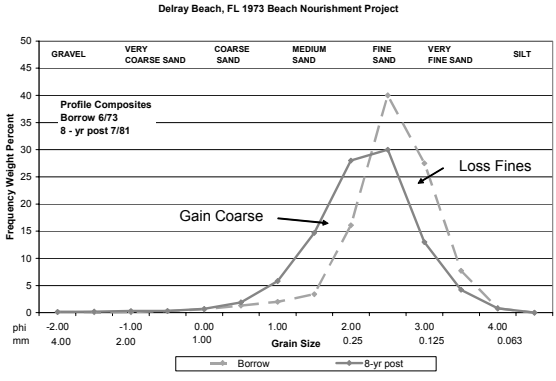

Figure 7b. Borrow and 8-year post fill grain size distributions at Delray Beach, FL.

sediment and profiles provided a picture of project performance. The overfill factor was around 1.0 based on calculations using samples form cores of several offshore borrow areas (James Snyder, USACE Baltimore District, personal communications). The native beach intertidal composite (July 1988), was compared with the May 1994 post-fill proxy of the borrow area mix at a cold spot at 45th Street (Figure 9a) and a hot spot at 81st Street (Figure 9b). This proxy borrow composite of intertidal sand at 45th Street (south) matched up well with the native intertidal composite. Excess coarse material in the 1.41 to 0.35 mm (-0.5 to 1.5 phi) sizes was found at 81st Street (north), due to two different borrow areas used for the north and south sections of fill placement. At 45th Street, the native mean was 0.36 mm (1.48 phi) and sorting of 0.57 phi and the borrow composite had a mean of 0.44 mm (1.18 phi) with a less well sorting of 0.67 phi. At 81st Street, the native intertidal composite had a mean of 0.32 mm (1.65 phi) and a sorting of 0.74 phi, while the proxy borrow had a coarser mean of 0.46 mm (1.11 phi) and a less well sorting of 0.81 phi. A comparison of the proxy borrow composite with the intertidal composite collected in April 1998 (10-year post Phase I fill) indicated that the beach had become coarser at both sites. The long-term intertidal composite mean at 45th Street had a coarser mean of 0.49 mm (1.03 phi) and a better sorting of 0.44 phi (Figure 10a).

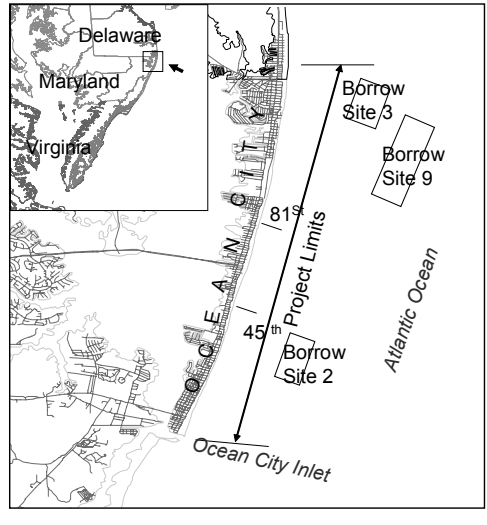

Figure 8. Location of the Ocean City, MD project.

At 81st Street the long-term intertidal composite had a mean of 0.74 mm (0.43 phi) and a poor sorting of

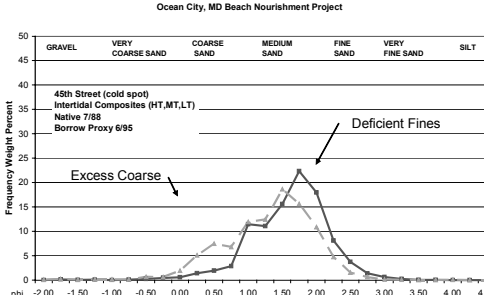

Figure 9a. Native beach and borrow grain size distributions placed at 45th St Ocean City, MD project.

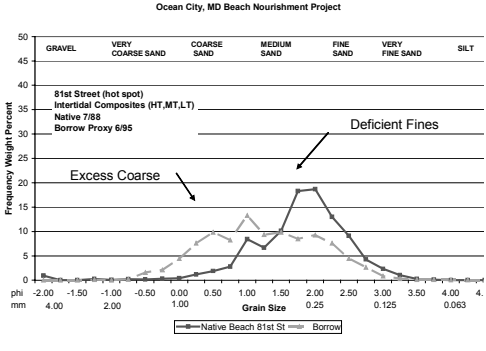

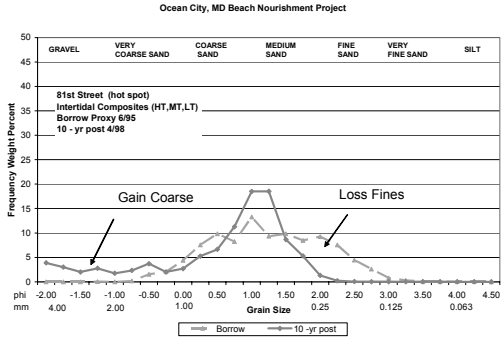

Figure 10a. Native Beach and borrow grain size distributions at 81st Street, Ocean City, MD project

1.03 phi. The hot spot has increased shell hash and pea gravel size material of between 4 and 2 mm (-2 to -1 phi) (Figure 10b). This coarsening may be from winnowing of the fine sand (0.25 to 1.25 m or 2 to 3 phi) over time. This 10 year long-term monitoring through a period of 65 intense storms showed that the volume of sand has remained within the project with the least amount of loss at the cold spots (45th street measures a total loss of around 10 cu m/m or about 89% of fill remains) and the largest loss at the hot spots (81st Street measures a loss of around 148 cu m/m or about 74% of fill remains) (Stauble and Bass 1999). The coarse borrow has provided the protection needed with little over all loss to the project but there is still a three-dimensional resorting on this project.

These four projects provide a verity of borrow to native sediment compatibilities. The Ocean City, NJ project had a borrow sediment that was similar to the native beach with an overfill factor of 1.75. The Indialantic/Melbourne Beach project had a dissimilar borrow which was bi-modal (containing both coarser and finer material than the native beach and had an overfill factor of 1.38. The Delray Beach project had a much finer borrow than the native with an overfill factor greater than 10. The Ocean City MD project had a borrow that was coarser but was about the same distribution as the native and had an overfill factor of around 1.0. The performance of each project (as measured by the percent of fill remaining) did not directly reflect the overfill factor or the grain size distribution change over time.

FILL DENSITY

The amount of fill placed also appears to be important in how well a project performs. Fill density is defined as the amount of fill placed per length of beach. Fill volumes of greater than 175 cu m/m (70 cu yd/ft) of beach were found to provide greater than 70% retention of fill after one year based on review of several projects (Stauble and Hoel 1986). Fill volumes less than the above resulted in projects with high fill losses in the first year. Table 1 shows the fill density of the four projects related to the other characteristics. The fill volume rule seems to hold except for the Delray Beach project. Here, even though the volume was high to compensate for the high overfill factor, the borrow grain size distribution was so fine that the fill was unstable and eroded easily. In project design both overfill factor calculations and design of fill volumes are needed to provide for a successful project. In the Delray Beach case, it appears that if the borrow is drastically different from the native sediment distribution, high overfills did not

Table 1. Project Characteristics

Project	Overfill Factor	Borrow to Native Sed. Distribution	Borrow to Out year Distribution	Fill Remaining %	Fill Density m^3/m
Ocean City, NJ	1.75	Similar match	Return to Native	69 (1 yr)	260
Indialantic/ Melbourne Beach, FL	1.38	Poorer Sorting	Return to Native	45 (1 yr)	75
Delray Beach, FL	> 10	Much Finer	Middle of both dist.	26 (8 yrs)	120 - 300
Ocean City, MD	1.00	Coarser	Coarser	74-89 (10 yrs)	270 - 440

overcompensate for such fine borrow material and changed the long-term sand distribution to become finer than the native.

Q MODE ANALYSIS

Analysis of a suite of sediment samples using just the mean and standard deviation or median values as in the overfill factor method or calculating an equilibrium profile using a single A value for fill profile design is somewhat limiting. As seen in these four case studies, the frequency curve comparisons show how specific grain sizes are either winnowed away or remain on the beach. A newer approach of Q-mode analysis of native and borrow area sediment distributions is suggested for a possible tool to assess suitability. The Q-mode analysis uses the entire sediment distribution instead of the more limiting mean and sorting statistics used in the existing methods and gives a more complete picture of sediment resorting over time. One of the main advantages of Q-mode factor analysis is that the entire grain-size distribution is considered in the analysis, providing a way to differentiate sediments based on the entire distribution. Using an analytical method to determine statistical relationships is more objective because it does not require arbitrary statistical descriptors or a-priori knowledge of the environment and location of samples (Klovan, 1966). A large number of samples can be objectively ordered by shape of a frequency curve to determine interrelationships between beach and borrow area samples. This method has not been used with beach fills, but it has been used to characterize the depositional patterns of a suite of samples at inlets and infer sediment pathways (Stauble and Cialone, 1997) and a study to couple the beach profile evolution, sediment deposition patterns and their resulting grain size distributions with the physical processes active at a native pre- and post-storm beach (Stauble and Cialone, 1996). This method may provide a way to use the entire sediment grain size distribution of a native beach and borrow area to identify fill suitability and some indication of fill behavior. More research is needed to apply this method to beach fill projects to improve suitability and stability determination.

CONCLUSION

Little work has been done on how a beach fill project actually performs relative to the sand suitability and design techniques commonly used. Four projects with good monitoring data have been presented to assess performance. On projects where native and borrow sediment grain size distributions are similar, the fill response over time very similar to the native beach. More uncertainty is introduced in the design process when the native and borrow sediments have different grain size characteristics as is the case in three of the four studies. The overfill factor and equilibrium profile methods have been commonly used to determine borrow area suitability and the volume of fill needed to produce a desired level of shore protection. Each method requires grain size analysis of both native beach and borrow area by standard sieve analysis.

The Overfill Factor Method using only the mean and sorting values of the native and borrows sediment, gives the best estimate of fill material to predict the volume of borrow material needed to produce a unit volume of stable fill material with the same general grain size as the native beach. This method does not take into account any coastal processes or profile changes. The CEM (2003) states that it should be used only to determine if the borrow material will be suitable to be placed on the beach, and give a ballpark value of a multiplier of how much borrow material will be needed to produce a stable fill. Overlaying a frequency curve of the representative native and borrow material will show the overlapping grain sizes and the excess or deficient grain sizes of the borrow material as compared to the native beach. The use of the foreshore composite in calculating the native beach and post-fill borrow sediment grain size data gave the best fit to actual fill project behavior and long-term resorting evaluation.

The CEM (2003) suggests methods for computing fill volumes and the shape of a design profile when the borrow material is of a different grain size distribution than the native beach. Based on the case histories, borrow material finer than the native beach winnowed out of the intertidal area. Some coarse material was also removed, possibly by burial of the coarse material under the finer fill. Post-placement fill distributions take on the characteristics of the native beach except in areas where the borrow sediment is either finer or coarser. The large volume of disparate borrow sands changes the filled beach distribution to that of the borrow material. Fill density also seems to play a part where greater than 175 cu m/m (70 cu yd/ft) of fill placed appears top play an important role in fill stability. More research is needed to improve the suitability determination of a borrow material. New Q-mode analysis suggest using the entire grain size distribution to quantify the suitability and stability of a borrow area as compared with native sediment.

ACKNOWLEDGEMENTS

This paper was based on research conducted under the Quantifying Vulnerabilities in Coastal Flood Damage Reduction work unit in the Technologies and Operational Innovations for Urban Watershed Networks (TOWNS) Program. Additional data was based on work originally funded by the Florida Sea Grant Program. Case study support

provided by the respective USACE Districts. Permission to publish has been granted by the Chief of Engineers.

Abstract: After more than a century of development in the field of coastal engineering and science, serious practical questions remain concerning the optimal design of coastal protection works including detached breakwaters, groins and seawalls. This paper reviews current technology applicable to coastal structure design with a critical assessment of existing and needed tools for practical applications involving sediment-structure interaction. This paper considers both functional and structural design issues and addresses the relative merits of these technologies. In this regard, it should be noted that sophisticated modeling technologies, with all of their advantages, have not yet obviated the use of empirical equations and rules of thumb in engineering practice. This is true both for design of structure plan-form arrangements (e.g., number, spacing and length of structures) as well as structure cross-section geometry (e.g., toe design, use of sacrificial toes, merits of armoring landward of a structure crest.)

INTRODUCTION

Coastal structures must be designed with a view towards functional and structural performance. With regard to functional design, the goal is to establish an efficacious structure plan-form which retains sand and considers both the near and far-field impacts of the proposed works recognizing that damaging far-field impacts will normally eliminate structure application as a feasible alternative. Structural design stems directly

from the beach profile bottom elevation that fronts the structure during storm wave attack. This bottom elevation, combined with the water level, establishes depth fronting the structure which, in turn, dictates the maximum wave that can reach the structure. Three technologies commonly bear on functional design: (1) rules of thumb and analytical/empirical equations, (2) physical model tests, and (3) numerical models. This paper discusses the tools available, the limitations of these tools, and the desirability of additional technology (preferably on the basis of full scale model tests and/or evaluation of existing prototype installations) to better determine design conditions. It is emphasized that many successful coastal structure installations have been constructed and serve their purposes well (be it sand retention or shore protection.) The discussions here are not a criticism of coastal engineering practice which, by and large, is diligently exercised using existing technology. The point here is that there are opportunities to further quantify important design issues that presently rely on empirical rules of thumb (e.g. sizing of a sacrificial toe, spacing/geometry of T-groins.) The most expedient means for extending design rules appears to be large- or full scale physical model tests (for seawalls & revetments) and/or monitored field investigations (for sand retention structures). Such investments would be small compared to the savings that could be saved on constructed installations.

DEPENDENCY OF STRUCTURAL DESIGN ON SEDIMENTARY CONDITIONS

Structural design focuses on the development of stable structure cross section for a range of wave, water level, and morphological conditions. Most coastal stabilization structures are subject to depth-limited design wave conditions. The principle design determinant is therefore the bottom depth that fronts the structure toe as these depths dictate the wave heights that reach the structure. The controlling depth normally consists, *a posteriori*, of: (1) the long-term equilibrium shoreline position and profile shape, (2) the general scour /deposition fronting the structure due to storm-induced cross-shore sediment transport and (3) localized scour owing to the complex interaction of waves/currents and sediments at the structure toe. These determinants are illustrated in Figure 1.

The geometry in Figure 1 pertains to design of a buried seawall (i.e., item (5)) at Dam Neck Virginia (Headland, 1992; Basco et al (1998)) but is relevant to any coastal structure placed on an active beach profile subject to breaking waves. Item (1) denotes the "normal" beach profile prior to any long-term or storm-induced erosion. If the shoreline in question is subject to long-term erosion, it is customary to assume that the profile will retreat without a change in geometry as indicated in Item (2). The eroded profile should be translated a distance equal to the product of the average annual long-term shoreline recession rate and period of time equal to the project life (e.g. 20-50 years) factoring in the desirability of using beach nourishment to ameliorate long-term erosion. It should be noted that the translated profile brings deep water closer to the structure toe.

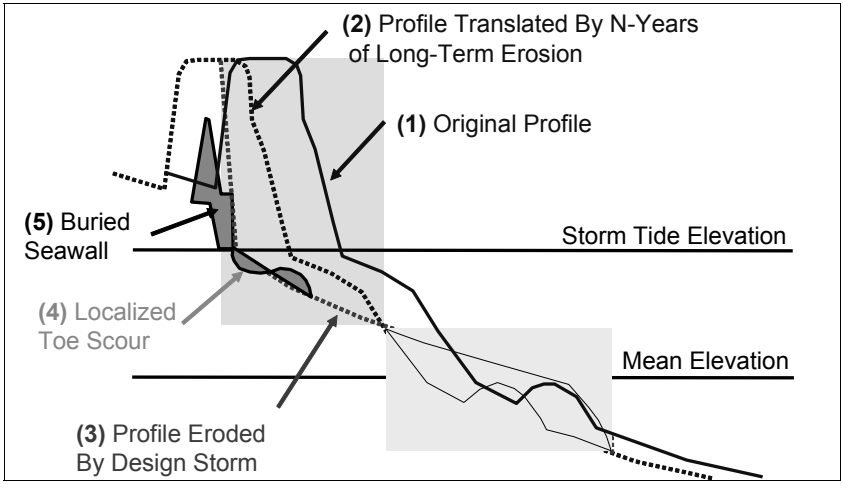

Fig. 1. Definition Sketch for Determining Design Toe Elevation at Foot of a Coastal Structure

Once item (2) geometry has been established, it is necessary to compute the storm-induced erosion profile, Item (3). The authors normally compute this profile using a beach/dune erosion model such as SBEACH. The difficulty here is that most beach/dune erosion models cannot simulate a typical sloping rubble mound structure. This is true of the beach profile areas both seaward and landward of the structure. Accordingly, approximations are necessary for practical applications. Normally, the authors will use the seawall feature in SBEACH (or similar model) and place the seawall at the horizontal centerline of the sloping structure with a height equal to the actual structure. This approach is judged to produce an exaggerated (i.e., conservative) amount of profile lowering in front of the actual sloping coastal structure as indicated in Figure 1. This subject would benefit dramatically from further, full scale, physical model tests of sloping rubble mound structures. The costs of such tests would be small in comparison the savings, both in initial construction and/or in avoided damages, that would be realized over a large range of applications. Furthermore, there are further opportunities to optimize the buried seawall concept.

Finally, it is necessary to estimate the local scour that immediately fronts the structure toe as indicated by item (4). While this scour is not separable from the storm profile estimated from cross-shore erosion models, the additional/accelerated local scour is not included in such models. It may be a conservative approach to add the local scour to the overall profile scour, but a necessary one in the absence of definitive design criteria. It should also be mentioned that sacrificial toe protection geometries are normally used to protect against local scour. While such measures are generally successful, the overall dimensions of such features are poorly understood as are stone sizes and gradations. Again, investments in physical model tests are recommended.

There are several means for estimating localized toe scour, nearly all of which are based on scaled, movable bed, physical model tests dating to the 1960s. Four methods are considered here: (1) SPM rule of thumb, (2) Hughes and Fowler, (3) MacDougal et al, and (4) Sumer and Fredsoe. The first method is quoted below from the 1973 version of the Shore Protection manual to emphasize the longevity of this guidance.

"*As a general rule, the maximum depth of a scour trough below the natural bed is about equal to the height of the maximum unbroken wave that can be supported by the original depth of water at the toe of the structure*."

The above approach has likely been applied with ubiquity and turns out to be a reasonable, if simple, approach. For example, Steetzel (1988) concluded from model tests that the depth of the scour trough at the seawall toe to be about 0.75 of the original depth at the toe (i.e. on the order of the breaking wave height of 0.78 of the same original depth.) Methods 2 and 3 pertain to vertical seawalls. Method 4 was developed for sloping structures exposed to non-breaking waves and is included only for comparison purposes. Figure 2 presents example results for each of the four methods. Local wave conditions at the toe of the structure were computed using Goda's surf zone model.

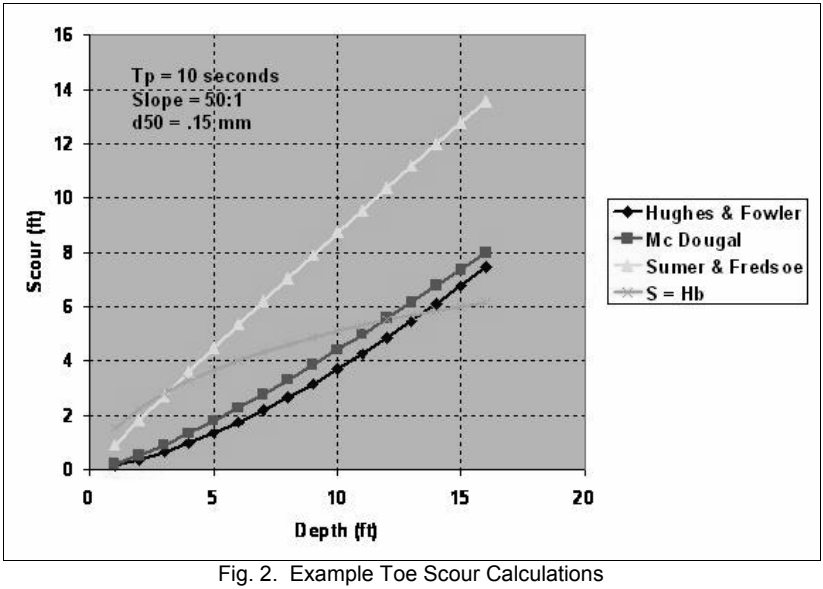

Fig. 2. Example Toe Scour Calculations

Interestingly, Figure 2 shows that the SPM guidance (S=Hb) gives reasonably similar results to both Hughes and Fowler as well as McDougal et al. The results also show how critically the original depth at the toe of the structure bears on the level of scour. As emphasized previously, the resulting depth dictates all of the additional variables that

govern design of a rubble mound structure. This is shown in Figure 3 for a typical 2:1 (H:V) sloping rubble mound seawall exposed to waves having a peak spectral period of 10 seconds. Calculations were made using Van der Meer's equations for wave runup, overtopping, and stone size. Figure 3 shows that the required crest elevation for the specified allowable overtopping and the required armor stone size are both a very strong function of the predicted bottom elevation at the toe of the structure.

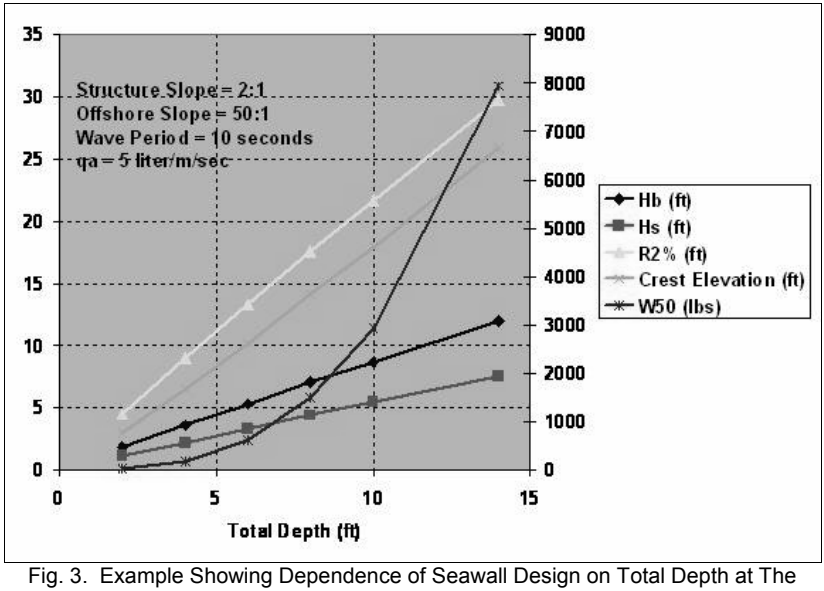

Fig. 3. Example Showing Dependence of Seawall Design on Total Depth at The Structure Toe.

Designs for the previously mentioned seawall at Dam Neck, Virginia were developed using procedures similar to those presented above as presented by Headland (1992) and Basco et al (1998.) Results of the design procedure and performance during Hurricane Isabel (an event within 0.8 feet of the design 100-year storm) are summarized below.

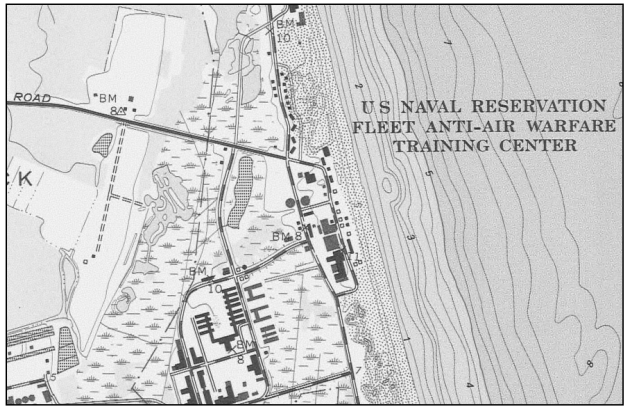

Fig. 4. Project Location, Dam Neck, Virginia

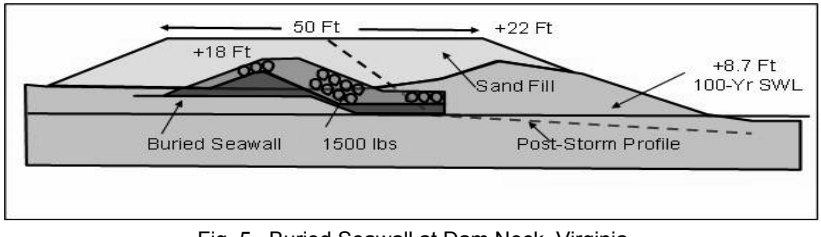

Fig. 5. Buried Seawall at Dam Neck, Virginia

Storm conditions during hurricane Isabel resulted in erosion of the beach face to the seaward edge of the seawall sacrificial toe as suggested in Figure 7 and much as predicted in Figure 5. Overall, the performance is judged to corroborate the approach outlined in Figure 1. The Dam Neck examples and others like it demonstrate that reasonable design guidelines are available for practitioners. Numerous difficulties remain, however, as regards a generalized procedure for designing coastal structures fronted by beaches, namely: (1) there are no generalized full scale model tests to quantify the separation of general profile change from localized scour, (2) there are no available means for evaluating the influence of structure slope, roughness or crest elevation on eroded profile shape, and (3) there is no means for quantifying the dimensions/elevations of a sacrificial toes other than rules of thumb. Although present practices have been demonstrated to be safe, there is much fundamental knowledge to be gained in sediment/structure interaction to improve design methods.

