Inhaled nitric oxide (INO) at 1 to 20 ppm relaxes pulmonary vascular smooth muscle. INO clinically reduces elevated pulmonary artery pressures and improves arterial oxygenation by increasing the blood flow to the lung regions that remained functional, thereby improving matching of perfusion to ventilation.[130,131] Effective doses in adults with ARDS varied from a few ppm to efficiently reduce pulmonary hypertension to a few ppb to significantly improve oxygenation.[132] Responsiveness to such low doses of NO suggests that tracheal intubation inadvertently creates an NO deficiency state by preventing autoinhalation of NO from the upper respiratory airways.[133] However, efficient doses appeared to be higher (5 to 20 ppm) in children and neonates.[134] Although INO may also benefit alveolar neutrophil function and cytokine release,[135] several clinical trials enrolling adults with ARDS from various causes were unable to demonstrate any significant improvement in survival.[136-140] Likewise, in children with severe hypoxemic respiratory failure, although INO at 20 ppm acutely improved oxygenation and lowered mean pulmonary artery pressure,[141] there was no clear effect on survival.[142] As 35% of children who initially did not respond to INO did so after lung volumes were increased by HFOV, combined use of HFOV and INO may provide more predictable improvement in children with ARDS.[143]

Extracorporeal life support (ECLS) provides both gas exchange and circulatory support for patients with life-threatening ALI and ARDS, and allows the lung to rest from mechanical ventilation. ECLS can be provided by venoarterial or venovenous bypass techniques, using artificial membranes or hollow fibers to provide oxygen and remove carbon dioxide and intravascular fluid. In a retrospective case-cohort study of 331 children with respiratory failure, 53 children who received ECLS were compared to 53 diagnosis- and risk-matched children who did not receive ECLS. The ECLS patients had a 26% mortality rate, whereas those who were treated in a standard fashion had a mortality rate of 49%.[144] In 84 adults with ARDS, ECLS was used in an algorithm of care when patients worsened despite a ventilator-protective strategy, prone positioning, and INO therapy.[145] Eighty-five percent of patients did not require ECLS with 83% survival. Of the 13 patients who had ECLS, 62% survived. Overall survival was 80%, suggesting that a combination of treatments can improve ARDS-related survival.

Ventilator-acquired pneumonia is the most common late complication of ALI and ARDS. Prolonged intubation, frequent suctioning, and suboptimal nutritional status all contribute to ventilator-associated pneumonia.[146] This infection is frequently polymicrobial, and commonly includes *Streptococcus pneumoniae*, *Staphylococcus* spp., and *Pseudomonas aeruginosa* or other multiresistant gram-negative rods that are frequently encountered in ICUs not having a restrictive antibiotic policy. Diagnosis of ventilator-acquired pneumonia is difficult, and is often based on fever, purulent aspect of the sputum, new infiltrates, and blood gas exchange worsening. Identification of the responsible germs usually requires the use of protected brush or bronchoalveolar lavage under fibroscopic guidance,[147] but these procedures are not easy in small

children. Recently, 8 and 15 days of appropriate antibiotic therapy have been found equally effective treatment of ventilator-associated pneumonia.[148] Mortality from nosocomial pneumonia in these patients is reported to be as high as 80%.

Corticosteroids are extensively used in acute respiratory failure,[149] including the most serious forms of ALI or acute respiratory distress syndrome.[150] In a first study, Meduri et al. treated 9 adult patients with ARDS of 7 days duration with 2 mg/kg methylprednisolone four times daily, then with stepwise decreased doses; eight patients improved after the fifth day of treatment, and six survived.[151] In a second study, the authors have treated 25 new patients similar to the eight

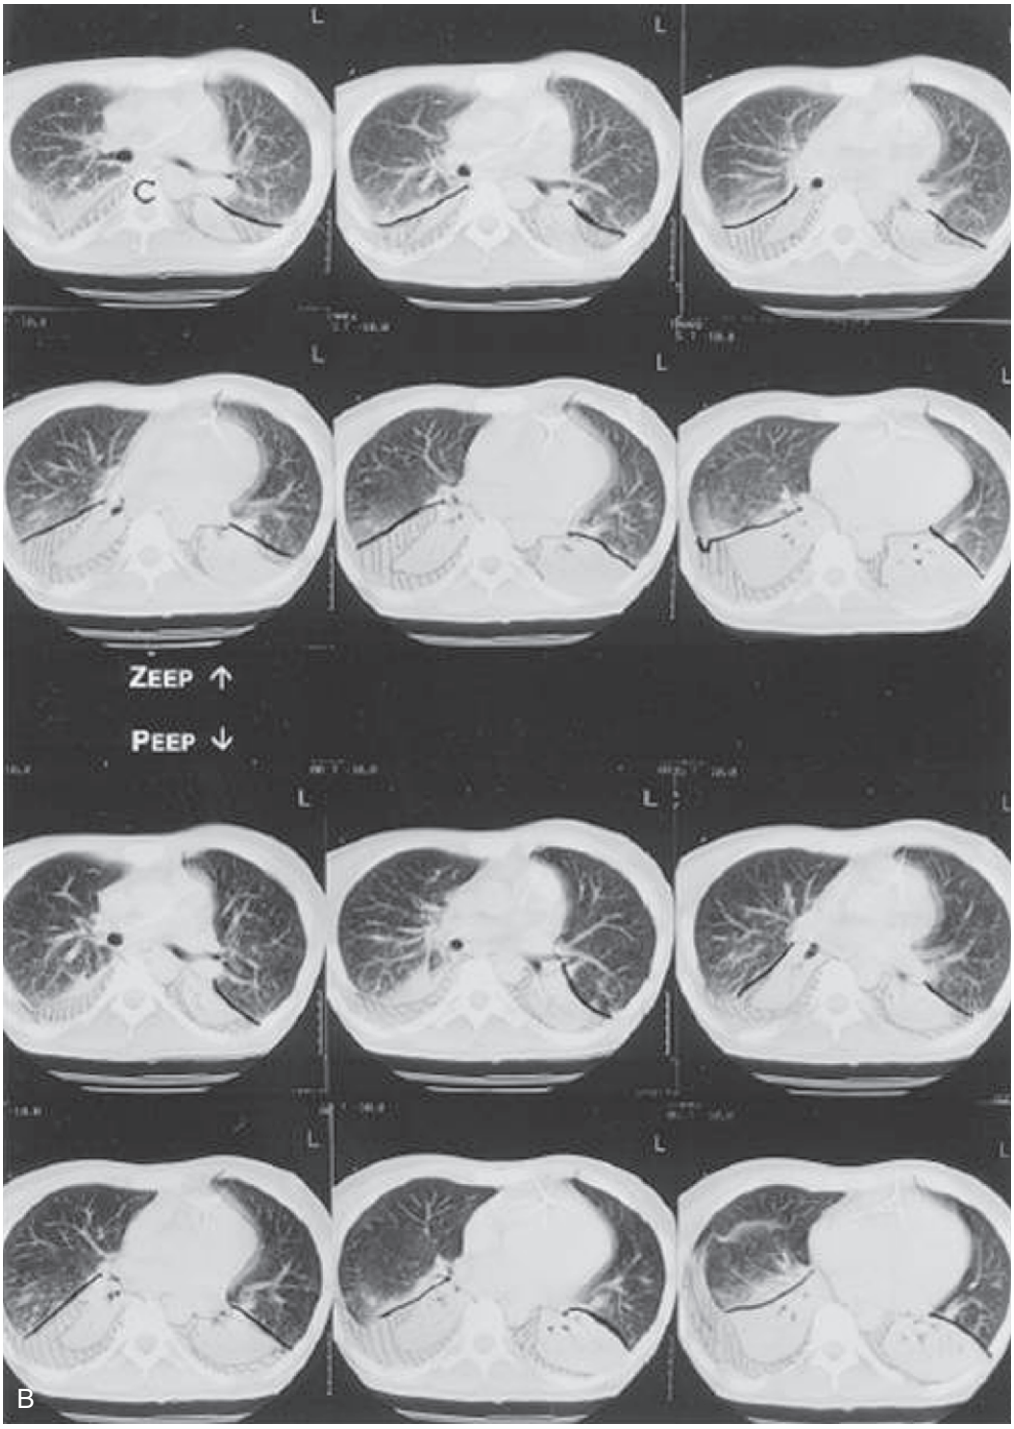

Figure 52–4.—cont'd

previous ones.[152] Steroids were initiated on the fifteenth day of mechanical ventilation at 2 mg/kg four times per day, with slow weaning over 6 weeks. After 1 week, blood gas exchange improved and survival was 76%. Interestingly, survival was 86% in the 21 responders compared with 25% in the four nonresponders. Then, in a small randomized trial of adult patients with severe ARDS who did not improve after the seventh day of mechanical ventilation, improvement in lung injury and multiple organ dysfunction scores as well as reduced mortality were observed after prolonged methylprednisolone treatment.[153] The efficacy and safety of corticosteroid therapy at the fibrosing stage of ARDS was proven in a large randomized trial by the ARDS network.[154]

Noninvasive Ventilation

The pulmonary complications of solid organ and hematopoietic stem cell transplantation have been recently reviewed.[155] Paramount among these are pulmonary complications, which arise as a consequence of the immunosuppressed status of

Table 52–2 Recommendations for Ventilator Settings in ARDS

CONVENTIONAL MECHANICAL VENTILATION		
Mode		Volume- or pressure-controlled "Airway pressure release ventilation" preferred when preservation of spontaneous ventilation is desired
Tidal volume	6–10 mL/kg	Permissive hypercapnia (increase <5 mm Hg/h) $PaCO_2$ 65–85 mm Hg well tolerated unless increased ICP Arterial pH >7.15
End-inspiratory plateau pressure	<30 cm H_2O	Above this limit, increased risks of barotrauma and air leaks
Positive end-expiratory pressure	10–15 cm H_2O	Lower PEEP levels, if heterogeneous lung injury Higher PEEP levels, if diffuse lung injury Consider early prone positioning (6–12 h)
Respiratory rate	20-60 bpm	Adjusted to age; higher than normal may limit hypercapnia
Inspiratory/expiratory ratio	1:2 to 1:1	Check for inadvertent PEEP
FiO_2	<60%–80%	Depends on how the diseased lung may be recruited PaO_2 40–60 mm Hg, SpO_2 85%–95%
HIGH-FREQUENCY OSCILLATORY VENTILATION		
Amplitude pressure	30–50 cm H_2O	To achieve visible chest vibrations
Mean airway pressure	15–30 cm H_2O	To achieve adequate chest recruitment (7 to 9 ribs)
Respiratory rate	3–10 Hz	Decrease to increase tidal volume (usually not measured)
Inspiratory/expiratory ratio	1:3 to 1:1	1:1 more appropriate in diffuse lung injury
FiO_2	<60%–80%	Depends on whether the lung may be recruited

ICP, Intracranial pressure.

the recipient as well as from such factors as the initial surgical insult of organ transplantation, the chemotherapy and radiation conditioning regimens that precede hematopoietic stem cell transplantation, and alloimmune mechanisms mediating host-versus-graft and graft-versus-host responses. Worsening of the respiratory status by a bacterial or viral process is often indistinguishable from ALI or ARDS. Thus, sepsis work-up should encompass blood cultures, tracheal fluid aspirates at intubation, bronchoalveolar lavage, viral tests by immunofluorescence or PCR in the blood, the urine, the stools, the tracheal aspirates, or bronchoalveolar fluid. *Pneumocystis* pneumonia is frequently seen in this context, and it is important to rapidly isolate the organism, usually by bronchoalveolar lavage, since the association of prolonged trimethoprim-sulfamethoxazole and short-term steroids is regularly efficacious.[156] Otherwise, the prognosis of the immunocompromised patients with ALI or ARDS severe enough to require tracheal intubation and mechanical ventilation is poor in all the series.

Avoiding intubation and mechanical ventilation is therefore a major goal in the management of respiratory failure in immunocompromised patients. A prospective, randomized trial of intermittent noninvasive ventilation, as compared with standard treatment with supplemental oxygen and no ventilatory support was conducted in 52 immunocompromised adult patients with pulmonary infiltrates, fever, and an early stage of hypoxemic respiratory failure.[157] Periods of noninvasive ventilation set in the pressure support mode delivering 7 to 10 mL/kg tidal volume at a respiratory rate of fewer than 25 breaths/min and PEEP stepwise increased by 2 cm H_2O up to a level of 10 cm H_2O through a face mask lasted at least 45 minutes and alternated every 3 hours with periods of spontaneous breathing. Each group of 26 adult patients included 15 patients with hematologic cancer and neutropenia. Fewer patients in the noninvasive ventilation group than in the standard-treatment group required tracheal intubation (12 vs. 20, $P = .03$), died in the intensive care unit (10 vs. 18, $P = .03$), or died in the hospital (13 vs. 21, $P = .02$).

In immunocompetent patients, after initially rather negative results,[158] there has been a renewal of interest in noninvasive ventilation in the early stages of ALI and ARDS. In a small randomized trial, 20 (62%) of 32 patients in the noninvasive-ventilation group and 15 (47%) of 32 in the conventional-ventilation group had an improved PaO_2/FiO_2 ratio within the first hour of ventilation.[159] Ten patients in the noninvasive-ventilation group subsequently required tracheal intubation. Twenty-three patients in the noninvasive-ventilation group (72%) and 17 in the conventional-ventilation group (53%) survived their stay in the intensive care unit (odds ratio, 0.4; 95% confidence interval, 0.1 to 1.4; $P = .19$), and 22 and 16 were discharged from the hospital, respectively. In a larger trial, 105 patients with severe acute hypoxemic respiratory failure were allocated to noninvasive ventilation (n = 51) or high-concentration oxygen therapy (n = 54).[160] Compared with oxygen therapy, noninvasive ventilation decreased the need for intubation (25% vs. 39%; $P = .028$), and increased the cumulative 90-day survival ($P = .025$). Multivariate analysis showed that noninvasive ventilation was independently associated with decreased risks of intubation, reduced risks of septic shock, and improved 90-day survival. Likewise, the same beneficial effect of noninvasive ventilation was confirmed in another trial not yet fully published.[161] However, in a recent preliminary study in 93 children with diverse causes of acute respiratory failure treated either initially or during weaning, the use of noninvasive positive pressure ventilation appeared

to reduce the rate of endotracheal intubation, except in the nine children with ARDS.[162] Moreover, several adult intensivists, experts in that field, recently cautioned that noninvasive positive pressure ventilation might actually delay the timing of endotracheal intubation which may become more hazardous in a hypoxic patient.

The success of noninvasive ventilation, however, critically depends upon several factors, including the choice of face masks,[163] the replacement of the filter-humidifier by a heated humidifier,[164] the removal of any device adding any extra dead space, and the use of a ventilator having a sensitive inspiratory trigger and a built-in algorithm to correct for leaks.[165] The most frequently used ventilatory mode is pressure support ventilation in combination with the necessary level of PEEP to recruit the lung, but the "airway pressure release ventilation" mode is increasingly used.

Conclusion

Substantial progress has been made in the understanding of ALI and ARDS. Significant actions have been made in recent years to reduce the aggressiveness of mechanical ventilation: reduction of tidal volume to a safer margin of 6 to 10 mL/kg, maintenance of a end-inspiratory plateau pressure less than 30 cm H_2O, acceptance of permissive hypercapnia, and use of a reasonable level of PEEP that allows a decrease in FiO_2 to safe margins. When respiratory failure worsens despite these measures, prone positioning and HFOV to optimize lung recruitment, INO therapy to reduce pulmonary hypertension and prevent cor pulmonale, and ECLS may all be helpful to buy time for the underlying pathology to recover. Mortality remains high, particularly when there is associated sepsis and evolving multiple organ dysfunction.[166] Further research is, therefore, needed to better understand the genetic polymorphisms that favor the occurrence of ALI and ARDS, and the mechanisms of alveolar fluid clearance and lung healing that may hasten recovery from ALI.

Extracorporeal Life Support

Heidi J. Dalton and Sharad Menon

PEARLS

- Venoarterial access for extracorporeal membrane oxygenation (ECMO) has been the most common cannulation technique because it provides both respiratory and cardiac support.
- Venovenous cannulation for ECMO is currently preferred for patients with adequate cardiac function.
- In venoarterial ECMO, desaturated venous blood is drained from the body and reinfused into a large artery after being oxygenated in the ECMO circuit.
- Venovenous ECMO differs from venoarterial ECMO in that blood is both withdrawn and returned into the venous circulation of the patient.
- The use of ECMO in patients with neonatal respiratory failure has decreased as new methods of support, such as inhaled nitric oxide, surfactant, and high-frequency oscillation, have been developed.
- As experience with ECMO support in older patients has grown, expansion to clinical situations such as cancer, sepsis, burns, and trauma has occurred.
- The largest area of growth of extracorporeal support is in patients with cardiogenic shock or following repair of congenital heart defects.
- One quickly expanding area of extracorporeal support is as a means of resuscitation in cardiac arrest. One third of the patient survived extracorporeal cardiopulmonary resuscitation, with two thirds of the survivors having good neurologic outcomes.
- Improvements in extracorporeal pumps, cannula, circuitry, and oxygenators are making ECMO safer and easier to use.
- A recent study of a trial of ECMO in adults with respiratory failure noted 63% survival in the ECMO group versus 43% in the conventional ventilation group at 6 months.

Aided by the discovery of heparin in 1916[1] and by advances in the technology of membrane oxygenators, extracorporeal life support has changed dramatically since the early 1950s, when John Gibbon first used a machine of his own design to provide extracorporeal life support for a cat whose pulmonary artery was occluded with a clamp.[2] Early experiences with the use of cardiopulmonary bypass for operations on the heart were mixed, but as experience and technology have continued to advance, the field of cardiopulmonary bypass has expanded at a rapid rate.[3-5] Today the dreams of clinicians like Gibbon have been realized, and extracorporeal support for the heart and lungs is used daily throughout the world. Nowhere is the impact of cardiopulmonary bypass seen more clearly than in pediatrics, where increasingly intricate intracardiac repairs of once-lethal congenital heart defects are performed every day with the aid of cardiopulmonary bypass.

As experience with bypass techniques in the operating suite grew, investigation of the use of extracorporeal support of patients with cardiopulmonary failure outside the operating room began.[6,7] Infants with severe respiratory disease or pulmonary hypertension were among the groups for whom use of a temporary cardiopulmonary bypass system seemed appropriate. This technique of modified cardiopulmonary bypass came to be known as "extracorporeal membrane oxygenation" (ECMO).[8] Although premature infants had an unacceptably high incidence of intracranial hemorrhage as a result of the systemic heparinization, infants of more than 35 weeks' gestation with respiratory failure were successfully supported with ECMO.[9,10] An abandoned infant with severe hypoxemia named "Esperanza" (hope) by her caregivers was among the first to be treated with ECMO by Bartlett in 1976.[10a] Today, Esperanza is a grown woman with children of her own. Efforts to organize and collate data on patients treated with ECMO resulted in the formation of the Extracorporeal Life Support Organization (ELSO). In 2009, ELSO celebrated its 20th anniversary. This largely volunteer network of physicians, surgeons, nurses, respiratory therapists, and all those with an interest in extracorporeal life support comprises more than 100 centers and contains data on more than 40,000 patients treated with extracorporeal life support throughout the world.[11]

As more patients have been treated and techniques have been refined, ECMO procedures and management of patients have evolved to the point that ECMO now can be offered to patient groups previously excluded from consideration.[12-14] Despite multiple attempts to define specific selection criteria for ECMO candidates, no well-defined and universally applied criteria exist. The decision regarding when a patient should be treated with ECMO remains empirical and based on experience. Similarly, although there is little complete standardization of ECMO circuit design, cannulation technique, and patient management, the general principles are fairly constant. Guidelines for ECMO center training, equipment selection, and patient selection and management recently have been developed by expert consensus and are posted on the ELSO Web site. Although the guidelines are fairly general, it is hoped that they will enable more standardization of practice

in the future. The information in this chapter represents general practice, the authors' experience, and a review of the literature. For more detailed information regarding extracorporeal life support, the reader is directed to the excellent text regarding this subject published by the ELSO organization.[10a]

Materials and Methods

Cannulation Techniques

Several modes of ECMO, or extracorporeal life support (ECLS), as it is also known, have been developed that differ according to cannulation site and minor physiologic principles. However, the basic circuit is similar for all modes. Cannulation is achieved either by the venoarterial or venovenous mode. Venoarterial access has been used most commonly and will be discussed first.

Venoarterial Extracorporeal Membrane Oxygenation

Venous Access. In venoarterial ECMO, desaturated systemic venous blood is drained from the body and reinfused into a large artery after being oxygenated in the ECMO circuit (Figure 53-1). The right atrium is the usual site accessed for ECMO cannulation. The internal jugular (IJ) vein is a large vessel with a fairly short, straight course to the right atrium and thus is preferred during cervical cannulation. To augment cerebral venous drainage in patients who undergo cannulation via the right IJ vein, some centers also place a smaller cannula retrograde in the vessel to the level of the jugular venous bulb at the base of the skull. This catheter can facilitate cerebral venous drainage and provide a means of monitoring jugular venous oxygen saturation. Some clinicians believe that monitoring jugular venous saturation provides information on adequacy of oxygen delivery to the brain and that it is valuable during ECMO, although this practice is relatively controversial. Reports of an increase in venous drainage via the retrograde cannula of up to one third have been noted in some centers.[15] The retrograde catheter is connected by a Y-adapter into the larger venous drainage line.[16,17]

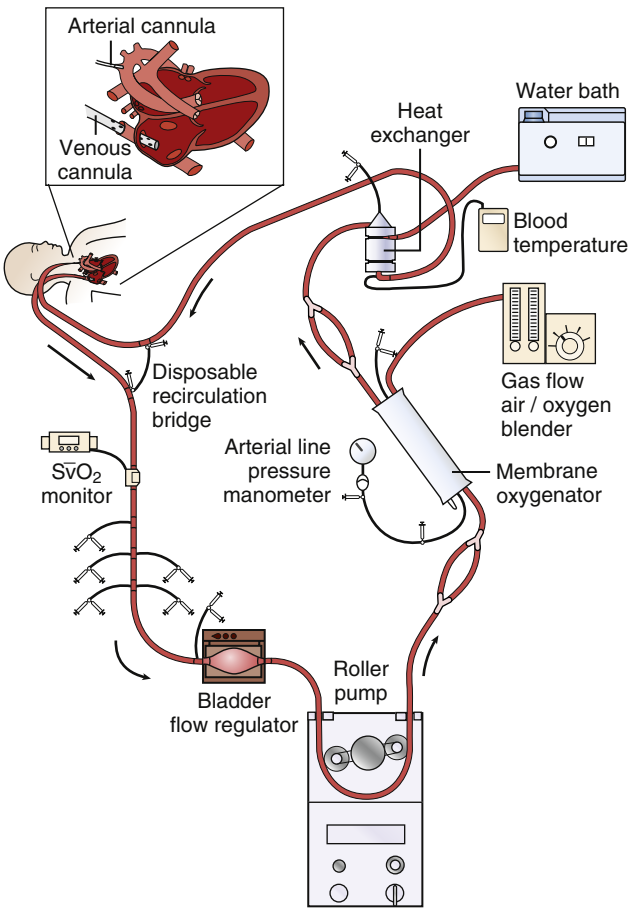

Figure 53–1. Venoarterial extracorporeal life support via cervical cannulation. Svo_2, Venous oxygen saturation. *(M. Dowhy, with permission. Courtesy Children's Hospital, Pittsburgh, Pa.)*

In older children and adults, the femoral vessels can be used for cannulation.[18] Venous access is obtained from the saphenous or femoral vein into the inferior vena cava (IVC), or the cannula can be advanced further up the IVC to the right atrial/IVC junction. Although femoral vein cannulation diverts less venous return to the pump than a catheter positioned in the right atrium, the amount of blood drained is often adequate to meet the needs of the patient. Femoral cannulation is generally restricted by age and size to adolescents or adults. Some surgeons suggest that if the child is old enough to walk and run, the femoral vessels are of adequate size to consider femoral cannulation. One author (H.J.D.) has successfully used femoral vessels in a 13-kg 6-year-old child without difficulty. For patients with femoral venous access who exhibit venous stasis or obstruction of the extremity distal to the cannula, a similar catheter to that used for jugular venous drainage can be placed down the leg via the saphenous or femoral vein to augment decompression of the leg and augment venous return. This catheter is then connected by a Y adapter into the venous drainage line of the ECLS circuit. Compartment syndrome from venous stasis in femoral venous cannulation has been described, and thus careful monitoring of the extremity is mandatory.[19]

In patients who undergo cannulation via the mediastinum, the venous cannula is often placed directly into the right atrial appendage.[20] Although other vessels, such as the subclavian vein or left IJ vein, have been used for ECLS, they have been associated with limb perfusion abnormalities or difficulties with adequate blood flow.

Arterial Access. Arterial access is obtained for cervical venoarterial ECMO by cannulating the right carotid artery and advancing the cannula to the arch of the aorta. Care must be taken not to direct the end of the cannula toward the aortic valve, because this position may result in aortic insufficiency induced by the high-velocity blood flow returning from the ECMO circuit and being directed toward the aortic valve leaflets. Alternatively, if the arterial cannula is advanced too far down the aortic arch, it can occlude blood flow to the left carotid artery and the brain. Concern over use of the carotid artery for cervical ECMO cannulation and the potential for neurologic abnormalities or stroke later in life is a predominant reason why cervical venoarterial ECMO may be less desirable than venovenous support.

The femoral artery also can be used for access during venoarterial ECMO. If a long femoral artery cannula that reaches the thorax is used, good oxygenation to the upper body is assured, but resistance to flow will be elevated.[21] If a short femoral

artery cannula is used, it normally sits in the iliac vessels. The amount of arterial return reaching the upper body, heart, and brain in this mode of ECMO is dependent on antegrade flow out of the native left heart and the retrograde flow from the ECMO arterial return. In patients with severe cardiac dysfunction, arterial return from the ECMO circuit flows further up the aorta and may predominate. In patients with good cardiac function, the majority of upper body arterial flow may be from native left heart ejection. Arterial flow from low-lying ECMO cannulas with good native heart function may thus preferentially flow to the lower body. This arterial flow will mix with venous return from the lower body before the oxygenated blood flows through the cardiopulmonary circuit and out the aorta. In patients with impaired gas exchange, the amount of venous mixing prior to reaching the ascending aorta reduces the amount of oxygen that is delivered to the upper body (heart and brain). Thus the PaO_2 and arterial oxygen saturations in the upper body may be lower than that obtained with cervical venoarterial ECMO. Concern over limited oxygen delivery to the brain has resulted in slow acceptance of venoarterial ECMO with a low-lying femoral arterial cannula. Successful use of ECMO has been achieved, however, with this mode. Monitoring obtained oxygenation with a pulse oximeter on the right hand, ear, or nose of the patient is a good safety precaution to assess the amount of oxygenated flow getting to the head during this mode of ECMO. Echocardiography often can determine the extent of retrograde aortic flow versus native heart ejection. Femoral arterial cannulation also can be associated with impaired flow to the distal limb and resultant ischemia. A small "feeder" cannula can be directed distally down the leg artery and then connected by a Y adapter into the arterial cannula to improve perfusion. Additionally, placement of a 14-gauge catheter into the posterior tibial artery that is then connected by a Y adapter into the arterial side of the ECMO circuit also can provide distal limb perfusion. Ischemia and the need for amputation with femoral artery cannulation has been reported, and thus meticulous attention to limb perfusion is required to prevent this complication.

In mediastinal cannulation, the arterial return cannula is usually placed into the aortic arch under direct vision.[22] During mediastinal cannulation, patients with severe left ventricular dysfunction who cannot open the aortic valve to eject blood often have a left atrial venting catheter inserted to allow decompression of the left heart. This technique prevents pulmonary venous hypertension, which can lead to severe pulmonary edema or hemorrhage. This catheter can be connected by a Y adapter into the venous drainage of the ECLS circuit to provide adequate left heart decompression. Patients with intact sternums who require left atrial decompression often are taken to the cardiac catheterization suite for a blade atrial septostomy that then allows the left heart to decompress into the right atrium and the blood to be drained into the venous ECMO cannula.[23]

Other arterial access sites such as the subclavian also have been used but have resulted in difficulty with limb perfusion. One recent report described the successful use of the axillary artery by means of a Gore-Tex graft placed into the side of the vessel for venoarterial support in adult lung transplant patients supported by ECMO.[24]

The primary modality to verify proper cannula position has traditionally been chest radiography. In a recent report comparing echocardiography and chest radiographs for evaluation of cannula placement during pediatric ECMO, 12% of patients had an abnormal cannula position noted with ECHO that was not identified on a chest radiograph. An additional 7% of patients were noted to have an abnormal cannula position during incidental echocardiography for other reasons. Any concerns with cannula position should be clarified by an echocardiographic examination.[25]

Venovenous Extracorporeal Membrane Oxygenation

Venovenous ECMO differs from venoarterial ECMO in that blood is both withdrawn and reinfused into the patient's venous circulation (Figure 53-2). Cannulation can be introduced via either the cervical or femoral vessels.[26] Currently several types of multiple lumen, single cannulas exist. One such cannula, manufactured by Origen Inc (Austin, Tex.), is available in sizes from 12 to 18 Fr and can support patients weighing up to 12 kg. This cannula is placed into the right IJ vein and requires only one surgical site. The drainage and infusion lumens in this cannula are separated by a distance of a few centimeters. Careful placement and orientation of the cannula can reduce recirculation of reinfused blood from the ECMO circuit, although some amount of recirculation (which will be discussed later in further detail) always occurs. A new venovenous cannula manufactured by Avalon Inc also has become available in sizes from 13 to 31 Fr and is able to obtain flow rates to support even large adult patients. This cannula has two drainage lumens, one of which is positioned in the IVC and one in the superior vena cava. A reinfusion port that sits between the two lumens is directed at the tricuspid valve. Placement of this cannula requires meticulous assessment with echocardiography or fluoroscopy for optimal performance. Although experience with the Avalon cannula is not very extensive at this time, it has the advantage of reducing the need for multiple venous cannulation sites. Time will tell if the advantages of this cannula outweigh its increased cost. Preliminary results are encouraging.

Venovenous ECMO also can be provided via two (or more) separate access sites. The right IJ and femoral vein provide access in the majority of patients. Patients with venovenous cannulation may have venous blood drained from the right atrium via the IJ vein or from the IVC via the femoral vein. Although more venous drainage usually can be obtained from a cervical cannula (which is usually shorter and larger than a cannula that can be placed into the femoral vein), the femoral site often may prove adequate. Older children and adults also may undergo bilateral saphenous or femoral cannulations, with one cannula placed into the high IVC and the other ending in the low IVC or iliac vessels[27] (Figure 53-3).

Several features unique to venovenous cannulation are important to understand. First, because blood is both withdrawn and reinfused into the venous circulation, adequate native cardiac function must exist to provide the "pumping" of oxygenated ECMO return to the patient's systemic circulation. One factor that may influence cardiac function during venovenous ECMO is that well-oxygenated blood returning from the ECMO circuit will enter the right heart. This highly oxygenated blood may reduce pulmonary artery pressure by reducing pulmonary vascular resistance, which may in turn improve right heart function.[28] Likewise, highly saturated blood ejected from the left ventricle to the coronary arteries may improve myocardial blood flow and improve cardiac

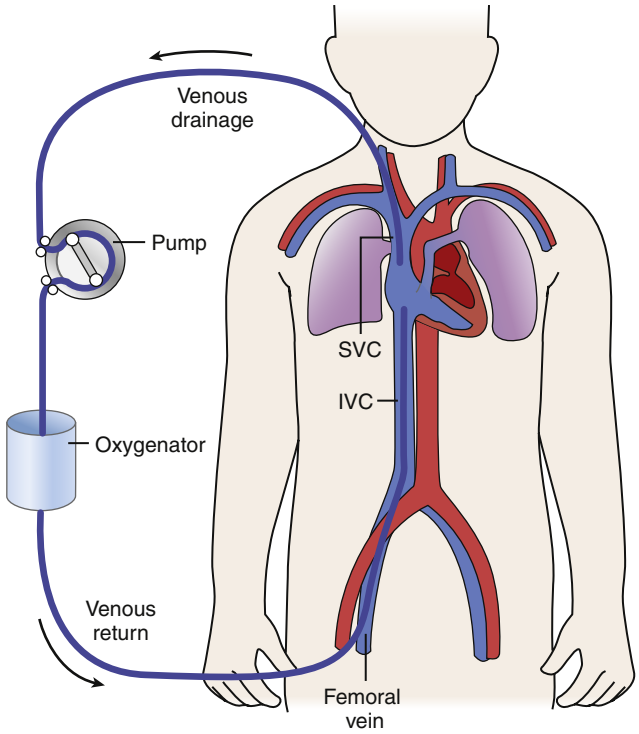

Figure 53–2. Venovenous extracorporeal life support. Note superior vena cava (SVC) to right atrium as venous outflow tract and femoral vein to inferior vena cava (IVC) as inflow tract. Outflow and inflow drainage and reinfusion directions can be reversed.

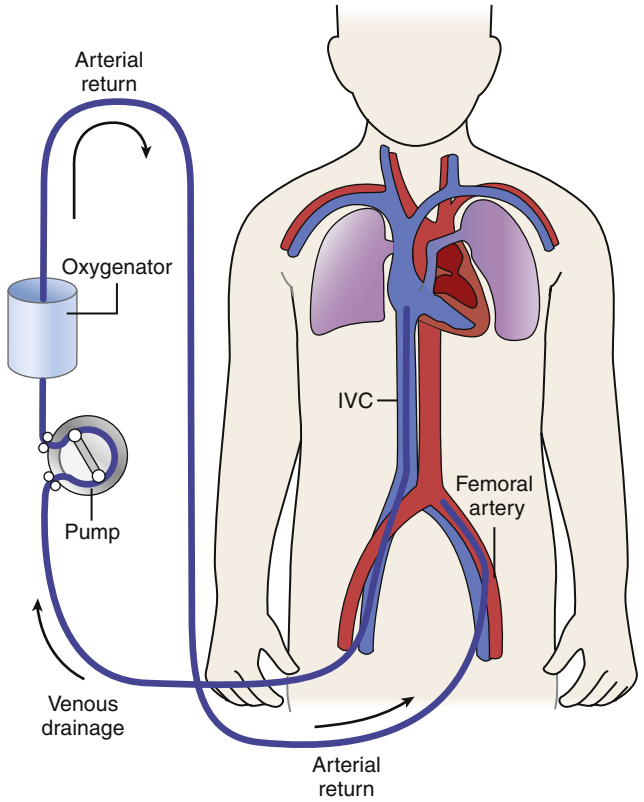

Figure 53–3. Modified venoarterial extracorporeal membrane oxygenation circuit. Bilateral femoral venous and arterial cannulation for extracorporeal life support. *IVC,* Inferior vena cava.

performance. For these reasons, some clinicians will initiate venovenous ECMO even in patients with cardiac dysfunction and transition to venoarterial ECMO if support is inadequate. Other clinicians prefer to use venoarterial ECMO preferentially if cardiac dysfunction exists.

Another feature of venovenous ECMO is that because blood is withdrawn and reinfused into the venous side of the circulation, some of the return coming from the ECMO circuit will be drained by the venous drainage cannula before it goes through the patient's heart into the systemic circulation. This phenomenon is known as "recirculation," and it can be a major limiting factor in providing adequate patient support with venovenous ECMO.[29] With double-lumen cannulas placed via the right IJ vein to the right atrium, careful orientation of the inflow lumen toward the tricuspid valve may limit recirculation. The larger separation of drainage and inflow lumens with the Avalon device seems to be associated with fewer recirculation difficulties.

With two-site venous cannulation, recirculation can be limited to some degree by ensuring that some distance separates the end tips of the drainage and infusion cannulas in the body. Recirculation also can be reduced by draining from the femoral vein cannula and reinfusing into the right IJ vein cannula. The extent of recirculation can be estimated by following the venous saturation in the ECLS circuit; high levels of recirculation will elevate the displayed venous saturation on the drainage line because some of the highly saturated return from the ECLS circuit is immediately drawn out by the drainage cannula. Whether venovenous cannulation will provide adequate capture of the patient's cardiac output for ECMO support depends on how large the cannulas are, where they lie in the vessel, and how much overall ECMO support the patient requires.[30]

Percutaneous Cannulation

Although the historical approach to vessel access has been via an open procedure with placement of cannulas under direct vision, kits for percutaneous placement now exist in many sizes. These kits use a modified Seldinger technique with obturators increasing in size to dilate the vessel. Once the appropriate size is reached, the cannula is passed into the vessel over the largest obturator.[31]

Percutaneous cannulation carries with it the inherent risks of potentially tearing a large vessel during cannulation. Although percutaneous cannulation in some centers is performed by nonsurgical personnel, surgical backup to perform an immediate cutdown for control of bleeding from a disrupted vessel may be needed. Despite the obvious fear of vessel disruption, this complication occurs infrequently. In one early series of 21 patients who underwent cannulation percutaneously, only 18% required any purse-string suturing around the cannulation site for bleeding, and none experienced vessel disruption.[32] Percutaneous cannulation avoids the need for an open surgical site, thus decreasing surgical site bleeding and risk of infection.

Decannulation

Decannulation involves removal of surgically placed cannulas and repair of the operative site, with or without vessel repair. Vessels used in traditional, open venotomy or arteriotomy ECMO often can be repaired at decannulation, although this approach is not used universally. Whether avoiding ligation or repairing cannulated vessels results in long-term improvement in blood flow or reduced risk of stroke from thrombosis or infarct is unknown.[33-37] The longest follow-up study of repaired carotid vessels found restenosis or occlusion in 24%. Patients with reconstructed vessels had fewer neuroradiologic abnormalities and a smaller incidence of cerebral palsy than did unrepaired historical control subjects, although these data represent a small, single-center report and are not the result of a randomized study.[38] Femoral vessels are sometimes accessed via a Gore-Tex or similar graft sewn into the side of the vessel. This graft is tied off at decannulation.

Percutaneously placed cannulas are merely withdrawn at decannulation while gentle pressure is applied to the site until hemostasis is obtained. Vessels accessed percutaneously are not usually ligated either at initiation or decannulation from ECMO. Femoral artery repair often is performed to ensure continued integrity of the vessel and limb perfusion.

Heparin is discontinued at decannulation, and normalization of coagulation usually occurs within a few hours. Protamine can be used for the reversal of heparin-induced coagulation effects if desired, although the risk-benefit ratio of this approach must be considered. Venous thrombosis may develop after ECLS has been discontinued, especially if femoral cannulation is used, which may be an additional reason why heparinization should not be reversed.

Venous Reservoir and Venous Saturation Monitor

Following cannulation, venous ECMO blood flows by gravity through the attached tubing to a reservoir called the "bladder." The bladder historically is a 30- to 50-mL oblong device that sits at the lowest point of the ECMO circuit and allows blood to collect and be drawn from it to the pump-head. It also acts as an air trap and normally has access ports to allow aspiration of any air collected in the bladder chamber. The output of the ECMO circuit is determined primarily by the amount of venous blood that can be withdrawn from the patient to enter the circuit. The venous drainage to the bladder is gravity dependent, generated by the pressure difference between the column of blood in the venous cannula and the reservoir. Thus the siphon effect of venous return is augmented by elevating the patient higher above the venous reservoir.[39] Because the venous cannula can drain only as much blood as is available at the cannulation site, adequate systemic venous return must be maintained. In addition to systemic hypovolemia, any process that limits right atrial filling, such as pneumothorax or pneumopericardium, will also impede drainage to the ECMO circuit.[40] Changes in venous and arterial tone also may alter right atrial and venous filling pressures and affect the amount of venous drainage that can be obtained. The bladder can be used as a servoregulating device that helps to match forward flow to venous return. Advancement in bladder technology has resulted in the Better Bladder (Circulatory Technology Inc, Oyster Bay, NY), which is a piece of collapsible tubing encased in a hard shell. Changes in venous return cause contraction of the tubing, which is registered as a change in negative venous pressure in the circuit. This device provides servoregulation of flow. The vertical orientation of the bladder reduces clotting compared with older oblong, horizontal devices. Servoregulation by monitoring of direct negative and positive pressure within the ECMO circuit has eliminated the use of the bladder in some centers, although most still incorporate some sort of "bladder" within the circuit.

Most centers use a venous saturation monitoring device along the venous drainage line. Monitoring venous saturation over time gives information regarding the balance of oxygen delivery and extraction. Especially in patients receiving ECLS for cardiac support and who have minimal lung injury, care must be taken in interpretation of the observed venous saturation. The presence of left atrial drains or left-to-right intracardiac shunts will increase the observed venous saturation in the ECLS drainage line but may not reflect overall venous saturation in the body. Measuring venous saturation as an index of oxygen delivery and consumption balance from another site not involved with the ECLS circuit is recommended in this circumstance.

Types of Pumps and Oxygenators

Roller-Head Pumps

The majority of ECMO centers use a roller-head pump during extracorporeal support. This device contains steel roller heads enclosed in a box (the pump housing) (Figure 53-4). The heads rotate and push against the ECMO circuit tubing, which is threaded through the box. The piece of tubing in contact with the roller heads is called the raceway and is generally composed of a special material called super-Tygon, which is less likely to rupture under the wear and tear induced by the roller heads. Blood contained in the tubing is advanced forward by the motion of the roller heads. The amount of blood advanced from the raceway is dependent on the number of revolutions of the roller heads, the tubing size, and the

occlusion between the heads and the tubing. Too little contact between the roller heads and the tubing (loose occlusion) will decrease the amount of blood advanced, while excessive pressure of the roller heads against the tubing (tight occlusion) will obstruct blood from moving forward and cause excessive wear on the tubing, which may result in rupture. The correct occlusion is set by measuring the displacement of fluid during roller-head rotation during setup of the ECMO circuit. Newer pumps used for ECMO now often incorporate flow probes that display the actual amount of blood flowing through the ECMO circuit. Transonic probes also can be attached to the outside surface of the ECMO tubing to monitor flow.

Loss of venous return with continuous rotation of the roller heads results in generation of high negative pressure in the ECMO tubing that can lead to hemolysis and cavitation as air is drawn out of solution.[41] The collapse of the tubing and cannula that can be induced by high negative pressure also can lead to damage of the endothelium of the vessel or the right atrium. To protect the patient as venous return is lost and the bladder starts to collapse, a signal is sent to the pump head that causes it to slow down or stop until adequate venous return is achieved and the bladder is once again full. Older versions of the servoregulation system stop the pump whenever venous return diminishes and then restart it when venous return is adequate. This on/off action of servoregulation has been shown to result in acute changes in cerebral blood flow in patients who have undergone cannulation via the cervical route, which may be harmful.[42] Newer circuit and pump designs have eliminated the traditional "bladder box" in favor of the Better Bladder previously described, which performs a similar servoregulating function. The elimination of the bladder reduces the potential for clot formation. It also removes a potential site for air trapping, however, which was easily accomplished with the older cylindrical bladder design. In the new systems, as venous return to the ECMO circuit diminishes, the collapsible tubing signals the roller heads to slow down and then speed up again once adequate venous return is obtained. This mechanism may decrease the on/off action of the roller-head pump and potentially limit the acute changes in blood flow noted with the older style of servoregulation. Newer pumps also may be able to provide pulsatile flow, which may be useful in maintaining normal perfusion patterns to the body. The nonpulsatile nature of venoarterial ECMO flow has been implicated in the renal dysfunction sometimes noted in patients treated with venoarterial ECMO. The pulsatile flow of the newer pumps has yet to be effectively linked to native heart ejection, although this link is a goal in the future.

Roller pumps generate high pressure in the circuit distal to the raceway/roller heads. Thus acute interruption to forward flow as may occur with kinking of the arterial cannula or elevated resistance to blood flow on the high-pressure side of the circuit can result in immediate and potentially lethal circuit rupture. Monitoring of the high pressure side of the ECMO circuit is universal, with critical high limits for arterial line pressure determined based on tubing size and pump flow. Pressures below 300 to 350 mm Hg are desired. Newer pump systems provide safety mechanisms to stop the ECMO pump if line pressure limits are exceeded. Some centers use filters in the ECMO circuit prior to blood return to the patient, which can help detect air bubbles or trap debris. While using a filter seems practical, in reality these devices may be so sensitive that they result in many episodes of stopping ECMO to check alarms or maintain the filters. This stoppage of ECMO may harm the patient and is one reason that air detectors or filters are not used universally.

Centrifugal Pumps

Centrifugal pumps also are used for ECMO support (Figure 53-5). Advanced technology in this area has resulted in many centers changing from roller-head to centrifugal pumps. Some centrifugal pump heads contain a spinning rotor that is controlled by magnets within and without the cone.[43,44] Blood enters the cone at the apex and is propelled tangentially to the base of the pump head, where it is expelled. The longer blood sits in the centrifugal head and the faster the head spins, the more hemolysis will be created. It is also postulated that as blood clots develop in the membrane oxygenator over time and increase outflow resistance, this scenario may also increase hemolysis within the rotor head. Hemolysis has limited the use of centrifugal pumps. Newer pump designs have small heads that require little priming volume and technical advancements in generating the "spinning" motion, which may be associated with less hemolysis than in the past. Use of low-resistance hollow fiber oxygenators

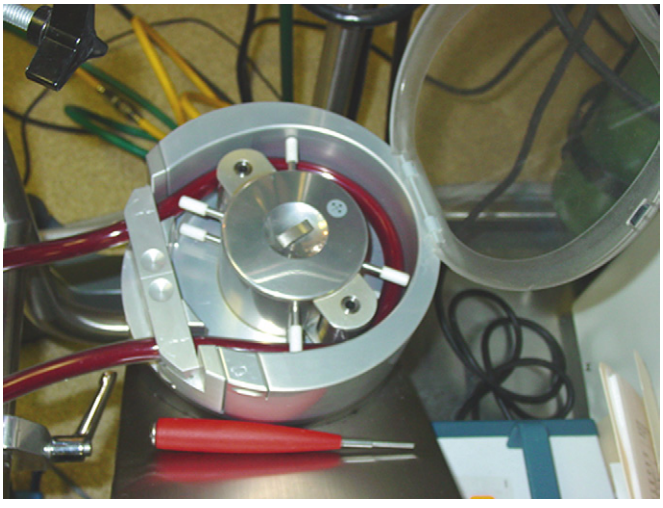

Figure 53–4. Roller (occlusive) pump.

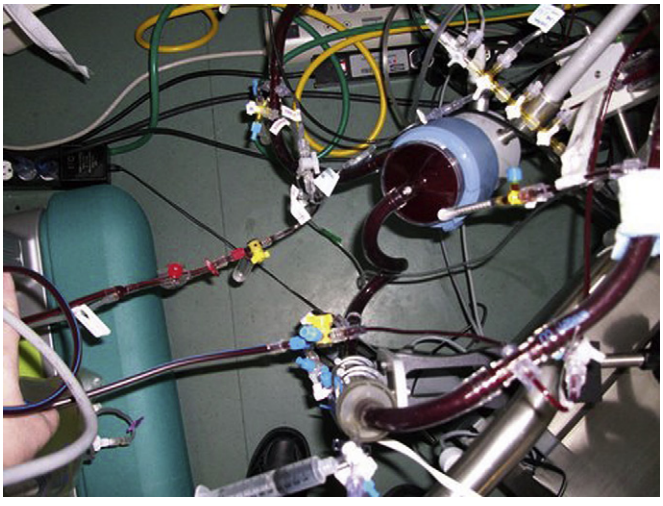

Figure 53–5. Centrifugal pump.

also may reduce hemolysis and make centrifugal pumps even more efficient.

Blood flow to the centrifugal head is augmented by the "suction" effect of the spinning pump head and thus is not as dependent on gravity drainage as are roller-head pumps. Thus centrifugal pumps can be placed at any level relative to the patient, which makes transporting the patient who is being treated with ECMO easier than with roller-head devices. The active suction effect of centrifugal heads can create levels of negative pressures as high as −200 to −700 within the venous inlet tubing. High amounts of negative pressure generated by centrifugal pumps can result in hemolysis, endothelial damage of cannulated vessels, or cavitation of air. Monitoring of venous pressure with alarm limits to signal when excessive negative pressure is occurring is common in most centers. Monitoring venous return and understanding the function of centrifugal pumps are keys to safe and appropriate use of this form of support.[45,46] Another advantage of centrifugal pumping devices is that air and debris are trapped within the vortex of the pump head and may be less likely to embolize to the patient than with roller-head circuits. This advantage is countered by some reports that centrifugal pumps generate more microbubbles than do roller-head devices. A recent publication examining causes of hemolysis noted that the direct interaction of blood with air and high negative pressure (such as occurs with cardiotomy suction during bypass surgery) resulted in the greatest amount of hemolysis.[47] Centrifugal circuits contain a flow probe that displays how much blood is being returned to the patient. Servoregulation occurs by the same method as with roller pumps, in that venous and arterial pressure limits and goals are set and the pump (or the specialist) adjusts flow to maintain set goals. Another advantage of centrifugal pumps is that if there is occlusion of the circuit past the centrifugal head, no high back pressure is exerted to result in rupture of the circuit. Obstruction to forward flow, however, will result in increased hemolysis from the blood trapped in the centrifugal head. The components of ECMO circuits used with centrifugal pumps can be completely coated with heparin, which may limit bleeding or the need for exogenous heparin. Although centrifugal pumps are easy to set up and operate, lack of familiarity with them compared with roller-head pumps requires that close attention to patient physiology and pump interaction be maintained. The newer designs of centrifugal systems allow miniaturization such that transport systems can be more compact and much less cumbersome than in years past.

Advances in ACLS will likely be drawn from continuing work with artificial heart or ventricular support devices. One intriguing report from Japan noted successful use of a self-regulating ECMO device that contained two sac-type blood pumps that are placed in parallel and use compressed air to eject blood. This pump is completely self-regulated and provides pulsatile ECMO return. Three neonatal patients with respiratory failure were successfully supported in Japan with use of this device.[48]

Whether by semiocclusive contact between pump roller heads and ECMO tubing or by advancement through a centrifugal head, blood moves past the pumping device to the membrane oxygenator, where gas exchange occurs. Oxygenated blood then flows through a heat exchanger, where it is rewarmed or cooled depending on the clinical situation, and then it returns to the patient.

Membrane Oxygenator

Until recently, the predominant membrane oxygenator was a silicone membrane envelope (with a plastic spacer screen inside) wound in a spiral fashion around a polycarbonate spool. Gas flows within the interior of the envelope, and blood flows between the turns in the membrane envelope. Blood flow to the membrane lung is controlled by the pump setting.

Gas exchange in the membrane oxygenator is determined by the permeability of the membrane to oxygen and carbon dioxide (their diffusion coefficients), the available membrane surface area, the pressure gradient for oxygen or carbon dioxide between the gas compartment and the blood, and the amount of time gas and blood interface across the membrane.[49] Viscosity, temperature, and pH of the blood also can influence the amount of oxygen binding to the blood as it passes through the oxygenator. Each membrane has a predetermined maximum blood flow above which the thickness of the blood film will limit oxygenation. Blood or gas flow in excess of the manufacturer's specifications may generate high pressure within the membrane oxygenator, which may cause it to rupture. If the blood side of the envelope ruptures, blood will escape into the gas side of the envelope and will drip out through the gas exit port at the bottom of the oxygenator (colloquially called a *nosebleed*). Small breaks in the integrity of the blood/gas barrier with little bleeding can be tolerated because the small tear will usually clot off. More vigorous bleeding often requires an emergent oxygenator change. Rupture of the gas side of the envelope from excessive gas pressure can result in air being transferred to the blood phase of the membrane. This scenario is a true emergency that requires immediate stopping of ECMO and replacement of the oxygenator. Although it is an uncommon complication, a massive air embolus and death can occur in this scenario.

Countercurrent gas and blood flows in the oxygenator provide optimal gas exchange by maintaining the pressure gradient for oxygen transfer from gas to blood along the entire length of the membrane surface. The gravitational gas flow through the membrane also helps remove the condensation that forms when warm blood flows by cooler gas in the membrane. Water droplets are expelled from the membrane surface via the gas exhaust port. Membrane failure can be characterized by a decrease in the capacity to remove carbon dioxide or to oxygenate blood. Membrane failure may result from clot formation on the membrane, which decreases the available surface area for gas exchange; excess condensation in the membrane lung ("pulmonary edema"); or technical defects in the membrane itself. A difference of greater than 100 torr between the estimated PAo_2 in membrane gas and that in blood leaving the oxygenator may indicate early membrane failure. Membrane failure also can be predicted when the pressure drop between blood entering the membrane and leaving it increases and becomes >100 torr. This situation may indicate clotting in the membrane oxygenator with restriction to blood flow. Initially, increasing the partial pressure of oxygen (PO_2) in the membrane gas may augment diffusion of oxygen across the available surface area into the blood and maintain adequate oxygenation. Increasing the flow rate of gas across the membrane also may help remove condensation and improve gas diffusion. When these methods fail or the pressure difference between entry and exit of blood in the oxygenator continues to rise, the oxygenator may need to be

replaced. Although the exact timing for membrane oxygenator failure varies, generally they are not rated for use beyond 7 days. Replacement of the oxygenator is usually a quick and uncomplicated process.

Hollow-Fiber Oxygenator

Hollow-fiber oxygenators are becoming more available for ECMO use and are quickly replacing the silicone oxygenator. These devices are microporous and have long, thin fibers. Blood flows either between the inside or the outside of the fibers. These devices have a lower resistance to blood flow and a lower priming volume than the traditional silicone membrane lung, which makes them faster and easier to prime.[50] Early versions of these oxygenators were plagued by plasma leakage difficulties that resulted in very short life spans for the oxygenator and limited their use. Newer versions hold promise as in vivo studies have shown excellent gas exchange, little hemolysis, and durability of days to weeks without failure from plasma leakage. European versions of hollow-fiber oxygenators, now available in the United States, last for weeks at a time.

In one survey, 80 of 103 North American ECMO centers listed in the ELSO directory as neonatal centers (78%) responded to a survey regarding use of different ECMO devices. Of the responding centers, 82.5% routinely used roller pumps for neonatal ECMO, and the remaining 17.5% used centrifugal pumps. Silicone membrane oxygenators were used by 67% of the respondents, whereas 19% used microporous hollow-fiber oxygenators, and 14% used polymethylpentene hollow-fiber oxygenators. A bladder was used by 85% of the centers, and 4% of these used a mechanical bladder box for servoregulation; the remaining 96% used pressure servoregulation. An air bubble detector was used by 88% of the responding centers. A surface coating was used by 44% of the centers on all their neonatal patients treated with ECMO. Thirty-one percent of the centers use an activated clotting time of 180 to 220 seconds.[51] It is likely that a survey done today would find an increasing number of centrifugal pumps and hollow-fiber oxygenators being used in many centers.

Other advances in oxygenator development have allowed adequate oxygenation without an intercurrent pump to be incorporated. One device, the Novalung, takes arterial blood from the femoral artery and directs it through a hollow-fiber device for oxygenation and carbon dioxide removal, and then reinfused blood is directed into the femoral vein.[52] Experience with this device is growing, and multiple reports of bridging to lung transplantation or to resolution of lung injury can be found in the literature. In addition, an implantable artificial lung is close to being ready for clinical trial.

Other Points

One recent concern with ECMO circuitry is the potential for high levels of Di(2-ethylhexyl)phthalate (DEHP) to be leeched from the polyvinyl tubing over time and thus increase the exposure of the patient to this chemical. One neonatal ECMO circuit evaluation noted that high levels of DHEP were found with routine roller head use over time.[53] High levels of DHEP have been shown to cause sterility and endocrine abnormalities in rats. A recent follow-up report of 22 neonatal patients treated with ECMO who are now 14 to 16 years of age found no abnormalities in observed genital development, sex hormone levels, or thyroid, renal, or hepatic function.[54] Another study found no accumulation of DEHP in the circulating fluid of ECMO circuits that were pre-primed for up to 30 days prior to clinical use.[55]

Work with heparin-bonded tubing also has resulted in several commercially available products. Although none has been proved to effectively reduce the need for systemic heparin administration on a long-term basis, short periods (<24 hours) of support without heparin have been achieved without clotting of the circuit or observable thrombosis in the patient. Complete heparin-bonded ECMO circuits that include a hollow-fiber oxygenator are now available and are used especially in situations where bleeding is expected (in postoperative patients, for example) to lessen or avoid the need for anticoagulation. Research into other ways to prevent circuit clotting such as altering platelet aggregation with agents such as nitric oxide also holds promise for the future.[56]

Patient Populations Treated with Extracorporeal Life Support

The demographics of patients who have received ECMO support over time is shown in Table 53-1.

Neonatal Cardiopulmonary Failure

Most patients treated with ECMO have been neonates with severe respiratory failure with an overall survival rate of 75%. Common diagnoses include meconium aspiration syndrome, respiratory distress syndrome, sepsis, and persistent

pulmonary hypertension of the newborn (PPHN). With the exception of the last group, most of these infants experience a combination of pulmonary parenchymal and vascular dysfunction that leads to impaired gas exchange.[57] The diagnosis, outcome, and mode of ECMO applied in neonatal patients are shown in Table 53-2.

Because vasodilation in the pulmonary circuit depends on alveolar oxygen tension (PAo_2) and pH, any process that results in hypoxia or acidosis can cause persistently high pulmonary vascular resistance, failure of the foramen ovale and ductus arteriosus to close, right-to-left shunting, and profound cyanosis. Obstruction to pulmonary venous drainage or abnormalities in the pulmonary vascular circuit also can result in pulmonary hypertension. Whatever the cause, the resulting systemic arterial desaturation may depress myocardial performance, worsen acidosis, and perpetuate the dysfunctional circulation. The impact of parenchymal lung disease and PPHN varies among infants, but the circulatory contribution to hypoxia of PPHN is commonly very important.

When medical therapies fail to relieve hypoxia and pulmonary hypertension in an infant, ECMO may be an effective means of support. ECMO provides adequate gas exchange and circulatory support without further exposure to high oxygen concentrations or high airway pressures, thus fostering healing of the damaged lungs. The circulatory changes that result from initiation of ECMO also lower pulmonary vascular resistance. Draining right atrial blood reduces right atrial pressure and promotes closure of the foramen ovale. In addition, the reduced blood flow to the pulmonary vascular bed decreases pulmonary flow, reduces pulmonary artery pressure, and relieves right-to-left shunting through the patent ductus arteriosus. Well-oxygenated blood flowing left –to right through the patent ductus arteriosus promotes its closure. By relieving hypoxia, hypercapnia, and acidosis, ECMO promotes relaxation of pulmonary vascular tone. The amount and extent of pulmonary arteriolar smooth muscle begins to regress.[58] These changes allow the transition to a mature circulation. The infant continues to receive ECMO until the parenchymal lung disease heals sufficiently to allow adequate gas exchange. However, pulmonary function tests indicate that commonly infants are weaned from ECMO with only moderate improvement in mechanical lung function.[59] These observations support the impression that circulatory abnormalities contribute importantly to neonatal "respiratory" failure and may partially explain the dramatic difference in outcome between neonates and older patients treated with ECMO.

Infants with congenital diaphragmatic hernia comprise a special subgroup of patients treated with ECMO for severe pulmonary hypertension and respiratory failure.[60,61] Severe pulmonary hypertension or lung hypoplasia leads to about 50% mortality even with ECMO support.[62] Morphologic examination, better understanding of the pathophysiology of this lesion, and stabilization with ECMO as needed preoperatively has improved the survival rate in some centers in this challenging group of patients.[63-66]

As alternative support methods such as high-frequency ventilation (HFV), surfactant, and inhaled nitric oxide (iNO) have been developed and have gained acceptance, the need for ECMO support of neonates has declined.[67] Annual neonatal ECMO cases now number around 800 per year, down from the peak of 1500 cases in the early 1990s. Survival rates also have decreased in the neonatal population during the last few years, which is speculated to be related to delays in institution of ECMO while other less invasive therapies are attempted. Infants for whom all other therapies fail and who require ECMO may thus be sicker than in years past when ECMO was the only "rescue" therapy available. While this explanation seems logical, in an evaluation of the ELSO registry data, there was no difference in outcome between infants who received treatment with iNO, HFV, or both prior to ECMO and those who did not (H. J. Dalton and P. Rycus, unpublished data, 2002). Similarly, there was no statistical difference in measures of respiratory severity such as the arterio-alveolar oxygen tension difference ($AaDO_2$) or oxygenation index in the past few years. An alternative explanation is that use of ECMO has expanded from "simple" neonates with respiratory failure to include a variety of neonates with comorbidities that also may influence survival.

Pediatric and Adult Patients

Approximately 250 nonneonatal pediatric patients undergo ECMO each year for severe respiratory failure, with an overall survival rate of 53% (Table 53-3).[68] Most of these patients have severe hypoxia, hypercapnia, or intractable air leaks. Pulmonary dysfunction resulting from bacterial or viral pneumonia, aspiration syndromes, intrapulmonary hemorrhage, acute respiratory distress syndrome, and other poorly defined disorders have been treated successfully with ECMO. The uncertainties accompanying the use of ECMO in neonates, who compose a homogeneous group relative to other age groups, are compounded in older children. The enormously heterogeneous older pediatric population spans nearly two

decades of physiologic development, and cardiorespiratory failure develops as a result of a multitude of different disorders. Furthermore, many patients have varying degrees of multiple organ failure along with respiratory disease at the time ECMO is instituted. Resolution of both lung disease and secondary organ dysfunction must occur to achieve survival. These factors result in lower survival rates in older patients treated with ECMO than that achieved with the neonatal patient population.[69]

One small subgroup of persons receiving ECLS support are patients with status asthmaticus. In a recent study comparing results with patients who had asthma and that of the ELSO database, the center reported 13 patients who underwent ECLS between 1986 and 2007.[70] The median time from intubation to ECLS was 14 hours (range, 1 to 34 hours). The mean arterial pH was 6.93 (range, 6.78 to 7.03), and $Paco_2$ was greater than 130 prior to institution of ECLS. Four of the thirteen patients (31%) had a cardiorespiratory arrest in the intensive care unit (ICU) prior to institution of ECLS. Use of medical therapies prior to ECLS included intravenous β-agonist in 100%, ketamine infusion in 92%, administration of magnesium sulfate in 69%, helium/oxygen in 69%, and use of an anesthetic inhalational agent in 62%. The mean duration of ECLS was 95 hours (range, 42 to 395 hours). The survival rate was 100%, with no neurologic sequelae noted. Venovenous cannulation was done in 95% of the patients. A second asthma group can be found in the ELSO database, with a total of 64 patients supported by ECLS over the same time frame (including the aforementioned 13 patients). There was little difference in the pre-ECLS variables of age, $Paco_2$, and pH between the groups. The mean duration of ECMO was 94 hours, and 94% of the patients survived. Venovenous cannulation was done in 86% of patients.[70]

Despite attempts to define predictive models for ECMO candidacy and institution, none have proved universally applicable. The clinician still most often relies on clinical judgment at the bedside when determining when conventional medical therapy has failed. Perhaps the largest change in nonneonatal ECMO in the past few years is the variety of patients to whom it has been applied. Patients with recent trauma, tracheal injury requiring reconstruction, burns, smoke inhalation, and severe sepsis, along with those who are immunocompromised, and those who have had a toxic ingestion with cardiopulmonary collapse, are but a few of the types of patients who might have been excluded from ECMO support a few years ago but have now received successful ECMO therapy.[71-74] The multiple exclusion criteria used in the early days of ECMO have now been fairly well eliminated, and each potential patient is generally considered on a case-by-case basis. Even patients with known bleeding disorders such as hemophilia have successfully received ECMO support.[75]

Perhaps one group in which ECMO is still cautiously avoided or rarely applied is patients with malignancy and bone marrow transplant. The continued high mortality in these patients when respiratory failure develops, however, has recently caused several clinicians to advocate for application of ECMO at an early point in the disease to see if outcomes can be improved.

In a recent review of the ELSO data registry, 107 patients with malignancy and respiratory and/or cardiac failure were analyzed. Seventy percent of patients had hematologic disease and 30% had solid tumor malignancy; 80% of the patients required ECLS primarily for pulmonary support. Forty-two percent of patients were weaned off ECLS support, with 35% surviving to hospital discharge. Risk factors for death in the pre-ECMO period were a lower Pao_2, higher oxygenation index, and a higher level of positive end-expiratory pressure (PEEP). Development of renal or cardiopulmonary complications during ECMO also was associated with poor outcome. Deaths were attributed to irreversible organ failure (34%), diagnosis incompatible with life (10%), hemorrhage (5%), and family request to withdraw support (7%). No difference in outcomes was noted in patients with either hematologic malignancies or solid tumors.[76]

This article also commented on the response to a questionnaire by 118 ECMO centers, which noted that 95% of responding sites would consider use of ECMO in a patient with malignancy. This response demonstrates the change in attitude among many clinicians with regard to patients with cancer, which has been a contraindication to ECMO in the past.

Although initiation of ECMO support prior to the development of multiple organ system failure is desired, many patients present with established organ failure already in progress. ECMO may provide an optimal environment for organ recovery in such patients, not just providing respiratory or cardiac support. Further, the ability to add adjunctive devices such as hemofiltration or dialysis (Figure 53-6) to augment renal function and allow use of plasmapheresis or plasma exchange or hepatic support devices is another aspect of ECMO support that may facilitate patient care and organ recovery. Implementation of ECMO during multiple organ systems failure now occurs under a variety of conditions, with resolution of organ

dysfunction and good outcome often obtained.[77] Furthermore, because it avoids the circulatory derangements that often result from extreme forms of mechanical ventilation and provides systemic perfusion without the need for high-dose levels of inotropic agents, ECMO also may prevent damage to other systems.

Extracorporeal Membrane Oxygenation in Adults

ECMO support in adults has been limited (Table 53-4). Early randomized trials of ECMO use in adults did not show benefit of ECMO, and this has closed the door for ECMO consideration for adults in many clinician's eyes.[78] However, these studies had design and procedure flaws that may have affected results. Patients were maintained on high levels of ventilator support, despite ECMO, and bleeding complications were excessive when compared with today's standards. Many reports of successful use of ECMO in adults exist.[79,80] Recently a randomized trial of venovenous ECMO compared with conventional mechanical ventilation in adults with respiratory failure in the United Kingdom was completed and published (the Conventional ventilation or ECMO for Severe Adult Respiratory failure [CESAR] study). A total of 180 patients were enrolled and randomly allocated to receive treatment by ECMO (n = 90) at the single ECMO center in the United Kingdom or to receive conventional management ventilation (CMV) (n = 90) at a designated CMV center. Randomization criteria included a Murray score of >3 or severe respiratory acidosis with pH <7.20. Study results noted that 63% of patients allocated to "consideration for treatment by ECMO" survived to 6 months without disability compared with 47% of those allocated to conventional management (P = .03; risk ratio, 0.69; 95% confidence interval 0.05 to 0.97). Of note, however, 17 of 90 patients randomly assigned to "consideration for treatment by ECMO" who were treated within the ECMO center with a "gentle ventilation" (low tidal volume, limited pressure) strategy were not treated with ECMO and 14 survived. Whether this finding represents the beneficial effects of increased expertise within centers that support patients with severe respiratory failure with ECMO availability or other factors is unknown. Early transfer of patients with potentially reversible respiratory failure who meet similar criteria as those in the CESAR study may be recommended. This study also found a cost/benefit ratio in terms of quality of life and economics that was favorable in the ECMO group.[81]

In another report of ECMO in 255 adults with severe respiratory failure, 68% were weaned off ECMO support and 53% survived to discharge. Multivariate analysis noted that age, gender, pH less than 7.10, the number of pre-ECMO days in which a ventilator was used, and the pre-ECMO Pao_2/Fio_2 ratio were associated with outcome.[82] Other reports of the successful use of ECMO for adult patients with burns, trauma, myocardial infarct with arrest, and a variety of other disease processes exist in the literature. The recent H1N1 flu epidemic reports from Australia, Canada, and the United States in which ECMO use in adults resulted in a 50% to 70% survival rate has caused a sudden increase in the willingness of many adult clinicians to consider use of ECMO. Whether the current surge of centers that are supporting adults with ECMO or that are quickly developing adult ECMO programs will continue or fade as the flu pandemic dissipates is unknown.