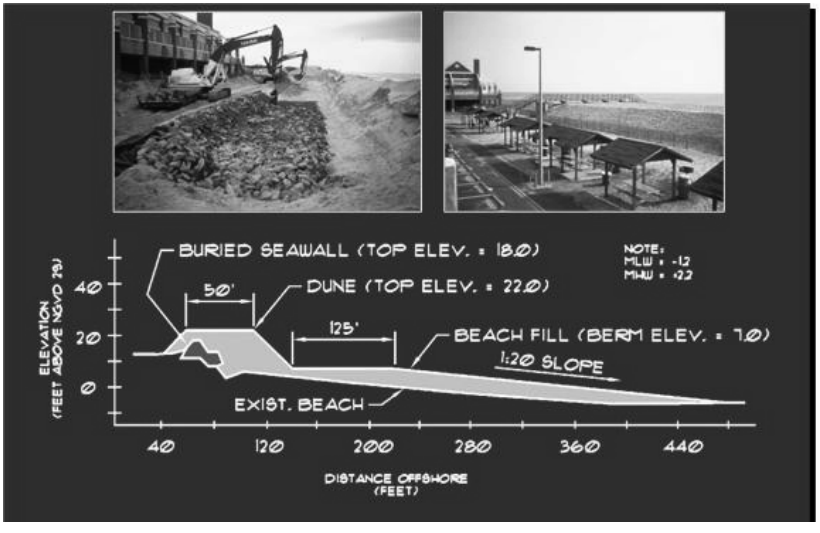

Fig. 6. Buried Seawall under Construction

Fig. 7. Dam Neck Buried Seawall- Post Isabel (provided by D. Basco)

LINKAGE BETWEEN OVERTOPPING DISCHARGE OR VELOCITY AND STRUCTURAL/SEDIMENTARY CONDITIONS

It has become commonplace to establish seawall/revetment crest elevations on the basis of allowable overtopping discharges, q_a (liters/s/m). Typical limits are summarized in terms of qualitative descriptions. The Coastal Engineering Manual (CEM) q_a guidance

for "revetments" ranges from 50 to 1000 depending on whether the "promenade" is paved or not. Similarly, q_a for "embankment seawalls" ranges from 2 to 1000 depending on whether the "crest is not protected", the "backslope is not protected," or the seawall is "fully protected." While this appears, *prima facie*, to be sufficiently quantitative, many questions remain. For example, what is the difference between a "revetment" and a "seawall?" As best as the authors can tell, the difference is that a revetment does not have an armored back slope. Similarly, what pavement cross section is needed to prevent damage? What size armor is needed on the structure crest? Can the upper slope of a structure be protected with vegetation? Unfortunately, these questions are fundamental from a practitioner's point of view and have a large bearing on selected crest elevations and costs of typical coastal structures. While it may not seem so, the issue is very much an issue of sediment/structure interaction inasmuch as most damage experience by heavily overtopped coastal structures involves erosion of the crest and back-slope areas comprised of earthen or partially armored slopes (i.e., armored with rock, pavement, blocks, or vegetation.)

Figure 8 presents a system of coastal dikes located at Poplar Island in the Chesapeake Bay exposed to hurricane wave conditions. The original structure was designed for 30 to 40-year conditions based on economic optimization techniques. The site is designed to serve as a clean dredged material placement site which will eventually be a restoration project comprised of upland and inter-tidal habitat. The economic optimization analysis of the protection works made it clear that it was preferable to repair the protection works after a major storm rather than design for an event more severe that 30- to 40 years. Furthermore, physical model tests indicated that the seaward rock portions of the containment dikes would remain intact in a 100-year storm although the structure would be heavily overtopped. The total length of armored dikes for the project is over 7 miles.

The structure was exposed to a 100-year water level and roughly 20-year storm waves during hurricane Isabel in September, 2003. All but 300 feet of structure stood up without any damage whatsoever. The rock portion of the damaged section remained fully intact as predicted by physical model test. The areas landward of the rock crest, however, were damaged. Specifically, portions of a gravel roadway and the sand back slope were washed out. The project sponsors were very pleased with the performance of Poplar Island during the 100-year event and the minor repairs were expeditiously carried out with equipment on site. Still, it is instructive to examine the nature of the limited damage that was experienced.

Figure 9 shows a cross section of the original dike section. Figure 10 shows a photo of the damaged area. An analysis of the dike system is presented in Figure 11. The structure was originally design using a Van der Meer et al (1995) method (Old); the New method is taken from Van der Meer (2002). The q_a used for design was the difference in required crest elevation is about 2 feet (higher with the new method), which is of concern. The originally required crest elevation was 10 feet (lowered to 9.5 feet for other reasons in the damaged area; the higher adjacent areas were undamaged). The required

crest elevation for the Hurricane Isabel event (shown as 100-year return period for convenience) was computed as 12 feet (old) to 14 feet (new).

Fig. 8. Poplar Island Dike System; Damaged Area Shaded upper Right

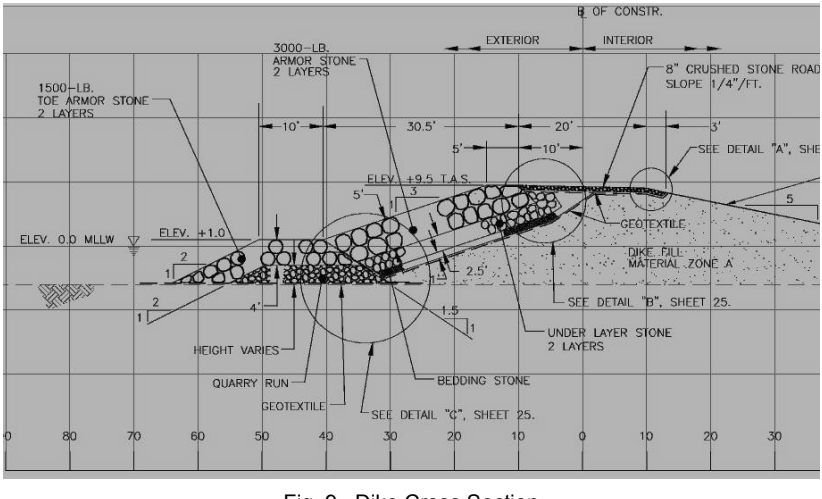

Fig. 9. Dike Cross Section

Fig. 10. Erosion of Sediment on Lee Side of Dike

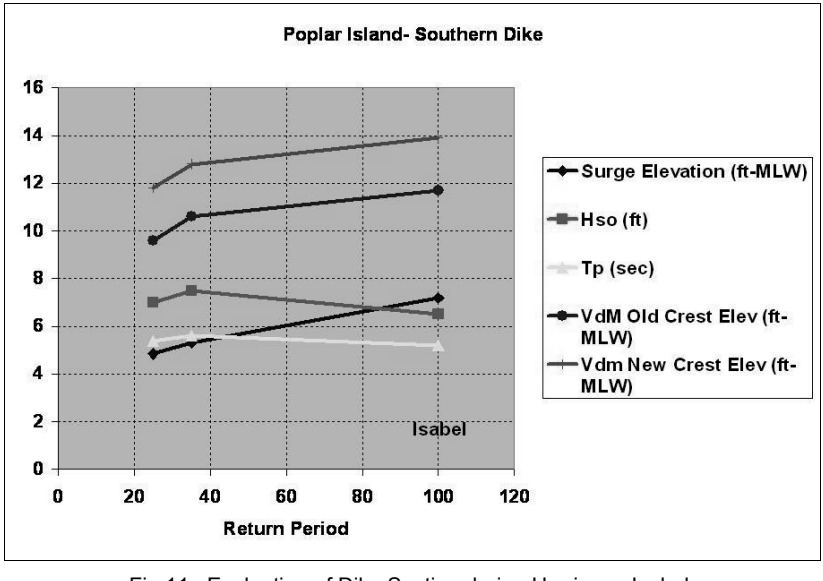

Fig.11. Evaluation of Dike Section during Hurricane Isabel.

Accordingly, the dike was heavily overtopped and eroded despite the presence of a crushed rock roadway that remained largely in place (Figure 10.) The difficulty here, as

mentioned above, is that there is no connection between the sedimentary damage experienced landward of the rock dike and the overtopping discharges. In this regard, the consequence of excessive overtopping is poorly understood for most coastal structures backed by earthen and/or vegetated slopes. As stated above for the Dam Neck case, the practicing profession would be greatly served by systematic model tests (preferably at full scale) to examine the consequence of excessive overtopping for a variety of surfaces (e.g., armored, unarmored, vegetated, sloped, flat, etc.) Additionally, it would be desirable to correlate damages (or percent damages) with overtopping velocity per Schuttrumpf et al (2002), rather than the more nebulous overtopping discharge.

ALTERNATIVE METHODS FOR FUNCTIONAL DESIGN OF T-GROINS

A new system of T-groins is envisaged for the western end of Coney Island in New York City, see Figure 12. Detailed planning, modeling and engineering task have been carried out to layout and prepare design documents for the proposed works. The work offers an opportunity to compare various functional methods including: (1) empirical design, (2) designs based on physical modeling techniques, (3) numerical modeling based on Delft 3D morphological simulation technology and (4) GENSIS modeling tools. Observations regarding the efficacy of each method are described below. Details surrounding each of the functional design methods are described in further detail in Smith et al (2006.)

Fig. 12. Coney Island Project Area

The project has been designed for a 50-year life, the need to maintain a shoreline that is seaward of the 1988 historical shoreline, structure crests no higher than +6 feet NGVD for aesthetic reasons, and a 10-year re-nourishment cycle. Empirical modeling techniques were based on equilibrium shoreline concepts. Moveable bed physical model

tests were conducted at the Canadian Hydraulics Laboratory. The resulting shorelines are presented in Figure 13. Figure 14 presents projected shorelines from Delft3D modeling, while Figure 15 presents results from GENESIS modeling. The empirical methods cannot be dismissed despite the lack of sophistication owing to the fact that they are grounded in experience at other successful T-groin installations. The physical model tests, though subject to interpretation owing to scale effects issue, served two purposes, namely, they served to evaluate the structural integrity of the T-groins and they served as a check on equilibrium shoreline shapes under the joint action of both waves and tidal currents. The DELFT3D results provided a similar role relative to wave and current forcing of the shoreline but do not fully represent the physics of wave diffraction and recommend a shorter period of simulation than GENESIS simulation. Finally, the GENESIS results further corroborate the basic findings of the other tools but extend over a longer period of time albeit only as a one-line model when strong two dimensional effects are apparent from both the model tests and the DEFLT3D model. Each functional design technique has its shortcomings and final selection of system structural geometry necessarily involved engineering judgment. This particular design exercise, though thorough, demonstrate some of the short comings of existing technology to solve the most fundamental sediment-structure interactions facing engineer, scientists and other decision makers.

Fig. 15. Shoreline Conditions Based on GENESIS Modeling

CONCLUSIONS

Existing methods for evaluating the structural and function design of coastal protection works located on dynamic sandy shoreline are reasonable useful in many applications. Many fundamental issues remain, however, and have been examined in this paper. These include the need to more accurately evaluate: (1) the beach profile geometry fronting a

vertical and/or sloping rubble mound structure, and (2) the connection between overtopping wave conditions and the structural/sedimentary features leeward of a coastal structure. Both of these problems should be addressed through systematic full scale physical model tests. An additional area requiring further research includes functional design of sediment retaining structures such as groins, t-groins and headlands. Empirical design methods remain very useful and physical and numerical models can serve to corroborate the empirical methods. Advancing knowledge regarding functional design of these systems will require further field installations with detailed measurements and monitoring. It is hoped that practitioner's observations advanced in this paper will help to provide impetus for further, focused, research in the highlighted areas.

Abstract: On Oharai Beach, a large amount of sand has accumulated owing to the formation of a wave shelter zone of the port breakwater, causing excess deposition in the navigation channel, whereas severe beach erosion has occurred south of Oharai Port. With these large-scale beach changes, the grain size of the seabed materials has significantly changed, and the area covered with coarse sand has been expanding. Simultaneously, the catch of Japanese hard clams, the habitat of which lies in a seabed composed of fine sand, has decreased. A model for predicting the changes in contour lines and grain size was applied to Oharai Beach; the controlling effect on longshore sand transport of an artificial headland was quantitatively evaluated in terms of beach and grain size changes, and the optimum depth of the headland was determined.

INTRODUCTION

On Oharai Beach on the Kashimanada coast, facing the Pacific Ocean, a large amount of sand has accumulated in the port since the 1980s owing to the formation of a wave shelter zone associated with the construction of the port breakwater, resulting in sand deposition in the navigation channel. Simultaneously, severe erosion has occurred on the coast outside the wave shelter zone (Uda *et al.*, 1986). The grain size of the seabed materials has also changed with these beach changes, resulting in a

rapid decrease in the catch of Japanese hard clams, *Mertrix lamarckii*, which are a local speciality of the Kashimanada coast and live on sand beds covered with fine sand. These bathymetric and grain size changes are closely related to the preservation of a sound coastal environment. However, such changes have not yet been sufficiently studied. Here, the model for predicting the changes in contour lines and grain size proposed by Kumada *et al.* (2006) is applied to Oharai Beach to solve these problems. The controlling effect on longshore sand transport of an artificial headland under construction is quantitatively evaluated, and the optimum depth of the headland is determined.

CHARACTERISTICS OF BEACH CHANGES IN STUDY AREA

2.1 Analysis of shoreline changes using aerial photographs

To investigate the beach changes around Oharai Port, shoreline changes were measured using aerial photographs in the study area of a 39-km-long stretch of the Kashimanada coast between Oharai and Kashima Ports. **Figure 1** shows the shoreline changes in the study area with reference to the shoreline in 1964 with the names of the local coasts. The pulse-like shoreline changes in 2002 mean that the shoreline changes are caused by the construction of artificial headlands. The shoreline markedly advanced in the wave shelter zones owing to the breakwaters of Oharai and Kashima Ports, resulting in a maximum shoreline advance of 700 m in the vicinity of Oharai Port, whereas the shoreline receded as a whole in the central part of the coast.

Figure 2 shows an aerial photograph of the vicinity of Oharai Port taken in 2002. An offshore breakwater extends east of the port, and a triangular beach had formed in the wave shelter zone because of this offshore breakwater. There is a navigation channel between the north breakwater and the beach south of the port. Therefore, longshore sand transport, having originally been supplied from the Naka River located 3 km north of the port and flowing south, can no longer reach the south beach. In terms of the mass conservation of sand, it is suggested that all the sand accumulated in the wave shelter zone of the port breakwater must have been supplied from the south coast. This resulted in erosion in an extensive area south of Oharai

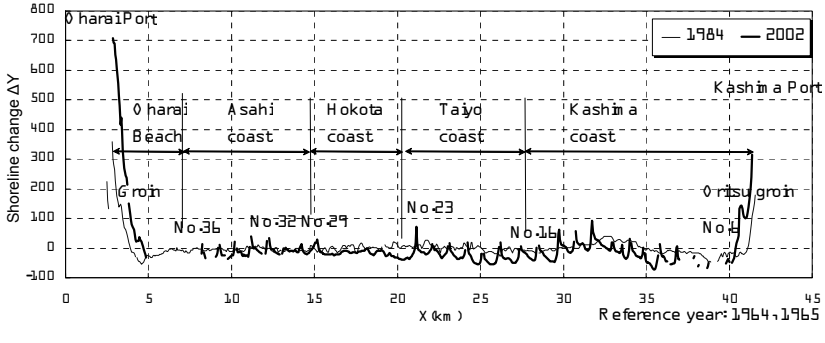

Fig. 1. Longshore distribution of shoreline changes with reference to shoreline in 1964

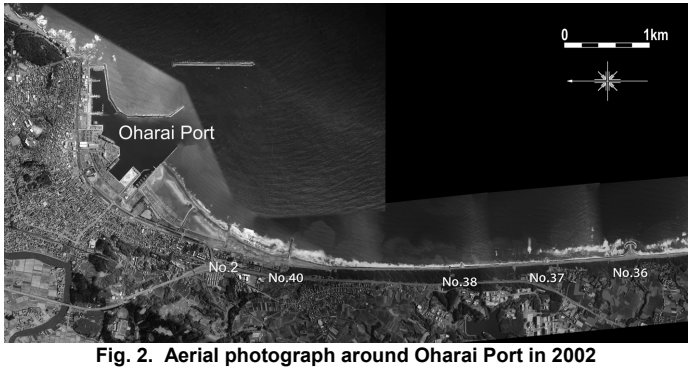

Fig. 2. Aerial photograph around Oharai Port in 2002

Port. **Figure 2** clearly shows that the foreshore in front of the seawall had completely disappeared for a distance of 3.5 km in the south part of Oharai Port.

Shoreline changes with the same pattern as those in the vicinity of Oharai Port occurred in the north part of Kashima Port, as shown in **Fig. 1**; the foreshore was markedly extended on the adjacent beach, whereas the beach north of the port was eroded. In other words, longshore sand transport from outside to inside the wave shelter zone of the port breakwater had been induced, resulting in shoreline advance inside the port and shoreline recession north of the accretion zone.

2.2 Analysis of beach changes using bathymetric survey data

To investigate the beach changes in the offshore zone, the bathymetric survey data were analyzed. **Figure 3** shows the bathymetry in 2004 and the planar distribution of the changes in depth between 1984 and 2004 calculated from the bathymetric survey data. A large amount of sand was deposited at both ends of the coastline; in contrast, the other areas eroded. **Figure 4** shows the changes in sand volume with time around Oharai Port (A), on the Hokota coast (B) and around Kashima Port (C). In the twenty-year period between 1984 and 2005, volumes of sand of 5.0×10^6 m^3 and 3.0×10^6 m^3 accumulated in the vicinity of Oharai and Kashima Ports, respectively, whereas 1.0×10^6 m^3 of sand was lost from the Hokota coast, although there were variations to some extent. In conclusion, it is clear that accretion occurred over an extensive area including the offshore zone around the port area, and in contrast, erosion occurred on the neighboring coast.

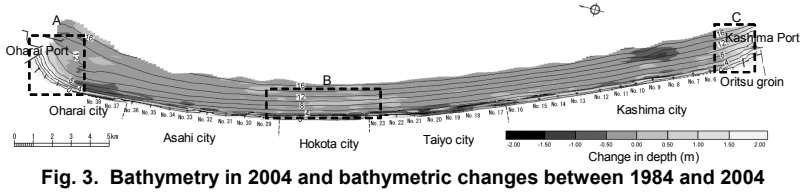

Fig. 3. Bathymetry in 2004 and bathymetric changes between 1984 and 2004

2.3 Grain size analysis of foreshore materials

Grain size analysis of the foreshore materials was carried out in July 2005 between Oharai and Kashima Ports. **Figure 5** shows the longshore distribution of the median diameter d_{50}. Sand accumulated in the wave shelter zone is composed of fine sand with a grain size of 0.1 mm, and the grain size tends to become large in the erosion zone. When longshore sand transport is induced from outside to inside the wave shelter zone of the offshore breakwater, fine sand is selectively transported from the surrounding coast toward the wave shelter zone and deposited in the port area, resulting in the accumulation of fine sand in the port and leaving the seabed covered with coarse sand in the surrounding area. Accordingly, the occurrence of longshore sand transport from the surrounding coasts toward the port is also inferred from the longshore distribution of the grain size of the foreshore materials. The phenomenon in which the composition of seabed materials of the surrounding coast becomes coarser is assumed to be the main factor devastating the habitat of Japanese hard clams, which prefer fine sand of 0.106-0.16 mm grain size (Higano *et al.*, 1993).

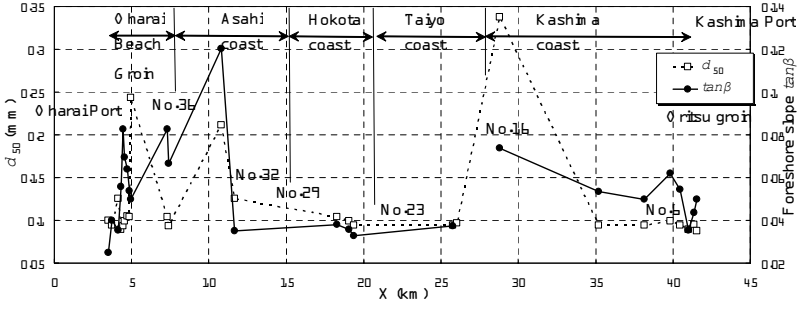

Fig. 5. Longshore distribution of median diameter of foreshore materials and foreshore slope measured in 2005

PREDICTION OF CHANGES IN CONTOUR LINES AND GRAIN SIZE

3.1 Calculation conditions

On the basis of the field data, the model for predicting topographic changes and grain size change developed by Kumada *et al.* (2006) was applied to Oharai Port and the Hokota coast, and the effects of extending the headland on the beach topography and grain size were evaluated to determine the optimum countermeasure against beach erosion. The calculation domain is from Oharai Port to the Hokota coast south of headland No. 29, where the effect of the wave shelter zone of the breakwater of Oharai Port may diminish, as shown in **Fig. 1**.

Calculations for four cases were carried out. In case 1, the bathymetry in 2004 was reproduced given the initial topography in 1964 under the natural conditions before the construction of Oharai Port. The initial topography had straight, parallel contours deformed by the wave-sheltering effect of Cape Oharai. The point depth of the artificial headland is assumed to be 7 m in case 2, and the effect of changing the point depth was investigated in cases 3 and 4 with point depths of 6 m and 8 m, respectively. In all cases, the bathymetry in 2024 was predicted given the reproduced topography and grain size distribution in 2004 as the initial conditions.

For the incident wave conditions, rough waves occurring several times a year were assumed; the breaker height and wave period were H_b= 4 m and T=9 s, respectively. The wave direction was set to be from the east, which is approximately normal to the coastline and the most frequent incident direction. The depth range where the beach changes occur is between the berm height of h_R=3 m and the depth of closure of h_c=12 m, which sufficiently covers the depth range, characterized by the occurrence of small bathymetric changes in the offshore zone composed of fine materials such as silt, as determined by comparing longitudinal profiles (Mimura and Kato, 1991). The south boundary of the calculation domain is a free boundary, through which longshore sand transport can freely occur. The equilibrium slopes were set to be 1/65 in the depth zone shallower than 5 m and 1/100 in the depth zone between 5 m and 12 m, since the longitudinal slopes in each depth zone have been stably expressed by combining these two slopes on the basis of the comparison of the measured profiles.

The initial content rates of the grains in the zone shallower than 5 m with a longitudinal slope of 1/65 were assumed to be the average of all the sampling data of the sand grains measured at the foreshore in July 2005 in the study area. For the initial content rates of the grains in the zone deeper than 5 m with a longitudinal slope of 1/100, the content rate for each grain size in the offshore zone was adjusted so that the equilibrium slope was 1/100, using the method proposed by Noshi *et al.* (2006), in which the equilibrium slope corresponding to the grain size is given, assuming that the range of grain sizes in the offshore zone is the same as that measured on the shoreline but that there is a difference in the content rates. Finally, the content rates of fine sand and silt, medium sand and coarse sand were assumed to be 59.4, 40.3 and 0.3%, respectively, at depths less than 5 m, and 85, 15 and 0%, respectively, at depths greater than 5 m.

3.2 Reproduction of bathymetry and grain size (case 1)

Figures 6(a) and **6(b)** show the reproduced bathymetry in 2004 and the changes in depth since 1964. Because longshore sand transport from outside to inside the wave shelter zone of the breakwater of Oharai Port was triggered by the extension of the long breakwater, sand accumulated inside the port and erosion occurred on the surrounding coast far from the port. The contour lines retreated particularly rapidly around headlands No.38-No.36 at X=4-7 km, respectively, and this is in good agreement with the severe erosion at these sites.

Figure 7 shows the comparison between the measured and calculated shoreline changes between 1964 and 2004. The shoreline advance ΔY of 700 m in the wave shelter zone of the port and the shoreline recession of 65 m on the surrounding coast outside the wave shelter zone are accurately reproduced, although the eroded and accreted areas are slightly overestimated. In the calculation, the shoreline changes in the wave shelter zone due to the headland were not reproduced, because the headland was regarded as a short groin without a wave-sheltering effect.

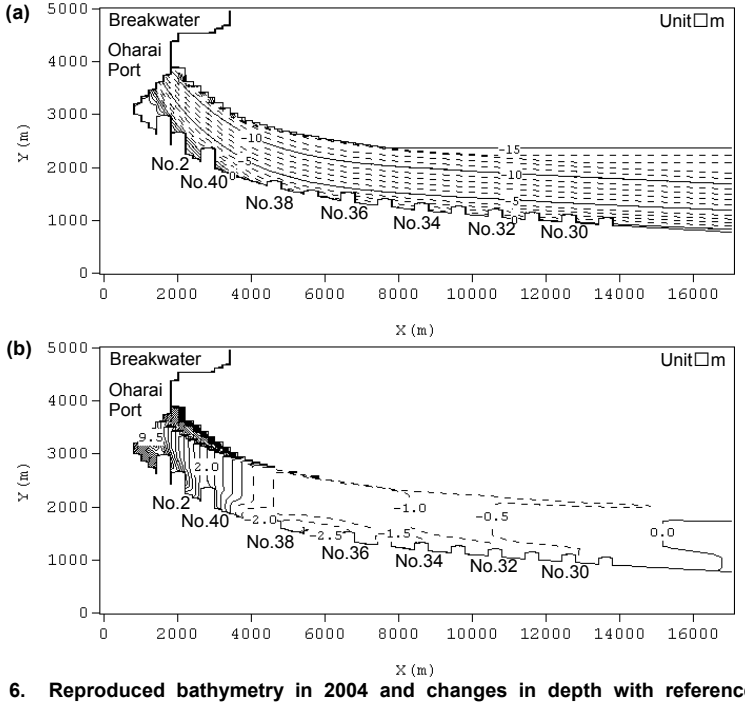

Fig. 6. Reproduced bathymetry in 2004 and changes in depth with reference to bathymetry in 1964 (case 1)

Figure 8 shows the predicted mean diameter of the bed materials in 2004. The grain size of the bed materials became fine with an average size of 0.09 mm in the wave shelter zone. In contrast, outside the wave shelter zone, comparatively coarse materials of 0.11 mm and 0.16 mm size were left in the offshore zone and near the shoreline, respectively. In particular, the grain size increased in both shoreward and offshore zones of the area between X=3.5 km and 8.0 km, where severe erosion occurred. This is because fine sand was selectively transported from outside the wave shelter zone, resulting in the coverage of the seabed surface with coarse sand, whereas fine sand accumulated in the wave shelter zone, when longshore sand transport from outside to inside the wave shelter zone took place.

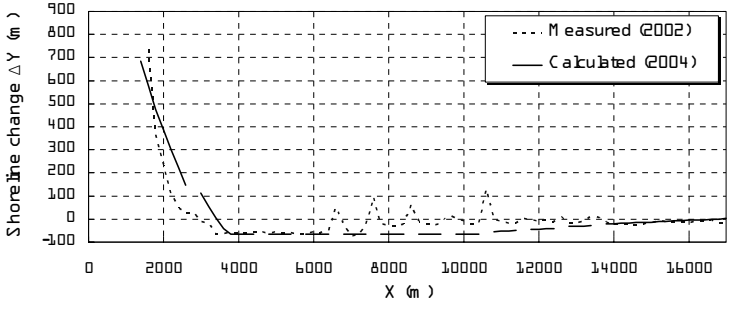

Fig. 7. Measured and calculated shoreline changes between 1964 and 2004 in case 1

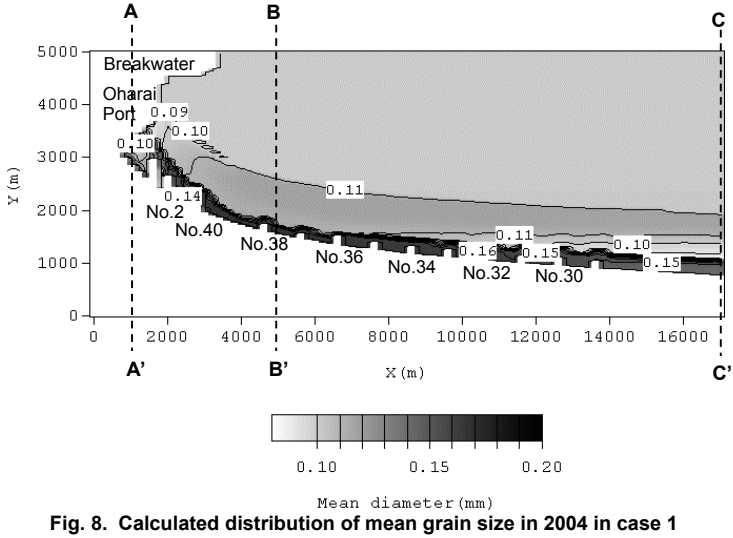

Fig. 8. Calculated distribution of mean grain size in 2004 in case 1

Figure 9 shows the calculated and measured content rates by percentage of sand along survey lines AA' in an accretion zone, BB' in an erosion zone and CC' crossing the free boundary of the south end of the calculation domain, as shown in **Fig. 8**. Both results were in good agreement, in that the content rate of fine sand is higher than 80% at survey line AA' and as low as 50% at survey line BB'. Moreover, there is no significant difference between the measured and calculated content rates at survey line CC', further showing the good agreement of both results.