The availability of new, large, percutaneous cannulas for venovenous ECMO support, along with small centrifugal pumps and less cumbersome total ECMO systems, are all advantageous to the adult population. Alternative support techniques such as pumpless extracorporeal support and the implantable artificial lung are additional clinical modalities for adult respiratory failure.[83-85]

Extracorporeal Membrane Oxygenation for Myocardial Dysfunction

Perhaps the largest expansion in application of ECMO has been in patients with cardiogenic shock or following repair of congenital heart defects.[86-88] The International ELSO Registry lists more than 9000 patients who have received ECMO for cardiac failure, predominantly following surgical repair of congenital heart defects (Table 53-5).[89] Outcome of neonatal and pediatric patients notes that 60% are successfully weaned from ECMO and 43% survive to be discharged from the hospital. Adult cardiac patients have slightly worse survival rates, with 48% weaned off ECMO and 34% discharged from the hospital.

Table 53–5 Extracorporeal Life Support for Cardiac Failure: Cardiac Runs by Diagnosis

Modified from Extracorporeal Life Support Organization: *International ECMO registry report of the Extracorporeal Life Support Organization,* Ann Arbor, MI, 2009, Extracorporeal Life Support Organization.

Although center-specific factors separating patients with myocardial dysfunction who will die from those who will recover adequate function without such invasive support have been put forth in the literature, none have proved to be universally accepted.[90-93] Patients with evidence of low cardiac output and shock (including low urine output, poor perfusion, hypotension, elevated cardiac filling pressures, and low mixed venous oxygen saturation) despite maximal respiratory and pharmacologic support are candidates for ECMO rescue. The absence of clear criteria for using ECMO and the reluctance to initiate such invasive support often delays use until cardiac arrest has occurred. As a result, a significant number of patients treated with ECMO have recovered myocardial function only to die of hypoxic/ischemic encephalopathy that was experienced before ECMO was begun.

One seeming trend in cardiac patients is to consider ECMO earlier in the course of dysfunction. Availability of ECMO is now a mandatory piece of many cardiac surgical programs. As newer and smaller cardiac assist devices are developed for pediatric patients, the need for ECMO support in this population may wane, but at this time ECMO provides the most readily available support technique over a wide range of patient ages and sizes for cardiac failure.[94,95]

Most patients requiring ECMO for circulatory support have undergone venoarterial ECMO because of its capacity to provide both respiratory and circulatory support. Whereas for many patients cannulation is achieved through the carotid and jugular vessels, transthoracic cannulation is performed frequently in postoperative patients via a reopened sternotomy. Use of the femoral vessels is also feasible in larger patients. Patients with severe left ventricular failure may require a left atrial vent or atrial septostomy to decompress the left ventricle and prevent pulmonary hemorrhage from pulmonary venous congestion. After evidence of myocardial recovery on ECMO, patients are tested with progressively lower flows, with assessment of myocardial function by echocardiography and observation of systemic blood pressure, perfusion, blood gas tensions, and mixed venous oxygen saturation. When a patient exhibits good ventricular function and adequate systemic circulation at low flow, ECMO is discontinued and conventional therapy is resumed. The majority of survivors recover myocardial function within 72 hours of ECMO support, although patients with myocarditis or cardiomyopathy can have good survival rates even after prolonged ECMO support. In most reports, patients whose myocardial function has not improved substantially within 24 to 72 hours of rest on ECMO are not likely to recover cardiac function sufficient to support life.[96,97] Transplantation may be an option in these patients if their underlying cardiac anatomy and general clinical condition make them appropriate candidates.[98] Patients who fail to improve often are evaluated by cardiac catheterization during ECMO to identify residual lesions (if postoperative) or abnormalities that may be amenable to further surgical repair or catheterization laboratory interventions. Cardiac patients with good respiratory function may not routinely require ventilator support. Such patients may require only low levels of ventilator support or be extubated during ECMO, which may alleviate the need for heavy sedation to maintain endotracheal tube position.

Myocarditis and cardiomyopathy are two categories of nonsurgical cardiac failure that have increasingly received ECLS support. While it may be difficult acutely to differentiate unknown cardiomyopathy from viral myocarditis, both diseases may benefit from mechanical support with ECMO or ventricular assist devices that creates a stable hemodynamic milieu where the heart can "rest" and recover. One review of the ELSO registry noted a 61% survival rate in 255 children with myocarditis. Seven patients received cardiac transplantation, with six surviving to discharge. The average duration of ECLS in nontransplant patients was 168 hours, with a range of 145 to 226 hours. Multivariate analysis showed that female gender, arrhythmia while undergoing ECMO, and renal failure requiring dialysis were associated with increased inhospital mortality.[99]

One analysis of a single institution's experience of ECLS following cardiac surgery in children spanning a 17-year period found that 38% of cardiac patients survived to discharge. One third of the children had single ventricle cardiac pathology. Cannulation occurred in the operating room in 46%

of patients, and 51% of cannulations took place in the ICU. Complications included reexploration for bleeding (56%), neurologic complications such as ischemic brain injury or intracranial hemorrhage (17%), renal dysfunction (10%), and pulmonary hemorrhage (5%). Factors associated with mortality were renal failure, neurologic complications, longer ECLS duration, and need for recurrent ECMO support. Mortality also may have been affected by the lack of a cardiac transplant program for patients not recovering myocardial function.[100]

In another recent review of 58 patients receiving ECMO following congenital heart defect repair (January 2003 through June 2008), 67% of patients were weaned off ECMO support and 41% survived to hospital discharge. Single ventricle repair was noted in 53% of patients. When analyzed for factors associated with outcome, ECMO duration longer than 10 days (odds ratio [OR], 6.1), urine output less than 2 mL/kg/h in the first 24 hours (OR, 15), renal failure (OR, 9.4), and pH less than 7.35 after 24 hours of ECMO (OR, 82.3) were all found to be independent predictors of failure to wean from ECMO. Independent predictors of failure of hospital discharge in spite of successful decannulation were: ECMO time of 10 or more days (OR, 11.5), a red blood cell transfusion volume greater than 1000 mL/kg during the entire period of ECMO course (OR, 11.5), and sepsis. Patients who underwent single ventricle repair were at higher risk of hospital mortality (OR, 4.9). This study also developed a probability of weaning from ECMO table based on the four previously mentioned predictors. For example, a patient with an ECMO duration of more than 10 days who had renal failure and poor urine output and pH at 24 hours of ECMO would have a predicted mortality rate of 100%. Similar evaluations in larger series of patients to validate such assessments should be performed to refine ECMO care and improve family counseling regarding prognosis.[101]

To obtain more detailed information on cardiac surgical patients who receive ECLS, an addendum to the general ELSO registry data form was developed several years ago. Data analysis from this subgroup of ECLS patients is under way and should be published soon.

Extracorporeal Membrane Oxygenation for Resuscitation

Perhaps the fastest expansion of the use of ECLS is in support of patients with refractory cardiac arrest. This type of support is termed extracorporeal cardiopulmonary resuscitation (ECPR), or ECMO during cardiac arrest. Designed as a resuscitative tool for patients in cardiac arrest, ECPR has been reported in more than 2000 neonates, children, and adults, with an overall survival to discharge rate of 34%. To facilitate expedient access to ECMO support for ECPR, in situations of acute deterioration or whenever there is insufficient time or personnel for routine ECMO, many centers maintain a "rapid deployment" ECMO circuit setup that is either preprimed with a crystalloid solution or can be primed within a very short period. Other centers use a portable, centrifugal bypass perfusion system that also is easily set up within 10 to 20 minutes. Both methods often use a hollow-fiber membrane oxygenator, which is less difficult and faster to prime for use than a traditional silicone-coated membrane lung.

In a recently published metaanalysis of ECPR, 288 patients were identified, with 40% surviving to hospital discharge. Venoarterial ECMO was used in 99% of patients, and 63% underwent cannulation through an open chest. Median length of stay on ECMO was 4.3 days. The overall occurrence of complications was high (59%). The most commonly occurring complications were neurologic (27%), renal (25%), sepsis (17%), bleeding (7%), and multisystem organ failure (9%).[102]

Another review from the National Registry of CPR found 199 pediatric patients who were treated with ECMO during arrest with an overall survival rate of 44%. In 59 survivors who had their neurologic outcome recorded, 95% had favorable outcomes based on Pediatric Cerebral Performance Scores. By multivariate analysis, renal insufficiency, metabolic or electrolyte abnormality at the time of arrest, and use of sodium bicarbonate or tromethamine were associated with decreased rates of survival. Underlying cardiac illness was associated with an increased rate of survival to discharge.[103]

No definitive criteria exist for patient selection and management for ECPR. One cautionary note is that cardiac patients often are reported to have improved outcomes when compared with noncardiac patients. Whether this finding represents disparity in access to ECPR between cardiac and noncardiac patients, underlying pathophysiology, or other factors requires ongoing study. An addendum to the ELSO registry that has been specifically designed for patients experiencing cardiac arrest may provide more detailed information to answer ongoing questions.[104,105]

Trauma Patients

Trauma patients, particularly those with multiple injuries, are at risk of respiratory failure. Trauma remains the leading cause of death in young adults. Common pathophysiological mechanisms include direct chest injury causing pulmonary contusion, long bone or pelvic fractures causing fat embolization, or as an inflammatory-mediated event following systemic injury known as acute respiratory distress syndrome. Extracorporeal membrane oxygenation provides "lung rest" by permitting reduced ventilator settings and limiting further barotrauma while maintaining tissue perfusion and oxygenation. In this study comprising 28 adult patients treated with ECMO because of trauma-related respiratory failure, 20 patients were successfully weaned off ECMO and discharged. Eight patients died as a result of overwhelming sepsis and irreversible cardiogenic shock.[106] Good outcomes in pediatric patients undergoing ECMO following trauma also have been reported.

A newly funded National Institutes of Health trial of penetrating trauma resuscitation by means of an extracorporeal life support variant holds interest for the future. This protocol involves placement of a femoral arterial cannula in the descending aorta, above which a balloon is inflated and a cold flush solution is delivered to the upper body (heart/brain). This procedure results in a state of suspended animation, allowing the patient to be taken to the operating suite for definitive repair of injuries; bypass then allows rewarming and recovery.

Other applications of ECMO include management of patients with extreme hypothermia who require gradual extracorporeal rewarming. Trauma patients with massive hemorrhage and ongoing coagulopathy from transfusion-related hypothermia also have received short-term extracorporeal support with bypass to facilitate rewarming to temperatures

that help normalize the coagulation process. Once rewarming is achieved, cannulas are withdrawn.

Patient Selection Criteria

Various mortality prediction criteria have been put forth as indicators of when ECMO rescue is best applied, although many of these criteria have been derived from small series of historical data for patients with respiratory failure or were extrapolated from neonatal respiratory failure data.[107-110] Attempts to provide universally accepted criteria for institution of ECMO have proved difficult.

The predominant listed criteria for treating a pediatric patient with ECMO remains "failure to respond." Although no strict definition of what failure to respond entails exists, the basic premise may be interpreted as a determination by the clinician who is caring for the patient that current support is insufficient and death is imminent without ECMO rescue. More than 50% of pediatric patients treated with ECMO who were reported to the ELSO registry have failure to respond as the major criteria for initiation of ECMO.

For the majority of patients who undergo ECMO, less invasive methods of respiratory support have failed.Such methods of support often include conventional mechanical ventilation in pressure control or pressure-regulated volume control modes, high PEEP, HFV, surfactant, or iNO. An evaluation of the ELSO registry noted that in pediatric patients who underwent ECMO, use of both iNO and high-frequency oscillatory ventilation prior to ECMO was associated with poorer outcome than in patients who received neither or only one of these modalities prior to ECMO (H.J. Dalton and P. Rycus, unpublished data, 2004). Examples of selection criteria used for ECLS in the past include the following:

1. Requirement for Fio_2 greater than 60% to maintain arterial oxygen saturation more than 85% to 90% despite high PEEP
2. Mean airway pressures higher than 20 cm H_2O on conventional mechanical ventilation
3. Mean airway pressures higher than 25 to 35 cmH_2O on HFV
4. Evidence of ongoing barotrauma in the form of air leak or pulmonary interstitial edema
5. An oxygenation index (OI) of greater than 40, where OI = (100 × [Mean airway pressure × Fio_2])/Pao_2
6. Mechanical ventilation less than 7 to 14 days
7. Lack of an underlying irreversible illness
8. Lack of known significant neurologic damage
9. Lack of an ongoing bleeding diathesis
10. Inability to ventilate

Concern has been expressed that respiratory severity indices reported in the past are not applicable to patients of today who experience respiratory failure, although few recent reports compare past severity indices to outcome in the current era. One recent report examined the current utility of respiratory severity indices used in the past for potential ECMO eligibility in 118 children with acute hypoxemic respiratory failure.[99] Indices examined included the $AaDO_2$, OI, Pao_2/Fio_2, ventilation index, and mean airway pressure (Paw), as well as individual ventilator settings and arterial blood gas values. When risk of mortality based on respiratory severity indices predictions were compared with actual mortality observed in these 118 children, survival was much better than would have been predicted based on historical data.[111] As an example, an OI greater than 40 has been associated with more than 80% risk of death in the past. Although only 15 patients reached an OI greater than 40 in this study, the positive predictive risk of mortality in these patients was 40%, significantly lower than predicted by past reports. An $AaDO_2$ greater than 450 for 24 hours, Paw higher than 23, or $AaDO_2$ higher than 420 had positive predictive value for mortality rate of 32% to 40%. Using logistic regression, no respiratory parameter ($AaDO_2$, OI, Paw, ventilator settings, or blood gas values) was independently correlated with death. All deaths were associated with multiorgan system failure, coincident pathology, or perceived treatment futility, leading to limitation or withdrawal of care. The overall mortality rate of these 118 children was 22%, with no previously healthy child dying from respiratory failure. Nonconventional therapies applied included HFV in 25 (21%) of 119 (64% survival), surfactant administration in 15 (13%) of 119 (73% survival), iNO in 38 (32%) of 119 (69% survival), and ECMO in 4 (3%) of 119 (75% survival) of patients.

In another review of factors associated with death in children with severe respiratory failure, the peak oxygenation index and pediatric risk of mortality (PRISM) score were found to be independent predictors of outcome, although no definitive OI cutoff that predicted death could be identified.[112] Using this parameter as a tool to serially assess the severity of hypoxemic respiratory failure is useful.

Gas Exchange and Oxygen Delivery

Oxygenation

The difference between the PO_2 in the gas supplied to the oxygenator and that in the patient's systemic venous blood provides the "driving pressure" across the membrane lung. As an example, 30% oxygen blended into the gas entering the oxygenator will result in an estimated PAo_2 about 228 torr at sea level. The PO_2 of venous blood entering the oxygenator depends on the difference between oxygen delivery and consumption in the patient, but is usually about 40 torr. The driving pressure for oxygen diffusion into the blood thus would be approximately 188 torr (228 torr – 40 torr = 188 torr), which is usually adequate to achieve 100% saturation of hemoglobin. Higher oxygen concentrations in the gas phase may be necessary to compensate for loss of membrane surface area over time to maintain hemoglobin saturation. At post-oxygenator oxygen saturations greater than 95%, increasing the oxygen concentration of the sweep gas has little incremental effect on blood oxygen content. For this reason, oxygen concentration in sweep gas usually is adjusted to maintain an oxygen saturation of approximately 95% in postoxygenator blood.

Carbon Dioxide Exchange

The pressure gradient for carbon dioxide between blood and gas is less than that for oxygen. The partial pressure of carbon dioxide in the body is usually low (the venous partial pressure of carbon dioxide, $Pvco_2$, is 45 to 55 torr), so that the pressure difference between the blood and gas phase in the oxygenator is much less than it is for oxygen. Despite the small pressure difference, the membrane's high diffusion coefficient for carbon dioxide (at least six times that for oxygen) allows excellent carbon dioxide removal, even at low flow rates.

To eliminate more carbon dioxide, the gas flow in the membrane must be increased, much as alveolar ventilation must increase to eliminate carbon dioxide from the body under physiologic conditions. Carbon dioxide removal is also limited by the surface area across which gas exchange can occur. Thus increased carbon dioxide clearance may be obtained by using larger oxygenators or using more than one oxygenator in parallel in the circuit. Conversely, to prevent excessive CO_2 removal and hypocapnia in small infants and neonates, carbon dioxide may be blended into the gas mixture to further reduce the partial pressure difference between blood and gas and maintain normocarbia.

Oxygen Delivery

During venoarterial ECMO, both increasing oxygen delivery and increasing the patient's Pao_2 and arterial saturation can be accomplished by increasing the ECMO flow rate. This strategy diverts more of the systemic venous return into the ECMO circuit for oxygenation while at the same time proportionally decreasing the amount of venous blood that enters the diseased pulmonary circuit. The result of increasing ECMO flow, then, will be an increase in oxygen delivery provided by the circuit and an elevation in measured systemic arterial saturation and Pao_2. Another means to change the proportion of native blood flow to that from the ECMO circuit is to decrease the overall blood volume in the patient. During cardiopulmonary bypass, filling pressures and overall blood volume can be adjusted by removal of blood volume into the bypass circuit. Circulating volume is also frequently decreased by modified ultrafiltration. During ECMO, these same principles can be followed: excessively high filling pressures can be lowered by simple removal of blood volume from the circuit, and diuretics and renal replacement strategies can be used to control fluid balance. Care must be taken, however, to avoid decreasing circulating volume excessively, because this may in turn cause tissue hypoperfusion or an increase in oxygen extraction.

Systemic oxygen delivery is defined as the product of cardiac output and arterial oxygen content.[113] By altering the amount of cardiac output diverted from the patient to the ECMO circuit, venoarterial ECMO can be "complete" or "partial." In the patient undergoing complete venoarterial ECMO, the cardiopulmonary circuit is almost totally bypassed and oxygen delivery is determined by the product of pump flow and the oxygen content of blood leaving the oxygenator. Most centers use partial venoarterial ECMO because adequate systemic oxygenation can be achieved by diverting 60% or more of cardiac output to the ECMO circuit. Studies have suggested that complete bypass of the pulmonary circuit may lead to pulmonary alkalosis or ischemia and cause direct damage of the pulmonary capillary bed.[114] Microsphere studies have shown that the majority of coronary artery perfusion comes from native left heart ejection during ECMO, which is another reason to avoid total bypass.[115] Monitoring of adequate oxygen delivery is aided by following venous saturation.[116] Most ECMO circuits contain a sensor along the venous return line that measures and displays venous saturation. Other centers use an in-dwelling blood gas monitor for the same purpose. Low venous saturation and other markers such as elevated lactate, poor perfusion, decreased urine output, and mental status changes may indicate the need for improved oxygen delivery. If ECMO flow cannot be increased to provide adequate support, an additional drainage cannula to augment ECMO flow and allow increased support may be needed.

In patients who undergo cannulation via the venovenous route, reduced systemic oxygenation will be observed compared with patients with venoarterial ECMO. This reduced systemic oxygenation is a result of the lower amount of native cardiac output that can be processed by the oxygenator and recirculation effects that limit the return of oxygenated blood to the patient from the ECMO circuit. Persistent signs of inadequate oxygen delivery or continued hemodynamic instability with venovenous ECMO may require conversion to venoarterial ECMO. Patients receiving venovenous ECMO support or who have a left atrial communication to the ECMO circuit may have artificially high measured venous saturations because of mixing of well-oxygenated blood with systemic venous return. Monitoring venous saturations from another site in the body may be helpful to monitor adequacy of support in this circumstance.

One novel means of improving oxygenation to the head and upper body in patients who have undergone cannulation through the bilateral femoral veins is to add an additional venous cannula via the right IJ vein to the right atrium. Connecting this cannula to the inflow return side of the ECMO circuit will increase the amount of oxygenated bypass directly returning to the right heart. This procedure may improve overall oxygen delivery to the patient while still avoiding the need for arterial vessel cannulation.

Loose occlusion of the roller heads against the raceway tubing also can lead to less blood being propelled forward through the ECMO circuit and reduce systemic oxygen delivery. In centrifugal pumps, low head revolutions also can result in inadequate forward flow of blood to the patient, and if the patient's arterial blood pressure is higher than that generated within the centrifugal circuit, arterial blood can flow from the patient into the centrifugal circuit. Increasing the revolutions per minute in the pump head will reverse this problem. Persistent vasodilation, which occurs in patients with sepsis, may require the administration of low levels of vasoconstricting agents to maintain adequate central venous pressures and adequate pump return without massive fluid administration

Patient Management

Screening

Infants who are candidates for ECMO undergo routine cranial ultrasonography to identify existing intracranial hemorrhage.[117,118] The presence of hemorrhage greater than that confined to the germinal matrix (grade I) is a contraindication to ECMO, because heparinization may cause additional bleeding. Older patients also may have evaluation of intracranial bleeding by ultrasound if an open fontanelle is present. Computed tomography also can be useful if the patient is stable enough to undergo such an examination. Frequently, however, older patients are not stable enough to undergo a computed tomography scan, and a clinical neurologic evaluation may be hampered by sedation or neuromuscular blockade prior to ECMO. The decision to treat a patient with ECMO thus is made on the best assessment of neurologic function. Echocardiography is usually performed prior to institution of ECMO to determine if hypoxia is a result of structural defects in the heart, which may be better served by surgical repair

than by ECMO support. Echocardiography also can identify ventricular dysfunction, pulmonary hypertension, and pericardial effusions; all these data are useful to properly manage the patient and to select the optimal form of ECMO or even to avoid it if less invasive procedures can be undertaken. ECHO also is used to detect the presence and direction of central shunts within the cardiac system.[119,120]

Interhospital transport of patients either for ECMO consideration or those for whom ECMO was initiated at a non-ECMO facility is a challenge. Transporting patients undergoing ECMO can be technically challenging and expensive. At present in the United States only three facilities routinely provide this service. One single center report found no statistical difference in survival rates for patients for whom ECMO was initiated in their center compared with patients who underwent cannulation at an outside facility and were brought to their center while receiving ECMO support. The logistics involved with such endeavors require meticulous planning. The transport team consisted typically of an ECMO coordinator, pediatric cardiac surgeon, surgical assistant, and intensivist. The predominant mode of transport was by helicopter (75%). No patient died during transport. Whether increased use of ECLS will occur and the need for ECMO transport capabilities throughout the United States will increase is unknown at this time. This is one area where regionalization of such services might prove practical.[121]

Cannulation and Initiation of Extracorporeal Life Support

A guideline for selection of cannula size and circuit components based on patient weight is shown in Table 53-6 (cardiac and respiratory failure patients).

Cannulation is usually performed at the bedside, with the patient receiving a combination of local anesthetics and intravenous analgesics, sedatives, and neuromuscular blocking drugs. An initial bolus of heparin (usually 50 to 100 units per kg) and continued heparin infusion ensures systemic anticoagulation for the duration of ECMO. Activated clotting time, measured at the bedside, provides a gauge for adjusting the heparin dose to avoid either catastrophic clotting in the circuit or bleeding complications.[122] The ECMO flow is initially begun at 50 mL/kg/min and is increased in 50- to 100-mL increments. In infants, a rate of 100 to 200 mL/kg/min usually provides adequate perfusion and oxygenation, although patients in a state of high cardiac output, such as sepsis, may require a higher rate. Use of high-flow ECMO also is recommended in patients with single ventricle physiology and a systemic-to-pulmonary artery shunt to provide adequate circulation for both systemic and pulmonary organs.[123] Pediatric patients usually require about 90 mL/kg/min of ECMO flow to maintain adequate oxygen delivery, and adult patients require rates of 50 to 70 mL/kg/min. Estimates of flow needs also can be predicted by using cardiac index data based on body surface area (BSA). One caution in estimating ECMO flow in this manner is that patients with sepsis or multiple organ dysfunction may require flows that are much higher than predicted. These factors must be taken into account when selecting cannula size, because larger cannulas than that predicted by BSA may be required. Patients with sepsis or critical illness may require flows that are higher than that predicted from BSA algorithms. In venoarterial ECMO, the arterial waveform provides a rough estimation of the degree of bypass provided by the ECMO circuit. Because ECMO flow is nonpulsatile, increasing flow and decreasing left ventricular output will result in a flattening of the arterial wave contour and a narrowing of the pulse pressure. Severe myocardial dysfunction also may cause a flattened wave contour because left ventricular output may be minimal. This effect must be kept in mind when waveform contour is used to monitor the extent of bypass.

Priming

Priming of the ECMO circuit prior to initiation is accomplished with a crystalloid solution that is then replaced with blood. Because required blood usually has been citrated and stored, it may be acidotic, depleted of calcium, and have a high potassium level. Calcium (usually as calcium chloride), bicarbonate or tromethamine, and heparin are added during the priming procedure. Electrolytes should be measured in the priming blood before bypass is begun, because disturbances of cardiac rhythm or frank cardiac arrest can occur upon initiation of ECMO.[124] Hyperkalemia exists almost universally in the ECMO primed circuit despite buffering by calcium and bicarbonate. The potassium level rarely causes systemic effects once the ECMO prime is diluted with the patient's intrinsic blood volume. As an example, if a neonatal patient with a

Table 53–6 Sample Component Requirements Based on Weight for Extracorporeal Life Support (Respiratory and Cardiac Support: Roller-Head Pump)

Modified from University of Michigan, Ann Arbor, MI, and Children's National Medical Center, Washington, DC.

blood volume similar to that of the ECMO circuit has a potassium level of three and the ECMO prime has a potassium level of seven, the circulating potassium level may be around five upon ECMO initiation. This scenario is unlikely to cause systemic or cardiac effects. Larger patients with blood volumes proportionally much greater than that of the ECMO circuit will have less risk of hyperkalemia or hypocalcemia. Use of the freshest blood available also may lessen the degree of hyperkalemia in the primed circuit. Rarely, hyperkalemia may be of such concern that blood must be washed prior to ECMO use or the primed ECMO circuit cannot be used until the potassium level is reduced. In this circumstance, blood in the circuit is replaced with fresh frozen plasma or albumin to lower the circulating potassium concentration in the prime.

Patient Management During Extracorporeal Life Support

Hypovolemia causes low central venous pressures and results in decreased venous return to the circuit. This situation can be corrected easily with fluid administration. Increased oxygen delivery also can be accomplished by increasing the pump flow rate, which increases blood diverted into the ECMO circuit for oxygenation. Anemia can be corrected with transfusion of blood products. Maintenance of hemoglobin is needed to sustain adequate oxygen content.[125,126] Although clinicians disagree about the level of hemoglobin needed during ECMO, all clinicians agree that transfusion up to a hemoglobin level of 14 to 15 g/dL gives the greatest amount of support. Patients who have a hemoglobin level much lower (10 g/dL) also may do well. The needs of the patient and the risks of transfusion are a balance that the clinical team assesses on an ongoing basis. Treatment of sepsis requires identification of the responsible organisms and initiation of antibiotic therapy.

Intermittent administration of packed red blood cells to maintain adequate blood volume and hematocrit will be required.[127-129] Fresh frozen plasma also may be given intermittently to provide adequate clotting factors and help prevent excessive bleeding.[130] Platelet sequestration in the ECMO circuit is a constant problem. Historically, platelet counts of 80,000 to 100,000/mm^3 have been maintained routinely for patients undergoing ECMO to deter bleeding, but multiple examples now exist of patients undergoing ECMO with thrombocytopenia of 30,000/mm^3 or lower and in whom massive bleeding was not a problem. Although patients often require frequent platelet transfusions, the capacity of transfusions to increase platelet counts to high levels may be limited in some patients, such as those with cancer. In such patients, lower platelet counts may be allowed and careful monitoring for bleeding is maintained.

Another recently identified problem with ECMO, especially for prolonged runs, is heparin-induced thrombocytopenia (HIT). HIT should be suspected in any patient receiving heparin when a drop in platelet count occurs that is unresponsive to platelet transfusion or when the platelet count continues to fall without an identified reason. Although HIT usually develops 5 to 15 days after the initial exposure to heparin, it can occur immediately in patients with previous exposure to heparin, such as patients who have undergone cardiac surgery. HIT associated with immune response to heparin can result in severe thrombocytopenia. The only "cure" is to stop the patient from being exposed to heparin. During ECMO, stopping exposure to heparin necessitates the use of other anticoagulation methods. Currently, lepirudin and Argatroban are the two alternatives that have been commented upon with regard to ECMO, although neither is widely used in the pediatric population in general.[131-133]

Lepirudin is a derivative of the leech anticoagulant hirudin. Two reports of its use during ECMO noted no bleeding or clotting complications. It works rapidly and has a relatively short half-life of 1.3 hours, and the dosage is determined on the basis of weight. In one pediatric report a 0.1 mg/kg bolus was administered followed by an infusion of 0.12 mg/kg/h and the patient was monitored to maintain the activated partial thromboplastin time at two times the control level. Use of lepirudin is relatively contraindicated in patients with renal failure.

Argatroban is also a direct thrombin inhibitor approved for use in patients with HIT. It is metabolized predominantly by the liver but excreted normally even in patients with severe renal failure. In one report of two infants with congenital diaphragmatic hernia and HIT who were treated with Argatroban at a dose of 0.5 to 10 μg/kg/min to maintain activated clotting time around 200 seconds, the infants had no associated bleeding or thrombotic complications. Another report of thrombin production in ECMO circuits comparing heparin-prepared circuits with Argatroban-primed circuits found that the circuits primed with Argatroban had less thrombin generation.[134] Thrombocytopenia due to platelet antibodies also has been described.

Adequate nutrition is essential for healing and is provided as total parenteral nutrition, enteral feeding, or a combination of both. The old concern of lipids potentially causing either platelet malfunction (bleeding) or increased lung damage from metabolism of arachidonic acid seems to have died away. Anecdotally lipids have been associated with shortened circuit lifespan and with the development of cracks in stopcocks used to connect the lipid infusion line to the ECMO circuit. [135] Use of lipids also may be associated with a shortened lifespan of hollow-fiber oxygenators. Enteral feeding has been shown to be safe and effective during ECMO and may limit the need for total parenteral nutrition with its associated complications.[136,137]

Currently, maintaining strict fluid balance in critically ill patients is popular, and patients undergoing ECMO are no exception. The use of diuretics, concentrated drug infusions, and hemofiltration in patients with renal insufficiency are other important aspects of patient care.[138,139] Renal failure, hypervolemia, and fluid overload are frequently seen in patients undergoing ECMO. Use of continuous renal replacement therapies (CRRTs) has become commonplace during ECMO, both to maintain fluid balance, support failing kidneys, and potentially clear "bad humours" from the blood. One of the proposed mechanisms for development of acute renal failure (ARF) in patients undergoing ECMO is a reduction in the pulsatile character of renal perfusion. Circuit-associated hemolysis in patients receiving CRRT also can perpetuate ARF. The most widely used technique for providing CRRT is to connect a hemofiltration filter into the ECMO circuit and to control the ultrafiltrate volume using an intravenous infusion pump.[140]

A study that examined acute renal failure in patients who were undergoing ECMO and required CRRT noted that ARF was present in 70% of patients and CRRT was initiated in 58% of patients. The study concluded that the odds of developing

ARF increased with duration of ECMO support. Patients undergoing ECMO in whom ARF developed had a 4.7-fold increase in the odds of inhospital mortality.[141]

One recent abstract noted that CRRT with continuous venovenous hemofiltration (CVVH) was used in 27 (32%) of 84 pediatric patients undergoing ECMO, usually to maintain fluid balance. Overall survival was 75% for patients with respiratory failure. Of these 84 patients, 27 were matched for age, diagnosis, and PRISM III score with patients undergoing ECMO who did not receive CVVH. Improved fluid balance over time, less use of diuretics, and the tendency to reaching caloric-intake goals more quickly were noted in patients undergoing renal replacement. No difference was found in survival (67% CVVH, 82% non-CVVH, $P = .352$), duration of ventilation after ECMO, or the need for potassium supplementation between groups.[142] Data from the ELSO registry shows that about 30% of pediatric and adult patients undergoing ECMO undergo renal replacement either by hemofiltration or dialysis, although elevations of creatinine greater than 1.5 were reported in only 15% of pediatric patients. Other adjunct extracorporeal therapies such as plasmapheresis or liver support systems also have been used successfully during ECMO.

The optimal ventilatory management for patients undergoing ECMO is not known, and each center may have its own preference for how to treat the lungs during ECMO. Minimizing further barotrauma or oxygen toxicity and providing an environment that promotes lung healing are basic goals. For neonatal patients undergoing venoarterial ECMO, most centers use ventilator settings with low peak inspiratory pressure (PIP) (25 to 30 cm H_2O), PEEP (5 cm H_2O), intermittent mandatory ventilation rate (6 to 12 breaths/min), and fraction of inspired oxygen (Fio_2, 0.21). Lung volume decreases dramatically with such settings in most patients undergoing ECMO, resulting in generalized opacification on the chest radiograph. Maintaining lung expansion and functional residual capacity with higher levels of PEEP (10 to 15 cmH_2O) was associated with shorter ECMO durations in one neonatal study, and this approach is used frequently at many centers.[143] Given the recent evidence supporting the role of atelectasis in ongoing cytokine production, maintaining some lung distention with PEEP even during ECMO seems prudent. In older patients, use of PEEP with reduced peak airway pressures, low ventilator rates, and low concentrations of inspired oxygen is also the predominant method of support. Commonly, PEEP levels in the range of 5 to 15 cm H_2O, PIP less than 30 cm H_2O, and breath rates of 10 to 12 with inspired oxygen concentrations between 30% and 40% are reported in the pediatric and adult ECMO literature.

Patients with barotrauma and persistent air leaks even at low distending airway pressures on ECMO may benefit from a period of total apnea to allow the lungs to rest.[144] The technique of allowing airway pressure to equilibrate with atmospheric pressure has been used successfully to promote healing of ruptured parenchyma within 48 to 72 hours. Reinflation is accomplished by lavage to remove accumulated secretions, hand ventilation to begin recruiting collapsed alveoli, and then resumption of mechanical ventilation to complete alveolar reexpansion. Use of HFV to improve lung recruitment, bronchoscopy to remove inspissated secretions, and prone positioning to improve lung mechanics have all been used successfully in patients undergoing ECMO. Surfactant also has been given to improve oxygenation and lung mechanics, although data on its effectiveness during ECMO is lacking.

At high flow rates in patients undergoing venoarterial ECMO, a minimal amount of blood is entering the pulmonary circuit. Manipulating ventilator settings, especially in patients with diseased lungs with impaired gas exchange, has little effect on blood gas tensions. Oxygenation and carbon dioxide elimination depend on the function of the ECMO circuit. With venovenous cannulation, less overall bypass is obtained, and the systemic oxygenation provided by ECLS is less than with venoarterial access. Arterial oxygen saturations are thus lower with venovenous support. While the majority of patients do well with saturations in the 80s, monitoring of adequate oxygen delivery by following lactate, venous saturation, urine output, metabolic acid-base balance, and mental status is recommended with these patients.

Increasing oxygenation over time may herald recovery of native pulmonary function. As the lungs heal, compliance and tidal volume increase.[145] The radiograph of the lung fields gradually improves from atelectatic opacification to increasing lung aeration. Increasing concentration and absolute volume of expired carbon dioxide also heralds improved alveolar/capillary gas exchange. These changes, along with evidence of decreasing pulmonary artery pressure (indicated by resolution of right-to-left intracardiac shunting), may signal that the patient is ready to be weaned from ECMO.[146]

Maintaining patient comfort during ECMO can be a challenge, especially in prolonged ECMO runs. Sedation and analgesia are provided by routine medications such as morphine, fentanyl, midazolam, lorazepam, and other agents. If lorazepam infusions are used, intermittent osmolality and the osmol gap should be calculated to prevent propylene glycol toxicity.[147] Medications may be absorbed by the membrane oxygenator, and patients can become tolerant to them over time.[148] The extraordinary amount of medications some patients require has led some centers to use anesthesia gas in the membrane oxygenator, although a protocol for appropriate scavenging of these gases must be developed for use. European centers are facile in maintaining patients in a "normal" awake state in which they can play games, read books, and even eat during their ECMO course. Nursing and family support play a major role in the success of providing ECMO with little sedation.

Weaning from Extracorporeal Membrane Oxygenation

A patient can be weaned from ECMO in several ways. The most common mode involves reducing the ECMO flow rate in increments every 1 to 2 hours, provided that arterial and mixed venous oxygen saturations remain adequate. Once ECMO flow is reduced to provide only about two thirds of cardiac output, ventilator support is increased (PIP 20 to 30 cm H_2O, intermittent mechanical ventilation 20-30, PEEP 5 cm H_2O, and Fio_2 30% to 40%). Weaning continues to an ECMO flow of 50 to 100 mL/min in infants or an estimated 10% of cardiac output. If the patient remains physiologically stable with acceptable blood gas tensions at this low flow, the ECMO cannulas are clamped and the infant is observed while off ECMO support for a short time. If respiration and circulation remain stable during the trial, the cannulas are removed and conventional therapy is resumed. Quicker weaning

methods involve decreasing ECMO flow in larger increments over shorter periods, similar to the way it is performed during cardiopulmonary bypass in the operating room.[149]

Complications

Complications that occur during ECMO can be mechanical or related to the particular patient. The most common adverse events reported to the ELSO Registry are shown in Table 53-7 (patients with respiratory failure) and Table 53-8 (cardiac patients).

Table 53–7 Mechanical and Patient-Related Complications for Respiratory Population

Complication	Neonatal Respiratory n (%)	Pediatric Respiratory n (%)	Adult Respiratory n (%)
MECHANICAL			
Oxygenator failure	5.9 (53)	13.3 (44)	19.3 (43)
Tubing rupture	0.6 (72)	2.7 (47)	2.5 (30)
Pump malfunction	1.7 (67)	2.8 (46)	3.0 (33)
Cannula problems	11.5 (68)	15.3 (50)	9.1 (39)
PATIENT-RELATED			
Gastrointestinal hemorrhage	1.7 (45)	4.2 (25)	4.2 (21)
Cannula site bleeding	6.9 (65)	14.4 (51)	14.9 (44)
Surgical site bleeding	6.2 (45)	14.7 (46)	19.8 (36)
Hemolysis	11.1 (65)	9.3 (43)	7.1 (27)
Brain death	1.0 (0)	5.7 (0)	4.2 (0)

Modified from Extracorporeal Life Support Organization: *International ECMO registry report of the Extracorporeal Life Support Organization,* Ann Arbor, MI, 2009, Extracorporeal Life Support Organization.

Bleeding

Bleeding as a result of the systemic heparinization required with ECMO is the major complication associated with ECMO.[150] Whereas bleeding occurs predominately from cannulation or surgical sites, intracranial hemorrhage is the most dreaded site for bleeding to occur. Intracranial bleeding occurs in approximately 11% of patients overall, with the rate highest in the neonatal patient and lowest in the adult population. Bleeding that occurs outside the head that cannot be controlled with medical means requires surgical investigation. Although obvious risks accompany surgical intervention in a bleeding patient who has undergone systemic anticoagulation, many operative repairs have been accomplished during ECMO support.[151] Initial attempts to control bleeding focus on decreasing the rate of heparin infusion and lowering activated clotting time levels. Limitation of heparin may put the circuit at risk for increased clotting, especially at lower flow levels. This risk must be balanced against the bleeding risk.

Medications to help prevent clot breakdown in the patient also are used. Historically, aminocaproic acid, also known by the trade name Amicar, has been the predominant medication used during ECMO.[152] An antifibrinolytic amino acid, Amicar displaces plasminogen from fibrin and inhibits clot breakdown. Although a recent survey found that a wide range of doses are used, one common algorithm follows a dosage scheme of 100 mg/kg as a load followed by an infusion of 25 to 50 mg/kg/h. Although it has been used in ECMO centers for many years, a recent randomized controlled trial of Amicar versus placebo in neonates found no difference between groups in the need for transfusion or the need for circuit changes due to thrombosis. More recently, aprotinin was a favored agent in many centers.[153] A serine protease inhibitor, aprotinin is an anti-fibrinolytic agent that inhibits protein C and factors Va and VIIIa in the extrinsic coagulation pathway and inhibits the intrinsic pathway as well. It also preserves platelet function, reduces vascular permeability, and has been suggested to decrease the inflammatory response to cardiopulmonary bypass. Aprotinin has not been compared

Table 53–8 Mechanical and Patient-Related Complications for the Cardiac Population

Complication	0-30 Days n (%)	31 Days to <1 Year n (%)	1 Year to <16 Years n (%)	≥16 Years n (%)
MECHANICAL				
Oxygenator failure	7.5 (22)	8.4 (27)	9.2 (40)	20.0 (30)

Brain death	1.2 (0)	3.9 (0)	7.9 (0)	7.5 (0)
Seizures: clinically determined	7.8 (29)	9.6 (26)	5.2 (22)	3.2 (15)

Modified from Extracorporeal Life Support Organization: *International ECMO registry report of the Extracorporeal Life Support Organization,* Ann Arbor, MI, 2009, Extracorporeal Life Support Organization.

in a randomized fashion to Amicar or placebo during ECMO. Aprotinin is administered as a loading dose of 10,000 units/kg and continued at an infusion rate of 10,000 units/kg/h. Reports in adult patients of an increase in renal failure and poor outcome in cardiac patients receiving aprotinin during bypass surgery has caused it to be removed from the market at this time. Circuit thromboses may be noted with use of Amicar or aprotinin.

Several recent reports of intractable bleeding on ECMO have commented on the benefits of factor VIIa, although the data regarding this medication are still too sparse to recommend it without further investigation.[154] In a recent study, use of R factor VIIa was noted to be effective in decreasing chest tube bleeding from 47 to 10 mL/kg/h in four patients with refractory hemorrhage. Each patient received two doses of R factor VIIa (dose, 90 to 120 μg/kg) 4 hours apart.[155]

In another report, 92% of patients undergoing ECMO with bleeding responded to R factor VIIa therapy. A significant reduction in chest tube bleeding was noted, along with a significant reduction in the administration of blood products. Major thrombosis was noted in two of the patient who received R factor VIIa therapy.[156]

Other centers have reported decreased bleeding with lower doses of R factor VIIa administration; they have administered 40 μg/kg and then increasing the dose to 90 μg if bleeding continued. Anecdotal reports of thrombosis with factor VIIa are more frequent than those found in the literature, and thus careful assessment of risks and benefits should be undertaken prior to factor VIIa use.

Discontinuation of heparin to help control intractable bleeding also can be beneficial and has been used for variable periods, up to 36 hours or more, without significant clotting in the ECMO circuit.[157] Larger patients with faster ECMO flow rates are more likely to tolerate discontinuation of heparin without significant clotting. However, it is wise to have a backup circuit readily available if clotting does occur and the ECMO system requires an emergent replacement.

Infection

Infection is another potential complication of ECMO.[158] Colonization of indwelling catheters, selective adherence of bacteria to polyurethane surfaces, sequestration of bacteria from the body's normal antibody and phagocytic defense mechanisms, and the patient's prior debilitated state are all factors that may increase the risk of infection.[159,160] Successful therapy may be difficult without eliminating invasive equipment, most significantly the ECMO catheters. Viral infection from blood transfusions may occur rarely. The risk may be limited by minimizing the exposure to blood products from multiple donors with multi-aliquoted, sequentially dispensed units of packed red cells. Although sepsis (which was either preexisting or developed as the patient underwent ECMO) was once seen as a reason to exclude patients from ECMO support, several reports have demonstrated that sepsis can be cleared and septic patients can be treated successfully with ECMO. In fact, the most recent guidelines for hemodynamic support of pediatric patients with septic shock note that ECMO should be considered in patients with refractory catecholamine-resistant shock.[161] Although some debate still occurs about whether patients in a state of high-cardiac output shock will obtain any benefit from augmenting cardiac output further with ECMO, such patients have been treated successfully with ECMO support.[162]

Long-Term Outcome

Patients undergoing ECMO are at risk of neurologic damage from hypoxia, acidosis, hypotension, induced alkalosis prior to ECMO, and hemorrhage or ischemia related to systemic heparinization and alterations in cerebral blood flow following ligation of the carotid artery and internal jugular vein.[163-168] Nevertheless, two thirds of neonates who survive respiratory failure appear to have a normal neurodevelopmental outcome. The remaining third experience mild to severe deficits in motor or cognitive function. Sensorineural hearing loss has been noted in 23% of patients, an incidence comparable with that in infants with persistent pulmonary hypertension who are treated conventionally. The long-term effects of carotid artery and jugular vein ligation are unknown.

Severe chronic respiratory disease in patients treated with ECMO is uncommon.[169] Most reports relate an incidence of bronchopulmonary dysplasia (defined as the need for oxygen beyond the first month of life) from 4% to 27%. Most cases occurred in patients who had required extreme ventilator settings for more than 7 days before ECMO rescue. A follow-up report of neonates treated with ECMO who were evaluated at 10 to 15 years after ECMO found that although they had some diminished lung function by pulmonary function testing, they had similar aerobic capacity and were able to reach anaerobic exercise goals similar to those of age-matched healthy control subjects.[170]

Of 4000 pediatric respiratory ECMO patients listed in the Registry through July 2009, 9% had intracranial infarct or hemorrhage found on computed tomography examination. Brain death occurred in 6% of the patients, and 6% of patients had reported seizures. Long-term neurologic outcome data are sorely missing in the pediatric population. Few centers maintain regular follow-up clinics, and patients often are referred for ECMO from distant sites, which makes follow-up difficult as well. In one report of 15 pediatric and four adult patients, 58% survived to discharge. Patients were evaluated with use of the Pediatric Cerebral Performance Category (which measures cognitive impairment) and the Pediatric Overall Performance Category (which measures functional morbidity). Overall, 64% of survivors had normal Pediatric Cerebral Performance Category scores, 27% had mild disabilities, and 9% had moderate cognitive disability. Functional morbidity was normal in 27%, while 45% had mild disability, 18% had moderate disability, and 9% were severely disabled.[171] In another small series of 26 patients monitored 1 to 3 years after ECMO, 38% of preschool-age children were described as normal and 31% had observed abnormalities. Four patients (31%) who had prior neurologic dysfunction remained at baseline following ECMO. Among children who were school-age, 77% were described as normal by parental report.[172] More specific neurologic follow-up in the pediatric age groups is needed.

Neurologic complications in cardiac patients who undergo ECMO parallel that of patients who have respiratory failure. Brain death occurred in 4% of patients, 3% had intracranial infarct, and 6% had intracranial hemorrhage. Because many cardiac patients are in a state of prolonged low cardiac output or sudden cardiac arrest prior to ECMO, the ability to assess neurologic function once ECMO is instituted is vitally

important. Paralysis and sedation should be minimized until a neurologic examination can occur. This information is especially important in patients who are being listed for transplantation to avoid transplanting a viable organ into an inappropriate recipient.

A recent study that sought to identify risk factors for acute neurologic injury in children undergoing ECPR found that 22% patients had acute neurologic injury, which they defined as occurrence of brain death, brain infarction, or intracranial hemorrhage identified by ultrasound or computerized tomography imaging. Brain death occurred in 11%, cerebral infarction in 7%, and intracranial hemorrhage in 7%. The inhospital mortality rate in patients with acute neurologic injury was 89%.

During ECMO, neurologic injury was associated with ECMO complications including pulmonary hemorrhage, dialysis use, and CPR during ECMO. Pre-ECMO factors including cardiac disease and pH greater than 6.8 were associated with decreased odds of neurologic injuries.[173]

In a recent study of 2-year survival, mental, and motor outcomes after cardiac extracorporeal life support in patients younger than 5 years, 46% of patients survived to discharge, with 41% of patients alive at 2-year assessment. Neurodevelopmental concerns were identified in most survivors, with a mean mental score of 73 ± 16, mental delay in 50% of survivors, and motor or sensory disability in 12%.[174]

This study outlines the need for more intricate and intensive follow-up of patients undergoing ECMO to identify residual neurologic damage that may be improved with early intervention.

Another report of 64 cardiac patients undergoing ECMO found that 28 (44%) had neurologic complications.[175] Seizures occurred in 18 patients (28%), 3 patients (5%) had an embolus or thrombus, 9 patients (14%) had an intraventricular hemorrhage higher than grade 2, and 13 patients (20%) had anoxic encephalopathy. In 68% of patients with neurologic complications, hemodynamic compromise had occurred prior to ECMO. Five patients had evidence of neurologic complication prior to ECMO, 30% of patients with neurologic complications had received cardiopulmonary resuscitation prior to ECMO, and 14% had several hours of low cardiac output prior to ECMO. Sixty-nine percent of patients who were electively removed from ECMO had neurologic and/or multisystems organ failure.

The long-term follow-up of children with cardiac disease who required mechanical circulatory support during a decade of experience at Children's Hospital in Boston was recently analyzed.[176] Thirty-seven children (26 who survived ECMO and 11 who survived treatment with a ventricular assist device) were monitored for an average of more than 4 years. Only a single patient died in either group, for an overall long-term survival rate of 95%. Eighty percent of the patients in both groups were described as exhibiting good to excellent general health. Both low weight at the time that support was originally instituted and a long duration of hypothermic circulatory arrest in operative patients were associated with poor neurologic outcome. The majority of patients with these characteristics were supported with ECMO. Neurologic impairment of a moderate to severe degree was noted in more than 60% of the patients who underwent ECMO and in 20% of ventricular assist device survivors. Adverse neurologic outcomes were not associated with presupport cardiac arrest, carotid cannulation, or carotid reconstruction. Other series have noted neurologic complications in 20% to 30% of cardiac patients undergoing ECMO. Survivors generally are described as "normal" neurologically, although the extent of examination or radiologic assessment of the brain is unknown.

Another study of neonatal ECMO found sensorineural hearing loss in 26% of patients. Of those affected neonates, 72% had progressive sensorineural hearing loss, with 48% having a delayed onset of hearing loss identified. Factors identified with increased risk for sensorineural hearing loss were a primary diagnosis of congenital diaphragmatic hernia, duration of ECMO therapy longer than 7 days, and the total number of days the children received aminoglycoside antibiotics.[177]

Longer term evaluation of patients surviving ECLS and comparison with patients who had a similar disease severity and diagnosis are imperative to adequately interpret neurologic outcome.[178]

The Future

The use of ECMO in the neonatal patients with respiratory failure has been accepted medical practice for many years, although improved care and management of these patients has reduced the need for ECMO in this population. The current extension of ECLS systems to older pediatric and adult patients in a variety of clinical settings highlights the changes that have occurred in the ECLS environment. Progress in renal replacement, liver support, and plasmapheresis and the development of new cardiac support devices applicable to pediatrics also may expand the use of ECMO or related techniques overall. Additionally, the development of small, portable systems for cardiopulmonary resuscitation may herald a new age of extracorporeal support. Technical advances in ECLS equipment continue to make such support safer and more efficient. Venovenous ECMO techniques have been refined and used successfully in patients from neonatal to adult age groups. Single-cannula, double-lumen catheters for venovenous ECMO may obviate the risks of arterial cannulation and offer the benefit of requiring only one surgical site for venous access. Heparin-bonded circuits may decrease the need for systemic anticoagulation and the risk of hemorrhagic complications. Until the day when medical science may make the need for extracorporeal life support obsolete, research into ways to make it safer and more efficient should continue.

Pediatric Neurocritical Care

Michael J. Bell

PEARLS

The nine steps that must be accomplished when building a successful critical care program include:

- Planning and organization
- Training basic nursing/physician skills
- Building and equipping the unit
- Opening the unit
- Developing special standards and protocols
- Training nonphysician personnel
- Continuing education of nurses/physicians
- Developing full-time coverage
- Developing research programs

Efforts have been made in recent years to develop programs to care for children with critical neurologic conditions with the use of teams of dedicated specialists, generally pediatric intensivists and neurologists. These programs, termed *pediatric neurocritical care* at present, depend upon the ability of dedicated staff to focus much (if not all) of their clinical and research endeavors toward common or uncommon neurologic conditions in order to improve outcomes for this vulnerable population of children. This chapter will describe the evolution of pediatric neurocritical care as a care paradigm from a historical perspective, outline several rationales for embarking on this new organization of clinical care, and describe challenges for the future development of these programs. Throughout this chapter and for the sake of simplicity, the phrase "neurocritical care program" is used to describe critical care programs developed to treat adults (and more recently children) with neurologic disorders. This chapter does *not* review neurocritical care disorders or pathophysiological principles, such as status epilepticus or management of intracranial pressure, because these disorders and principles are comprehensively reviewed in other chapters of this book. However, studies of neurocritical care disorders that serve to argue for the further development of a neurocritical care focus in pediatric critical care will be discussed.

Historical Context

Advances in medical care have either emerged as a result of tectonic shifts of the mantle of the health care system or by incremental shifts of the landscape. As an example, military conflicts have contributed to cataclysmic changes in health care, from the development of life-saving trauma surgical techniques (from the U.S. Civil War to current conflicts) to the development of effective triage systems for evacuating and treating wounded soldiers (culminating in improved systems developed during World War II through the Korean and Vietnam conflicts).[1] As a specialty, Critical Care Medicine was a product of yet another seismic blast to the health care system—the polio epidemics that raged throughout Europe and the United States in the late 1940s and early 1950s. Advances in ventilation allowed patients to survive this debilitating affliction, culminating in the organization of the first intensive care unit (ICU) at the Baltimore City Hospital in 1961 that was staffed by in-house physicians.[2] The director of this first multidisciplinary ICU was Dr. Peter Safar, a founding father of cerebral protection from cardiac arrest who advanced the field of neuroprotection during his long, storied career.

The subspecialty of neurological critical care has evolved in a more gradual fashion compared with the overall specialty. Dr. D.W. Dandy is credited with developing the first three-bed neurosurgical ICU at the Johns Hopkins Hospital in Baltimore in 1929, while the first fully staffed, large-scale neurocritical care unit was formed in 1969 at the University of Colorado by Dr. Michael Earnest.[3] Gradually, similar neurological critical care units were established in many universities and tertiary care centers, paralleling the development of other subspecialty ICUs for coronary, cardiovascular, surgical, pulmonary, and other conditions. Currently neurological critical care units can be further subdivided in many centers into neurotrauma, neurovascular, neurosurgical, and others. In 2002, several dozen practicing neurointensivists formed the Neurocritical Care Society (with membership now numbering greater than 800) and held its first annual meeting in February 2003. And in 2007, the United Council on Neurological Subspecialties offered the first examination in neurocritical care and accredited fellowship programs across the United States.

For pediatrics, caring for neurologically injured children was always at the forefront in establishing critical care programs. In their landmark paper from 1975, Downes and Raphaely[4] begin by writing, "The major objective of intensive care is to provide maximum surveillance and support of vital systems in patients with acute, but reversible life-threatening disease. In pediatric patients, the reversal of life threatening conditions and preservation of essential functions, **especially those of the brain**, may result in many years of useful life." During this time, Reye's syndrome epidemics were commonly afflicting previously healthy children and intensive

neuroprotective measures were used with increasing success to restore full neurologic function.[5]

These early years of pediatric critical care led to many advances, including: (1) management of respiratory failure (e.g., the advent of exogenous surfactant for respiratory distress syndrome,[6,7] high-frequency oscillatory ventilation,[8] permissive hypercapnia, inhaled nitric oxide,[9] and extracorporeal membrane oxygenation[10]); (2) surgical correction of congenital heart diseases (e.g., palliative surgery—Blalock-Taussig shunts,[11] the Norwood procedure,[12] definitive repair—arterial switch procedure for Transposition of the Great Vessels, the Fontan procedure,[14] supportive care—cardiopulmonary bypass,[15,16] and ventricular-assist devices[17,18]); (3) therapies for sepsis (e.g., goal-directed resuscitation therapy[19] and development of new antibiotics); and (4) supportive therapies for failing organs (e.g., hemofiltration, hemodialysis, continuous renal replacement therapy, plasmapheresis/plasma exchange, and organ transplantation). The culmination of these and many other clinical advances have led to decreases in mortality rates in most pediatric critical care units to between 3% to 5%.

With this impressive reduction in mortality, the necessary next step in improving clinical care for critically ill children is to minimize morbidity. It is in this context that pediatric neurocritical care has emerged, because neurologic morbidity was seen as one of the greatest challenges to future advancement of the field. In 2000, Robert Tasker[20] was among the first to write about a conceptual framework of multiple neurologic conditions that might benefit from particular expertise within pediatric neurocritical care when he provided an evidence-based summary of three important neurologic conditions of critically ill children: the management of severe head injury, use of benzodiazepines to treat status epilepticus, and the emergence of new forms of encephalopathies in children. In the intervening years, various groups have argued for the introduction of pediatric neurocritical care within the specialty of pediatric critical care medicine. The remainder of this chapter will examine the various rationales for advancing pediatric neurocritical care programs and possible future directions for this effort.

Rationales for Development of Pediatric Neurocritical Care

Rationale 1

The first rationale for advancing pediatric neurocritical care programs is that sufficient numbers of children with critical neurologic conditions exist to justify the establishment of a new service specifically for this population of children.

An important question for the development of pediatric neurocritical care programs involves an assessment of whether there are enough patients to justify the formation of this type of clinical service. As stated earlier, adult neurocritical care units and programs have been in existence for years and have therefore answered this question in the affirmative. During their early period, Bleck and colleagues[21] surveyed admissions to their 14-bed general medical ICU and found that only 92 of 1850 admissions were related directly to neurologic conditions, mostly stroke and intracerebral hemorrhages. However, they found that 217 patients experienced neurologic complications during the admission, including hypoxic/ischemic encephalopathy, seizures, metabolic encephalopathy, and stroke. A more recent analysis demonstrated that brain tumors, strokes, and subarachnoid hemorrhages accounted for more than 50% of admissions to neurocritical care units[22] but failed to provide an absolute number of admissions. In the intervening years, thrombolytic therapy for ischemic stroke, neurovascular procedures for aneurysmal subarachnoid hemorrhage, and the advent of comprehensive traumatic brain injury and stroke teams have increased the need for intensive care for adults. The evidence that adult neurocritical care is a viable program in many centers largely rests with its widespread implementation. Although the absolute number of neurocritical care units has not been collated, the United Council of Neurological Subspecialties has certified 25 programs in the United States and 215 diplomates in Neurocritical Care (see http://www neurocriticalcare.org/files/public/NCS. neurocriticalcare.org/files/public/NCS Volume4Number4).

The only pediatric experience in subspecialty critical care program development comes from pediatric cardiac intensive care programs. Large pediatric institutions—for example, Children's Hospital of Boston, Children's Hospital of Philadelphia, and The Hospital for Sick Children in Toronto—have long histories of cardiac intensive care programs.[23] These programs are based on the philosophy that a multidisciplinary team of cardiac intensivists, cardiologists, cardiac surgeons, anesthesiologists, neonatologists, and specially trained nursing and ancillary staffs can most effectively treat the unique pathophysiology encountered in correction of congenital heart disease. The viability of these programs is generally related to the volume of congenital heart surgery cases referred to the institution, and patients admitted to the hospital on this service generally are located in a unique space outside of the general pediatric intensive care unit (PICU). As of 2004, there were 132 pediatric cardiac intensive care programs and 250 members of the Pediatric Cardiac Intensive Care Society (http://www.pcics.org/), indicating that these types of programs have certainly been viable for many institutions.

At the time of this writing, limited information exists regarding the number of patients receiving care in pediatric neurocritical care programs. LaRovere and Riviello[24] summarized their experience in developing a pediatric neurocritical care service at Children's Hospital of Boston. They reported that 557 neurocritical care consultations were obtained over a multiyear period. Because little information is provided about the disorders treated and the role of the pediatric neurocritical care team in patient management, it is difficult to discern the precise difference between this effort and an active neurologic consulting service. At Children's National Medical Center, a neurocritical care consulting service consisting of an intensivist, two neurologists, and neurosurgical staff was formed within the framework of the PICU.[25] This service was designed to improve collaboration between the services and implement evidence-based guidelines for care of children with traumatic brain injury, stroke, status epilepticus, and other neurologic disorders. In a 14-month period, 373 neurocritical care consults were obtained from 1423 patient admissions. Approximately two thirds of the consultations were obtained in children with primary neurological diagnoses at PICU admission, but a substantial portion (34.1%) of the consultations were obtained among children admitted with other medical/surgical conditions (Table 54-1). The wide variety of diagnoses observed argued strongly that at least the three main specialties (intensivist, neurologist, and neurosurgeon) were required to make a comprehensive clinical team. Weaknesses

Table 54–1 Admission Diagnoses for Children Who Had a Pediatric Neurocritical Care Medicine Consultation

Primary Neurologic Diagnosis	No. (%)	Primary Medical Diagnosis	No. (%)
Status epilepticus	70 (18.9)		
TBI	53 (14.2)	Respiratory failure	41 (11.0)
Tumor	48 (12.8)	Cardiovascular, non-CNS	27 (7.2)
Neurosurgical procedure, other	24 (6.4)	Shock	22 (5.9)
Hydrocephalus	17 (4.6)	Cardiac arrest	14 (3.8)

Totals	239 (64.1)		134 (35.9)

CNS, Central nervous system; *DKA,* abnormal neurologic findings associated with diabetic ketoacidosis; *meningitis,* inclusive of meningitis and meningoencephalitis disorders; *SAH/ICH,* atraumatic subarachnoid hemorrhage or intraventricular hemorrhage; *stroke,* all arterial ischemic strokes and cerebral sinovenous thromboses; *TBI,* traumatic brain injury.

of this study included the inability to determine if the consulting service led to improved outcomes for patients and lack of analysis on the financial viability of this model of care. Most recently, a fully independent primary pediatric neurocritical care service staffed by intensivists with extensive neurological experience has begun at the Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center. This service has seen 297 patients in the first 9 months, and a full description of the patient composition and viability of the program is currently under review. Other pediatric neurocritical care programs are currently active at several institutions, including at Children's Memorial Hospital (Northwestern University), St. Louis Children's Hospital (Washington University in St. Louis), and Weill-Cornell Medical Center.

Rationale 2

The second rationale for advancing pediatric neurocritical care programs is that the development of pediatric neurocritical care programs will improve the overall outcome of children under their care.

Any successful new program in critical care must lead to improved patient outcomes to justify changing existing approaches. At its basic level, improvements in mortality would provide the ultimate justification for such efforts, with concomitant decreases in neuropsychological and neurological morbidity also being important. Seminal work has indicated that adult or pediatric intensivist–led clinical teams are associated with improved outcome[26-29] and serve as a model for future innovations in changes in care teams.

Adult neurocritical care programs have demonstrated an association between their services and outcomes in a variety of ways and for several medical disorders. In 2001, Mirski and colleagues[30] demonstrated that admission to a "Neuroscience Intensive Care Unit" in a single institution was associated with improved outcome (decreased mortality and decreased length of stay) when compared with the similar institution prior to formation of this new ICU. On a larger scale, Diringer and Edwards[31] analyzed more than 1000 admissions of patients with intracerebral hemorrhage from hospitals with and without neurocritical care programs. They found that patients admitted to hospitals without neurointensivists had a 3.4-fold increased risk of inhospital mortality (odds ratio, 3.4; confidence interval, 1.65 to 7.6) after controlling for patient demographics, severity of intracranial hemorrhage, and hospital size. Varelas and colleagues[32] demonstrated that patients with stroke also benefited from neurocritical care programs. Specifically, in prospectively studying a total of 433 stroke patients (174 admitted prior to development of the neurocritical care unit and 259 admitted after development of the unit), they found no difference in mortality between the groups but decreased length of stay across all stroke subgroups. Lastly, Josephson and colleagues[33] demonstrated that patients with subarachnoid hemorrhage treated in a neurocritical care setting had decreased length of ICU stay (12.4 days vs. 10.9 days) and decreased need for cerebral spinal fluid diversion (23.0% vs. 11.5%) but no change in hospital mortality.

Presently no studies have assessed the utility of pediatric neurocritical care programs for improving mortality or other important outcome parameters, which is not surprising considering the dearth of studies outlining these programs in the literature. Nor does the literature contain any studies demonstrating improved mortality or morbidity after the institution of pediatric cardiac intensive care programs, despite their significantly longer history compared with pediatric neurocritical care programs. In moving forward it will be important to demonstrate improvements in outcomes, but this task will be particularly challenging because of the variety of developmental stages of childhood. In assessing mortality it will be important to avoid the limitations in the adult neurocritical care studies (i.e., comparison to historical control subjects) and utilize expected mortality measured by standardized severity of illness measures (such as PRISM or other scoring systems).

Rationale 3

The third rationale for advancing pediatric neurocritical care programs is that advances in care, either technologic or experimental, will be integrated more effectively with a pediatric neurocritical care program compared with the standard approach.

Advances in the delivery of neurological-specific care, based either on new technologies or on standardized guidelines based on new evidence, continue at an increasing rate, and some persons have argued that these advances justify a dedicated team of clinicians to provide such care. As outlined in other chapters within this textbook, the number of monitoring devices and technical advances for children with neurological injuries continues to grow. Digitally acquired electroencephalograms and electronic interpretations that can be gleaned at the bedside in real time, brain tissue oxygen catheters that provide second-to-second assessments of local cerebral oxygen tension, and noninvasive measures of regional brain saturations by near-infrared spectroscopy devices are now in routine use for children. Other techniques, including cerebral microdialysis and cerebral blood flow (CBF) devices (either catheters to assess local CBF or imaging studies to determine global CBF), are poised to be used in the coming years. Determining the correct combination of monitoring systems and implementing protocols to maximize their potential benefit and minimize possible harm is a daunting challenge that will be faced by all practitioners in the coming years. This argument was proposed by Suarez[34] as a justification for widespread adoption of adult neurocritical services and by Chang[35] to support development of pediatric cardiac intensive care programs.

Evidence-based guidelines covering several neurologic disorders of children continue to emerge, and effective integration of these guidelines, along with technological advances, into clinical practice in critically ill children will be an important challenge for clinicians. Consider the following examples: (1) in 2003 the Brain Trauma Foundation published guidelines (currently being revised) for management of children after traumatic brain injury[36]; (2) the American Heart Association has published guidelines for caring for children after stroke (including the use of antithrombotic therapies)[37]; (3) the American Academy of Neurology published a practice parameter to recommend treatment guidelines for children with status epilepticus[38]; and (4) the American Heart Association published guidelines on cardiopulmonary resuscitation and emergency cardiovascular care for children and neonates that also includes opinions regarding the neuroprotective strategy of hypothermia.[39-41] All of these general guidelines have important consequences for caring for the critically ill child, and successful incorporation of these recommendations into clinical protocols within the ICU will be an important step in optimizing care.

Several recent clinical studies also outline the importance of rigorously controlled neuroprotective strategies and argue for specialists who might improve the chances of successful implementation. First, in one of the most significant studies in the past decade in pediatric critical care, Hutchison and colleagues from the Canadian Critical Care Trials Group tested if early institution of hypothermia—basically the only neuroprotective strategy currently available for testing—would improve outcome after severe traumatic brain injury in children.[42] In a trial involving 225 children, a strong trend toward worse outcome in the treated group was noted, including both death and poor neurologic outcome. However, significant methodological problems with the trial were discerned by the authors, including an increased number of children with hypotension in the treatment group, an increased incidence of the necessary use of vasoactive agents during the rewarming phase, and administration of an incomplete dose of hypothermia (approximately 16 hours based on data within the manuscript compared with 24 hours in the proposed protocol). In a smaller study of a single center, Fink and colleagues[43] found that children undergoing hypothermia for cardiac arrest had the same mortality rate compared with those remaining in normothermia in an uncontrolled audit of a single center. More importantly, they found that overshooting of the target temperature was common (10% with a rectal temperature of <30° C) in this nonprotocol-driven care plan. Both of these studies argue that careful control of neuroprotective strategies is essential for the safety of clinical trials and ultimately for clinical care. In the future, if neuroprotective strategies are used for any of a number of neurological conditions, it may be the role of the pediatric neurointensivist to effectively implement the strategy.