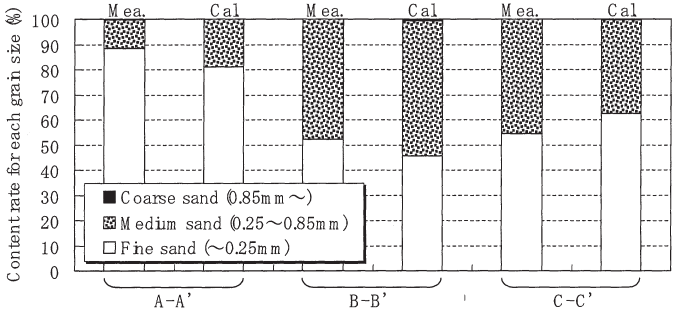

Fig. 9. Calculated and measured content rates by percentage of sand along survey lines AA', BB' and CC'

3.3 Prediction of bathymetry and grain size (cases 2, 3 and 4)

Figure 10 shows the predicted bathymetric changes for case 2 in 2024, in which the point depth of headland No. 40 was extended to a depth of 7 m, given the reproduced topography in 2004 as the initial conditions. The change in depth is measured with reference to that in 2004. If the headland is extended, a large amount of sand accumulates south of the headland, because northward longshore sand transport is more obstructed by the headland. In contrast, erosion occurred between the short groin No. 2 and headland No. 40, implying the occurrence of the secondary damage associated with the extension of the headland. Furthermore, beach erosion is still in progress in the zone between X=6 km and 14 km.

Figure 11 shows the predicted distribution of the mean diameter of bed materials for case 2 in 2024. When compared with the results in case 1, as shown in **Fig. 8**, the mean grain size becomes fine with sand accumulation south of headland No. 40, but the mean grain size is still larger than that in the offshore zone. In contrast, the grain size increases along with erosion north of the headland, and a zone with a large change in mean grain size reaches the port. Since many young Japanese hard clams live there, their habitat will be significantly damaged. In the offshore zone north of headland No. 40, the zone covered with fine sand expands compared with the present condition. This implies that the extension of headland No. 40 increases wave calmness, resulting in the accumulation of fine sand in this area. This area seems to

have an appropriate environment for full-grown Japanese hard clams in terms of the distribution of fine sand, but in the calculation, the mud content rate becomes too high in this area, resulting in the formation of an inappropriate environment for full-grown Japanese hard clams.

Figure 12 shows the bathymetric changes for case 3 in 2024, in which the point depth of headland No. 40 was extended to a depth of 6 m. Comparing this result with that in case 2, as shown in **Fig. 10**, erosion does not occur north of the headland, although there is no change in the accreted volume of sand south of headland No. 40. This is because more sand can pass the tip of the headland in case 3, resulting in an increase in sand supply north of the headland, since the point depth of the headland was 1 m lower. Conversely, it can be said that the trapping effect of longshore sand transport in case 3 is slightly smaller than that in case 2 with the point depth of 7 m,

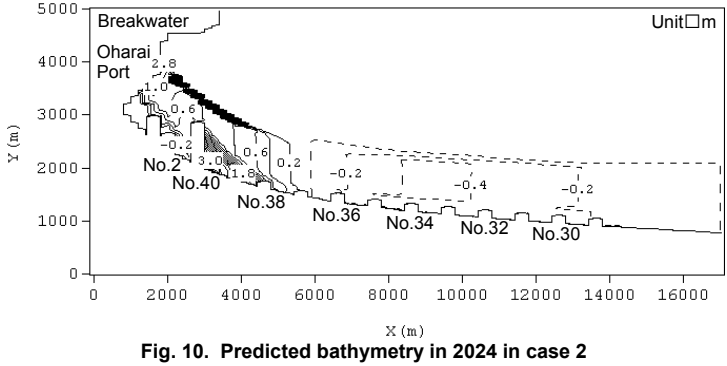

Fig. 10. Predicted bathymetry in 2024 in case 2

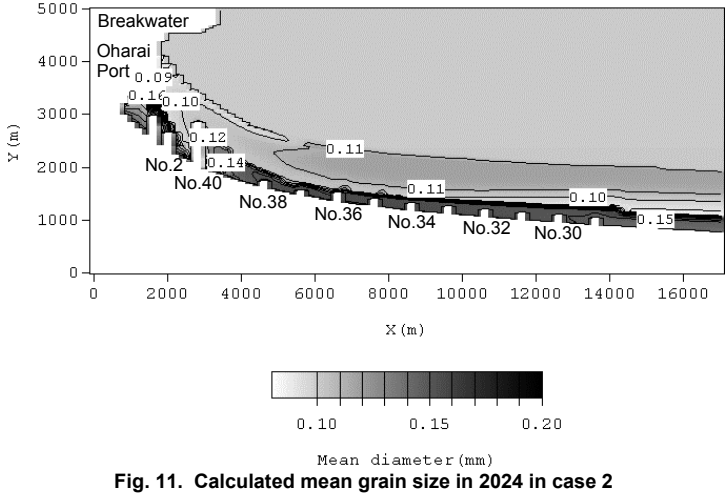

Fig. 11. Calculated mean grain size in 2024 in case 2

inferring a trade-off relationship between the trapping and erosion effects of the headland.

Figure 13 shows the predicted distribution of the mean diameter of bed materials for case 3 in 2024, in which the point depth of the headland was extended to the depth of 6 m. Comparing this result with that in case 2, as shown in **Fig. 11**, the area covered with coarse sand north of headland No. 40 disappeared owing to the reduction in beach erosion, inferring less damage to the habitat of young Japanese hard clams. However, in the offshore zone north of headland No. 40, fine sand still accumulates, resulting in a severe environment for full-grown Japanese hard clams.

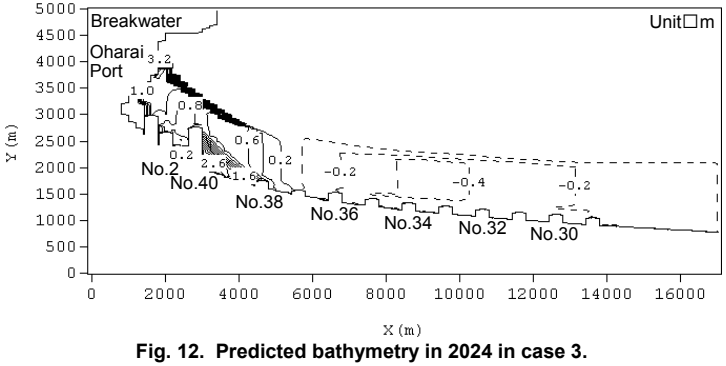

Fig. 12. Predicted bathymetry in 2024 in case 3.

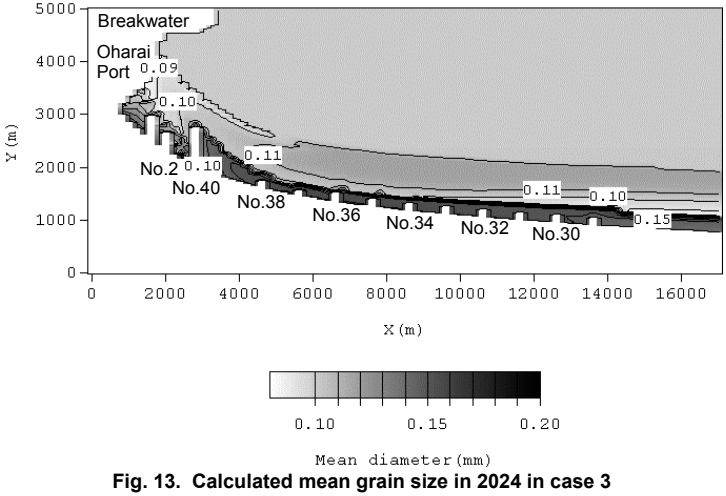

Fig. 13. Calculated mean grain size in 2024 in case 3

Figure 14 shows the bathymetric changes for case 4 in 2024, in which the point depth of headland No. 40 was extended to a depth of 8 m. Comparing this result with that in case 2, as shown in **Fig. 10**, sand accumulation south of the headland does not change, but erosion occurs between headland No. 40 and the short groin No. 2, inferring the possibility of secondary coastal damage associated with the extension of the headland.

Figure 15 shows the predicted distribution of the mean diameter of bed materials of case 4 in 2024. Comparing this result with that in case 2, as shown in **Fig. 11**, the seabed area covered with coarse sand north of headland No. 40 further expands. The increase in the effect of obstructing longshore sand transport caused by the extension of the headland significantly affects the beach changes and erosion accelerates. Accordingly, in this case, the most severe changes on the habitat of young Japanese

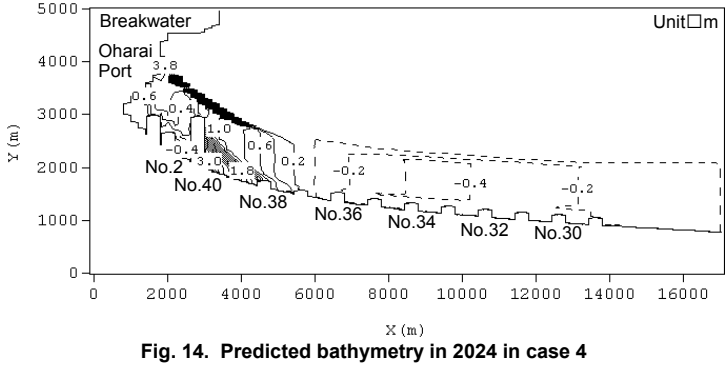

Fig. 14. Predicted bathymetry in 2024 in case 4

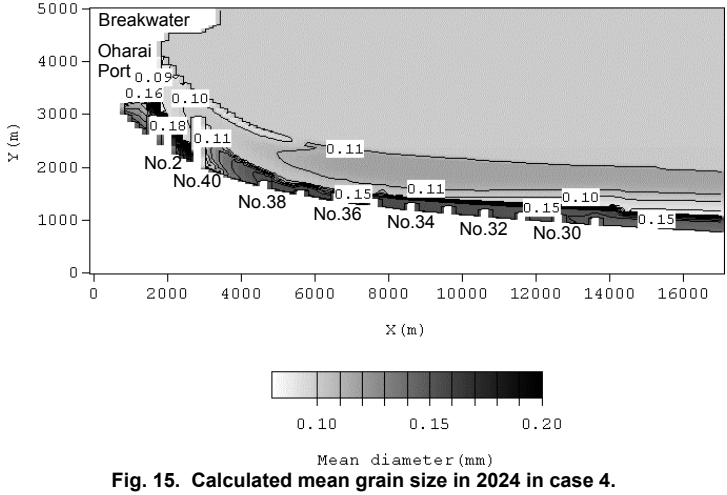

Fig. 15. Calculated mean grain size in 2024 in case 4.

hard clams will be induced.

Figure 16 shows the shoreline changes for cases 2, 3 and 4 in 2024 with reference to the shoreline in 2004, in which the point depth of headland No. 40 is extended to 7, 6 and 8 m, respectively. With the extension of the headland, the shoreline advances south of the headland, and the maximum shoreline advance approaches a constant value of approximately 200 m in the case of the point depths of 7 and 8 m. In contrast, the shoreline recedes north of the headland and the maximum shoreline recession tends to approach approximately 50 m as in the case of the point depths of 7 and 8 m. Considering the aim of preventing erosion between headlands No. 38 and No. 40, the effect of the trapping of longshore sand transport caused by headland No.40, as a measure against deposition in the navigation channel, and the resulting erosion north of headland No. 40, it is difficult to select the cases of the point depths of 7 and 8 m.

This conclusion is obtained only from the comparison of the shoreline changes in 2024, but the bathymetry had not yet reached a stable form in 2004. Therefore, the shoreline changes with time on both sides of headland No. 40 were investigated. **Figure 17** shows the time sequences of the shoreline position on both sides of the headland between 2004 and 2044. The volume of sand trapped on the south side of the headland increases with the point depth of the headland, whereas on the north side, the shoreline recedes 50 m until 2014 independent of the point depth of the groin, and then it advances. This is because sand can pass the tip of the headland, resulting in sand supply from south to north and accretion north of the headland.

Note that the time when the shoreline alteration north of the headland changes from erosive to accretive is delayed with the increase in the point depth. Although the proportion of longshore sand transport obstructed is increased with the extension of the headland, there is no change in the maximum shoreline recession of approximately 50 m, and instead, the time until accretion starts is delayed. Since a shore width of approximately 100 m still remains at the foot of headland No. 40 at

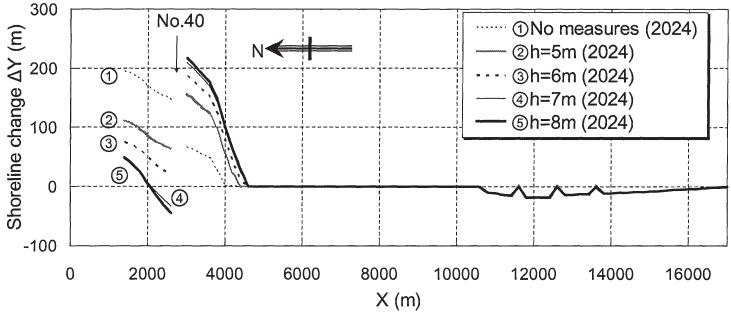

Fig. 16. Shoreline changes in 2024 in cases 2, 3 and 4 with reference to that in 2004

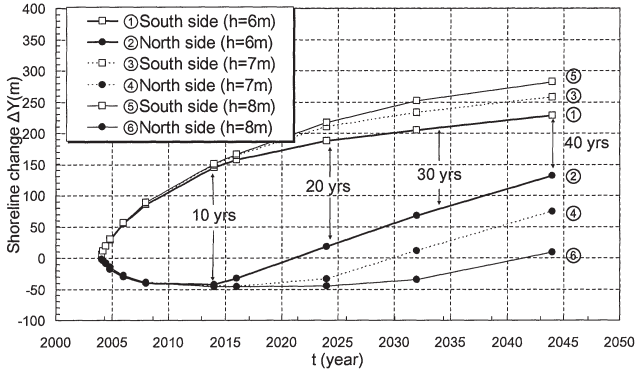

Fig. 17. Changes in shoreline position with time on both sides of headland No. 40

present, the selection of the time that erosion can occur in the future becomes important, even if a shoreline recession of approximately 50 m is permitted.

In the technological sense, a 20-year period is assumed to be an appropriate duration for determining the effect of the extension of the headland. In this case, the most appropriate measure is considered to be case 3 with the point depth of 6 m, in which the time of erosion is shortest. The longshore sand transport passing through off the tip of the headland after its completion causes deposition in the navigation channel, and therefore, 'sand back pass' in which sand is removed from the area south of the headland and deposited further south along the coast, becomes one of the valuable measures of preventing erosion, as in the case of the southern Kashimanada coast (Sumiya *et al.*, 2006). A shore width of 50 m is considered to be sufficient to prevent wave overtopping disasters, but there is a possibility of the expansion of the seabed area covered with coarse sand owing to the temporary erosion. Accordingly, further discussion is required for the evaluation of measures to preserve the habitat of Japanese hard clams.

CONCLUSIONS

A model predicting changes in bathymetry and the grain size of seabed materials was applied to the quantitative evaluation of the depth of an artificial headland as a measure against beach erosion associated with the formation of a wave shelter zone around Oharai Port. The point depth of 6 m was selected to be optimum in terms of accretion on the updrift side of the headland, prevention of the shoaling of the port navigation channel, preservation of the habitat of Japanese hard clams and the reduction in erosion downcoast of the headland. It is clear that the present model is a useful tool for predicting not only beach changes, but also grain size changes.

Abstract: The contour-line-change model was applied for predicting the beach changes around headlands on the Shimizu coast, which were built using pairs of detached breakwaters. Before constructing the headlands, there was a dynamically stable beach, at which longshore sand transport of 1.3×10^5 m^3/yr flowed continuously alongshore, but it was altered to a new equilibrium state, in which longshore sand transport was reduced to 7×10^4 m^3/yr owing to the construction of the headlands. The effect of countermeasures against beach erosion was also predicted using this model. It was found that the extension of the present detached breakwaters by 50 m in the updrift and downdrift directions to narrow the interval between the detached breakwaters is effective for reducing the necessary amount of sand nourishment by (0.5-1.0) $\times 10^4$ m^3/yr.

INTRODUCTION

The Shizuoka and Shimizu coasts have a 17-km-long coastline extending from the mouth of the Abe River along the outer margin of the Mihono-Matsubara sand spit. On these coasts, 1.3×10^5 m^3/yr of sand was continuously transported by northeastward longshore sand transport before extensive riverbed mining, and sand was deposited at the north end of the sand spit, as well as being discharged into the deep ocean through a submarine canyon (Uda, 1997). The fluvial sand supply from the mouth of the Abe River markedly decreased owing to the extensive riverbed mining before 1967 (Uda and Yamamoto, 1994; Itabashi and Uda, 1998), and

simultaneously, its impact started to propagate downcoast as a wave of erosion. Then, a wave of accretion, which was generated in 1983 by large floods in the Abe River, started to propagate from the Shizuoka coast to the Shimizu coast because of the prohibition of riverbed mining.

By 1983, the wave of erosion had reached the tip of the Mihono-Matsubara sand spit on the Shimizu coast. As a measure against beach erosion, a group of headlands each consisting of a couple of detached breakwaters have been built since 1983 to stabilize the shoreline. Five sets of headlands have now been built. After their construction, the shoreline downcoast of the detached breakwaters retreated, forming a hook-shaped bay, and resulted in the exposure of the foot of the seawall at the eroded sites, increasing the probability of collapse of the seawall.

As another measure, beach nourishment, using 3.5×10^4 m^3 of sand, has been carried out annually to compensate the shortage of sand supply, but its effect has been very limited and the sand has been quickly lost. Therefore, whether the reduction in beach nourishment is possible without increasing the severity of beach erosion is one of the present issues. In this study, a dynamically stable beach of the Shimizu coast is reproduced using the contour-line-change model, in which a large amount of sediment is continuously transported alongshore, and then the possibility of reducing the annual amount of beach nourishment necessary is investigated by altering the configuration of the detached breakwaters.

CHARACTERISTICS OF SHIMIZU COAST

The study area is the area between No. 54 and No. 68 of the Shimizu coast, as shown in **Fig. 1**, located at the outer margin of the Mihono-Matsubara sand spit. Off the coastline in the vicinity of the study area, a continental shelf with a gentle slope has developed, whereas in the vicinity of No. 30, a steep submarine canyon has developed. The beach changes associated with the construction of headlands built as a set of two detached breakwaters on the Shimizu coast have been described in detail in Uda (1997).

Figure 2 shows the results of this paper. In 1988, the offshore contours extended parallel to the gradually curved shoreline, and a steep slope of 1/10 had formed between the foreshore and a depth of 5 m, whereas in the zone deeper than 5 m, the seabed slope became as gentle as 1/50. At this stage, 1.3×10^5 m^3/yr of sand was continuously transported by the northeastward longshore sand transport on the Shimizu coast (Itabashi and Uda, 1998); this was a dynamically stable state, in which the same amount of sand flows in and out from both ends of the study area, as shown in **Fig. 2**.

On this coast, headlands composed of a set of two detached breakwaters had been built at two locations by 1992, and a straight shoreline remained west of detached breakwaters･and ･, as shown in **Fig. 2(b)**, whereas the shoreline had significantly retreated east of the detached breakwaters.

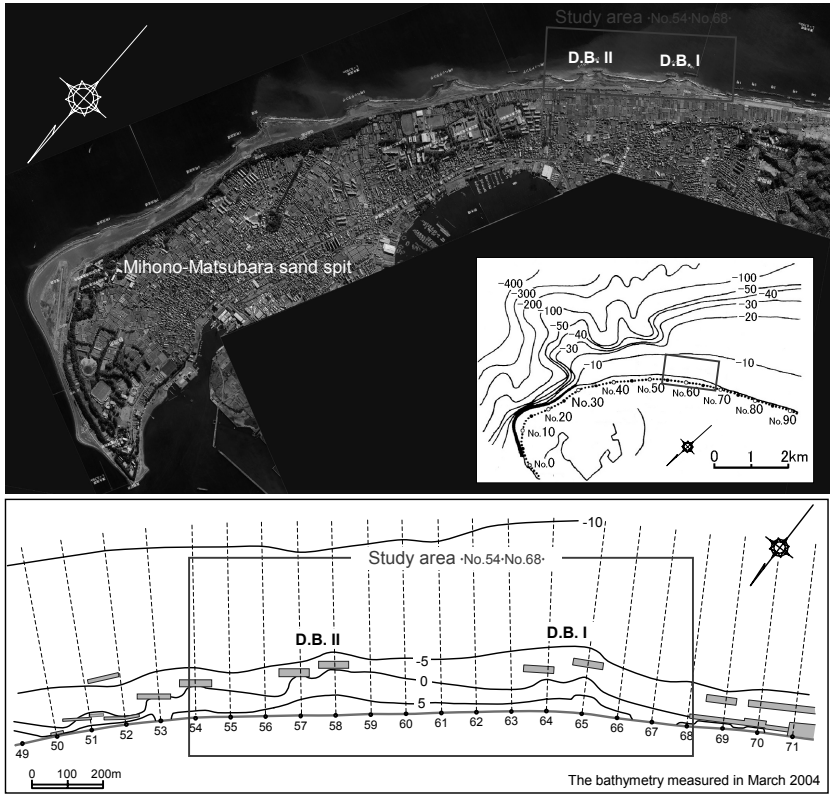

Fig. 1. Study area along Shimizu coast

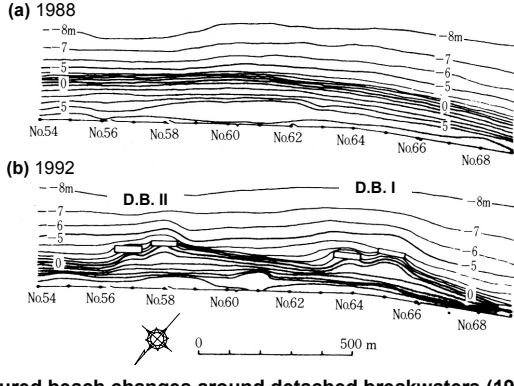

Fig. 2. Measured beach changes around detached breakwaters (1988 vs. 1992)

For example, **Fig. 3** shows the shoreline near detached breakwaters I on October 14, 2005. A new berm had formed owing to the accumulation of gravel from the concrete armor units shown at the right corner of the figure, and a generally concave shoreline had formed, allowing the approach of the berm to the foot of the seawall downcoast. In this area, severe wave overtopping has taken place, and the foreshore in front of the seawall has eroded away in recent years, resulting in the exposure of the foot of the seawall. To prevent seawall damage and reduce wave overtopping, 3.5×10^4 m^3 of sand has been nourished every year, but the effect of the beach nourishment has been regarded as questionable, since the same amount of sand is discharged immediately after the nourishment.

Fig. 3. Beach around detached breakwaters I taken on October 14, 2005

The detached breakwaters must have contributed to the reduction in longshore sand transport relative to that in the natural condition, 1.3×10^5 m^3/yr, but its effect has not yet been evaluated. The meandering of the contours offshore the detached breakwaters implies that part of the longshore sand transport may pass offshore of the detached breakwaters, but its quantitative evaluation is difficult using only **Fig. 2**.

REPRODUCTION OF DYNAMICALLY STABLE BEACH

A dynamically stable beach of the Shimizu coast is reproduced using a numerical model, and the controlling effect of longshore sand transport due to the detached breakwaters is investigated. **Figure 1** shows the bathymetry measured in March 2004. This figure is very similar to **Fig. 2(b)**, implying that the topography of the coast has reached an approximately dynamically stable state after the construction of the detached breakwaters. From this reason, a 1.4-km-long and 500-m-wide rectangular domain, as shown in **Fig. 1**, was selected, and beach changes in this study area were predicted. In this case, to reproduce the phenomenon that part of the longshore sand transport is diverted by the detached breakwaters and is carried downcoast, the contour-line-change model (Serizawa *et al.*, 2003) is applied, in which the effects of cross-shore sand transport depending on the balance between the local slope and the equilibrium slope, and the effect of longshore sand transport are taken into account, and the prediction of three-dimensional beach changes is possible. **Table 1** shows the calculation conditions for the model.

Table 1. Calculation conditions

Initial topography	Straight parallel contours (shoreline in 1989) Uniform slope of $tan\beta$ =1/10 Detached breakwaters (K_t=0.6)
Wave conditions	Breaker height: H_0'=3 m, T=9 s Breaker angle: α_b=17 deg. Tide level: mean sea level
Depth of closure	h_c=7 m
Berm height	h_R=3 m
Coefficients of sand transport	K_1=0.0042 K_2=0.2K_1 K_2=1.62K_1
Depth distribution of sand transport rate	Cubic equation given by Uda *et al.* (1996)
Equilibrium slope	$tan\beta_c$ =1/10
Critical slope	1/2 on land and 1/2 on seabed
Calculation domain	z=+3.5 to -7.5 m
Mesh size	Δx =10 m and Δz=1 m
Time interval	Δt=2 hrs
Total time of calculation	t = 5 years (21,900 steps)
Boundary conditions	Right boundary : Q_{in} =1.3x10^5 m^3/yr Left boundary : Free boundary Landward and offshore boundaries : q_z=0
Calculation method	Explicit finite difference method

An initial topography with straight parallel contours is set using an expanded coordinate system, to which the curvilinear coordinates fixed along the shoreline in 1989 are assigned, in accordance with the method of Uda *et al.* (1998a). The x-axis is taken to be alongshore and the y-axis is perpendicular to the x-axis. The initial beach slope is 1/10 on the basis of the measured bathymetry, and the detached breakwaters are set in this coordinate system. The reproduced period of beach change is 15 years between 1989 and 2004, and the beach change five years from the present is predicted, after confirming the applicability of the model for this calculation. The selection of a prediction period of five years is due to the fact that urgent measures are required because of severe beach erosion on the Shimizu coast.

For the wave conditions, rough waves with a 5% probability of occurrence are selected on the basis of the results of wave observation off the Shimizu coast, and considering that beach changes are more significantly affected by rough waves than normal waves. The selected equivalent wave height H_0' and the wave period are 3 m and 9 s, respectively. The predominant wave direction of this coast is south, and under oblique wave incidence, Snell's law gives a breaker angle of α_b=17 deg.

For the other important factors, the depth of closure h_c and berm height h_R are 7 and 3 m, respectively, on the basis of the analysis of bathymetric survey data (Itabashi and Uda, 1998; Uda *et al.*, 1998b), and the equilibrium slope is assumed to be 1/10 in the model. For the calculation in the vertical direction, the depth range between z=-7.5 m and z=3.5 m was divided into cells with Δz=1 m. Since the seabed slope in the offshore zone is as gentle as 1/50, there is no sinking of sand to a deeper zone. As a boundary condition, a longshore sand transport Q_{in} of 1.3×10^5 m^3/yr is introduced at the right boundary of the calculation domain, and longshore sand transport is distributed over depth in accordance with the depth distribution reported by Uda *et al.* (1996).

At the left boundary, a free boundary permitting the passage of longshore sand transport is set; longshore sand transport along each contour line invariant. The coefficient of longshore sand transport is adjusted so that Q at any point along the initial shoreline is equal to Q_{in}, satisfying the condition that the same amount of longshore sand transport as the inflow flows out from the left boundary. For this purpose, the coefficient of longshore sand transport K_1 was selected as 0.0042, which is two orders of magnitude smaller than the ordinary value. This is because the continuous action of rough waves with a small probability of occurrence over a year is assumed.

If we assume the ordinary value of the coefficient, excess longshore sand transport may be generated, and a dynamically stable beach cannot be reproduced. Under these conditions, a dynamically stable beach under the natural conditions before the construction of the detached breakwaters was reproduced using the model. Then, the detached breakwaters were placed on this dynamically stable beach, and the above-mentioned rough waves were generated for 15 years using the coefficient of longshore sand transport.

Figure 4(a) shows the initial and predicted topographies after 10 years; both results completely coincide with each other. **Figures 4(b)** and **4(c)** show the bathymetry after the detached breakwaters were built and show a comparison of the measured and predicted shoreline changes ΔY, respectively. In the calculation, the contour lines around the detached breakwaters approach this stable form within several years, and a dynamically stable beach is obtained in about ten years. Note that if only the present sand supply of 3.5×10^4 m^3/yr is given from upcoast, erosion gradually proceeds from upcoast, and the real shoreline changes cannot be reproduced. Sand supply from upcoast was increased by the trial-and-error method, and finally, it was found that if a sand supply of 7.0×10^4 m^3/yr is given, the present shoreline remains dynamically stable.

Figure 4(b) shows the dynamically stable beach topography predicted when the detached breakwaters were built, which corresponds well to the measured beach topography in 1992, as shown in **Fig. 2**. The contour line changes upcoast and downcoast of the detached breakwaters were accurately reproduced, as well as the

prediction of the meandering of contour lines offshore of the detached breakwaters, which corresponds to the passage of part of the longshore sand transport offshore of the detached breakwaters. **Figure 4(c)** shows the comparison between measured and predicted shoreline changes. The measured shoreline changes are accurately reproduced by the numerical simulation.

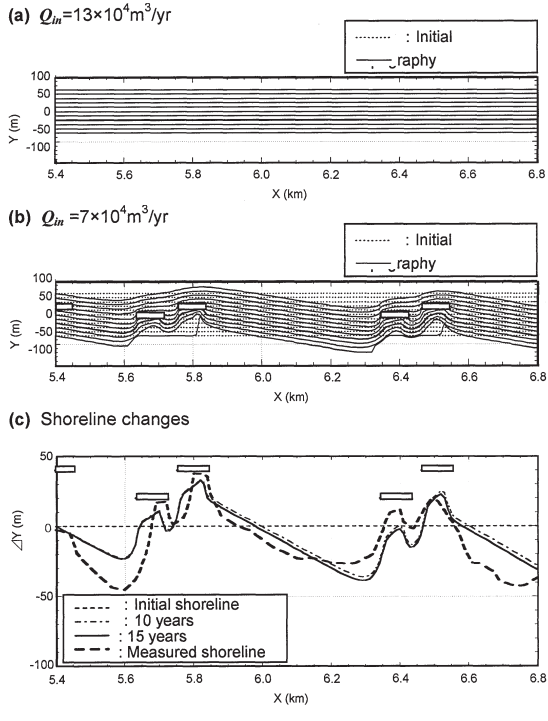

Fig. 4. Dynamically stable beach topography predicted when detached breakwaters were built and comparison of shoreline changes

IMPROVEMENT OF SHAPE OF DETACHED BREAKWATERS AND BEACH NOURISHMENT AS MEASURE AGAINST EROSION

4.1 Effect of beach nourishment on surrounding coast

Since the Shimizu coast is currently in dynamical equilibrium, the hasty construction of various facilities is feared to cause a rapid expansion of the eroded zone. Therefore, the effect of beach nourishment on the surrounding coast was investigated by varying the volume and location of the beach nourishment. **Figure 5(a)** shows the shoreline changes in the case that the annual nourishment volume from upcoast is reduced by 1.0x10^4 m^3/yr. In this case, the shoreline significantly receded in an extensive area updrift of detached breakwaters I, and the maximum shoreline recession reached as large as 20 m on the updrift boundary at X=6.8 km. This means

that the reduction of the present nourishment volume to reduce cost will cause severe erosion.

An additional supply of sand of 1.0×10^4 m^3/yr was considered at the eroded location immediately downcoast of detached breakwaters I, instead of the nourishment upcoast of the detached breakwaters, although this is slightly aside from the original aim of determining whether the reduction in nourishment volume is possible. The results are shown in **Fig. 5(b)**. This method is effective in reducing the shoreline recession immediately downcoast of the detached breakwaters to some extent, as shown in the figure, but the continuation of sand nourishment every year aggravate the problem.

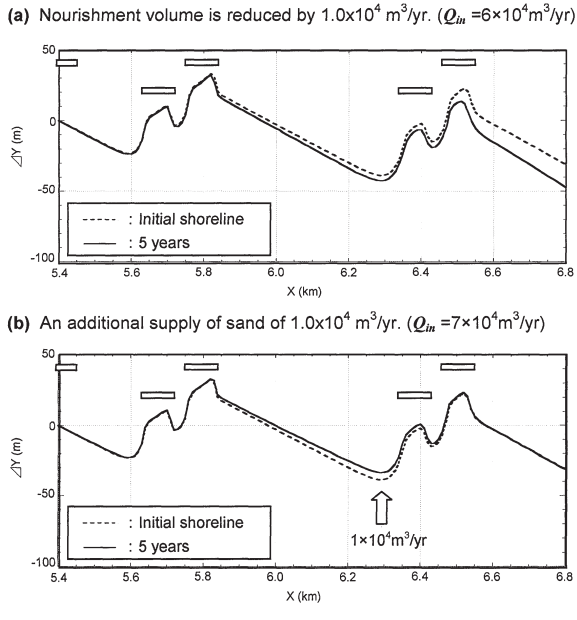

Fig. 5. Comparison of shoreline changes when changing volume of beach nourishment

4.2 Comparison of beach changes around detached breakwaters and T-shaped groin

In the case of the headlands using the detached breakwaters, longshore sand transport may pass between the breakwaters and the shoreline during storm wave conditions, resulting in a reduction in the obstruction effect of longshore sand transport due to detached breakwaters, and nourished sand may be transported away downcoast. Because of this, the alteration of the detached breakwaters to T-shaped groins has been proposed locally. To investigate this point, beach changes were predicted in

cases that longshore sand transport passing through behind the detached breakwaters was totally obstructed owing to the alteration of the detached breakwaters to T-shaped groins, while maintaining the present volume of nourishment.

Figure 6(a) shows the bathymetry in a dynamically stable condition in the case when one of detached breakwaters I, located on the updrift side of the detached breakwaters, was altered to a T-shaped groin, and **Fig. 6(b)** shows the shoreline changes. In this case, the salient formed behind the detached breakwaters was significantly eroded and then disappeared, because longshore sand transport was blocked by the T-shaped groin. It is clear that the alteration of the detached breakwater to a T-shaped groin is ineffective in maintaining a dynamically stable beach and in conserving the beach without large changes.

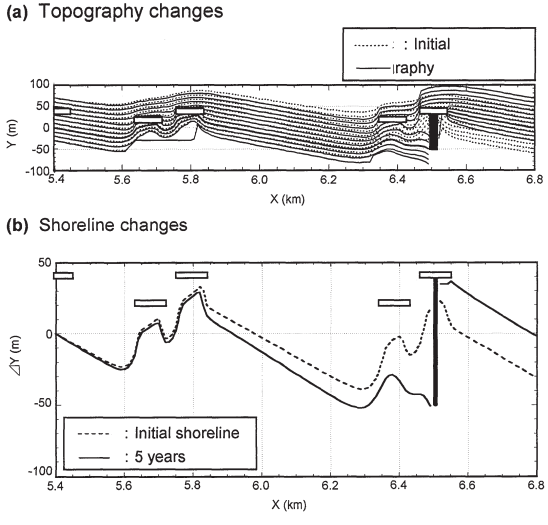

Fig. 6. Dynamically stable beach topography when one of detached breakwaters was altered to T-shaped groin and comparison of shoreline changes

4.3 Beach changes associated with extension in length of detached breakwaters

The dynamically equilibrium condition was predicted in the case that the length of each detached breakwater was extended by 50 m alongshore without changing the present volume of nourishment. The results of the shoreline changes are shown in **Fig. 7**. In the case that detached breakwater I-1 was extended in the updrift direction, the shoreline upcoast of detached breakwaters I gradually advanced, as shown in **Fig. 7(a)**, whereas the shoreline recession increased by 5 m downcoast of detached breakwaters I, as an adverse effect.

In the case that detached breakwater I-2 was extended in the downdrift direction, the location of the maximum shoreline recession downcoast of detached breakwaters I

shifted by 50 m, as shown in **Fig. 7(b)**, but the shoreline recession did not change compared with the present. In the case that detached breakwater II-1 was extended in the updrift direction, the shoreline advanced in an extensive area upcoast, as shown in **Fig. 7(c)**, but the change was ineffective in reducing the shoreline recession immediately downcoast of detached breakwaters I, because the distance between the detached breakwaters was is too long.

In the case that detached breakwaters I-2 and II-1 were extended simultaneously, the location where the shoreline retreated most severely downcoast of detached breakwaters I was shifted by 50 m downdriftward, and shoreline recession was reduced, as shown in **Fig. 7(d)**. It is clear that narrowing the distance between the detached breakwaters is effective in preventing beach erosion. In the case that both of detached breakwaters I were simultaneously extended, the shoreline on the updrift side advanced significantly, because the effect of obstructing longshore sand transport due to detached breakwaters I was increased, but the shoreline recession immediately downcoast increased by 5 m.

4.4 Reduction in beach nourishment volume by extension of detached breakwaters

In the previous sections, to reduce the beach nourishment volume, the case in which beach nourishment volume is simply reduced and the case using T-shaped groins were investigated, but no effective results were obtained. On the other hand, the extension of the detached breakwaters was found to be effective in reducing the shoreline recession to some extent. Therefore, the possibility of the reduction in beach nourishment volume was investigated here under the condition that the distance between the detached breakwaters is shortened by extending the length of each detached breakwater by 50 m.

First, the shoreline advance was investigated in the case that the same beach nourishment volume as present was supplied to beaches after the extension of the detached breakwaters. The bathymetry and shoreline changes are shown in **Figs. 8(a)** and **8(b)**. In this case, the location where the shoreline markedly receded immediately downcoast of detached breakwaters I shifted by 50 m, the shoreline upcoast of detached breakwaters I advanced significantly, and the maximum shoreline recession was reduced. Thus, it was found that this method is very effective.

Furthermore, the annual sand supply rate was reduced to 6.0×10^5 and 6.5×10^5 m^3/yr, which means reductions in sand supply by 0.5×10^4 and 1.0×10^4 m^3/yr, respectively, compared with the present nourishment volume, to investigate the possibility of a reduction in beach nourishment volume. **Figure 8(c)** shows the results of the case in which nourishment volume was reduced by 1.0×10^4 m^3/yr. Although the shoreline receded both upcoast and downcoast of the detached breakwater owing to the reduction in nourishment volume, the shoreline recession downcoast of the detached breakwaters was insignificant compared with that in the case shown in **Fig. 8(a)**.

Thus, extending detached breakwaters is effective in reducing the annual sand supply from 3.5×10^4 to 2.5×10^4 m^3/yr.

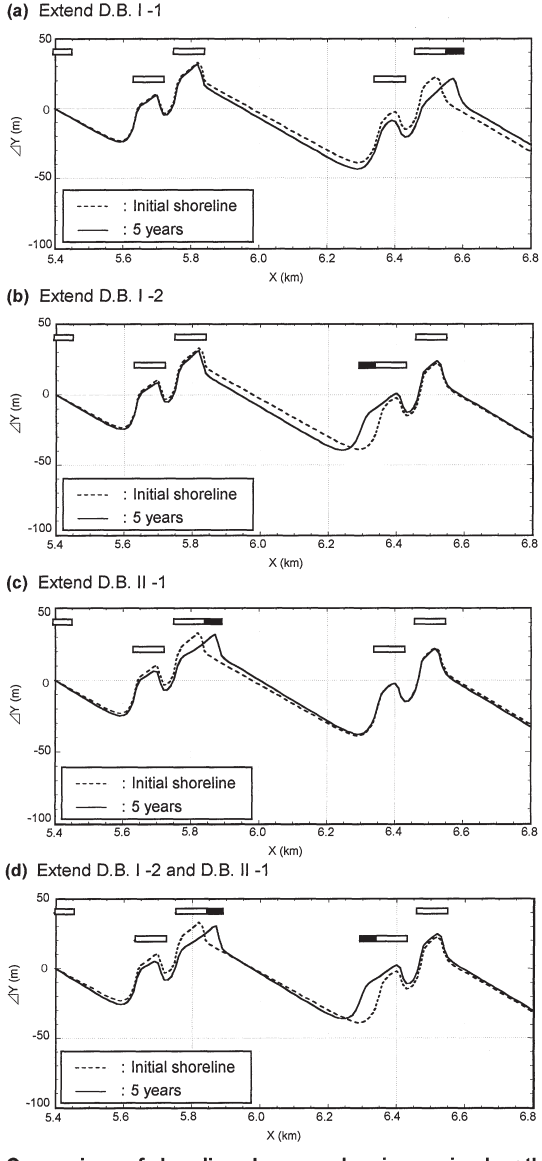

Fig. 6. Comparison of shoreline changes when increasing length of detached breakwaters.

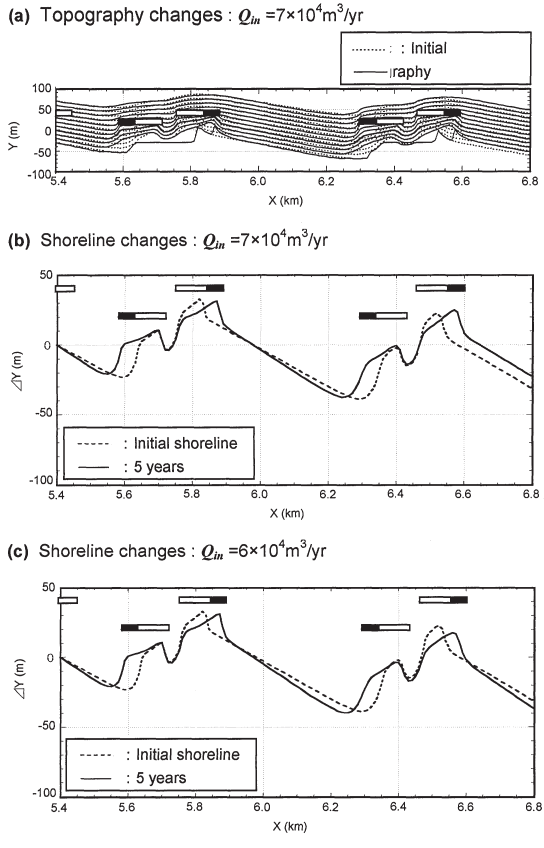

Fig. 8. Dynamically stable beach topography when detached breakwaters were extended and comparison of shoreline changes when reducing beach nourishment

CONCLUSIONS

(1) On the Shimizu coast, 1.3x10^5 m^3/yr of sand had been continuously transported by northeastward longshore sand transport before the construction of the detached breakwaters, while maintaining a dynamically stable state. After the construction of the detached breakwaters, the longshore sand transport rate was reduced to 7.0x10^4 m^3/yr, resulting in a new dynamically stable state.

(2) Because the longshore sand transport rate in the new dynamically stable state is larger than the annual amount of beach nourishment of 3.5x10^4 m^3/yr, the beach has eroded. Erosion downcoast of the detached breakwaters has occurred, increasing the probability of seawall damage.

(3) As a measure to ease beach erosion and to reduce longshore sand transport, reshaping the detached breakwater into a T-shaped groin was studied, but this was ineffective because of the occurrence of severe downcoast erosion.
(4) Extending the existing detached breakwaters by 50 m to narrow the distance between them is effective in mitigating erosion and in reducing the annual amount of beach nourishment necessary.

Abstract: Geologic maps depicting offshore sedimentary features serve many scientific and applied purposes. Such maps have been lacking, but recent computer technology and software offer promise in the capture and display of diverse marine data. Continental margins contain landforms which provide a variety of important functions and contain important sedimentary records. Some shelf areas also contain deposits regarded as potential aggregate resources. Because proper management of coastal and offshore areas is increasingly important, knowledge of the framework geology and marine processes is critical. Especially valuable are comprehensive and integrated digital databases based on high-quality information from original sources. Products of interest are GIS maps containing thematic information, such as sediment character and texture. These products are useful to scientists modeling nearshore and shelf processes as well as planners and managers. The U.S. Geological Survey is leading a national program to gather a variety of extant marine geologic data into the usSEABED database system. This provides centralized, integrated marine geologic data collected over the past 50 years. To date, over 340,000 sediment data points from the U.S. reside in usSEABED,

which combines an array of physical data and analytical and descriptive information about the sea floor and are available to the marine community through three USGS data reports for the Atlantic, Gulf of Mexico, and Pacific published in 2006, and the project web sites: (http://woodshole.er.usgs.gov/project-pages/aggregates/ and http://walrus.wr.usgs.gov/usseabed/)

INTRODUCTION

Rapid population growth and development in the coastal zone continues and demographic projections suggest that people will continue moving to the coast to live and recreate, placing more people and development at risk. With climate change likely causing accelerating global sea-level rise and increased storminess, coastal regions may become even more dynamic, experiencing greater vulnerability to erosion, inundation, and more frequent storm-surge flooding.

Beach nourishment is increasingly viewed as the preferred soft-engineering method for use on developed coasts to mitigate erosion, reduce storm and flooding risk and enhance recreation. Over the past 80 years more than 650 million cubic meters of sand have been used throughout the U.S. for beach nourishment, mostly from offshore dredging. For beach nourishment to be viable, however, large volumes of high-quality sand are necessary. Also, the sand deposits must be located reasonably close to the beaches being nourished and in water depths ranging typically from approximately about -10 m, an approximate "depth of closure" for sediment transport, to -40 m, an approximate current limit of U.S. commercial dredging (Williams, 1992).

Continental shelf regions adjacent to the mainland are products of a complex geologic history and dynamic oceanographic processes, dominated by the Holocene marine transgression (>100 m sea-level rise) during the past 20,000 years. The area of the Exclusive Economic Zone, extending 200 nautical miles seaward of the coast, is larger than the continental U.S. This area contains submerged landforms that provide a variety of natural functions and societal benefits, such as: critical habitats for fisheries, ship navigation and home-land security, and engineering activities (i.e., oil and gas platforms, pipeline and cable routes, potentially wind energy generation). Some parts of the continental margins also contain unconsolidated hard-mineral deposits, such as sand and gravel, regarded as potential aggregate resources to augment needs not met by onshore deposits.

A broad and diverse range of sedimentary deposits (Figure 1) on the inner continental shelf, considered the best quality sand sources for beach nourishment, are not random in occurrence, but instead are well defined in terms of their stratigraphic framework, sediment texture and character, and geologic origins. Some of the sand bodies are relict landforms, some are associated with modern shelf processes, while others are relict but highly modified by the late Holocene marine transgression and modern processes.

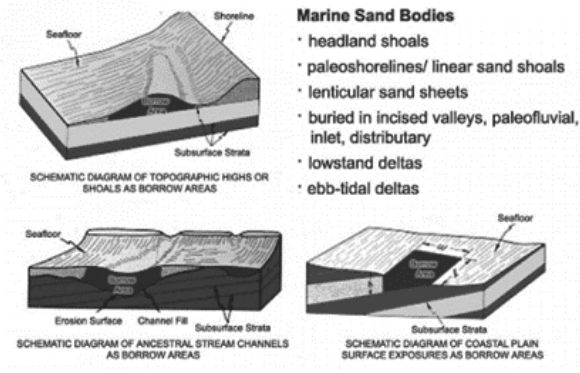

Figure 1. Schematic of the variety of surface and buried marine sand bodies on the shelf.

Onshore aggregate shortages in some parts of the country might be met using marine aggregates. However offshore aggregate resources are sparse or mostly unknown for many regions, and sand volumes needed to meet beach nourishment requirements and sustain long-term (50 yr projects) beach nourishment are uncertain (Williams et al., 2003). For example, projects planned for Long Island, New York, and the Mississippi-Alabama coast will each require an estimated 40 million cubic meters of suitable sand. Coastal restoration of Louisiana, following Hurricanes Katrina and Rita in 2005, is projected to require more than 100 million cubic meters of assorted sediment types including sand for barrier nourishment, clay for levees, and sandy muds for wetlands restoration.

Because offshore aggregate areas are increasingly important for a variety of purposes, knowledge of the geological framework and processes is critical. Further comprehensive, up-to-date, and integrated computer databases are needed by a variety of users. Products of greatest value are Geographic Information System (GIS) compatible base maps displaying thematic information such as sea floor physiography, geology, sediment character and texture, sea floor roughness, and geotechnical engineering properties. Digital geologic maps, based on unified national datasets showing the sedimentary character of continental margins, are critical for scientists to better understand and interpret the geologic history and sedimentary processes that formed and continue to modify the sea floor. These map products are useful to planners and managers for regulating and managing coastal and offshore areas. This paper presents examples of usSEABED data use and application for two regions, New York Bight and Louisiana.

Assessing Marine Aggregate Resources

The U.S.Geological Survey (USGS), in collaboration with other Federal agencies (e.g., Office of Naval Research, Minerals Management Service, U.S. Army Corps of

Engineers, National Oceanic and Atmospheric Administration) and a number of universities (e.g., University of Colorado, University of Texas, University of New Orleans), is leading a nationwide effort to assemble legacy marine geologic data shown in Figure 2 into a unified database system called usSEABED, as a task of the Marine Aggregate Resources and Processes (MARP) project.

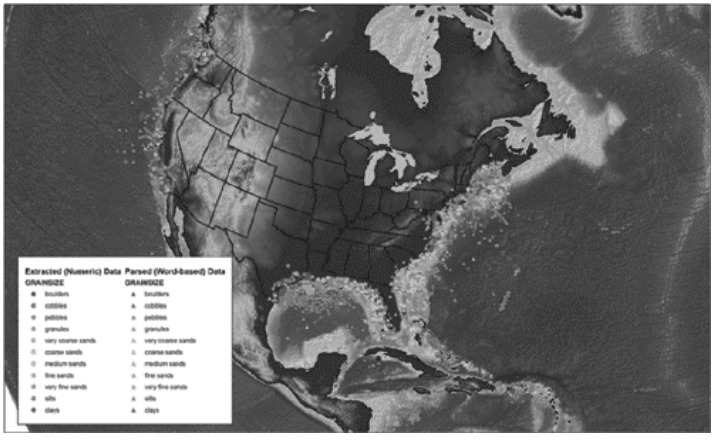

Figure 2. Map of current usSEABED data coverage and sediment grain size.

The objectives of MARP are to produce a series of new geologic maps and reports of the sea floor that will provide scientific insights into the character and geologic development of U.S. continental margins. These maps and information are used to assess the potential availability of offshore sand and gravel resources using stochastic techniques such as resource modeling and Monte Carlo simulations in combination with GIS maps. The mapping and aggregate resource assessments are being conducted on a national scale using the usSEABED database as described in Williams et al. (2006a; 2006b). Potential uses for these data include: (1) defining the geological variability of the sea floor, in relation to benthic habitat diversity; (2) improving our understanding of the processes that control the distribution and transport of bottom sediments and benthic habitats; (3) locating aggregate resources for beach nourishment and industrial applications; and (4) providing a detailed geospatial framework for future marine science research, monitoring, and management activities. The initial assessments are in progress for the New York Bight and the Louisiana offshore deltaic plain.

The first three of the usSEABED data releases: Atlantic Coast Offshore Surficial Data Release, version 1.0 (Reid et al., 2005) was published as USGS Data Series 118. Its sister publication, Gulf of Mexico and Caribbean Offshore Surficial Data Release, version 1.0 (Buczkowski et al., 2006), is available as USGS Data Series 146. A third data release, covering the Pacific Coast (Reid et al., 2006), was published in late

2006. Other data series reports for Hawaii and Alaska will be published in 2007. Altogether, the database currently includes over 340,000 locations of sea floor data and sediment characteristics (Figure 2). Although the majority of these samples are surficial samples, additional sampling devices include piston and vibracores and dredge samples. The data supplied in these reports are made available with geographic coordinates to allow the data to be incorporated into any GIS system. Federal Geographic Data Committee compliant metadata are included with the data layers.

In an effort to make the data more accessible to the public, geographically relevant subsets of data are being posted to coastal state GIS clearinghouse websites. Many of these sites serve as the primary source of GIS information for state and local researchers and agencies. The majority of the holdings on these sites are on-land features and the addition of usSEABED data constitutes a substantial expansion of their coverage for offshore areas. As an added bonus, many of the clearinghouses have helped the USGS establish additional connections with local agencies and their data collections.

METHODS and RESULTS

usSEABED Sediment Database and dbSEABED Processing System

The usSEABED database is based on the dbSEABED system for integrating sea floor datasets. The approach differs from traditional relational databases in that processing seeks the parts of each dataset that conform to standards or can be brought to conformance (Jenkins, 1997; Jenkins, 2002; Reid et al., 2001). The result is an information rich, quality assured, GIS-ready point dataset.