Future of Pediatric Neurocritical Care

As described throughout this chapter, pediatric neurocritical care is a new concept, and currently more questions than answers exist regarding its implementation. A basic question of staffing and leadership of this effort remains in question. Models including pediatric intensivist–led programs (Children's National Medical Center, Children's Hospital of Pittsburgh of University of Pittsburgh Medical Center, and St. Louis Children's Hospital) and pediatric neurologist–led programs (Children's Hospital of Boston, Children's Memorial Hospital, and Texas Children's Hospital) exist currently. At this juncture it seems likely that an integrative approach with both of these services and neurosurgery will be required for the foreseeable future, because it is as unlikely that an intensivist-trained neurocritical care specialist will feel completely comfortable reading electroencephalograms as it is for a neurologist-trained specialist to feel comfortable managing a critical airway. Scher[44] argues that the approach of "cross-disciplinary training" may be the most effective means to achieve this cross-pollination of skills.

The overall organization of pediatric neurocritical care programs in the future and the scope of their missions is yet to be determined. The Neurocritical Care Society has formed a Pediatric Neurocritical Care Subcommittee (whose Chair is James Riviello of Baylor College of Medicine) to explore the incorporation of pediatric topics into the mission of the Neurocritical Care Society. An independent, pediatric-based administrative approach was proposed in September 2008 when a pediatric neurocritical care investigators meeting was convened in Chicago (Northwestern University; Mark Wainwright, Chair). The focus of this international group (more than 50 attendees) was "to bring together bench and clinical investigators with interests related to pediatric CNS injuries including stroke, traumatic brain injury, seizures and neurologic complications of critical illness, with a goal of beginning to identify research priorities, and approaches to management in pediatric neurocritical care common to all these disorders." Yet another approach is being proposed by the Pediatric Acute Lung Injury and Sepsis Investigators, who convened a Pediatric Neurocritical Care subgroup in March 2009. This group advocates for national efforts to spur research into neurocritical care topics for children with the anticipation that these efforts will lead to improvements in care.

In summary, enthusiasm for the practice of pediatric neurocritical care continues to grow across the United States and abroad. At this time, University-affiliated pediatric critical

care and neurology divisions have started clinical services in pediatric neurocritical care. In going forward, it is important to determine if these clinical programs effect important outcomes for children and which team structure allows for the best results. In their landmark paper, Safar and Grenvik[2] argue that a sequence of nine steps must be accomplished when building a successful critical care program: (1) planning and organization, (2) training in basic nursing/physician skills, (3) building and equipping the unit, (4) opening the unit, (5) developing special standards and protocols, (6) training nonphysician personnel, (7) continuing education of nurses/physicians, (8) developing full-time coverage, and (9) developing research programs. At present, step 3 may be omitted, because there is little ongoing effort to build self-standing neurocritical care units for children at this time. Nevertheless, it seems that many programs have accomplished a number of the eight remaining steps with some success. It remains to be seen how implementation of these programs will fare in the coming years and what advances in care and outcome may be obtained.

Chapter 55

Pediatric Neurologic Assessment and Monitoring

Mark S. Wainwright

PEARLS

- The examiner should focus both on localization of a neurologic deficit and identifying mechanism(s) of injury (or potential injury) as a means to adjusting therapy.
- Communication between team members, serial examinations, and early recognition of changes in the examination or other monitoring parameters are essential.
- Metabolic monitoring methods, including partial pressure of oxygen and microdialysis, have great potential to advance the detection of, and therapy for, secondary neurologic injury in pediatric acute brain injury. The application of these tools to neurocritical care and demonstration of their efficacy in improving outcomes will require advances in data collection, bioinformatics, and methods of data analysis.

Overview and Basic Principles of Pediatric Intensive Care Unit Neurology

The approach to the neurologic assessment of the patient in the pediatric intensive care unit (PICU) requires an interdisciplinary approach using bedside neurologic examination and laboratory testing combined with invasive and noninvasive monitoring.[1] While this approach to patients with neurologic disorders recapitulates elements of the approach to differential diagnosis used in the outpatient setting and non-ICU inpatient care, there are important fundamental differences that are specific to the practice of critical care neurology.[2,3] In general, these differences involve the need to obtain testing (imaging, neurophysiology, laboratory) on patients who may appear neurologically intact, the need to intervene before a specific neurologic diagnosis has been obtained, and the challenge of determining whether such interventions affect long-term outcome. Thus, the cardinal features of the practice of neurology in the PICU are the need for serial neurologic examinations, the importance of communication between nurses and physicians and between multiple medical services, the need for early recognition of changes in the neurologic exam, and the anticipatory management of patients with the potential for progressive neurologic deterioration. The confounding effects of sedation and/or postoperative anesthesia on neurologic functioning pose an additional set of challenges to the assessment of these patients. Nevertheless, a logical approach to the neurologic examination is possible by using the standard structure of a neurologic examination, combining this exam with attention to the mechanisms of injury (present or potential), and thereby developing a plan for ongoing monitoring and management. Last, it is prudent to regard every patient in the PICU as having the potential for neurologic complications of his or her illness. These patients, whose primary diagnoses range from neurologic complications of solid organ transplant to liver failure to congenital heart disease, may suffer neurologic injury from any combination of hypoxic, ischemic, inflammatory, or metabolic cerebral insults.

Recognition of Neurologic Complications in the PICU Patient

Children who develop neurologic complications of critical illness deserve a specific mention. This is likely an underrecognized population in many PICUs, not least because of the prevalence of nonconvulsive seizures[4] (NCS) or ICU-acquired paresis.[5] In these cases, the recognition of new neurologic deficit(s) relies on the ability of the PICU team to recognize changes in the neurologic exam. In general, interventions to treat or attenuate neurologic insults, whether seizures, ischemia, or increasing intracranial pressure (ICP), are more likely to be successful if initiated early in the process of injury. This means that effective neurologic monitoring in the PICU does not rely solely on the availability of a neurologist, electroencephalogram (EEG), or neuroimaging. Rather, the prerequisite to using these monitoring tools is a high index of suspicion for new neurologic injury on the part of the medical team for patients who do not have primary neurologic injuries.

In addition to the physical exam, there are a number of modalities that can be used for the monitoring of neurologic function in critically ill children and adults.[6,7] This includes continuous EEG monitoring, which is well-established as a modality essential for the detection of NCS in the adult and PICU populations,[8,9] ICP monitoring, transcranial Doppler,[10] and metabolic[11] and tissue oxygen monitoring.[6,12] Thresholds for detection of cerebral ischemic injury have been proposed for brain oxygen tension[13] and near-infrared spectroscopy (NIRS).[14] With respect to pediatric neuromonitoring, as yet

there is no consensus on normal values or the age-dependence of these endpoints.

Establishing a Baseline Neurologic Examination and Anticipatory Planning for New Deficits

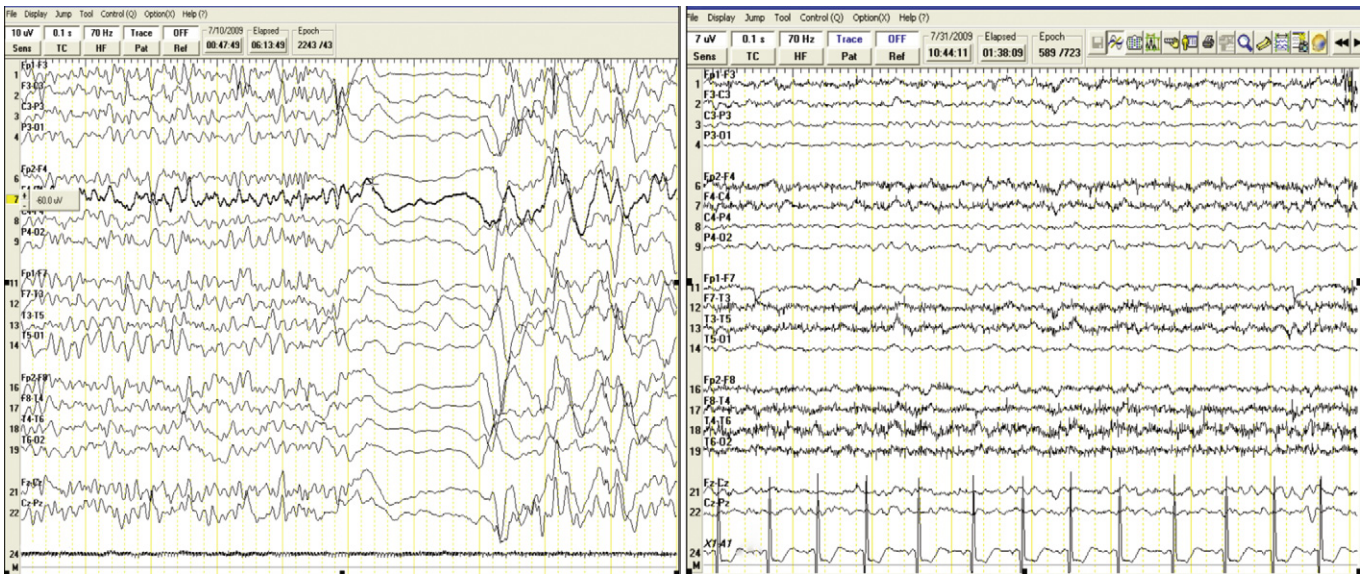
The examiner should discuss the findings with the bedside nurse and other members of the medical team. If possible, abnormal findings should be demonstrated to the members of the team. There should be a consensus on the key findings and the approach to be taken for evaluation and management if the neurologic exam changes. Important features of the approach to the neurologic examination of the child in the PICU include the need for serial examinations and the need to establish a plan to manage any changes in this exam before they occur. This is the most important message of this chapter.

History and Assessment of Risk Factors

For children in the PICU, the medical history may provide essential information about the mechanisms and timing of neurologic insult. This information is needed for the interpretation of the neurologic exam and assessment of potential mechanisms of neurologic injury. These data are then used to assess the risk for progression of neurologic injury, to prioritize therapeutic interventions, and to determine the need for, and timing of, additional evaluations, including imaging, EEG, and laboratory studies. In many cases, the decisions to treat (or not treat) a neurologic injury in the PICU will have to be empiric and based on a careful assessment of risk factors and potential mechanisms of injury as well as a weighing of the risks and benefits of such intervention. For example, the approach to evaluation of altered mental status presenting to the PICU will be different with children with an established complex partial seizure disorder, sickle cell disease, or a stem cell transplant recipient on immunosuppressant drugs. Before examining the patient, knowledge of salient details of the medical history allows the examiner to begin to formulate a diagnostic approach and to prepare the early steps in management. The patient with a history of epilepsy in the example above would likely require an emergent EEG to rule out NCS, while the patient with sickle cell disease and risk factors of vascular injury with the same symptoms may require an imaging study, and the immunosuppressed patient a lumbar puncture. The presenting neurologic symptoms may be similar, but the history dictates the assessment based on the likely mechanisms producing the deficits found on neurologic examination.

Iatrogenic Complications of Pharmacotherapy

It is not uncommon to overlook the side effects of drugs in the PICU. A review of medications should be part of the neurologic assessment of any patient with new neurologic symptoms. The initial assessment of the patient should include attention to medications that cross the blood-brain barrier, or that may interfere with the renal or hepatic metabolism of centrally active drugs. In patients in renal or liver failure, or requiring dialysis, the side effects of a centrally acting drug must be considered in the differential diagnosis for any neurologic symptom. This may occur even in the presence of "normal" doses of drugs or levels of anticonvulsants, as off-target drug toxicities may be due to metabolites, not the drug itself. An example is shown of a child with a mild static encephalopathy and spasticity, on dialysis as the sequela of perinatal renal injury, who developed progressive encephalopathy (Figure 55-1). Treatment with flumazenil with immediate improvement in mental status, confirmed that the accumulation of baclofen in this dialysis-dependent patient was the source of a waxing and waning encephalopathy. Common examples in the PICU include immunophilin-associated



A B

Figure 55–1. Bipolar EEG montage (**A**) of a child with a mild static encephalopathy and spasticity, on dialysis as the sequela of perinatal renal injury, who developed progressive encephalopathy with high-amplitude epileptiform discharges. Treatment with flumazenil resulted in immediate improvement in mental status and sustained improvement in the EEG (**B**), confirming that the accumulation of baclofen in this dialysis-dependent patient was the source of a waxing and waning encephalopathy.

seizures, encephalopathy, hypertension; oculogyric crisis, delirium during reduction of sedation, and persistent paralysis from prolonged neuromuscular blockade. In many cases, the attribution of the symptoms to a drug side effect (excess level, too-rapid withdrawal, idiosyncratic reaction, impairment of clearance) will be a diagnosis of exclusion. Nevertheless, a review of medications and recent changes should be a routine component of the neurologic assessment.

Approach to the Physical Exam

Vital Signs

Therapies that target specific mechanisms of cell injury for acute CNS disease are lacking in adult and pediatric neurocritical care. Nevertheless, one simple intervention, the prevention of hyperthermia, may significantly reduce neurologic injury after stroke or traumatic brain injury (TBI). The neuroprotective benefit of induced hypothermia remains to be proven for pediatric TBI.[15-17] While hypothermia may remain as yet an unproven therapy for neurologic insults, the prevention of hyperthermia can be regarded as a safe, and probably effective, intervention.[18] Therefore, as a general principal for ICU neurology in patients with known or suspected central nervous system (CNS) injury, the neurologic exam should first include vital signs and fever should be treated aggressively. The range of temperatures determined to be "normothermic" may vary but a consensus should be reached and temperatures above the accepted range treated quickly.

In contrast to adults, there are limited data on the optimum ranges for blood pressure, ICP, and cerebral perfusion pressure (CPP) for children. In adults, there are goal-directed protocols aimed at improving outcome following TBI. The targets of ICP less than 20 mm Hg and CPP above 60 mm Hg are based on a number of studies.[19-23] In contrast, very limited data exist for children with TBI.[24,25] Guidelines suggest an ICP threshold of 20 mm Hg for all ages and a CPP threshold of 40 to 65 mm Hg as an "age-related continuum."[26] In children younger than 15 years of age, a mean CPP less than 40 mm Hg during the first 48 hours following injury has been associated with increased mortality.[27] Although children with TBI younger than 2 years of age have a high mortality rate compared with older children, no thresholds for ICP or CPP have been established for this age group.[28] Accordingly, blood pressure, temperatures, and oxygenation must be interpreted in the context of the underlying neurologic insult or risk for further injury. As a general principle, hyperthermia with the attendant increase in cerebral metabolic demand should be treated aggressively whatever the primary injury.[29]

General Physical Exam

An essential component of the neurologic examination is obtaining an accurate head circumference. This may serve as a baseline for following the development of hydrocephalus in the at-risk infant. In older children, an abnormal (large or small) head circumference may be a previously overlooked sign of pathology. The fontanelle should be palpated and the findings on the exam agreed upon with the infant in a quiet, resting state. A bulging fontantelle is an important finding of meningeal irritation or increased ICP. Examination of skin for the cardinal features of the phakomatoses may identify café au lait spots characteristic of neurofibromatosis, or shagreen patches, hypopigmented macules, and angiomyofibromas characteristic of tuberous sclerosis. The physical findings associated with inflicted trauma deserve particular mention as these may be subtle[30]; they include unusual patterns of bruising, blood in the oropharynx, and burn or belt marks.

Importance of Observation in the Neurologic Exam

The elements of the neurologic examination in the PICU comprise the same features of the neurologic exam as for patients who are not critically ill. The assessment of mental status, cranial nerves, motor function, reflexes, sensation, and cerebellar function must be adapted to each patient, but the structure of the neurologic exam in the PICU is no different from the outpatient examination. If possible, sedating drugs and paralytic agents should be reduced prior to the exam. If this is not feasible, the exam must be interpreted in the context of these confounds.

The assessment of mental status begins with observation. The examiner should first confirm the drugs used for sedation if any, and recent changes in dosing. It is not possible to give precise dose ranges for typical sedating agents associated with a mental status exam. For commonly used agents in the PICU (midazolam, morphine, fentanyl, dexmedetomidine) the effects of the drug on arousal and responsiveness will vary with the age of the patient, duration of exposure, nature of the neurologic insult, effect of other drugs on metabolism, and genetically determined ability to clear these drugs. This complex set of interactions underscores the importance of experience in the examination of these patients to determine what is an acceptable level of arousal, as well as the need for serial neurologic examinations.

The observations of the nurses and parents should first be solicited. The examiner should enquire about evidence for changes in arousal or awareness, such as spontaneous eye-opening, evidence of a sleep-wake cycle, change in activity, or response to interventions such as suctioning. If family members are present, their observations of response to their presence or voice are important and may represent the first signs of awareness on the part of the patient. It is quite appropriate to have a family member carry out part of the exam, asking the patient to follow commands, as young children are more likely to respond to their family than to a stranger.

The pattern of breathing rate and rhythm should be observed. Specific patterns may help localize the site of neurologic dysfunction but not the mechanism involved (Table 55-1). The crescendo-decrescendo pattern alternating with periods of apnea, characteristic of Cheyne-Stokes respiration, may be due to dysfunction of the cerebral hemispheres, the thalamus, or the hypothalamus with preserved brainstem function, but can also be found in patients with congestive heart failure or primary respiratory disease. Similarly, the sustained, deep breathing pattern of central neurogenic hyperventilation may be due to either structural injury to the midbrain, sepsis, pulmonary disease, or compensated metabolic acidosis.

The conventional neurologic examination proceeds from mental status, cranial nerves, motor (bulk, tone, and strength), reflexes, and sensation to cerebellar exam and gait. In children and in the PICU in particular, the exam must be based on good observation and typically performed out of sequence. It is easier to assess tone and reflexes in the asleep, relaxed patient, before waking the patient up to assess mental status. While the exam is discussed in the standard order

Table 55–1 Approach to the ICU Neurologic Examination: Localization and Mechanism

Exam Finding	Structural-Vascular Insult	Toxic-Metabolic
Consciousness	Stays at same level or deteriorates	Waxes and wanes, milder impairment; toxins may cause progressive decline
Respiration	Cheyne-Stokes (crescendo-decrescendo alternating with apnea): loss of cerebral, thalamic, or hypothalamic control of breathing Neurogenic hyperventilation (sustained, rapid, deep breathing): midbrain disease Gasping respiration (irregularly irregular): dysfunction of lower brainstem or medulla	Cheyne-Stokes: congestive heart failure, primary respiratory disease Neurogenic hyperventilation, metabolic acidosis, sepsis, liver failure Gasping respiration, intoxication (opiates, barbiturate), hypothyroidism
Fundoscopy	Papilledema due to increased ICP	Papilledema does not occur except in hypertensive encephalopathy, lead intoxication, hypoparathyroidism
Eye position	Versive deviation Stroke ipsilateral to direction of deviation Retraction or convergence nystagmus Midbrain Ocular bobbing Pons Intranuclear opthalmoplegia Pons or midbrain Oculomotor nerve palsy Midbrain or herniation Skew gaze Brainstem	Versive deviation Seizure contralateral to direction of deviation No extraocular movement with preserved pupil reactivity Toxin
Pupil reactivity	Small reactive Thalamus, hypothalamus Midposition, fixed Midbrain Pinpoint, reactive Pons Small, combined with ptosis Horner syndrome, lateral medulla, sympathetic chain Large, fixed Oculomotor nerve, tectum	Small, reactive Large, fixed Botulism, opthalmic drops
Eye movements	If asymmetric, likely structural Oculomotor nerve palsy Midbrain or herniation syndrome Abducens nerve palsy Unreliable localization Internuclear ophthalmoplegia Midbrain or pons Dysconjugate or skew gaze Brainstem Absent vertical and retained horizontal movement Midbrain Absent horizontal and retained vertical movements Pons	Roving more common with metabolic derangements Absence of all movement with intact pupil light reflex
Adventitous movements	Posturing; sign of herniation Myoclonus following severe cerebral ischemia	Restlessness, tremor, spasm, myoclonus, chorea, akathisia
Muscle tone	Asymmetric; increased, normal, or decreased	Symmetric, normal, or decreased

below, it is often more informative to begin the hands-on part of the exam with assessment of tone and reflexes. Once awake and agitated, it may be difficult to elucidate subtle asymmetries of tone and reflexes, which may be key findings of the exam.

The state of arousal (awake, asleep), responsiveness, (interactive, verbal, nonresponsive), position (tone and asymmetry of limb position), movement (purposeful, spontaneous, dystonic, choreic, asymmetry of movement) can all be reliably assessed by observation. In a nonintubated, nonsedated patient the examiner may proceed directly with a standard mental status exam adjusted for age. In the young child who is able to cooperate, the specific cognitive and language skills expected for age can be assessed (Table 55-2).

Nonorganic Pathology in the Pediatric Intensive Care Unit

Not all neurologic deficits in the PICU are organic. Conversion disorders also occur in critically ill patients or result in patients being admitted to the PICU. In the latter case, this is most often associated with nonepileptiform seizures. These cases may

Table 55–2 Age-Dependent Motor and Language Patterns

Age (mo)	Motor	Language
15	Walks alone, crawls up stairs	Jargon; follows simple commands
18	Runs, sits on chair, walks up stairs with hand held	Knows 10 words, names pictures, identifies body parts
24	Runs well, walks up and down stairs	Uses three-word sentences
30	Jumps	Refers to self as "I"
36	Stands on one foot, goes up stairs with alternating feet	Knows age and gender, counts three objects
48	Hops on one foot, throws ball	Tells a story
60	Skips	Names four colors, repeats 10-syllable sentences

Modified from Behrman RE, Kliegman RM, Nelson WE, et al: *Nelson textbook of pediatrics*, ed 14, Philadelphia, 1992, WB Saunders, pp 18–104.

Table 55–3 Clinical Features of Seizures and Nonepileptic Spells

	Seizures	Nonepileptic Spells
Eyes	Open	Closed
Automatisms	Common	Rare
Stereotypical behavior	Common	Rare
Gradual onset	Rare	Common
Waxing and waning course	Rare	Common
Thrashing movements	Rare	Common

have been treated with anticonvulsants, resulting in respiratory depression requiring intubation or ICU monitoring. A number of features of the examination and history may help make this distinction (Table 55-3). Seizures are a common complication of critical illness in adults and children[31] and are also a common reason for neurologic consultation in the PICU. A high index of suspicion for seizures in the PICU is important in order to decrease the risk for secondary brain injury resulting from the metabolic stress imposed by seizures. In such cases, video EEG monitoring is the most efficient means of distinguishing ictal from nonictal events. While continuous EEG monitoring may be needed to determine whether such events are seizures or not, there are features of the physical exam that may aid in making this diagnosis. In general, and particularly in infants, the eyes are open during a seizure. In one series,[32] over 90% of cases with electrographically confirmed seizures occurred with eye opening. The eyes may look straight ahead, versively deviate to one side contralateral to the hemisphere from which the seizures originate, or exhibit only nystagmus. Seizures are typically a "positive" phenomenon and will have movement associated with them unless there has been injury to the corticospinal tracts resulting in a paretic limb. Other features of the exam or description of the spells including stereotypy, crescendo-decrescendo behavior, or the presence of automatisms may help to distinguish ictal and nonictal behavior. In most cases, video EEG monitoring is the most efficient means of distinguishing ictal from nonictal events.

Even in the PICU, the examiner should remember that functional deficits may occur, and a number of motor signs may help identify the origin of functional symptoms. Given the complex pathophysiology of many critically ill patients and the multiple potential mechanisms of neurologic injury, the diagnosis of a functional neurologic deficit should be made only after a thorough evaluation for organic causes. Although this is uncommon in the PICU, a functional etiology should not be overlooked and early identification may help to minimize diagnostic testing and unnecessary or high-risk treatment. There are a number of elements of the physical exam that may help distinguish between organic and functional neurologic deficits.[33] An inconsistent examination may be the first clue; for example, a patient with apparent weakness during bedside strength testing may be noted to change position during sleep or another may walk despite apparent paresis on bedside testing. These observations can often be very helpful in the assessment of children with weakness thought to be due to a neuromuscular disease. After first observing for inconsistency, the most useful test for functional weakness is the Hoover sign. This test relies on the principle that when flexing one's hip, the natural accompanying movement is to extend the contralateral hip.[33] With the patient supine, the examiner places one hand on the weak leg and the other hand under the ankle of the strong leg. The patient is then asked to perform a straight-leg raise of the healthy limb. In a functional pattern of weakness, the examiner will feel no downward pressure from the good leg since there is no effort being applied to raise the ostensibly weak leg. Other tests include the "arm-drop" in which a paretic or plegic arm is dropped over the patient's face (the patient with organic weakness is more likely to allow the arm to strike the face), or observation of exact splitting of sensory or vibration deficits in the midline. A number of functional gait disturbances are also characteristic, including a monoplegic dragging gait (the whole limb is dragged without the circumduction present in pyramidal hemiparesis), a "walking on ice" pattern, excessive slowness, or sudden buckling at the knees with recovery. Of these, none are definitively diagnostic of a functional pathology, and in children in particular must be interpreted with caution. Importantly, functional and organic deficits may coexist.

Assessment of Level of Consciousness and Mental Status

For children with depressed consciousness, the precise stimulus required to elicit a response and the nature of this response should be specified. It is not helpful to describe the patient as "lethargic" or "obtunded." First, the child is called by name to determine whether there is a response. If this is not effective, the examiner may ask a family member to speak to the child. Next, the stimulus is increased. It is most helpful to simply describe the patient's response to specific stimuli and to use the same stimuli for serial examinations. The Glasgow Coma Scale score, although of limited use in preverbal children, is a quantitative measure (Table 55-4). If the patient's eyes open to voice, the response to commands is next tested. This is discussed in more detail below, but the commands should be increased in complexity from one-step to two- or

Table 55–4 Glasgow Coma Scale

Activity	Best Response	Score
Eye opening	Spontaneous	4
	To command	3
	To pain	2
	None	1
Verbal	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Motor response	Obeys commands	6
	Localizes pain	5
	Withdraws to pain	4
	Abnormal flexion to pain	3
	Abnormal extension	2
	None	1
Total		3–15

three-step. If there is no response to voice, a painful stimulus is next applied. It should be noted that in patients with sensory deficits due to neuropathy, spinal cord, or CNS lesions or with focal limb weakness, the extremity or dermatome selected for testing should have intact sensory or motor function. In the sedated or severely impaired patient the response may comprise only increase in heart rate. It is important that the stimulus and the specific response, rather than vague descriptors ("lethargic, drowsy, sleepy") are documented, as this will be more helpful in assessing serial examinations. The rate of sedating drugs or recent administration of sedating drugs should be documented with this exam.

The assessment of higher cognitive function, and the early recognition of compromise of cognitive function, is a challenge at any time when evaluating young children. In the ICU, where the additional confounds of sedation, other organ dysfunction, sleep disturbance, and anxiety must be accounted for, this evaluation is somewhat more challenging. Of course, this is usually the most important component of the exam and the technologies used for neurologic monitoring in the ICU (imaging, EEG, NIRS, microdialysis, tissue oxygenation) all serve the same goal of the bedside exam, of detecting compromise of cerebral function to enable directed therapeutic intervention.

In the older, awake child a complete mental status exam can be performed. This must be adjusted for age (see Table 55-2) but should include assessment of language (fluency and comprehension): the ability to name, repeat, write, read, and respond to written commands. Simple mathematical problems should be adjusted to the child's age-dependent ability. Praxis can be assessed quickly even in the PICU by demonstration of learned behaviors, even in the young child (brush your teeth, brush your hair). Other components of the mental status exam, including memory, fund of knowledge, and reasoning can be assessed by holding a conversation with the patient.

Most importantly, the examiner needs to have an appropriate index of suspicion for these subtle neurologic deficits of attention, memory, praxis, language comprehension, and reading comprehension which may be the early sign of new neurologic injury. This is particularly true for patients with metabolic (often liver or renal failure), infectious, or iatrogenic (sedation, immunophilins) risk factors for CNS dysfunction and may easily be missed if not specifically investigated.

Fundoscopic Examination

Examination of the fundi may reveal hemorrhages or papilledema. Hemorrhages indicate either acute subarachnoid or subdural hemorrhage, cranial trauma from a direct blow or shaking injury, or malignant hypertension. Papilledema indicates raised ICP from any cause. Usually papilledema develops hours after the onset of the elevated ICP. Acute severe increases, however, as with subarachnoid hemorrhage (SAH) from a ruptured saccular aneurysm, can result in almost instantaneous papilledema. Sometimes papilledema never develops, despite prolonged severe elevations of ICP.

Cranial Nerve Examination

The pupillary reaction to light is abolished only by structural damage to the midbrain or third cranial nerve. Loss of the pupillary reflexes is always an ominous finding. Preservation of pupillary reflexes in the presence of deep coma suggests a metabolic-toxic cause. The interpretation of the patterns of pupil reactivity is summarized in Table 55-1.

Measurement of pupil size and light response is a quantifiable measure of brainstem and autonomic nervous system function, and absence of pupil reactivity is a poor prognostic sign after TBI or cardiac arrest. To provide a very precise measure of pupil size and speed of contraction and relaxation, a portable handheld device (pupillometer) is now available that illuminates the eye with an infrared light (850 nm) while acquiring 124 images for analysis. The data (pupil size, rate of contraction and relaxation) are stored on the device and can be downloaded to a computer. In a study of healthy volunteers and adult patients with TBI and ICP monitors in place, a discrepancy in pupil size of more than 0.5 mm appeared to be associated with ICP above 20 mm Hg.[34] Normal values for pediatrics have yet to be determined and the interpretation of these values in the setting of pediatric neurologic critical care is unclear. Nevertheless, as a quantitative, noninvasive adjunct to the neurologic exam, this technology holds promise.

Eye movements are assessed first by observation and then elicited in the patient with depressed mental status with doll's head maneuver (oculocephalic response) or cold caloric stimulation (oculovestibular response). The interpretation of eye movements and position is summarized in Table 55-1. In general, coma produced by metabolic dysfunction is initially associated with roving, dysconjugate movement and may progress to the cessation of movement. Cold caloric stimulation will produce nystagmus, with the rapid phase contralateral to the ear that has been stimulated. This rapid phase is the equivalent of saccadic eye movements and also indicates

intact functioning of the cerebral cortex. The ears are irrigated separately several minutes apart. In comatose patients the fast "corrective" phase of nystagmus is lost and the eyes are tonically deflected to the side irrigated with cold water or away from the side irrigated with warm water. These vestibuloocular responses are lost or disrupted in brainstem lesions. Versive eye deviation is a common finding suspicious for seizures. In this case, the eye deviation is contralateral to the hemisphere with the ictal focus. Alternatively, stroke in the ipsilateral hemisphere may also produce versive eye deviation toward the side of the stroke.

An abnormal corneal reflex may indicate either fifth nerve afferent disease (ipsilateral stimulation results in neither a direct nor consensual eye blink) or seventh nerve efferent disease (ipsilateral stimulation results in a brisk consensual but no direct response).

Unilateral weakness of eye closure, forehead movement, and mouth movement indicates peripheral seventh cranial nerve palsy, whereas failure to move only the mouth with preservation of upper face movements indicates a central corticospinal tract lesion rostral to the pons. Facial weakness may be noted during grimacing while responses to painful stimuli are evaluated. Voluntary pharyngeal and laryngeal control is tested by asking the patient to speak and say "ahh." In the absence of voluntary movement, a hypoactive gag indicates medullary or vagal dysfunction and a hyperactive gag indicates interruption of corticospinal inhibition to the medulla. In a comatose patient or one whose consciousness is rapidly deteriorating, one must quickly determine whether the patient is experiencing raised ICP. Papilledema or third cranial nerve palsy are strong evidence of elevated ICP.

Approach to the Motor Exam

In the comatose or obtunded patient, asymmetry of resting tone or spontaneous movement are simple signs of paresis that can be detected by first observing the patient. In children, this is particularly important, as a subtle weakness may not be apparent once the child is more awake and resisting cooperation with the exam. An externally rotated, partly flexed abducted leg may indicate an ipsilateral hemiparesis due to an upper motor neuron lesion. Facial weakness should also be first evaluated by observation before attempting formal testing (often impossible or unreliable in young, anxious, or sedated children). Signs of facial weakness at rest may include a widened palpebral fissure, diminished nasolabial fold, or flattened corner of the mouth. The examiner should next attend to the initial movement of the face, either spontaneously or in response to a noxious stimulus. Subtle weakness may be apparent only in a delayed response to these stimuli.

Weakness may be due to lesions at any level of the neuraxis. The goal of the examination of the weak patient is to identify the pattern of weakness as upper or lower motor neuron and thereby identify the most likely mechanisms. The upper motor neuron (UMN) comprises the corticospinal tract and its neurons. The corticospinal tract begins in the motor and premotor cortex anterior to the central sulcus, descends through the central white matter of the cerebral hemispheres, decussates in the lower medulla, and terminates on the anterior horn cells or interneurons closely associated with the anterior horn cells. The innervation of muscles that control movement of the jaw, pharynx, larynx, upper half of the face, neck, thorax, and abdomen is derived from both cerebral hemispheres. Consequently, unilateral cerebral lesions lead only to weakness of the contralateral limbs and lower face. The lower motor neuron (LMN) is comprised of the anterior horn cells, motor roots, peripheral nerves, pre- and postsynaptic components of the neuromuscular junction, and the muscles receiving this innervation. Stereotyped reflex movements may be present despite spinal cord injury, because these responses are coordinated by local spinal reflexes below the level of the lesion. In contrast, movement is absent following injury to the LMN because it is the final common pathway producing muscle activity. If the patient is not able to cooperate with a complete exam testing all muscle groups, in addition to observing for asymmetric posture, the observation of facial movement, testing for neck flexion, grip strength, pronator drift, and counting the duration (up to 10 seconds) that the patient can maintain a straight leg raise are efficient means of assessment.

A number of key findings on the pattern of weakness can distinguish between UMN and LMN injury, chronic and acute injury, neuropathy, and neuromuscular disorders including ICU-acquired paresis, myasthenia gravis, and Guillain-Barré syndrome (GBS). Acute UMN lesions result in a hypotonic or flaccid pattern of weakness, and in the legs may be associated with the Babinski sign. In contrast, chronic UMN injury results in a hypertonic limb with associated hyperreflexia. An LMN pattern of weakness is more likely to be associated with a decrease in muscle tone and bulk and decreased or absent reflexes. In general, proximal weakness suggests a myopathic process, while a distal pattern of weakness suggests a neuropathy. The precise incidence of critical illness neuropathy and myopathy (CIPMN) is uncertain in children.[5] Extensive data from adult studies have identified CIPMN, manifest as a variable combination of weakness, muscle atrophy, hyporeflexia, and sensory deficits, as a common cause of extubation failure with a high incidence of long-term morbidity. The contribution of the risk factors in adults, (sepsis, hyperosmolarity, neuromuscular blockage, prolonged ventilation, and corticosteroids) to pediatric CIPMN is not known. CIPMN is primarily a clinical diagnosis, although nerve conduction and electromyography studies may be confirmatory. Management, particularly in children, is empirical but this disorder should be suspected in any critically ill child with diminished reflexes and new weakness or difficulty with extubation.

The two most common neuromuscular disorders that require ICU level of care in children are GBS and myasthenia gravis (discussed in Chapter 64). A number of practical steps can aid in the diagnosis or recognition of progression of each disorder. For patients with known myasthenia admitted to the ICU in crisis, it is important to note the timing of anticholinesterase treatment and the timing in relation to each evaluation of strength. In general, testing should be performed at the nadir of weakness prior to each treatment. This is the only reliable way in which a decline in strength can be detected in these patients for whom one should have a very low threshold for intubation, particularly in the patients with bulbar involvement. In the case of GBS, patients who cannot walk unaided should be treated with intravenous immunoglobulin.[35] Neither GBS nor myasthenia should alter pupil reactivity. If the pupils are slow to react or do not react in a weak infant, the diagnosis of botulism should be considered.[36]

Posturing, due to increased ICP, should be distinguished from abnormal movements including chorea and dystonia.

Decorticate posturing consists of adduction and stiff extension of the legs, flexion and supination of the arms, and fisting of the hands. This occurs when the midbrain and red nucleus control body posture without inhibition by diencephalon, basal ganglia, and cerebral cortex. Decerebrate posturing consists of stiff extension of legs, arms, trunk, and head with hyperpronation of lower arms and plantar flexion of the feet. This indicates pontine and vestibular nucleus control of posture without inhibition from more rostral structures. Lesions below the level of vestibular nuclei lead to flaccidity and abolition of all postures and movements. These movements should be distinguished from dystonia or chorea, which may be seen as side effects of medications, or as the sequelae of basal ganglia injury, metabolic disorders, or neurotransmitter disorders.

Reflexes

In the PICU, reflexes may be absent, wax and wane during the course of the day, or be elicited by some examiners but not others. This variability can be diminished by taking time to elicit the reflex, performing the exam when the child is in a quiet, resting state, by experience, and by focusing on key reflexes. In general, the purpose of the exam is to determine whether there are changes in intensity (a reduction or increase) or symmetry or development of pathologic reflexes. It is common for upper extremity reflex testing to be limited by the presence of one or more armboards. Thus, the lower extremities are usually the most reliable site for evaluation of symmetry and intensity.

At a minimum, reflexes to be tested include the tendon jerks in the upper (if available) and lower extremities and the Babinski sign (dorsiflexion of the great toe, sometimes accompanied by fanning of the toes in response to stimulation of the lateral plantar aspect of the foot), as the cardinal screening test for intact functioning of the pyramidal system. If an extensor plantar reflex is present, this reflects injury along the corticospinal tract. The rest of the neurologic exam is then used to identify the level at which this injury is present. A number of other techniques (e.g., Chaddock, Oppenheim, Gordon, Strumpell, Moniz, Gonda-Allen) may be used[37] to elicit the extensor response but the Babinski is the most reliable.

In patients with decreased or altered mental status, frontal lobe release signs may be tested. These signs reflect diffuse cerebral dysfunction or injury. The grasp reflex involves the patient reflexively gripping the examiners finger or hand as the palm is brushed. The palmomental reflex is elicited by scratching the thenar eminence and observing for twitching of ispsilateral lower jaw muscles. The snout reflex is elicited by tapping on the mouth and producing puckering of the lips. To elicit the rooting reflex, the mouth is lightly scratched resulting in the patient turning to align the mouth with the finger. The glabellar reflex is elicited by tapping the forehead in the midline (this is done from above to head so as not to confuse the response with the reflex response to visual threat), and observing for repeated blinking each time the forehead above the bridge of the nose is tapped.

Cerebellar Function and Gait Evaluation

Normal coordination requires that both muscle strength and proprioception are intact. The interpretation of the cerebellar exam testing should be done with these systems already evaluated. Abnormal eye movements including dysmetria (overshoots of the target or a series of ratchet-like undershooting movements to reach the target when the eyes are rapidly brought from fixation on one object to another), gaze-evoked or downbeat nystagmus, or speech (slow, impaired prosody, distorted consonants or vowels, mutism) may be the only observable manifestations of cerebellar dysfunction in a patient who is sedated or too weak to cooperate with the remainder of the exam. Truncal ataxia can be detected by sitting the patient up in the bed. If possible, gait should be evaluated and observed for a widened base and the ability to perform rapid turns while maintaining normal balance.

Sensory Examination

Even in the alert patient, this component of the neurologic examination is the least reliable and the first to be discarded if necessary. This examination requires a cooperative patient. Of the components of this exam, vibration and joint position sense are the most sensitive. In the sedated patient or patient with depressed level of consciousness, sensation testing may need to be limited to noting withdrawal or flexion of the stimulated limb or an increase in heart rate. In the cooperative patient, temperature sensation can be evaluated using a tuning fork, that should feel cool. The examiner should be particularly alert to detecting a level at which sensation (pain, temperature, light touch) is lost or diminished in patients with spinal cord injury, TBI (with unrecognized cord injury), inflammatory (transverse myelitis) or demyelinating disorders of childhood (e.g., acute disseminated encephalomyelitis, multiple sclerosis), that may involve the spinal cord. In patients with cerebral injury, a lack of response to sensory testing should be distinguished from neglect.

Abnormal Movements or Altered Sensorium in the Child with Static Encephalopathy

This is a common issue in the PICU, often because of concern that the patient may be seizing, and may prompt obtaining additional imaging or EEGs since these children have primary neurologic disorders. A stepwise approach is helpful. These patients may have a limited behavioral repertoire but are at risk for multiple subtle medical problems including unrecognized pain, all of which may initially manifest with the same behavior. For a neurologist, this evaluation should also present an opportunity to revisit the diagnosis of "cerebral palsy" or "static encephalopathy," which may be obscuring a diagnosable (and perhaps treatable) disorder such as DOPA-responsive dystonia. In such cases, in addition to (often instead of) monitoring for neurologic injury evaluations, other etiologies should be considered, including unrecognized trauma, hip subluxation, long bone fractures, constipation, volvulus, inguinal hernia, gastric distension, or bowel adhesions.

Goals of the Neurologic Examination in the Pediatric Intensive Care Unit

At the conclusion of the neurologic examination in the PICU, the examiner should be able to identify the location(s) of neurologic dysfunction at the very least in terms of injury to grey (encephalopathy, seizures, neglect, aphasia) or white (weakness, spasticity) matter, posterior circulation (brainstem

dysfunction, cranial nerve palsy with contralateral weakness), spinal cord (sensory or motor level), peripheral nerve (decreased or absent reflexes), neuromuscular junction, or muscle, along with the presence of any signs of increased ICP. This should be established either as the baseline exam or compared to previous examinations and therefore assessed as progressing, improving, or stable. Next, the mechanism producing this injury should be assessed and ranked in order of likelihood. In general, this will involve either primary neurologic insult such as TBI, stroke, CNS infection, neurodegenerative disease, autoimmune or parainfectious processes, or the complications of other common pediatric disorders requiring ICU care including sepsis, congenital heart disease, liver failure, organ transplant, diabetic ketoacidosis, renal disease and dialysis, status epilepticus, or iatrogenic complications of commonly used drugs such as immunophilins or intrathecal chemotherapy.

The goal of the examiner is to combine data from the history, presenting signs, and physical examination (which may, of necessity, involve only observation of the patient) in order to develop a differential diagnosis for both the site of injury and mechanism. In general, these mechanisms will involve one or more common etiologies including: vascular (ischemia, hemorrhage, large or small vessel, arterial or venous, artery-to-artery, or cardioembolic); metabolic (either iatrogenic, often abnormalities of sodium, glucose, or ammonia; or the first presentation of a metabolic disorder); autoimmune (CNS lupus, autoimmune encephalopathies and epilepsies); parainfectious (e.g., acute disseminated encephalomyelitis); iatrogenic (sedation, neuromuscular blockade, immunophilins); toxic (drugs of abuse, drug metabolite accumulation in liver or renal failure); and infectious (systemic infection with CNS involvement, meningitis, or encephalitis, reactivation of a latent CNS infection in the immunosuppressed patient).

Based on the postulated location of the insult, the stability of the neurologic examination, the mechanism of injury, and the risk for progression of neurologic injury, the monitoring modalities can then be selected based on the need to either establish a diagnosis, monitor for secondary neurologic injury, or both.

Neuromonitoring

Neuroimaging

Computerized tomography (CT) and magnetic resonance imaging (MRI) each have specific advantages (Table 55-5) and should be selected for specific purposes (discussed in Chapter 56). CT measures x-ray density, is available easily, can be performed quickly, and is a sensitive means of detection of cerebral edema or blood. CT is relatively insensitive to acute ischemic injury and does not provide sufficient resolution in the posterior fossa, where lesions may be missed. Diagnostic CT scans should be performed first without contrast and then with contrast. Contraindications to contrast are renal failure, incipient renal failure, or a history of allergy to contrast media. White (dense) lesions on the noncontrast study are either hemorrhage or calcification. In most patients in the PICU, these white areas represent hemorrhage. Contrast enhancement indicates either local breakdown of the blood-brain barrier or excess vascularity and is associated with neoplasms, infections, inflammatory lesions, and subacute stroke.

The increasing availability of MRI is leading to greater use of it in the evaluation of acute brain injuries. MRI stimulates tissue with a specific radiofrequency pulse, after which the tissue returns to its preexcited state by processes known as T1 or T2 relaxation. In the T1 sequences, which measure T1 relaxation, cerebrospinal fluid appears dark, while it appears white in the T2 sequences. Gradient echo (GRE) sequences are most sensitive for detection of hemorrhage on MRI. In these sequences blood appears dark early (4 to 6 hours) after hemorrhage and remains dark in all later stages of hemorrhage. Small infarcts, infections, inflammatory areas, and demyelinating plaques are much more readily detected on MRI than on CT. Fluid-attenuated inversion recovery imaging uses T2-weighted sequences in which cerebrospinal fluid appears dark. For detection of ischemia, diffusion-weighted imaging (DWI) is more sensitive than CT scan in the visualization of acute cytotoxic edema. This sequence can identify acute ischemic strokes as bright lesions within minutes of their occurrence (Figure 55-2, *A*). Bright lesions on DWI indicate a restriction in the movement of water and thus are consistent with an increased water content of that region. The degree of water proton mobility is quantified by the apparent diffusion coefficient (ADC). On ADC maps, areas of restricted diffusion appear as hypointense (dark) (Figure 55-2, *B*). The reason for early decline in ADC is thought to be cytotoxic edema as a result of cellular energy failure causing a loss of ion homeostasis and a subsequent shift of water to the intracellular compartment. Not all restricted diffusion is ischemic in origin (Figure 55-2, *C* and *D*) and may instead be associated with inflammation (infection, demyelination) or metabolic derangement as in the case shown, an example of a metabolic

Table 55–5 Neuroimaging Advantages and Limitations

	Plain CT	MRI	CTA	MRA	Conventional Angiogram
Purpose	Detection of edema or blood	Higher anatomic resolution; DWI can detect early ischemic changes	Evaluate large cerebral arteries	Evaluate large cerebral arteries	Gold standard; obtain if CTA or MRA is negative and dissection or vasculitis is suspected
Advantage	Fast, widely available	DWI can detect acute ischemia	Better detection of intracranial stenosis and occlusion than MRA	Detects large-vessel arteriopathy	Most sensitive to small-vessel disease, dissection, vasculitis
Limitations	May not detect acute ischemia; insensitive to posterior fossa lesions	Less available on emergent basis; patient may need sedation	Large radiation dose	Not a measure of flow; not sensitive to small vessel disease	1% risk of complication

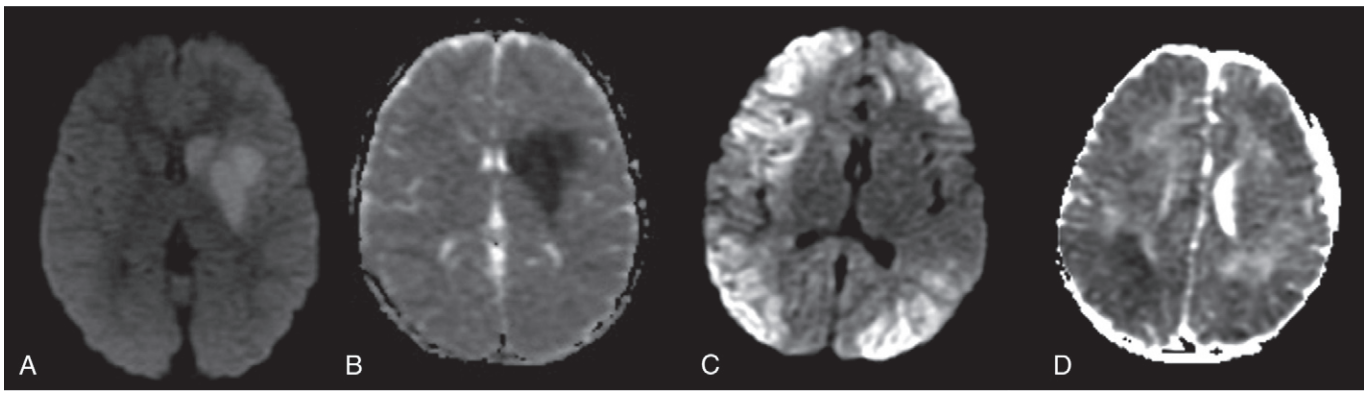


Figure 55–2. **A,** Restricted diffusion manifest as hyperintense signal in the left caudate, putamen, and globus pallidus in a 5-year-old girl with acute onset of right-sided weakness due to carotid dissection after a fall. **B,** Dark signal on the ADC map supports the mechanism as ischemic in this clinical context. **C,** Restricted diffusion in a watershed pattern in a previously healthy 1-year-old child with partial ornithine transcarbamylase deficiency and associated reduced signal in the corresponding ADC map (**D**). In this case, the mechanism is due to metabolic compromise, not ischemia.

stroke due to partial ornithine transcarbamylase deficiency mimicking a watershed stroke.

MR angiography (MRA) and MR venography (MRV) are used to detect vascular occlusions in large- and medium-size vessels in the head and neck, cerebral aneurysms larger than 5 mm and arterial dissection. As dissection is a relatively common cause of stroke in the young, MRA is a useful modality in the evaluation of pediatric stroke. This sequence detects the presence of methemoglobin in the false lumen within the vessel wall. CT angiography (CTA) is an alternative to MRA and is also noninvasive. MRA may be preferable to CTA because contrast agent is not required and the procedure does not use ionizing radiation. If MRA or CTA is negative and a dissection is suspected, conventional angiogram should be obtained. Similarly, if small vessel arteriopathy or vasculitis is suspected and MRA or CTA is negative, conventional angiography should also be obtained. Magnetic resonance spectroscopy (MRS) is used to measure the peak concentrations of certain brain metabolites such as *N*-acetylaspartate, creatine, lactate, and choline in defined areas of the brain. Measures of injury such as elevated lactate or reduction of *N*-acetylaspartate are not reliably specific to metabolic disease, metabolic stress, ischemia, demyelination, malignancy, or inflammation. When present, these measures may confirm cell injury but their absence does not rule out tissue damage.

For traumatic diffuse axonal injury (DAI) in particular following TBI, diffusion tensor imaging (DTI) has emerged as a promising means of detection of injury. DAI is thought to be a major contributor to cognitive dysfunction ranging from cognitive difficulty to coma following TBI,[38,39] but it is difficult to diagnose or characterize noninvasively. Advances in imaging technology using DTI MRI have allowed early detection of axonal injury in patients following TBI and have linked cognitive disability in these patients to white matter signal changes.[38,40] Animal studies of TBI comparing DTI findings to histopathological evidence of axonal injury show that this imaging modality is a sensitive tool to detect axonal injury.[41]

The effect of therapeutic hypothermia on the radiographic evolution of restricted diffusion on DWI in children following cerebral ischemia is not known. In practice, this means that as the use of hypothermia is extended from the asphyxiated newborn to children with cardiac arrest[42] and TBI, the results of DWI studies may potentially underestimate the degree of ischemia if obtained during or close to treatment with hypothermia. Transport of the critically ill child, the increased duration of the scan (compared with CT), and the availability of the scanner are important in the decision to obtain MRI. One approach is to streamline the use of MRI by only obtaining sequences specific to the insult being evaluated. Thus, for suspected ischemia only DWI and ADC sequences are obtained; for hemorrhage, GRE; for hydrocephalus, MR of the ventricles; for sinus thrombosis, MRV; for dissection or large vessel vasculitis, MRA; for metabolic disease, MRS; and for cortical dysplasia in epilepsy patients, standard MRI. This means that a patient admitted with suspected stroke can complete a study (MR ventricles and DWI) in a much shorter time than is otherwise required and the most important initial question (presence or absence of ischemia) can be addressed so that therapy can be adjusted.

Intracranial Pressure Monitoring

The most common indication for ICP monitoring in critically ill children is TBI (discussed in Chapter 61), in which the measurement of ICP serves to direct therapy with the goal of preventing the secondary complications of TBI resulting from cerebral hypoperfusion or metabolic stress. For children with severe TBI, a CPP between 40 and 65 mm Hg is recommended,[26] and CPP of 60 to 70 mm Hg for adolescents. Optimal CPP levels for children under 2 years of age have not been established. Nevertheless, it is possible that outcome from other neurologic insults resulting in cytotoxic or vasogenic cerebral edema may be improved by therapy optimized to maintain cerebral perfusion, as directed by monitoring of ICP. In pediatric acute liver failure, the main determinant of outcome is neurologic morbidity[43] with compromise of astrocyte metabolism postulated as a pivotal mechanism in the development of cerebral edema associated with hepatic encephalopathy.[44] ICP monitoring is used in approximately 7% of patients with meningitis,[45] and mortality is higher in patients with meningitis and mean CPP less than 50 mm Hg.[46] In the longer term, other indications for ICP monitoring may expand to include diabetic ketoacidosis, cardiac arrest, near-drowning, or refractory status epilepticus. At present, there is no consensus for

ICP monitoring other than following TBI, as there are no data to show any improvement in outcome and there are concerns that the risks outweigh the potential benefits.[47,48] It is important to keep in mind that, in children in particular, neuroimaging cannot be used as the definitive measure of the presence or absence of intracranial hypertension (Figure 55-3). Rather, the examiner must rely on a combination of assessment of risk factors, clinical examination, and changes in the examination, combined with imaging findings (which may be unremarkable).

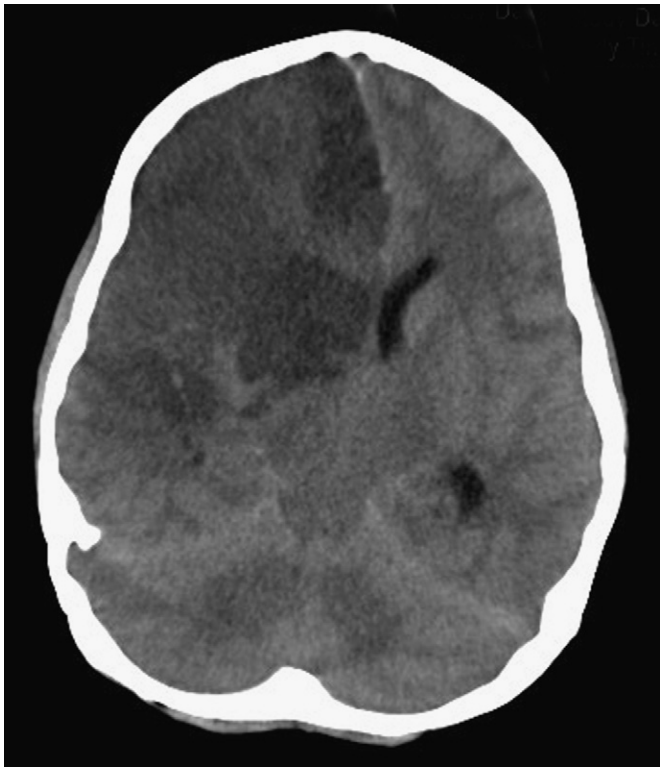

Figure 55–3. Cranial CT without contrast in a 9-year-old with acute onset of left-sided weakness, demonstrating extensive edema with midline shift in the right cerebral hemisphere, consistent with infarctions in the right anterior cerebral and middle cerebral artery distribution, sulcal effacement, and compression of the right lateral and third ventricle. This patient was still awake and following commands when this scan was obtained.

Brain Tissue Oxygen Monitoring

Maintaining adequate tissue oxygenation is a fundamental goal in management of any compromised organ in the critically ill patient. Accordingly, brain tissue oxygen ($PbtO_2$) monitors are now included in the treatment guidelines for management of TBI.[49] The Neurotrend system, using a colorimetric method with optical fluorescence, measures three variables: O_2, pH, and CO_2, but is rarely used in clinical practice in the United States and is currently not commercially available. The Licox system (Integra Neurosciences, Plainsboro, NJ) uses a Clark-type electrode with a catheter 7 mm in length and measures both $PbtO_2$ and temperature. The indications for placing the $PbtO_2$ monitor are the same as those for patients requiring ICP monitoring following TBI. Typically, the probe is placed in the white matter of the brain, because it is more metabolically stable than the gray matter. If the region of injury is to be monitored, the catheter is placed adjacent to, but not in the region of, the contusion or clot, the area of insult, or in the ischemic penumbra. While there have been no randomized trials evaluating $PbtO_2$ monitors, a retrospective analysis of 150 evaluable patients with severe TBI[50] found that brain hypoxia ($PbtO_2$ <10 mm Hg) was associated with worse outcome and mortality. Notably, the complication rate was less than 1%. There is debate as to whether the $PbtO_2$ monitor is measuring oxygen extraction or cerebral blood flow (CBF).[51] Animal studies suggest that the monitor is not simply measuring CBF,[52] consistent with data from human severe-TBI cases using a probe in the least-injured hemisphere, showing a significant relationship between $PbtO_2$ and the product of CBF and cerebral arteriovenous oxygen tension difference.[53] Taken together, these data indicate that this monitor detects both oxygen tension and CBF. The promise of this technology for pediatric neuromonitoring is considerable but a number of caveats remain. The threshold (10 to 15 mm Hg) for poor outcome is based on mostly adult data. The age dependence of this threshold, the dose dependence of an exposure to cerebral hypoxia, and the disease specificity (for insults other than TBI) of this endpoint remain to be determined.

Cerebral Microdialysis

Cerebral microdialysis, like $PbtO_2$ monitoring, is an invasive method for estimating cerebral metabolism. This technology uses the capillary technique to measure the concentration of key metabolites (glucose, pyruvate, lactate), excitotoxic amino acids (glutamate and aspartate), and membrane breakdown products (glycerol) in the brain parenchyma in order to detect evolution of primary injury and the development of secondary injury.[54] The microdialysis catheter is a fine tube, placed via a burr hole, within a semipermeable dialysis membrane that permits diffusion of molecules from the extracellular space along the catheter and into a vial. This vial is then placed in the microdialysis analyzer. In general, the catheter is placed via the same burr hole as the $PbtO_2$ and ICP monitors into the normal brain or the penumbra of the injured brain. The most common system is the CMA 600 microdialysis analyzer (CMA Microdialysis, Stockholm, Sweden). As with $PbtO_2$ monitoring, results will vary, depending on whether the probe is placed in healthy tissue, tissue adjacent to the primary site of injury (penumbra), or in the injured tissue. For adults with TBI or SAH requiring ICP monitoring, the use of microdialysis has been recommended, following a consensus meeting.[55] A number of adult studies have shown, in TBI and SAH cases, an association between metabolic stress (lactate/pyruvate ratio >40) and poor outcome.[11] In a retrospective analysis of 20 adult patients with severe brain injury, tight systemic glucose control was associated with reduced cerebral glucose and with corresponding evidence (increased lactate/pyruvate ratio) of compromised brain metabolism.[56] While prospective studies are needed to determine whether metabolism-directed therapy can improve outcome, as are data on age- and disease-specific values in children, and a consensus is needed on the indications for in pediatric neurocritical care, it is clear that the ability to monitor and react to compromised cerebral metabolism in the long term will be essential to improving neurologic outcome.

Near-Infrared Spectroscopy

NIRS measures tissue oxygen saturation by determining the difference in intensity between transmitted and received light delivered at specific wavelengths.[57] Commercial cerebral NIRS products measure oxygenation by using light between 700 and 1000 nm wavelength to measure transparency of tissue to light. Since hemoglobin absorbs near-infrared light depending on its oxygenation state, changes in hemoglobin oxygenation can be quantified using the modified Lambert-Beer law. In theory, NIRS may therefore serve as a noninvasive method for detection of cerebral or somatic hypoxia. In practice, the reliability of cerebral NIRS has been questioned in a study showing that in infants up to 190 days old, cerebral NIRS values were not reproducible.[58] In a study of adult human cadavers, the cerebral tissue oxygenation measured by NIRS in a third of these subjects was higher than the lowest value of normal controls.[59] While there remains controversy over the relationship between NIRS values, particularly for the CNS, the cumulative evidence from studies in congenital heart disease supports a role for NIRS in physiologic monitoring. In a study of postoperative congenital heart disease patients, cerebral and flank regional oxygen saturation were correlated with central venous oxygen saturation in both cyanotic or acyanotic patients and single-ventricle or two-ventricle physiology.[60] Change in arterial pressure of carbon dioxide was associated with change in cerebral, but not flank regional oxygen saturation, suggesting that cerebral NIRS is detecting changes in cerebral oxygenation. In patients with elevated ICP, cerebral regional oxygen saturation measured by NIRS was significantly reduced,[61] but this association was present only in cases of brain tumors and hydrocephalus. The cumulative evidence suggests that NIRS may ultimately prove useful both in the monitoring for neurologic complications following surgery for congenital heart disease[62] and in other neurologic disorders.

Electroencephalographic Monitoring

The importance of the EEG as a monitoring tool in the PICU is not only in its role in the detection of electrographic seizures but also, in doing so, as a means for detecting and treating secondary insults in the critically ill patient. The objective of neurologic monitoring in the ICU, from the bedside exam to ICP, is the early recognition of secondary insults to the brain, and the EEG is a noninvasive tool to include in this armamentarium. In a full montage, 20 scalp electrodes are placed over the skull and record the electrical activity of the surface of the brain. In general, the EEG is used to detect seizures, electrographic alone (NCS), epileptiform activity, and focal slowing or discharges. Criteria for the use of continuous EEG (cEEG) monitoring in the PICU have not been established and there is wide variation in the use of this technology.[63]

Importantly for ICU neurology, the EEG cannot be used to determine the etiology of abnormal patterns, discharges, or seizures. Seizures may be the presenting symptom of new ischemic (venous or arterial) or hemorrhagic injury in the critically ill patient. In the PICU, the detection of electrographic or clinical seizures should prompt investigation of common PICU causes of seizures such as metabolic derangement, drug reaction, vascular injury, or infection. Often, a change in EEG pattern (loss of complexity, slowing, new epileptiform discharges) in the absence of seizures may also reflect new neurologic insult. The import of these changes can only be interpreted in the context of each patient's risk factors for neurologic injury.

Figure 55–4. Bipolar EEG montage of an 11-year-old girl 4 weeks after umbilical cord transplant for acute myelocytic leukemia. Note the electrographic seizures at F4 and F8. This patient has had limbic encephalitis due to reactivation of latent human herpesvirus-6 infection. The only clinical manifestations of nonconvulsive seizures in this patient were loss of short-term memory and decreased sleep.

Status epilepticus and refractory status epilepticus are associated with a significant increase in mortality in adults and children (discussed in Chapter 60).[64-67] Since repetitive seizures become self-sustaining and pharmacoresistant after 15 minutes,[68] early recognition of clinical or electrographic seizures is an important factor in enhancing the efficacy of anticonvulsants to terminate seizures and reduce the additional metabolic stress seizures impose on the injured brain. However, NCS or status epilepticus may be difficult to diagnose. Both are often unrecognized in comatose patients.[69,70] Convulsive or nonconvulsive seizures have been detected in up to 50% of patients in an ICU when examined with cEEG monitoring.[71-73] Many of these patients are in electrographic nonconvulsive status epilepticus (NCSE).[74] Importantly, routine (r)EEG recording fails to detect NCS in approximately 50% of critically ill patients whose NCS were detected with cEEG monitoring.[73,75] In patients in whom NCS are suspected, cEEG monitoring for at least 12 hours is required to detect NCS,[4,31,73] since the majority of these seizures will be not be detected during the short duration of an EEG. An example of NCSE is shown in Figure 55-4 in a patient with limbic encephalitis following cord blood cell transplantation, whose only neurologic deficits were decreased sleep and loss of short-term memory. Thus cEEG monitoring rather than rEEG should be used in any comatose or obtunded patient in whom seizures are suspected. While cEEG is recommended over rEEG because of the greater sensitivity of NCS detection with prolonged monitoring, there are no established criteria to determine patients to select for such monitoring. Given the prevalence of NCS in adult and PICU studies (up to 50% of comatose ICU patients) a reasonable approach is to monitor any obtunded or comatose ICU patient with a primary neurologic injury or in whom neurologic complications of therapy or disease may occur.

In addition to the detection of NCS, EEG is used to guide therapy during induction of or withdrawal from burst suppression. This is most easily achieved using cEEG, but if this is not available serial rEEGs may serve the purpose. In the

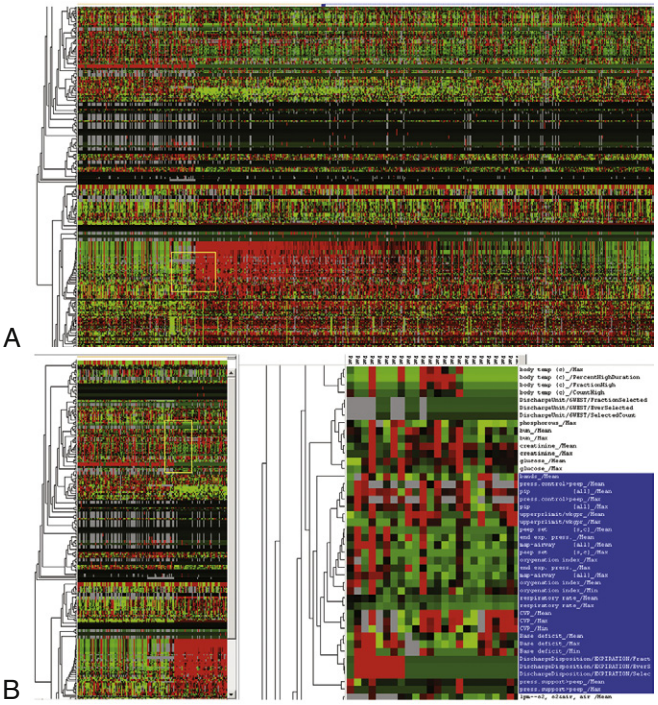

Figure 55–5. **A,** Master view of heat-map analysis of all PICU patients over a 5-year period, older than 1 year of age, who required mechanical ventilation. The differences between survivors (*left*) and nonsurvivors (*right*) can easily be seen. This analysis incorporated thousands of variables ranging from census tract data to laboratory results and ventilator settings. **B,** View of selected cluster of variables highlighting those associated with differences in outcome after ventilation. This approach is proof principle of the potential of data mining in the ICU to discover novel relationships and generate hypotheses.

PICU, careful attention should be paid to the integrity of the scalp as skin breakdown following prolonged exposure to the EEG electrodes may occur within 1 to 2 days and may limit the ability to perform serial monitoring studies.

Integrating Neurologic Monitoring Data

The growth in tools for invasive and noninvasive neuromonitoring in the ICU forces the issue of how to collect, integrate, and interpret these data.[76] It is clear that the use of physiologic thresholds to define "good" or "bad" values is oversimplified for pediatric neurocritical care in particular, and based on limited data with no well-established age-dependent parameters. This approach tends to interpret one variable in isolation from others and relies on the skill and experience of the clinician interpreting the data. Further, the volume of data generated on a minute-to-minute basis in the PICU places demands on the network used for storage of these data. The goal of "plug-and-play" for all devices (monitors, infusion pumps, ventilators), that generate potentially clinically important data has not yet been achieved in the PICU. Indeed, these devices typically do not have a common source for recording time, rendering even the interpretation of the timing of treatment, changes in ventilator parameters, laboratory results, or physiology open to question even if the obstacles to acquiring these data have been overcome. One approach may be to limit the acquisition of data to only those variables best validated for outcomes in TBI. This approach will likely miss unanticipated relationships that may emerge only using an unbiased non-hypothesis-driven analysis of multiple variables. An example of this approach from a retrospective analysis of PICU data is shown in Figure 55-5. Using a cluster analysis of all patients older than 1 year who required mechanical ventilation, the differences between survivors and nonsurvivors can easily be seen. This analysis incorporated thousands of variables ranging from census tract data to laboratory results and ventilator settings, and demonstrates the potential of the application of these tools to the array of data generated in the PICU. Therefore, in order to make use of the data generated by neuromonitoring, to interpret these data in relation to other physiologic and laboratory variables, and to develop new methods of analyses beyond thresholds and values at single time points rather than trends over time, it will be necessary to establish real-time data collection from all devices attached to the PICU patient, link these data (including waveforms) to laboratory and socioeconomic data, direct the flow of this information to new analysis tools, validate the data returning to the bedside, and iteratively develop and test predictive tools for the recognition of new cerebral or systemic injury. Thus progress in the application of neuromonitoring for management of children with brain injury is fundamentally linked to the development of improved (better integrated, higher granularity) data collection and tools for bedside analysis using the emerging methods of bioinformatics.

Neuroimaging

Paritosh C. Khanna and Dennis W.W. Shaw

PEARLS

- Multiple imaging modalities are available for evaluation of the brain, head, neck, and spine of the critically ill child. The most appropriate modality depends on consideration of patient pretest probability for the clinically suspected diagnosis, the modality sensitivity, and the patient's age and condition.
- When ordering radiographic studies, particularly computed tomography scans, keep in mind the radiation burden, especially for infants. When ordering magnetic resonance imaging for young children, one must keep in mind the risk related to sedation and general anesthesia.
- The ever-increasing complexity of imaging modalities and medical problems in the intensive care unit warrants liberal consultation with radiology colleagues to yield an appropriately tailored imaging protocol and a more relevant interpretation.
- In the pediatric population and especially in critically ill patients, noninvasive imaging modalities that are likely to answer the clinical question should carefully be considered as an alternative to a catheter angiogram, which is minimally invasive but has a real, non-zero risk of procedure-related complications.

Imaging Modality Overview

Multiple imaging modalities are available to investigate the neurologic status of children in the intensive care unit (ICU). Selection of the most appropriate examination requires weighing factors of modality sensitivity against the suspected pathology, having a degree of suspicion for a particular pathology, and considering the practicalities afforded by the complexity of the examination and the child's condition. In this chapter, available imaging modalities and the disease processes most likely to be subject to neuroimaging evaluation are reviewed.

Ultrasound

Standard cranial ultrasound has been a mainstay in the neonatal ICU. Ultrasound generates gray-scale digital images from components of an ultrasound beam reflected off tissue interfaces with no ionizing radiation, and with the added advantage that bedside imaging can be performed. However, cranial ultrasound has a restricted window through which to visualize the brain, primarily through an open anterior fontanelle, and therefore it is limited for the most part to the first few (4 to 6) months of life. Ultrasound is sensitive to some intracranial pathology, including the detection of germinal matrix hemorrhage, evaluation of ventricular size, and evaluation of severe white matter lesions in premature infants, including cystic periventricular leukomalacia (PVL). It is less sensitive for pathologies such as mild to moderate parenchymal ischemic changes, subarachnoid and punctate parenchymal hemorrhage, and subtle cerebral malformations. Extra-axial collections, especially those along the lateral cerebral convexities, also can be difficult to appreciate on ultrasound performed through a midline fontanelle.

Color Doppler with the standard ultrasound machine uses the shift in frequency associated with reflection of the sound beam off a moving interface (the "Doppler shift" phenomenon) to detect motion in the image field, most commonly from blood in vessels. Those pixels with movement are assigned a color to distinguish them from pixels without movement. The color assigned (most often red and blue) is different depending on whether movement is away from or toward the transducer, and the color assigned is arbitrary so that arteries and veins are not necessarily red and blue, respectively. Color Doppler allows for some investigation of the cerebral circulation, primarily through the open fontanelle. Transcranial Doppler (TCD) uses the same Doppler shift to produce waveforms that give information about flow velocity and direction. TCD has the advantage that it can be performed through the thinner portions of the skull, primarily the temporal squamosa, in older children and adults (Figure 56-1). TCD has been used in evaluation of cerebral perfusion in patients with sickle cell disease[1] and vasospasm secondary to subarachnoid hemorrhage.[2] TCD is generally sensitive to stenoses greater than 50% in the central cerebral circulation, with the highest sensitivity and specificity being in the middle cerebral artery (MCA).[3,4]

Computerized Tomography

Computerized tomographic (CT) scanning has higher sensitivity compared with ultrasound for many intracranial pathologies, including most neurosurgical emergencies, and is not limited by closing and closed fontanelles. Imaging on modern scanners with multiarray detectors can be performed very rapidly. CT, however, requires transporting the patient from the ICU (although some portable units are available) and uses ionizing radiation (x-rays) to produce digital computer–reconstructed images based on differences in tissue density

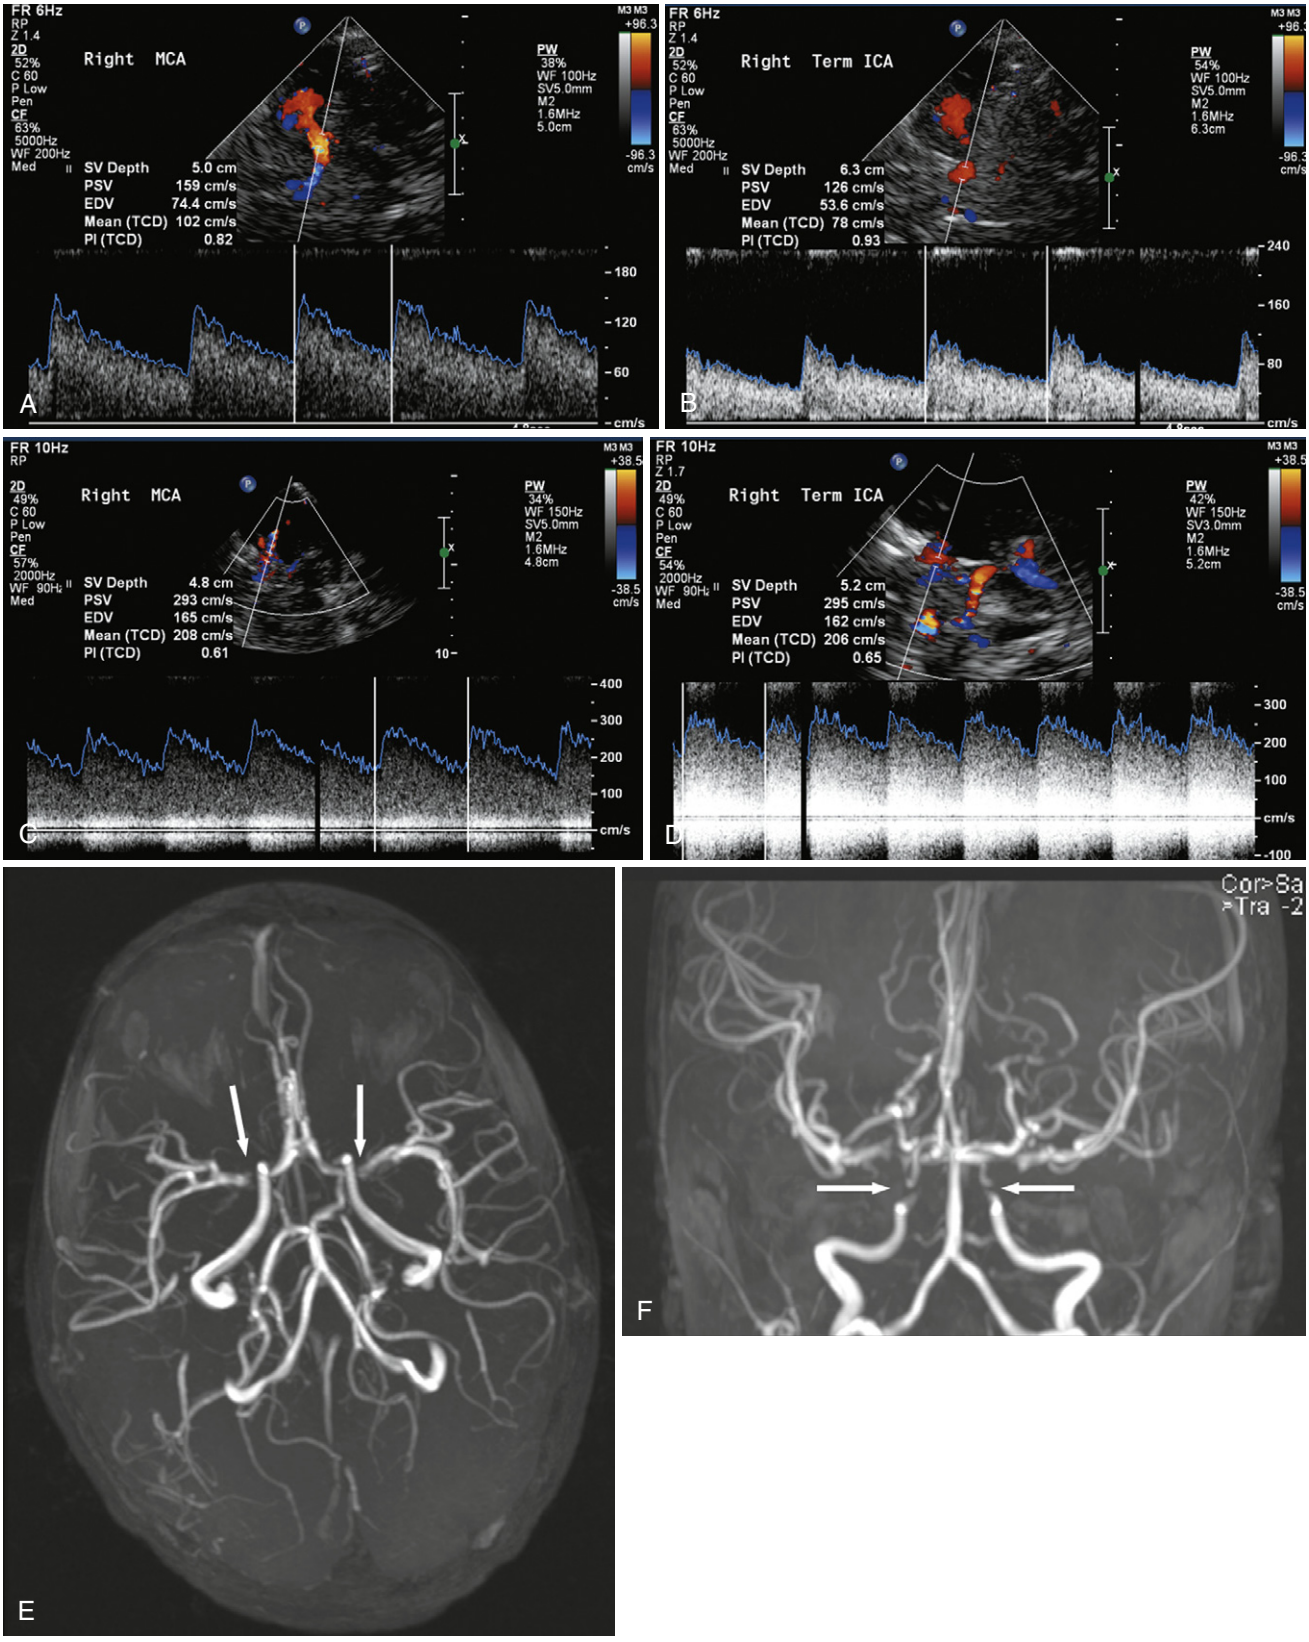

Figure 56–1. Transcranial Doppler ultrasound images. Color and spectral Doppler waveforms from (**A**) normal right MCA and (**B**) right terminal ICA. Abnormal right middle cerebral (**C**) and terminal internal carotid (**D**) waveforms in another patient with sickle cell disease and prior history of stroke. MR angiographic images (**E** and **F**) of this patient with abnormal Transcranial Doppler demonstrate narrowed proximal MCAs and terminal ICAs.

(which affects x-ray attenuation). The choice of radiation parameters, slice thickness, post-processing, and image viewing (window width and level) must be tailored to the particular clinical question to optimize the images. Bone and other calcifications have the highest density, and in decreasing density are (nonadipose) soft tissue (such as the brain), water (e.g., cerebrospinal fluid [CSF]), fat, and then air. The difference in density between bone and brain is great, whereas the difference between brain and fat is less. The density difference between gray and white matter is much smaller but is sufficient to be appreciated with the appropriate window and level. Generally, as edema develops in non-fatty tissue, there is a decrease in density. Acute blood (approximately between 12 and 72 hours old) is of higher density than brain, and CT is very sensitive in detection of acute (generally less than 1 week old) parenchymal and subarachnoid hemorrhage (SAH). CT is also useful in the evaluation of ventricular size and extra-axial collections.

Iodinated intravenous (IV) contrast can be used with CT to evaluate the integrity of the blood-brain barrier (BBB) and differences in tissue perfusion. With injection of IV contrast, vessels demonstrate a transient increase in density, with a variable rate of contrast leak into the tissues, depending on the local pathophysiology. The rate of equilibration of contrast concentration between vessels and parenchyma is much slower in the brain because of the intact BBB. Contrast then is especially useful in the brain, where disruption of the normal BBB can reveal underlying pathology. This increased density from contrast material is also used to image arteries and venous structures with CT angiography (CTA) and CT venography (CTV), respectively. With the appropriate software, post-processing of the data can produce three-dimensional (3D) images of the vessels.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) utilizes a high field strength magnet in combination with radiofrequency pulses to produce images based on the nuclear resonance of hydrogen protons in tissue, primarily in water and fat. MRI provides the most sensitive measure of most (but not all) central nervous system (CNS) pathologies, and unlike CT, imaging can be acquired in any plane (although state-of-the-art multidetector CT scanners can acquire volumetric data that can be reformatted in any plane). Imaging, however, requires patient transport to the scanner; increased examination complexity and potential safety concerns are primarily related to the high-field-strength magnet (typically 1.5 or 3.0 Tesla) and long imaging sequences (1 to 10 minutes). MRI provides the greatest tissue characterization, facilitated by several sequences obtained in a complete study. MRI is particularly useful in evaluation of the posterior fossa (brainstem and cerebellum) and spinal cord, where "beam-hardening" due to bone results in considerable artifact on CT, although this problem has become less of an issue with modern multidetector CT scanners.

To ensure safety, MRI-compatible monitoring and life support systems must be used. Patients need to be screened for any internal hardware or implants that would preclude scanning, such as MRI-incompatible aneurysm clips. Electronic devices such as pacemakers are rendered dysfunctional by the changing magnetic field occurring during MRI and hence patients with such devices generally should not undergo MRI (further details are available at http://www.mrisafety.com/). Injuries and deaths have been reported because of the failure to recognize these dangers. Most MRI sequences require imaging times in the range of minutes and are very susceptible to motion degradation. For patients who are unable to cooperate, deep sedation or anesthesia is often required. It also is important to screen the renal function of patients who might get an MRI because gadolinium-based contrast may need to be used. Gadolinium recently has been implicated in the development of nephrogenic systemic fibrosis in some patients with compromised renal function, which is not uncommon in the ICU setting.[5]

MRI exploits nuclear characteristics of hydrogen protons principally in tissue water, referred to as the T1 (longitudinal relaxation) and T2 (spin-spin relaxation) of the tissue. An imaging sequence includes both T1 and T2 components to create an image; however, an individual sequence can be formulated to be predominately one or the other, that is, T1 weighted or T2 weighted (often referred to as simply T1 or T2 sequences). Because most pathobiology results in some disturbance of water, these imaging parameters turn out to be quite sensitive to many pathologies. On T1-weighted images, water—such as CSF in the ventricles or vitreous in the globes—is dark. This water is bright on T2-weighted images. One point to be aware of is that for the most part the signal intensity of any tissue being imaged on MRI is relative (unlike the absolute density measure in CT). Hence the detection of pathology is dependent upon visualizing differences in intensity of one tissue relative to another.

Fluid-attenuated inversion recovery (FLAIR) is a variation of T2-weighted imaging where the CSF is specifically rendered dark or suppressed so as to enhance visibility of hyperintense pathology in parenchyma, especially adjacent to normal CSF spaces. Fat is hyperintense on T1-weighted sequences and is also fairly bright on fast T2-weighted sequences, which is possible with most modern-day scanners. In some situations it is advantageous to suppress the brightness of fat, which can be specifically done at the cost of increased scan time. Gradient-recalled echo (GRE) and susceptibility-weighted MRI sequences are often utilized for detection of hemorrhage, although these sequences generally also result in more artifacts. The appearance of acute blood on CT is fairly straightforward, appearing hyperdense initially (because of the extraction of serum), becoming isodense by about a week, and appearing hypodense thereafter. The appearance of blood on MRI is much more complex, and although generally it is detectable much longer, it can be difficult to appreciate hyperacute blood (approximately less than 12 hours old) with MRI, especially subarachnoid hemorrhage. Overall, the detection of calcium and hyperacute blood can be quite difficult by MRI, and CT is often better in this regard. IV contrast is also used in MRI, with similar application with CT. In this case the contrast is a gadolinium chelate that shortens the T1 relaxation time of nearby water. The result is that the water near gadolinium is hyperintense on T1-weighted images. This effect can be used to detect BBB disruption, which is seen in various pathologies including ischemia, inflammation/infection, and status epilepticus. Malignant and some benign brain tumors also demonstrate enhanced capillary permeability with enhancement following contrast. MRI with gadolinium is about an order of magnitude more sensitive than CT using iodinated contrast in detecting BBB disruption. Some areas of the brain lack the BBB, including the choroid plexus, pituitary gland, and the median eminence, and thus they enhance normally.

Diffusion-weighted imaging (DWI) has assumed an invaluable role, particularly in the intensive care setting. This sequence is now integrated into most brain MRI examinations and is particularly sensitive to areas where brain parenchyma has sustained acute cytotoxic injury, most commonly but not limited to ischemia. DWI is sensitive to the motion of water at the molecular level.[6] Detecting this molecular level motion requires strong fast gradients that have become standard on modern-day MRI scanners to allow sufficiently rapid scanning to effectively "freeze" the gross tissue motion that normally swamps this molecular level motion. Different cerebral pathologies produce different types of edema (e.g., cytotoxic, vasogenic, and interstitial). Evaluation of the molecular (Brownian) motion of water turns out to be a sensitive measure of some pathologic states, the most significant application currently being cytotoxic edema associated with the detection of ischemia.[7] Cytotoxic edema causes "restriction" of water diffusion with a decrease in the apparent diffusion coefficient (ADC). This is seen as hypointensity on the calculated ADC map image but is more easily appreciated as hyperintensity on the DWI "trace" image. In contrast to cytotoxic edema, vasogenic and interstitial edema result in "increased" water diffusion and therefore an increase in the ADC. Care must be taken in interpreting the DWI trace images because they have some T2 weighting, and "T2 shine-through" can result in a focus of increased signal on DWI trace images that does not represent true restricted diffusion. Review of the calculated ADC map images should show a corresponding darkening in a focus of cytotoxic edema to confirm restricted diffusion. Also, the hyperintensity on DWI trace images may "pseudo-normalize" for a period of time several days following the ictus because of the development of associated vasogenic edema. Restricted diffusion due to infarct will generally resolve over the course of 1 to 3 weeks and allows a new infarct to be distinguished from older lesions. It also should be noted that restricted diffusion is not limited to ischemia and can be seen in other acute cerebral pathologies.

Advanced Magnetic Resonance Imaging Techniques

Newer techniques in MRI such as MR perfusion, MR spectroscopy (MRS), and diffusion tensor imaging are providing new information that is being increasingly utilized in the management of critically ill patients.

Perfusion MR is used in the evaluation of cerebral perfusion. The most widely available techniques use rapid scanning associated with a bolus of IV gadolinium contrast to measure first-pass changes in signal intensity. These techniques give a relative measure of perfusion, but not quantitative flow. This relative measure can be used to detect diminished cerebral blood flow in one area compared with another. Newer noncontrast MRI techniques such as arterial spin labeling generally have lower signal to noise ratio (sensitivity) but are improving and potentially quantifiable. There is some early experience with arterial spin labeling in pediatric stroke resulting from sickle cell disease.[8,9]

Conventional MRI is based on the signal intensities derived from the hydrogen bonded to oxygen in water and, to a lesser extent, the hydrogen bonded to carbon in fat. With the appropriate software, MR can be used as a "probe" for hydrogen bonded to other molecules (termed *MR spectroscopy*). The sensitivity is sufficient to detect metabolite molecules in the millimolar range, although at a much lower resolution than that used to detect water for imaging. The non-water molecules are most commonly reported as ratios of signal peaks that correspond to one of several molecules. In the brain the most common metabolite peaks detected are N-acetyl aspartate, creatine, choline, and in some physiologic states, lactate. The MRS signal is either obtained from a single voxel (usually several mL in volume; voxel is the "volume element" of the image = pixel × depth) or multiple voxels (as small as 1 to 2 mL in volume). Multivoxel MRS can be used to make low-resolution images using a technique termed chemical shift imaging for some of the more prevalent metabolite peaks. The utility of MRS is still in evolution, and newer variants of MRS are constantly being evaluated. Detection of lactate to evaluate newborn ischemia and some metabolic diseases is one of the ongoing applications and areas of research. MRS also has a role in children with mitochondrial disorders.[10]

Magnetic Resonance Angiography

Fluid motion within tissues can be used by MRI to image flow in vessels and CSF. This imaging can be accomplished with and without contrast, although contrast techniques are generally more sensitive for vascular flow, with some newer contrast angiography sequences also providing temporal/flow information. The MR angiogram can be tailored for artery (MRA) or vein (MRV) visualization, primarily based on flow direction, and is usually most effective if the area of interest can be narrowed, for example, the circle of Willis, although newer techniques have greatly increased the area that can be covered in one scan. The maximum resolution of MRA of slightly under 1 mm is generally less than CTA, where maximum resolution can be under 0.25 mm.[11] In addition to the source images (the thin angiographic sections obtained during the scan), various reconstructed images can be obtained, including 3D rotational reformations derived from maximum intensity projection reconstructions (Figures 56-2 and 56-3) and surface renderings, which also can be viewed from multiple projections. Many clinical cerebral arterial questions are now answered with MRA, and MRV of the superficial and deep venous systems has largely replaced diagnostic catheter venograms.

Catheter Angiograms

Although significant inroads have been made in cerebral vascular evaluation with both CTA and MRA, when indicated, catheter angiography remains the gold standard for most vessel imaging. Catheter angiography also provides temporal/flow data, such as appreciation of early venous drainage with arteriovenous malformations. Angiography is basically a rapid series of radiographs obtained during injection of iodinated contrast directly into the arteries or veins being imaged. Most angiography units produce digital images using digital subtraction (hence the term "digital subtraction angiography"), that is, images where the background "mask" has been subtracted, leaving an image primarily of the contrast-filled vessels. High-end modern-day units utilize biplane technology that permits acquisition of digital angiographic images from multiple projections using a single contrast injection. This technology also can be used to derive 3D rotational angiograms, images from which can be further post-processed to obtain volume rendered and surface-shaded images.

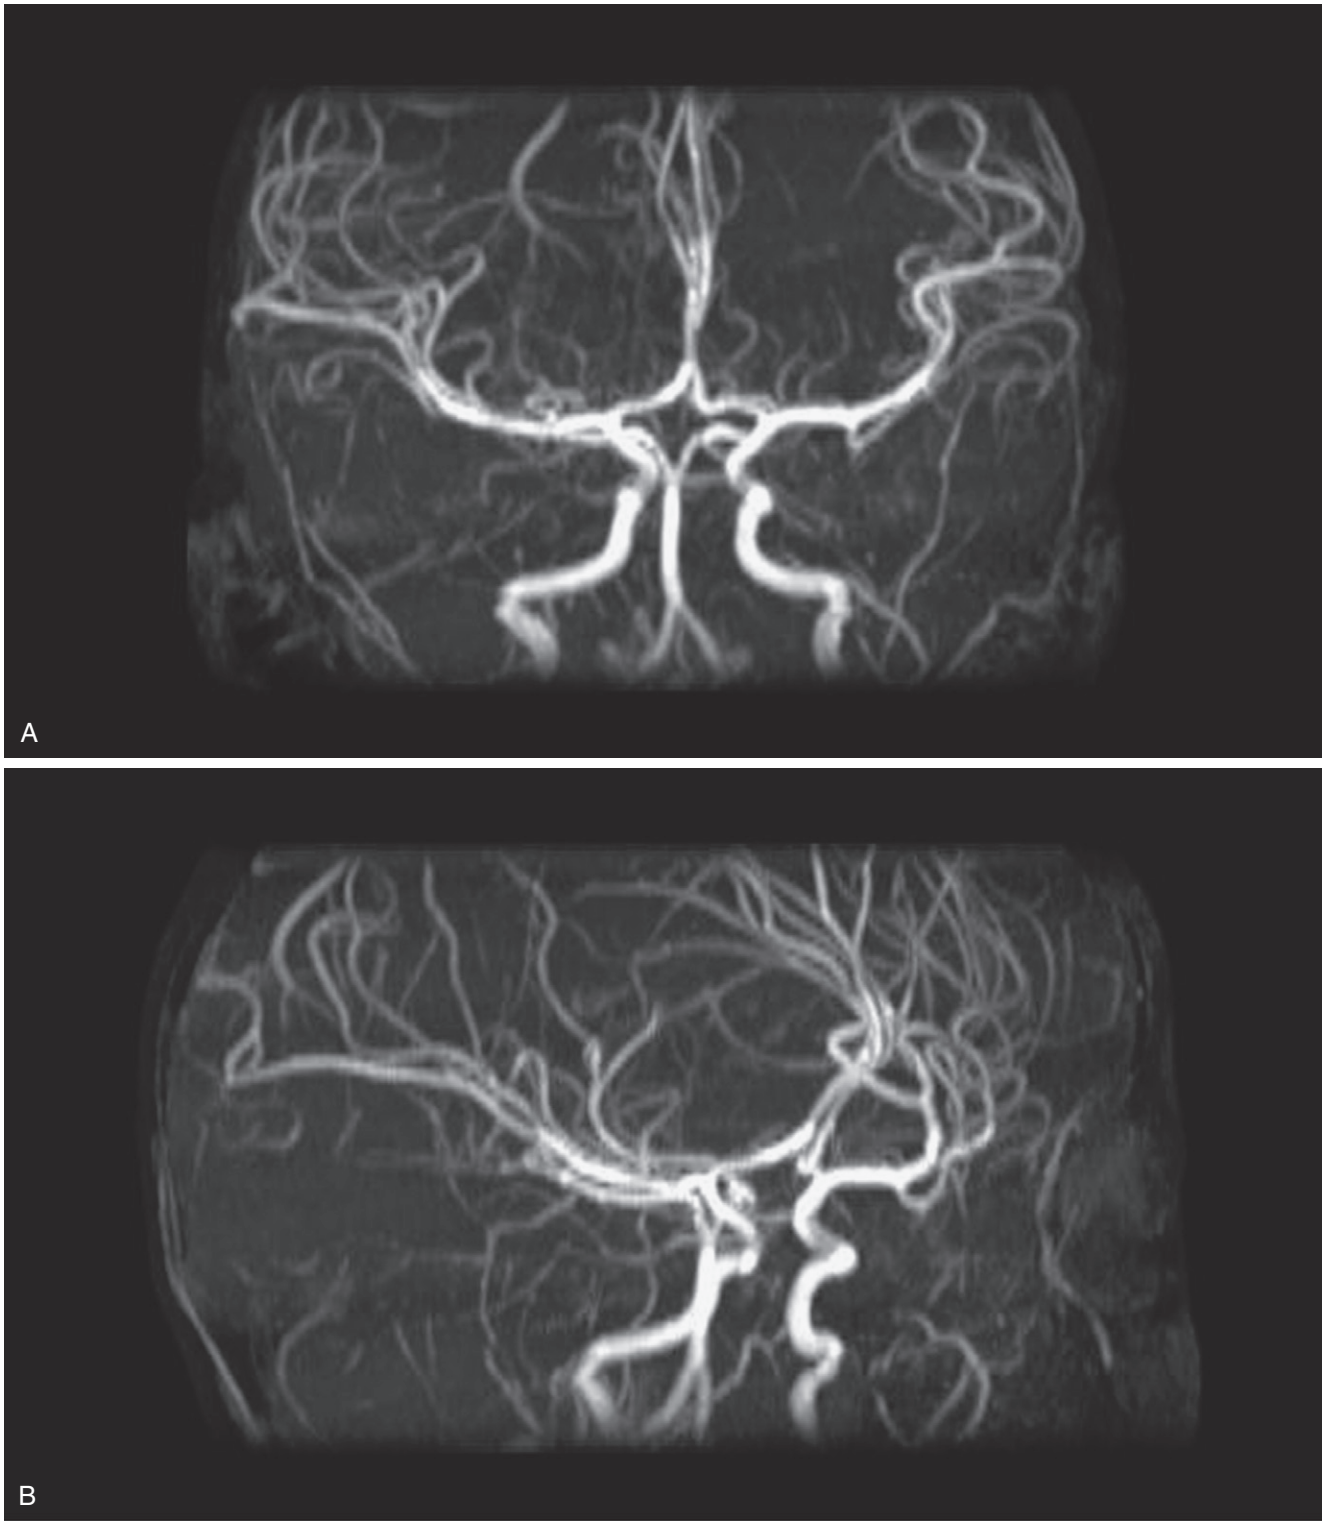

Figure 56–2. Normal MRA scans. Frontal (**A**) and oblique (**B**) maximum intensity projection images from an MRA demonstrate normal anterior and posterior circulations.

Catheter angiography requires transport to and patient support in the angiography suite. Vascular access for arterial studies is usually through the femoral artery and generally has a small but "non-zero" risk of vessel injury, including dissection and embolization. In very young patients, injury to the femoral artery is of greater concern, and although any acute risk to the limb is extremely uncommon, relative diminished leg growth in some cases has been documented. Risks of neurologic complication following cerebral angiography are small but do exist, with the reported incidence of permanent defects typically ranging from about 0.5% to 0.07%.[12,13] Therapeutic endovascular procedures carry higher risks but generally are

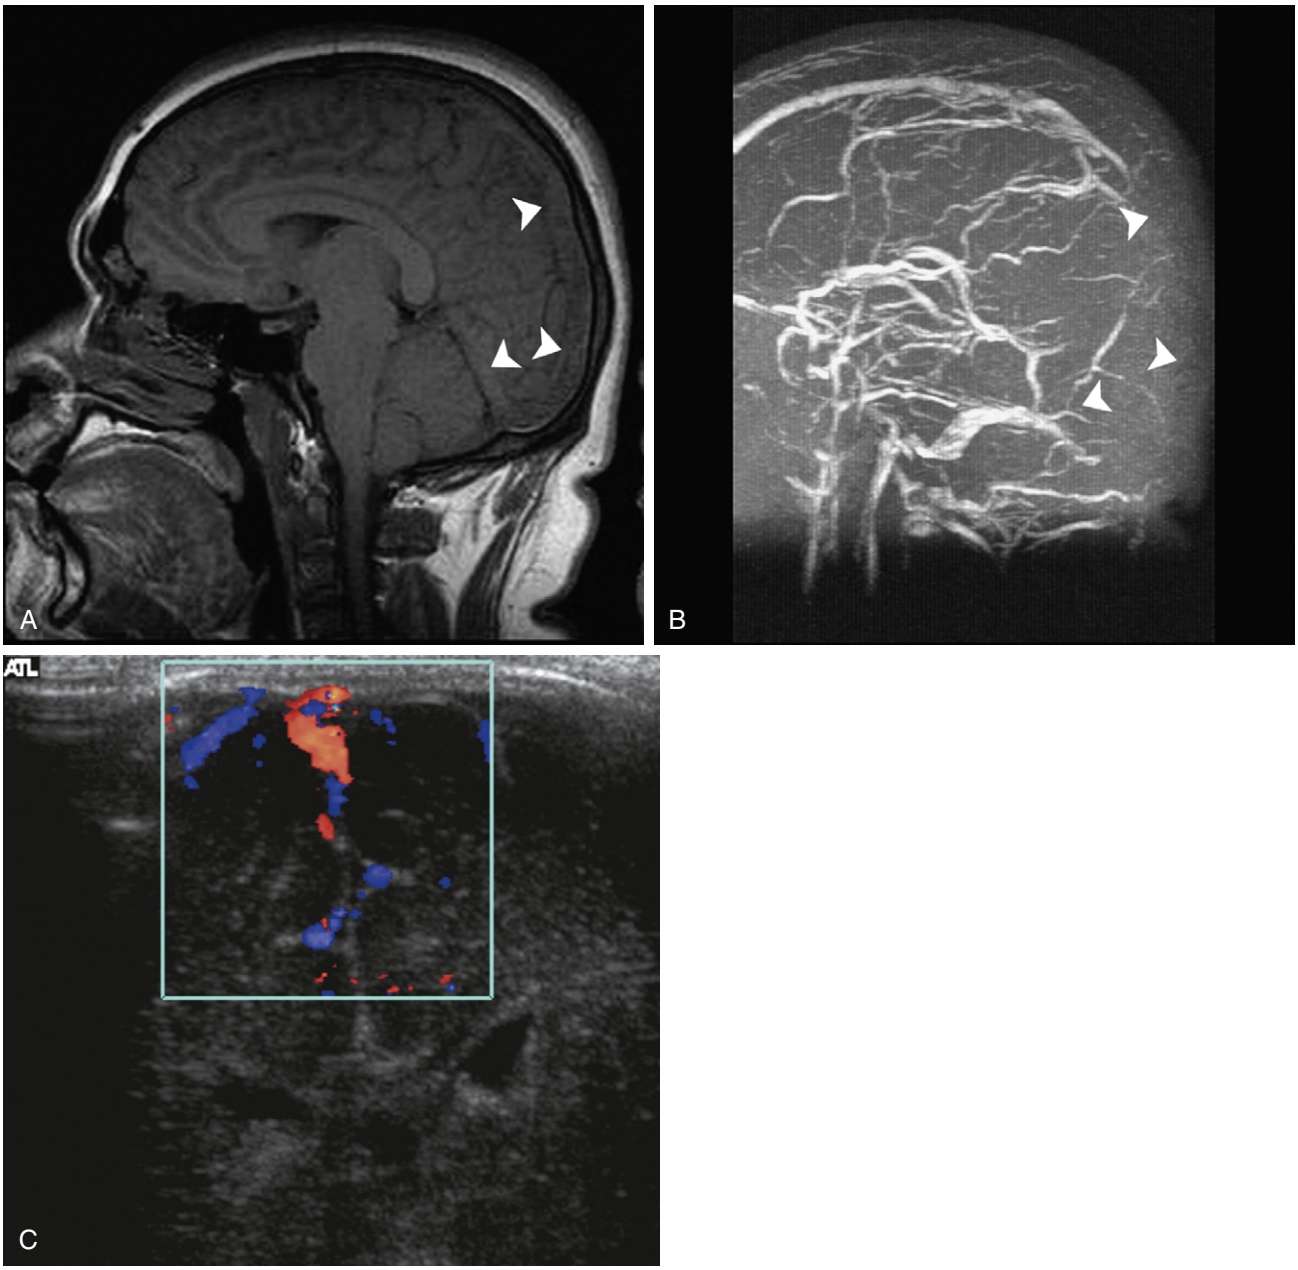

Figure 56–3. Superior sagittal sinus (*SSS*) thrombosis on MRV. Sagittal T1 magnetic resonance imaging (**A**) shows intermediate signal intensity in sagittal and straight sinuses (*arrowheads*). No flow is seen on MRV (**B**) in these vessels (*arrowheads*), which is consistent with thrombosis. Color Doppler evaluation (**C**) of the SSS in another 6-month-old patient with suspected thrombosis demonstrated a patent SSS with normal draining cortical veins (see color insert).

in lieu of riskier neurosurgical procedures or at times are the only avenue of treatment.

Myelography

Myelography involves radiographs and/or CT of the spine following opacification of the subarachnoid space by intrathecal injection of iodinated contrast, most commonly injected at the lumbar level. The myelogram has almost completely been replaced by MRI, especially in the pediatric population, because MRI can depict both extrathecal encroachment and intrathecal masses, as well as evaluate signal characteristics of the spinal cord itself and any mass. Exceptions include the inability to obtain an MRI either because of local field disruption, most commonly from ferromagnetic spinal rods, or because of MRI incompatibility due to safety issues (e.g., a pacemaker). CT provides better results than MRI in the evaluation of the bony spinal column, particularly in patients with trauma, whereas MRI is used in patients with trauma to evaluate soft tissues in the spinal column, most importantly the cord.

Nuclear Medicine

Most nuclear medicine studies involve injection of a very small amount of radioactively labeled substance (radiopharmaceutical tracer compound or radiotracer) and either follow

the physiologic uptake and metabolism of the radiotracer or the movement of the radiotracer with a gamma camera.

Technetium pertechnetate and technetium-diethylenetriamine pentaacetic acid are radiotracers used for radionuclide cerebral angiography to evaluate cerebral perfusion, thereby confirming a clinical diagnosis of brain death. Single photon emission computed tomography imaging using technetium-hexamethylpropyleneamine oxime as the radiotracer is used to monitor for cerebral perfusion defects in patients with subarachnoid hemorrhage who are at risk for vasospasm. With use of acetazolamide (Diamox), a carbonic anhydrase inhibitor, hexamethylpropyleneamine oxime single photon emission CT can be used to evaluate cerebral reserve in patients with stroke.

Ventriculoperitoneal (and ventriculoatrial) shunt function evaluation often includes a nuclear medicine shunt study. Flow in the shunt is assessed by injecting a small amount of radiotracer in the shunt reservoir and following the movement of the activity with a gamma camera.

Preterm and Term Neonate Imaging

In the premature infant, ultrasound remains the primary modality for detection and follow-up of germinal matrix hemorrhage and to detect intraventricular extension, and in the neonate, it remains the primary modality to evaluate for hydrocephalus (Figure 56-4). Furthermore, assessment can be made for white matter injury including periventricular leukomalacia, especially the cystic form, although MRI will be more sensitive for noncystic periventricular leukomalacia, and MRI in preemies performed at about the third week of life has been reported as predictive of outcome at term.[14] Routine screening cranial ultrasound has been recommended for all infants younger than 30 weeks' gestation between day 7 and 14, optimally repeated at 36 to 40 weeks' gestation.[15] Moderate to large parenchymal and extraaxial areas of bleeding also can be detected with ultrasound. As previously mentioned, smaller extraaxial collections, especially laterally along the cerebral convexities, can be missed with ultrasound, as can small parenchymal hemorrhages.

As noted in Chapters 57 and 62, understanding of hypoxic-ischemic encephalopathy (HIE) in children is complicated by the developmental status of the child. The pattern of injury seen is determined by the characteristics of the insult and the maturational state of the brain. Metabolic demands and regions of selective vulnerability evolve during development. Grayscale ultrasound, which is widely used for intracranial imaging in the neonate, is relatively insensitive to acute changes associated with HIE.[16] As edema develops, usually after several hours, increased echogenicity of brain parenchyma can be seen, but this measure is nonspecific and relative and often is difficult to appreciate. Blood associated with a hemorrhagic infarct also will appear as increased echogenicity. As mass effect develops secondary to edema, ventricular and sulcal effacement can be seen. Later, vascular and perivascular mineralization can result in linear thalamic and basal ganglia echogenicities (lenticulostriate vasculopathy or mineralizing angiopathy).[17] Ultrasound Doppler evaluation of newborn ischemia has shown some utility. Brain perfusion can be investigated by determining the resistive index (RI). RI in the normal neonate (0.75 ± 0.1) is higher than that seen in the older infant before (0.65 ± 0.5) and after (0.55 ± 0.5) fontanelle closure.[16] An increase in the RI with a decrease in the peak systolic velocity and end diastolic velocity in infants with HIE within the first 12 hours of life as measured in the anterior and middle cerebral arteries correlated with a poor prognosis at 1 year of life. A decrease in RI to less than 0.60 at 12 hours (anterior and middle cerebral arteries) and 24 hours (all insonated arteries, including basilar artery) after neonatal asphyxia, which is thought to be a result of the decreased vascular tone associated with loss of autoregulation, has been associated with a poorer outcome at 12 to 18 months of life.[18,19] Approximately half of these patients with low RI scores have normal grayscale images. There is a host of other reasons for low RI scores, however, including cardiac disease, extracorporeal membrane oxygenation, ongoing hypoxia, hypercapnia, and technical issues. It also should be noted that increased fontanelle pressure can increase the RI measure by 20%, hence there is considerable user dependence to this application. If hyperemia persists, and as HIE evolves, cytotoxic edema increases and leads to increased intracranial pressure and increased RI measurements. A high RI score on the first day of life with evidence of neonatal insult suggests an in-utero injury. Although some centers have continued to pursue use of ultrasound, much of this evaluation has been supplanted by MRI.

CT detection of acute ischemic injury also depends on edema resulting from the injury. Edema is seen as decreased attenuation and loss of gray-white differentiation, usually several hours post ictus.[20] Small or early infarcts can be missed with CT, and detection of ischemia in the newborn is made more difficult by the generally lower attenuation of the relatively "watery" unmyelinated newborn brain. For this reason, in some instances of neonatal ischemic injury, there may actually be an increase in the attenuation of this "watery" unmyelinated white matter because of an outpouring of serum proteins from damaged blood vessels. As brain swelling develops in the first few days, there can be a loss of CSF spaces seen as ventricular compression, sulcal effacement, and loss of perimesencephalic cisterns. Acute thrombotic stroke associated with arterial thrombosis can at times be appreciated acutely as a hyperdense artery, most commonly the middle cerebral artery on noncontrast CT. Acute hemorrhage, such as with hemorrhagic arterial (from reperfusion) or venous infarcts, will be hyperdense initially on CT, evolving to isodense over the first week.

Standard MR sequences exploiting T1 and T2 relaxation times also depend on the development of edema to appreciate acute ischemic injury, which results in hyperintensity on T2-weighted and FLAIR images and hypointensity on T1-weighted images. This change typically takes at least several hours to develop, and although generally more sensitive than CT in adults, evaluation of the newborn is again made somewhat difficult by the lack of myelination. As a result ischemia sometimes can be more conspicuous on CT than on T1- or T2-weighted MRI (Figure 56-5). The FLAIR sequence has proven to be more sensitive than T1 and T2 to ischemic changes in older myelinated children and adults. DWI is more sensitive than T2 and FLAIR sequences and correlates well with at least short-term neurologic outcome in neonates and infants.[21] These sequences, as previously discussed, have been shown to be acutely sensitive to the cytotoxic edema associated with ischemia.[7] This cytotoxic edema results in diminished diffusion of water in the affected area. DWI in experimental

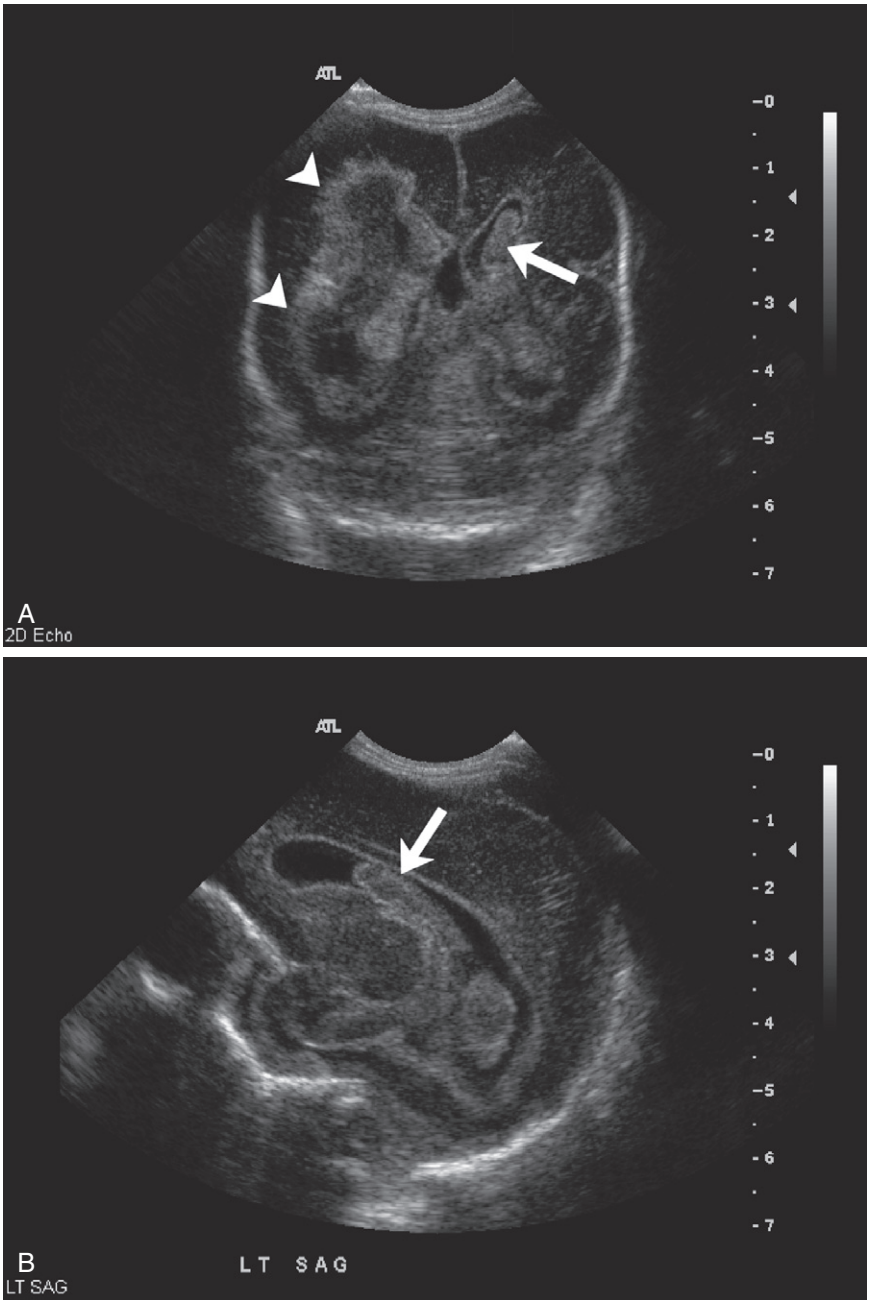

Figure 56–4. Germinal matrix hemorrhage in a premature infant. Coronal (**A**) and left parasagittal (**B**) ultrasound images through the anterior fontanelle demonstrate dilated lateral ventricles with intraventricular extension of clot on the left (*arrows*) and parenchymal extension on the right (*arrowheads*) consistent with a grade 3 bleed on the left and grade 4 bleed on the right (some radiologists would assign this hemorrhage an overall grade of 4).

models can detect ischemia in minutes after onset as a region of restricted diffusion.[22,23] These sequences have now become widely implemented in adult and pediatric neuroimaging, where differentiation of acute ischemic stroke from other neurologic disorders permits appropriate implementation of stroke therapies. The restricted diffusion associated with ischemia evolves over a 1- to 3-week period, at which time the diffusion image usually normalizes. If sufficient tissue destruction has occurred, the diffusion ultimately will increase because of the greater amount of free water following necrosis. This change in diffusion is also useful in distinguishing a new stroke (which will show decreased diffusion) from an older lesion (which will have increased diffusion), whereas both lesions may be of similar signal intensity on standard T1 and T2 imaging (Figure 56-6).

Timelines for relative T2 and diffusion changes have been shown to differ in neonates and infants versus older children and adults. Animal models have suggested that diffusion changes in neonates and infants with HIE do not necessarily precede T2 changes. This finding is presumably a result of age-dependent differences in brain water content and changes therein as a result of differences in vascular permeability in response to hypoxic-ischemic insult.[24,25] The initial diffusion abnormality may increase over the first day, and the extent of the diffusion abnormality can encompass both the core infarct as well as penumbra and hence potentially

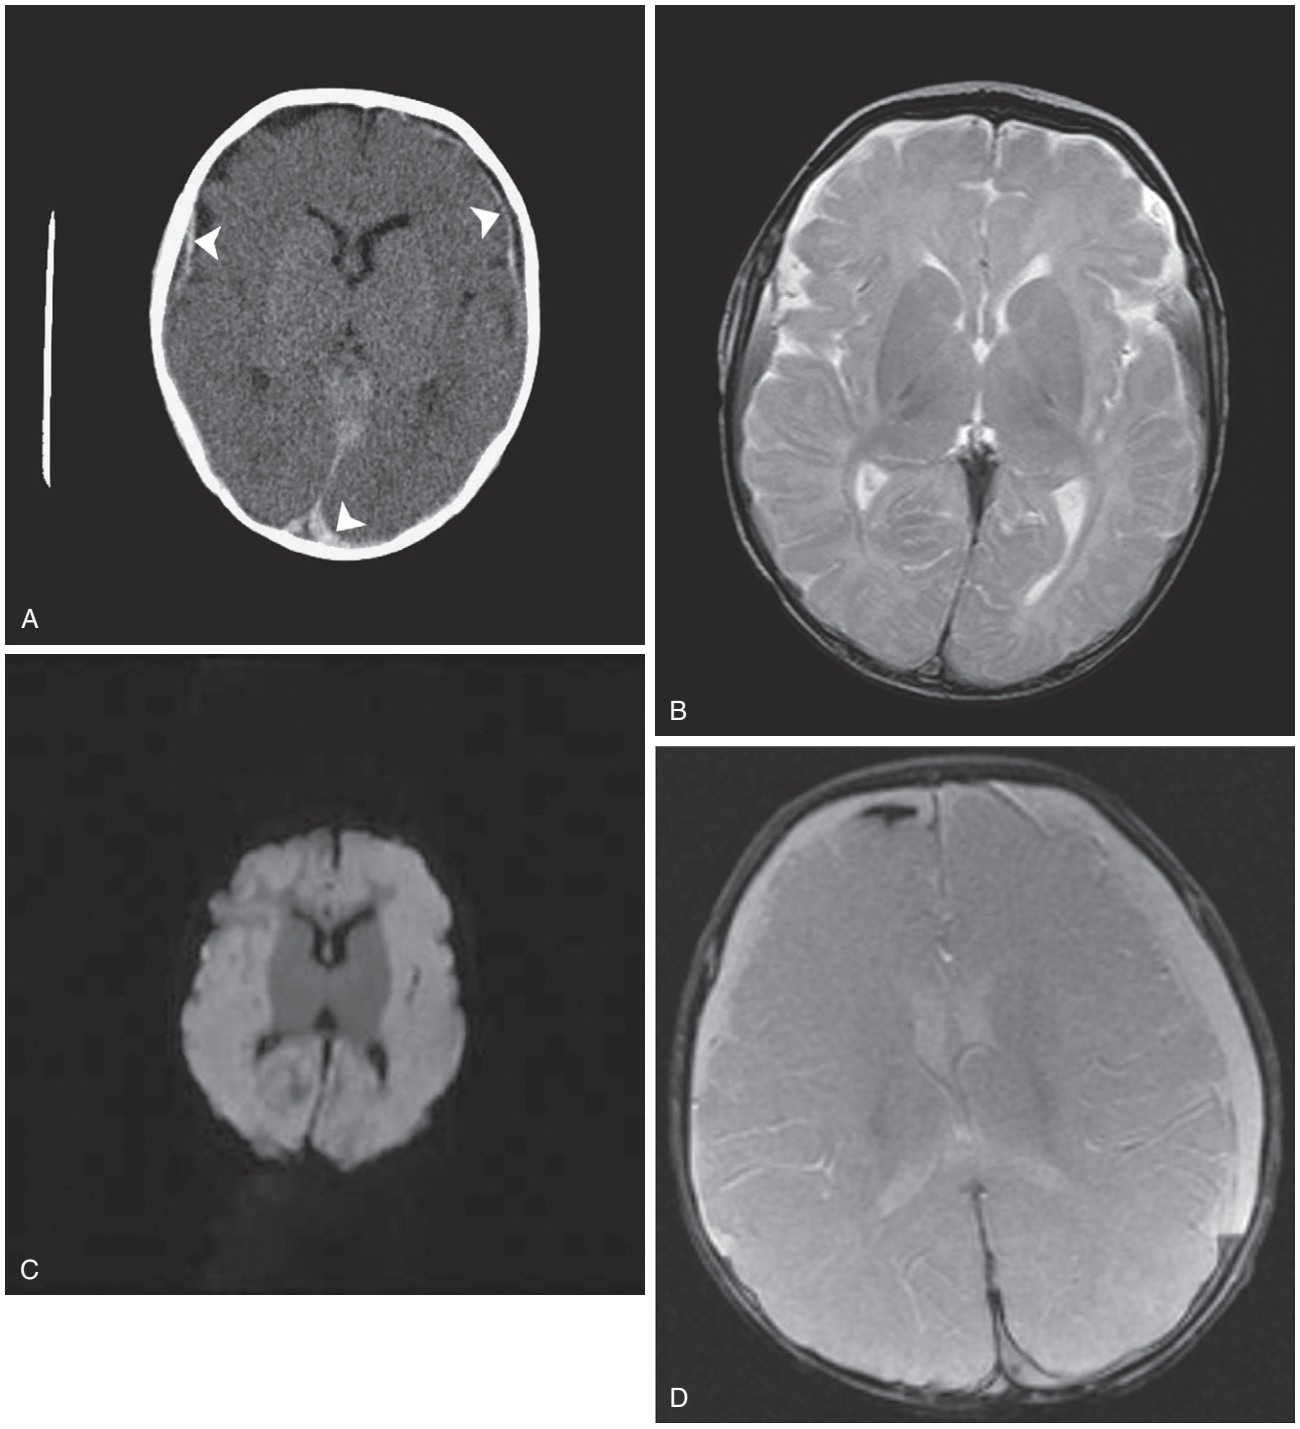

Figure 56–5. Nonaccidental trauma with diffuse cerebral ischemia. Axial noncontrast CT (**A**), axial T2-weighted (**B**), and diffusion-weighted MRI (**C**). **A,** CT shows a thin layer of acute subdural blood (*arrowheads*) and diffuse loss of gray-white demarcation in the cerebral hemispheres. **B,** Although the T2 image appears remarkably normal with appropriate lack of myelination in this 3-month-old child, the relative brightness of the cerebral hemispheres compared with the central gray on diffusion-weighted images (**C**) is consistent with a diffuse ischemic insult. **D,** Gradient-recalled echo MRI in another 4-month-old with nonaccidental trauma demonstrates dark, low signal areas in the right frontal subdural space and left posterior parafalcine regions, consistent with subdural hematomas.

overestimate the ultimate infarct. This potential overestimation could be an indication for MR perfusion, which can separate the areas of core infarction and penumbra.[26] The identification of lactate on MRS is also evolving as a useful tool that may serve as a predictor for the severity of perinatal asphyxia, although considerable complexity is involved in applying this technology. [22,27]

As previously mentioned, the pattern of hypoxic-ischemic injury varies with the etiology of the insult, as well as the developmental state of the brain. Early in-utero insults result in tissue resorption, without the ability to mount a gliotic response that is not seen until the third trimester. During early brain development, insults can result in congenital malformations. HIE or injury in the early to mid second trimester may result

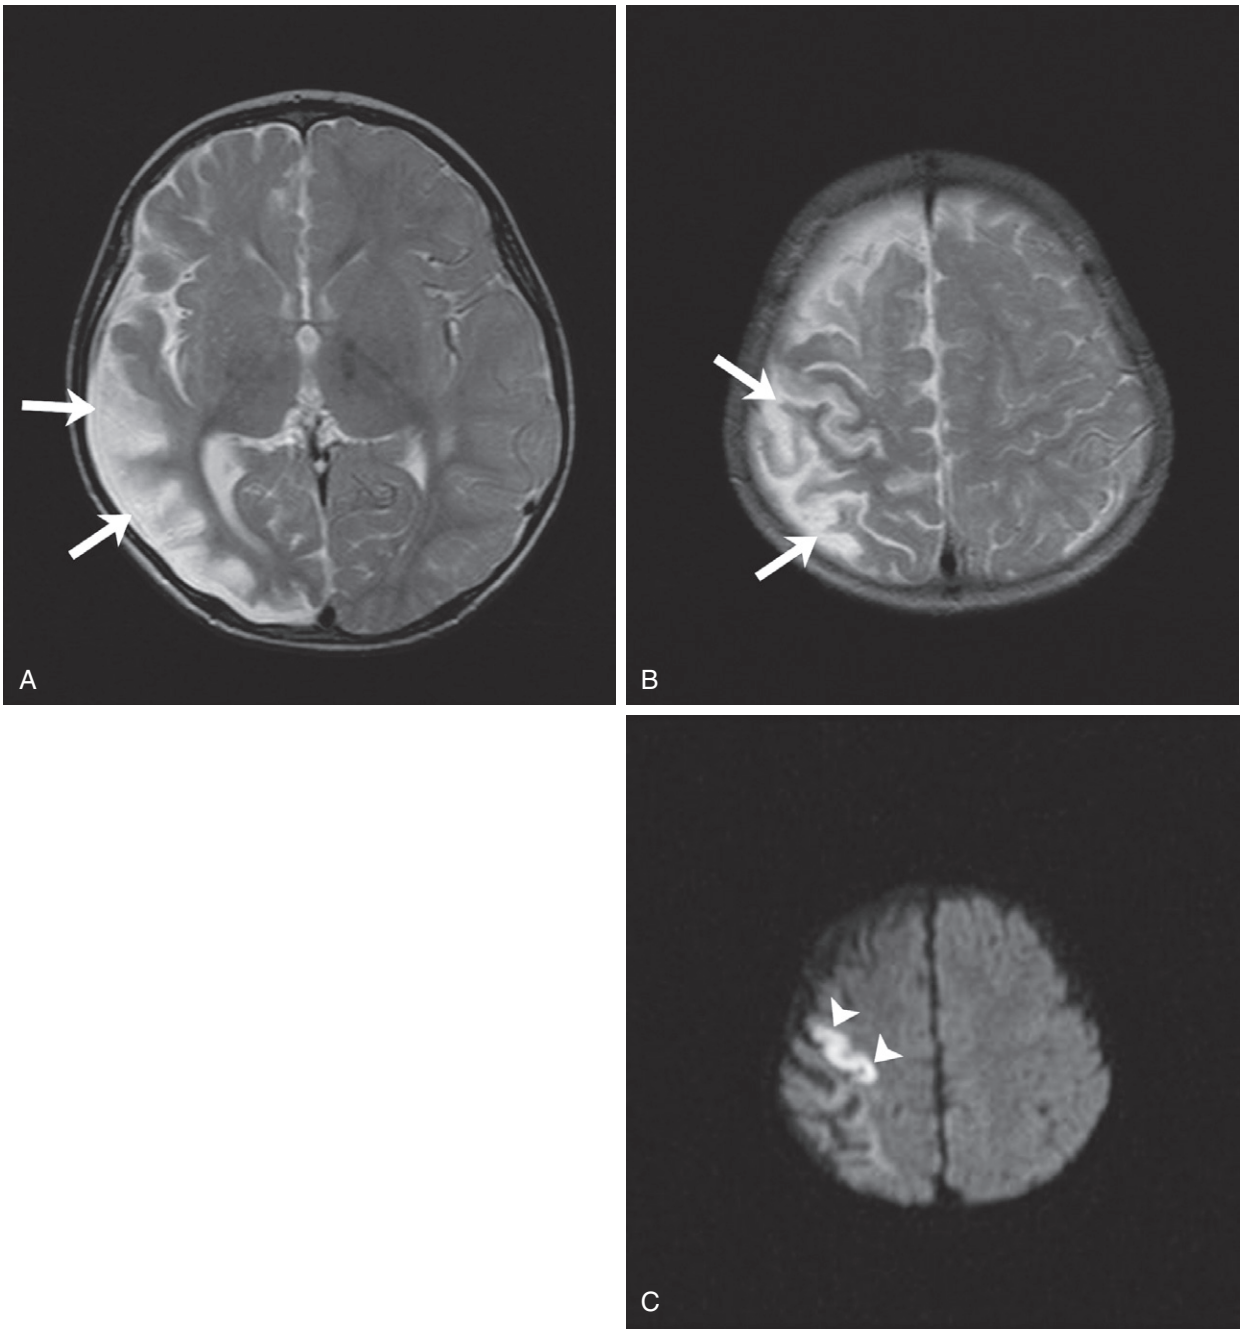

Figure 56–6. Remote and acute infarcts. Axial T2-weighted MRI (**A** and **B**) shows cerebral volume loss with encephalomalacia and gliosis (*arrows*) associated with an old stroke in this child with new onset of progressive left-sided weakness. Diffusion-weighted MRI (**C**) reveals a new area of infarct (*arrowheads*) at the edge of the remote abnormality.

in polymicrogyria. In the twenty-fourth to twenty-sixth week of gestation range, HIE can preferentially injure the deep gray matter nuclei in the setting of total asphyxia. PVL is the pattern of injury seen with prolonged partial hypoxia at 24 to 34 weeks. Typically with PVL on neonatal gray scale ultrasound there may be increased echogenicity in the periventricular white matter, an appearance that is indistinguishable at this stage from edema or from parenchymal hemorrhage, which also may be seen. As PVL progresses cystic change occurs that progresses to coalescent cavitation of the involved white matter, and collapse of these spaces results ultimately in the thinning and volume loss of the white matter, particularly in the posterior periventricular white matter. Although cranial ultrasound affords better resolution for the visualization of cystic change of early PVL in the premature neonate, MRI has overall greater sensitivity to white matter injury, especially in the more advanced stages of PVL, and demonstrates an undulating ventricular margin with associated periventricular T2/FLAIR signal abnormality with or without a paucity of white matter. However, it is not yet clear if this increased sensitivity is of significant prognostic value. Ischemic insults to the term child demonstrate different patterns of injury, determined by the specifics of the insult and the vulnerability of various areas. Profound hypoxia in the term infant results in injury

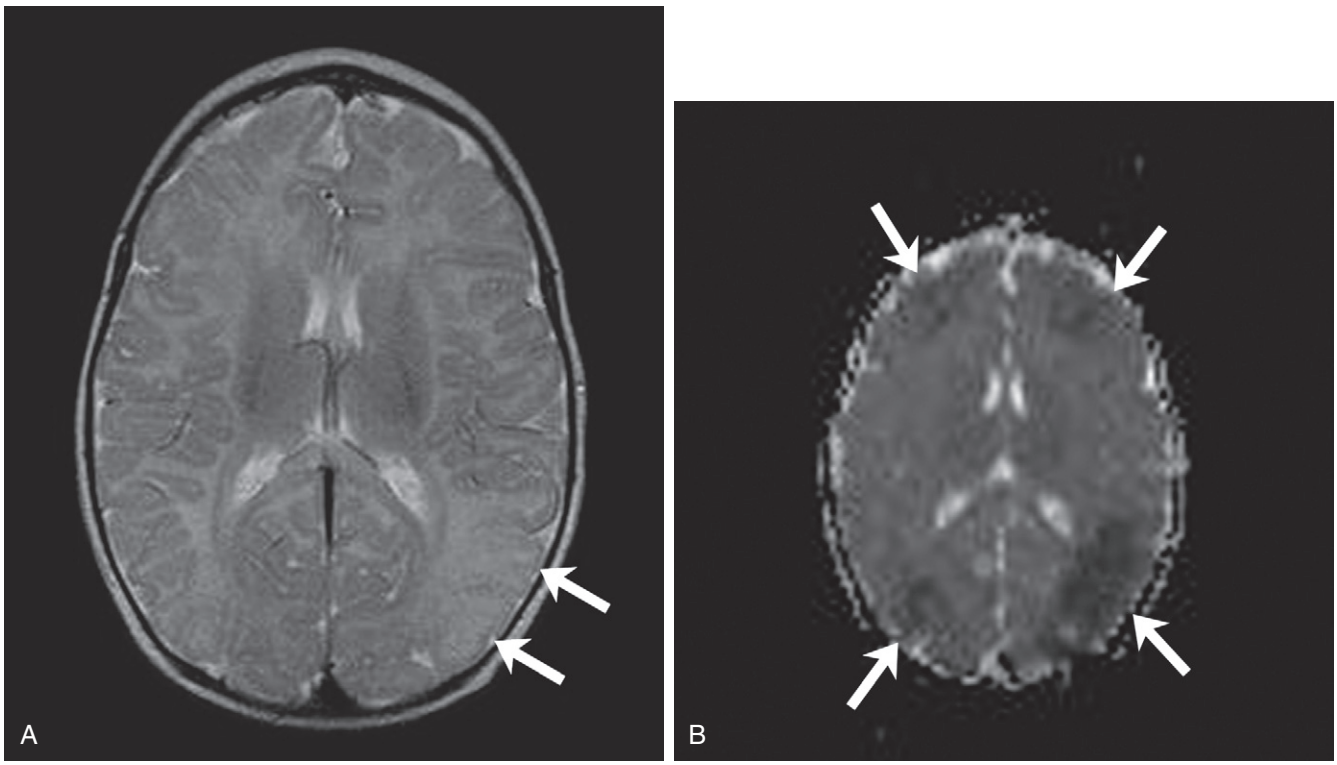

Figure 56–7. Watershed infarct. **A,** Axial T2-weighted MR image shows some loss of the gray-white interface on the left posteriorly (*arrows*). **B,** Diffusion-weighted image shows bilateral restricted diffusion consistent with ischemic injury in a watershed distribution (*arrows*).

largely to areas that are most actively myelinating, in particular the perirolandic white matter and the associated corticospinal tracts and the white matter tracts associated with the occipital cortex. In contrast, a watershed pattern of injury discussed in the next section develops with prolonged partial ischemia that is not sufficient to cause an infarct of the entire cerebrum. Current recommendations for the encephalopathic term infant have included early CT to assess for intracranial hemorrhage, with consideration for MRI with DWI and GRE sequences later in the first postnatal week to assess for extent of injury.[15]

Stroke in the Older Infant/Child

Although the imaging picture may not be specific, a diagnosis of acute stroke usually can be made in combination with the clinical history (as discussed in Chapter 63).[28] The imaging pattern can be of help in determining an etiology. A watershed distribution is consistent with a low flow/hypotensive cause (Figure 56-7). Specifically, changes of ischemic injury are seen at the boundary regions between the major cerebral distributions, that is, between anterior and middle cerebral territories and between middle and posterior cerebral arterial territories. Lesions involving multiple arterial distributions suggest a central thrombotic source, although other causes such as a vasculitis or demyelinating diseases also can have this multivessel or multifocal picture (Figure 56-8). Classically, embolic lesions will tend to be seen at the gray-white junction and most commonly in the MCA distribution. Individual variability of boundary regions[29] and pathology-induced alteration in flow limit the definitiveness of arterial distribution categorization following vascular insult.