In addition to the usual forms of numeric analytical sediment data, estimates of seabed characteristics are produced from word-based descriptions. The ability to handle word-based data greatly extends the power of the system to map seabed, where on a global average greater than 85 percent of the data characterizing the seabed are word-based (Jenkins, 1997). Also, it extends to information to biogenic, very coarse and rock terrains that are hard to sample or analyze. The handling of word-based descriptive data is based on a parser that divides the descriptions into linear equations around objects, quantifiers and modifiers (Jenkins, 1997), a thesaurus that attaches meanings and memberships, and a linear weighted assembly of the numerical totals. Term meanings and memberships are defined with using Fuzzy Set Theory.

The dbSEABED's expanded capability to extract data increases the overall spatial coverage of the data, but also requires users to understand a clearly defined distinction between the variations in output data. Altogether, five output files are written, each classified by its processing history and content (Extracted, Parsed, Calculated, Component and Facies). Extracted data, those data from strictly performed, lab-based, numeric analyses, are written to a data file with the _EXT tag. Most data in this file are listed as reported by the source data report, and are based on rigorous lab-determined values. These data are the most precise, but used alone may

cause a lack of representation since they refer mainly to finer sediments. Alternatively, outputs obtained from deck and lab descriptions (including core descriptions), video or photographic descriptions, or geophysical mapping are held in the parsed data set. Together, these two types of output represent the actual values from the original survey and laboratory materials/reports.

Additional values that can be calculated or estimated from the extracted and parsed results using documented empirical or theoretical relationships are reported in the calculated outputs. Although the calculated data could be combined with the extracted and the parsed, they are kept separate and are the least reliable of the three data file types and should be used with caution.

The final two file types, Component and Facies have similar in content. The Component file contains component abundance and feature intensity information. The abundances intensities are evaluated solely on major the synonyms of the specific terms within the original descriptions. On the other hand, the facies file identifies how strongly a sample expresses groups of components and features.

Uncertainty and variability of marine sediments

Sea floor sediments comprising the continental shelf are spatially heterogeneous on many scales: from regional-scale variations, such as those associated with depocenters or the shoreline, to micro-scale variations, such as those associated with ripple bedforms. Between these extremes, are variations associated with different bedforms, or patchiness caused by factors such as localized erosion, biologic processes, or glacial deposits (Goff et al., 2004; 2006). Because spatial sediment variability is related to geological framework and processes, Goff et al., (in prep) are using usSEABED and statistical tools to achieve basic understanding of the geologic response to the oceanographic forcing at the sea floor. The next step will be to use these data as a predictive tool. Although usSEABED coverage is far from uniform, it provides, in many continental shelf and estuarine regions, data sets that are sufficient in quantity and coverage to robustly estimate spatial variability functions such as the semi-variogram. Such a predictive capability would have important scientific and engineering applications in ocean acoustics, where seabed variability strongly affects signal detection. Understanding sediment variability is also important for interpolation and GIS map making using kriging and other similar mapping methods.

Sand and Gravel Resources on the Continental Shelf

A wide variety of sedimentary sand bodies or deposits, such as cape-associated and linear shoals (Figure 1) develop, and are preserved on storm dominated shelves. They are particularly notable on the mid-Atlantic shelf from Long Island to South Carolina. Other sand bodies, such as those off the Louisiana delta plain, are remnants of older deltas and transgressed barrier islands. These marine sand deposits are recognized as containing desirable sand suitable for beach nourishment and related activities. There is now a need to provide a quantitative assessment of these sand resources that permits a probabilistic estimate of how much sand may be present as a potential resource. To carry out such assessments, a statistical approach extensively used for quantitative mineral resource assessment is being used in the MARP project

(Bliss and Bolm, in review). Assessments are underway for the New York Bight region and offshore Louisiana and will be reported in 2007.

Mineral-resource assessments may be considered a form of regional mineral-deposit planning that is highly formalized and are conducted by an assessment team. Such assessments have also found application in land planning, land exchanges, and in the evaluation of possible management and development situations. Application of the approach calls for a number of new models that are a simplification of information and data about marine deposit systems, such as cape-associated and linear shoals. One type of model is descriptive in that it is a narrative that allows for a consistent recognition of marine sand deposits. Also needed are a number of quantitative models that are statistical or empirical distributions that describe quantitative characteristics to help recognize known sand deposits. This model also includes helping to recognize targets for deposits that have not been characterized.

Variables of deposits considered for quantitative modeling include: area, thickness, bathymetry, mean sand grain size, volume, portions of the deposit that are sand-dominated facies, and spatial density. The last variable, spatial density is particularly helpful in estimating the number of undiscovered deposits within permissive tracts on the shelf. Two of the models being used in Monte Carlo simulations include the volume model and sand facies model. These models, together with estimates of number of undiscovered deposits, allow a probabilistic prediction of how much sand may be present within each tract (Bliss and Bolm, in review).

New York Bight Region

Broad regions of the continental shelf, such as the New York Bight, are the product of a complex geologic history and dynamic oceanographic processes, dominated by the Holocene marine transgression (>100 m sea-level rise) following the last Pleistocene ice sheet advance about 20,000 years ago. The present distribution of surficial sediment off the northeastern U.S. is shaped from the deposits left by the last glaciation and reflects the cumulative effects of erosion, transport, sorting, and deposition by storm and tidal processes during the Holocene rise in sea level. As a result, the sediments on the sea floor represent both an historical record of former conditions and an indication of present oceanographic processes (Williams et al., 2006a).

Figures 3, 4 and 5, from Williams et al. (2006a) based on data in Reid et al. (2005), are example GIS products that are possible using usSEABED. These figures present the distribution of sediment size (mean grain size in phi units), the percent composition of sea floor samples (gravel, sand and mud), sorting ratios, and percentages of sand (often used to identify high quality sand for beach nourishment). Figure 4 shows potential borrow areas.

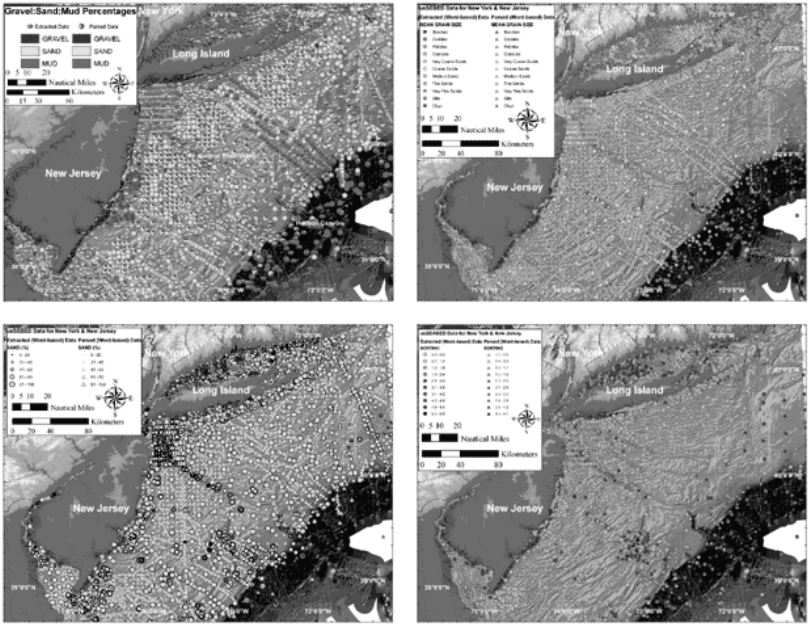

Figure 3. Maps of sediment character in the New York Bight offshore region. While sand predominates across the region, muddy sediments are associated with the Hudson shelf valley and deeper regions. Gravelly sands are common in erosional areas.
(From Williams et al. 2006a).

Louisiana Delta Plain Region

The Louisiana coastal zone, comprising the Mississippi River delta plain and stretching nearly 400 km from Sabine Pass at the Texas border east to the Chandeleur Islands at the Mississippi border, represents one of North America's most important coastal ecosystems in terms of natural resources, human infrastructure, and cultural heritage (Figure 6). At the same time, this region has the highest rates of coastal erosion and wetland loss in the Nation due to the complex interaction of natural processes and anthropogenic actions over the past century. Comparison of historical maps dating back to 1855 and recent aerial photography and Lidar surveys show the Louisiana coast undergoing net erosion at highly variable rates. These rates have increased significantly during the past several decades. (Williams et al. in press).

Earlier published rates of statewide average shoreline erosion were >6 m/yr; rates have increased to more than 10 m/yr. The increase is attributable to the collective actions of storms (e.g., Hurricanes Katrina and Rita), rapid natural and hydrocarbon-removal induced subsidence, and pervasive man-made alterations of the rivers, wetlands and the coast. In response to the dramatic landloss, regional-scale restoration plans are being developed by a partnership of federal and state agencies for the delta plain that have the objectives of maintaining the barrier islands, reducing

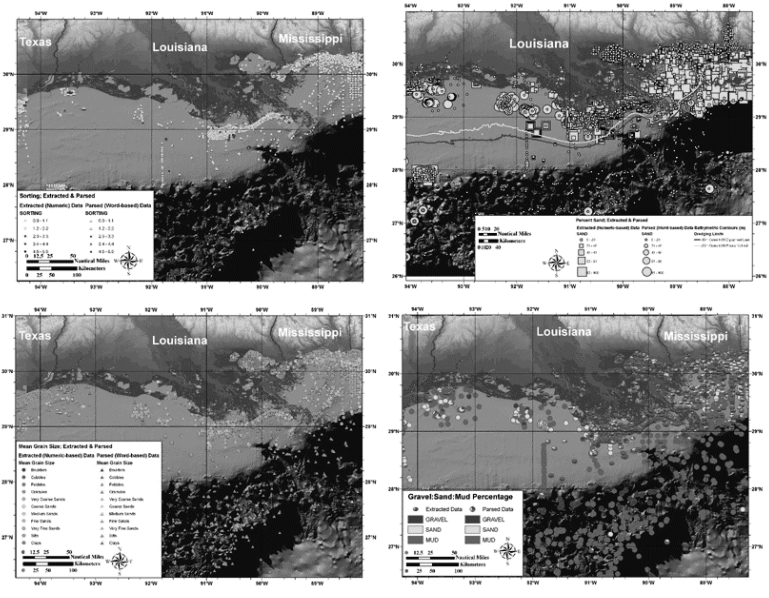

Figure 6. Maps of sediment character of the Louisiana offshore. While muddy sediments predominate due to the Mississippi River, sands are present in nearshore deposits and relict submerged sand bodies on the shelf. (From Williams et al. 2006b).

wetland loss, and enhancing the natural sediment delivery processes. There is growing awareness that the sustainability of Louisiana's coastal features and human infrastructure depends on the successful restoration of natural geologic processes. Critical to the long term success of restoration is scientific understanding of the geologic history and processes of the coastal zone region, including interactions between the rivers, wetlands, coast, and inner shelf.

A variety of geophysical studies and mapping of Late Quaternary sedimentary framework and coastal processes by USGS and other scientists have documented that the Louisiana delta plain is the product of a complex history of cyclic delta switching by the Mississippi River and its distributaries over the past approximately 10,000 years, resulting in laterally overlapping deltaic depocenters (Williams, et al., 2006b). The interactions among riverine, coastal, and inner shelf processes have been superimposed on the Holocene transgression resulting in distinctive landforms and sedimentary sequences.

Four Holocene shelf-phase delta complexes have been identified using seismic-reflection data and vibracores. Each delta complex is bounded by transgressive surfaces. Following each cycle of deposition and abandonment, the delta lobes

undergo regional subsidence and marine reworking that forms transgressive coastal systems and barrier islands. Ultimately, the distal end of each of the abandoned delta lobes is marked by submerged marine sand bodies representing drowned barriers. These five sand bodies, shown in Figures 7 and 8 (e.g., Ship Shoal, Outer Shoal, Trinity Shoal, Tiger Shoal, Cat Island Ebb Shoal, St. Bernard Shoal), offer the largest volumes and highest quality sand offshore Louisiana for beach nourishment and wetlands restoration (Kulp et al., 2005; Williams et al., 2006b).

The four large sand shoals on the inner shelf, representing the reworked remnants of former prograded deltaic headlands that existed on the continental shelf at lower sea level, were generated in the retreat path of the Mississippi River delta plain during the Holocene transgression. Kulp et al. (2005) and Williams et al. (in press) describe how these sand bodies represent former shoreline positions associated with lower stands of sea level. Cat Island Ebb Shoal is a modern feature. Short periods of rapid relative sea-level rise led to the transgressive submergence of the shorelines which today can be recognized at the -10 m to -20 m isobaths on the Louisiana continental shelf. Trinity Shoal and Ship Shoal represent the -10 m middle-to-late Holocene shoreline trend, whereas Outer Shoal and the St. Bernard Shoals define the -20 m middle Holocene shoreline trend. Collectively, these sand shoals constitute a large volume of high quality sandy sediment potentially suitable for barrier island nourishment and coastal restoration.

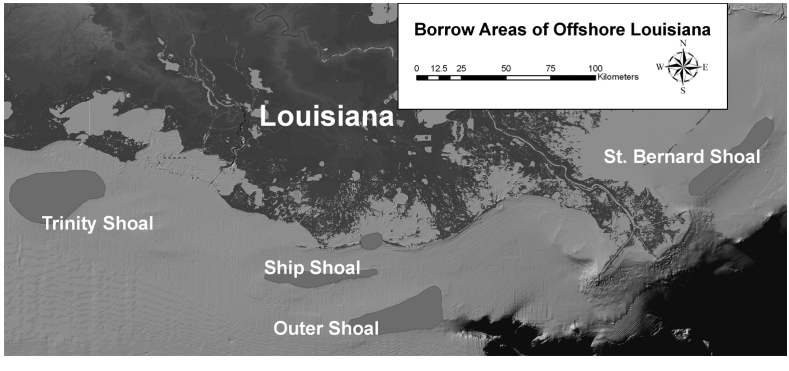

Figure 7. Map of five major sand bodies and potential borrow areas offshore Louisiana being considered in the sand and gravel assessment study. Cat Island Ebb Shoal is the central unlabeled feature.

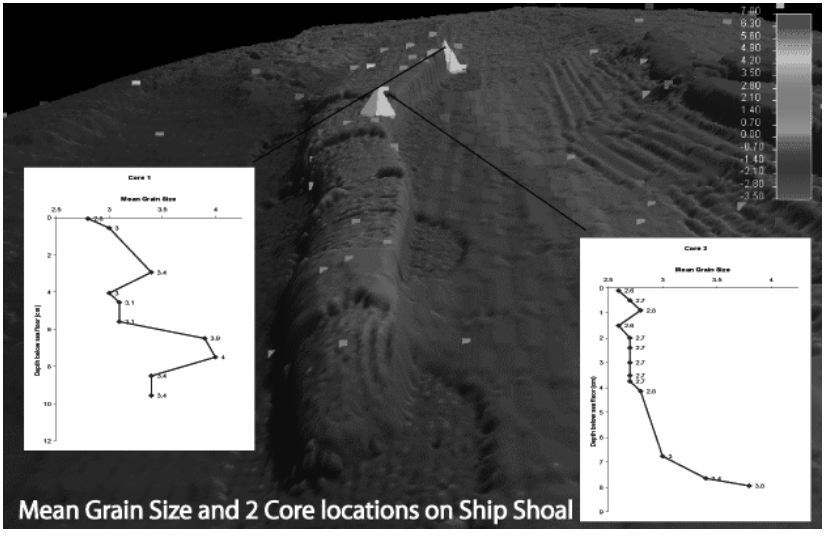

Figure 8. Diagram of Ship Shoal, Louisiana showing the elongate and asymmetric morphology of the feature, 50km in length and 3- 5m in height, and internal grain size based on representative cores. Ship Shoal, a drowned barrier island, is a premier marine sand body on the Louisiana shelf.

CONCLUSIONS

A national program led by the USGS is gathering a variety of extant marine geologic data into the usSEABED system. The data in this system are being used to generate new geologic maps of offshore areas and assessing potential marine aggregate resources. The usSEABED system provides a centralized, fully integrated digital database of marine geologic data collected by USGS, other federal and state agencies, universities and private companies. The usSEABED, which combines a broad array of physical data and information about the sea floor, including sediment textural, statistical, geochemical, geophysical, and compositional information, is available to the marine community through USGS Data Series publications. The use of usSEABED and derivative GIS map products is part of ongoing USGS efforts to conduct regional assessments of potential marine sand and gravel resources, map benthic habitats, and support research in understanding sea floor character and sediment transport processes.

ACKNOWLEDGEMENTS

This study, supported by the USGS Coastal and Marine Geology Program, represents a partnership with the University of Colorado and University of Texas, as well as other federal and state agencies. In particular, ONR supports the studies on sediment uncertainty and variability. The support of these partners in moving this study along

is appreciated. Constructive reviews of this paper by L.J. Poppe and E. Pendleton, both USGS, are appreciated.

ADDITIONAL INFORMATION

The opportunities for multidisciplinary studies of offshore areas using the usSEABED database are significant and the marine science community is encouraged to learn more about the Marine Aggregates Assessment project and usSEABED. In addition, the community is encouraged to contribute additional datasets to continue building this marine sediment archive. Questions about the Marine Aggregate Resources and Processes project may be addressed to S.J. Williams; inquiries for adding data to usSEABED may be addressed to M.A. Arsenault.

Abstract: The U.S. Geological Survey (USGS) has been involved in geological mapping of the sea floor for the past thirty years. Early geophysical and acoustic mapping efforts using GLORIA (Geologic LOng Range Inclined ASDIC) a long-range sidescan-sonar system, provided broad-scale imagery of deep waters within the U.S. Exclusive Economic Zone (EEZ). In the early 1990's, research emphasis shifted from deep- to shallow-water environments to address pertinent coastal research and resource management issues. Use of shallow-water, high-resolution geophysical systems has enhanced our understanding of the processes shaping shallow marine environments. However, research within these shallow-water environments continues to present technological challenges.

INTRODUCTION

The U.S. Geological Survey (USGS) has been heavily involved in geological mapping of the sea floor since the 1960's; fulfilling its mission to provide objective scientific information to the research community, federal and state governments, and the public. Over the past thirty years, USGS sea-floor mapping programs have migrated from low-resolution reconnaissance mapping of the deep ocean to detailed, high-resolution mapping of the inner continental shelf and estuarine settings. This migration from deep-

to shallow-water research evolved in order to address pertinent coastal issues such as erosion, sediment availability, sediment transport, geologic controls on shoreline evolution, vulnerability of coastal areas to natural and anthropogenic hazards, and habitat and resource management. Coupled with this shift in scientific focus were technological advances in acoustic, positioning and computing systems that enabled efficient operation within the shallow coastal ocean (Hughes Clarke, 1996; Driscoll, 1999; Lurton, 2002; Mayer, 2006).

Development and use of the high-resolution geophysical systems designed for shallow-water operation has improved our understanding of the processes shaping marine and coastal environments. However, research in the shallow inner shelf continues to present technological challenges due to the dynamics of the environment, high volume of data collected, and the geophysical limitations of operating in shallow water. This paper describes the evolution of the sea-floor mapping operation at the USGS. Examples of deep-water and inner-shelf studies are presented to illustrate the evolution and integration of emerging technology and demonstrate the contribution to advancements in coastal geoscience.

DEEP-WATER MAPPING: THE EEZ (1980's)

In 1984, the USGS began an eight-year program to conduct the world's first reconnaissance mapping of the sea floor within the Exclusive Economic Zone (EEZ), an area extending from 3 to 200 nautical miles off the coast of United States territories. The United States claimed sovereign rights and jurisdiction to all natural resources within the EEZ in 1983. With the formation of the EEZ, the USGS mandate to map territorial lands extended to the newly claimed submarine lands. The objective of the USGS 'EEZ-SCAN' mapping effort was to identify and define the natural resources, physiography and geologic processes acting within the EEZ in order to assess the resource potential and consequences of exploration to the sea-floor environment. Ultimately, the results from these extensive mapping efforts would also provide a base for future site-specific geologic and oceanographic studies (Gardner and others, 1996).

Mapping the vast territories of the EEZ presented technological challenges. Many sonar systems of the early 1980's were not practical for use in deep-water reconnaissance mapping due to their limited swath width and bottom coverage (Gardner and others, 1996; Mayer, 2006). The most economical use of time and funds was to utilize a wide-swath sonar that could efficiently map the sea floor within the deep waters (> 200 m) of the EEZ (Gardner and others, 1998). Thus, the United Kingdom's Institute of Oceanographic Sciences (IOS), GLORIA II (Geologic LOng Range Inclined ASDIC) sidescan-sonar system was selected because of its wide-swath reconnaissance mapping capabilities. GLORIA II was a long-range, low-frequency (6.5 kHz), digital sidescan-sonar capable of achieving swath widths on the order of 10's of kilometers and resolving features on the order of 50 - 100 meters. By June 1991, the USGS and IOS scientists had successfully mapped over six million square kilometers of the deep-waters of the EEZ at close to 100% bottom coverage. Seismic-reflection profiling, gravity, magnetic and ground-truth surveys were also conducted in order to define the geologic framework

within the deeper regions of the EEZ (Gardner and others, 1996).

GLORIA II demonstrated that systematic, reconnaissance mapping of the sea floor was possible (Figure 1). Interpretation of these and other geophysical data provided insight into geologic processes that contribute to the formation and development of continental margins, tectonics, earthquake and volcanic activity, and sedimentary processes acting within the EEZ (Gardner and others, 1996). Additionally, the challenge of maintaining and operating GLORIA II and managing digital data led to the development of new methodologies and computing software for data acquisition and processing; specifically in development of digital sidescan-sonar mosaicking techniques (Chavez, 1986; Gardner and others, 1996).

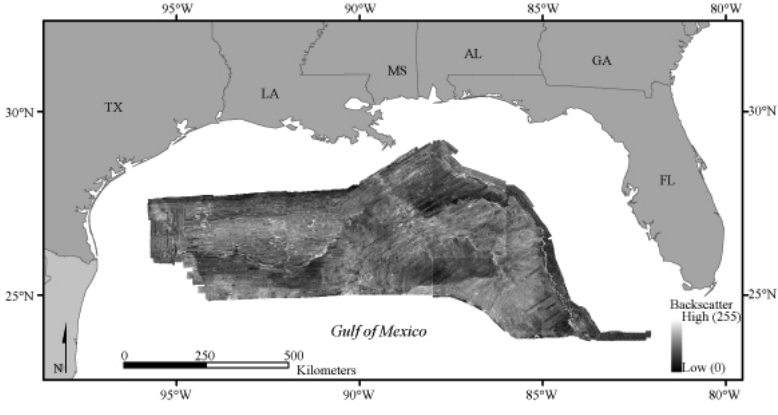

Figure 1: GLORIA II imagery collected within the Gulf of Mexico, 1982 – 1991. High backscatter is represented by light tones within the imagery and low backscatter is represented by dark tones.

SHALLOW-WATER MAPPING, PART I: THE INNER SHELF (1990's)

GLORIA II proved an effective reconnaissance mapping tool for deep-water, however it was not designed for surveying the relatively shallow waters of the inner-continental shelf; leaving the most heavily used portion of the sea floor unmapped. The migration from low-resolution (10's of meters) reconnaissance mapping of the deep-waters of the EEZ to high-resolution (meters), regionally-focused mapping in the shallow-waters (< 50 m) of the inner continental shelf was ultimately spurred by technological advances in sonar, navigation, ancillary systems and computing power of the late-1980's and early 1990's (Gardner and others, 1998; Pickrill and Todd, 2003; Mayer, 2006). Advancements in frequency-modulated (chirp) technology allowed for improved range and resolution in sidescan-sonar, and increased vertical resolution in seismic-reflection systems (Parent, 1993). Additionally, developments in positioning systems improved data accuracy. The USGS implemented these latest technologies to initiate inner shelf

studies designed to provide detailed, geologic framework (surficial and sub-surface) information to guide marine and coastal resource management and to support additional site-specific studies.

The use of improved mapping systems required the collection of large volumes of data due to high repetition and sample rates. Data volumes climbed from 10's of megabytes per day during early sea-floor mapping operations, to 100's of gigabytes per day by the end of the 1990's. Data management and processing software modifications were necessary in order to accommodate the higher data volumes and extract additional information contained within the higher bandwidth (Danforth and others, 1991; Cohen and Stockwell, 2001; Paskevich, 1992; Henkart, 2005). Also, continued development of data visualization and data integration software began to alter the way in which geophysical data were analyzed and presented (Lurton, 2002; Mayer, 2006). During this time, the USGS looked to streamline sea-floor mapping operations and refine data acquisition and processing techniques in order to build on these developments. By the mid- to late- 1990's, equipment was in place to accomplish these goals on a routine basis; systematic, high-resolution mapping of the inner shelf became a core component to USGS shallow-marine geologic studies.

In 1995, the USGS began a five-year collaborative research effort with the U.S. Army Corps of Engineers (USACE) New York District to map the surficial geology and shallow stratigraphy of the inner shelf offshore of New York-New Jersey. This mapping effort integrated high-resolution geophysical and sampling techniques (Figure 2) to define sea-floor physiography, the structure and geometry of underlying strata and its role in the evolution of this coastal region, and assess sand resource availability (Schwab and others, 1997; 2000; 2003). By achieving 100% sea-floor coverage, acquired primarily with chirp sidescan-sonar along with a dense grid of chirp seismic-reflection profiles, this study provided detailed views of the small-scale heterogeneity of the sea floor within a ~200 km long by 10 – 30 km wide area (Figure 3). This new view of the sea floor and its variability highlighted the variety of processes shaping the inner shelf and the importance of the underlying geologic framework in controlling the sea-floor geology. The data proved essential for assessing anthropogenic impacts to the sea-floor environment and addressing marine and coastal resource management issues (Schwab and others, 1997; 2003; Butman and others, 2002).

Although, the sidescan-sonar imagery and closely spaced high-resolution seismic-reflection profiles greatly improved our understanding of the sea-floor geology, the ability to map the geomorphology of the sea floor was limited. Traditionally, as part of any sea-floor mapping effort, the USGS acquired bathymetry with single-beam echosounders to define the gross morphology of the sea floor; bathymetric systems were supplemental to sidescan-sonar and seismic-reflection systems due to their low resolution and limited bottom coverage. However, the advent of high-resolution multibeam echosounders enabled mapping of sea-floor morphology at sub-meter scales; defining the complexity and heterogeneities of the sea bed in new detail (Hughes Clark and others, 1996; Locat and Sanfaçon, 2002; Pickrill and Todd, 2003; Mayer, 2006).