As previously discussed, diffusion-weighted imaging also proves to be very useful in earlier imaging detection of cerebral infarcts (Figure 56-9) and separating recent infarcts from a background of abnormality, such as prior infarcts (see Figure 56-6). The area of restricted diffusion on DWI is generally thought to represent irreversible injury, especially when associated with T2/FLAIR signal abnormality, although there may be some cases in which the lesions are at least potentially reversible. In the setting of acute stroke, perfusion MRI may have a contributory role in demonstrating the total region of brain at risk (penumbra) and predicting the ultimate extent of infarct.[26] The area of perfusion abnormality beyond that of diffusion abnormality is thought to represent the penumbra and to be at risk but potentially salvageable. The presence of hemorrhage with a stroke can represent hemorrhagic conversion of a "bland" stroke or an underlying vascular lesion. A large recent study found an incidence of hemorrhagic stroke of 1.4 per 100,000 person years in those younger than 20 years of age. An underlying aneurysm was found in 13%, including 57% of those with pure subarachnoid hemorrhage, 2% of those with a pure parenchymal hemorrhage, and 5% of those with a mixed hemorrhage.[30]

Posterior Reversible Encephalopathy Syndrome

Posterior reversible encephalopathy syndrome results from a loss of autoregulation in the older infant and child as seen in hypertensive encephalopathy, cytotoxic and immunosuppressive drug neurotoxicity, and thrombotic thrombocytopenia purpura (see also Chapter 81). Typically posterior reversible encephalopathy syndrome preferentially involves a posterior

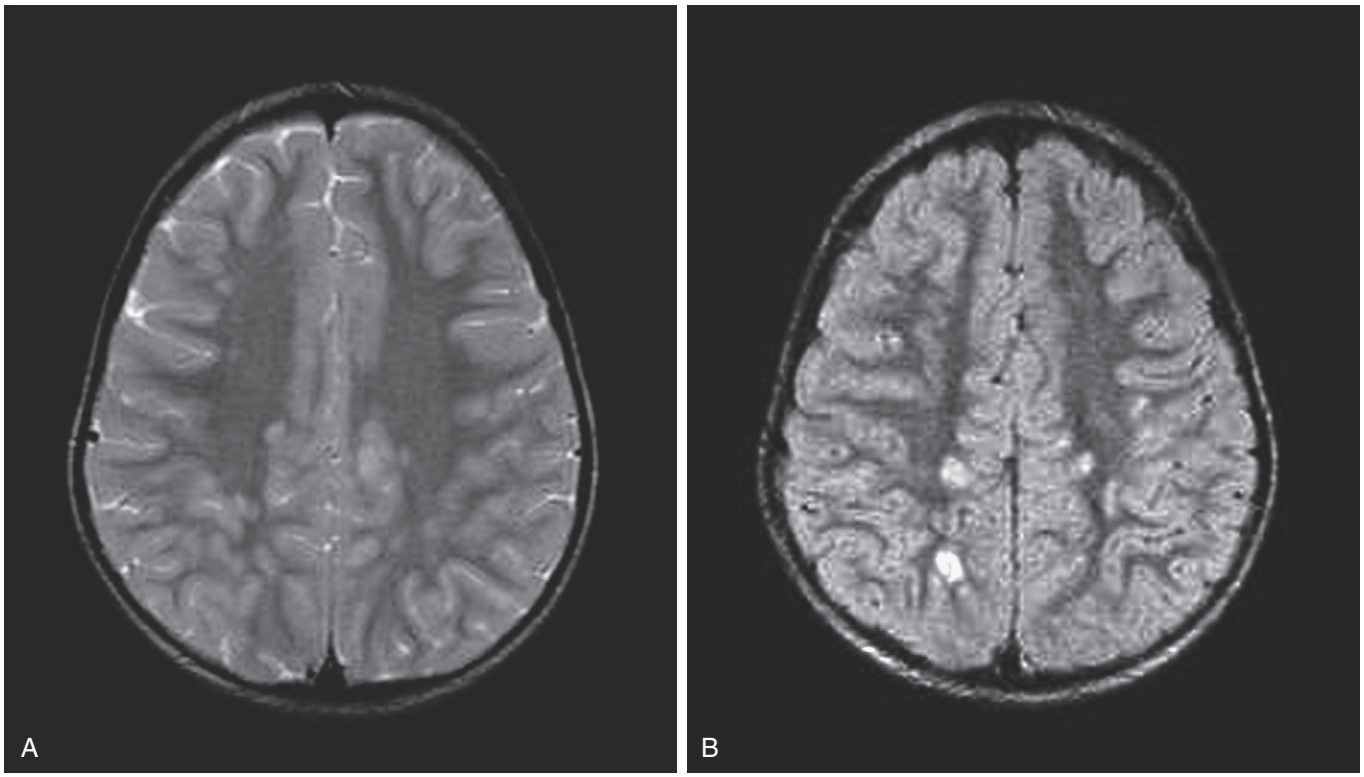

Figure 56–8. ADEM. T2-weighted (**A**) and FLAIR (**B**) images show multiple foci of hyperintensity. In addition to ADEM, vasculitis and multiple emboli could have this imaging appearance.

and parasagittal distribution of the brain with T2 and FLAIR hyperintensities and also less frequently can involve the frontal lobes and brainstem.[31-33] Lesions often are relatively symmetric with confluent lesions centered in the subcortical white matter that may demonstrate patchy enhancement (Figure 56-10). Frequently, because the underlying pathology causes only vasogenic edema, these lesions will not be restricted on DWI. However, ischemia can be triggered by a severe increase in blood pressure, resulting in superimposed cytotoxic edema and therefore diffusion-restricted lesions that usually result in infarctions, the severity of which often correlates with prognosis.

Venous Infarct

The presence of blood in an area of cerebral infarct raises consideration for a venous stroke, although an arterial-induced stroke occasionally can have associated hemorrhage (reperfusion injury). A nonarterial distribution infarct also raises suspicion of a venous stroke. In the setting of suspected venous stroke, evaluation of the cerebral venous system should be undertaken. Ultrasound has limited utility in this setting, although evaluation of superior sagittal sinus flow can be undertaken in the young infant with an open fontanelle (see Figure 56-3, *C*). CT evidence of a venous clot can be detected as hyperdense venous sinuses acutely on noncontrast scans and as the "empty delta sign" (lower density in area of clot surrounded by enhancing blood) in the superior sagittal sinus on contrast-enhanced scans. This assessment can be problematic in the newborn in whom the normal low-density unmyelinated brain and typically higher hematocrit makes the venous sinuses appear dense normally on CT. Classically, the venous phase of a catheter angiogram has been used to look for venous sinus thrombosis. Catheter evaluation of the venous sinuses, however, has been effectively replaced with MRV techniques. MRV uses flow-sensitive sequences that can delineate the major venous sinuses quite effectively (see Figure 56-3, *A* and *B*). A subacute clot in a venous sinus also can be evident on standard T1- and T2-weighted MRI as bright areas in the venous sinuses, although an acute clot can be more difficult to appreciate. On MRI, GRE sequences may demonstrate low signal, and T1 contrast-enhanced sequences may demonstrate areas of nonenhancement of thrombosed venous sinuses.

Etiologic workup of stroke in children includes a broad differential. Although catheter angiogram remains the gold standard and is necessary occasionally, ruling out a vascular lesion has evolved in recent years with greater use of MRA and CTA.

Arterial dissections can be diagnosed with MRI and MRA or with CTA. Visualization of methemoglobin in the false lumen with fat-saturated T1-weighted or proton density–weighted MRI sequences detects most dissections, although subtle lesions may still require catheter angiogram for diagnosis. On CTA, the false lumen is detected by the absent or diminished enhancement compared with the true lumen. Suspicion for dissection is raised in the setting of multiple apparent embolic strokes in a single carotid distribution or within the posterior circulation when there is a history of trauma, although spontaneous dissections are seen occasionally. As previously mentioned, the presence of emboli in multiple circulations raises the question of a more central etiology such as a heart valve vegetation.

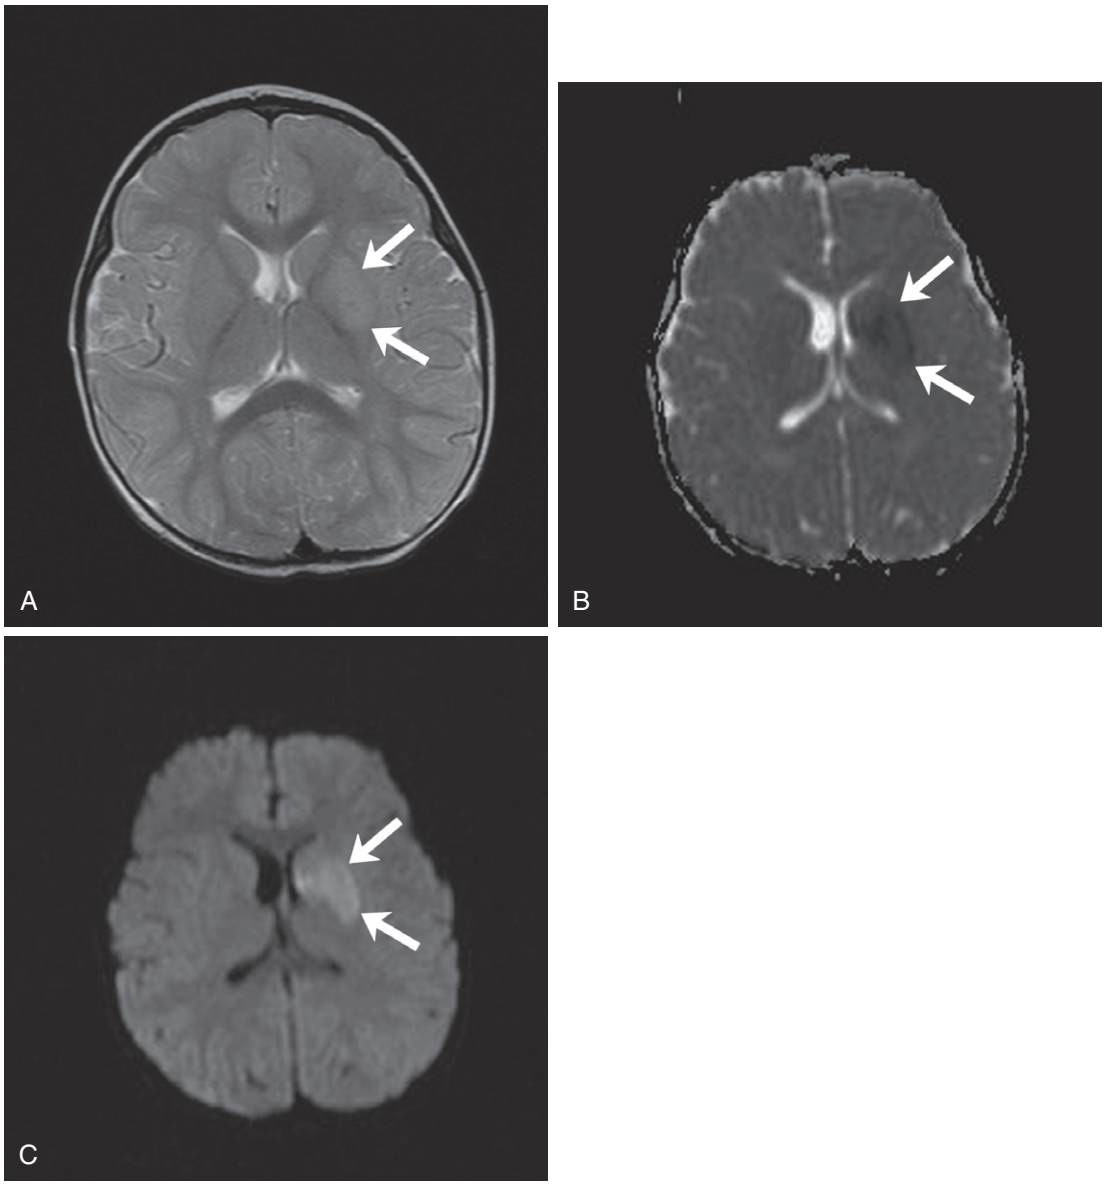

Figure 56–9. Basal ganglia acute infarct. Axial T2-weighted MR image (**A**) shows subtle increased T2 signal in left basal ganglia (*arrows*). More conspicuously shown on the apparent diffusion coefficient map (**B**) and diffusion-weighted images (**C**) is restricted diffusion (*arrows*) associated with an early infarct involving the left caudate and lentiform nuclei.

Vasculopathy/Vasculitis

Acquired vasculopathies can be a result of known infectious or noninfectious causes or of unknown pathophysiology such as in primary cerebral vasculitis, which tends to involve medium and small vessels, or moyamoya syndrome, which demonstrates greatest involvement of the central cerebral vessels. Vasculopathy involving large and medium-sized vessels can be seen on MRA, although more subtle irregularities and small vessel involvement still requires a catheter angiogram, which remains the gold standard imaging modality.

In acute hemiplegia of childhood, classically a basal ganglia infarct resulting from M1 MCA segment narrowing and occlusion of lenticulostriate vessels is seen, with cortical injury being less common. Narrowing typically of the terminal carotid and proximal M1 MCA segment of the affected side often can be delineated on MRA. A lack of well-developed collaterals also will be noted, as is typical of moyamoya syndrome, where the vessel occlusion has been more slowly progressive over a longer period. Moyamoya "syndrome" denotes the pattern of vessel involvement that can be associated with type 1 neurofibromatosis, radiation injury, or other pathology. When it is idiopathic, the term moyamoya "disease" is used. More commonly, moyamoya syndrome/disease will be bilateral and MRI will demonstrate evidence of chronic ischemic insult. The enlarged lenticulostriate collaterals generally will be appreciable on both a good MRA (with a "puff of smoke appearance" initially described with catheter arteriography) and as flow voids through the basal ganglia on MRI (Figure 56-11). These apparent flow voids need to be distinguished from enlarged perivascular spaces that also are seen in this region.

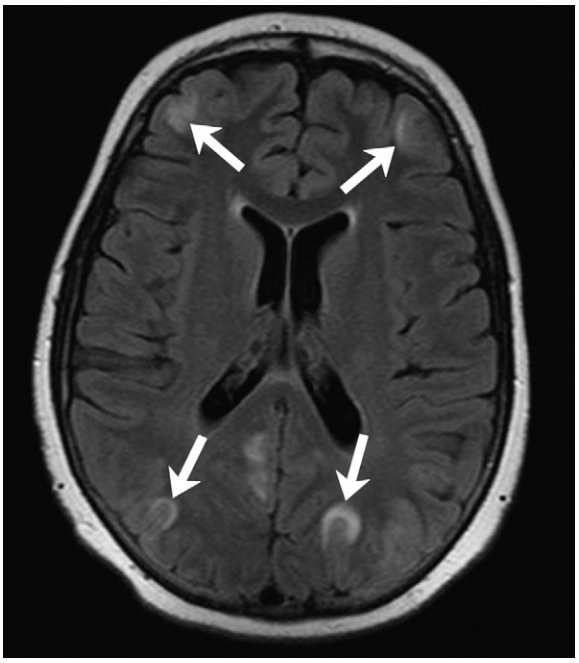

Figure 56–10. Posterior reversible encephalopathy syndrome. Axial FLAIR MRI showing subcortical foci of hyperintensity (*arrows*) associated with cyclosporin toxicity. Note that abnormalities may have a variable distribution and are frequently, but not always, posterior in location.

Vasculitic changes can accompany infections including meningitis, either through direct invasion of vessels or by an immune response to the particular pathogen. Parenchymal injury, if present, is mediated by ischemic changes. The pattern of involvement in the immune-mediated mechanism may be fairly symmetric, as can be seen in acute disseminated encephalomyelitis (ADEM) or some metabolic diseases. Noninfectious vasculitides, including those associated with systemic disease, for example, systemic lupus erythematosus and, in particular, primary CNS vasculitis, can be more problematic in diagnosis. Classically, a catheter angiogram and occasionally a brain biopsy have been used to evaluate the possibility of primary CNS vasculitis. Most cases of symptomatic vasculitis will demonstrate abnormality on standard MRI (T2, FLAIR, and DWI) sequences, and thus a completely normal MRI makes the likelihood of CNS vasculitis low. Occasionally, however, there can be a vasculitic process in the presence of a normal MRI.[34] Furthermore, cases have been reported of biopsy-proven CNS vasculitis in which the MRI was abnormal and results of a catheter angiogram were normal.[35] Because medium and small vessels often are involved in the setting of CNS vasculitis, to which MRA has less sensitivity, a catheter angiogram may be indicated in the setting of very strong concern for vasculitis with a normal MRA and occasionally even a normal MRI.

Vascular Malformations

Most arteriovenous malformations and aneurysms can be detected with a combination of MRI and MRA or CTA, although small lesions can be missed (Figure 56-12). Catheter angiogram remains the gold standard for arteriovenous malformation diagnosis, confirming flow dynamics and the presence of intranidal aneurysms, and generally will be required before surgical intervention. In the appropriate clinical setting such as a spontaneous SAH without etiology, a negative MRI, MRA, or CTA, however, should not exclude a catheter angiogram. Arterial aneurysms are much less common in children than in adults, with many of those seen likely being congenital or due to infection in contrast to the typical acquired berry aneurysms seen in adults. As in adults, all but the smallest aneurysms can be seen on MRA or CTA, with CTA sensitivity for berry aneurysms in adult series reported in the range of 80% to 97%.[11] These studies, though, need to be of optimum resolution, generally targeted to the high-risk locations for aneurysms in adults, and may not include less common aneurysm locations, which are seen with greater frequency in children. Angiographically occult lesions including capillary telangiectasia, cavernous malformation, and developmental venous anomalies are seen on MRI but usually are not of consequence except in cases of the occasional large cavernous malformation.

A vein of Galen aneurysmal malformation (VGAM) is a misnomer because it is not the vein of Galen but a persistent embryonic vein that is dilated in association with a large fistula.[36] VGAMs presenting in the newborn period will manifest with cardiac symptoms resulting from the large shunt and high-flow congestive cardiac failure. Although the malformation can be seen with ultrasound, a CT scan is useful as a quick evaluation to visualize the malformation and determine the status of the cerebral cortex, which may be severely affected even at term. A noncontrast CT scan is sufficient because the density of blood (usually with an increased hematocrit) provides good contrast against the relatively less dense newborn brain (Figure 56-13). In the presence of a VGAM, MRI with MR angiography will give an overall vascular road map for planning endovascular intervention, because the limited amount of contrast that can be used in a neonate necessitates directed intervention.

Central Nervous System Infection

Imaging findings and the role of imaging in cerebral infection will depend on the organism and location of the infection (see also Chapter 65). The appearance will depend on the cell type infected and the host immune response. Infection can involve the subarachnoid spaces and meninges, the parameningeal spaces, or the brain parenchyma itself either primarily or secondarily. With bacterial meningitis the appearance on CT and MRI may range from normal to diffuse swelling with loss of gray-white differentiation and obliteration of ventricular and cisternal CSF spaces. Coxsackie virus, echovirus, and mumps infect the meninges more than the neurons, whereas poliovirus infects the neurons, particularly the motor neurons. Herpes simplex virus type I has a predilection for the limbic system, most commonly affects the temporal lobes, and is the most common sporadic viral encephalitis.[37] Herpes simplex virus type II encephalitis is most commonly acquired at birth and does not display a predilection for the temporal lobes. Although MRI is more sensitive than CT, a normal MRI still does not entirely exclude a viral encephalitis. In the clinical setting of suspected meningeal infection, CT may be indicated prior to lumbar puncture to exclude hydrocephalus or swelling that potentially would preclude lumbar puncture without neurosurgical consultation.

Imaging alone should not be used, however, to exclude meningeal infection. Particularly early in the setting of meningitis, contrast-enhanced CT is often normal. Although MRI

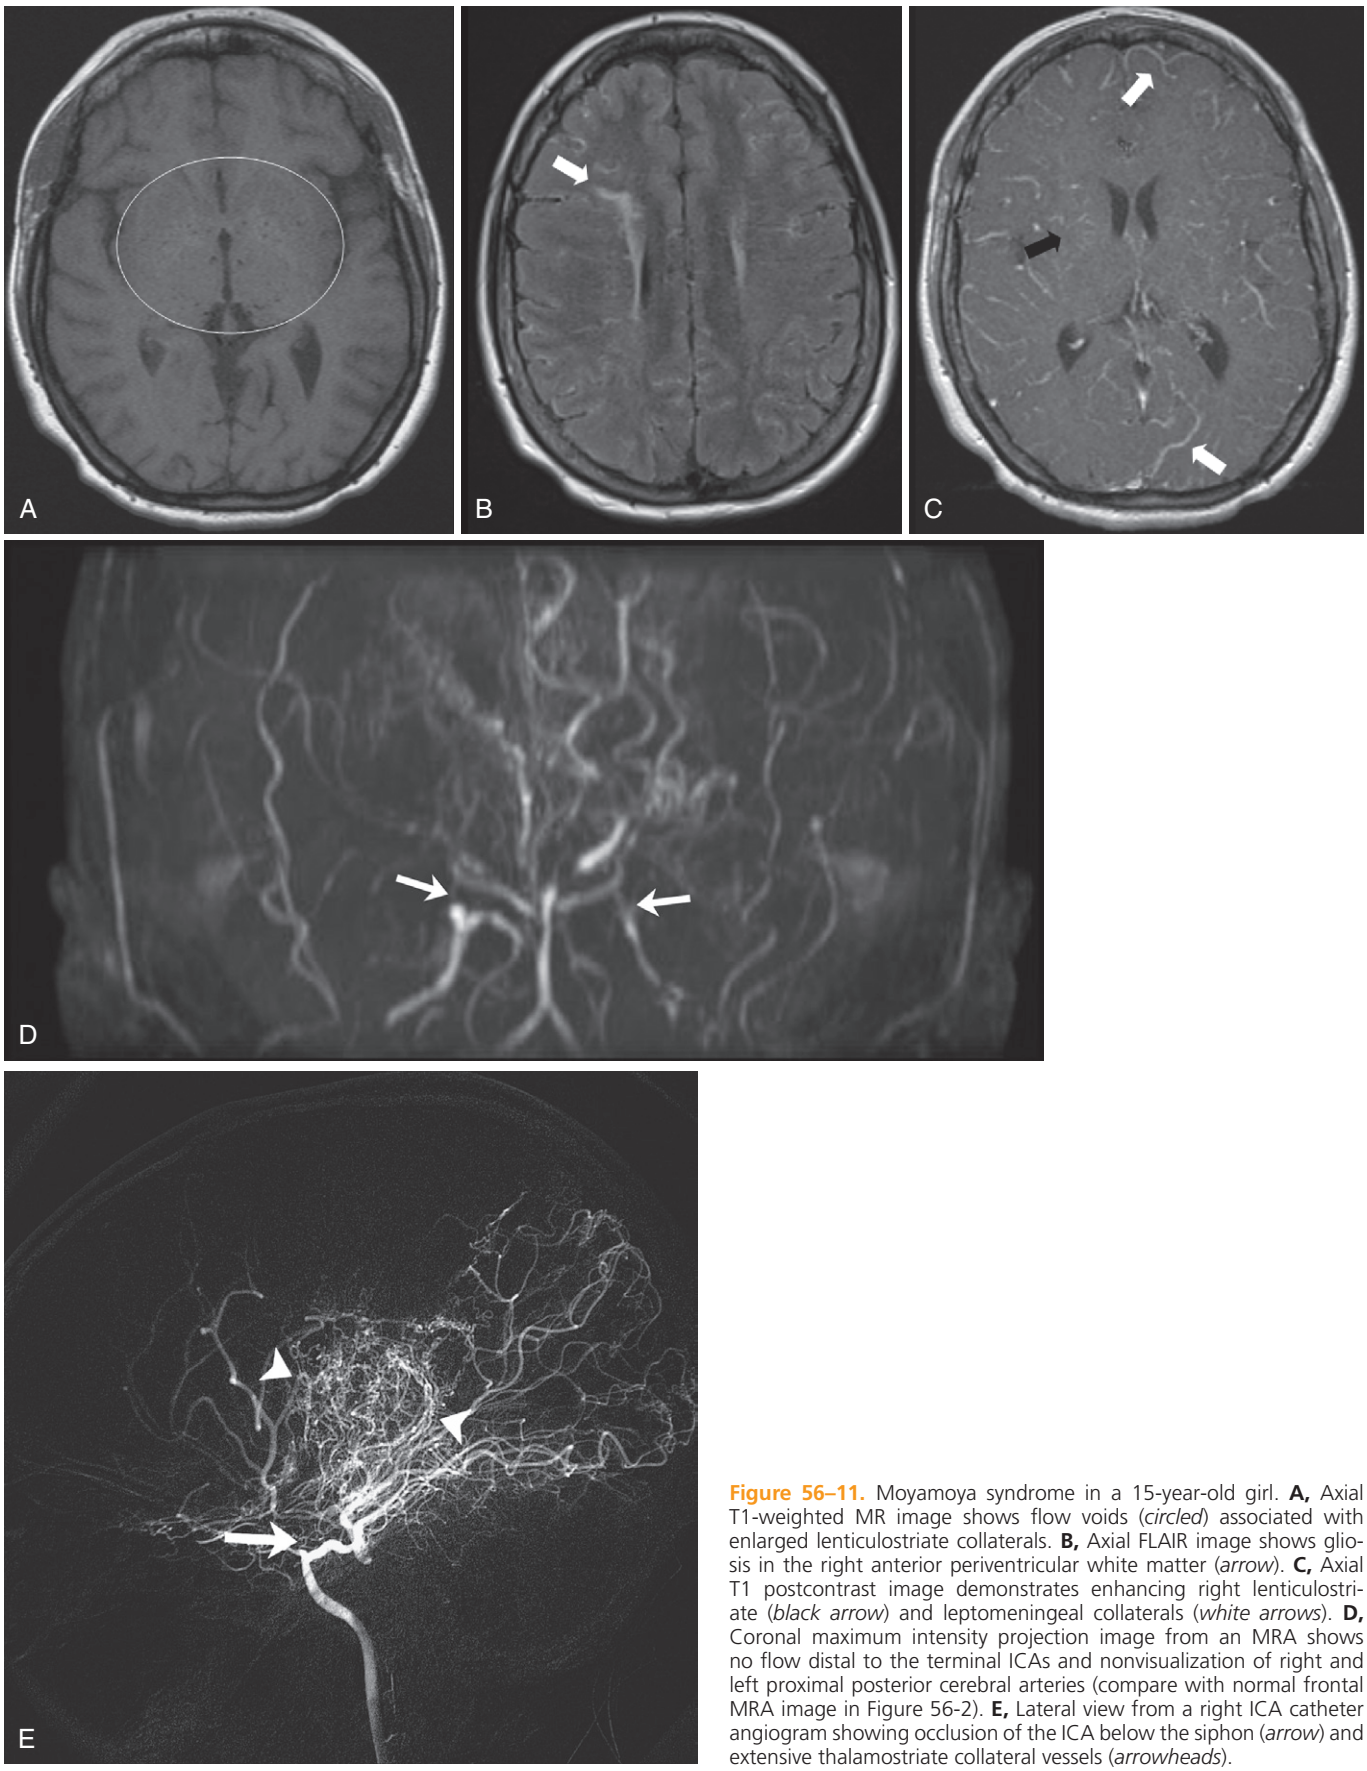

Figure 56–11. Moyamoya syndrome in a 15-year-old girl. **A,** Axial T1-weighted MR image shows flow voids (*circled*) associated with enlarged lenticulostriate collaterals. **B,** Axial FLAIR image shows gliosis in the right anterior periventricular white matter (*arrow*). **C,** Axial T1 postcontrast image demonstrates enhancing right lenticulostriate (*black arrow*) and leptomeningeal collaterals (*white arrows*). **D,** Coronal maximum intensity projection image from an MRA shows no flow distal to the terminal ICAs and nonvisualization of right and left proximal posterior cerebral arteries (compare with normal frontal MRA image in Figure 56-2). **E,** Lateral view from a right ICA catheter angiogram showing occlusion of the ICA below the siphon (*arrow*) and extensive thalamostriate collateral vessels (*arrowheads*).

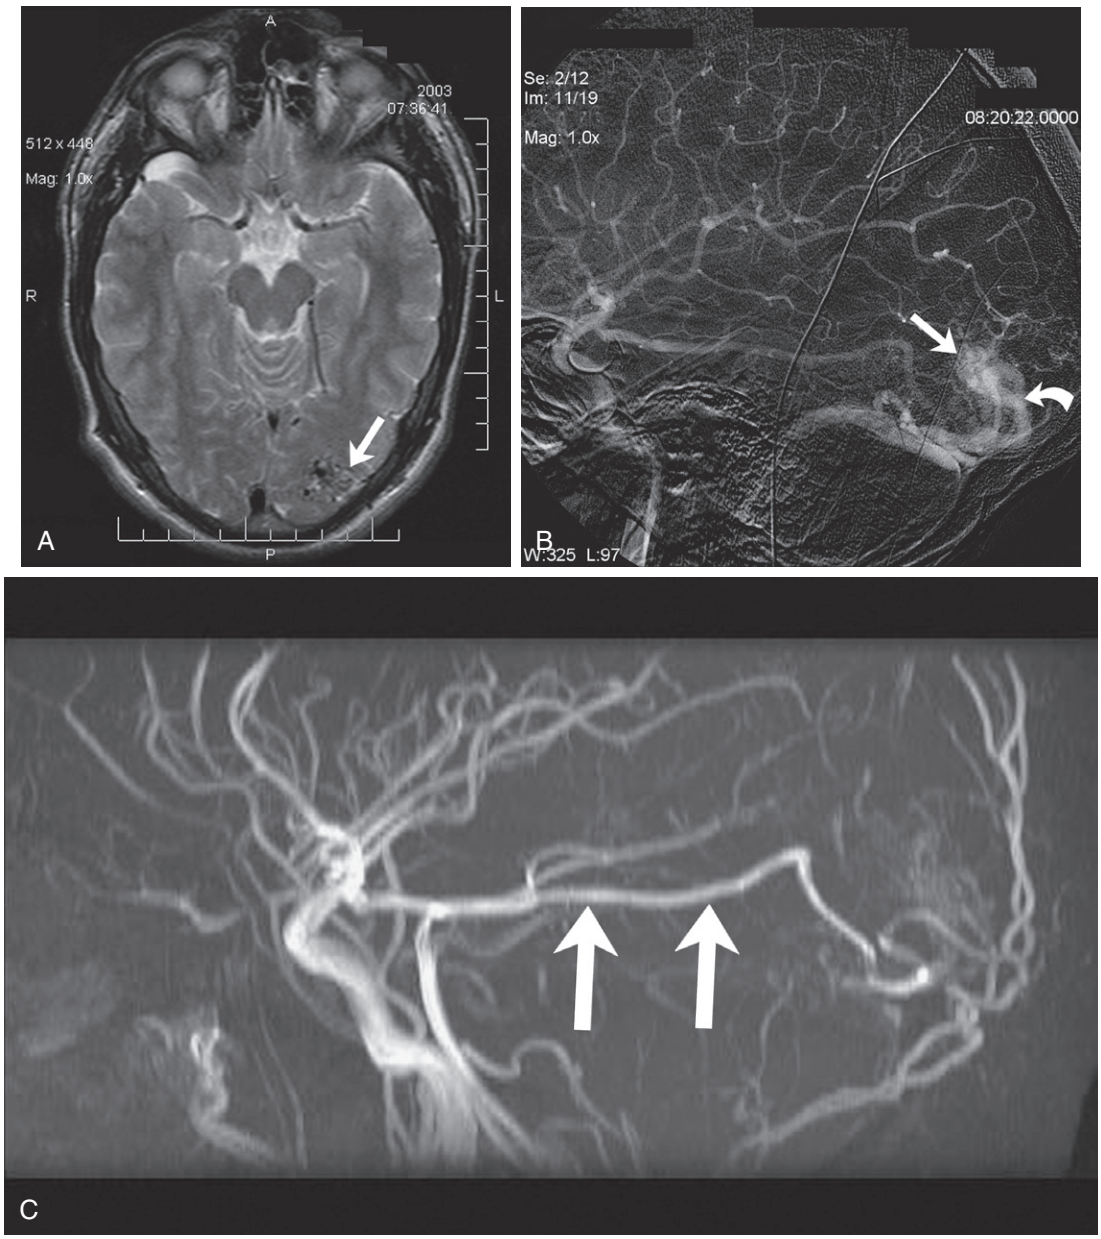

Figure 56–12. A 14-year-old child with a left occipital arteriovenous malformation (AVM). **A,** MRI shows multiple flow voids in the left occipital lobe (*arrow*). **B,** Lateral view from catheter angiogram confirms the presence of an AVM (*arrow*) and early draining veins (*curved arrow*). **C,** Lateral maximum intensity projection image from an MR angiogram shows an enlarged posterior cerebral artery branch (*arrows*), which feeds the tangle of abnormal vessels.

with gadolinium is more sensitive, only 55% to 70% of persons with proven meningitis have abnormal scans.[38] Some investigators believe that CSF hyperintensity on the FLAIR sequence is more sensitive than gadolinium-enhanced T1-weighted sequence for meningitis; however, CSF hyperintensity on FLAIR associated with supplemental oxygen and anesthesia as well as noninfectious meningeal irritation and leptomeningeal tumor render this finding less specific.[39,40]

Complications associated with meningeal infection include compromise of the BBB leading to vasogenic edema, arterial spasm that can cause ischemia with cytotoxic edema and eventual infarction, and hydrocephalus potentially with the development of transependymal CSF flow/interstitial edema. Hydrocephalus can be obstructive, typically at the level of the aqueduct (Figure 56-14) or outlet of the fourth ventricle, or more commonly communicating because of impaired CSF resorption from arachnoid granulation obstruction with exudates. This impairment of CSF resorption can become permanent because of leptomeningeal-ependymal fibrosis and require shunting. Ultrasound can be used in very young patients; otherwise, CT and more recently half Fourier acquisition single shot turbo spin echo (HASTE) or other rapid, heavily T2-weighted MRI sequences usually are used to follow ventricular dilation. The role of imaging in meningitis is primarily to evaluate for these complications. Two patterns of abnormal meningeal enhancement are seen on MRI with meningitis. A pachymeningeal pattern appears as diffuse linear thickening of the normal dural lining. This appearance,

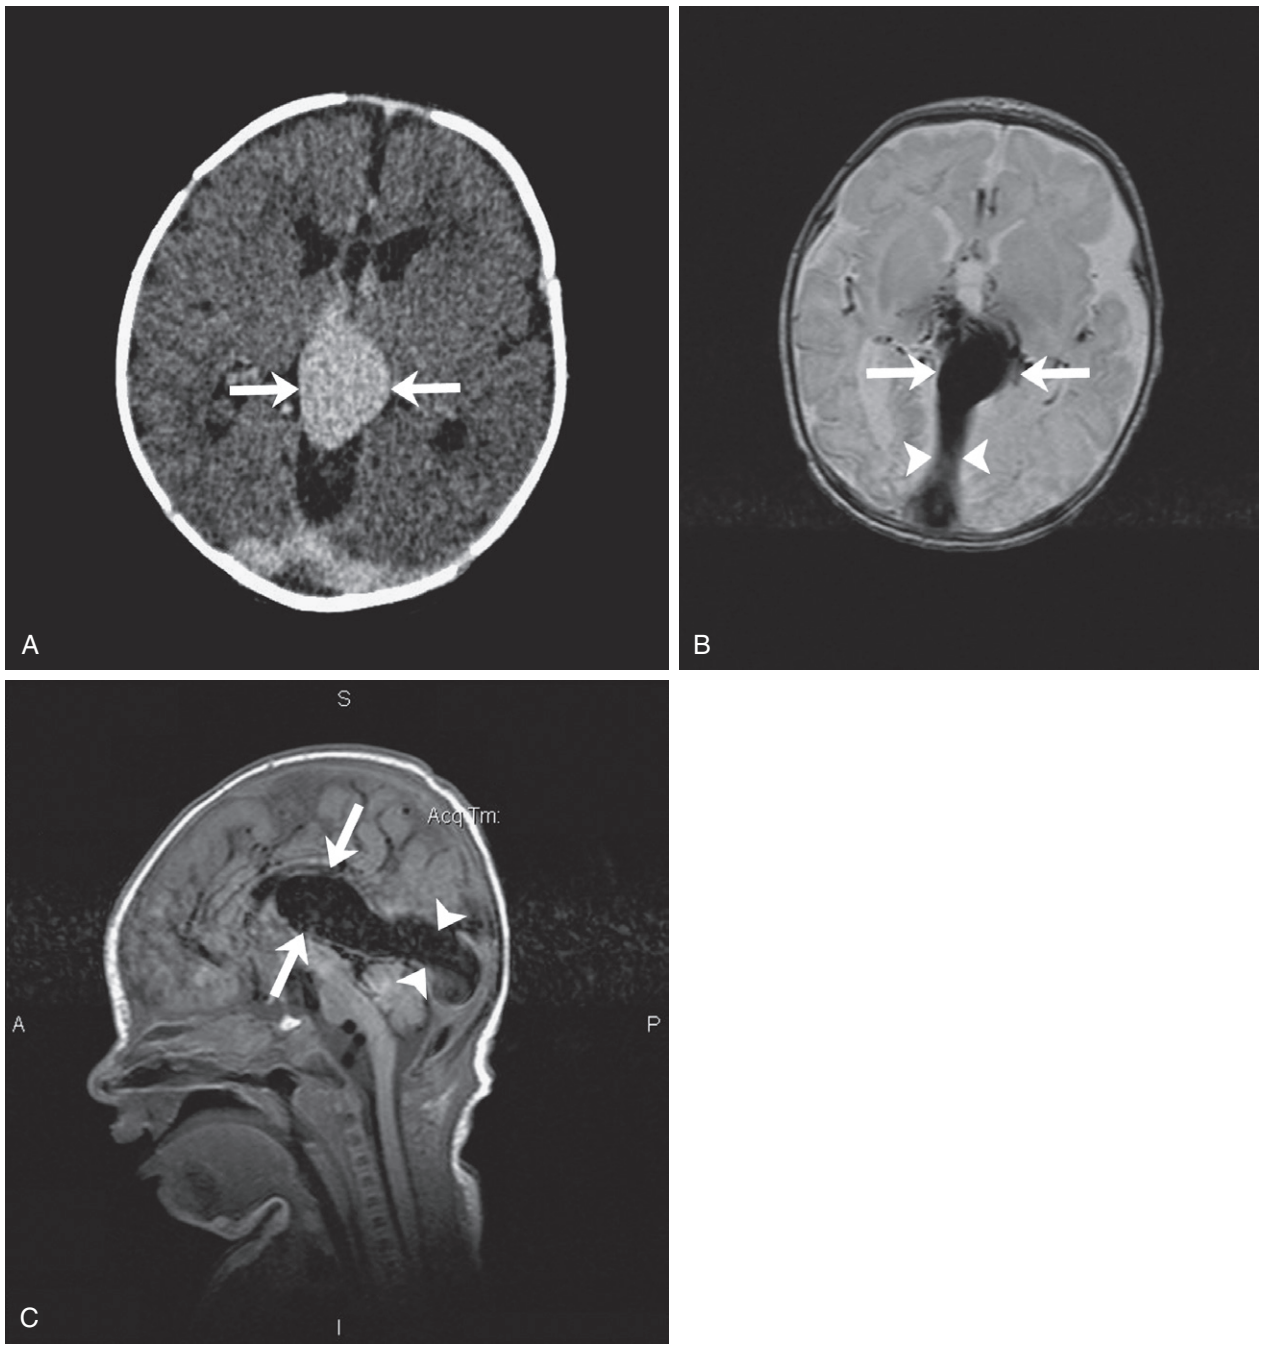

Figure 56–13. Vein of Galen aneurysmal malformation (VGAM). **A,** Axial noncontrast CT shows the dilated embryonic vein (*arrows*). Axial T2 (**B**) and sagittal T1 (**C**) MRI demonstrates the dilated embryonic vein (*arrows*) and the draining vein (*arrowheads*).

however, is not specific because the same pattern can be seen in other settings, including after surgery and occasionally following shunt revision, in some cases because of intracranial hypotension. The other pattern is a leptomeningeal enhancement, where enhancement is seen along the pia-arachnoid membranes, following the sulcal grooves. This pattern also is not specific, with a similar appearance being seen at times with leptomeningeal spread of tumor.

Extraaxial collections can develop in association with meningitis, including subdural effusions and, less commonly, subdural abscesses or empyema. Effusions are crescentic collections that typically are isodense to CSF on CT and isointense to CSF on most MRI sequences, although because the protein level may be increased, the collections may be hyperintense on T1 and FLAIR (Figure 56-15). Subdural abscesses can be crescentic or lentiform when larger and typically slightly denser than CSF on CT. A rim of enhancement of variable thickness is generally better detected on MRI (Figure 56-16). DWI can demonstrate restricted diffusion in subdural empyemas. Subdural (and brain) abscess also can occur as a direct extension of paranasal sinus or mastoid infection.

Infection of the brain parenchyma can take the form of a focal abscess(es) or a more diffuse encephalitis. Encephalitis in isolation or associated with meningitis generally will produce

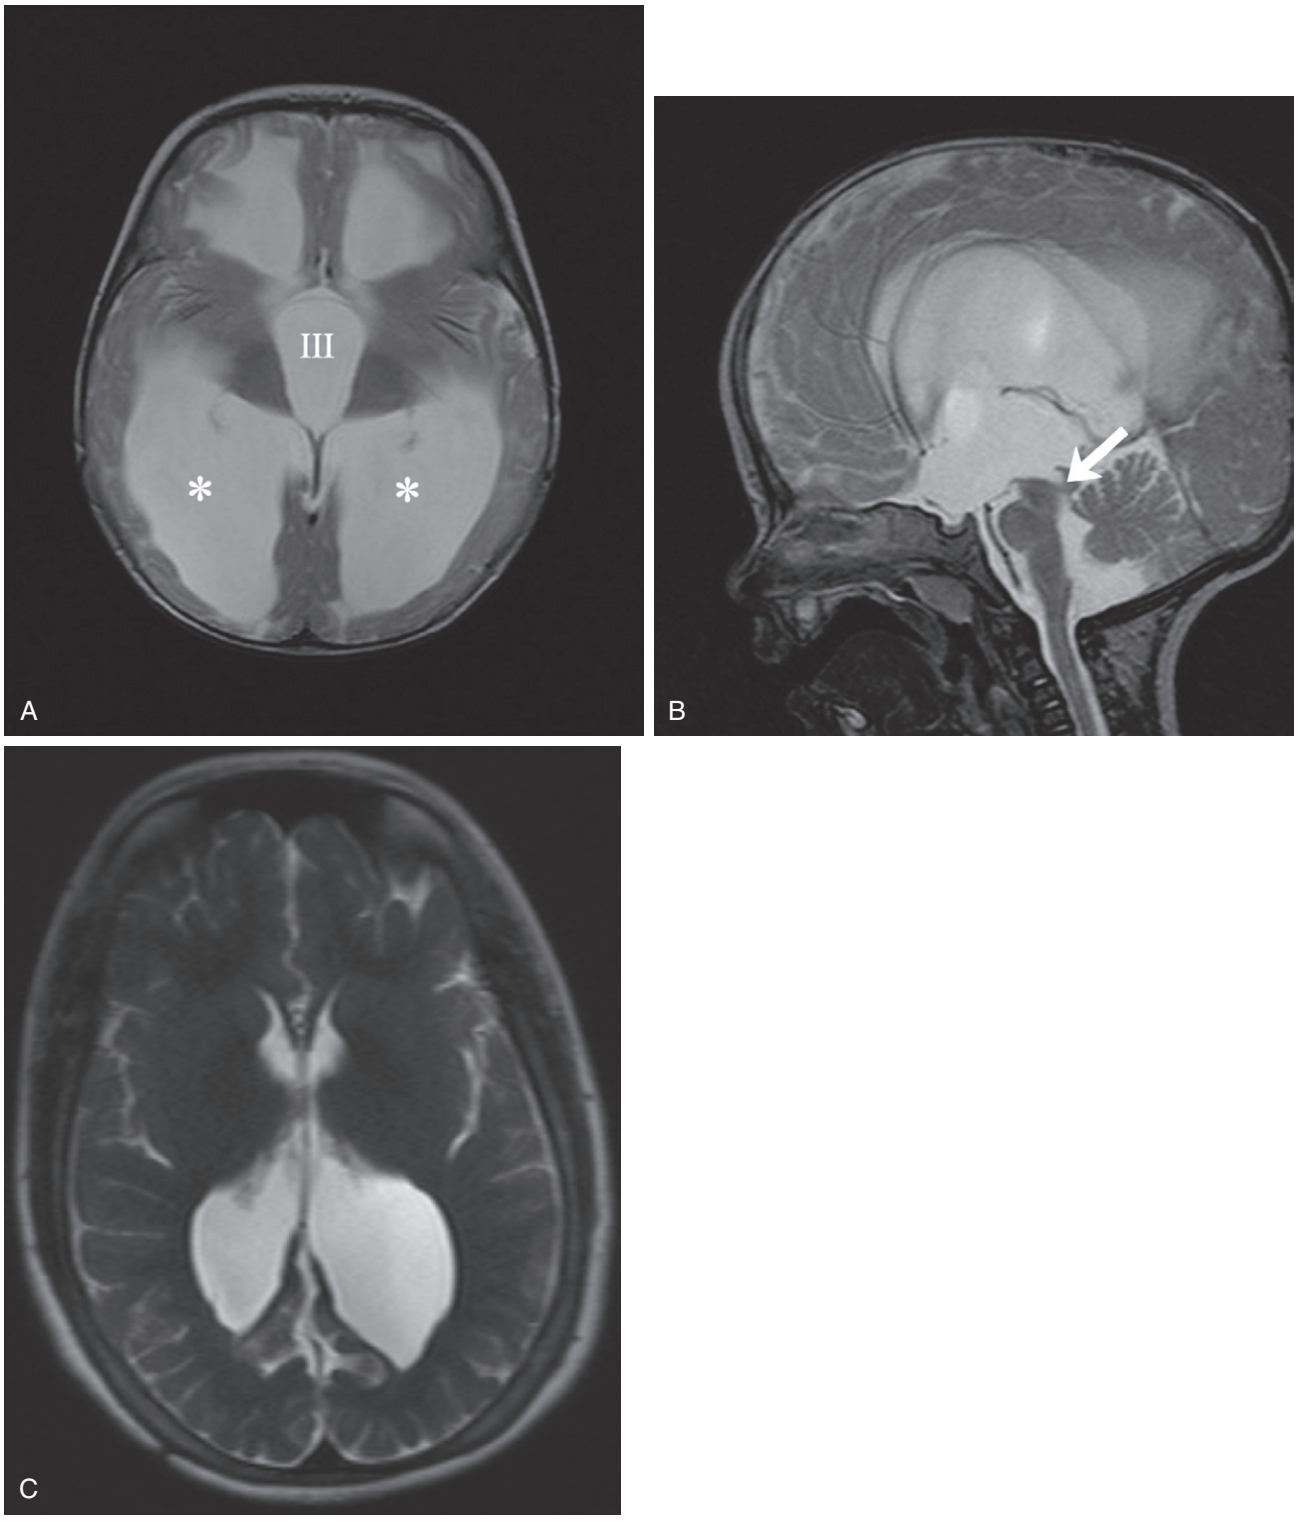

Figure 56–14. Obstructive hydrocephalus. Axial (**A**) and midline sagittal (**B**) T2 MRI shows dilated lateral (*asterisks*) and third (III) ventricles that result from aqueductal obstruction (*arrow*). **C**, Chiari II malformation with hydrocephalus. Image demonstrates utility of heavily T2-weighted, half-Fourier acquisition, single-shot, turbo spin-echo MRI in evaluation of ventricles. Sequence can be obtained rapidly without the need for sedation; this avoids the radiation associated with repeated CT scans.

nonspecific cerebral parenchymal changes or cerebritis that appear bright on T2 and FLAIR sequences. Differentiation of cerebritis from ischemic changes associated with meningoencephalitis by imaging is problematic, especially because cerebritis also can demonstrate restricted diffusion. Areas of cerebritis evolve into focal abscesses that will generally demonstrate a central focus of low density on CT and low T1, high T2, and FLAIR signal on MRI, with a ring of enhancement and variable surrounding edema (Figure 56-17). More commonly in adults with a ring-enhancing lesion, there can be

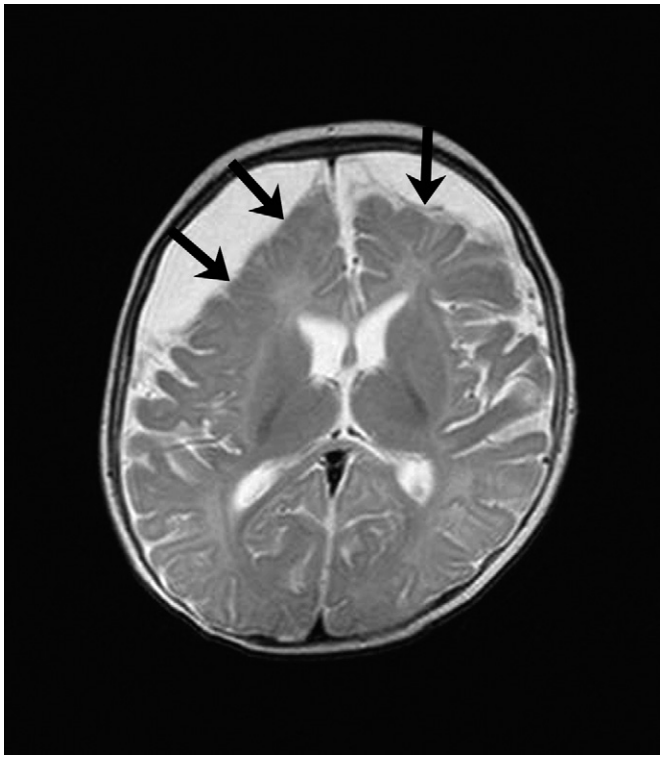

Figure 56–15. Chronic subdural effusions following meningitis. Axial T2-weighted MRI shows mass effect with sulcal compression associated with bifrontal subdural collections (*arrows*). Note that these subdural collections can be differentiated from enlarged subarachnoid spaces because the latter would have bridging vessels crossing the cerebrospinal fluid in the subarachnoid spaces.

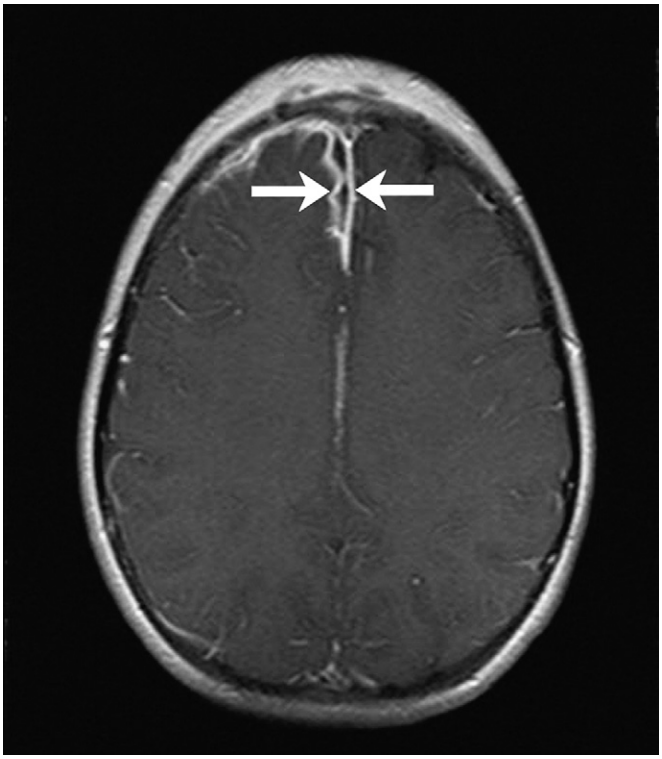

Figure 56–16. Subdural abscess or subdural empyema. Axial T1-weighted MRI with gadolinium demonstrates a small rim-enhancing right frontal paramedian subdural abscess (*arrows*). This area was restricted on DWI (not shown).

uncertainty between a brain abscess and necrotic tumor. The brain abscess generally will have a thinner rim of enhancement and on DWI a pyogenic abscess will demonstrate restricted diffusion. The necrotic tumor often shows a thick, irregular rim with increased diffusion or T2 shine-through. In differentiating pyogenic, tubercular, and fungal abscesses, some studies have described a greater likelihood of homogeneous diffusion restriction with pyogenic and tubercular abscesses but a variable pattern with fungal abscesses.[41,42] Exclusion of a meningeal or parameningeal abscess in the head can be accomplished largely with contrast-enhanced CT, looking for a fluid collection with a surrounding enhancing rim, although occasionally a small collection may be missed on CT but detected by MRI. Evaluation for meningeal or parameningeal abscess in the spine should be approached with MRI.

Demyelinating Disease

Multiple sclerosis (MS) is much less common in children than in adults, while ADEM primarily occurs in children. ADEM can at times manifest with very symmetric involvement (Figure 56-18), with an imaging picture that overlaps with some metabolic diseases. In other cases of ADEM, lesions can be scattered with a picture similar to vasculitis or embolic infarction. The appearance of MS and ADEM can be similar. The presence of lesions of multiple ages would be consistent with MS (Figure 56-19) rather than ADEM. Demyelinating lesions are seen most commonly in white matter but appear in gray matter as well. Acute demyelinating lesions demonstrate enhancement. Acute lesions also can demonstrate restricted diffusion, with an appearance on DWI that mimics an acute ischemic lesion. Often, however, the pattern of involvement is useful in distinguishing demyelinating disease from ischemic disease. The spinal cord can be involved with MS or ADEM (Figure 56-20), although relatively rarely in isolation, hence imaging the brain to look for additional involvement can be useful in some cases to distinguish between a cord demyelinating process and infarct, which can have a similar imaging appearance.

Trauma

CT remains the primary imaging modality in persons with acute cerebral trauma and has the advantage of relative ease of scanning compared with MRI, including speed of scanning and allowing non-MRI compatible monitoring and life support equipment to be used during imaging (discussed in Chapter 61). CT is usually sufficient for evaluation of most cerebral neurosurgical trauma, including assessment of swelling and acute hemorrhage within the intra-axial and extra-axial compartments. CT is generally more sensitive than MRI in detecting acute SAH and in the evaluation of bony injury (Figure 56-21). CT is generally sufficient to detect cerebral swelling associated with herniation syndromes and therefore identify the potential need for neurosurgical intervention (Figure 56-22). MRI is more sensitive for the detection of parenchymal injury and for more subtle extra-axial collections including more chronic epidural and subdural hematomas,

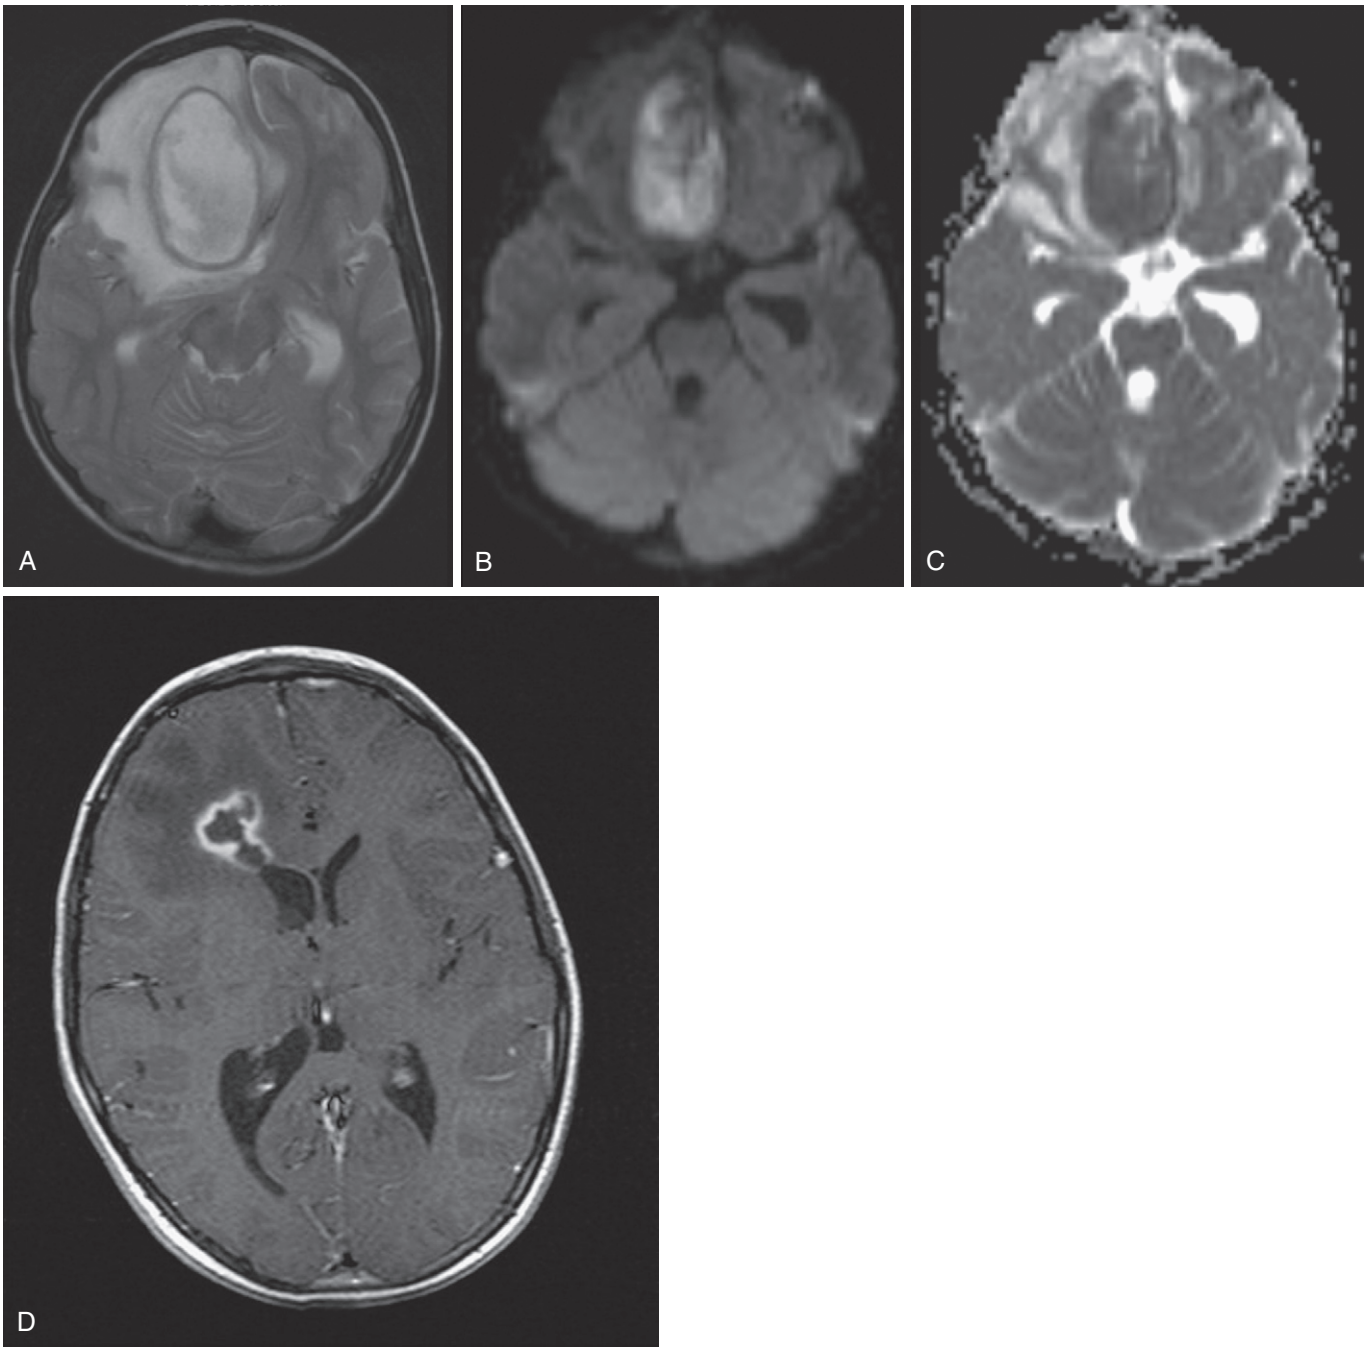

Figure 56–17. Frontal brain abscesses. Axial T2-weighted MRI (**A**) demonstrates a right frontal ring-enhancing lesion with a T2 hypointense capsule that has considerable surrounding vasogenic edema and leftward midline shift. The lesion is bright on diffusion (**B**) and dark on the apparent diffusion coefficient map (**C**), suggesting that it is diffusion restricted. **D,** In another patient, axial postcontrast T1-weighted MR image demonstrates a right frontal periventricular ring-enhancing lesion with T1 hypointense vasogenic edema surrounding it.

common in inflicted traumatic brain injury associated with child abuse. MRI is indicated when there is doubt as to the presence of a subdural collection in the setting of suspected trauma. Also, in the setting of inflicted traumatic brain injury, MRI can detect evidence of old parenchymal or extraaxial hemorrhage not seen with CT using the GRE sequence (see Figure 56-5, *D*) In particular, gradient sequences and susceptibility-weighted imaging can reveal evidence of old parenchymal hemorrhages. Bony injury of the spine also is better evaluated with CT, although cord compression and injury is better assessed with MRI.

Hydrocephalus

Hydrocephalus can be congenital, or caused by hemorrhage, tumor and meningitis. In the neonatal period, ultrasound is used as a screening tool in evaluating for ventricular enlargement, in particular associated with germinal matrix hemorrhage. Beyond this period, most monitoring of ventricular size and shunts is accomplished with CT. Recently, rapidly acquired heavily T2-weighted half Fourier acquisition single shot turbo spin echo MRI sequences have been used in the evaluation of hydrocephalus. These sequences can be

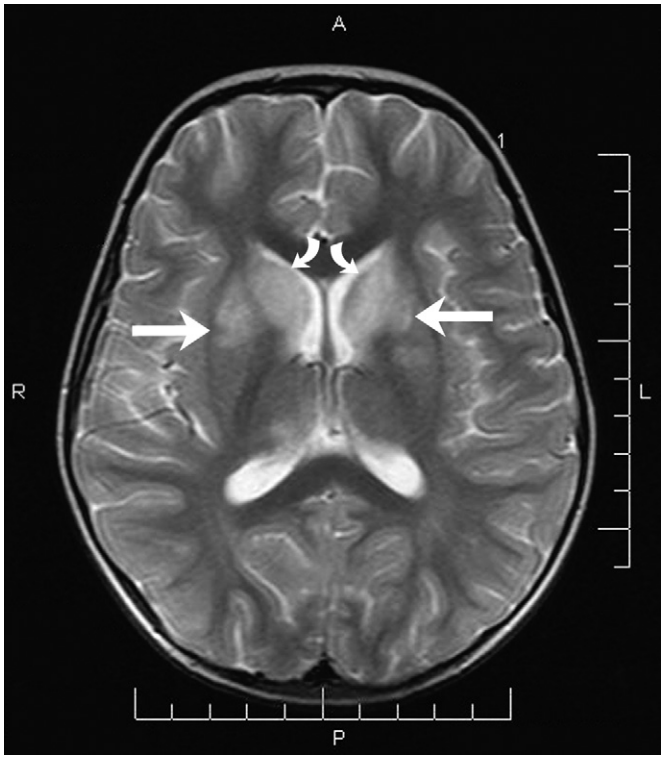

Figure 56–18. ADEM. Axial T2-weighted MR image shows symmetric increased signal in the head of the caudate nucleus (*curved arrows*) and anterior lentiform nuclei (*straight arrows*) associated with ADEM.

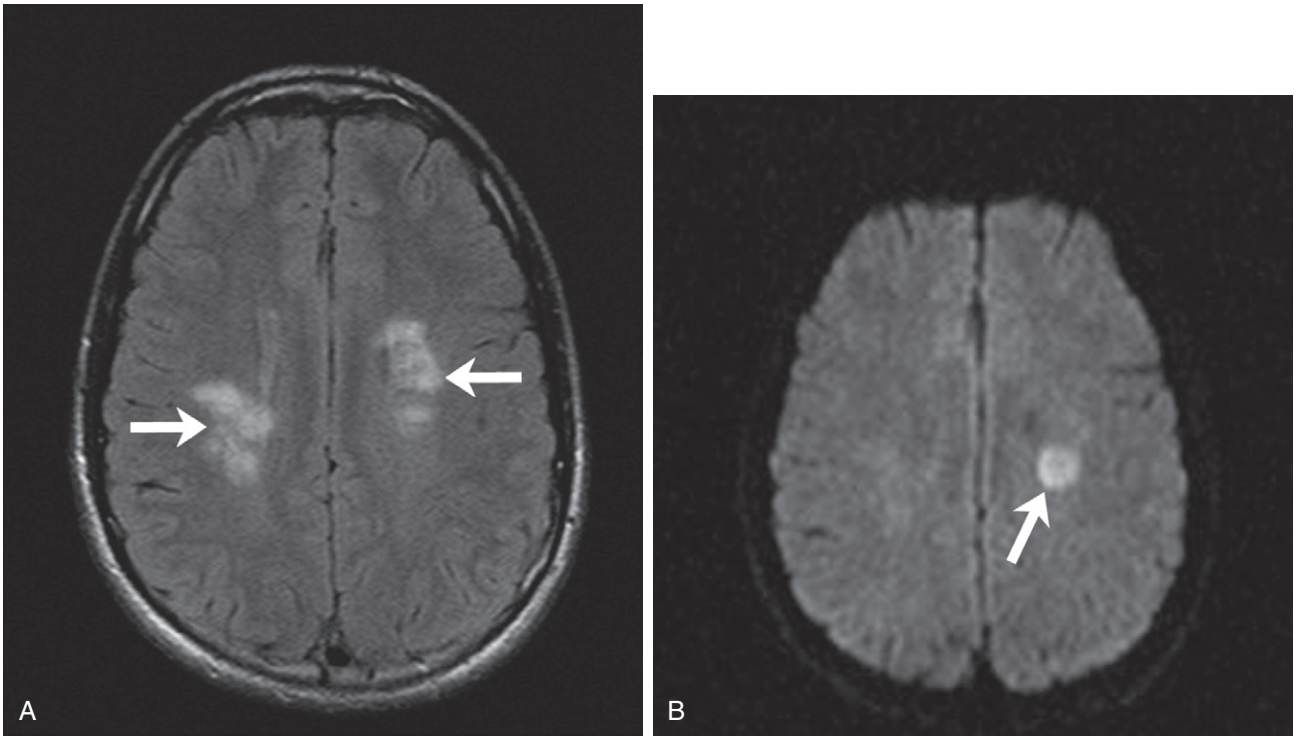

Figure 56–19. Multiple sclerosis in a 16-year-old child. **A,** FLAIR MRI shows bilateral white matter lesions. **B,** DWI demonstrates restriction of the left centrum semiovale lesion that was enhanced on postcontrast T1 MRI (not shown), suggesting an acute or active lesion (*arrow*).

Figure 56–20. Patient with clinical picture of transverse myelitis. Sagittal T2-weighted MRI of the distal cord shows central T2 hyperintensity within the conus medullaris (*arrows*) in this case of ADEM. An acute spinal cord infarct also could have this imaging appearance.

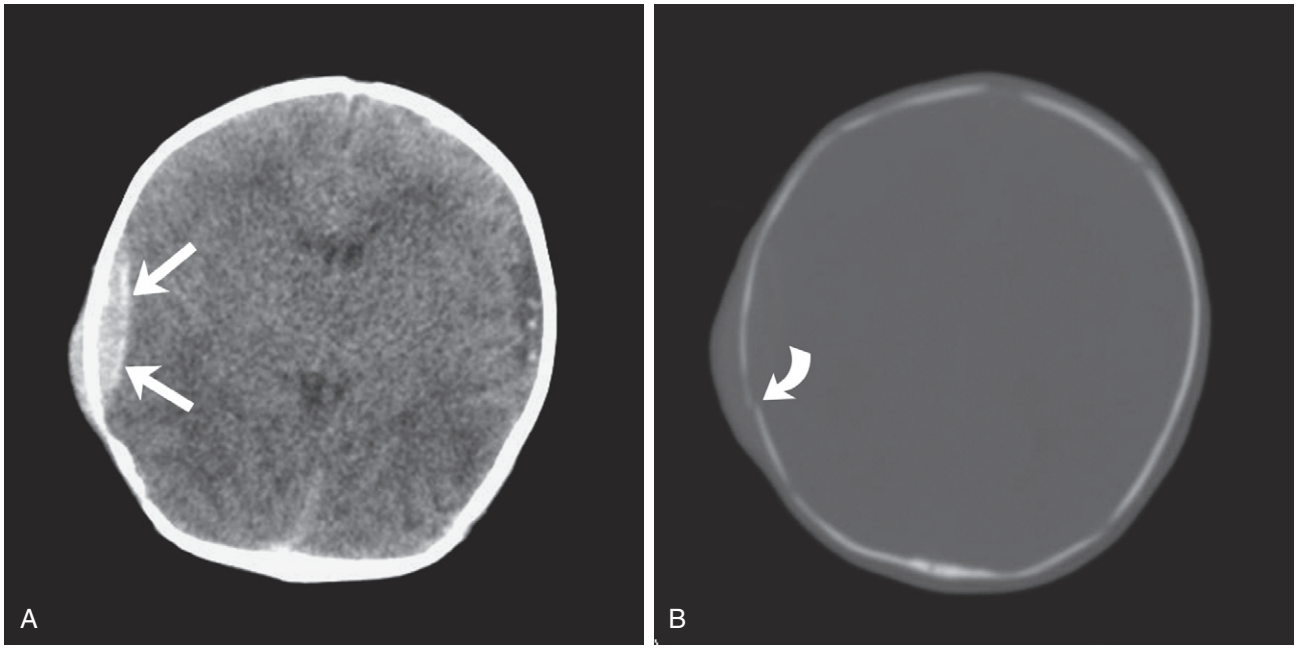

Figure 56–21. Epidural hematoma with skull fracture. A CT scan in brain (**A**) and bone (**B**) windows shows the typical lentiform configuration of right-sided epidural hematoma (*arrows*). The bone window reveals an associated fracture (*curved arrow*).