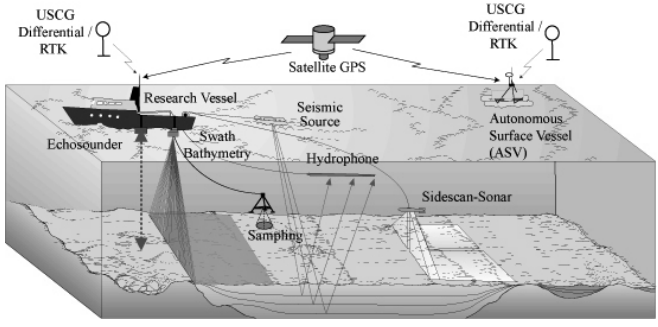

Figure 2: Illustration of the systems used to define the surficial sediment distribution, sea-floor topography, and underlying geologic structure.

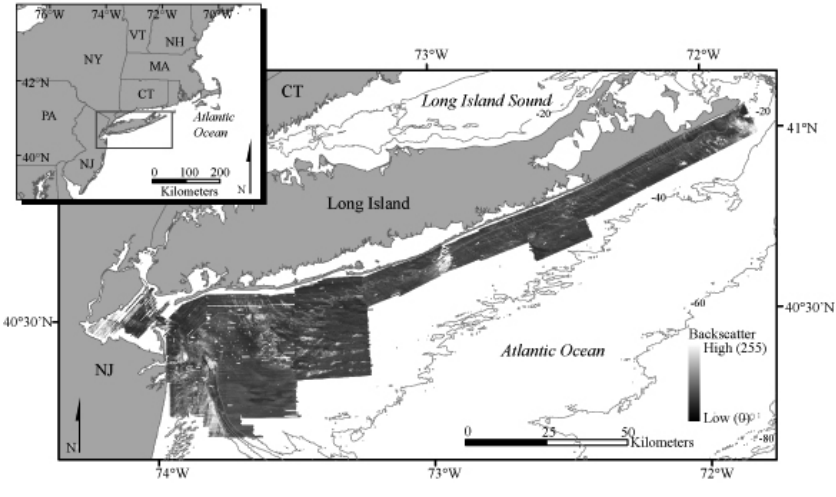

Figure 3: Sidescan-sonar mosaic collected within the New York Bight, 1995 - 1998. High-backscatter is displayed as light tones within the imagery, low-backscatter as dark tones. Bathymetric contours are in meters. Inset shows regional location.

Concurrent with the start of the New York-New Jersey mapping effort, was a collaborate research effort off the coast of New England involving the USGS, University of New Brunswick (UNB), Canadian Hydrographic Service (CHS), and National Oceanic and

Atmospheric Administration (NOAA) to map the Stellwagen Bank National Marine Sanctuary (SBNMS) and western Massachusetts Bay using multibeam echosounder technology (Figure 4). These mapping efforts defined the distribution of surficial sediment, sea-floor morphology and biological habitats in order to: 1) foster successful management of natural resources within SBNMS, and 2) to assess sediment and pollutant transport within Massachusetts Bay (Valentine and others, 1998; Butman and others, 2004; Valentine, 2005).

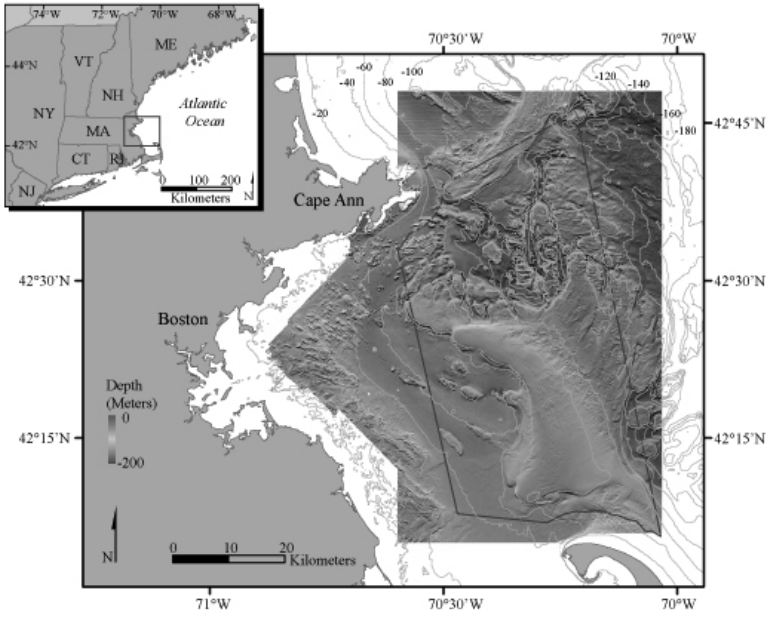

Figure 4: Shaded-relief bathymetry collected with a multibeam echosounder off the coast of Massachusetts, 1994 – 1999. Red box indicates area of Stellwagen Bank National Marine Sanctuary (SBNMS). Inset shows regional location.

An interesting by-product of the multibeam echosounder surveys off the New England coast was its large impact on the broader oceanographic research and management communities. Interpretive maps generated from these high-resolution data and subsequent sampling programs within SBNMS and western Massachusetts Bay, provided insight into the distribution of benthic habitats, the relationship between biologic communities and physiography of the sea floor, and geologic, oceanographic and biologic processes modifying the sea floor (Butman and others, 2004;Valentine, 2005). Additionally, these data have provided critical information for fisheries research, and environmental and resource management (Auster and others, 2001; Valentine, 2005).

SHALLOW-WATER MAPPING, PART II: THE COASTAL ZONE (1999 – 2004)

The introduction of multibeam echosounders into sea-floor mapping operations enhanced interpretations of sea-floor geology by providing highly detailed images of sea bed topography and acoustic backscatter (Gardner and others, 1998; Butman and others, 2002; 2004; Schwab and others, 2003; Pickrill and Todd, 2003; Valentine, 2005). Use of multibeam echosounders in USGS research continued, primarily through collaborative efforts with universities, other Federal agencies and the private sector (Butman and others, 2003; 2006). However, as USGS research interests moved into coastal and estuarine environments (water depths ranging from 2 to 30 meters), the use of multibeam echosounders for 100% coverage of the sea floor became impractical due to their limited bottom coverage in shallow water (swath widths on the order of 3-5 times water depth). In order to efficiently and economically map sea-floor topography within the nearshore environment, the USGS looked to incorporate a bathymetric system that could achieve wide swath widths in shallow water and be easily configured to run concurrently with existing geophysical systems (Figure 2). In the late 1990's, interferometric sonars had developed into viable shallow-water, wide-swath bathymetric surveying systems, generally achieving swath widths on the order of 7-10 times water depth (Geen, 1999). These systems have multiple (two or more), parallel receiving elements in the sonar transducers. A comparison of the phase of the return signal between the receive elements is used to determine depth to the sea floor (Geen, 1999). Acoustic backscatter data similar to data collected with traditional sidescan-sonar systems are also acquired (Geen, 1999; Lurton, 2002). In 1999, the USGS took delivery of an interferometric sonar to augment inner shelf geophysical studies. Additionally, further advancements in chirp seismic-reflection systems at this time allowed for increased vertical resolution of the subsurface and enabled high-resolution mapping of the shallow stratigraphy (Driscoll, 1999; Baldwin and others, 2004). Fine-scale (sub-meter to meter) geomorphology of the sea floor could now be defined through integrated use of these surficial and sub-surface mapping systems.

The first use of interferometric sonar and improved chirp seismic-reflection systems was along the northern coast of South Carolina as part of a regional coastal erosion study. In 1999, the USGS in partnership with the NOAA South Carolina Sea Grant Consortium (SCSGC) began a study to investigate inner continental shelf and shoreface processes offshore of the Grand Strand, SC (Figure 5). The objectives of the USGS/SCSGC cooperative program were to define the shallow geologic framework and its role in coastal evolution; to identify and model the physical processes affecting coastal ocean circulation and sediment transport; and to identify sediment sources and transport pathways (Gayes, 2003; Baldwin and others, 2004; Sullivan and others, 2006; Denny and others, 2007). Incorporation of the new technologies provided highly-detailed imagery of the region, identifying a complex, condensed stratigraphy capped by an extremely sediment-limited, modern coastal system (Figure 6). These data improved our understanding of long-term changes in sea level, sediment supply and coastal geomorphology, allowing for reconstruction of an extensive paleofluvial system and identification of several relict, inner-shelf sediment bodies (Baldwin and others, 2006;

Denny and others, 2007; Barnhardt and others, 2007 (this volume)). See Barnhardt and others, 2007 (this volume) for a more detailed description of the scientific findings.

VERY SHALLOW-WATER MAPPING: ESTUARIES (2004 - 2006)

High-resolution geophysical and sampling systems were routinely used in all inner shelf mapping studies by the end of the 1990's. By early 2000, USGS research interests began migrating farther inshore. Studies were focused on addressing the spatial and temporal variability of nearshore sedimentary processes and shallow geologic framework on a variety of time scales, and their implications for coastal evolution. The dynamics of operating within nearshore environments due to shallow depths, high-energy conditions, and high data volumes posed new challenges to geophysical surveying.

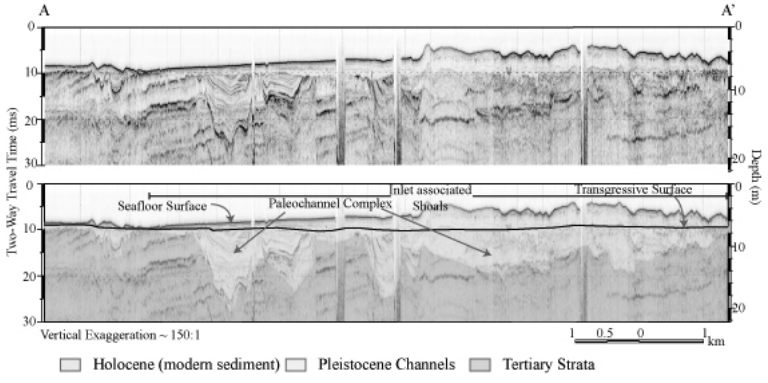

Figure 6: Example of chirp seismic-reflection profile collected offshore of the Grand Strand, South Carolina showing the thickness of modern sediment above the transgressive unconformity and structure of underlying strata. See Figure 5 for location.

In 2004, the USGS, in cooperation with NOAA Coastal Services Center and the Apalachicola National Estuarine Research Reserve, began a study to define the distribution of oyster resources within Apalachicola Bay, Florida. The bay is located in the northern Gulf of Mexico along the Florida panhandle (Figure 7) and is the largest oyster fishery in Florida and the third largest within the United States. Potential changes to the influx of fresh water due to dam placement on the Apalachicola River system and coastal development may prove harmful to the oyster fishery. The USGS/NOAA collaborative effort was designed to map the present distribution of oyster beds and the shallow geologic framework, in order to provide baseline information on the benthic resources within the bay.

Geophysical mapping within Apalachicola Bay presented technological challenges that required modification of standard surveying techniques. The bay is very shallow, ranging from 0.5 to 5 m water depth, with oyster beds concentrated in water depths < 2 m. Additionally, the waters are very turbid, precluding the use of aerial mapping technologies such as bathymetric LIDAR (Light Detection and Ranging). The deeper waters of the bay (> 2 m) were successfully mapped with sidescan-sonar, chirp seismic-reflection, and interferometric sonar systems deployed from a 25-foot, shallow-draft research vessel. However, the oyster beds remained inaccessible due to their location in shallow depths. In order to operate in such extremely shallow waters, the USGS collaborated with engineers in the private sector to develop a shallow-draft Autonomous Surface Vessel (ASV) configured with chirp sidescan-sonar and seismic-reflection systems, and a single-beam echosounder (Figure 8). The ASV was first deployed in June, 2006 and acquired imagery of the sea bed and underlying strata in shallow, previously inaccessible areas that enhanced interpretations of the shallow geologic framework within the bay. Operation and testing of the ASV is on-going. Modifications

to acquisition and processing methodologies will continue in order to maximize data quality and functionality of the vehicle.

FUTURE DIRECTIONS

The interplay of science and technology will continue to enhance research within the broader oceanographic community. Further advancements in sonar and positioning technology will allow for finer spatial and temporal resolution; defining sea-floor geology in ever greater detail. Continued improvements in visualization and data integration will further alter the way in which marine geophysical data are analyzed and presented. And, new developments with surface vessels such as the ASV will enable more efficient operation within the shallow-marine environment to bridge the gap between marine and onshore geology.

CONCLUSION

Sea-floor mapping has evolved from reconnaissance, wide-swath mapping in the deep ocean areas to high-resolution mapping of the inner continental shelf to the very shallow estuarine settings. Significant technologic advances have enabled changing research directions that increasingly focus on the shallow coastal ocean. Advances in sonar design, positioning, and computing power have produced systems for mapping and visualization of the sea floor and subsurface in unprecedented detail. Integrated use of surficial, sub-bottom, and sampling instruments within inner shelf geologic studies has contributed to enhancing our understanding of modern sedimentary processes, sea bed dynamics and the evolution of coastal systems.

ACKNOWLEDGEMENTS

We would like to thank all of our colleagues who have contributed to the growth and success of the USGS mapping efforts, specifically Dave Russ, John Haines, Debbie Hutchinson, Jeff Williams, John Hughes Clarke, Larry Mayer, Neal Driscoll, Larry Kooker, Mike Boyle, VeeAnn Cross, Ken Parolski, Valerie Paskevich, Dann Blackwood, Chris Polloni, Shawn Dadisman, Kathy Scanlon, Larry Popppe, Uri ten Brink, Ann McKinney and Paul Gayes. We would also like to thank Walter Barnhardt and John Warner for the reviews of this manuscript.

A RAPID COMPATIBILITY ANALYSIS OF POTENTIAL OFFSHORE SAND SOURCES FOR BEACHES OF THE SANTA BARBARA LITTORAL CELL

Abstract: The beaches of the Santa Barbara Littoral Cell, which are narrow as a result of either natural and/or anthropogenic factors, may benefit from nourishment. Sand compatibility is fundamental to beach nourishment success and grain size is the parameter often used to evaluate equivalence. Only after understanding which sand sizes naturally compose beaches in a specific cell, especially the smallest size that remains on the beach, can the potential compatibility of source areas, such as offshore borrow sites, be accurately assessed. This study examines sediments on the beach and in the nearshore (5-20m depth) for the entire Santa Barbara Littoral Cell east of Point Conception. A digital bed sediment camera, the Eyeball©, and spatial autocorrelation technique were used to determine sediment grain size. Here we report on whether nearshore sediments are comparable and compatible with beach sands of the Santa Barbara Littoral Cell.

INTRODUCTION

Beaches are extremely important in California: they provide a large recreational area for an ever increasing tourist and coastal population, they offer invaluable protection to bluffs, cliffs and back beach development from direct wave attack, and they provide unique habitats supporting many diverse species. In addition, the beaches of California benefit not only the economy of local communities and the state, but also the entire United States (King 2002; King and Symes 2003). Most of the beaches of the eastern Santa Barbara Littoral Cell (from Point Conception to Point Mugu) are naturally narrow (Flick 1993; Wiegel 1994). Although beach widths fluctuate in response to seasonal and

climatic cycles (e.g. PDO, ENSO), there is data suggesting that the beaches of this cell are also narrowing in response to human activities (Runyan and Griggs 2003; Willis and Griggs 2003; Revell and Griggs 2006). Because the beaches of California are a valuable natural resource, it is important to consider approaches to expand the existing beaches to a healthy width that will allow the surrounding coastal communities to maintain beaches that are safe and appealing for recreation, suitable for existing biological diversity, and are economically productive.

One possible way to widen a beach is through nourishment, or the addition of sediment to the beach. For a nourishment project to be successful, however, suitable sediment-sand with a grain size equivalent to or slightly coarser than sand found naturally on the beach-must be used (National Research Council 1995; Dean 2002; U.S. Army Corps of Engineers 2002). In this study we have surveyed the Santa Barbara Littoral Cell beaches and nearshore inner shelf to inventory natural grain size distributions and determine whether suitable material for nourishment exists offshore. Traditional methods of grain size analysis require considerable time to process samples, whether through sieving or settling. As an alternative, we used a relatively new method, the USGS-developed digital bed sediment Eyeball© camera and autocorrelation algorithms, to rapidly collect and process over 400 sediment samples (Rubin 2004; 2006). The speed and efficiency of both the collection process and the grain size determination technique have allowed for an unprecedented amount of data to be gathered quickly (within a summer) for the study area, thus allowing us to quickly assess the broad compatibility of inner shelf and onshore sediments throughout a very large area-about 149 km (~93 miles) of coastline.

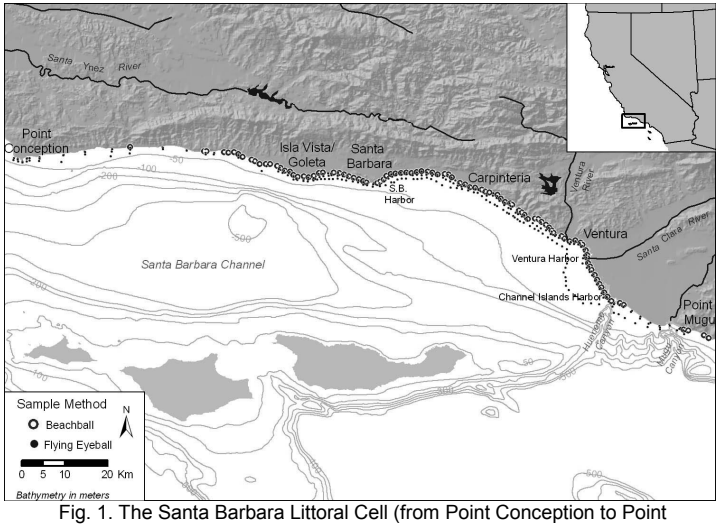

Fig. 1. The Santa Barbara Littoral Cell (from Point Conception to Point Mugu), with beach (Beachball) and nearshore (Flying Eyeball) sampling locations.

BACKGROUND

The Santa Barbara Littoral Cell, east of Point Conception, extends 149 km southeast, terminating at the Hueneme and Mugu Submarine Canyons (Fig. 1). In the west, the majority of the south facing coastline consists of thin, narrow beaches backed by vertical sedimentary cliffs. South of the Ventura River, the coast opens up into a large, populated alluvial plain, fronted by wider beaches and coastal dunes. Sediment is supplied to the cell from north of Point Conception, coastal cliffs and small coastal streams along the northern Santa Barbara Channel, and two large rivers (the Ventura and Santa Clara) in the eastern portion of the cell (Patsch and Griggs 2005). Sediment is transported through the cell primarily by longshore currents, which flow dominantly from west to east due to the common oblique wave approach. Although waves drive the longshore current, the wave climate is generally mild along most of the south-facing coast. This is a result of the coastal orientation which limits wave exposure: waves must enter the Channel directly from the west, bend around Point Conception from the north, or pass between the Channel Islands from the south. From Isla Vista to the Mugu Naval Air Base human development dominates the coast. In addition to building coastal protection structures directly on the beach, people have also extensively developed atop coastal dunes, bluffs and reclaimed wetland areas.

Nourishment may be a solution to the problem of narrow beaches, although many concerns still exist (Griggs 2006; Patsch and Griggs 2006). One issue along this coast is that a very large volume of sediment would be needed for a successful project, as the rates of littoral drift are very high throughout the cell; rates are estimated to be ~300,000 yds^3/yr at the Santa Barbara Harbor, ~600,000 yds^3/yr at the Ventura Harbor and ~1,000,000 yds^3/yr at the Channel Islands Harbor (Patsch and Griggs 2005). As a result of the large volume of sediment needed for nourishment, offshore sediment sources, as opposed to inland sources, may be the more economical option (Patsch and Griggs 2006). When initially locating a suitable offshore source, or potential borrow area, sediment characteristics, environmental impacts and dredging feasibility, both technological and economical, must be considered (National Research Council 1995; McLellan and Hopman 2000; Dean 2002).

Sediment characteristics, such as grain size, sorting, and thickness, in the potential borrow area are very important. Sediment that is too fine-grained is not suitable nourishment material: fine sediment will not remain on the beach, is undesirable by the user population and may also store contaminants (National Research Council 1995). Previously, the sand-silt cutoff diameter, 0.0625 mm, has been used to determine what could be placed on the beach. However, recent studies have shown that on some of California's high-energy beaches very fine-grained sand, or in some cases, even fine-grained sand, is not stable (Limber et al. in press). As a result d_{10}, or the finest 10% of a sample's sediment distribution, has been used to define the littoral cutoff diameter (LCD), or the smallest size of grains that are present or stable on any particular beach (Best and Griggs 1991; Runyan and Griggs 2003; Limber et al. in press).

Offshore California, there is generally a gradation from coarser to finer sediments

moving offshore and typically coarser sediments (consistent with a transgressive shoreline) in the subsurface. Processes that operate along the coast-wind, wave and current driven-control the ultimate site of sediment deposition. Coarse sediments can be deposited in high-energy environments, while fine sediments are kept in suspension until they are transported into calmer environments where they can settle out. The California coast is dominated by very fine sands and mud; however, the Offshore Surficial Geology Map of California also indicates that there may be medium and coarse sands, suitable deposits for beach nourishment, offshore (Welday and Williams 1975). Deposits of coarse sediment may be found in localized, present-day high-energy environments, or as relict beach or channel deposits trapped within tectonically controlled structural highs and lows which were deposited when sea level was lower (Welday and Williams 1975; Fischer 1983).

Recently, the USGS has compiled data on seafloor sediment characteristics, including surficial grain size from cores, into a comprehensive database, usSEABED (Reid et al. 2006). Some nearshore cores reported in usSEABED are inconsistent with the Offshore Surficial Geology Map of California: instead of coarse and medium-grained sand, cores contain very fine sand or silt (Welday and Williams 1975; Reid et al. 2006). While these differences may represent natural changes within a dynamic environment, the change may alternately result from limitations of the Welday and Williams map. The Offshore Surficial Geology Map was compiled from various sources which were collected between 1855 and 1975. Currently there is no detailed information about data density, data quality or the original data collection methods or classification schemes. In addition, fine sands and very fine sands were mapped together as one unit, and if the specific class of sand was undefined in the original data set, it was mapped as medium sand by Welday and Williams. The present study will rework and update this surface sediment map for the innershelf.

Previous studies have surveyed the continental shelf, with geophysical profiling and coring, to assess offshore sand sources in various locations of the Santa Barbara Littoral Cell (Noble Consultants 1989). This study takes a different approach to locate additional suitable sand deposits; we examine and map mean surface grain size over a wide area of the inner shelf using the Eyeball© camera and spatial autocorrelation algorithm. The major shortcoming of this method is that only surface grain size is captured. However, this bias can be limited by testing Eyeball© images with grab samples that penetrate several centimeters beneath the surface. The major advantages of this method are the extensive amount of area that can be covered as a result of the speed of the collection method, the number of samples that can be processed as a result of the rapid grain size determination method, and that samples can be taken in very shallow depths-as shallow and close to shore as small coastal research vessels can safely transit.

METHODS

The field survey was designed to collect samples along a cross-shore profile, from the beach and the nearshore at 5, 10 and 20 m water depth, with transects spaced at least every kilometer alongshore, throughout the entire Santa Barbara Littoral Cell (Fig. 1). To

compare seasonal grain size variations, beach samples were also collected in March and October (winter and summer samples) at Isla Vista/Goleta, Carpinteria, and Ventura at a higher spatial resolution.

Two different Eyeball© camera systems were used to collect digital samples. Swash samples were collected with the Beachball© camera, a 5-megapixel digital camera encased in a waterproof housing (Rubin 2006). To sample the beach, the camera is placed flush against the sediment, which is illuminated by a ring of LED lights. Camera settings such as aperture, shutter speed, zoom, focus, and pixel resolution of the image are held constant. Nearshore samples were collected with the underwater Eyeball© version, the Flying Eyeball©, which is a video camera illuminated by LED lights encased in a wrecking ball (Rubin 2006). Live video is reviewed on deck while the instrument is repeatedly raised and lowered to the seafloor to collect digital video samples. The clearest frames of video are then captured as still images and processed for grain size. For both systems, multiple images are taken at each location and later averaged into one grain size result.

Images are processed by running a Matlab© script that uses a spatial autocorrelation algorithm developed by Rubin (2004). This algorithm determines the correlation (as measured by pixel intensities) between a pixel and subsequent pixels at increasing distances. Grain size of an image is then interpolated by comparing the spatial autocorrelation result to a calibration matrix. The calibration matrix contains spatial autocorrelation results of calibrated sample images and was produced by imaging ¼ phi interval sieved sediment collected from throughout the study area with the same equipment and camera settings as used in the field. The calculated calibration matrices are valid only for sediment of similar size, shape and mineralogy as the sediment initially sieved and imaged. Figure 2 shows the mean grain size determined from the autocorrelation method compared to mean grain size from both processing samples in a settling tube (Fig. 2b) and from point counting, or calculating the mean of an image by hand-measuring the size of 100 grains in the image (Fig. 2a).

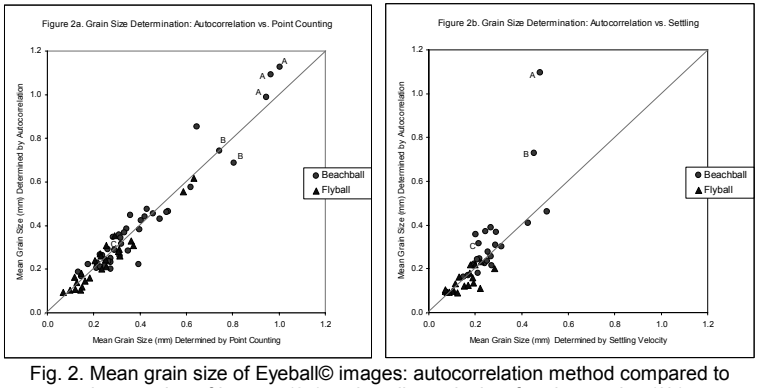

Fig. 2. Mean grain size of Eyeball© images: autocorrelation method compared to point counting of images (2a) and settling velocity of grab samples (2b). Samples A, B, and C are labeled in both 2a and 2b.

On the beach, there is a potential bias for sampling coarser surficial sediments (Fig. 2b). This may occur if fine sediments have been winnowed away or if a coarsening-upward sequence has developed. Beach samples that fall off the 1:1 line of correlation in Figure 2b may be a result of either of these two processes. However, the autocorrelation method is still valid-samples off the 1:1 line in 2b, appear near the 1:1 line in 2a-since point counting determines whether the algorithm accurately determines grain size of the image. In the nearshore, there is a potential bias for surface sediments to be finer than the immediate subsurface layer (Fig. 2). Consistent with rising sea level, this may be a result of recent fine sediment deposition. Alternately, fine sediments could have been winnowed or washed while bringing the grab sampler to the surface, resulting in grab samples appearing coarser than they actually were.

The autocorrelation method, especially when using the Flying Eyeball©, is limited by pixel resolution: once grains become very small (as small as or smaller than two or three pixels) clusters or flocs of small grains begin to look (in terms of correlation) like larger grains. As a result, when nearshore grain size is less than 0.09 or 0.10 mm, the ability to accurately determine grain size by the autocorrelation method is diminished. However, this is not a significant problem for this study because the aim of offshore sampling is to determine if beach compatible material exists, and from the following conclusions, an acceptable grain size cutoff for the Santa Barbara Littoral Cell beaches is 0.125 mm, making the Flying Eyeball© results adequate and this study applicable.

RESULTS

The mean grain size of 93 swash zone samples from throughout the Santa Barbara Littoral Cell ranged from 0.15 mm to 0.43 mm (fine to medium sand; Fig. 3). The mean of one sample just north of the Port Hueneme Harbor was 0.60 mm, or coarse sand. The average of all (94) samples was 0.27 mm. Grab samples were well sorted: in most cases, 80% of a sample's grain size was distributed across only one phi interval. The finest sediment on the beach (d_{10}) varied from location to location, but followed the mean well (when the mean increased so did d_{10}). Very fine-grained sand did not remain on the beach in any significant amount anywhere throughout the cell (Fig. 3). Mean grain sizes of summer swash samples were smaller than winter swash samples throughout the beaches of Isla Vista/Goleta, Carpinteria, and Ventura. Grain size in the southeast decreased seasonally more than in the northwest: Ventura beaches seasonally fined an average of 0.15 mm, Carpinteria beaches fined an average of 0.08 mm, while Isla Vista/Goleta beaches fined an average of only 0.05 mm.

Throughout the cell, 319 nearshore locations were examined, although some areas were cobble or bedrock reefs, which did not allow for grain size determination. Mean grain size was determined for about 100 samples at each water depth (5, 10, and 20 m). Grain size fined moving from the beach offshore (Fig. 4). Only 2% of all samples were medium

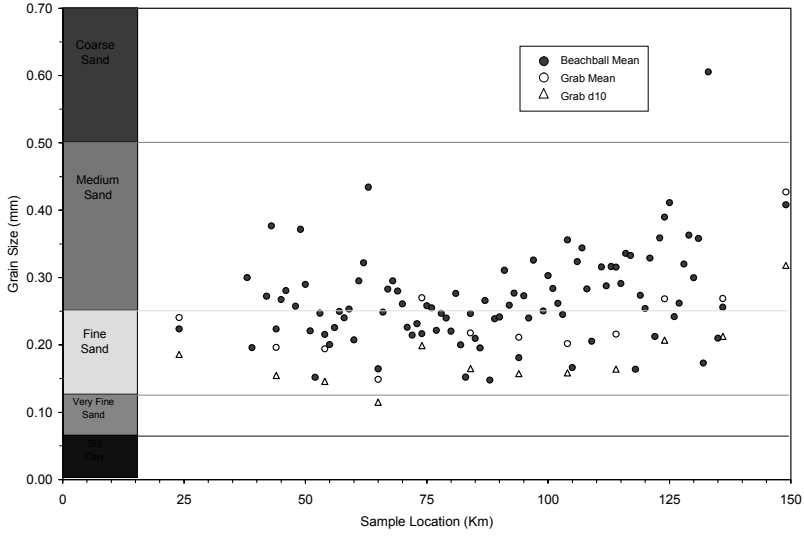

Fig. 3. Mean grain size and d_{10} of beach samples. Horizontal axis is distance east of Pt. Conception.

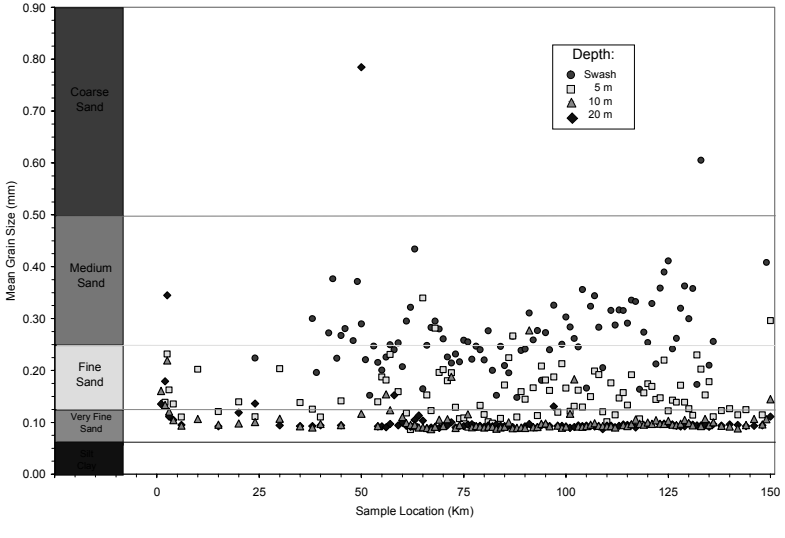

Fig. 4. Mean grain size of beach and nearshore samples. Horizontal axis is distance east of Pt. Conception.

sand, 24% were fine sand and 74% were very fine sand or smaller. The coarsest samples were found in shallow depths: 82% of all samples coarser than very fine sand were located in 5 m water depth. Only 5% of all Flying Eyeball© (15 samples) found in 10 or 20 m water depth were coarser than very fine sand. Some of these coarser, deep samples were located near major headlands, such as Point Conception and Point Mugu, near offshore reefs, such as west of Coal Oil Point in Isla Vista and Sand Point in Carpinteria, or offshore rivers and streams, such as Gaviota Creek and Rincon Creek. Samples coarser than very fine sand not located near headlands, were likely to be fine sand (75%) rather than medium or coarse sand (25%).

DISCUSSION

The majority of Santa Barbara Littoral Cell beach sediment is fine to medium-grained sand (Fig. 5). When the cell is divided based on physical setting by the Ventura River (location #117), beach sand in the western portion of the study area is finer grained than in the eastern portion. This is likely a result of regional differences in both sediment inputs and coastal processes. For example, if the Ventura and Santa Clara rivers in the southeast deliver a coarse load, and if the fine-grained bluffs of the west contribute fine sediments to the beach, than the resulting beach grain size could be a result of sediment source grain size. Differences in wave energy and nearshore current velocities are also important in determining what sediment grain sizes compose the beach. Coarser beaches in the east are more exposed to high wave energy as compared to finer beaches in the west/central, which are more sheltered from the dominant wave energy. (Beaches at the westernmost end of the Channel would also be exposed to greater wave energies and may also be comparatively coarser, but these beaches were not sampled.) Seasonal alongshore variation, as measured by the magnitude of grain size change, may be a result of alongshore differences in both sources and processes acting on each particular beach.

Summer grain size distributions represent the finest sediment that remains on the beach. An examination of the grain size distribution of summer grab samples indicates that nowhere in the cell does the sand/silt break define what grain sizes compose the beach. Runyan and Griggs (2003) previously determined that the average Santa Barbara LCD was about 0.125 mm. However, results from this study indicate that a single value cannot accurately define what remains on the beaches throughout the entire cell. When nourishing a beach, the appropriate cutoff diameter, specific to that beach, should be used. In general terms, when assessing potential offshore sources for the cell, the boundary between fine sand and very fine sand (i.e. 0.125 mm), can be used as a general LCD because this value will not underestimate what will remain on the beach. However, in some cases-possibly more in the eastern portion of the study area-this value may be an extreme overestimation.

As expected, finer sediments are found offshore. Coarser sediments are not transported into deeper waters since they are not easily kept in suspension; instead they settle nearshore. Overall, the coarsest offshore sediments exist in an extremely narrow zone close to shore, probably within the depth of closure. These fine and medium-grained sands are likely an active part of the littoral drift system and anchor the submarine beach

Flying Eyeball Samples, eastern Santa Barbara Littoral Cell.

profile. As a result these coarser, shallow sediments should only be considered sources for beach nourishment with a thorough evaluation of the coastal impact. This includes sediment within 5 m and other deeper areas affected by higher energy.

The coarsest offshore sediments deeper than 5 m are found at only a few locations throughout the cell (Fig. 6 and 7). Coarser sediments are commonly found near major headlands, such as Point Conception and Point Mugu, as a result of the steeper nearshore slopes and/or higher energy environment. As a result of additional energy focused onto the headland and because these sediments are located close to shore, within ¾ of a km at Point Conception, these deep, coarser sediments may still be part of the active littoral drift system, within the depth of closure. However, more information is needed. If it is confirmed that these deposits are part of the active littoral system, then they should not be dredged. However, if they are not, then thickness of the deposit and the economics of dredging these areas should be evaluated-keeping in mind that these sediments are located far from populated beaches needing nourishment.

If Point Conception is not considered too far to serve as a potential borrow area, then one other site should be examined: an offshore geology map indicates a large sand deposit just offshore of Point Conception (Greene and Kennedy 1989). The sediment here could be a final sink for the Santa Maria Littoral Cell (a debated cell extending from the Santa Maria River to Point Conception), or if there is a single continuous cell around the point, then this deposit could be a partial sink within the Santa Barbara Littoral Cell (Patsch and Griggs 2005). Either way the deposit is likely to have accumulated as a result of the longshore current deflecting sediments offshore as it encounters the headland. Further investigation of the area is recommended; both sediment thickness and grain size data should be obtained.

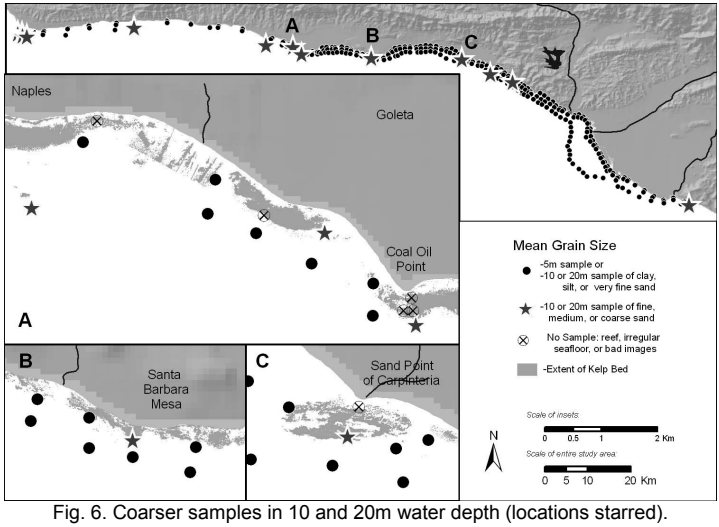

Fig. 6. Coarser samples in 10 and 20m water depth (locations starred). Insets show coarser samples and proximity to kelp beds.

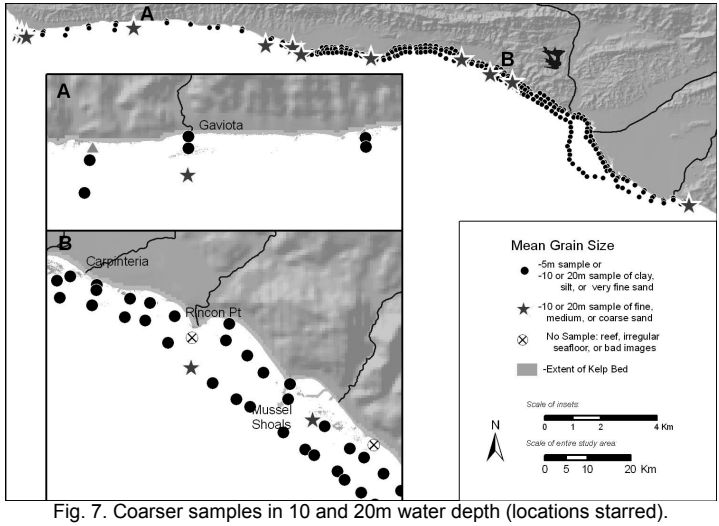

Fig. 7. Coarser samples in 10 and 20m water depth (locations starred). Insets show coarser samples and proximity to kelp beds and streams.

Sample locations of coarser sediment found deeper than 5 m, were examined with respect to distance from kelp beds, a proxy for exposed bedrock outcrops on the seafloor (Fischer 1983; California Department of Fish and Game 2006). Sediments found near rocky reefs are likely to be composed of coarser broken reef fragments which have accumulated in reef pockets. These deposits are presumably very thin and therefore not viable for dredging. The samples west of Coal Oil Point and offshore of Sand Point in Carpinteria are in very close proximity to the mapped kelp beds (Fig. 6). In addition it was noted in the cruise field notes that the Flying Eyeball© had to be navigated through kelp to reach the seafloor at these locations. As a result, these coarser deposits are most likely only thin deposits within reef pockets and are therefore not considered suitable borrow areas for beach nourishment. For a few locations, south of Coal Oil Point, Naples, and the Santa Barbara Mesa, it is not clear whether coarser samples are related to the nearby reefs (Fig. 6). All three of these samples were in close proximity to kelp; however, the isopach maps of Fischer et al (1983) indicate that the unconsolidated sediment is at least 4 m thick at each of these locations.

Coarser samples deeper than 5 m are sometimes found offshore rivers and streams (Fig. 7). If these deposits are not relict beaches, than they may be associated with the stream as either part of a paleostream deposit or as a result of a more recent hyperpycnal flow (Fischer 1983; Warrick and Milliman 2003). If the deposit is related to an old stream channel from an earlier sea level, it would be expected to contain coarser sands and gravels, which may or may not be suitable for nourishment. Grain parameters such as shape and roundness, and characteristics such as sorting and layering of grain sizes within the deposit, should be thoroughly examined to determine if sediments are compatible with the beach. In addition, it should be confirmed whether sediment

thickness is sufficient in these areas. The isopach maps of Fischer et al (1983) indicate adequately thick unconsolidated sediments at Gaviota, Rincon Point, and Mussel Shoals. However, while these samples are not located within the present-day kelp cover, they are located within the historic kelp extent as mapped by Fischer et al. (1983).

In addition, because the Flying Eyeball© only samples surface sediments and coarser deposits may exist beneath the surface, it is recommended that complete grain size distribution be obtained offshore Goleta, the Santa Barbara Mesa and Harbor, and the Ventura/Oxnard area (Fig. 8). However, since greater wave energy is received in the eastern portion of the study area, if compatible sediments are found at 10 m water depth in the Ventura/Oxnard area, it needs to be determined whether these sediments reside within the depth of closure before a borrow area is considered.

It is difficult to evaluate how well the results of this study compare to the offshore surficial deposits map, since an overwhelming 98% of the offshore samples observed were very fine sand or fine sand which was mapped as one unit by Welday and Williams (1975). However, some of the smaller pockets of medium and coarse sand delineated by Welday and Williams were found in this study to be composed of fine sand or very fine sand. It is not known however, if this is a result of the original data collection and processing methods, the mapping scheme of Welday and Williams (for example, undefined sand was mapped as medium sand), or as a result of sampling only the very surface with the Eyeball©. Alternately, the observed change may be legitimate and simply the consequence of sediment transport and deposition in a dynamic environment for over 100 years.

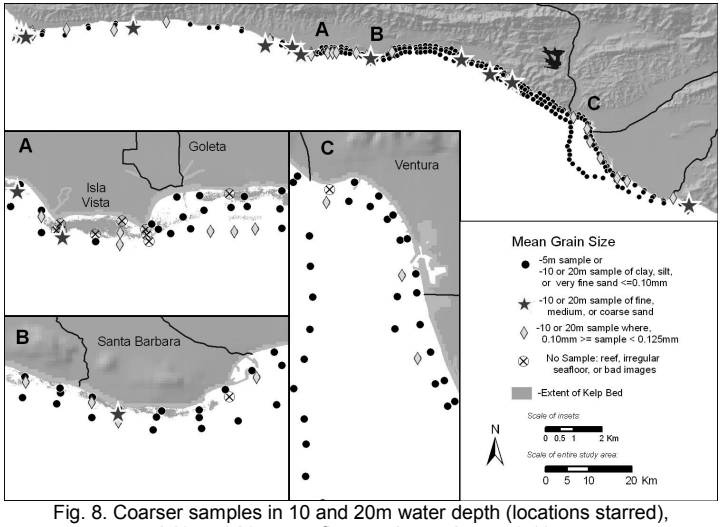

Fig. 8. Coarser samples in 10 and 20m water depth (locations starred), and 10 and 20m very fine sand samples >= 0.10mm.

CONCLUSION

The Eyeball© cameras provide a rapid way to determine the grain size of many surface sediments throughout a very large beach and offshore area. Overall, compatibility is poor between beach and nearshore surface sediments in the Santa Barbara Littoral Cell. The coarsest offshore sediments are found at 5 m, most likely within the depth of closure. Some coarser deposits exist deeper, for example at Naples, Coal Oil Point, the Santa Barbara Mesa, and Rincon Point, but it is unclear whether they are part of a thick deposit of suitable nourishment material, or simply a thin, coarser deposit within reef pockets. Further grain size analysis of cores is recommended to resolve this question. In addition, cores should also be taken at Goleta, the Santa Barbara Harbor, and the Ventura/Oxnard area; surface sediments at these locations were not coarser than very fine sand, but complete grain size distribution should be completed as they showed more promising results of coarser surface sediments and sufficient sediment thickness than most other locations.

ACKNOWLEDGEMENTS

We would like to thank the USGS, California Department of Boating and Waterways, Beach Erosion Authority for Clean Oceans and Nourishment (BEACON), and the City Carpinteria for funding this study. In addition, this study could not have been accomplished without the help of Hank Chezar (with the Flying Eyeball©), Shane Anderson and Dave Farrar of UCSB (for driving the R/V Connell as well as assisting the sample collection process), and also the many volunteers who helped sample the beach and nearshore. Thanks also to the UCSC Coastal Lab who read and greatly improved this manuscript.

Presence of Beach-Compatible Sediments in Offshore Borrows: New Challenges and Trade Offs in Developing Codifications

Charles W. Finkl[1], Jeffrey L. Andrews[1], and Lindino Benedet[1]

1. Coastal Planning & Engineering, Inc., 2481 NW Boca Raton Boulevard, Boca Raton, FL 33431, USA. cfinkl@coastalplanning.net; jandrews@coastalplanning.net; lbebedet@coastalplanning.net

Abstract Appropriate protocols are required for selection of beach-compatible sediments from offshore borrows. Determination of what constitutes 'native' beach sand can be problematic where prior renourishment modifies true native beach sediments. Because borrow sands must at some level approximate 'native beach sediments,' offshore exploration methodologies need to efficiently differentiate bottom sediments into usable and non-usable categories. Sand search models (SSMs) are one approach where exploration protocols are based on literature searches and geophysical-geotechnical techniques that are conditioned by regional geomorphology, sediment dynamics, sedimentary properties, seismostratigraphy (calibrated with vibracores), and deposit morphologies (including facies recognition). Engineering-environmental performance guides attempts to 'match' borrow sediments with existing beach sands, but exact matches always may not be found in offshore materials. This guidance is, in large part, a balancing act that attempts to replicate beach stability and biological beach performance where trade offs are inevitable.

INTRODUCTION

Over the last few decades, beach nourishment has become the method of choice for shore protection (Finkl and Walker, 2002). Most commonly, sediments are dredged from offshore areas, referred to as borrows, and placed onshore as sand-water slurries pumped from the dredge. In the early stages of nourishment when sand was pumped onshore from offshore borrows, the deposited sediment was regarded as 'fill' that met volumetric needs to supply wide subaerial beaches for shore protection and recreation. Over time, as some undesirable materials were inadvertently pumped onshore to produce unsightly beaches or beaches that performed poorly from an engineering or environmental point of view, it became apparent

that more effort was required to characterize the nature of offshore sediments (Finkl, 1981). Eventually, it became apparent that grain size was an important determining factor of the engineering performance of beaches (*e.g.* Dean, 2002). Most recently, environmental concerns not only focused on grain size but also other parameters such as sand color and mineralogical composition of borrow materials as well as properties of the placed materials such as modes of grain packing (voids), aeration (oxygen levels), and moisture because these properties were important to sea turtle nesting sites (Maloney *et al*., 1990; Wood and Bjorndal, 2000). Thus, the list of do's and don'ts for beach nourishment grew over time until some states such as Florida and North Carolina codified in administrative codes what can and can not be placed on the beach. These guidelines attempt to define 'native beach sediments,' types of borrow materials, and identify degrees of agreement between the two. That is, how well borrow materials match native beach sediments. Implicit in these codifications are levels of uncertainty and risk of assessment, factors that are considered in different ways.

The purpose of rules and regulations regarding the kinds of materials that can be placed on the beach (or in dunes) is to ensure that only appropriate sediments comprise beach fills. The development of guidelines is a complicated task that has to account for numerous variables, be specific and yet broad enough to be practical, while at the same time conforming to engineering-environmental requirements. The process is not only driven by advances in increased understanding of coastal morphodynamics, such as relationships between grain size and beach state, but also by negative impacts to beaches that have accrued over time due to unknown materials occurring in borrows or below intended cuts (when dredges cut too deep into undesirable materials). Some of these processes are discussed below as exemplars of problematic situations, especially the so-called "compatibility problem." The procedure here will be to discuss perceptions of materials that constitute 'native beach' sediments, processes for evaluating the nature and properties of offshore sediments, and methodologies for estimating the 'match' between the two. Explicit to these discussions are considerations of various risk factors, temporal and spatial accuracy of parameter measurement, and levels of risk or variance that are acceptable.

CHARACTERIZATION OF NATIVE BEACH SEDIMENTS

The term 'native beach sediment' is deceptively complex for numerous reasons but mainly because concepts of 'native' are time-dependent variables that are conditioned by pre-existing geology and ambient conditions such as wave climate, morphodynamic beach state, whether a beach is accreting or eroding, and local biology (*e.g.* presence of nearshore shell deposits, coral reefs). Because beaches are among the most dynamic geomorphic features on earth, the timing of sampling and location of samples is extremely important. In many locations such as occur in Florida, beaches have been renourished several times and it is difficult to determine what is 'native' because the original sediments (determined at some start point in time) have been modified by fill admixtures. Natural modification during severe storms (hurricanes) by storm surge erosion and deposition is an additional factor that complicates determination of what constitutes native beach sediments.

CONCEPTS OF NATIVE BEACH SAND

Perceptions of materials that constitute native beach sand are conditioned by educational backgrounds (*e.g.* geology vs. engineering vs. environmental science) as each discipline will have a different 'take' on the situation. Managerial needs influence the decision-making process, often accepting extent conditions as 'native' when in fact they might represent an end point in a natural cycle as would be observed, for example, on an eroded beach. What sediments remain on a severely eroded beach that is perched on top of bedrock, as variously occurs in Palm Beach County where lags are superposed on top of the Anastasia Formation,

should not be considered as representing normal conditions. Concepts of native beach sand are temporal perceptions that are tied to an arbitrary point in time, which may not be a good representation of conditions during beach half-life. Beach sand samples may be highly representative of existing conditions, but ranges of variability vary within themselves depending on what particular parameter is addressed (Smith, 1992). Perceptions of native beach sands are thus largely spatio-temporal compromises that are conditioned by numerous variables, some of which are discussed below.

Spatio-Temporal Variability of Beach Grain Size

Collection of representative beach samples is no easy task because beaches are dynamic morphosedimentary bodies in a constant state of flux due to changing energy conditions (Komar, 1998). Of the few examples of regional beach sediment sampling programs, efforts in Florida (Charles, Malakar and Dean, 1994) and North Carolina (Rice, 2003) are notable. Beach sand data collected along the east coast of Florida, from mean sea level to -3.6 m (NGVD), was later used by Benedet, Finkl and Klein (2004) to determine site-specific (beach profile) grain sizes for the same region. In attempts to determine the degree of variation in sedimentary characteristics for different areas, these examinations summarized a wide range of parameters that were believed to be important: location (geographic coordinates), station, sample number, elevation, distance from benchmark, geomorphic position, carbonate content, collection date, grain size distribution, data source, *etc*. In the example of North Carolina, Rice (2003) reports average sedimentary characteristics for oceanfront beaches where the statewide average beach sediment is predominantly medium to fine sand with ~2.9% gravel (<2 mm by weight), ~2% fines (silt plus clay), and ~5.8% shell material (based on the Wentworth Classification). Carbonate contents were highly variable (ranging from 0 to 99%) but showed a mean statewide content of ~5.8% and a median content of 2%. Beaches of the northern Outer Banks (north of Cape Hatteras) are slightly coarser than the statewide average whereas Brunswick County beaches are finer grained. The average beach sediments of Onslow Bay and the southern Outer Banks (Cape Hatteras to Cape Lookout) are similar to statewide averages.

These kinds of efforts (*i.e*. Florida and North Carolina beach sediment studies) help establish baseline data that can be used for comparative purposes when evaluating compatibility of borrow sediments. The main points to consider when working with these data is that they are variable and dynamic. That is, beach sediments are prone to change in time and space depending on weather systems and interference by human activities (*e.g*. coastal construction, beach nourishment).

It is impossible in the space allotted here to adequately discuss all of the problems associated with sediment sampling and characterization of beaches by grain size. Some of the overriding problems include bias in sample selection and variation in grain size caused by cross-shore selective sorting of bimodal sediments (*e.g*. admixtures of biogenic carbonate fragments and silicate grains), temporal changes in beach grain size, seasonal wave patterns, and inputs of new sediments to the littoral system, as discussed by Benedet, Finkl and Klein (2004) for the Florida Atlantic coast. Grain sizes of beaches are known, for example, to show high-frequency event-related variability (Komar, 1998; Wright and Short, 1984), especially after significant wave events that sort beach grains. Just as timing of sampling is critical to characterization of native sediment status, so are spatial considerations of exactly where samples are collected alongshore, cross-shore, and at what depth (surface sample vs. depth of sampling). Beach sediments are normally collected from toe of the dune (beach back berm area) to the theoretical depth of closure (DoC). This morphodynamic zone typically incorporates numerous sediment collection sub-zones viz. back berm, middle berm, mean

high water line, mean tide line, bar and trough systems, and at specified intervals on the upper shoreface to a defined depth (such as the DoC). Even on a single morphodynamic unit such as the beachface there can be considerable variability in grain size both alongshore and cross shore. This situation becomes poignantly evident where the beachface is decorated by beach cusps where coarser grains tend to accumulate in the horns and finer grains in the bays. Sediment sampling without regard for process-from relationships evident in beach systems can bias results that are then used to determine native beach sediment grain-size distribution patterns. Low frequency sampling in time and space provides a weak database upon which to base assumptions of native beach sediments. Additionally, small changes in grain size may be statistically insignificant (see discussion below).