Figure 56–22. Diffuse brain edema with herniation. T2-weighted MRI shows diffuse cerebral swelling with effacement of cerebrospinal fluid spaces associated with the ambient (*straight arrows*) and suprasellar cisterns (*curved arrows*).

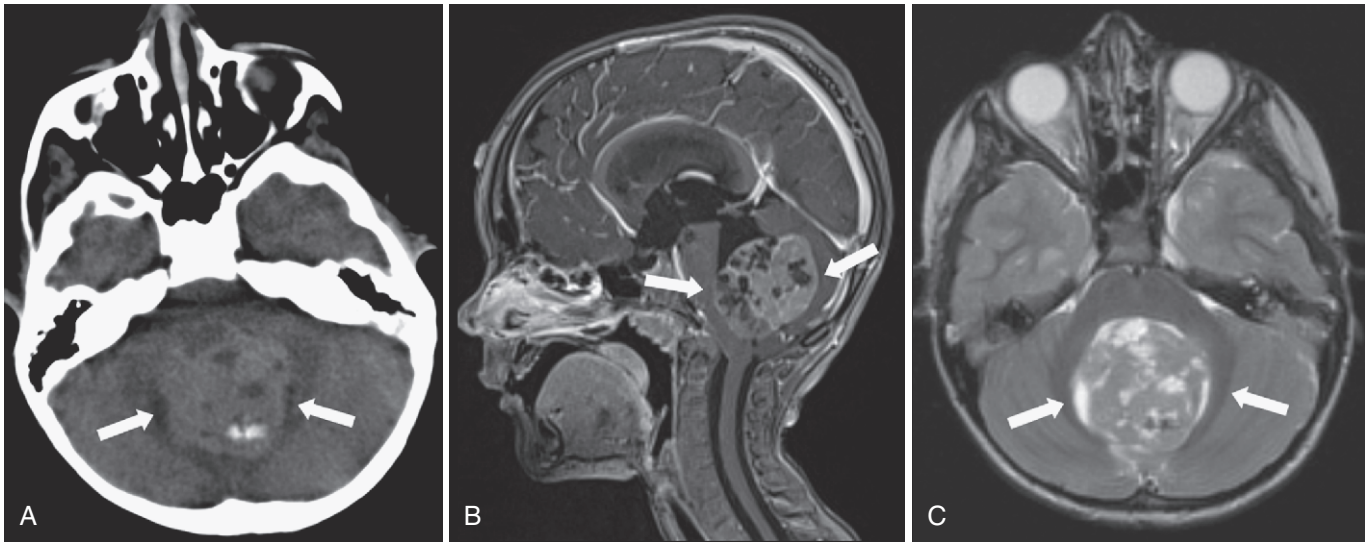

Figure 56–23. Posterior fossa medulloblastoma. Axial noncontrast CT (**A**) and sagittal T1-weighted MRI with gadolinium (**B**) show a midline posterior fossa mass that has heterogeneous enhancement on postcontrast T1 and heterogeneous signal on axial T2-weighted MRI (**C**).

obtained in as little as 12 seconds on a 3.0 Tesla scanner and 19 seconds on a 1.5 Tesla scanner and hence do not necessarily require patient sedation. Use of this technique offsets the radiation burden of repeated CT scans. In the initial evaluation of hydrocephalus, MRI can be helpful in determining the level and possible cause of CSF obstruction (see Figure 56-14). Acute hydrocephalus can be associated with evidence of transependymal CSF flow across the walls of the ventricular system, better appreciated on MRI. The absence of this appearance, however, does not reliably predict the absence of increased pressure. Physiologic/functional evaluation of shunt patency is achieved with nuclear medicine shunt studies, as described previously.

Tumor

Cerebral tumors are best imaged with MRI (Figure 56-23). Expedited evaluation of a cerebral mass can be accomplished in the acute setting with CT, which will demonstrate the degree of mass effect and any impending herniation or midline shift.

Posterior fossa tumors, which are more common in children and occur more often than supratentorial tumors in the 4- to 11-year age group,[43] and suspected acute spinal cord abnormalities, possibly associated with tumor, are best evaluated with MRI. CT is hampered by beam hardening artifact in the posterior fossa, at the skull base, and within the spinal canal.

Seizures

The CT imaging yield for a single self-limited seizure with no focal neurologic deficit is low, although most children currently will ultimately get scanned with CT or MRI. With focal neurologic deficit or prolonged seizure activity, the imaging yield increases. As discussed in Chapter 60, after seizures are controlled, MRI is indicated in the absence of a clinically apparent etiology for the seizures. Acute abnormalities on MRI, however, may be secondary to rather than reflecting the underlying cause of seizures. Prolonged seizures can be associated with transient enhancement due to BBB disruption and cytotoxic edema with hyperintensity on DWI that may be confused with stroke.

Conclusion

The ultimate selection of imaging modality will depend upon clinical question(s), age and condition of the patient, and the locally available imaging technology. Consultation with radiology colleagues is encouraged, and discussion of the clinical scenario and suspicions yields an appropriately tailored imaging protocol and a more relevant interpretation, which is becoming increasingly important with the ever-increasing complexity of imaging modalities.

Structure, Function, and Development of the Nervous System

Mish Shoykhet and Robert S.B. Clark

PEARLS

- In humans, general central nervous anatomy is established by birth. However, the brain undergoes substantial postnatal development including changes in synaptic density and dendritic arborization, maturation of neurotransmitter systems, and experience-dependent modification of neuronal circuits.
- Normal cerebral blood flow (CBF) changes significantly with age. For term human newborns, normal CBF is approximately 40 mL/100 g brain/min. CBF peaks around 4 to 8 years of age at approximately 100 mL/100 g brain/min, declining to adult values of 50 mL/100 g brain/min in late adolescents.
- Normal CBF regulation to changes in blood pressure, CO_2 and O_2 is operative from birth in term human newborns. While cerebrovascular reactivity to CO_2 and O_2 remains relatively unchanged with age, blood pressure-dependent autoregulation operates over a narrower blood pressure range in younger children than in older children and adults.

The nervous system, unlike any other organ system in the human body, stands at the intersection of biology and philosophy. While composed of cells and governed by chemical messages like all biological systems, it comprises the essence of each individual as a human being. The former can be quantified and studied; the latter enters the realm of religion, philosophy, and spirituality. Indeed, in a "brain-centric" approach to pediatric critical care, it can be argued that all interventions are ultimately targeted at preserving and protecting the child's nervous system function. Thus, knowledge of the structure and function of the nervous system, together with understanding of the developmental processes that are active in children who become patients in the intensive care unit (ICU), is essential to the practice of the pediatric intensivist. Furthermore, the impact of disease and injury in the context of the developing nervous system is only now beginning to be understood, with many new advances in diagnosis and treatment undoubtedly yet to come.

Major Cell Types

The nervous system contains two major cell types: neurons and glia. Neurons are responsible for the major operations traditionally ascribed to the nervous system: sensation, movement, thought, memory and emotion, as well as homeostasis of bodily functions. Interconnected networks of neuronal cells carry out all brain and spinal cord–based behaviors. Glia, although significantly more numerous than the neurons, function to support neuronally based information processing and long-distance information transfer. Both neurons and glia are broad classes of cells, each containing a multitude of specialized cells dedicated to carrying out specific functions in the nervous system.

All neurons, regardless of type and location within the nervous system, contain several standard cellular components that allow them to receive, process and relay information. The neuronal soma (cell body) contains the nucleus where genes are transcribed into mRNA, the endoplasmic reticulum where mRNA is translated into proteins and a multitude of mitochondria for cellular respiration and adenosine triphosphate synthesis. Originating from the soma are two types of processes: a number of dendrites and a single axon. Dendrites are short, local processes specialized for receiving information transmitted from other neurons via chemical or electrical synapses (see below). The axon is the output of the neuron, carrying information in the form of action potentials to be received by other neurons, muscles and many additional body organs, at distances up to meters away.

Glial cells are typically divided into microglia and macroglia. Microglia are phagocytic cells derived from peripheral macrophages, and normally exist in a resting, or quiescent state in the central nervous system (CNS). Microglia are activated by several physiologically relevant factors, including bacterial lipopolysaccharide in the setting of infection and thrombin in the setting of injury.[1] Whether microglial activation is neurotoxic or neuroprotective in these settings has yet to be fully characterized. In addition, activated microglia play an important role in the neuropathology of Alzheimer disease, HIV-associated dementia, and prion diseases. Therapeutic

strategies targeting microglial activation are just now beginning to emerge in animal disease models[2-3] and human clinical trials.[4]

Macroglia comprise several distinct cell subtypes within the nervous system: astrocytes and oligodendrocytes in the CNS, and Schwann cells in the peripheral nervous system (PNS). Astrocytes are by far the most numerous cell type in the brain, performing several vital functions. At the synapse, astrocytes regulate ion and neurotransmitter concentrations, contributing to the modern notion that the synapse is a tripartite structure consisting of the presynaptic and postsynaptic neurons and the astrocyte. At the blood-brain barrier (BBB), astrocytes direct their processes towards the endothelial cells and contribute to the proper development of tight junctions (see below). In contrast to the relatively diverse functions of astrocytes, oligodendrocytes' and Schwann cells' primary purpose is to provide myelination for axons in the CNS and the PNS, respectively. Myelination ensures faithful signal propagation along the entire axonal length. Each oligodendrocyte contributes myelin to between 10 and 15 axons in the CNS; each Schwann cell envelopes a single axon in the PNS. From a clinical perspective, disorders of myelination contribute significantly to a range of diseases observed in pediatric critical care, including perinatal asphyxia-induced periventricular leukomalacia, Canavan disease due to mutation in the oligodendrocyte-specific aspartoacylase gene, and Guillain-Barré syndrome, caused commonly by autoimmune-mediated injury to peripheral nerve myelin sheaths.

Intercellular Communication in the Nervous System

Early descriptions of neuronal cell structure by Camillo Golgi and Ramon Cajal in the late nineteenth century gave rise to two diverging theories of neuronal communication. Golgi proposed that neurons form an interconnected reticulum, much like cardiac muscle cells, and communicate directly with each other via openings in their membranes. Cajal, on the other hand, argued that neurons are individual cells with contiguous cell membranes, and that communication takes place chemically at the sites of contact between individual neurons. Despite the radically opposed views, both theories are now known to be correct and both mechanisms contribute to aspects of neuronal communication in the mammalian brain. Direct communication between neurons, known as the electrical synapse, is accomplished via gap junctions. Communication across cell membranes at sites where two neurons contact each other is accomplished using neurotransmitters, with the contact site known as the chemical synapse.

Electrical Synapses

At the electrical synapse, cell membranes of the adjoining neurons are tightly bound together into a gap-junction plaque.[5] Each plaque contains numerous channels made of connexin proteins. There are 21 known connexin genes in humans. Each channel consists of two hemichannels, with one on each cell membrane. Two hemichannels join together to form a functional gap junction between two neurons, allowing intercellular diffusion of ions and small molecules such as glucose, cyclic AMP, and ATP. Gap junctions thus allow neurons to share information about their metabolic and excitable states, providing a mechanism for large-scale regulation of energy demands and neuronal network dynamics. Additionally, gap junction channels close in response to lowered intracellular pH or elevated Ca^{2+} levels; since both events occur in damaged cells, paired hemichannels at the gap junction may function to isolate healthy neurons from those damaged during ischemia or trauma. Recent evidence suggests that unpaired hemichannels outside of the gap junction plaques may also contribute to ischemic neuronal cell death.[6]

Glia, like neurons, are also connected by gap junctions. For example, brain astrocytes form an interconnected cellular network, which allows long-distance propagation of calcium signals across many cells. Additionally, layers of myelin generated by oligodendrocytes in the CNS and by Schwann cells in the PNS are linked by gap junctions. Myelin gap junctions provide structural stability to the myelin sheath and allow for rapid diffusion of nutrients and other substances across the sheath towards the underlying axon. In humans, mutations in gap junction protein connexin 32 result in X-linked Charcot-Marie-Tooth disease, a demyelinating neuropathy.[7]

Chemical Synapses

Neuromuscular Junction

The neuromuscular junction (NMJ) is one of the most widely studied examples of chemical synaptic transmission in the nervous system. The overall concept is deceivingly simple: an action potential at the presynaptic neuron releases a neurotransmitter that in turn activates ion channels on the muscle cell membrane, resulting in postsynaptic action potential. Yet, every step in this process is exquisitely controlled and modulated in health and may be disrupted in disease. Our evolving understanding of the NMJ provides a critical window into synapse function and pathophysiology.

The NMJ consists of three distinct anatomic components: the presynaptic nerve terminal, the synaptic cleft containing the basement membrane, and the postsynaptic muscle fiber. The presynaptic nerve terminal originates from the myelinated axon of a motoneuron in the spinal cord. Lower motoneurons in the ventral gray matter of the spinal cord send their myelinated axons through the ventral root towards peripheral muscle targets. As the axon approaches the muscle fibers, it loses its myelin sheath and branches into a fine network of terminals, each approximately 2 μm in diameter. Each branch has several swellings along its course, termed presynaptic boutons, where the nerve makes synaptic contact with the muscle fiber. Presynaptic boutons are covered by terminal Schwann cells, which provide growth factors, recycle neurotransmitters, and may participate in recovery after nerve and muscle injury. Presynaptic boutons are positioned over specialized regions of the muscle cell membrane called the end-plate regions. Furthermore, underlying each bouton is a specialized invagination of the cell membrane that contains a very high concentration of nicotinic acetylcholine (ACh) receptors and voltage-gated Na^+ channels. The presynaptic bouton and the end-plate are separated by a 100 nm-wide synaptic cleft containing the basement membrane and the extracellular matrix. The basement membrane anchors a number of proteins, including acetylcholinesterase, the enzyme responsible for rapid hydrolysis of ACh in the synaptic cleft.

Several distinct functional steps occur during synaptic transmission at the NMJ. First, the action potential arriving from the motor axon depolarizes the membrane in the presynaptic boutons, causing Ca^{2+} entry via voltage-gated Ca^{2+} channels on the presynaptic membrane. Ca^{2+} entry results in fusion of synaptic vesicles containing ACh with the presynaptic cell membrane and release of ACh into the synaptic cleft. ACh rapidly diffuses towards the postsynaptic membrane and binds to the nicotinic ACh receptor (nACh); two ACh molecules are required to activate the nACh receptor. Upon activation, the nACh receptor opens and allows both Na^+ and K^+ to flow through the ion pore. The inward Na^+ current, however, dominates over the outward K^+ current, resulting in net depolarization of the muscle membrane at the end-plate. This so-called end-plate potential propagates a short distance before encountering voltage-gated Na^+ channels. These Na^+ channels open when membrane potential rises to a critical threshold value, allowing only Na^+ ions to flow into the cell and generating the all-or-none muscle action potential. Acetylcholinesterases in the synaptic cleft terminate the depolarizing action of ACh at the postsynaptic membrane by rapidly hydrolyzing ACh into acetate and choline.

A detailed understanding of diseases that affect synaptic transmission at the NMJ, as well as familiarity with clinical pharmacology as it applies to the NMJ, are essential in critical care. Specific diseases affecting the NMJ include toxin-mediated botulism and autoimmune disorders such as myasthenia gravis, Lambert-Eaton syndrome, and neuromyotonia. These are discussed in detail in Chapter 64 (see also Tseng-Ong and Mitchell[8] and Lang and Vincent[9]). Among the pharmacotherapies targeted at the NMJ are some of the most commonly used drugs in the pediatric ICU: neuromuscular blockers (NMB). NMB agents are reviewed in Chapter 122. Furthermore, a number of toxins either decrease (anticholinergic agents) or increase (acetylcholinestrase inhibitors) the amount of ACh available at cholinergic synapses, resulting in corresponding toxidromes (see Chapter 106).

Chemical Synapses in the Central Nervous System

Chemical synapses in the CNS operate on basic principles similar to those governing synaptic transmission at the NMJ, although the cadre of neurotransmitters and postsynaptic receptors is significantly more diverse in the CNS. Importantly, a given neuron in the CNS may synthesize and store more than a single neurotransmitter, but it releases the same set of neurotransmitters at all of its synapses (Dale's principle). CNS synapses are generally divided into asymmetric (Gray type I) synapses and symmetric (Gray type II) synapses on the basis of their appearance under electron microscopy. Physiologically, these correspond to excitatory and inhibitory synapses, respectively. Each neuron synthesizes its own complement of neurotransmitters, which are delivered to all synaptic contact sites in the axon and packaged into synaptic vesicles. When an action potential reaches the axon, Ca^{2+} currents cause the synaptic vesicles to fuse with the cell membrane, releasing neurotransmitters into the synaptic cleft. Neurotransmitters then act on their corresponding ionotropic and metabotropic receptors on the postsynaptic membrane. Ionotropic receptor activation leads to either a depolarizing, excitatory current or a hyperpolarizing, inhibitory current. These subthreshold currents are called excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs), respectively. Temporal and spatial summation of EPSPs in the dendritic tree of the postsynaptic neuron occasionally depolarizes the somatic membrane sufficiently to cross threshold and to generate an action potential. One of the distinguishing features of chemical synaptic transmission in the CNS, compared to the NMJ, is its lack of reliability on a single cell level; an action potential in the presynaptic neuron does not necessarily cause a postsynaptic neuron to fire its own action potential. Such lack of determinism likely allows for individual differences in responses to the same stimuli. After interaction with the receptor, the neurotransmitter is cleared from the synapse by diffusion, active reuptake into the terminal, or by enzymatic destruction, similar to ACh hydrolysis at the NMJ.

Neurotransmitter Systems

Several substances are employed for communicating information chemically between neurons in the nervous system or between a neuron and a muscle at the neuromuscular junction. These substances are called neurotransmitters, and generally fall into three categories: amines, amino acids, and peptides (Table 57-1). Each neurotransmitter requires its own synthetic machinery and exerts specific actions on the postsynaptic target. Furthermore, neurons tend to be characterized anatomically, immunohistochemically, and functionally by the main neurotransmitter they use, allowing insight into the role of each neurotransmitter system in CNS function.

Neurotransmitters

Acetylcholine

Acetycholine is an amine that functions as a neurotransmitter at the NMJ as well as in the CNS. At the NMJ, its actions are quick and precise, whereas in the CNS it functions as a slow, more global modulator of synaptic activity. Cholinergic CNS neurons include all the motoneurons in the spinal cord, as well as a number of cell nuclei in the brainstem reticular formation and the basal forebrain. Cholinergic neurons synthesize ACh using choline acetyltransferase (ChAT), which transfers an acetyl group from acetyl coenzyme A (CoA) to choline (Figure 57-1, *A*). Choline concentration in the extracellular fluid is the rate-limiting step in the reaction. Cholinergic neurons also synthesize acetylcholinesterase (AChE), the enzyme that breaks down ACh. AChE is released with ACh

Table 57–1 Neurotransmitter Classes

Amines	Amino Acids	Peptides
Acetylcholine	γ-Aminobutyric acid	Substance P
Dopamine	Glutamate	*Vasoactive intestinal peptide*
Norepinephrine	Glycine	Dynorphin
Epinephrine		Enkephalins
Serotonin		*Neuropeptide Y*
Histamine		*Cholecystokinin*

Neurotransmitters operative exclusively in the central nervous system are in normal font, those used both in the central and peripheral nervous systems are in *italics,* and those used exclusively in the peripheral nervous system are in **bold**.

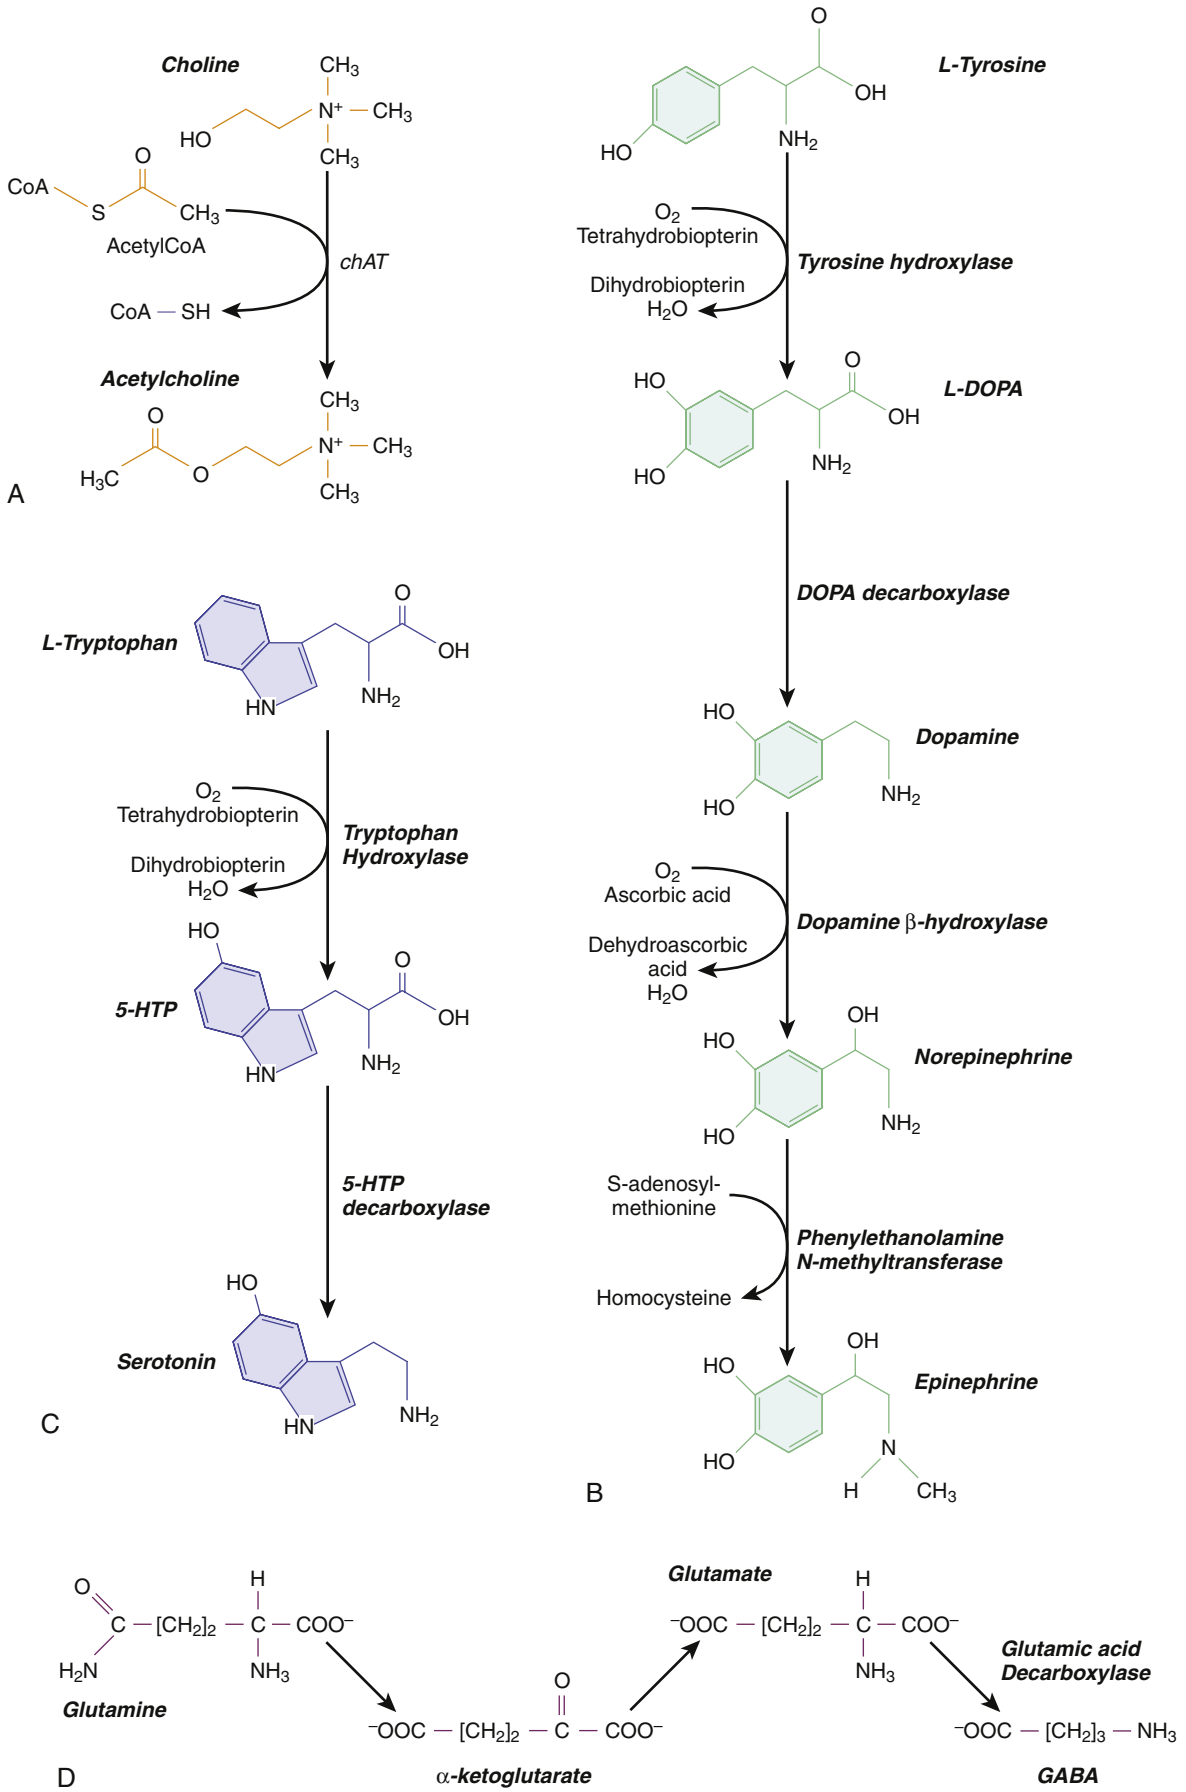

Figure 57–1. Neurotransmitter structure and synthesis. **A,** Acetycholine. **B,** Catecholamines. It should be noted that synthesis of norepinephrine and epinephrine requires dopamine as a precursor. **C,** Serotonin, an amine synthesized from tryptophan. **D,** Glutamate and GABA, amino acid derivatives.

into the synaptic cleft, where it rapidly hydrolyzes ACh into acetic acid and choline.

Low concentrations of choline in the CNS have been associated with neurologic impairment during fetal[10] and postnatal life.[11] Thus, choline supplementation represents an attractive therapeutic strategy in neurologic disorders characterized by decreased CNS choline. Interestingly, patients receiving long-term parenteral nutrition (TPN) occasionally develop choline deficiency, which has been associated with TPN-related liver failure[12] and possibly, cognitive dysfunction. Hence, choline supplementation in TPN-dependent patients may ameliorate some neurologic deficits.[13]

Catecholamines

Catecholamine neurotransmitters include dopamine, norepinephrine and epinephrine. For all three, the initial starting point in biochemical synthesis is the amino acid tyrosine (Figure 57-1, *B*). Tyrosine is converted into an intermediate compound, called dopa, by tyrosine hydroxylase (TH). In dopaminergic neurons, dopa is converted into dopamine by dopa decarboxylase. Noradrenergic neurons, which utilize norepinephrine as a neurotransmitter, further convert dopamine into norepinephrine using dopamine β-hydroxylase. Finally, norepinephrine is converted into epinephrine by an enzyme phentolamine *N*-methyltransferase, which is found only in adrenergic neurons. Thus all neurons that synthesize catecholamines contain TH and dopa decarboxylase, but only noradrenergic and adrenergic neurons contain the synthetic enzymes required to produce norepinephrine and epinephrine, respectively.

Catecholamine-utilizing neurons reside primarily in the brainstem. Dopaminergic neurons in humans are located in two mesencephalic nuclei: the substantia nigra and its medial neighbor, the ventral tegmental area. Dopaminergic neurons in the substantia nigra project primarily to the basal ganglia, where they are involved with initiation of voluntary movement. Ventral tegmental neurons send dopaminergic fibers to the amygdala and the cerebral cortex and participate in regulation of emotion, reward and addiction. Brainstem noradrenergic neurons are located in the locus ceruleus and in the reticular formation. They project widely to the thalamus and cortex as well as to the spinal cord, and play a significant role in arousal and vigilance. Adrenergic CNS neurons are located in the ventrolateral medulla, and participate in temperature regulation via their projections to the hypothalamus.

Unlike ACh, which is cleared from the synapse by hydrolysis, catecholamines are cleared from the synaptic cleft by reuptake into the axonal terminal. Once inside the cell, catecholamines are either repackaged into vesicles or destroyed by monoamine oxidase (MAO). Pharmacologic manipulation of synaptic catecholamine concentrations plays a therapeutic role in the management of several disorders, such as depression and attention deficit-hyperactivity disorder (ADHD). Furthermore, recreational drugs affecting catecholamine concentrations at the synapse continue to gain popularity and to grow in number. Therapeutic uses include treatment of severe depression with MAO inhibitors, which inhibit catecholamine breakdown, and treatment of ADHD with amphetamines, that interfere with dopamine transport and increase dopamine concentrations. Recreational drugs include amphetamine and its analogues, as well as cocaine, a selective norepinephrine transporter blocker. Excess catecholamine levels at the synapse result in sensations of euphoria, increased energy levels and improved focus, as well as anxiety, paranoia, and jitteriness. Notably, hypertensive crises leading to myocardial infarction and stroke may occur with use of cocaine, amphetamines, and MAO inhibitors.

Serotonin

Serotonin is an amine neurotransmitter synthesized from the amino acid tryptophan in a two-step process (Figure 57-1, *C*). First, tryptophan is hydroxylated by tryptophan hydroxylase to form 5-hydroxytryptophan (5-HTP). 5-HTP is then decarboxylated by 5-HTP decarboxylase to form serotonin, also known as 5-hydroxytryptamine (5-HT). After 5-HT is released at the synapse, it is cleared by a specific serotonin reuptake transporter. Serotonergic neurons are located in the rostral and caudal raphe nuclei in the brainstem. Rostral raphe neurons innervate the cerebral cortex, including the limbic system, where serotonin levels help regulate mood and attention. Caudal raphe neurons project to the brainstem and the spinal cord, where they are involved in regulation of general arousal and pain perception, respectively. Importantly, dysfunction of the serotonergic pathways originating in the raphe nuclei has been linked with sudden infant death syndrome (SIDS).[14] Additionally, serotonin levels play a key role in depression, giving rise to an entire class of drugs in clinical use called selective serotonin reuptake inhibitors (SSRIs). SSRI abuse or overdose is rare, but may result in patients presenting with the potentially life-threatening "serotonin syndrome," characterized by hypertension, tachycardia, mental status changes, myoclonus, and severe hyperthermia. The latter may lead to shock, rhabdomyolysis, renal failure, and death. The serotonin syndrome is particularly likely to occur when SSRIs and MAO inhibitors, inadvertently or intentionally, are taken together. Treatment includes serotonin antagonists, blood pressure control with either adrenergic antagonists or agonists as clinically indicated, and temperature control with benzodiazepines and neuromuscular blockade.

Amino Acids

Neurotransmitters derived from common amino acids include glutamate, gamma-aminobutyric acid (GABA), and glycine. These are among the most widely distributed neurotransmitters in the CNS. Glutamate and glycine exist as amino acids in all cells, where they are utilized as protein building blocks. Glutamatergic and glycinergic neurons have the additional capacity to package glutamate and glycine, respectively, into synaptic vesicles and release them at the synapse. GABA must be synthesized from glutamate via an additional reaction catalyzed by an enzyme glutamic acid decarboxylase (GAD) (Figure 57-1, *D*). Only GABA-ergic neurons contain GAD.

Glutamate is generally an excitatory neurotransmitter, whereas GABA and glycine are inhibitory. Excitatory glutamatergic neurons exert their influence both locally and over long distance, depending on the shape of their axons. Inhibitory neurons, on the other hand, tend to exert local inhibitory control over neuronal circuitry either in the brain (GABA) or in the spinal cord (glycine). A major exception are cerebellar Purkinje cells, which are GABA-ergic but project over long distances to the brainstem, thalamus, and cerebral cortex (see below).

Adenosine, Peptides, and Nitric Oxide

In addition to the "classic" neurotransmitters described above, a number of substances have been documented to mediate or modulate information transfer between neurons. These include adenosine triphosphate (ATP) and adenosine, which at the synapse is a metabolite of ATP released in the synaptic vesicle. ATP modulates neuronal excitability such that energy may be conserved during times of ATP depletion. Adenosine functions as a neurotransmitter in the autonomic nervous system (ANS), in the basal ganglia, and at some cortical synapses. It also modulates the respiratory rate, and adenosine antagonists, such as caffeine, are used to treat apnea and bradycardia of prematurity. In addition to ATP and adenosine, a number of peptides can be released in synaptic vesicles, including substance P, vasoactive intestinal peptide (VIP), endogenous opioids, and endogenous cannabinoids. These peptides are involved in pain sensation and perception (substance P and opioids), modulation of vascular tone (VIP), and as yet uncharacterized processes (cannabinoids).

Finally, several gaseous molecules function as neurotransmitters. These include nitric oxide (NO) and carbon monoxide (CO), and possibly hydrogen sulfide. NO, the most thoroughly studied of the gaseous neurotransmitters, is produced by brainstem neurons in the nucleus tractus solitarius, where it interacts with α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA)-type and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and regulates cardiovascular function.[15] Hydrogen sulfide is produced from the amino acid cysteine, and may influence cellular redox state and glutamatergic transmission.[16] Intriguingly, hydrogen sulfide induces a suspended animation-like state in animals.[17] and may be protective after resuscitation from cardiac arrest.[18]

Neurotransmitter Receptors

Nicotinic Acetylcholine Receptors

Nicotinic ACh receptors are ligand-gated ion channels, related structurally and functionally to $GABA_A$ channels, and a subset of serotonin receptors. Five transmembrane subunits comprise the nAChR and form a central pore that allows ionic currents to pass. There are two subunit classes, α and β, with multiple members in each class. nAChR is generally a heteromer, but homomer channels have been described. Each nAChR binds two acetycholine molecules, with affinity for ACh and for nicotine dependent on subunit composition. The receptor exists in three distinct states: closed, open, and desensitized. In the closed position, no ionic current passes through the central core. When an agonist, such as ACh or nicotine, binds the nAChR, the receptor opens, becoming permeable to monovalent and divalent cations. After a short period of time, the receptor spontaneously closes. Upon continued exposure to an agonist, however, the nAChR assumes a permanently closed, or desensitized, conformation.[19] As discussed above, nAChRs mediate neuromuscular coupling at the NMJ. In addition, nAChRs are widely distributed in the CNS, where they perform a variety of functions depending on subunit composition and location.

In the CNS, unlike at the NMJ, nAChRs are permeable to both Na^+ and Ca^{2+}. In neurons, however, nAChR-evoked Ca^{2+} current exceeds the Na^+ current twofold to tenfold. The greater Ca^{2+} permeability indicates that nAChRs mostly modulate synaptic transmission and release of other neurotransmitters. Indeed, although direct nAChR-dependent responses have been observed in the hippocampus and the developing visual cortex, the overwhelming evidence points to nicotinic receptors playing the role of modulator in the CNS. Their wide distribution in the CNS with locations presynaptically, postsynaptically, and extrasynaptically further supports that role. Activation of presynaptic nAChRs enhances release of ACh, dopamine, glutamate, and GABA. Coupling of enhanced glutamate release with nAChR-dependent increase in intracellular Ca^{2+} suggests that nAChRs participate in synaptic plasticity during learning. Postsynaptic and extrasynaptic nAChRs regulate excitability and signal propagation in neuronal circuits. In the hippocampus, for example, nAChR activation leads to increased release of GABA from inhibitory interneurons, which decreases the excitability of hippocampal pyramidal neurons. Nicotinic receptors also interact with the dopaminergic system in regulating neuronal circuitry in the basal ganglia and the limbic system. Thus, nicotinic receptors have been implicated not only in learning and memory, but also in regulation of addiction and reward. Furthermore, loss of cholinergic neurons represents one of the distinguishing neuropathologic features of Alzheimer disease, and cholinesterase inhibitors are widely used to improve cognition and memory in Alzheimer patients.[19] In pediatrics, a mutation in nAChR is responsible for a specific clinical epilepsy phenotype, called autosomal dominant nocturnal frontal lobe epilepsy.[20] Seizure onset usually occurs around 12 years of age in otherwise healthy children. Seizures originate in the frontal lobe, and occur predominantly during non-REM sleep.[21] The mutant nAChR is more sensitive to ACh than the wild-type receptor, suggesting that cholinergic medications should be avoided in these patients.

Muscarinic Acetylcholine Receptors

Muscarinic ACh receptors (mAChRs) comprise a group of metabotropic receptors that link ACh exposure at the surface with G protein activation inside the cell. There are five distinct subtypes of mAChRs, designated M_1 through M_5, and these subtypes are divided into two broad classes based on the identity of the G protein with which they interact. M_2 and M_4 mAChRs couple with G_i proteins, and inhibit adenylyl cyclase activity and reduce intracellular cAMP levels. M_1, M_3, and M_5 receptor subtypes couple with G_q proteins, and increase intracellular Ca^{2+} levels via activation of phospholipase C.[22] In the CNS, the M_1 mAChR is the most abundant subtype, located on neurons in the cortex, thalamus and striatum.[23] mAChRs are also present in the PNS in the sweat glands and organs of lacrimation and salivation, as well as in the heart, where they mediate the parasympathetic control of heart rate and contractility. Muscarinic AChRs thus mediate many of the systemic effects of organophosphate exposure and nerve gas poisoning.[24]

Glutamate Receptors

Glutamate is the major excitatory neurotransmitter in the central nervous system. In mammals, it depolarizes postsynaptic neurons by binding to three types of ionotropic glutamate receptors (iGluR), each of which is characterized by different affinities for synthetic analogues, by different selectivity to ions, and by different time-course of the current that is

permitted to pass through the cell membrane. The three types of iGluR are the AMPA receptor, the NMDA receptor, and the kainate receptor. All three channels types are widely present throughout the CNS, with AMPA and NMDA channels mediating the bulk of the excitatory transmission. At present, the function of the kainate channel remains to be clearly defined.

AMPA and NMDA receptors differ from each other with respect to ion permeability and time-course of ion flow through the channel. Upon binding of glutamate, AMPA receptors open their pores, which are permeable to Na^+ and K^+ ions. At the negative resting potential of the neuronal cell membrane, Na^+, driven by the electrochemical gradient, flows into the cell and causes a large, fast depolarization. AMPA receptors are generally impermeable to Ca^{2+}, although more recent findings indicate that Ca^{2+}-permeable AMPA receptors do exist and may significantly contribute to pathology observed in ALS and stroke.[25] In contrast, NMDA receptors are universally permeable to Ca^{2+}, as well as to Na^+ and K^+, generating a slow inward depolarizing current. NMDA receptors possess a unique property, however, that allows them to pass current only when the neuronal membrane is already depolarized. This property, termed *voltage-dependence*, stems from Mg^{2+} ions blocking the entry pore of the NMDA channel at negative membrane potentials even in the presence of glutamate. As the neuron depolarizes further, mostly due to current flow via the AMPA receptor, the Mg^{2+} block is relieved, and Ca^{2+}, as well as Na^+, flow into the cell. Once inside the cell, Ca^{2+} ions mediate a multitude of effects, from modifying protein phosphorylation and gene expression to overt *excitotoxicity* and cell death. NMDA receptors are thus thought to function as coincidence detectors, linking events at the cell membrane, e.g., AMPA receptor-mediated depolarization, with long-term changes in synaptic strength and gene expression in the neuron.

In addition to directly modulating current flow via the ionotropic channels, glutamate modulates effector molecules within the neuron by binding to a diversity of G protein-linked metabotropic glutamate receptors (mGluRs). Eight mammalian subtypes of mGluR are divided into three categories, based on sequence homology and coupling to secondary effector systems.[26] Group I mGluRs (mGlurR1 and mGluR5) are localized at the edge of the postsynaptic neuronal membrane and are positively coupled to phospholipase C (PLC) via the G_q protein. Group II and III mGluRs are located on the edge of the presynaptic neuronal membrane and are negatively coupled to adenylyl cyclase (AC) via the G_i protein. All three groups are activated only when excess glutamate spills out of the synaptic cleft and diffuses towards mGluRs located at the periphery of the synaptic membrane.

Differential secondary messenger coupling and synaptic localization of the three mGluR groups points to their divergent roles in regulating neuronal function. Binding of glutamate to group I mGluRs leads to activation of PLC, which releases two secondary messengers—diacylglycerol (DAG) and inositol triphosphate (IP_3)—from the membrane phospholipid phosphoinositol 1,4,5-bisphosphate (PIP_2). DAG activates protein kinase C in the neuronal membrane, whereas PIP_2 diffuses towards its receptor on the internal cell membrane and triggers a massive Ca^{2+} release into the cytoplasm. Downstream events lead to 1) modulation of K^+ currents, resulting in increased neuronal excitability and 2) potentiation of glutamate-dependent current at NMDA receptors specific to the synapses at which excess glutamate release has occurred. Group I mGluRs thus participate in activity-dependent strengthening of synaptic connections and play a significant role in learning and memory.

In contrast, group III, and probably group II, mGluRs on presynaptic neurons provide a negative feedback loop by inhibiting glutamate release. When glutamate binds to group III mGluRs, an inhibitory G protein (G_i) is activated, that then functions to decrease AC-mediated production of cAMP. A decrease in cAMP leads to lower Ca^{2+} concentrations at the presynaptic neuronal membrane and decreased synaptic vesicle fusion. The net effect is a decrease in the amount of glutamate released at the synapse and a reduction in synaptic transmission. Recently, mGluRs have emerged as a major therapeutic target due to the multitude of effects they exert on synaptic transmission. Their extrasynaptic location presumably will allow newly developed pharmaceutical agents to maximize therapeutic value and minimize unwanted side effects.[27]

$GABA_A$ and $GABA_B$ Receptors

GABA is the major inhibitory neurotransmitter in the brain. Like glutamate and ACh, it binds two distinct classes of GABA receptors; $GABA_A$ receptors are ionotropic, and $GABA_B$ receptors are metabotropic. Both receptor classes are involved in regulation of physiologic and pathologic states, and pharmacological manipulation of GABA receptors plays a major role in the management of pediatric critical illness.

$GABA_A$ receptors are chloride channels. At the normal resting membrane potential, opening of the $GABA_A$ receptor allows chloride ions to flow into the cell down their electrochemical gradient. Influx of negatively charged Cl^- ions results in hyperpolarization of the cell membrane. In neurons, membrane hyperpolarization decreases the probability that the neuron will reach threshold and fire an action potential. Thus, on an individual cell level, GABA decreases neuronal activity via the $GABA_A$ receptor.

$GABA_A$ receptors are heteropentamers, similar in structure to the nAChRs. At least eight subunit classes exist in mammals, including humans, and each class consists of several members, allowing for a staggering 150,000 possible subunit combinations to create one functional $GABA_A$ receptor. Only 500 combinations are known to exist, and most receptors contain a various complement of the α, β, and γ subunits.[28] Most $GABA_A$ receptors cluster at postsynaptic densities, and such clustering appears to depend on presence of the γ subunit. However, a subset of the $GABA_A$ receptors, in particular those containing the δ subunit, localize to extrasynaptic sites, mediate tonic levels of inhibition in the brain, and may underlie the pathophysiology of absence seizures.[29]

The pharmacology of the $GABA_A$ receptor is of particular relevance in critical care, since the two classes of first-line anticonvulsants and anxiolytics in clinical practice—the benzodiazepines and the barbiturates—allosterically modulate the $GABA_A$ receptor. GABA itself binds the receptor at the junction of the α and β subunits. Benzodiazepines bind the $GABA_A$ receptor at a different site, classically between the α and γ_2 subunits, and, in the presence of GABA, increase the frequency with which the chloride channel opens. Barbiturates, in contrast, bind at yet a different site and increase the duration of the open state in the presence of GABA. Thus both benzodiazepines and barbiturates increase the efficacy

of endogenous GABA in hyperpolarizing the cell membrane. A major difference between the two drug classes is that at increasing concentrations, barbiturates, but not benzodiazepines, become direct GABA agonists and can open $GABA_A$ channels independent of endogenous GABA release. Hence, barbiturates have a significantly narrower safety window compared to benzodiazepines.

Additional $GABA_A$ receptor ligands of clinical importance include (1) general inhalational anesthetics, which are thought to modulate tonic inhibition via the δ subunit-containing receptors; (2) alcohol, although its mechanistic action is poorly understood; and (3) flumazenil, a competitive benzodiazepine antagonist used clinically to reverse benzodiazepine overdose.

$GABA_A$ receptors mutations contribute to several known disease states in humans. Two different point mutations on chromosome 5, both affecting the γ_2 subunit, are associated with development of febrile seizures and generalized epilepsy as well as with a link between the two conditions.[30-31] In patients with temporal lobe epilepsy, $GABA_A$ receptor expression is altered in hippocampal neurons,[32] and GABA-evoked responses actually depolarize, rather than hyperpolarize, neurons in excised tissue (see also Developmental Processes section later in the chapter).[33] $GABA_A$ receptor dysfunction is also thought to contribute to anxiety, panic disorder, schizophrenia, and sleep disturbances.[34] Thus, pharmacologic modulation of $GABA_A$ receptor function represents an active area of research and novel drug development.

$GABA_B$ receptors are heterodimeric proteins that activate G protein-coupled second messenger systems upon interaction with GABA at the membrane.[35] The $GABA_{B1}$ subunit binds GABA at the cell membrane, while the $GABA_{B2}$ subunit interacts with the G protein on the cytosolic surface. $GABA_B$ receptors are widely distributed throughout the CNS but are particularly abundant in the thalamus, cerebellum, and hippocampus. They can be located both presynaptically and postsynaptically. Presynaptic $GABA_B$ receptors allow G protein–coupled Ca^{2+} influx into the cell, and leads to feedback inhibition of transmitter release. Postsynaptic $GABA_B$ receptors function as K^+ channels by allowing a slow, G protein–dependent K^+ current to leak out of the cell, and leads to cell hyperpolarization (since positive ions have left the inside of the cell membrane).[36]

Baclofen is the only pharmacologic $GABA_B$ receptor ligand in current clinical use. It directly activates the $GABA_B$ receptor and, through its action in the spinal cord, leads to reduction in muscle tone. Thus it is used primarily to relieve spasticity after CNS injury. When administered systemically, it has a significant side-effect profile, including hypotension and bradycardia.[35] Systemic side effects have been minimized with intrathecal administration via an indwelling catheter and pump.[37,38] Indeed, intrathecal baclofen infusion has emerged as an alternative to the more invasive dorsal rhizotomy in the treatment of spasticity refractory to medical therapy in pediatric patients.[39] Although intrathecal baclofen delivery systems are effective, they have a 10% to 20% failure rate over time. When an intrathecal baclofen pump fails, patients can develop baclofen withdrawal symptoms characterized by agitation, increasing spasticity and dystonia, hypertension, tachycardia, hyperthermia, and potentially death.[39] Thus baclofen withdrawal should be considered in the differential diagnosis of an agitated child with an indwelling baclofen pump.

Major Anatomic Organization of the Nervous System

The nervous system in mammals is organized along an evolutionarily conserved axis. It can be divided anatomically and functionally into the central and peripheral nervous systems. Broadly speaking, the CNS consists of the spinal cord and the brain inside the skull. All other components, such as nerves after they leave the spinal canal or exit the brain as well as autonomic ganglia in the body, comprise the PNS. The general subdivisions are shown in Figure 57-2. The following sections focus on well-defined functions of these subdivisions as well as on their clinical relevance in pediatric critical care medicine.

Central Nervous System

Spinal Cord

The spinal cord is organized into segments delineated by the exiting spinal nerves. In humans, there are 31 segments: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal.[40] The first seven cervical nerves exit the spinal canal above the corresponding vertebra, that is, the C1 nerve exits between the occiput and the C1 vertebra (the atlas). Since in humans there are only seven cervical vertebra and eight cervical nerves, the last cervical nerve, C8, exits the spinal canal between C7 and T1. From T1 on, each corresponding spinal nerve exits the spinal cord below its corresponding vertebra, that is, the T12 nerve exits between T12 and L1. Early in fetal life, the spinal cord extends throughout the entire length of the spinal canal. Beginning in gestation week 12, the growth rate of the vertebrae exceeds that of the spinal cord, such that by birth in humans, the spinal cord ends at L3. During postnatal development, further differential growth occurs, and in adults, the spinal cord ends more rostrally, between L1 and L2. The nerve roots continue to exit the spinal canal through their corresponding foraminae, such that the caudal spinal roots extend past the end of the spinal cord towards their exit points and form the cauda equina. The end of the spinal cord forms an important landmark during development, since the lumbar puncture must be performed below the spinal cord in order to avoid severe injury. Hence, in infants, the preferred location of the lumbar puncture is between L4 and L5 vertebrae, with an alternate site between L3 and L4. In adults, it is safe to perform the lumbar puncture between L3 and L4, with both the L2/L3 and the L4/L5 intervertebral spaces as alternative sites.

Spinal cord lesions result in two general subsets of neurologic deficits: those caused by interruption of ascending information flow towards the brain, and those caused by interruption of descending brain control of the spinal cord circuitry and the PNS. Thus complete spinal cord transection leads to loss of sensation and muscular paralysis below the level of the lesion due to injury to the ascending sensory pathways and descending motor pathways, respectively. Immediately after the transection, paralysis is flaccid with loss of deep tendon reflexes, characteristic of spinal shock (not to be confused with neurogenic shock, see below). After a period of time, paralysis becomes spastic, with increased muscle tone and hyperactive deep tendon reflexes, due to disrupted inhibitory control of spinal cord circuitry by the brain's motor centers.

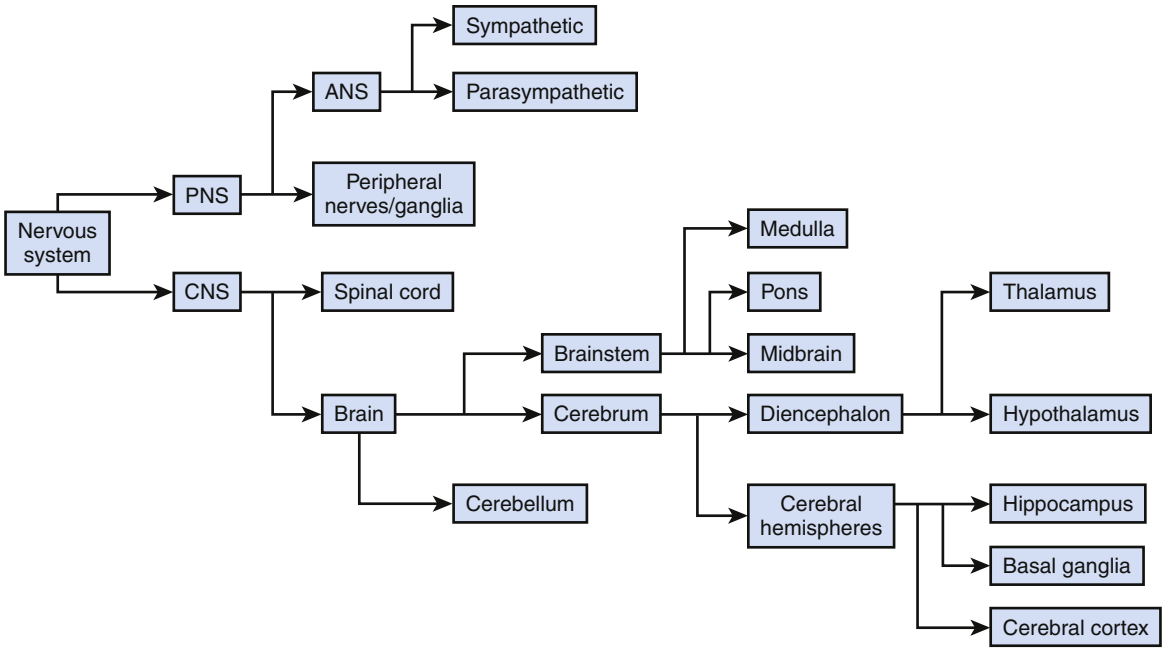

Figure 57–2. General subdivisions of the nervous system. *(Modified from Nolte J,* The human brain. An introduction to its functional anatomy, *ed 3, St Louis, 1993, Mosby–Year Book.)*

Medulla

The medulla extends rostrally from the spinal cord in the rough shape of an ice cream scoop.[40] The closed "handle" portion contains an enclosed central canal contiguous with that in the spinal cord. The open "scoop" portion is located rostrally where the central canal opens into the fourth ventricle. The medulla gives origin to four cranial nerves (CN): the glossopharyngeal (CN IX), vagus (CN X), accessory (CN XI), and hypoglossal (CN XII). It also contains decussations (crossings) of two major fiber tracts. The postsynaptic fibers from the nuclei gracilis and cuneatus, that carry tactile information from the lower and upper parts of the body, respectively, cross the midline in the caudal medulla, giving rise to the sensory decussation. The pyramidal tracts, that contain fibers descending from the motor cortex into the spinal cord, decussate slightly more rostrally, giving rise to the pyramidal, or motor decussation. These decussations are responsible for the fact that the left half of the brain controls and senses the right half of the body, and vice versa. Thus in general, damage to brain structures above the decussation gives rise to contralateral symptoms whereas damage below the decussation results in ipsilateral symptoms (except for the cerebellum as discussed below). Finally, the medulla contains the brain's respiratory control center, which is of paramount importance in determining brain death (see below). In the absence of neuromuscular blockade, complete apnea in response to rising $PaCO_2$ results only when the medulla has been extensively injured.

Although extensive damage to the medullary structures is often quickly fatal due to ensuing apnea, more localized injury produces a number of recognizable syndromes. Wallenberg, or lateral medullary, syndrome occurs when the territory supplied by posterior inferior cerebellar artery has been compromised, and consists of loss of temperature and pain sensation on the contralateral side of the body and on the ipsilateral side of the face. Additionally, Horner syndrome and varying degrees of vertigo, dysphagia, and dysarthria can be present. The medial medullary syndrome (Dejerine or inferior alternating syndrome) results from injury to the territory supplied by the anterior spinal artery or, occasionally, the vertebral artery. It is characterized by weakness or complete hemiplegia and loss of tactile and vibratory perception on the contralateral side of the body, together with preservation of temperature and pain sensation in the body and full sensation in the face. Medullary injury also occurs as a life-threatening, albeit rare, complication of tonsillectomy and adenoidectomy.[41]

Pons

The pons extends from the medulla to the midbrain, and is readily recognized by the massive, bulbous structure with horizontally-oriented fibers on its ventral surface that gives rise to its name (from the Latin, *bridge*). The pons begins at the pontine-medullary junction, characterized by a groove from which the abducens (CN VI), facial (CN VII) and vestibulocochlear (CN VIII) nerves emerge. It extends rostrally to the point of emergence of the trochlear nerve (CN IV) where it transitions into the midbrain. The trigeminal nerve (CN V) exits from the lateral aspect of the pons approximately midway between the medulla and the midbrain.

In addition to the cranial nerves, the pons contains several other important structures. Its eponymous bulb, called the basis pontis, is formed by bundles of corticopontine fibers that connect the cerebral cortex with ipsilateral pontine nuclei. Postsynaptic fibers originating in the pontine nuclei then cross the midline and form the middle cerebellar peduncle, which comprises one of the major input pathways into the cerebellum. Cerebellar output to the thalamus and other structures takes place via the superior cerebellar peduncle contained in the rostral pons. Additionally, the rostral pons contains the locus ceruleus (from the Latin, *blue spot*). Locus ceruleus

neurons utilize norepinephrine as a neurotransmitter, innervate wide-ranging areas of the brain, and likely regulate sleep and arousal.

Injury to pontine structures is of significant relevance in the PICU. First, increased intracranial pressure (ICP) from any cause may result in compression of the medially located small abducens nerve (CN VI), leading to paralysis of the lateral rectus eye muscle and associated turning in of the affected eye. Abducens nerve palsy due to increased ICP may precede the notorious fixed and dilated pupil phenomenon observed when CN III is compressed during impending uncal herniation (see below). Second, damage to the rostral pons (or lower midbrain) results in decerebrate posturing, characterized by extension of both upper and lower extremities upon painful stimulation. Importantly, decerebrate posturing corresponds to the motor score of 2 on the Glasgow Coma Scale (GCS). Finally, infarction of the basis pontis with sparing of the more dorsal pontine structures results in the "locked-in" syndrome. The locked-in state is characterized by complete paralysis of all voluntary muscles except the muscles of ocular movement and by complete cognitive awareness. Since the locked-in patient can communicate only via eye gaze, recognition of the locked-in state by the physician requires extreme diligence in patients with brainstem lesions, lest the patient be misdiagnosed as comatose, with potentially dire consequences.

Midbrain

The midbrain is the most rostral and the smallest of the brainstem structures. It is characterized by the presence of the bilateral inferior and superior colliculi on its dorsal surface. Additionally, the oculomotor nerve (CN III) emerges from its ventral surface, immediately below the temporal lobe of the cerebral hemisphere. The midbrain contains structures important for hearing, sound localization, and generation of saccadic eye movements. Furthermore, the substantia nigra in the midbrain contains neurons that utilize dopamine as their neurotransmitter. These dopaminergic neurons project to the basal ganglia where dopamine release participates in initiation of voluntary movements, to the limbic system in the cerebral cortex where dopamine plays a role in reward and emotion, and to the frontal and temporal cortices, indicating that dopamine affects thought and memory. Destruction of dopaminergic substantia nigra neurons underlies the pathology of idiopathic Parkinson disease in older individuals and of Parkinsonian symptoms in drug abusers exposed to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, sometimes a contaminant in heroin preparations.

Two clinical phenomena of significant importance in pediatric critical care medicine arise from damage to midbrain structures. First, global injury to the midbrain results in decorticate posturing, characterized by flexion of upper extremities and extension of lower extremities in response to painful stimulation. Decorticate posturing corresponds to a motor score of 3 on the GCS. Second, the "blown" pupil universally recognized as a sign of increased ICP and impending transtentorial brain herniation results from compression of the oculomotor nerve (CN III) as it exits the midbrain. Pupillary dilatation results from compression and inactivation of the parasympathetic fibers that run on the outer surface of CN III and which are actually responsible for pupillary constriction. When these fibers are damaged, unopposed sympathetic stimulation arising from the cervical sympathetic ganglia results in a constitutively dilated pupil that cannot constrict in response to light stimulation, or in other words, is "fixed." Unilateral fixed and dilated pupil is an emergency that requires immediate medical and/or surgical intervention.

Reticular Formation

The brainstem reticular formation is not a separate anatomic structure but is instead distributed throughout the core of the brainstem from the medulla into the midbrain. It plays a fundamental role in arousal and consciousness, control of movement and sensation, and in regulation of visceral functions. A subset of the reticular formation neurons sends fibers to the intralaminar thalamic nuclei, which in turn project widely throughout the cerebral cortex. Damage to these ascending brainstem fibers, collectively called the ascending reticular activating system, results in loss of consciousness and coma, even in the absence of any damage to the cerebral hemispheres. Thus the cerebral cortex requires input from the brainstem to maintain awareness and arousal. In addition, the reticular formation contains neuronal circuits responsible for regulation of respiration, for cardiovascular responses to blood pressure and oxygen level modulations, as well as for coordination of swallowing and other oromotor functions. Finally, complex reflexes such as walking and maintenance of body orientation with respect to gravity are coordinated by the brainstem reticular formation and may occur in the absence of input from higher brain regions. Immaturity of the brainstem reticular formation, in particular of its serotonergic component, has been implicated in the etiology of SIDS.[14]

Cerebellum

The cerebellum overlies the majority of the brainstem and is separated from the cerebral cortex by a sheetlike reflection of the dura mater, called the tentorium cerebelli. Hence, the brainstem and the cerebellum are referred to as infratentorial structures while the cerebral cortex and the diencephalon are referred to as supratentorial structures. The cerebellum consists of a midline vermis and two large cerebellar hemispheres.[40] The outer surface of the cerebellum consists of a three-layered cortex, which includes the outer molecular layer, the Purkinje cell layer, and the granular layer. The molecular layer contains mostly axons and dendrites. The Purkinje cell layer contains the eponymous large GABA-ergic neurons that constitute the sole cerebellar output. Finally, the granular layer contains small granule cells that interact with other granule cells and with Purkinje neurons. In addition to the cerebellar cortex, each cerebellar hemisphere also contains a set of deep nuclei. From lateral to medial, these are the dentate, the interposed, and the fastigial nuclei.

Cerebellar function has traditionally been confined to regulation and coordination of movement of the eyes, head, and body in space. However, evidence from neuroanatomic and functional neuroimaging studies has suggested that the cerebellum, and in particular the dentate nucleus, plays a significant role in cognition, memory, and language.[42,43] Consequently, lesions to the cerebellum are characterized by ataxia, ipsilateral dysmetria, and intention tremor as well as by scanning speech, in which each syllable is produced slowly and separately, and by disorders of memory and executive function.[43] In the PICU, cerebellar lesions are seen most frequently in the setting of infratentorial tumors but also occasionally in cerebellar strokes.

Diencephalon

The diencephalon consists of four major structures: thalamus, hypothalamus, subthalamus, and epithalamus. Of these, only the thalamus and the hypothalamus will be discussed in detail as they serve crucial functions relevant to pediatric critical care medicine. The thalamus is the major relay station for all sensory information except olfaction as it travels from peripheral sensory organs to the cerebral cortex. For example, optic nerve neurons carrying visual information synapse onto neurons in the lateral geniculate nucleus in the thalamus, which process and transmit the signal to the primary visual cortex in the occipital lobe. Furthermore, the thalamus participates in coordination of motor activity via multiple neuronal loops that connect the cerebellum with the basal ganglia and the cerebral cortex.[43] Lastly, inhibitory thalamic nuclei such as the reticular nucleus (distinct from the brainstem reticular formation) are thought to participate in gating of attention and consciousness.[44]

Injury to the thalamus occurs frequently in both term and preterm neonates exposed to hypoxia-ischemia at birth.[45] Additionally, thalamic necrosis is observed in infectious encephalitis, particularly that associated with the influenza virus[46,47] and *Mycoplasma pneumoniae*.[48] Vascular diseases, such as occlusion of the basilar artery or systemic lupus erythematosus can result in thalamic injury that can occasionally be reversible.[49] Apparent life-threatening events have been rarely associated with thalamic lesions.[50] Thalamic damage is associated with a wide range of symptoms, including pure sensory loss due to destruction of sensory relay nuclei, acute abnormalities in mental status, labile emotions, and motor dysfunction.

The hypothalamus is located inferior to the thalamus and plays a major role in regulation of emotion, homeostasis, circadian rhythms, and ANS function. Most importantly, it controls hormone release in the pituitary gland via two separate pathways. Large hypothalamic neurons in the supraoptic and paraventricular nuclei project their axons via the pituitary stalk into the posterior pituitary lobe (neurohypophysis), where they release antidiuretic hormone (ADH) and oxytocin directly into the bloodstream. ADH promotes water reabsorption in the kidney, whereas oxytocin participates in parturition and milk secretion. Damage to the posterior pituitary produces diabetes insipidus. Hypothalamic projections into the anterior pituitary (adenohypophysis) also travel down the pituitary stalk and release a multitude of release-promoting or release-inhibiting factors into the pituitary portal vein.[40] These factors then control the release of all anterior pituitary hormones, including adrenocorticotropic hormone, thyroid stimulating hormone, growth hormone, prolactin, and luteinizing/follicle-stimulating hormone. Of these, only prolactin release is constitutively inhibited by the hypothalamus, while the release of all remaining pituitary hormones is under positive control. Thus, transection of the pituitary stalk, as can occur during skull base and pituitary surgery,[51] results in panhypopituitary syndrome characterized by diabetes insipidus, hypothyroidism, cortisol deficiency, and hyperprolactinemia.

Damage to hypothalamic nuclei, in addition to disrupting control of the pituitary gland, also results in emotional lability, aggression, and extreme overeating or anorexia leading to rapid weight gain or loss, respectively. Thus overwhelming aggression combined with acute weight changes should raise suspicion for a hypothalamic tumor in a child.

Basal Ganglia

The basal ganglia are a set of deep nuclei that reside below the surface of the cerebral cortex and surround the thalamus. They are comprised of the caudate, putamen, and globus pallidus, as well as by the substantia nigra and the subthalamic nucleus. The caudate receives most of its input from the prefrontal cortex and projects via the globus pallidus and thalamus back to the prefrontal cortex. It is thus involved with cognitive function, and tends to be one of the nuclei that degenerate slowly over time after a hypoxic-ischemic insult to the cortex. The putamen receives most of its input from the somatosensory and motor cortices, and, like the caudate, projects back to these cortices via the globus pallidus and thalamus. The putamen plays a major role in coordination of motor function. The globus pallidus serves as an inhibitory modulator in the cortex–basal ganglia–thalamus–cortex loop. Hence, deep brain stimulation in the globus pallidus in patients with Parkinson's disease results in resolution of motor symptoms attributable to hyperactivity in the loop, such as tremor and rigidity. The substantia nigra contains dopaminergic neurons that project to the other nuclei in the basal ganglia and participate in initiation and coordination of voluntary movement.

The basal ganglia are the site of injury in multiple processes in pediatrics. They are often injured by hypoxia and hypoglycemia due to interruption of energy supply. Similarly, carbon monoxide poisoning effectively prevents oxygen delivery to the basal ganglia, resulting in characteristic neuroradiologic findings.[52] A number of metabolic diseases, including methylmalonic acidemia, Leigh disease, maple syrup urine disease, and glutaric acidemia type II also result in degeneration in the basal ganglia. The basal ganglia accumulate iron and copper, and consequently can be injured by iron overload or in Wilson disease. Finally, a juvenile form of Huntington disease presents with characteristic degeneration in the caudate nucleus.[52] Clinical signs of injury to the basal ganglia are often nonspecific: lethargy, irritability, and decreased mental status. Movement disorders such as dystonia or chorea can be seen early in the course of injury but are relatively uncommon, being more likely to emerge with chronic deterioration in basal ganglia function.

Cerebral Hemispheres

The cerebral hemispheres are the most rostral part of the CNS, and in humans and some other mammals, are characterized by extensive folding of the cerebral cortex. The folding greatly expands the area of the cerebral cortex that can fit into the cranial vault. In humans, the cortical sheet has an area of 2.5 square feet when all the folds are flattened, yet the surface area of the adult skull is closer to 0.5 square feet. The folds consist of ridges termed gyri (singular, *gyrus*), and spaces separating the ridges termed sulci (singular, *sulcus*). Although the detailed organization of each gyrus and sulcus is quite individualized, the larger organizational features are common to all mammals.

Each cerebral hemisphere is divided into four lobes: frontal, parietal, temporal, and occipital (Figure 57-3). The frontal lobe extends caudally from the rostral pole of the brain to the central sulcus and inferolaterally to the lateral sulcus. The

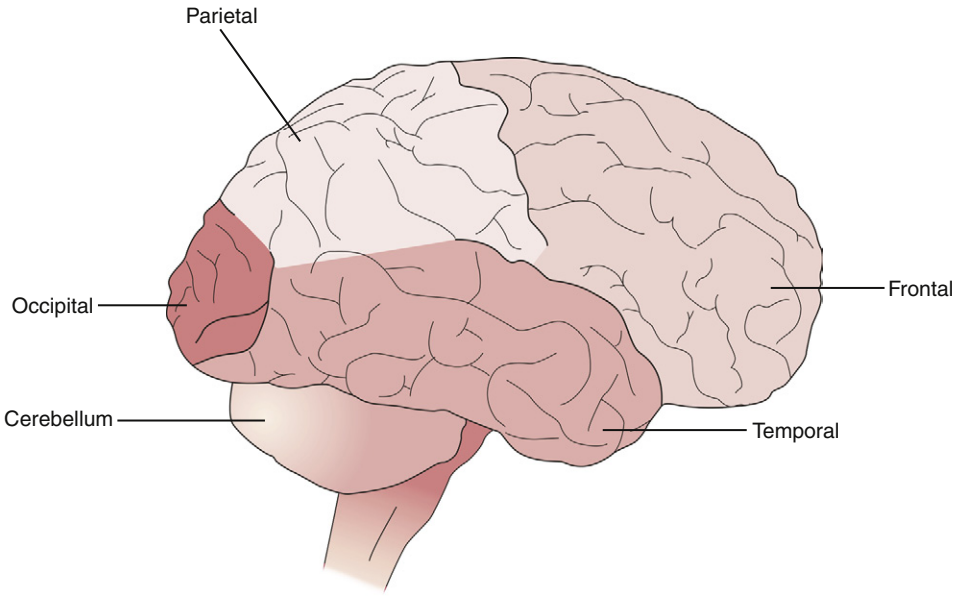

Figure 57–3. General subdivisions of the human cerebral cortex. Note that the cerebellum is not part of the cortex but is labeled for clarity.

parietal lobe begins at the central sulcus and extends caudally to the parietooccipital sulcus. Inferolaterally, the parietal lobe is bounded by the lateral sulcus and the imaginary line connecting the extension of the lateral sulcus with the parietooccipital sulcus. The temporal lobe is delineated primarily by the lateral sulcus. Finally, the occipital lobe resides posteriorly to the parietooccipital sulcus. Each of the four lobes performs dedicated functions, some of which are symmetric, occurring in both hemispheres, whereas others are lateralized, specific to either the right or the left cerebral hemisphere.

The frontal lobe is divided into four cortices, reflecting its functional organization. The primary motor cortex, located on the precentral gyrus, directly controls volitional movement on the contralateral side via upper motoneurons projecting to the lower motoneurons in the spinal cord. Moving rostrally, the premotor cortex is involved in planning, coordination and initiation of movement. The most rostral part of the frontal lobe, the prefrontal cortex, is generally associated with personality and foresight/planning. Additionally, one side of the frontal lobe, usually the left, contains the Broca area on its inferolateral surface. The Broca area participates in the production of spoken and written language.

The parietal lobe contains the primary somatosensory cortex, which is located on the postcentral gyrus and which receives all tactile and proprioceptive sensory information from the contralateral side of the body. The parietal cortex posterior to the primary somatosensory cortex possesses quite lateralized functional areas, with cortex on the left usually involved with language processing and comprehension, and that on the right responsible for perception of space and special orientation. The occipital lobe is generally devoted to vision in humans, containing the primary visual cortex and several secondary visual areas. The temporal lobe, on the other hand, serves more diverse functions. It contains the primary auditory cortex, which receives all auditory stimuli from the periphery. The temporal lobe also encompasses the hippocampus and the limbic system, thus participating in learning, memory, and emotion.

Peripheral Nervous System

The peripheral nervous system is generally divided into two components: the somatic PNS, which includes the peripheral nerves carrying information to and from muscle and skin, and the visceral (or autonomic) PNS, which regulates homeostatic bodily functions and mainly innervates visceral organs such as the heart, lungs, and intestines. Dysfunction of both the somatic and the autonomic systems contributes to the breadth of pathology encountered in pediatric critical care medicine, thus requiring the pediatric intensivist to be familiar with the basic organizational and functional principles of the PNS.

Somatic Peripheral Nervous System

The somatic PNS consists of efferent nerve fibers carrying information to muscle and skin, peripheral sensory receptors, and afferent nerve fibers carrying information from the periphery to the CNS. The efferent fibers emerge from neurons located in the spinal gray matter and exit the spinal cord via the ventral root. The afferent sensory fibers belong to neurons located in dorsal root ganglia, which send an axonal branch into the spinal cord via the dorsal root. The efferent and the afferent fibers travel together between the dorsal root ganglia and the target organ in the peripheral nerve. Diseases of the somatic PNS relevant to pediatric intensive care are generally disorders of myelination, such as Guillain-Barré syndrome, and are discussed in detail in Chapter 64).

Visceral or Autonomic Peripheral Nervous System

The autonomic nervous system regulates bodily functions that do not necessarily require conscious control or awareness, such as heart rate, blood pressure, sphincter function, and digestion. The ANS is divided into three distinct components: the enteric, parasympathetic, and sympathetic nervous systems. The enteric nervous system consists of the myenteric plexus of Auerbach and the submucosal plexus of Meissner,

both located in the wall of the alimentary canal. The enteric nervous system interacts with the CNS and the parasympathetic and sympathetic components of the ANS but can function entirely independently. It is responsible for sensation and coordination of peristalsis in the gut. Neurons in the enteric nervous system arise from the same progenitors as neurons in the CNS. Hence, many neurologic disorders concomitantly affect both the central and the enteric nervous systems, including irritable bowel syndrome, anxiety, and depression.[53]

Sympathetic Nervous System

The sympathetic nervous system consists of preganglionic and postganglionic components. Preganglionic fibers originate from neurons in the thoracolumbar region of the spinal cord, giving the sympathetic ANS its anatomic name: the thoracolumbar outflow. Preganglionic fibers exit the spinal cord via the ventral roots with the thoracic and lumbar nerves. After traveling together for a short distance, the preganglionic fibers diverge from the spinal nerves and enter the sympathetic ganglia via the white communicating rami (preganglionic fibers are thinly myelinated; hence, white). The preganglionic fibers carrying output to the head, thorax, and limbs synapse onto neurons in sympathetic ganglia located close to the spinal cord. These ganglia form the paravertebral sympathetic chain that extends from the cervix to the coccyx. The preganglionic fibers carrying output to the abdominal and pelvic viscera synapse onto cells located in sympathetic ganglia further away from the spinal cord, called the prevertebral ganglia. These include the celiac, the superior mesenteric, and the inferior mesenteric ganglia. Postganglionic neurons from either the paravertebral or prevertebral ganglia send their fibers to the target organs via the gray communicating rami (postganglionic fibers are unmyelinated, and, hence, gray). In the sympathetic ANS, preganglionic neurons use acetylcholine as a neurotransmitter, whereas postganglionic neurons utilize norepinephrine at the target organs. The exception is the sweat glands, which receive postganglionic sympathetic fibers utilizing acetylcholine.[40]

The sympathetic ANS generally functions to prepare the body for states of increased energy expenditure. Activation of the sympathetic ANS leads to increased heart rate, decreased peristalsis, redistribution of blood from the gut to the peripheral muscles, and pupillary dilatation (mydriasis). Furthermore, the sympathetic ANS directly innervates the adrenal medulla, and when activated, stimulates the medulla to release norepinephrine and epinephrine into the systemic circulation. Systemic catecholamine release produces relatively global and long-lasting effects. In critical care, a significant component of vasopressor support relies on mimicking the effect of sympathetic ANS activation with exogenously administered epinephrine and norepinephrine.

Although autonomous, the sympathetic nervous system is under significant central control. Interruption of the descending control pathways, such as occurs with spinal cord trauma above the level of T1, results in sudden loss of sympathetic tone, causing profound bradycardia and hypotension. This syndrome, termed neurogenic or spinal shock, emerges early after injury and requires aggressive pharmacologic intervention in order to minimize secondary insults resulting from hypoperfusion of the injured spinal cord.[54,55]

Parasympathetic Autonomic Nervous System

The preganglionic fibers of the parasympathetic ANS originate in the brainstem and sacral spinal cord. Hence, the parasympathetic ANS comprises the craniosacral outflow. The brainstem preganglionic fibers travel along cranial nerves III, VII, IX, and X, while the sacral preganglionic fibers travel with the pelvic splanchnic nerves. Parasympathetic ganglia are located close to their targets, unlike the ganglia in the sympathetic ANS. The parasympathetic ANS, also unlike its sympathetic counterpart, utilizes acetylcholine as a neurotransmitter both in presynaptic and postganglionic neurons. Target organs for the cranial portion of the parasympathetic ANS include the ciliary muscle and pupillary sphincter, innervated by CNIII via the ciliary ganglion; lacrimal and salivary glands; as well as the majority of thoracic and abdominal organs innervated by the vagus nerve (CNX). The sacral portion innervates the bladder and genitalia.

The parasympathetic system, in general, exerts effects opposite to those of the sympathetic ANS. Thus ACh release from parasympathetic fibers causes bradycardia, hypotension, increased gastrointestinal motility, and pupillary constriction. In critical care, atropine, a competitive antagonist of the muscarinic ACh receptor, is used to prevent or treat bradycardia associated with poor perfusion.[56]

Meninges

The CNS is protected by three membranous layers, which anchor the brain within the skull, contain CSF, and form the anatomic basis of the cerebral venous sinuses. From the outside in, these are the dura mater, arachnoid, and pia mater. Dura mater, often simply called dura, is physically the most substantial of the three membranes and is called the pachymeninx. The arachnoid and the pia together are referred to as leptomeninges. The dura attaches firmly to the inner surface of the skull and arachnoid. Under normal circumstances, no open space exists either between the dura and the skull (the epidural space) or between the dura and the arachnoid (the subdural space). Under pathologic conditions, however, blood can dissect the epidural and/or the subdural potential spaces to form potentially life-threatening hematomas. The dura's blood supply is provided by the middle meningeal artery, which traverses between the skull and the outer dural surface. Trauma to the skull and the middle meningeal artery can lead to an epidural hematoma. The dura also forms the cerebral venous sinuses into which cerebral veins drain. Rupture of the veins as they leave the brain and enter the venous sinuses can lead to a subdural hematoma.

The arachnoid membrane is significantly thinner than the dura, consisting of several cell layers and a spider web–like collagen network. Whereas it adheres to the dura on the outer surface, on the inner surface it is connected to the pia via thin strands of connective tissue called arachnoid trabeculae. The space between the arachnoid and the pia (subarachnoid space) forms the only true fluid-filled space around the brain, containing CSF, and forming the basis for CSF cisterns throughout the CNS. CSF from the subarachnoid space returns to the venous circulation via special adaptations in the arachnoid membrane called the arachnoid villi. Arachnoid villi protrude from the arachnoid into the dural venous sinuses and contain

special channels that allow the CSF to flow out of the subarachnoid space into the venous blood. Additionally, cerebral arteries and veins run in the subarachnoid space before diving below the brain surface. Hence, injury to these vessels results in subarachnoid hemorrhage.

The pia mater is the most delicate of the three membranes. Unlike the dura and the arachnoid, it follows the surface of the brain, diving into every sulcus and following blood vessels for some distance as they enter the brain. Around these blood vessels, it gives rise to potential perivascular spaces called the Virchow-Robin spaces that serve as a significant reservoir of malignant cells in pediatric leukemia and lymphoma, necessitating CNS irradiation and chemoprophylaxis.

Blood-Brain Barrier

Anatomy

Two experiments more than 100 years ago demonstrated conclusively the presence of a physical barrier between circulating blood and the brain. In 1885, Ehrlich injected a dye intravenously to show that the dye failed to stain the brain while staining almost all other internal organs.[57] In 1909, Goldman conducted the reverse experiment, injecting dye into the CSF to show that the dye stained the brain but did not penetrate into the general circulation.[58] Modern anatomical studies revealed that, actually, three physical barriers separate the blood and the brain: the BBB, established by the endothelial capillary cells in the brain; the blood-CSF barrier (BCSFB), established by cells in the choroid plexus; and finally, the CSF-brain barrier, comprised of ependymal cells lining the surface of the ventricles. All three systems shield the brain from changes in ionic and biochemical milieu that may jeopardize neuronal function, and all three are important for accomplishing drug transport into and out of the brain parenchyma.[59] However, from the standpoint of clinical relevance to pediatric critical care medicine, the subsequent discussion will focus primarily on the BBB and BCSFB.

The cellular component of the BBB in mammals comprises specialized endothelial cells in brain capillaries, pericytes, and foot processes of brain astrocytes as well as neurons (Figure 57-4). Endothelial cells in the brain are linked together by tight junctions, which prevent paracellular diffusion of substances from blood into the brain. The endothelial tight junctions in the brain possess extremely high electrical resistance, resulting in the exclusion of even small ions such as K^+ and Na^+.[60] In addition, the absence of fenestrations, high metabolic rate, and low vesicular transport in endothelial cells severely limit transcellular diffusion of water-soluble substances through the cell membrane. Pericytes surround the endothelial cells and display both contractile and phagocytic properties. Their presence likely contributes to the impermeability of the endothelial tight junctions, as well as to blood vessel reactivity[61] and vessel wall elastic properties in the brain.[62] Pericytes in turn are ensheathed by perivascular astrocytes,which extend cellular processes, known as "end feet," toward the brain vasculature.[60] The astrocytes are critical for the proper development of the brain-specific phenotype of endothelial cells comprising the BBB.[63] Finally, neurons have been shown to innervate the brain capillary endothelial cells directly, although their exact role in BBB function remains unknown.[64]

In addition to the cellular components, the BBB also contains two distinct and important acellular components: the basement membrane and the extracellular matrix. At present, the role of the extracellular matrix in maintaining or establishing the BBB is unknown. The role of the basement membrane, on the other hand, is better characterized. The basement membrane surrounding small draining venules consists of the endothelial layer, immediately adjacent to the brain capillary endothelium, and the parenchymal layer, which is adjacent to astrocyte end feet. Interposed between the two basement membranes is a layer of meningeal epithelium. Around the capillaries, however, the meningeal epithelium disappears, and the two layers of the basement membrane fuse to form a composite structure.[60] The basement membrane generally consists of four major types of glycoproteins: collagen type IV, laminin, nidogen, and heparan sulfate proteoglycan.

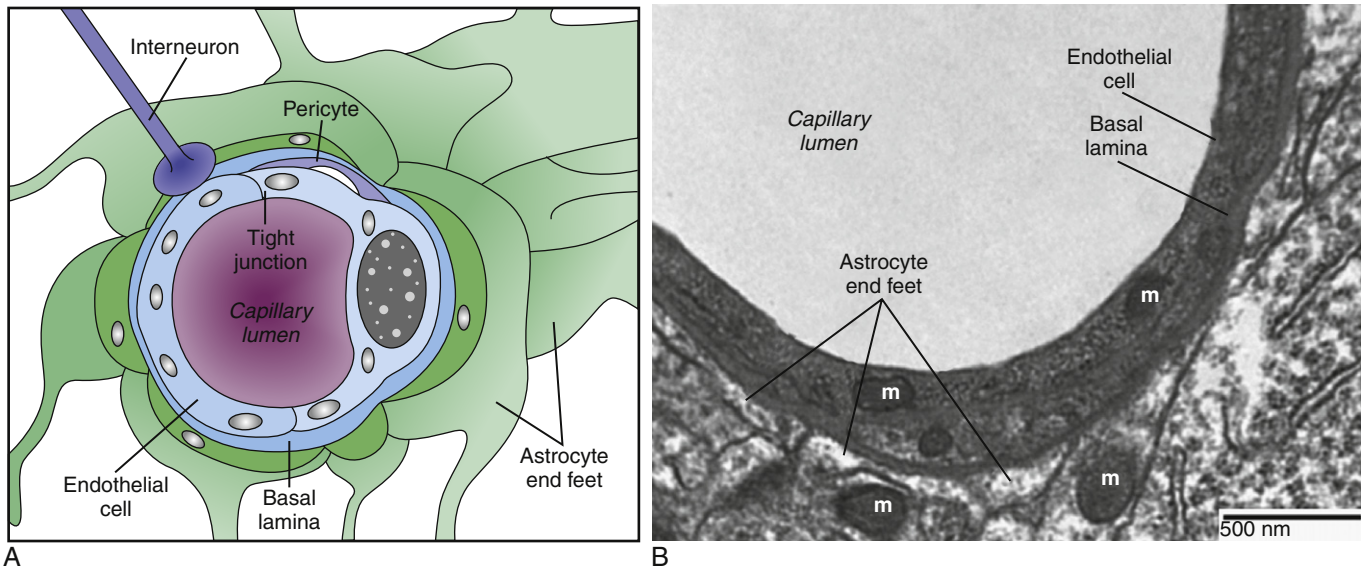

Figure 57–4. **A,** Schematic representation of the major anatomic features contributing to the BBB. It should be noted that endothelial cells surrounding the capillary are linked by tight junctions. **B,** An electron micrograph from mouse brain showing a brain capillary in cross-section. The BBB is an active structure, with high energy demands. Hence, BBB endothelial cells and astrocytes possess a large number of mitochondria (*m*).

The clinical relevance of these proteins, although not fully understood at this time, is underscored by mutations in collagen type IV that result in intracerebral hemorrhage and porencephaly in rodents and in humans.[65,66]

Selectivity

If the BBB limits the penetration of substances into the CSF, then how is transport of energy sources, signaling molecules, and drugs from blood into the CSF accomplished? Three general transport mechanisms allow chemicals to penetrate from the circulation into the CSF: (1) diffusion of lipid-soluble molecules; (2) receptor-facilitated transport, either energy-dependent or independent; and (3) ion channel-mediated transport. Additionally, several groups of transporters are dedicated to actively pumping substances out of CSF into the circulation.

As a general rule, lipid-soluble substances penetrate into CSF by diffusing across the endothelial plasma membrane, whereas water-soluble substances require active transport to cross the BBB. This property is illustrated by Figure 57-5, which demonstrates uptake of substances into the brain as a function of their oil-water partition coefficient. Compounds such as benzodiazepines, nicotine, and heroin are highly lipid-soluble and penetrate readily into the CSF. The synthetic opiate fentanyl induces the narcotic effect more rapidly than morphine because fentanyl is more lipophilic. The concentration of a lipophilic substance in the CSF is generally directly proportional to its concentration in the plasma. In contrast, mannitol and sodium ions are extremely water-soluble, do not penetrate into the CSF across the intact BBB, and are thus used clinically to increase serum osmolality relative to that of CSF and to draw water out of the brain in order to decrease ICP. Lipophilic substances with a significant protein-bound fraction (e.g., phenytoin) constitute an exception to the generalization that lipid-solubility and plasma concentration determine CSF concentration. Consequently, in the case of phenytoin and its commonly used prodrug fosphenytoin, therapeutic levels are determined by plasma, or free, concentration, rather than the total concentration, which includes the protein-bound fraction.

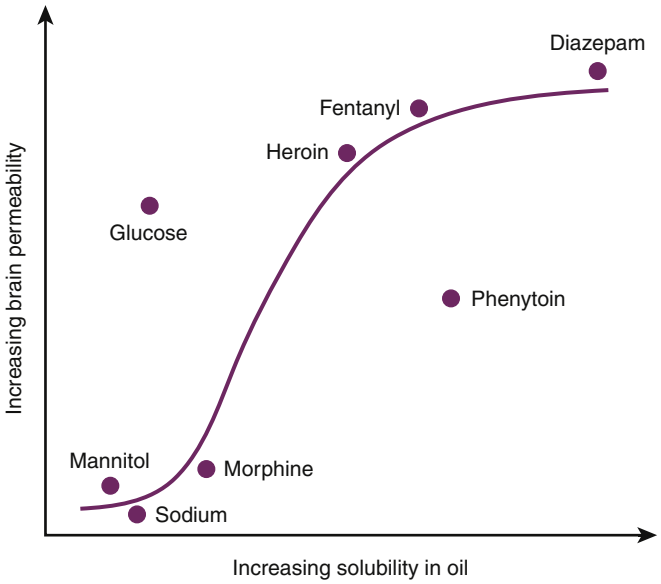

Figure 57–5. Lipid solubility predicts penetration across the blood-brain barrier (*BBB*). Substances to the left of the curve, such as glucose, cross the BBB at a higher rate than would be predicted on the basis of their oil solubility. These substances are transported by carriers across the BBB via either an energy-dependent or energy-independent process. In contrast, substances to the right of the curve, such as phenytoin, are highly lipid-soluble but are transported across the BBB out of the brain milieu. *(Adapted from Laterra J, Goldstein GW: Ventricular organization of cerebrospinal fluid: blood-brain barrier, brain edema, and hydrocephalus. In Kandel ER, Schwartz JH, Jessel TM, editors:* Principles of neural science, *New York, 2000, McGraw-Hill.)*

Receptor-facilitated transport across the BBB can be grouped into processes that require energy and those that do not. The best studied and perhaps most clinically relevant example of receptor-facilitated energy-independent transport is delivery of glucose from plasma into the CSF by the GLUT1 transporter. GLUT1 is a 492 amino-acid membrane protein that resides both on the luminal (facing the plasma) and the abluminal (facing the CSF) surfaces of the endothelial plasma membrane.[67] GLUT1 transports glucose down the concentration gradient, and can function in a bidirectional manner. The flow of glucose from plasma into the CSF, rather than in the opposite direction, is ensured by 1) higher plasma glucose concentration (approx 3:2 of CSF); 2) high glucose utilization rate by neurons and glia in the CNS such that glucose delivered into the CSF is exhausted rather quickly; and 3) higher density of GLUT1 transporters on the abluminal surface compared to the luminal surface.[68] In addition, metabolic factors such as hypoxia and ischemia exert transcriptional control over expression and distribution of the GLUT1 transporter, suggesting the existence of tightly-controlled mechanisms regulating glucose delivery into the CSF under stressful conditions. Recently, a disorder characterized by GLUT1 deficiency has been recognized in a subset of infants with developmental delay, intractable epilepsy, and delayed myelination.[69] Identification of the molecular underpinning of this disorder was driven by the clinical finding of low CSF glucose concentration (hypoglycorrhachia) on repeated lumbar punctures despite normal plasma glucose concentrations in two original patients from the study, highlighting the importance of biochemical BBB function.

While the energy-independent GLUT1 plays an important role in delivering its substrate down the concentration gradient into the CSF, energy-dependent transporters of the ATP-binding cassette (ABC) family function primarily to pump substances against the concentration gradient out of the CSF into plasma.[70] The ABC family of transporters is divided into seven known groups (A through G), of which groups B, C, and G are highly expressed on BBB endothelial cells. The best-described members of this family include the multidrug resistance (MDR) proteins, such as the P-glycoprotein (PgP), and the multidrug resistance-associated proteins (MRP). Human PgP transports a wide range of chemically and structurally diverse substances out of the CSF, including dexamethasone, phenytoin, ondansetron, and chemotherapeutic agents such as etoposide and vincristine.[70] MRPs also contribute to the ATP-dependent efflux of drugs such as 6-mercaptopurine, methotrexate, and, interestingly, pravastatin. The latter belongs to a class of drugs, hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitors, that confer protective effects in experimental models of ischemic and traumatic brain injury[71,72] and reduce stroke risk in humans by approximately 30%, to some extent independent of the reduction in cholesterol levels.[73] Thus, increasing the intracerebral levels of HMG-CoA reductase inhibitors via reduction in MRP-dependent efflux may represent a therapeutic strategy aimed at ameliorating

the effect of trauma and hypoxia on the brain parenchyma. Indeed, the general strategy of inhibiting MDR and MRP transporters to enhance drug delivery into the CNS is currently being tested in several clinical trials.

Blood-Brain Barrier–Deficient Areas

Several areas of the brain have special adaptations in the structure of the BBB that allow the CNS control centers to monitor and interact with the rest of the body. These include the posterior pituitary, the subfornical organ, and the area postrema; in all of these areas, capillaries contain fenestrations, and the BBB is quite leaky. The posterior pituitary contains projections of the hypothalamic vasopressin-containing secretory neurons. When salt concentration increases during volume depletion, these neurons are stimulated to release vasopressin (ADH) directly into the bloodstream, leading to increased water retention in the renal tubules and restoration of intravascular volume. The subfornical organ, located at the foramen of Monro on the ventral surface of the fornix, is also involved in maintaining salt-water homeostasis. Angiotensin II production during states of decreased renal perfusion is detected by neurons in the subfornical organ, which then stimulate vasopressin-containing neurons to release vasopressin and also stimulate neurons in the lateral hypothalamus to create an overwhelming sensation of thirst. Finally, neurons in the area postrema are exposed to toxins circulating in the plasma, and stimulate the vomiting reflex. Drugs such as ondansetron are thought to prevent nausea and vomiting by blocking serotonin receptors in the area postrema. All brain regions with a leaky BBB are surrounded by specialized cells, called tanycytes. Tanycytes are connected by tight junctions that prevent uncontrolled diffusion of substances out of these homeostatic brain regions into the rest of the CSF.

Ventricles and Cerebrospinal Fluid

Ventricular system

The ventricular system arises from the hollow space within the developing neural tube and gives rise to cisterns within the CNS, from the brain to the spinal cord. In the brain, the ventricular system consists of paired lateral ventricles that connect to the midline third ventricle via bilateral foramina of Monro. The third ventricle in turn connects to the fourth ventricle located in the pons and the medulla via the aqueduct of Sylvius. The fourth ventricle terminates caudally in the central spinal canal, and continues as a miniscule midline structure through the spinal cord. The ventricles contain the choroid plexus, which produces CSF, and serve as conduits for CSF flow in the CNS. Ventricular walls are lined with ependymal cells, which are connected by tight junctions and constitute a CSF-brain barrier.

Cerebrospinal Fluid Production and Flow

CSF is produced both by the choroid epithelial cells and by the brain parenchyma, with each system contributing approximately 50 percent to new CSF production. CSF produced by the choroid plexus flows directly into the ventricles, whereas CSF produced by the brain parenchyma must cross the ependymal lining to reach the ventricular system. CSF in humans is produced at a rate of 350 μL/min, resulting in total daily CSF production of approximately 500 mL. Daily CSF production rates, when taken in context of the ventricular volume (30 mL in adults) and of the total CSF volume present in the CNS at any given time (130 mL in adults), indicate that CSF circulates out of the ventricular system where it is produced and that CSF is continuously reabsorbed.

CSF flows via foramina of Monro out of the lateral ventricles into the third ventricle, and then via the aqueduct of Sylvius into the fourth ventricle. The former two are closed systems, whereas the latter, the fourth ventricle, has three openings that connect the ventricular space with the subarachnoid space. The midline median aperture (foramen of Magendie) and the paired lateral apertures (foramina of Luschka) connect the fourth ventricle with the cisterna magna and the pontine cistern, respectively. Thus, out of the fourth ventricle, CSF flows into the subarachnoid space surrounding the brain and the spinal cord. CSF is then reabsorbed by the arachnoid villi into the superior sagittal venous sinus (Figure 57-6). Knowledge of CSF flow and reabsorption patterns allows for prediction of pathologic findings when either process is interrupted. Obstruction to CSF outflow at any point in the pathway, such as often occurs with tumors, or abnormal CSF reabsorption, such as seen in meningitis or hemorrhage due to cellular debris blocking the arachnoid villi, results in intraventricular CSF accumulation and hydrocephalus. Hydrocephalus may then lead to increased ICP and cerebral herniation, either spontaneous or iatrogenic, for example when a lumbar puncture is performed on a patient with obstruction above the level of the foramen magnum.

Cerebrospinal Fluid Composition and Function

Cells in the choroid plexus actively secrete CSF from the plasma that filters through leaky choroid plexus capillaries. The process is controlled by multiple mechanisms, resulting in CSF ionic, chemical, and cellular composition that is distinct from blood and plasma. In general, CSF contains higher magnesium and chloride concentrations and lower potassium and calcium concentrations compared with plasma. Glucose concentrations in CSF are approximately two thirds of plasma levels. CSF has very few cells and a constant protein level. As is well known, these constituents are disrupted in disease. In bacterial meningitis, glucose concentrations are lower than expected and protein concentration is increased. In contrast, in viral meningitis, CSF glucose is usually normal while protein concentration is increased. More recently, levels of various cytokines and proteins leaked from neurons and myelin sheaths have been explored as potential biomarkers of the severity and type of brain injury.[74]

The primary purpose of the CSF is to provide a supportive buoyant environment for the brain. The human brain has the consistency of an incompletely hardened bowl of gelatin. Without the CSF, the human brain flattens significantly under the force of gravity, whereas, suspended in CSF, it retains its native shape. Furthermore, CSF provides a fluid cushion against acceleration-deceleration insults that may be delivered to the brain by the surrounding skull. CSF also functions both as a source of nutrients and a relatively large-volume sink for waste and toxic substances produced in the course of normal neuronal activity. For instance, excess glutamate released at

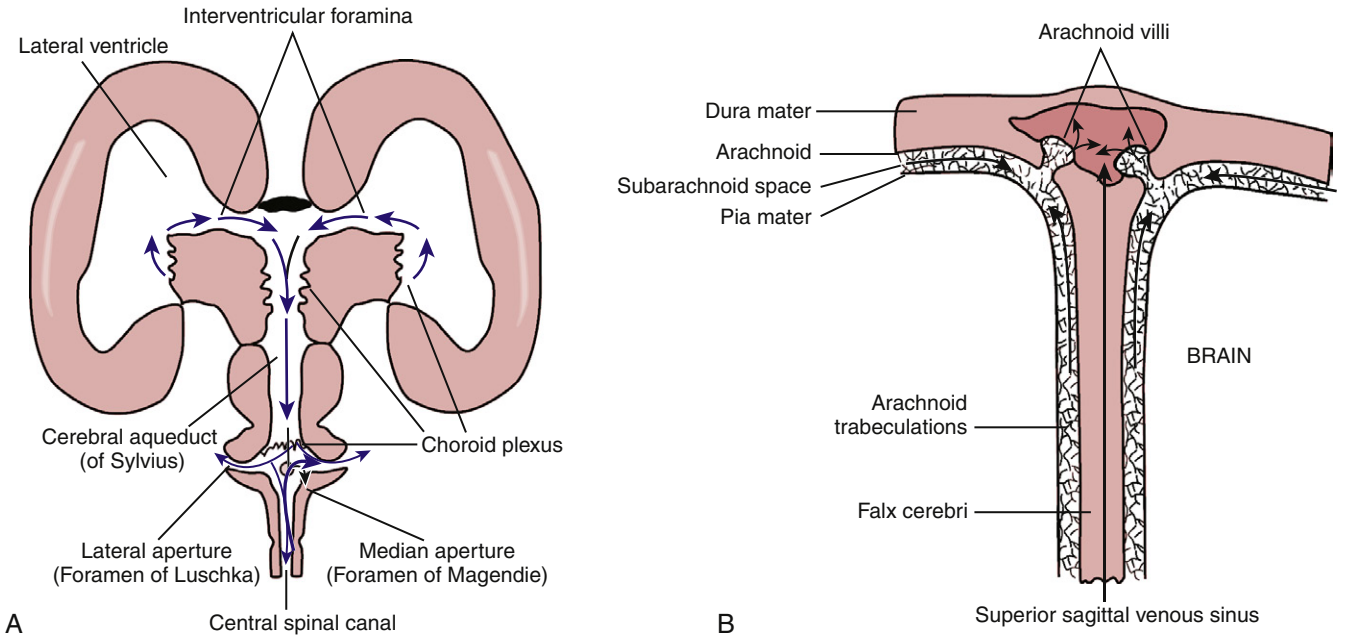

Figure 57–6. The ventricles and CSF flow. **A**, Flow of CSF from choroid plexus through the ventricular system into the subarachnoid space. the synapse rapidly diffuses into the CSF, minimizing potential excitotoxicity to both presynaptic and postsynaptic neurons. Excess magnesium ions in the CSF may also participate in the Mg^{2+} block at the NMDA receptors (see section on glutamate receptors), allowing for coincidence detection and learning.

Vasculature in the Central Nervous System

Brain Vasculature

The arterial blood supply to the brain is traditionally divided into an anterior portion supplied by the paired internal carotid arteries and the posterior portion supplied by the paired vertebral arteries. The anterior and posterior arterial circulations are interconnected at the base of the brain via circle of Willis.

The internal carotid artery originates from the common carotid artery at approximately the level of angle of the jaw in humans. It enters the skull through the carotid canal anterior to the jugular foramen, takes a relatively standard but tortuous course through the temporal bone and the cavernous sinus, and then enters the dura mater above the sinus, running horizontally inferolateral to the optic nerve. At this point, it gives off the ophthalmic artery, and a short distance later, the anterior choroidal artery and the posterior communicating artery. The former supplies several clinically relevant structures, including parts of the thalamus, hippocampus, optic tract and the internal capsule. The latter, the posterior communicating artery, forms part of the circle of Willis and connects the anterior internal carotid circulation with the posterior vertebral circulation. After generating the posterior communicating artery, the internal carotid bifurcates into major vessels supplying the brain: the anterior and middle cerebral arteries (ACA and MCA, respectively).

The bilateral ACAs connect via the anterior communicating artery at the circle of Willis. Both ACAs then run along the medial surface of the brain and supply the corpus callosum and the medial portions of the cerebral cortex on their respective sides, extending up to and including the postcentral gyrus. Thus ACA occlusion results in damage (among other areas) to the medial portions of the primary sensory and motor cortices, which correspond to the more caudal parts of the human body, such as legs, trunk, and shoulders.

While the ACA supplies blood to the medial cerebral cortex, the MCA provides blood flow to almost the entire lateral portion of the cortex. After diverging from the internal carotid artery, the MCA dives deep into the Sylvian fissure, where it supplies the insula. In addition, within the Sylvian fissure, the MCA gives off small lenticulostriate arteries that supply the thalamus and the basal ganglia. The MCA then emerges from the Sylvian fissure and divides into multiple branches responsible for nourishing the lateral components of the frontal, temporal, and parietal lobes. MCA occlusion secondary to ischemic stroke generally results in devastating neurologic deficits. Additionally, in cases of globally decreased perfusion such as seen during cardiac arrest or prolonged hypotension, the border (watershed) zone between the cortical areas supplied by the ACA and the MCA tend to be vulnerable to early injury.

The posterior circulation arises from the paired vertebral arteries, each of which gives rise to a posterior inferior cerebellar artery (PICA) before coalescing into a single basilar artery at the level of the junction between the medulla and the pons. The PICAs supply the inferior portion of the cerebellum as well as the choroid plexus in the fourth ventricle and the lateral medulla. The basilar artery proceeds rostrally and gives rise to the paired anterior inferior cerebellar and superior cerebellar arteries (AICA and SCA, respectively). At the level of the midbrain, the basilar artery bifurcates into the posterior cerebral arteries (PCA), which supply the occipital lobes and portions of the temporal lobes. In addition, the PCAs nourish

a number of thalamic sensory nuclei. Each PCA is connected to the ipsilateral internal carotid artery by the posterior communicating artery. Since the PCA supplies the areas of the thalamus concerned with sensation and cortical areas dedicated to vision, PCA occlusion often results in sensory and/or visual loss on the side contralateral to injury.

Spinal Cord Vasculature

The spinal cord is supplied by two interconnected arterial systems: the longitudinal vasculature that arises from the vertebral arteries and the segmental vasculature that arises from multiple levels along the vertebral arteries and the aorta. The longitudinal arteries consist of a single anterior spinal artery and paired posterior spinal arteries. The anterior spinal artery runs along the anterior median fissure and supplies the ventral two thirds of the spinal cord. Occlusion of the anterior spinal artery, which can occur with traumatic dissection or autoimmune arteritis, results in the anterior spinal syndrome, or Beck syndrome. Beck syndrome is characterized by symmetric weakness and loss of temperature and pain sensation with relative sparing of vibration and position sensation below the level of injury. The paired posterior spinal arteries run along the dorsal columns and supply blood to the posterior one third of the spinal cord, which includes the dorsal columns and most of the dorsal horns. Posterior spinal arteries are extensively interconnected and receive blood supply from multiple segmental arteries along their course. Thus, isolated lesions due to posterior spinal artery occlusion are rare.

The segmental arterial blood supply to the cervical spinal cord arises from the vertebral arteries via the radicular arteries, whereas that to the thoracic and lumbar spinal cord arises from the aorta via the thoracic intercostal arteries and the lumbar arteries. Both thoracic and lumbar segmental arteries give rise to smaller radicular arteries that penetrate the intervertebral foramina and supply the spinal cord. In addition, the lower thoracic aorta often gives rise to a single great radicular artery (artery of Adamkiewicz) that supplies the entire lower two thirds of the spinal column. The artery of Adamkiewicz is often the sole source of blood flow to the lower thoracic spinal cord during surgical repair of coarctation of the aorta. Thus, care is taken to ensure adequate distal perfusion pressure during cross-clamp to minimize the risk of paraplegia. In general, spinal cord watershed areas exist at the upper thoracic (T1-T4) and upper lumbar (L1) levels, where interconnections among the segmental arteries are less developed. At any given level, the interior portion of the spinal cord is most susceptible to hypoxic-ischemic injury. For example, in cases of severe cervical hyperextension, hypoxic and/or vascular injury to the central portion of the cervical spinal cord results in central cord syndrome, characterized by muscle weakness in upper extremities to a greater extent than in lower extremities, by urinary retention, and by variable degree of sensory loss.

Regulation of Cerebral Blood Flow

In healthy mammals, the perfusion of cerebral tissues is exquisitely controlled. Blood flow to the brain, as to many other vital organs, is autoregulated by homeostatic mechanisms designed to maintain adequate perfusion. Cerebral autoregulation occurs on the basis of three primary mechanisms: perfusion pressure-based autoregulation, pH-based (PCO_2-based) autoregulation, and metabolic coupling. All three play a major role in determining cerebral blood flow (CBF) in health and in disease, such as trauma and hypoxia-ischemia.

Perfusion Pressure–Related Autoregulation

Experiments in the mid-twentieth century demonstrated that normal CBF in young adults is 50 to 55 mL/100 g brain/minute, resulting in approximately 750 mL/min total CBF.[75] Thus under resting conditions, the brain receives approximately 15% of total cardiac output. In children, CBF is generally higher than in adults, on the order of 100 mL/100 g brain/min for an 8-year-old child.[76] CBF is kept relatively constant over a range of mean arterial blood pressures (MAP) by continuous adjustment of vascular tone in brain arterioles (Figure 57-7, *A*). In adults, CBF remains essentially invariant while MAP is between 50 and 150 mm Hg. Also in adults, CBF decreases and increases passively as a function of MAP when MAP is below 50 or above 150 mm Hg, respectively. The pressure-dependent autoregulatory range is different in newborns, with important clinical implications. The lower limit of autoregulation in neonates appears similar to that in adults at approximately 40 mm Hg; the upper limit, however, is much lower for infants than adults, with CBF increasing linearly as a function of MAP greater than 90 mm Hg.[77] Since infants have an MAP that is much closer to the lower limit of CBF autoregulation, even moderate hypotension in young children may severely impede oxygen delivery to the brain. Similarly, at the upper limit, moderate hypertension may result in unacceptable increases in CBF and damage to the BBB. One of the many clinical applications of this principle is the need for meticulous control of MAP in infants on cardiopulmonary bypass in order to minimize the risk of intracranial hemorrhage.

Oxygen-Related Autoregulation

CBF generally remains constant while PaO_2 remains over 60 mm Hg. When PaO_2 decreases below this threshold value, CBF increases almost exponentially as a function of PaO_2 (Figure 57-7, *B*). Several distinct pathways contribute mechanistically to oxygen-related regulation of CBF, including hydrogen and potassium ions, nitric oxide, arachidonic acid, adenosine, and ATP-sensitive potassium channels.[78,79] The shape of the PaO_2-CBF curve is explained by the hemoglobin-oxygen dissociation curve and the fact that, in humans, CBF depends on blood oxygen content and not on PaO_2.[80] When PaO_2 is less than 60 mm Hg, the percentage of oxyhemoglobin decreases sharply, significantly decreasing the blood oxygen content. CBF rises as a consequence of decreased oxygen delivery. Conversely, increasing PaO_2 above 60 mm Hg does not significantly increase blood oxygen content since hemoglobin is more than 90% saturated with oxygen at these partial pressures. Hence, in healthy people, CBF remains constant once PaO_2 crosses the threshold of 60 mm Hg.[81] Furthermore, when inspired oxygen fraction is increased further from 21% to 100%, CBF actually decreases by approximately 15% to 20%.[80] Both hypoxia-related vasodilatation and hyperoxia-related vasoconstriction may be impaired under pathologic conditions such as traumatic brain injury and may portend a poorer outcome. Nevertheless, a PaO_2 less than 60 mm Hg should be rigorously avoided in patients with increased ICP lest hypoxia-related vasodilatation further contribute to decreased compliance within the cranial vault.

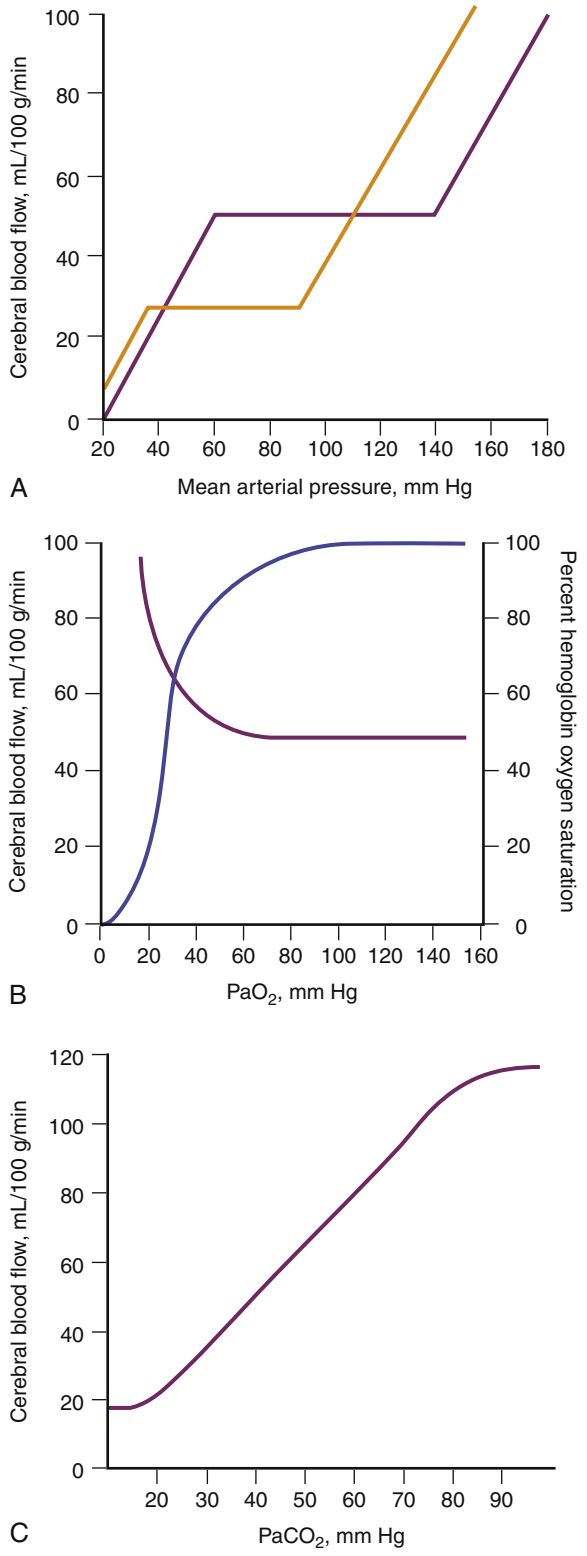

Figure 57–7. Regulation of cerebral blood flow (*CBF*). **A,** Blood pressure–dependent autoregulation, adult (*red curve*) and infant (*orange curve*). **B,** Oxygen-dependent regulation. *Red curve,* CBF (left ordinate); *blue curve,* hemoglobin-oxygen saturation curve (right ordinate). Note that CBF begins to increase at the PaO_2, at which hemoglobin oxygen saturation begins to decrease. Since oxygen delivery is determined by hemoglobin oxygen saturation to a much larger extent than by PaO_2 and dissolved oxygen in the blood, CBF in humans increases in response to decreasing oxygen delivery, which in turn is correlated with decreasing PaO_2. **C,** $PaCO_2$-dependent regulation CBF should increase linearly with $PaCO_2$ except at the extremes of the physiologic range.

Hydrogen Ion–Related Autoregulation

CBF is directly proportional to perivascular pH and, therefore, inversely proportional to the perivascular hydrogen ion concentration. In clinical practice, this relation translates into dependence of CBF on $PaCO_2$, since $PaCO_2$ is related to pH via the bicarbonate buffer system. Within a $PaCO_2$ range from 20 to 100 mm Hg, CBF increases by 2.5% to 4% for every 1 mm Hg increase in $PaCO_2$.[82] No further changes in CBF are observed when $PaCO_2$ is either below 20 mm Hg or above 100 mm Hg (Figure 57-7, *C*). The observed change in CBF in response to change in $PaCO_2$ is relatively transient, lasting hours. Restoration of intracerebral bicarbonate concentration is thought to be responsible for the temporary nature of the CBF response. Therefore, once the brain and the CBF have been "reset" to a new $PaCO_2$, acutely restoring $PaCO_2$ into a physiologically normal range actually results in disruption of the acid-base balance in the brain and may exacerbate injury. As such, chronic hyperventilation is not recommended as a therapy for increased ICP. Nevertheless, hyperventilation with concomitant rapid reduction in $PaCO_2$ remains one of the acute treatments for life-threatening increases in ICP and impending brain herniation.

Metabolic Coupling

Local CBF is coupled to the metabolic tissue demands in a relatively small, circumscribed area, reflecting both neuron- and astrocyte-specific energy needs. At rest, areas with greater energy needs, such as the gray matter, receive a greater proportion of CBF than areas with lesser energy needs, such as the white matter. The metabolic rate can be expressed as either cerebral metabolic rate of glucose (CMRGlu) or cerebral metabolic rate of oxygen ($CMRO_2$). Both CMRGlu and $CMRO_2$ have been correlated with CBF. Under conditions of sensory stimulation, however, the increase in CBF to the cortical sensory areas exceeds the increase in $CMRO_2$, suggesting that neuronal activity itself can influence CBF independent of the metabolic demand.[83] Neuronal activity–dependent increases in CBF forms the presumed basis of functional magnetic resonance imaging, allowing for detailed studies of brain processes in humans.[84] In children, $CMRO_2$ increases until about 14 years of age and then decreases to adult values.[85] Similarly, CMRGlu increases from infancy until around 9 years of age and then decreases until adulthood.[86] The relationship between disturbances in metabolic coupling of CBF and injury is unclear at this time, although emerging evidence indicates occurrence of metabolic crises in the brain after traumatic injury and cardiac arrest.[76] Whether these crises reflect abnormal CBF regulation and predict outcome remains under investigation.

Developmental Processes Relevant to Pediatric Critical Care Medicine

Cell Origin and Differentiation

Neurogenesis and gliogenesis in the human begin well before birth, in the eighth gestational week.[87] Neurons are born in the specialized proliferative zones located next to the lateral ventricles and migrate outwards towards the cortical surface during development. The neurons migrate along a subset of glial cells called the radial glia, that span the distance between

the ventricular zone and the brain surface early in development. The cortex is generated in an inside-out fashion, such that the deeper cortical layers are formed first. Glutamatergic neurons appear to originate in the dorsal aspect of the ventricular zone, whereas GABA-ergic inhibitory interneurons likely come primarily from the ventral aspect. Thus, GABA-ergic neurons have a longer migration path into the cortex than their glutamatergic counterparts, and occasionally must migrate tangentially rather than perpendicular to reach their final destination.[87] The process of establishing cortical layers appears complete in humans by the thirtieth gestational week.[88] Disruption of the radial migration process, due to either genetic or environmental factors, results in lissencephaly and seizures of varying severity.[89]

Synaptogenesis and Synaptic Pruning

By the time of birth in humans, both neurogenesis and neuronal migration have essentially been completed. Thus infants generally have the same neuronal density (number of soma per mm^3) as adults. Yet the human brain undergoes substantial postnatal development, reflected clinically as the maturation of behavioral milestones. The underlying process is evolution of axonal and dendritic processes by neurons in the CNS, together with an explosive increase in the number of synaptic contacts in the brain (Figure 57-8). Neuronal dendritic arbors increase in complexity, developing more branches and sampling a wider physical space during the first 2 years of life.[40] The number of synapses increases from birth until approximately 2 years of age, when it actually surpasses the number of synapses found in the adult brain. From 2 years until early adolescence, neurons the CNS undergo synaptic pruning, or elimination. Both synaptic development and pruning are under exquisite control by genetic and experience-dependent factors. For example, a major CNS abnormality found in individuals with fragile X syndrome, the most common cause of mental retardation, is overproduction and impaired pruning of synapses in cortical neurons.[90] Furthermore, a number of drugs used extensively in the PICU, including benzodiazepines, barbiturates, steroids, and opiates exert a profound effect on synaptogenesis and synaptic function. Steroid use in premature neonates has been associated with worse neurologic outcome,[91] and benzodiazepine use during experience-dependent critical periods in the visual system is associated with premature decline in synaptic plasticity.[92] Thus, the true extent of the interaction between the PICU environment and synaptic organization in the developing brain remains to be fully characterized.

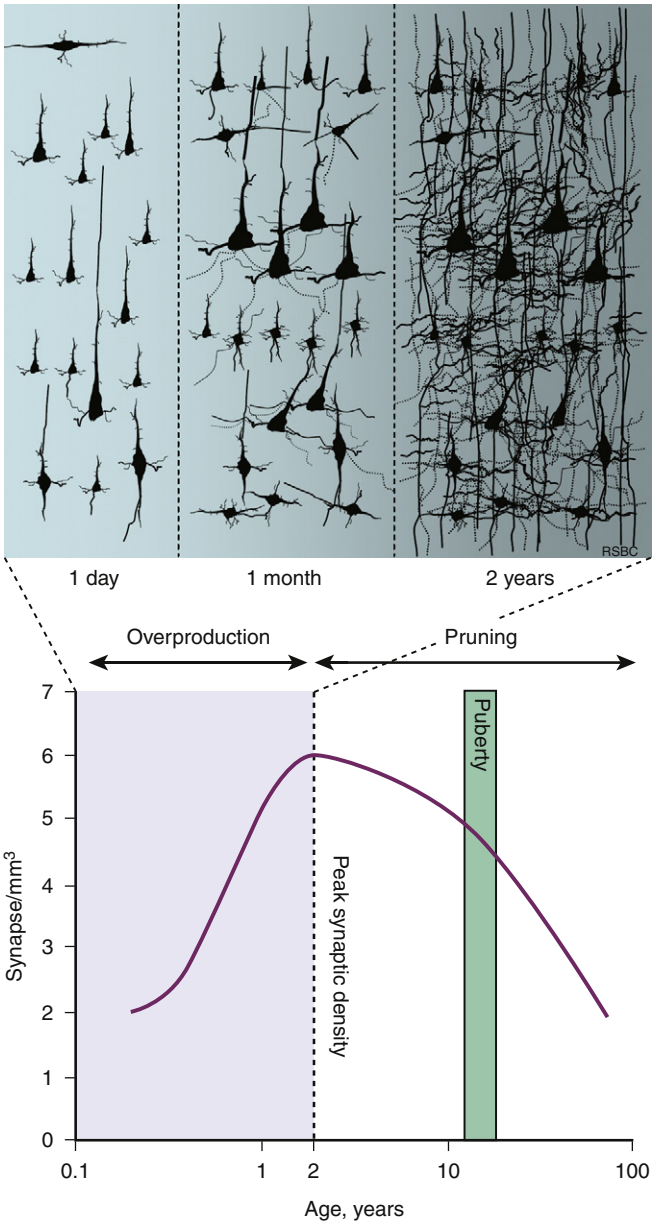

Figure 57–8. Cortical synaptic density and development of axons and dendrites with age. The synapse density is derived from the visual cortex. Note the logarithmic age scale as abscissa. *Top panel* is a schematic representation of synaptogenesis and dendritic arborization and maturation from birth to 2 years of age. *(Modified from Levitt P: Structural and functional maturation of the developing primate brain,* J Pediatr *143:S35-S45, 2003; and Nolte J:* The human brain. An introduction to its functional anatomy, *ed 3, St Louis, 1993, Mosby–Year Book.)*

Neurotransmitter System Maturation

Maturation of the neurotransmitter systems in the human CNS is a complicated and protracted process. It is complicated because each neurotransmitter system matures along its own developmental time course, and because the time course itself may be specific to each brain region. For some neurotransmitters, the process lasts into early adulthood. The complexity of the process is compounded further by the relative lack of human data, requiring extrapolation from animal studies. Nevertheless, some general principles that apply to critically ill children can be derived from the current knowledge.

The earliest neurotransmitter system to become apparent in the cortex is ACh. Thalamic afferent fibers contain AChE, and ACh staining in the cortex coincides with arrival of thalamic input during midgestation.[87,88] Cholinergic innervation in the cortex continues to mature through the third year of life. Development of the GABA-ergic system also begins in midgestation and continues until several months postnatally. GABA receptor α subunits expressed in cortex before birth differ from those expressed after birth.[93] Indeed, in young animals and probably in humans prior to late gestation, GABA is an excitatory neurotransmitter, evoking large depolarizing currents in postsynaptic neurons.[94] The precise significance of GABA as an excitatory neurotransmitter in guiding

organization of neuronal circuits remains to be determined. Development of the glutamatergic system occurs slightly later, with AMPA-type receptors becoming apparent in the basal ganglia in the thirty-second postnatal week. In the cortex, NMDA-type receptors precede the AMPA-type receptors in the course of their appearance at the synapse. Since NMDA receptors do not evoke fast depolarizations leading to an action potential, NMDA-only synapses are functionally silent. Yet, these silent synapses contribute to experience-dependent plasticity and possibly injury.[95]

Myelination

Myelination in the human CNS begins 1 to 2 months prior to birth in the visual system and extends to the other sensory systems over the first year of life.[96] Further myelination of subcortical and cortical tracts continues in the posterior to anterior direction well into the third decade of life, consistent with the time course of maturation of cognitive functions in children and adolescents.[87] Myelination is initiated by the preoligodendrocytes, which are exquisitely sensitive to injury by hypoxia and inflammation. Oligodendrocyte injury, with resulting disruption in axonal myelination, contributes significantly to the development of periventricular leukomalacia in preterm infants.[97]

Development of the Cerebrovasculature and Blood-Brain Barrier

Vascularization of the brain begins very early during development, with the first vascular plexus surrounding the primitive neural tube prior to the first heartbeat. Blood vessels then invade the developing brain, growing radially from the pia toward the deeper structures. The process is driven, at least in part, by oxygen sensing. Deeper cortical layers/structures are thought to be relatively oxygen-deficient.[98] Relative hypoxia leads to transcription of the hypoxia-inducible factor 1 (HIF1), that in turn leads to release of the vascular endothelial growth factor (VEGF). VEGF drives angiogenesis in the brain both prenatally and postnatally. Interestingly, chronic hypoxia such as is seen in patients with cyanotic heart disease increases the capillary density in the brain via an HIF1-dependent mechanism.[99] The increase is reversed over several weeks by restoring normal oxygenation in animal models, suggesting that brain vasculature has the potential to undergo continuous remodeling.

Development of the BBB coincides with early vascularization of the brain. Immunologic markers of tight junctions redistribute from the cytoplasm to their appropriate locations in the cell membrane by approximately 14 weeks of gestation.[100] Although anatomically intact, the BBB remains more permeable to amino acids, some drugs, and possibly toxins until approximately 6 months of age in humans.[100] However, the exact nature of BBB dynamics during development remains incompletely characterized.

Developmental Aspects of Cerebral Blood Flow, Autoregulation, and Cerebral Metabolism

In humans, gray matter CBF increases several-fold early in development and then decreases gradually after puberty (Figure 57-9). In normotensive preterm infants, CBF has been measured at 13 to 14 mL/100 g/min.[101] Estimated CBF increases with gestational age from 14 mL/100 g/min at 30 to 32 weeks to 20 mL/100 g/min at 38 to 40 weeks postconception.[102] Furthermore, CBF increases significantly in the first 2 days of life, regardless of gestational age.[103] In children aged 4 to 12 years, gray matter CBF reaches values of 90 to 100 mL/100 g/min, and then declines throughout adolescence to reach adult values of 50 to 60 mL/100 g/min by approximately 20 years of age.[104] Interestingly, white matter CBF is only 20% higher in children compared with adults, reflecting perhaps the greater degree of developmental changes in gray versus white matter.[104]

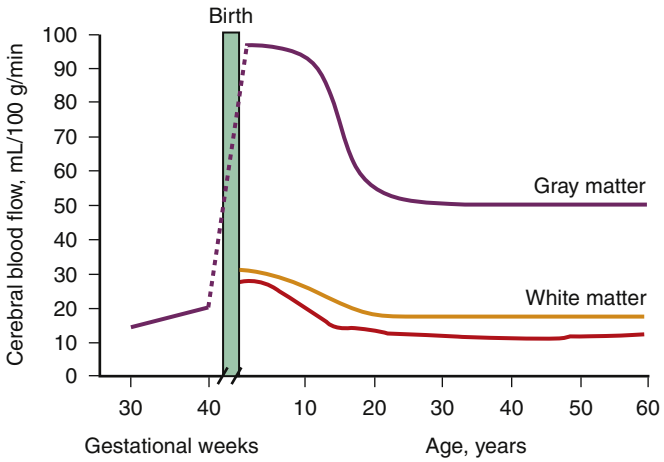

Figure 57–9. Cerebral blood flow (*CBF*) as a function of age. Gray matter CBF increases significantly after birth to reach a peak at approximately 4 years of age (note the change from age in gestational weeks to age in years). The *broken line* between the neonatal period and childhood indicates that data are extrapolated from existing experimental data. Gray matter CBF then decreases gradually to adult values. White matter CBF also decreases between 4 years of age and adulthood, but not as significantly as that in gray matter. At present, no data exist on the white matter CBF in premature or term newborns.

Perfusion pressure-related, $PaCO_2$-related and PaO_2-related autoregulation of CBF also undergo postnatal maturation. Studies in preterm infants suggest that perfusion pressure-related autoregulation of CBF is present shortly after birth, such that CBF changes by less than 1.5% per 1 mm Hg change in MAP.[105] As mentioned above, the upper and lower MAP limits in pressure-related autoregulation in neonates are shifted to the right, compared to adults,[77] leading to different thresholds for intervention in infants. Pressure-related autoregulation may be lost in critically ill infants, resulting in pressure-passive CBF[106] and poor outcome.[106] Similarly, $PaCO_2$-related autoregulation appears present in humans shortly after birth, with CBF changing approximately 1% for every 1 mm Hg change in $PaCO_2$.[101,103,107] In preterm infants, CBF also depends on the interaction between $PaCO_2$-related and MAP-related autoregulation, such that the percent change in CBF as a function of change in $PaCO_2$ increases as MAP increases.[107] Finally, oxygen tension-related CBF autoregulation also appears functional early in life, although much of the current data are derived from animals studies.[108,109] Thus in healthy humans, CBF autoregulation mechanisms are functional at birth and should be taken into account during management of systemic and intracerebral pathologic states, such as sepsis, hypotension, hypoxemia, and hypercarbia.

Cerebral metabolism undergoes substantial maturation during postnatal development in humans with respect to metabolic rate, distribution of metabolic activity, and energy source utilization. Shortly after birth, the CMRGlu is highest in sensory and motor cortices, thalamus, and brainstem.[110] Over the next 4 years, CMRGlu increases substantially in the thalamus and in the cortex but remains essentially stable in the brainstem. Cortical areas experiencing the most significant increase in CMRGlu during the first 4 years of life include the frontal, temporal, and occipital regions.[110] Between 4 and 9 years of age, CMRGlu in the cortex remains at consistently high values relative to adults, declining to adult levels by approximately 20 years of age.[86]

In addition to relying on glucose as a substrate, the developing brain also extensively utilizes ketone bodies as an energy substrate. Ketone utilization peaks during the period of maternal milk ingestion, accompanied by an increase in expression of monocarboxylate transporters in the BBB, that facilitate ketone entrance into the CNS.[111,112] Although reliance on ketones as an energy sources declines in the CNS with age, recent evidence indicates that ketone production and utilization may play a significant role during times of injury and stress even in an adult brain.[111]

Conclusion

The nervous system is undergoing active development and is often the primarily affected organ when children are hospitalized with a life-threatening illness. Appreciation of normal anatomy and development as well as knowledge of neurotransmitter systems and homeostatic mechanisms is required for prompt diagnosis and effective clinical care. Most importantly, ongoing research into the interaction between developmental processes and injury is likely to yield a wealth of new information, implying the need for continuous reevaluation of current knowledge and clinical practice in the light of new discoveries.

Coma and Depressed Sensorium

Tony Pearson-Shaver and Renuka Mehta

PEARLS

- A Glasgow Coma Scale score less than 15 in children should be taken seriously.
- The ABCs (airway, breathing, and circulation) should be the priority during management of a child with coma.
- A spinal tap should be deferred until the possibility of raised intracranial pressure has been ruled out.
- The patient's blood glucose level should be checked with urgency during the initial presentation of coma.
- When in doubt, it is better to protect the airway and prevent hypoxemia and hypercarbia electively.
- Unequal size of the pupils can be a sign of uncal herniation.
- The goal of therapy should be the prevention of secondary brain injury.

Coma, a state of unresponsiveness and unconsciousness, presents in many disorders ranging from structural central nervous system (CNS) injuries to diffuse systemic abnormalities. As a medical emergency, coma presents a challenge to providers because optimal care requires timely intervention; however, information is frequently limited during the initial evaluation. Knowledge of CNS anatomy and structures responsible for consciousness provide helpful clues as one attempts to interpret physical findings and optimize patient care. A careful general physical examination with a focused neurologic examination can suggest the diagnosis, aid in the location of lesions, guide therapeutic intervention, and determine prognosis. Further adjunctive radiologic and laboratory evaluation will then confirm physical findings. This chapter therefore considers CNS anatomy, the pathophysiology of coma, historical and physical findings that aid in localization of lesions, the emergent management and evaluation of patients presenting with an altered level of consciousness, and the prognosis of patients who present with coma.

Pathophysiology

The brain tolerates only limited physical or metabolic injury. Coma implies advanced brain failure, and the longer the brain failure lasts, the greater the possibility that the injury will result in permanent neurologic impairment. Coma may be described simplistically as a lack of consciousness. Posner and colleagues[1] describe coma as a "state of unresponsiveness in which the patient lies with eyes closed and cannot be aroused to respond appropriately to stimuli even with vigorous stimulation." Comatose patients may grimace in response to pain and the extremities may move in stereotypical withdrawal patterns, but the patient cannot localize responses or make defensive movements. As a coma deepens, responsiveness even to painful stimuli may be lost. Because motor reflexes are preserved, the depth of a coma cannot be assessed based only on motor responses. In many comatose patients, reflex movements will develop in response to stimuli. The depth of coma is best assessed by the patient's level of consciousness.

Consciousness is a set of neural processes that allows an individual to perceive, comprehend, and act on and in the internal and external environment.[1,2] Two neurophysiologic functions, *arousal* and *awareness,* which have discreet neuroanatomic locations, are integrated in the conscious person.[3] *Arousal* or *wakefulness* describes the degree to which an individual appears to be able to interact within the environment. *Awareness* reflects the depth and content of the arousal state. When one is aware, one is alert (or aroused) and cognizant of self and surroundings. The relationship between wakefulness and awareness is hierarchical: Awareness cannot occur without wakefulness, but wakefulness may be observed in the absence of awareness (e.g., sleep/wake cycles in a vegetative patient).

Sleeping and waking are common examples of different states of arousal. Although coma and sleep both abolish conscious interaction with the environment, they differ physiologically because sleep is an active physiologic process with several distinct stages, and mechanisms for arousal remain intact. Sleep is dominated by a cortically generated slow wave (electroencephalogram [EEG]) activity within networks of neurons and glia, modulated by extracellular ion currents. Wakefulness is produced through the activation of brainstem and basal forebrain structures that disrupt sleep oscillations and elicit a global change in extracellular ion flow that results in modifications of glial and cerebral blood flow. Coma, however, occurs as a result of an impairment of physiologic components responsible for arousal and an inability to consciously interact.[4-6]

Anatomy of Arousal and Ascending Reticular Activating System

Arousal occurs by physiologic mechanisms that can be selectively impaired by toxins, anesthetics, or physical destruction of the brain stem. Neuroanatomically, the ascending reticular

activating system (ARAS) and related structures responsible for arousal are primarily located in the brainstem in the paramedian tegmental grey matter immediately ventral to the pons. Three ARAS principle pathways have been identified (Figure 58-1). Communications have been identified between the ARAS and the cortex and the limbic system via the thalamic reticular nucleus, the cortex hypothalamus, the basal forebrain, and the brainstem median raphe (locus caeruleus).[4] Because the ARAS receives collaterals from and is stimulated by every major somatic and sensory pathway directly or indirectly, it is best regarded as a physiological rather than an anatomic entity. This partly explains why patients with very large discreet lesions (brain tumors) may be entirely alert, whereas patients with anatomically undetectable but biochemically widespread lesions (e.g., hepatic encephalopathy) may be deeply comatose.

Primarily, two types of lesions depress the level of arousal: direct brainstem-diencephalic injury involving the reticular formation and nuclei, or bilateral cerebral dysfunction. Consequently, conscious behavior depends on the interplay between the cerebral cortex and ARAS because these neural components are required for arousal and to maintain awareness.[1,4] Because the brain maintains a rich network of connections between the cortex, the ARAS, and the brainstem, patients with large discreet lesions might be alert on presentation, although localized neurological deficits are noted on physical examination. On the other hand, patients with only minimal exposure to CNS depressants present with a depressed sensorium. Changes in a patient's level of consciousness imply significant dysfunction and can occur with variable degrees of wakefulness.

States of Impaired Sensorium

Precise definitions and descriptions of the various levels of consciousness are helpful in establishing a baseline, communicating with other health care providers, and interpreting changes in a patient's condition. Box 58-1 describes definitions for varying levels of consciousness; however, many terms used to describe alterations in sensorium lack precision and are better avoided. Colloquial use of the terms lethargy, obtundation, somnolence, and stupor have rendered them imprecise, and health care workers are best served to avoid them when describing patients with altered consciousness. Numerous scoring systems have been developed to assess acute neurologic conditions. By far the most common is the Glasgow Coma Scale (GCS). Developed to classify the depth of coma in adults who have sustained a head injury, the use of the GCS has been expanded to evaluate patients who have sustained a variety of neurologic injuries. A GCS score of eight or less has been used as an alternative definition of coma. Although other scales are used to assess the severity of illness in coma (e.g., Liege coma scale, Apache II scale, and Reye syndrome), the GCS has gained wider acceptance because of its ease and familiarity.[7] A modified GCS has been devised that is more applicable to infants.

Several states of depressed consciousness are described and deserve mention. Consciousness disorders should be distinguished from *brain death*, an irreversible loss of all brain and brainstem function.[8-10] *Coma* is a state characterized by the absence of arousal and awareness. To differentiate coma from more transient causes of depressed sensorium (e.g., syncope and concussion), coma must last more than 1 hour. Comatose patients do not speak, open their eyes spontaneously, follow commands, move spontaneously, or respond meaningfully to painful stimuli. Spinally mediated stereotypical movements may be made in response to pain, but patients do not actively withdraw. Sleep-wake cycles are not preserved in patients who are in a coma. Patients in a coma are in a transitional state and can either deteriorate to a more permanent state of depressed sensorium, deteriorate to fulfill brain death criteria, or recover.