Sampling Limitations

The brief discussion above points to limitations in sampling and emphasizes sample location and timing of collection as important parameters that need to be considered in the determination or characterization of 'native' beach sand. Samples obtained within a day's difference, or within the same day, for example, can return different mean grain size values depending on sample location and sampler bias. Significant in this respect also is cognizance of wave conditions, and beach-surfzone morphology conditions that cause varying trends in beach state (whether transitioning from dissipative storm beach to intermediate fair weather beach). The value of grain-size data are thus of limited use unless morphodynamic parameters and other locational data are carefully noted at the time of collection. If this kind of collateral data does not accompany beach sediment sampling regimes, the data should be cautiously adjudicated in attempts to determine the status of native beach sediment or for comparison with other datasets. There are additional complications when beaches are artificially renourished and offshore sediments are introduced to the beach system. Artificial beach renourishments typically equilibrate to ambient conditions in distinct phases that lead to morphodynamic stability, and sometimes to instability, before the next renourishment cycle begins. These sediments are admixed with native beach sediments to produce a new 'native' beach sediment over time. Native beach sediments are thus not a constant but a variable or moving target.

Significance of Grain Size Differences to Beach Nourishment Design

Because of spatial and temporal variability of beach sediment, mean value estimates for grain size populations often vary widely for different sampling periods or sampling schemes. Beach nourishment often introduces new sands that have different textural characteristics than the "native" material. The equilibrium beach profile theory (EBP) (Dean, 1991, 2002) is often used to quantify the effects of nourishing a beach with a specified grain size diameter. The EBP is described by the relation

$$h = Ay^{2/3}$$

where h is depth, y is distance and A is the so called "profile scaling parameter". Appropriate values for A as a function of grain size are often estimated (Dean, 2002; USACE, 2002) but the overall premise is that finer-than-native grain sizes produce flatter beaches (less subaerial beach area per unit volume of beach fill) whereas coarser-than-native grain sizes produce steeper beaches (more subaerial beach area per unit volume of beach fill). Dean (2002) developed a simplified method for determining the value of additional beach width by calculating the ratio between the profiling scale parameter of the fill to the native beach.

As an example, consider application of the EBP, as described by Dean (2003), by assuming a native beach grain size of 0.2 mm (A factor = 0.15) and two potential borrow sites, one with a

mean grain size of 0.18 mm (A factor = 0.14) and another with a mean grain size of 0.22 mm (A factor = 0.159). A volume of 250 m^3/m is proposed for placement on a beach where the berm height is 1.8 m and the closure depth is 4.9 m. If the borrow sand had the same grain size as the native beach, an equilibrated dry beach width of 37.5 m would result.

Calculating A-factor ratios between the native beach and proposed fill volumes gives equilibrated additional dry beach widths for the smaller and larger grain sizes as 7.6 m and 56 m. These values compare to 37.5 m when borrow sediments are similar to native beach sediments, as described in Dean's (2002, 2003) procedure. It is thus seen that different predictions in equilibrated beach widths can result from minor differences in mean grain size.

Differences in predicted equilibrated beach widths between native and finer grains, for example, range more than 100% for a grain size variation of 0.02 mm, or less than 10% of the native grain estimate of 0.2 mm. Concern thus naturally arises over consideration of small difference in grain size. The problem boils down to predictions that are based on a mean grain size estimate that can be in error or biased by spatio-temporal variability, low sampling resolution, and statistical distributions (*e.g.* Benedet *et al*., 2004). In a Gaussian distribution, the mean has a standard deviation of ± 34%, thus a 10% difference in grain size will fall within the standard deviation. If native beach and borrow sands have the exact same statistical distribution, then variability about the mean would be minimal. Spatio-temporal and sampling density variability still exist, however.

Simply put, an estimated equilibrated beach width becomes less than meaningful unless variability of input data is comprehended. Although the EPB method is a useful complement to beach nourishment design, it is necessary to include probabilistic distributions in final design estimates, as suggested by Capobianco *et al.* (2002). Design estimates thus should ideally indicate equilibrated beach widths for mean grain sizes as well as for a number of possibilities around the mean with respective probabilities. This realization becomes ever more important when it is understood that mean grain size estimates used in common design procedures are not absolute numbers but highly uncertain estimates that variable.

DETERMINATION OF BORROW SEDIMENT PROPERTIES

Recognizing problems associated with the determination of native beach sediments and efforts to approximate them with offshore borrow materials, governmental agencies and proprietary organizations have adopted quality assurance (QA) and quality control (QC) measures to ensure placement of acceptable fill materials on the beach. Working with researchers and consulting groups, the Bureau of Beaches and Coastal Systems (BBCS, Florida Department of Environmental Protection) has codified QA/QC plans for beach nourishment projects that qualify sand searches and fill materials. Louisiana has established sand search protocols (Khalil, 2004; Finkl and Khalil, 2005a,b) and North Carolina is in the process of approving technical standards for beach fill projects. Efforts in these three states provide guidance for the middle and south Atlantic coasts (Carolinas and Florida east coast) and the Gulf of Mexico (Florida west coast and Louisiana). Extracts from state administrative codes and guidelines provide the basis for the discussion that follows, particularly the definition of native beach sediments, qualification of borrow materials, and the degree of correspondence between the two.

Initial determinations of sediments on the continental shelf of the southeast United States were provided, for example, by Gorsline (1963), Giles and Pilkey (1965), Duane and Meisburger (1969), Meisburger and Duane (1971), Field and Duane (1974), and Meisbureger

(1977), among others. In addition to these seminal large-scale studies, modern sediment surveys are conducted by university researchers and consultants.
Relational databases, generally supported or maintained by government agencies, collate much information on the character of seabed sediments viz. ROSS (Reconnaissance Offshore Sand Search in Florida), usSEABED (U.S. Geological Survey Data Series 118, usSEABED: Atlantic Coast Offshore Surficial Sediment Data; U.S. Geological Survey Data Series 146: usSEABED: Gulf of Mexico and Caribbean (Puerto Rico and U.S. Virgin Islands) Offshore Surficial Sediment Data) and LASARD (Louisiana Sand Resources Database) (Khalil, 2005). A recent summary for the North Carolina inner shelf, prepared by Boss and Hoffman (2000), investigates offshore resources but did not consider the issue of compatibility with beach sediments.

QA/QC PROCEDURES IN SAND SEARCHES

Methodologies for marine sand searches are specialized applications of geotechnical and geophysical procedures that have developed with experience over time in a range of seafloor conditions. Organization of techniques for sand exploration as a strategic approach has advantage over blanket exploratory surveys that do not target areas of interest prior to going to sea. The purpose of exploration protocols is to methodically narrow potential sand targets to those that are compatible with native beach sediments. To this end, QA/QC procedures help to comprehend natural variability in sedimentary deposits, reduce placement of unwanted materials on the beach, and better define borrow materials that will approximate desired environmental and engineering performance.

Exploration Protocols

There are no universal or comprehensive guidelines regarding the best possible way to conduct an offshore sand search, but several models for specific geographic regions have been developed (*e.g.* Finkl, Khalil and Andrews, 1997; Finkl, Khalil, and Spadoni, 2002; Finkl, Andrews, and Benedet, 2003; Khalil, 2004; Finkl and Khalil, 2005a,b). The lack of comprehensive guidelines occurs because sand searches are site specific and they must be geared to specific geographic environments that retain similar shelf histories. Continental shelves are drowned coastal plains and the characteristics of those plains are largely fashioned by terrestrial regimes of the hinterlands that reach the coast. Of particular note here are fluvial (incl. estuarine) systems that flowed across the coastal plains to the sea. The specificity of coastal marine environments is such an overwhelming problem that it militates against development of a comprehensive set of guidelines that cover all situations. Efforts thus tend to be localized and concentrate on coastal marine environments that are germane to jurisdictional boundaries. The Coastal Engineering Research Center (CERC) [now part of the Coastal and Hydraulics Laboratory, CHL], which developed some general guidelines for conducting sand searches, now includes them in the electronic version of the *Coastal Engineering Manual* (CEM) (USACE, 2002). Other works related to procedural methods for sand searches include the recommendations of Finkl, Benedet and Andrews (2003), Finkl, Khalil and Andrews, (2002), and Meisburger (1990).

Because sand searches must be geared or tailored to geological conditions in the area of the study, approaches to conducting the search must be compatible with the specific geographic parameters of that region. This means that exploration methodologies must be capable of resolving required detection limits that are determined by deposit configuration in different geographic areas. The same search techniques would not, by way of an extreme example, be deployed in the search for large sedimentary blanket or shoal deposits as would be required for the detection of fluvial valley infills that are buried by muddy overburden. Even though marine sand searches must be oriented to the detection of specific geologic

features, there are, however, broadly accepted procedures for conducting a geotechnical investigation for the purpose of identifying potential offshore borrow sites.

These general procedures consist of sequential tasks that are conducted in a phase-wise manner, as enumerated in Figure 1. The sequence of investigation boils down to ten essential steps that involve: (1) literature reviews and analyses of prior data, (2) development of action plans that incorporate digital databases of prior data, (3) reconnaissance geological (geotechnical) and geophysical surveys, (4) identification of target area, (5) detailed geophysical surveys, (6) detailed geotechnical surveys, (7) evaluation of geophysical and geotechnical data, (8) hazard and archaeological assessment survey, (9) selection of borrow area and depths of cut, and (10) preparation of reports. There are ranges of sub-tasks within each of these main phases of work, the whole process taking several months to complete depending on project size, location, amount of previous work completed (assuming that the data collected is adequate, appropriate, accurate, and relevant), available funding, weather conditions (especially sea state), *etc*. Ideally, all of these steps can be completed in a couple of months provided enough personnel are put on the job and sufficient funds are immediately available. Ideal conditions are seldom encountered in the real world, however, and completion times can lag significantly behind anticipated job closure. Weather conditions are an important variable where rough seas can delay marine surveys for days to weeks at a time, as in the case where there is passage of successive closely-spaced cold fronts or development of northeasters.

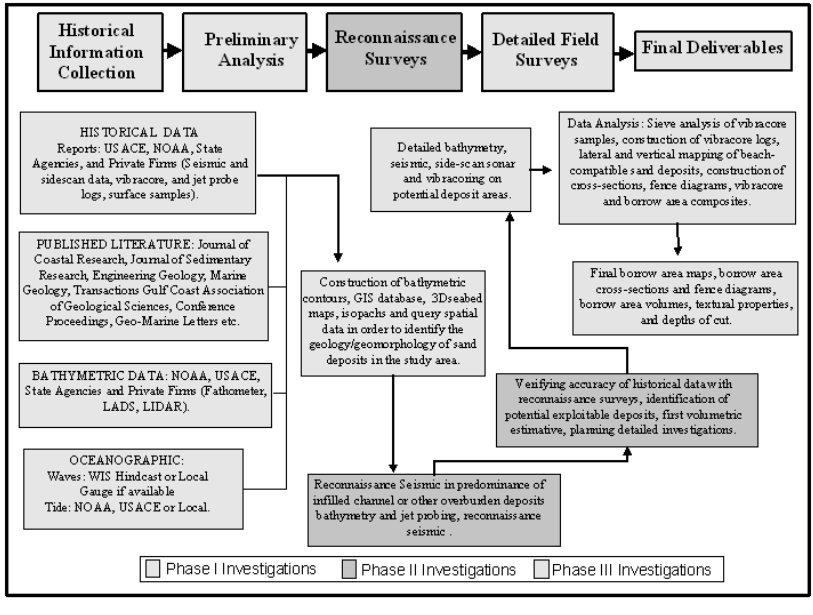

Fig 1. Generalized sequential steps in offshore sand searches, showing phases of marine investigation that lead to designation of specified deposits for borrow development.

These guidelines are briefly summarized in terms of tasks to be completed within ten main phases. The descriptions, which are here not meant to be definitive or binding, indicate general strategies that logically work toward completion of phases so that future work can build on prior accomplishments that, to a certain degree, direct the course of subsequent actions. Capstones occur at the end of Phases II and III where results and plans are reviewed and evaluated for the purpose of modifying or redirecting future search techniques. These capstone reviews may require that previous steps be revisited if there are problems with the resulting data that could adversely impact utilization or interpretation of the data.

This kind of methodological approach to marine sand searches should be adapted to sand search investigations by assimilating good quality legacy data so that existing information does not have to be duplicated. In comprehensive marine sand searches, comprehensive sequential survey procedures are employed to maximize resources and effectively characterize offshore sand deposits. These sequential surveys collect preliminary data over relatively large expanses of seafloor in the form of surface grab samples, jet probes, and reconnaissance bathymetry prior to the collection of remotely sensed data (*i.e*. seismic reflection profiles, side-scan characterization of the seafloor, and magnetometer surveys) and vibracores in smaller target areas. Reconnaissance-level surveys that cover large areas of the seafloor provide useful information that helps define smaller targets (areas with higher potential for containing materials that are suitable for beach nourishment) where more intensive (and more expensive) sand and cultural resource investigations are conducted.

Sand Search Models

Sand search methodologies presently deployed by CPE (*e.g*. Florida SSM (Panhandle, west coast, east coast), Delta SSM (Mississippi River deltaic area), Texas SSM, Carolinas SSM, New England SSM) are based on knowledge of prior work, coastal geological conditions, and advanced geophysical/geotechnical survey methods. Other useful tools for assessing sand quality on the seabed include the ROSS (Reconnaissance Offshore Sand Search) surficial sediment database and gINT®. ROSS allows the identification and assessment of potential offshore sand resources that are suitable for beach nourishment projects. The tool consists of a corporate database that can be addressed, searched, and manipulated through an online query builder as well as with existing ArcIMS® Geographic Information System (GIS) routines that provide access over the Internet (Web). The gINT® geotechnical and geoenvironmental software is used for fully customizable borehole/boring and well logs, cross sections, geotechnical testing, and other professional engineering reports. Based on a powerful relational database system, the user has full control over the design of database structures, report formats, and symbol libraries.

Risk and Variability

Spatial distributions of seafloor sediment and rock types, usually shown in maps and based on results of samplings or inspections of the seabed at numerous sites, leads to consideration of degrees of uncertainty. Information is gained about the seabed from direct sampling (e.g. vibracore, jet probe, grab sample), remote sensing (*e.g*. bathymetric-fathometer survey, sidescan sonar, seismic reflection profiling, multibeam survey, magnetic survey), diver inspections (*e.g*. by digital camera, videography), and from instrumented probes. These types of mapping are generally grouped as 'geological' but they are widely practiced in engineering as well. Uncertainties in geological seabed mapping are partly related to disturbed or incompletely recovered cores, variable levels of assurance in interpretation of remotely sensed data, extreme patchiness (variability) of seabed of materials, poor analyses by some laboratories, and validations that produce unexpected results. These problems relate to the

reliability of seabed mappings based on point-site data and often beg the question as to how these uncertainties should be quantified and displayed. Attempts to approach a rational understanding of deficiencies in geological point-site datasets focus attention on how they can best be overcome.

Risk comes from a variety of sources and avoidance must be multi-pronged. Rarely is risk eliminated altogether as it is too pervasive and costly to attempt elimination. So, from a practical point of view, risk is mitigated by attempting to reduce uncertainty as much as practical. Two major sources of risk are natural sediment variability within a deposit or borrow area and completeness of geological information. Variation within a deposit depends on numerous factors such as provenance, coastal geomorphic environment (quiescent vs. high-energy, transgressive-regressive sequences), spatio-temporal scales of depositional cyclicity, mode of deposition, syndepositional inclusions (facies changes), reworking by organisms (bioturbation), postdepositional compaction, and so on. Homogeneous borrows containing compatible materials thus have less risk than a borrow area known to contain strata of noncompatible material.

Point site data such as that obtained from vibracores is normally assumed to represent a volume greater than what was sampled in a 10-cm (4-inch) diameter core. The 'sphere of influence' of a vibracore depends on deposit architecture; homogeneous laminated deposits extend the zone of confidence a specified distance from the sample site. Conversely, the sphere of influence of a vibracore in a more heterogeneous deposit is restricted by a higher degree of uncertainty. Seismic reflection profiles often can extend the zone of confidence (decrease uncertainty). In a best-case scenario in a homogeneous deposit, based on 300 m centers for vibracore site sampling, extrapolation of deposit continuity from the vibracore would be a 150 m radius. That gives a potential seabed surface area of about 70,700 m^2 and a total sediment volume of about 495,000 m^3 per 7-m vibracore. Characterization of a sphere of influence for a sediment volume of nearly 500,000 m^3 from a 10-cm core (7 m long) is an industry standard but there is clearly room for concern as it seems clear that heterogeneous deposits offer greater scope for uncertainty. Closer spacing of vibracores in borrow areas with known variability is facilitated by dynamic vibracoring plans where spacing can be adjusted on the fly as cores are retrieved and inspected aboard ship. Risk of pumping undesirable material onshore is thus reduced by decreasing the representative sphere of influence, that is, by decreasing reliance of interpolated data between vibracores.

COMPATIBILITY OF BORROW AREA WITH NATIVE BEACH MATERIAL

The BBCS, for example, has codified geological information requirements in Rules 62B-41.007(2)(j) and 62B-41.008(1)(k)4, Florida Administrative Code (FAC) for determining the nature of proposed beach fill material and its compatibility with naturally occurring beach sediment when applying for a Joint Coastal Permit. The purpose of these standards and guidelines is to minimize risk by reducing uncertainty in the exploration process so that beach fill materials maintain the general character and functionality of the material occurring on the beach and adjacent dune in the coastal system. Guidelines are thus provided for sediment properties such as grain-size distribution, color, mineralogical composition (quartz vs. carbonate), and bulk properties of cementation and compaction. The term 'functionality' in the FAC refers to the suitability of the material as nesting substrate for marine turtles as well as maintenance of water quality standards (turbidity) and littoral transport performance. As an example, the rules provide specific grain size parameters that may not be exceed so that *compatible* beach fill material must not contain: (1) >5% (by weight) silt, clay, or colloids passing the #230 sieve (4.0φ), (2) >5% (by weight) fine gravel retained on the #4 sieve (-2.25 φ), and (3) coarse gravel, cobbles or material retained on the ¾ inch sieve in a percentage or

size greater than found on the native beach. After an identified sand deposit is determined not to exceed grain-size parameters specified in the rule, then similarity in color and grain-size distribution (sand grain frequency, mean and median grain size and sorting value) to the material in the existing coastal system at the disposal site becomes the determining factor in the acceptability of the borrow sediments. It should be noted that the character of the material within the dry beach berm is used to define the material within the existing coastal system. This is true because suitability is keyed to marine turtle nesting as the primary consideration of environmental functionality of the beach sediment.

Particle-size analyses may be conducted according to numerous procedures viz. hydrometer, pipette, sedimentation, and sieving methods. Although not specified in the state codes, grain size analyses are normally conducted for sand samples in accordance with the American Society for Testing and Materials (ASTM), Standard Material Designation D422-63 for partial-size analysis of soils. Mechanical sieving is accomplished using calibrated sieves, with a gradation of half phi intervals, per U.S. Army Corps of Engineers standards. Grain-size distribution curves are typically prepared and raw sedimentological data are developed into a GIS database that is available for electronic transfer. Sediment-size analysis of vibracore mud and clay samples can be conducted, for example, using a Coulter LS200 particle-size analyzer, which employs laser diffraction to measure the size distribution of sedimentary particles. The LS200 utilizes size-dependent optical characteristics of particles to determine the population of particle sizes within a sediment sample (see discussion in Finkl and Khalil, 2005a,b).

According to the NCAC Rule, compatibility of borrow sediments with those on the beach is determined by strict criteria that include, for example (in terms of average percentage by weight): (1) limits on fine-grained sediment (<0.0625 mm) in the borrow not to exceed fine-grained sediment of the recipient beach characterization plus 5%; (2) sediments in a navigation channel are compatible if the average of fine-grained (<0.0625 mm) sediment is less than 10%, (3) material other than natural sediment and shell is not considered compatible [which eliminates glass cullet as a possible new alternative sediment source that is being developed in other regions (Finkl, 1996; Thompson, Finkl and Kruempel, 2004)], (4) granular sediment (≥2 mm and <4.76 mm) or gravel (≥4.76 mm) can not exceed occurrence in the recipient beach by more than 5%, and (5) calcium carbonate content in a borrow can not exceed that of the recipient beach by more than 15%, *etc*.

CODIFICATION: RULES AND REGULATIONS FOR BEACH FILL PROJECTS

Beach renourishment projects require oversight to ensure proper placement of compatible materials. Although there are many caveats in the process, the State of Florida (BBCS) initiated codification of principles and practices to regulate offshore sand searches for compatible beach sediments in the early 1990s with subsequent amendments as, for example, Specific Authority 161.041, 370.021(1) FS (formerly 16B-41.007, amended 10-23-01). Guidelines for offshore sand searches in Louisiana (Khalil, 2004) provide a basis for codification as the Louisiana Department of Natural Resources moves towards strategic assessment of seabed sand resources in various types of deposits. The State of North Carolina is in the process of approving rules and regulations for beach nourishment projects. Both state efforts provide guidelines for offshore sand searches, borrow development, and onshore placement.

In the state of Florida, quality standards and QA/QC procedures for projects differ. Larger beach restoration projects, for example, must follow a comprehensive set of guidelines (as indicated above) whereas permits for individual residents and similar small projects are governed by a different permit program that has a broader sand quality standard. Smaller projects such as coastal buildings generally fall under the Coastal Construction Control Line Program (CCCL) (Chapter 62B-26-54 FAC, parts effective 1997), an essential element of Florida's coastal management program, which allows a wider range of acceptable standards for sand color and composition as specified in Chapter 62B-36 (Beach Management Assistance Program, effective 2003). Some communities such as Panama City Beach, Florida, for example, set their own standards for specific sand characteristics that meet local conditions. Given the prevalence of white sand in Florida Panhandle, Panama City Beach adopted ordnance that renourishment sand must have a Munsell Color value of 7 or greater. The state standard allows darker colored sand to be placed on the beach. Rules as occur in the FAC provide minimum standards for borrow materials that must approximate native beach sands. Local standards may be more restrictive as conditions necessitate.

Channel sediments in Florida are suitable for placement on the beach when they meet certain standards. Pursuant to subsection 62B-41.005(15) FAC, for example, sandy sediments with up to 10% fine material (-230 sieve sediments) by weight from the maintenance of coastal navigation channels can be used for beach placement, provided they meet other sediment and water quality standards.

DISCUSSION

Strict compliance with similarity criterion is rarely achieved because sediments in offshore borrows are typically poorly sorted or have a bimodal grain-size distribution compared to well-sorted berm sediments. Most offshore deposits in Florida, for example, contain admixtures of carbonate sand or shell fragments with a mean and median grain size greater than the beach sediments. Compliance with similarity criteria involves avoidance of borrow area sediments that contain a high percentage of fine-grained carbonate sands and/or shell fragments because they may cause post-placement compaction and cementation. To this end, compaction is limited to values less than 500 psi (700 kg m^{-2}) to protect marine turtles. Cementation is not allowed under any circumstances because it prevents nesting by sea turtles, reduces habitat for shorebirds, restricts groundwater flow in beach sediments, and causes a range of other environmental concerns as well as presenting safety issues for beach users. This limit is, however, an implied goal without definitive standing in the rules. Beach fills with a measured strength greater than 500 psi have to be tilled, but are not directly prevented from being built. Some unstated higher value of compaction would be against the rules, although this value is not mentioned in the rules directly.

The resulting mixtures of autochthanous (native) and allochthonous (introduced) sediments by default become a new ‘native beach sand’ that must be approximated by borrow sediments. The evolving beach sands on renourished beaches thus acquire new characteristics with each renourishment cycle producing a ‘moving target’ of what officially constitutes ‘native beach sand.’ Before conducting a marine sand search, it is thus necessary to ascertain what constitutes that so-called ‘native beach’, which in fact is a temporal perception. Comparison of pre-nourishment beach sands, in Florida for example, with beach sediments that have resulted from several renourishment cycles can be quite different, as seen for example at Captiva Island, Longboat Key, Delray Beach, *etc*.

Other problems that are associated with the development of borrow sand is determining exactly what is meant by the term ‘beach compatible.’ Although the term clearly has different

meanings, the one that counts is that adopted by the permitting agency, especially those that have been codified as in Florida and nearly so in North Carolina. Again, this can be largely perceptual and not definitively defined in sedimentological terms. Particularly troublesome, for example, are mixed sediment beaches where there are naturally variable amounts of siliciclastics and carbonates as occur on the central to southern east and west coasts of Florida. As a general rule, the percentage of siliciclastics decreases from north to south and the percentage of carbonate decreases from south to north. In northern Broward County on the southeast coast of Florida, for example, the siliciclastic-carbonate contents are about 50-50. Matching existing beach sands with 'beach compatible' sediments in borrows may be controversial because borrows typically do not exist as exact analogs to present combinations of beach sediments. On the east coast of Florida, borrows are developed in inter-reefal flats where sands are mostly siliceous whereas on the west coast borrows are often developed in carbonate-rich sand ridges. There thus occurs a trade off where borrow sediments are not exactly compositionally similar to existing beach sediments (quartz vs. carbonate, shell content) but they may be very similar in terms of the average silicate grain size expressed as D_{50}. In Louisiana, for example, restoration of barrier islands finds that there is not much compositional variation between beach and borrow sediments, both being derived from Mississippi River alluvium, but there can be difficulty finding deposits of appropriate quartz grain size along a muddy coast environment. Similarly, but this time in a glacial coastal environment along the coast of Nantucket in New England, location of suitable offshore borrows can be challenging in a marine-modified drowned pro-glacial landscape (sandur plain) where there is extreme spatial variation in sediment quality over short distances (*e.g.* moraine vs. outwash plain).

Efforts in the field, laboratory, and office combine to focus on the most advanced methodologies possible and yet the marine environment demands better understanding, more precise measurement, and better appreciation of complexity introduced by drowning of coastal plain terrestrial and coastal/marine deposits to become continental shelves and their subsequent modification by marine processes. Better matching of sedimentary deposits in borrows with beach sediments for proposed renourishment is a goal that should be approached judiciously and cautiously because there are no short cuts nor has the methodology been codified in most instances. Even though offshore materials may never achieve full compatibility, partial compatibility may be the best of all reasonable options that are sufficient and better than alternatives such as seawalls or shoreline retreat.

CONCLUSIONS

The determination of what constitutes beach-compatible sediments in offshore borrows is sometimes confounded by efforts to ascertain the true nature of 'native beaches.' The definition of 'native' sand along eroded or renourished coasts is an evolving paradigm because increased awareness (by governmental agencies, consultants, and environmental groups) is now achieving better focus on spatio-temporal problems of sediment sampling. Bias in sediment sampling on beaches is intrinsically problematical to characterization of 'native' beach sediments. Compatibility of borrow sediments with native beach sands posits new questions as the scope for onshore placement of unwanted materials is ever present in deposits of variable composition. Risk of dredging undesirable sediments in borrows can be reduced by increasing the number of vibracores (decreasing the vibracore sphere of influence) and achieving better understanding of coastal geological (incl. geomorphological and morphodynamic conditions) frameworks and environments of deposition. Florida's Bureau of Beaches and Coastal Systems is leading coastal states in the codification of sedimentary properties that are useful in beach renourishment activities, including development of offshore borrows. Rules and regulations will soon be in place in North Carolina

while Louisiana follows guidelines for offshore sand searches and characterization of marine sand resources.