In a *vegetative state*, arousal mechanisms are preserved but patients completely lack an awareness of self or the environment.[8, 9] Patients in a vegetative state demonstrate spontaneous eye opening without the ability to visually track or fixate. Although they may display "sleep-wake cycles," they cannot follow commands or move in a purposeful manner. Patients in a *minimally conscious state* do not meet the criteria for coma or the vegetative state. They demonstrate wakefulness and sleep-wake cycles and intermittently demonstrate self or environmental awareness. These patients may intermittently follow commands, communicate, and display purposeful behavior. Although data are limited, the minimally conscious state may be associated with a greater possibility of recovery than the vegetative state. Lesions associated with this state involve the

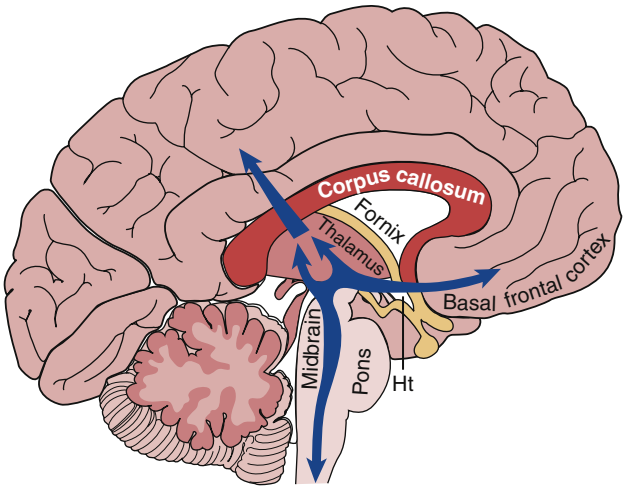

Figure 58–1. Reticular activating system. *(Modified from Hudson AJ: Consciousness: physiological dependence on rapid memory access,* Frontiers Biosci *14:2779-2800, 2009.)*

Box 58–1 Traditional Definitions of Levels of Conciousness

1. Clouding of consciousness—impaired capacity to think clearly and to remember current stimuli
2. Delirium—disturbed consciousness with motor restlessness, disorientation, and hallucination
3. Obtundation—reduced alertness; appears to sleep but responds to verbal and/or tactile stimuli
4. Stupor—markedly reduced alertness; only responds to noxious stimuli
5. Coma—no response to even noxious stimuli and will not utter understandable words

cerebral hemispheres, with possibly greater sparing of corticocortical and corticothalamic connective fibers.

Akinetic mutism is a state of wakefulness with limited evidence of awareness. Patients with akinetic mutism frequently have more diencephalic injury than injury to the motor tracts. Akinetic mutism[8-10] has been associated with bilateral medial frontal lobe injury. The medial frontal lobe injury leads to a profound deficiency in motivation and an inability to plan and initiate activity. Akinetic patients generally are unable to move or speak and have sleep-wake cycles indicated by eye opening. Unlike patients in a minimally conscious state, akinetic patients have no motor responsiveness to verbal, tactile, or noxious stimuli. Further, spasticity or abnormal reflexes do not develop in these patients as a result of relative sparing of the corticospinal tract.

Table 58–1 Common Considerations of Altered Mental Status at Various Ages

Infant	Child	Adolescent
Infection	Ingestion	Ingestion
Inborn error of metabolism	Infection	Intentional
Metabolic	Intussusception	Trauma
Abuse	Seizure	Drug/alcohol overdose
Trauma	Abuse	
	Trauma	

The *locked-in syndrome* is not a disorder of consciousness as much as it is an entity frequently confused with states of depressed sensorium due to the limited ability of these patients to communicate.[8,9] Locked-in patients are quadriplegic and anarthric, but awareness and arousal are preserved. The locked-in syndrome is associated with injury to the ventral pons below the level of the third nerve nuclei and sparing of the ascending reticular activating system. Vertical eye movements and blinking usually are spared. More rostral injury may result in a total locked-in syndrome with loss of eye and eyelid movement that eliminates the ability of the patient to interact or communicate.

Identification of Cause

Coma may present as part of the progression of a known neurologic illness or the unpredictable consequence or complication of a known systemic disease, or it may result from a totally unexpected event or illness.[10] An accurate history of the events and circumstances before the onset of the symptoms and information concerning the patient's medical history and use of medications may be invaluable in determining the cause of coma and quickly lead to the most appropriate diagnostic testing and treatment. As in most pediatric disease, the differential diagnosis of coma is age related as described in Table 58.1. Common etiologies of coma seen in the pediatric population are described in Box 58-2.

Box 58–2 Etiologies of Impaired Consciousness and Coma

Metabolic-Toxic

A. Hypoxia-ischemia
   1. Shock
   2. Cardiac or pulmonary failure
   3. Near drowning
   4. Carbon monoxide poisoning
   5. Strangulation
B. Metabolic disorders
   1. Hypoglycemia
   2. Acidosis
   3. Diabetic ketoacidosis
   4. Organic and aminoacidemias
   5. Hyperammonemias
   6. Hepatic encephalopathy
   7. Reye syndrome
   8. Urea cycle disorders
   9. Disorders of fatty acid metabolism
   10. Valproic acid encephalopathy
   11. Uremia
C. Fluid and electrolyte imbalance, dehydration, hyponatremia, calcium and magnesium imbalance
D. Endocrine disorders: thyroid dysfunction, adrenal insufficiency, hypoparathyroidism
E. Hypertensive encephalopathy
F. Vitamin deficiency (e.g., thiamin, pyridoxine, niacin)
G. Mitochondrial disorders
H. Exogenous toxins and poisons
   1. Narcotics, neuroleptics, antidepressants, antiepileptic drugs, stimulants
   2. Over-the-counter drugs, acetaminophen, mushroom
   3. Industrial toxins (e.g., heavy metals, organic phosphate, cyanide, volatile hydrocarbons)
   4. Substance abuse (e.g., alcohol, cocaine, heroin, amphetamine)
I. Poisoning in cases of Munchausen by proxy
J. Infection
   1. Bacterial
   2. Viral
   3. Rickettsial
K. Paroxysmal disorders
   1. Epilepsy
   2. Migraine

Structural-Intrinsic

A. Trauma
   1. Concussion
   2. Cerebral contusion
   3. Epidural hematoma
   4. Subdural hematoma/effusion
   5. Intracerebral hematoma
   6. Diffuse axonal injury
B. Neoplasms
C. Vascular disease
   1. Cerebral infraction
   2. Thrombosis, embolism
   3. Cerebral hemorrhage
   4. Arteriovenous malformation
   5. Aneurysm
   6. Vasculitis
   7. Trauma to carotid or vertebral artery in the neck
D. Focal infection
   1. Cerebritis
   2. Abscess
E. Hydrocephalus

Initial Assessment and Immediate Resuscitation

The initial assessment of the comatose patient should start with an evaluation of airway patency, the adequacy of ventilation, and the status of the patient's perfusion. Appropriate life support intervention should occur whenever life-threatening illness evolves throughout the assessment. Measurement of core temperature is an important adjunct. Many practitioners assign an initial GCS score at this time.

It is important to observe the respiratory pattern. The rate and regularity of respiration depends on a complex interplay of chemical and neural control systems that operate automatically to reset the rate and depth of breathing as changes occur in gas tensions and pH. In the comatose patient, abnormality may occur in rate and in the pattern. A low respiratory rate is associated with CNS depressants, for example, alcohol, barbiturates, benzodiazepines, and narcotics, and leads to hypoventilation. It also can be associated with elevated intracranial pressure (ICP). Tachypnea is far more commonly due to a physiologic response to hypoxia, metabolic acidosis, or fever, but central hyperventilation can be a sign of brainstem herniation.

The hemodynamic disturbance and hypotension leading to shock that occurs coincident with coma is mainly seen in systemic diseases (e.g., sepsis, drug ingestions, myocardial injury, and adrenal insufficiency), but it is not uncommon to see neurogenic shock related to severe traumatic brain injury (TBI) and spinal trauma as well. Hypertension is suggestive of an intracranial structural lesion and raised ICP but may be due to primary hypertensive encephalopathy.

Once the patient's airway, breathing, and hemodynamics are stabilized, a complete general examination and specific neurologic examination should be noted, along with any signs of trauma. Cervical immobilization should be maintained until trauma has been excluded or cervical spine has been cleared by radiographic and physical examinations. The patient should be completely exposed to allow a visual appraisal of swelling, lacerations, bruises, and other obvious signs of trauma. Blood or clear fluid noted in the nose or ears suggests a basilar skull fracture. Injuries with characteristic patterns (e.g., cigarette burns and glove and stocking burns), characteristic shapes, and characteristic locations (e.g., finger marks on the buttocks and bruises over ear lobes) suggest child abuse (see also Chapter 113).

Focused Neurologic Examination

A focused neurologic examination is key to documenting a baseline neurologic status and helps to locate lesions and determine prognosis in patients with diminished level of conscious (LOC).[11] Because a diminished LOC requires either reticular system or bilateral hemispheric dysfunction, testing the structures immediately adjacent to the reticular system provides clues to the etiology of coma and directs subsequent investigations.[2] A thorough physical examination must be systematic and is as valuable as radiographic and laboratory studies. The neurologic examination of a comatose patient differs from that of an awake, communicative subject and involves pupillary response, respiratory pattern, stimuli required to illicit a motor response, and the general character of the responses. History and presenting symptoms should be evaluated in the context of neurologic findings. Taken together, the history and presenting symptoms help determine the cause of diminished LOC. The level of neurologic dysfunction often is best defined by the respiratory pattern (Table 58-2), associated eye findings, and motor examination (Table 58-3).

Table 58–2 Respiratory Patterns in Patients with Altered Mental Consciousness

Pattern	Description	Localization
Posthyperventilation apnea	Apnea for >10 seconds after 5 deep breaths	Bilateral hemispheric dysfunction
Cheyne-Stokes respiration	Rhythmic waxing and waning of respiratory amplitude	Bilateral hemispheric dysfunction
Central reflex hyperpnea	Continuous deep breathing	Bilateral hemispheric (e.g., trauma), lower midbrain, upper pons
Apneustic respiration	Prolonged aspiratory time ("inspiratory cramp")	Pons
Ataxic respiration	Infrequent irregular breaths	Lower pons or upper medulla
Ondine's curse	Failure of involuntary respiration with retained voluntary respiration	Medulla
Apnea	No respiration	Medulla down to C4: peripheral nerves, neuromuscular junction

Table 58–3 Differentiating Characteristics of Structural and Metabolic Coma

Supratentorial Lesions	Infratentorial Lesions	Toxic, Metabolic, or Infectious Processes
Initial focal signs Retrocaudal progression Asymmetric examination often present early	Brainstem abnormalities often initial signs Sudden onset of coma Cranial nerve abnormality often seen Respiratory pattern often altered, such as central reflex hyperpnea	Confusion/stupor often precede signs Symmetric examination Pupillary reactions preserved Respiratory rate often altered, such as Cheyne-Stokes breathing

Respiratory Pattern

Breathing abnormalities in rate, depth, or regularity are associated with altered LOC. These abnormalities could be signs of overdose, increased ICP, or herniation. Observance of the respiratory pattern also can assist in localizing a lesion. Anatomic correlations between areas of injury and the resultant respiratory patterns are found in Table 58.2 and Figure 58-2.

Eye Examination

Specific eye findings can help localize the level of lesions and establish prognosis. Pupillary changes are informative during the examination of coma because the brainstem areas that control consciousness are adjacent to those that control pupillary response. It is important to distinguish between pupillary dilatation caused by disease or injury and that caused by medication. Pupillary changes due to structural lesions depend on the site of the primary lesion and secondarily on the effects of increased ICP as described in Table 58.3 and presented in Figure 58-3. Because pupillary pathways are relatively resistant to metabolic insults, the presence or absence of a light reflex is the single most important physical finding that distinguishes structural from metabolic disease. Any reactivity is indicative of intact pathways and would rule out brain death.

Pupillary size is the result of a balance in tone between two opposing muscle groups of the iris: the dilator pupillae and the sphincter pupillae muscles. The dilator pupillae is responsible for dilation of the pupils under the control of sympathetic nerve fibers. The sphincter pupillae muscle is responsible for constriction of the pupils under control of parasympathetic nerve fibers. Pupillary size is regulated by reflex mechanisms that occur as a result of ambient light. Size is further affected by age, emotional state, state of arousal, and intraocular pressure.

Anatomically, the pupillary light reflex requires a four-neuron pathway. Light information from retinal ganglion cells travels through the optic nerves, the optic chiasm (where the nasal fibers decussate), the optic tracts, and synapse in the pretectal nuclei of the dorsal midbrain. Pretectal nuclei receive input from both eyes and send axons to both Edinger-Westphal nuclei. The contra-lateral innervation of the Edinger-Westphal nuclei is the anatomic basis for the consensual light response.

Pupillary constriction occurs as a result of parasympathetic activity (Figure 58-4). Parasympathetic nerve fibers travel along the third cranial nerve to the ipsilateral ciliary ganglion within the orbit. The pupillary sphincter muscle (and ciliary muscle for lens accommodation) is innervated by the post-ganglionic parasympathetic fibers. Pupillary constriction to near stimuli occurs as a result of parasympathetic fibers that descend from higher cortical centers directly to the Edinger-Westphal nuclei, bypassing the pretectal nuclei in the dorsal midbrain. This redundancy explains the preservation of the near response when the dorsal midbrain and pretectal nuclei are injured.

Pupillary dilation is mediated through the three-neuron sympathetic (adrenergic) pathways (Figure 58-5). Sympathetic fibers originate in the hypothalamus and descend caudally to synapse in the cervical spinal cord between levels C8 and T2 at the area of the ciliospinal center of Budge. Neurons then travel from the cervical spinal synapse through the brachial plexus, over the lung apex, and ascend to the superior

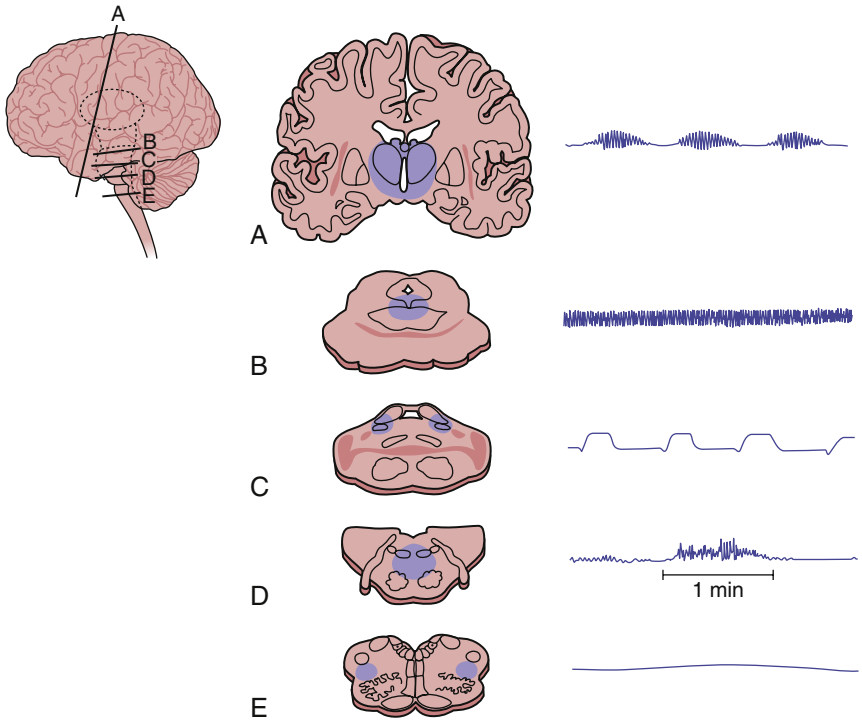

Figure 58–2. Respiratory patterns and associated levels of injury. **A,** Cheyne-Stokes respiration is seen with metabolic injury and lesions in the forebrain and diencephalon. **B,** Central neurogenic hyperventilation is most commonly seen with metabolic encephalopathies. **C,** Apneustic breathing (inspiratory pauses) is seen in patients with bilateral pontine lesions. **D,** Cluster breathing and ataxic breathing are seen in lesions at the pontine medullary junction. **E,** Apnea occurs when the medullary ventral respiratory nuclei are injured. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

cervical ganglion near the angle of the mandible at the bifurcation of the common carotid artery. Postganglionic fibers then ascend within the adventitia of the internal carotid artery through the cavernous sinus in close relation to the sixth cranial nerve. Finally, the oculosympathetic pathway joins the ophthalmic division of the fifth cranial nerve (trigeminal nerve) and innervates the dilator pupillae and Müller's muscle (a small smooth muscle in the eyelids responsible for a minor portion of the upper lid elevation and lower lid retraction).

Anisocoria is indicative of a lesion in the efferent fibers supplying the pupillary sphincter muscles (dilator pupillae and the sphincter pupillae). Pupillary size is determined by the average amount of illumination detected by each eye. Because the efferent limb of the pupillary reflex is bilateral, both pupils receive the same command and are always the same size. Lesions in the afferent limb of the pupillary reflex do not produce anisocoria if the consensual pupillary response to light is intact. Afferent pupillary defects are noted when the direct and consensual responses to light are different. The examiner will note that pupil's reaction to direct light is more sluggish, initially slower, or absent. If the afferent defect is severe, the pupil in the affected eye will dilate with direct light. An afferent papillary defect is a sensitive marker for abnormalities of the afferent limb of the visual pathways.

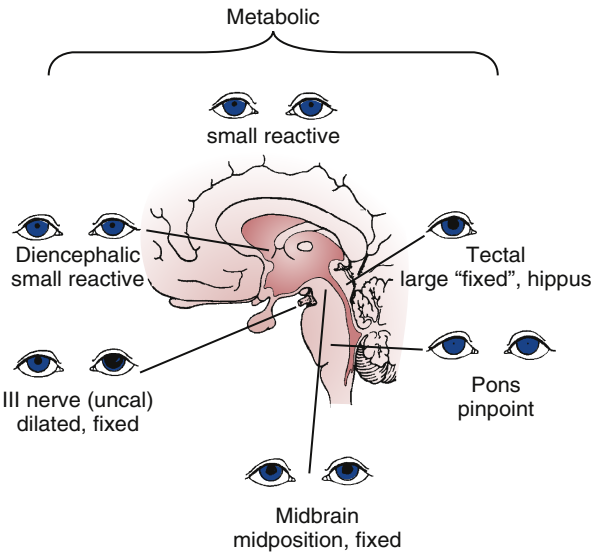

Figure 58–3. Pupils in comatose patients. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma*, ed 4, New York, 2007, Oxford University Press.)*

When anisocoria develops, it is important to determine the abnormal pupil (Figure 58-6). If the small pupil is abnormal, anisocoria is greater in darkness than in light and one will note poor pupillary dilation on the abnormal side. This problem is seen with abnormalities of the sympathetic system. If the larger pupil is abnormal, anisocoria is greater in light than in darkness and one notes poor pupillary constriction on the abnormal side. Poor pupillary constriction is consistent with an abnormality of the parasympathetic system.

Third nerve palsy is the result of lesions anywhere between the oculomotor nucleus and the extraocular muscles. The third cranial nerve originates in the region of the superior colliculus in the midbrain. Fibers travel ventrally in the midbrain and pass the red nucleus and the corticospinal tracts. The nerve exits the midbrain and passes along the brainstem and courses along the lateral wall of the cavernous sinus. The third nerve enters the orbit at the superior orbital fissure. In the orbit, parasympathetic fibers join the periphery of the nerve and travel to the ciliary ganglion. The third nerve innervates the levator muscle of the eyelid, four of the six ipsilateral extraocular muscles (the medial rectus, the superior rectus,

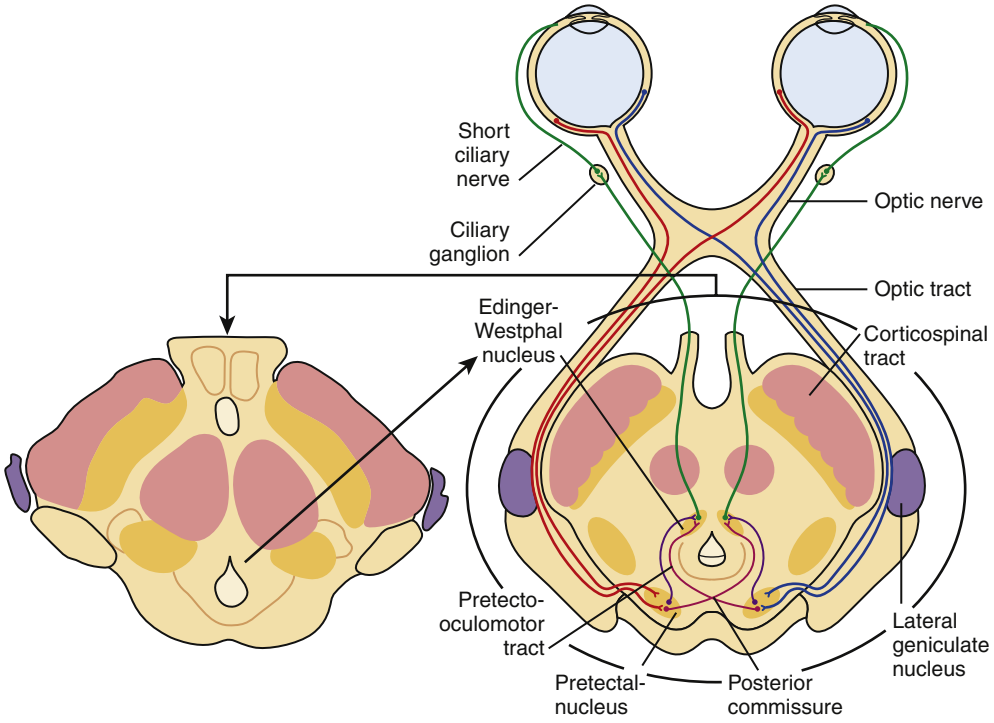

Figure 58–4. Parasympathetic pathway for pupillary innervations. *(Modified from Martin TJ, Corbett JJ: The pupil. In Krachmer JH, editor:* Neuro-ophthalmology: the requisites in ophthalmology*, St Louis, 2000, Mosby. Copyright 2000 Elsevier.)*

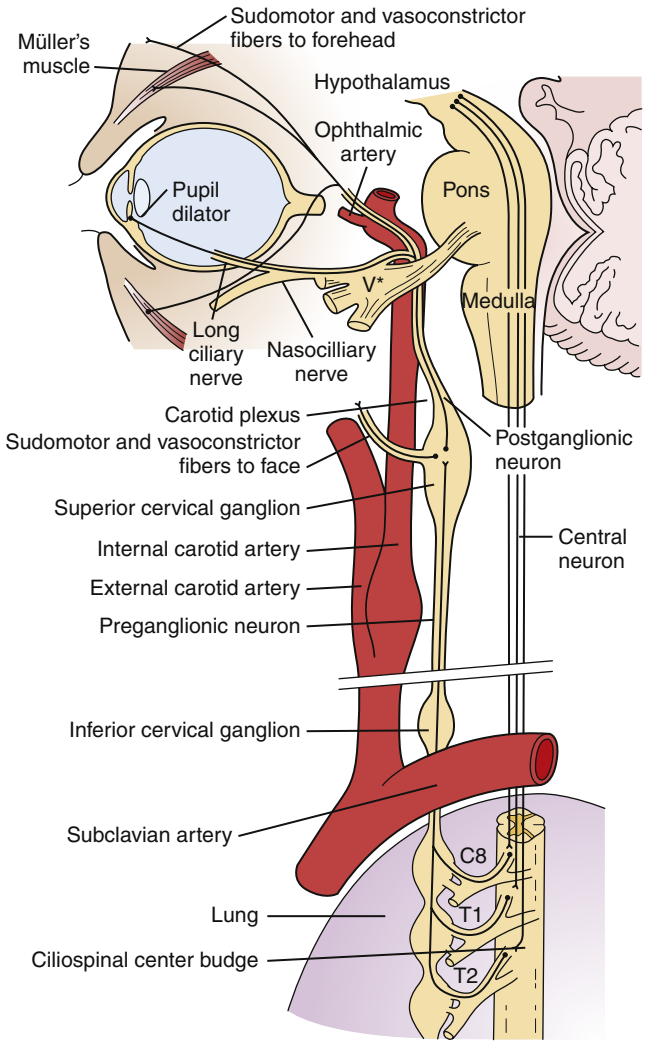

Figure 58–5. Sympathetic pathway for pupillary innervations. *(Modified from Martin TJ, Corbett JJ: The pupil. In Krachmer JH, editor:* Neuro-ophthalmology: the requisites in ophthalmology, *St Louis, 2000, Mosby. Copyright 2000 Elsevier.)*

the inferior rectus, and the inferior oblique), and the sphincter pupillae (parasympathetic fibers). Remaining extraocular muscles, the superior oblique muscle and the lateral rectus muscle, are innervated by fourth and sixth cranial nerves, respectively.

Third nerve palsies present with ptosis, gaze abnormalities, and varying degrees of pupillary dysfunction.[11a] Pupillary response will vary with the degree of injury, and pupils may be normal size with normal responses to light, dilated and poorly reactive to light, or dilated and unresponsive to light and near stimulus. Gaze abnormalities also vary with the site and severity of injury. Adduction abnormality occurs as a result of medial rectus weakness; the eye is turned out. Injury to the nerve supply of superior rectus or inferior oblique results in elevator muscle weakness, and the eye is turned down. Weak downward gaze results from injury to the nerve supply of the inferior rectus muscle, and the eye is turned up. Classically, third nerve palsy is complete and all muscles are affected, resulting in an eye that is turned down and out.

Fundi should be examined to assess the presence of papilledema and retinal hemorrhages. Papilledema is a late sign of increased ICP and its absence does not rule out raised ICP. Signs of papilledema include blurring of the margins of the optic disc and a decrease in venous pulsations. Retinal hemorrhages are most commonly associated with child abuse, although they may be seen following cardiopulmonary resuscitation. Hemorrhages in the retina appear as perivascular collections of blood that may coalesce to include large areas of the retina. Retinal hemorrhages appear to be associated primarily with significant head injury that disrupts retinal blood vessels between the internal limiting membrane and the ganglion cell layer and vessels in the nerve fiber layer of the retina.

The oculocephalic or "doll's eye" reflex and oculovestibular or caloric reflex are the two specific eye maneuvers used in evaluating the comatose child. A positive or normal response to these reflexes indicates that much of the brainstem is intact. Conjugate deviation is noted toward the side of cerebral lesions and away from the side of brainstem lesions. The corneal reflex is a good test for mid and low pontine function.

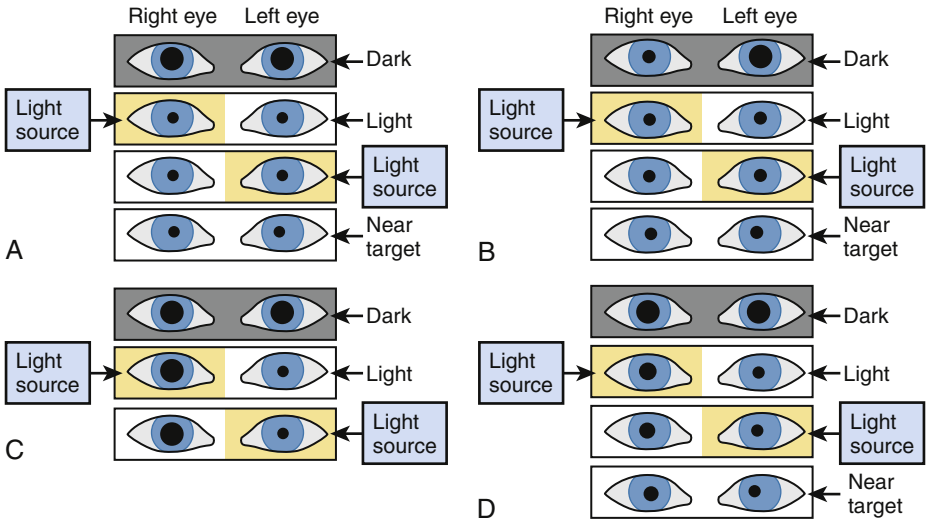

Figure 58–6. The pupillary examination. Identification of the abnormal pupil when anisocoria is present. **A,** Normal pupillary reactions. Both pupils are symmetric in the light and dark. **B,** The small pupil is abnormal. The right pupil does not dilate well in the dark. **C,** The large pupil is abnormal. The right pupil does not react well to light. **D,** Physiologic anisocoria. The amount of anisocoria is the same in light and dark. *(Modified from Kedar S, Biousse V, Newman NJ: Approach to the patient with anisocoria. In Brazis PW, Wilterdink JL, editors:* Up to date. Available at *www.uptodate.com.)*

Motor Examination

Motor examination may reveal focal or generalized neurologic deficits. The presence or absence of focal lateralizing neurologic signs sharply shortens the differential diagnosis. If a single anatomic lesion can explain all the signs, then the differential diagnosis shortens to structural CNS causes of coma. If there is neuroanatomic inconsistency, toxic and metabolic causes of coma are most common (Table 58.4). It is important to remember that focal dysfunction may be misinterpreted as altered LOC (i.e., a patient with receptive aphasia who is misdiagnosed as confused or psychotic).[12]

Figure 58-7 describes the path of the corticospinal tracts through the midbrain, pons, and medulla and their relationship to cranial nerve nuclei. The anatomic relationships between the cranial nerves and motor tracts can provide clues to the location of lesions when a careful physical examination is performed. Physical examination findings and their expected anatomic correlates are presented in Table 58.3.

Focal Neurologic Lesions Could Be Supratentorial or Subtentorial

The *supratentorial* compartment mainly contains the cortex, thalamus, and other structures above the midbrain (Figures 58-8 and 58-9). Patients presenting with asymmetrical examinations are indicative of those with cortical lesions. Given a "focal" or asymmetrical examination, hemiparesis suggests a lesion in a contralateral upper motor neuron pathway. Hypotonia, diminished LOC, and equal reactive pupils are likely to be localized to a cortical lesion on the contralateral side. It has been noted, however, that unilateral cortical lesions often dampen alertness but do not lead to stupor or coma, because ARAS is widely spread in the cerebral cortex region. Expansion of cortical lesions resulting in raised ICP may reduce cortical blood flow in the other areas of the brain, causing diminished LOC.

Contralateral thalamic lesions and cortical lesions with a retrocaudal progression present with contralateral hemiparesis, decorticate (flexor) posturing, eyes deviated inferiorly and medially, and pupils remaining equal, small, and reactive. Decorticate posturing (i.e., tonic flexion of upper extremities and tonic extension, adduction, and internal rotation of lower extremities) reflects a lesion above the midbrain as described in Figure 58-10.

The history and physical findings are relevant and may help determine the cause of the injury. A sudden change in LOC in an otherwise normal child may be due to a cerebrovascular accident from an arteriovenous malformation, a bleeding CNS tumor, or a ruptured aneurysm. Acute sinusitis may result in intracerebral or subdural empyema resulting either from direct extension or hematogenous spread. These infections may produce diminished LOC either as a result of the systemic inflammatory response to the infection or consequences of the expanding mass lesion. A history of fever associated with a diminished LOC may suggest encephalitis associated with herpes simplex or arboviruses infections (see also Chapter 65).

Table 58–4 Clinical Findings with Different Levels of Central Nervous System Dysfunction

Dysfunction	Response to Noxious Stimuli	Pupils	Eye Position and Movements	Breathing	Motor Findings for Structural Lesions
Both cortices	Withdrawal	Small, reactive	Extraocular movements can be elicited; ipsilateral deviation in frontal lobe lesion	Post hyperventilation apnea or Cheyne-Stokes respiration	Contra lateral hemiparesis
Thalamus	Decorticate posturing	Equal and small, unless the optic tract are also damaged	Eyes deviated down and in toward the side of lesion	Same as above	Contra lateral hemiparesis
Midbrain	Decorticate or decerebrate posturing	Midposition, fixed to light, spontaneous fluctuation	Nystagmus may be present; absent vertical but retained horizontal movements; loss of ability to adduct Both eyes may be deviated laterally and down in third cranial nerve damage	Usually same as above; potential for central reflex hyperpnea	Hemiplegia with contra lateral third cranial nerve palsy
Pons	Decerebrate posturing	Bilateral pinpoint pupils, reactive to light (especially with midline pontine hemorrhage); Horner's syndrome with lateral lesions	Ocular bobbing; absent conjugate horizontal movements with retained vertical movements and accommodation; often eyes are deviated medially; seventh cranial nerve damage	May exhibit central reflex hyperpnea, cluster (Biot's) breathing, or apneustic breathing	Hemiplegia with contralateral sixth and/or seventh cranial nerve palsy
Medulla	Weak leg flexion (or none)	Nonreactive, normal size; small, Horner syndrome with lateral lesions	Usually no effect on spontaneous eye movements; may interfere with reflex responses, nystagmus	Rarely ataxic respiration, apnea if respiratory centers involved	Flaccid weakness with difficulty swallowing, phonating, and incoordination
Spinal cord	None	Normal reaction, abnormal response if brainstem affected	Normal response	Normal	Flaccid weakness, loss of bowel and bladder control

A murmur, gallop, and/or dysrhythmias detected during a cardiovascular examination may suggest congenital heart disease or endocarditis, which may be associated with stroke or intracranial abscess formation.

When a traumatic injury occurs, coma may exist from the moment of impact or may be preceded by a lucid interval, suggesting an expanding epidural hematoma. A complete description of TBI is provided in Chapter 61.

Generalized petechia and purpura may be seen with thrombocytopenic purpura, which is a risk factor for spontaneous intracranial bleeding.

Patients presenting with an altered level of consciousness and underlying illnesses such as systemic lupus erythematosus, sickle cell anemia, nephrotic syndrome, homocystinuria, leukemia, or coagulation disorders such as protein C and S deficiency are at risk for cerebral infarction resulting from a vascular obstruction. Patients with diabetic ketoacidosis may have a sudden onset of coma that could be a result of cerebral edema or central venous thrombus (see also Chapter 78). Hypoxic insults and penetrating injuries to vertebral or carotid arteries (as a consequence of vascular disruption) result in cerebral infarction. Patients with strokes may have a period of lucidity following the acute vascular incident. Stupor and coma develop as swelling increases ICP and the blood supply to the midbrain and brainstem are compromised.

Vomiting and diarrhea leading to severe dehydration and hypercoagulable states may lead to sinus venous thrombosis, particularly in young infants. Orbital cellulitis can result in cavernous venous thrombosis. Children with congenital heart disease, especially with right-to-left shunts, are susceptible to cerebral embolism resulting from blood or air thrombus, or particles when patients are treated with intravenous therapy.

Diminished LOC also may occur because of bleeding, convulsions, or rapidly rising ICP as a result of a brain tumor. A history of headache may suggest elevated ICP resulting from hydrocephalus or neoplasm but also may be seen in migraine

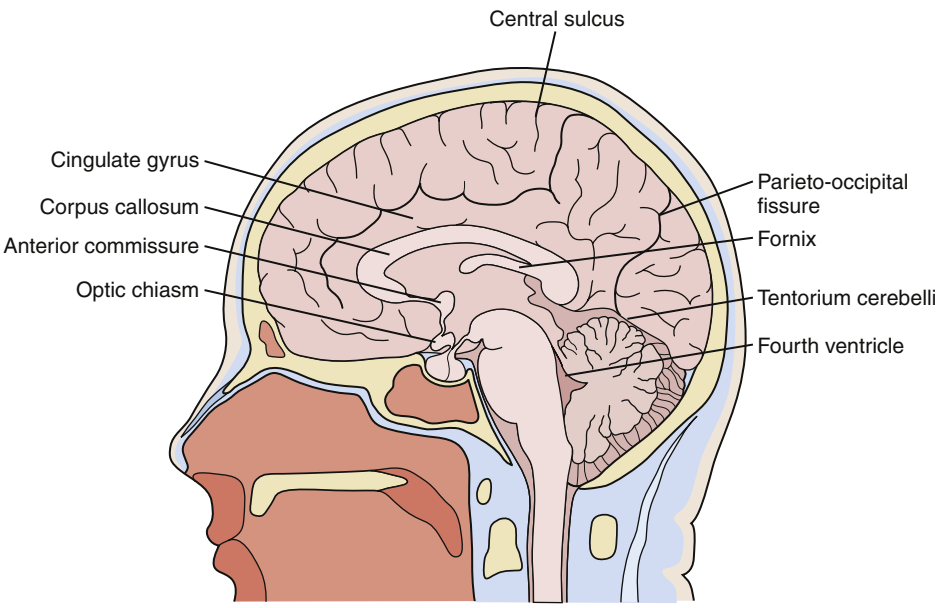

Figure 58–8. Supratentorial and subtentorial compartments. *(Modified from Gilman S, Newman SW:* Manter and Gatz's essentials of clinical neuroanatomy and neurophysiology, *ed 9, Philadelphia, 2003, FA Davis.)*

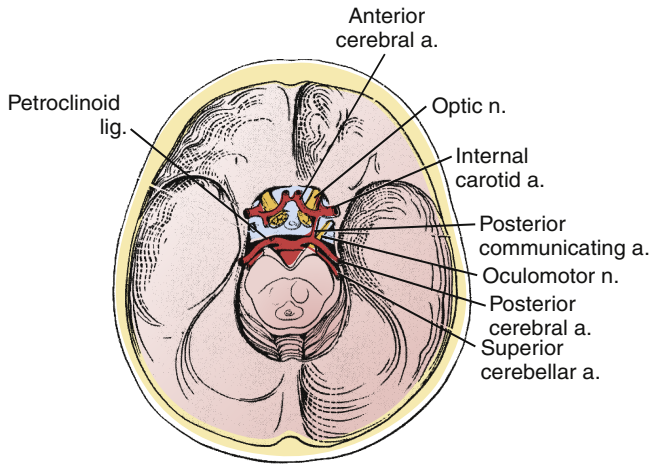

Figure 58–9. The floor of the anterior and middle fossa, illustrating the tentorial notch and relationship of the third nerve with other intracranial structures. *(Modified from Plum F, Posner JB:* The diagnosis of stupor and coma, *ed 3, Philadelphia, 1982, FA Davis.)*

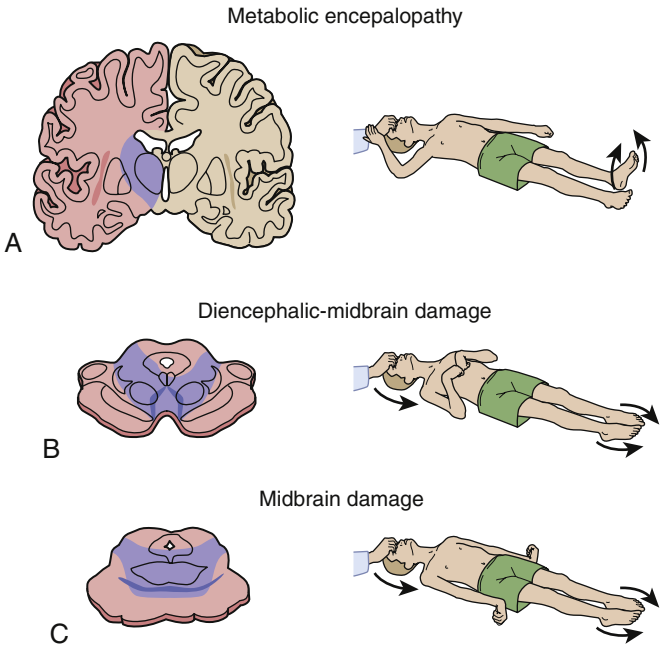

Figure 58–10. Motor responses to noxious stimulation in patients with cerebral dysfunction. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

syndrome with impaired consciousness. The presence of neurocutaneous lesions, such as depigmented areas of tuberous sclerosis, can suggest that seizures or intracranial masses are the cause of diminished LOC.

The *subtentorial* compartment is the area beneath the tentorium and contains most of the brainstem, the cerebellum, the exit sites for most of the cranial nerves, and passages for CSF movement (see Figures 58-8 and 58-9). Injury and insult can alter function of these components by either destruction or compression. Brainstem lesions are capable of creating immediate LOC because of the close proximity of ARAS. The relationship of cranial nerves to the brainstem is described in Figure 58-11.

Lesions in the brainstem may be due to demyelinating diseases, cerebrovascular diseases, neoplasm, or head trauma. Uncal herniation can occur following head trauma, which may be due to rapidly expanding subdural or epidural hematoma or diffuse axonal injury. A history of fever, vomiting, and LOC are noted in brainstem and cerebellar infarction. Cerebrovascular lesions disrupt blood supply and result in brainstem dysfunction. A history of headache, vomiting, and gait unsteadiness may suggest a neoplasm.

Midbrain lesions frequently present with ipsilateral weakness and midposition, nonreactive contralateral pupils due to third cranial nerve palsy. Third cranial nerve palsy generally causes both eyes to deviate laterally or inferiorly and laterally. When gaze is deviated down and out, the patient is said to have the "sun setting sign." Decerebrate (extensor) posturing is elicited in response to noxious stimuli in patients with midbrain lesions. Decerebrate posturing is tonic extension of upper extremities as well tonic extension, adduction, and internal rotation of lower extremities (see Figure 58-10).

Hemiparesis with medial deviation of the contralateral eye are hallmarks of pontine lesions (see Figure 58-3). Pupils remain small and reactive to light. However, bilateral pinpoint pupils are also seen when midline pontine hemorrhages occur. Horner's syndrome with a mildly constricted pupil ipsilateral to the lesion can be seen in lesions affecting pathways between the hypothalamus and brainstem.

Although hypertonia is a feature of preexisting corticospinal tract injury, it can be seen in acute injury to the midbrain or pons, when the more rostral corticospinal tract is disrupted, but the vestibulospinal motor system continues to exert a tonic influence on the spinal cord. These patients exhibit decerebrate posturing to noxious stimuli. It should be noted that acute lesions often cause extensor posturing regardless of anatomic location and both decorticate and decerebrate posturing may occur in combination. These facts render posturing less reliable for localization of CNS lesions. Although not always reliable for localization, posturing suggests that cortical control centers are not functioning.

Patients presenting with flaccid quadriplegia, swallowing difficulties, problems with phonation, nonreactive normal-sized pupils, and normal extraocular eye movements are likely to have an injury in the medulla. The eighth to twelfth cranial nerves exit the brainstem in the area of the medulla. Medullary lesions are associated with problems in bulbar muscles such as speech and swallowing. If respiratory centers are affected, patients may present with apnea. Cerebellar lesions usually produce coma by brainstem compression. Cerebellar signs in confused patients should raise the possibility of intoxication or nutritional deficiency (e.g., vitamin B_{12}).

Presentation of Nonfocal Neurologic Lesions

Once causes of focal neurologic lesions have been excluded, further evaluation should proceed to seek causes of coma as described in Box 58-2. Patients with nonfocal lesions and coma commonly lay motionless in an unnatural posture. In most metabolic conditions, pupils are small and reactive to light and extraocular movements are absent. Patients may hyperventilate or present with apnea or Cheyne-Stokes respiration.

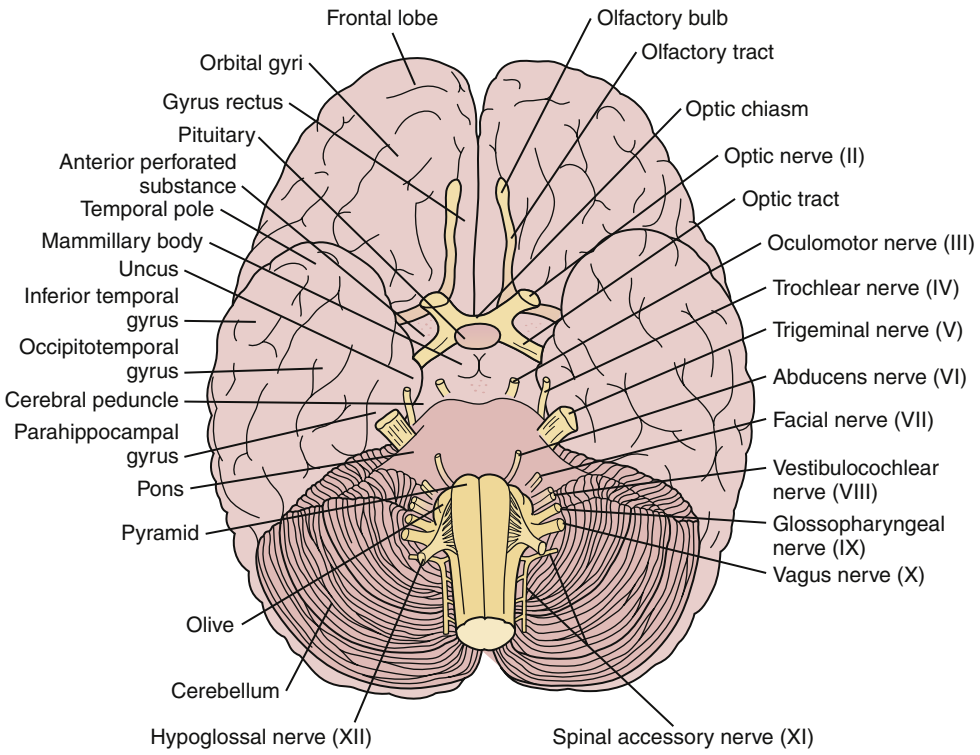

Figure 58–11. Ventral surface of the brain demonstrating the position of cranial nerves. *(Modified from Gilman S, Newman SW:* Manter and Gatz's essentials of clinical neuroanatomy and neurophysiology, *ed 9, Philadelphia, 2003, FA Davis.)*

Hypoxia and ischemia/reperfusion injury are important causes of coma in pediatric patients. These entities are thoroughly discussed in Chapter 62. Most of the causes of nonfocal neurologic lesions may be very obvious. In cases of unusual presentation, a detailed history and physical examination may give a clue to the diagnosis.

Coma preceded by sleepiness or unsteadiness suggests ingestion of a drug or toxin in a previously healthy child. Seizures may lead to a prolonged and deep loss of consciousness if there is an underlying reason for the seizure (e.g., cerebral palsy, hypoglycemia, and electrolyte abnormalities) or if metabolic demand during the seizure is not met by a concomitant increase in substrate delivery. A recent history of fever or upper respiratory tract illness may suggest complications of infectious diseases such as acute disseminated encephalomyelitis, Reye's syndrome, or mitochondrial disorders.

Intermittent episodes of coma may be due to recurrent drug overdose, inborn error of metabolism, or Munchausen syndrome by proxy. A toddler presenting with intermittent irritability followed by a decreased level of consciousness could be experiencing intussusceptions, perhaps because of a release of endorphins.

Inspection of skin can provide clues to an underlying illness (e.g., jaundice in patients with liver failure, or a cherry-red color in persons with carbon monoxide poisoning). Generalized increased pigmentation may be seen in Addison's disease or adrenoleukodystrophy.

Herniation Syndromes

Expanding mass lesions develop at the expense of one of the CNS compartments (brain, blood, or cerebrospinal fluid) (see also Chapter 59). Herniation occurs when the brain is subjected to pressure gradients that cause portions of it to flow from one intracranial compartment to another. Although the brain has substantial elasticity, the arteries and veins responsible for its blood supply are relatively fixed in space, creating a risk that brain shifts will cause moving portions to lose their blood supply. The supratentorial compartment is connected to the subtentorial compartment via the tentorium cerebelli, which passes through the tentorial notch (see Figure 58-9). Located in the tentorial notch are the midbrain, the third cranial nerve, and several arteries including choroidal arteries, the posterior cerebral arteries, and the superior cerebellar arteries. The cerebellum occupies the posterior part of notch. Close proximity of these important structures explains the constellation of symptoms that occur when supratentorial lesions lead to transtentorial shifts.[13]

Two herniation syndromes are principally important: central herniation and uncal herniation (Figure 58-12). *Central herniation* occurs when diffuse brain swelling or a centrally located mass causes the diencephalon to move caudally through the tentorial notch. Figures 58-13 and 58-14 describe the remote and catastrophic effects of supratentorial lesions leading to a shift of intracranial structures through the tentorial notch. Dysfunction of the ARAS and cerebral hypoperfusion cause the alteration of consciousness. Patients initially become less alert and later progress to stupor and coma. Diencephalic dysfunction initially produces small reactive pupils because sympathetic output from the hypothalamus is lost. At this stage, decorticate (flexor) posturing may be spontaneous or elicited by noxious stimuli, and Cheyne-Stokes respiration is noted (see Figures 58-10 and 58-14). It is important to recognize this constellation of symptoms because herniation at this stage is reversible. As rostral-caudal progression of central herniation continues into the midbrain and pons, the likelihood of reversibility markedly decreases. As the midbrain begins to fail,

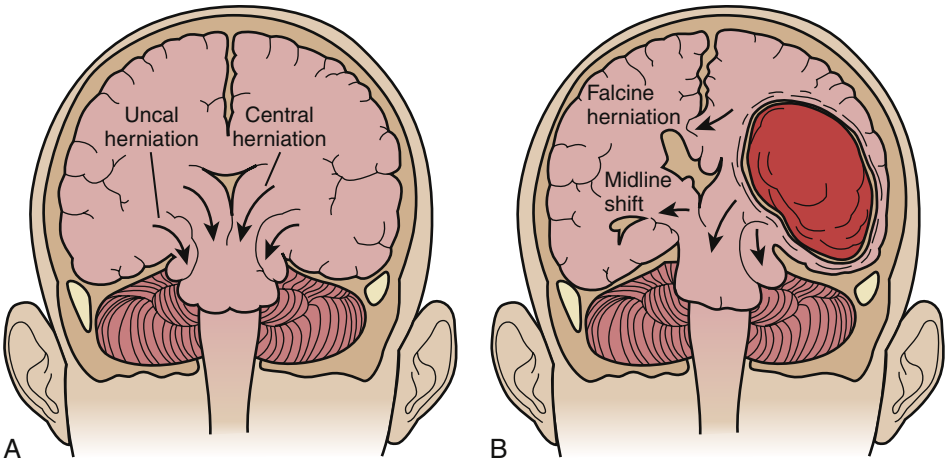

Figure 58–12. Central (**A**) and uncal (**B**) herniation. *(Adapted from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

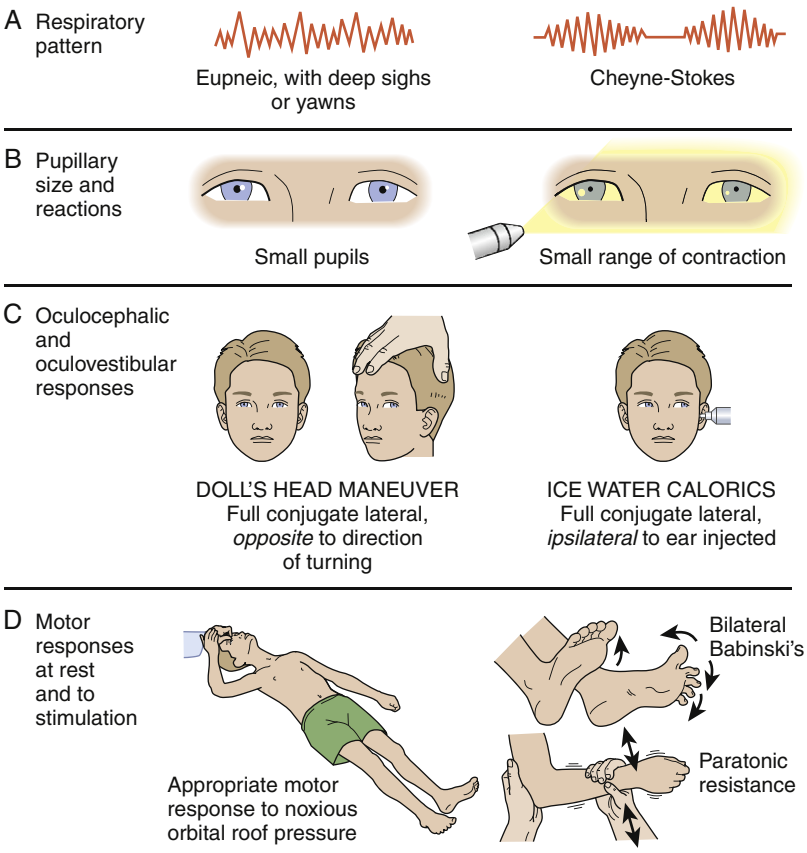

Figure 58–13. Central transtentorial herniation—early diencephalic stage. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

pupils enlarge to midposition, and decerebrate (extensor) posturing is noted. Attempts to elicit horizontal eye movements with either cerebroocular reflex or cerebrovestibular reflex fail and the respiratory rhythm becomes irregular. The patient becomes overtly comatose. Further progression affects the medullary respiratory centers. Virtually all brainstem reflexes are absent and death becomes imminent. The initial cardiovascular response to diminished brainstem perfusion is hypertension, which leads to reflex bradycardia. Classic Cushingoid reflex responses are seen mostly after the development of herniation syndromes. Radiographically, downward herniation is characterized by obliteration of the suprasellar cistern from temporal lobe herniation into the tentorial hiatus with associated compression on the cerebral peduncles.

Uncal herniation occurs when a lateral expanding cerebral mass pushes the uncus and hippocampal gyrus over the lateral edges of the tentorium, putting pressure on the brainstem, especially the midbrain. As the diencephalons begin to shift away from the mass, consciousness begins to diminish, and ipsilateral third cranial nerve palsy develops. When the third cranial nerve

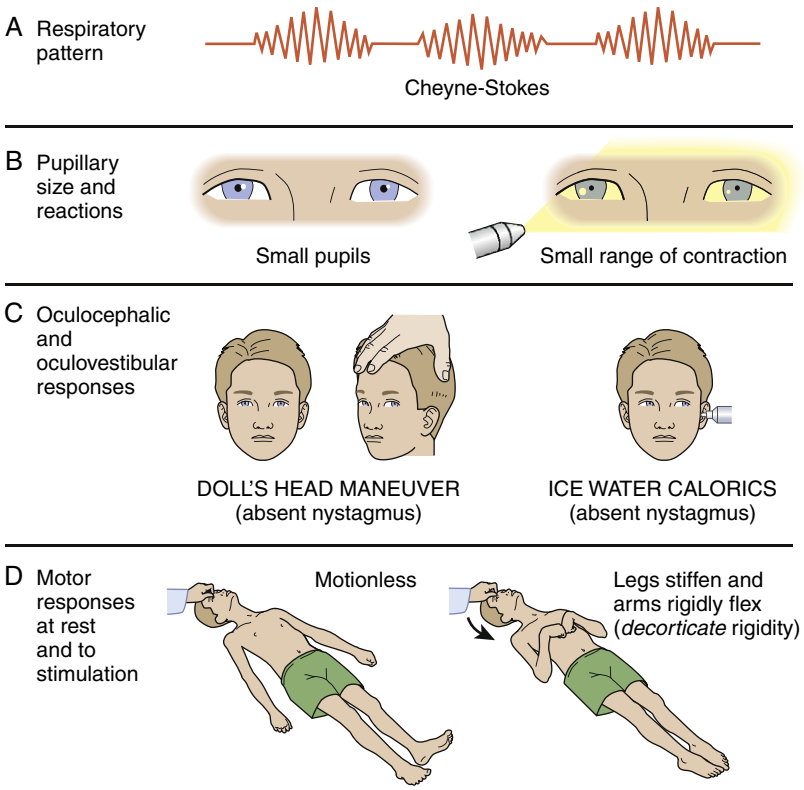

Figure 58–14. Central transtentorial herniation—late diencephalic stage. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

is compressed against the tentorial notch, the pupillary fibers controlling the parasympathetic control are primarily damaged, resulting in a large pupil of the affected side, which fails to constrict to the light. A unilateral dilated pupil that is first to appear, often without severe impairment of consciousness, and contralateral hemiparesis are the hallmark findings of uncal herniation (Figures 58-15 and 58-16). Other findings, such as impaired ocular motility pushing an eye "down and out," may take some time to develop. Cranial arteries may be compressed during herniation. Once present, changes in brainstem function, ipsilateral hemiplegia, and altered oculocephalic reflexes may proceed very rapidly. In some patients bilateral pupillary dilatation develops, presumably because of distortion of third cranial nerve anatomy and midbrain ischemia. At this point, uncal herniation begins to affect the midbrain and upper pons, producing fixed pupils and extensor posturing, lethargy, bradycardia, and respiratory abnormalities. Further progression is indistinguishable from central herniation.

Cerebellar tonsillar herniation is seen in patients with posterior fossa masses that cause compression of the brainstem, cranial nerve dysfunction, and obstructive hydrocephalus. As the pressure gradient across the foramen magnum increases, cerebellar tonsils may be pushed through the foramen and also can compress the upper cervical spinal cord. Increased pressure on the brainstem can result in dysfunction of brain centers responsible for controlling respiratory (and cardiac) functions, which may result in apnea. Patients with cerebellar tonsillar herniation may complain of neck pain before losing consciousness. *Upward transtentorial herniation* occurs when contents of the posterior fossa herniate into the diencephalic region. This syndrome is seen in patients who have ventricular drains placed for relief of hydrocephalus. If the ventricular drain is set to drain at a very low pressure, a pressure differential is created between the supratentorial and subtentorial regions, with the supratentorial pressure being lower.

Diagnostic Evaluation

Initial investigation falls into two broad categories, investigation facilitating supportive therapy during the child's illness and investigation to confirm a specific diagnosis (Box 58-3). These investigations, however, should be tailored to the individual child's history and physical examination. Blood chemistry profile should include glucose, sodium, potassium, blood urea nitrogen, calcium, magnesium, carbon dioxide (CO_2), and ammonia. Hypoglycemia may be a presenting feature of some endocrine disorders or inborn errors of metabolism (see also Chapters 76 and 77). Therefore all patients with significant impairment of consciousness should have a blood glucose determination performed immediately after presentation. Abnormalities of calcium and magnesium may precipitate unexpected seizures, especially in infants and young children. Hyperammonemia and metabolic acidemia may occur as a result of an inborn error of metabolism. If metabolic acidosis is noted, then lactate and pyruvate levels also should be determined. A complete blood cell count will assist in determining the presence of infection, anemia, and exposure to toxins such as lead. Blood and urine cultures should be obtained if infection is suspected. A urine sample also should be sent for toxicology screening.

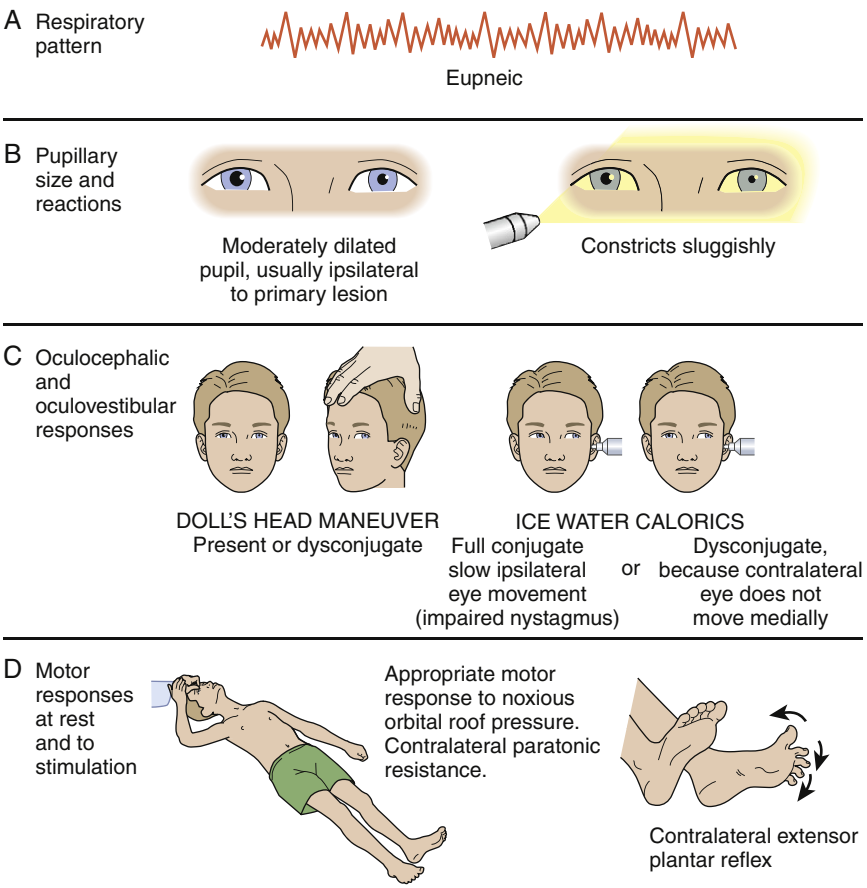

Figure 58–15. Uncal herniation—early third nerve stage. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

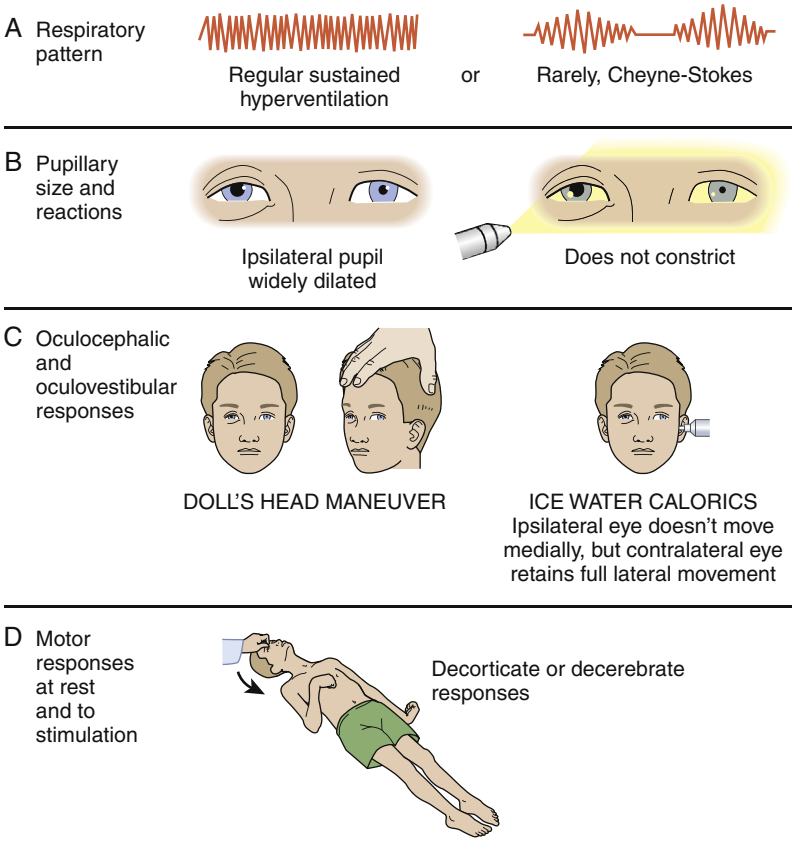

Figure 58–16. Uncal herniation—late third nerve stage. *(Modified from Posner JB, Saper CB, Schiff ND, et al, editors:* The diagnosis of stupor and coma, *ed 4, New York, 2007, Oxford University Press.)*

Box 58–3 Diagnostic Evaluation in a Patient with Coma

Investigations that Facilitate Supportive Therapy

Arterial blood gas level
Urea, electrolytes and creatinine, calcium, and magnesium levels
Blood sugar level
Osmolality of plasma and urine
Urine for ketones, sugar, and pH measurements
Complete blood cell count
Coagulation screening
Blood culture, urine culture, tracheal culture
Blood levels of anticonvulsants
Virology
Chest radiograph
Electrocardiogram
Electroencephalogram
Cerebral imaging: CT, MRI
Brainstem auditory-, visual-, and somatosensory-evoked potentials

Tests that May Provide a Specific Diagnosis

CSF examination
Toxicology screen
Blood ammonia level
Blood pyruvate and lactate levels
Amino acid profile
Organic acid analysis
Porphyrin levels
Liver function tests
Carnitine level
Serum lead level
Cortisol level
Skeletal survey
Cerebral imaging

Once they are medically stable, most patients with impaired consciousness of undetermined etiology should have a head computerized tomography (CT) scan or brain magnetic resonance imaging (MRI) performed to evaluate for structural causes of pathology (e.g., trauma, tumor, bleeding, infarction, abscess, or calcifications). MRI also is valuable in identifying sinus thrombosis, herpes simplex encephalitis, or acute demyelinating process (see also Chapter 56). Lumbar puncture should be deferred until the patient is neurologically and hemodynamically stable and the possibility of raised ICP is eliminated.[14] A normal CT scan is not a definitive indication of normal ICP; however, it can provide evidence in support of the physical examination. CSF should be collected to rule out bacterial infection as soon as it is deemed safe. Freezing a portion of the sample may assist in identifying viral or metabolic causes later. Additional blood or urine samples also may be obtained for further studies at later stages depending on the patient's clinical course and the initial laboratory evaluation. The EEG is essential to diagnose clinically apparent or subclinical seizures; it also is helpful in determining the prognosis in patients with hypoxic-ischemic encephalopathy (HIE) and in the diagnosis of brain death.[15,16]

Therapeutic Intervention

Pathophysiology following brain injury occurs in two phases: primary and secondary. Primary brain injury refers to the initial insult, whether it is ischemic, anoxic/hypoxic, or shear injury, each potentially resulting in irreversible neuronal cell injury or death. The only available treatment is prevention. Secondary brain injury occurs in otherwise salvageable brain tissue as a result of cerebral hypoxia, increased ICP, or decreased cerebral blood flow and may result in further neuronal damage. The goal of therapy is to prevent secondary brain injury.

In neurologic emergencies, evaluation of the patient's airway patency, ventilation, and circulatory status are paramount. Compared with other organs, metabolic activity in the brain is relatively high. The brain has little capacity to store glucose and accordingly depends on constant delivery of substrate and oxygen to maintain normal metabolic functions. Comatose patients often are hypercapnic and have hypoxemia. Thus supplemental oxygen should be provided to the patient with hypoxemia during the initial evaluation.

Upper airway obstruction as a result of decreased muscle tone of the pharyngeal soft tissue is a common problem in unresponsive patients. Once the cervical spine is protected, the clinician should always be prepared to support the airway with maneuvers that improve patency or with endotracheal intubation in unstable patients and in patients likely to become unstable. Once the patient's airway is maintained, adequacy of ventilation must be evaluated by examining the respiratory rate and respiratory effort. It also is common practice to endotracheally intubate patients with a GCS score less than 8, hemodynamic instability, and/or neurologic instability. In most circumstances, it is safer to endotracheally intubate electively rather than emergently to protect an already compromised brain from further injury as a result of respiratory failure. During endotracheal intubation, special precautions should be taken to protect cerebral circulation and prevent further increases in ICP. Pretreatment with lidocaine and thiopental may help to diminish raised ICP associated with airway manipulation. It is also important to maintain $Paco_2$ between 35 and 40 mm Hg.

Following stabilization of the airway and breathing, provision of adequate perfusion supersedes the need to treat any CNS lesion. Systemic shock must be corrected to reestablish adequate cerebral blood flow and hence oxygen and substrate delivery.[17] Once shock is corrected, some evidence indicates that blood pressure should be maintained higher than the 50th percentile for age to maintain adequate cerebral perfusion pressure pending placement of ICP monitoring equipment. Current guidelines suggest that isotonic solutions without dextrose are the preferred fluid for traumatic or ischemic CNS resuscitation in the absence of hypoglycemia.[18] However, any level of hypoglycemia must be avoided (see the next section).

Immediately Treatable Forms of Coma

After initial stabilization, clinicians should rapidly consider the causes of unresponsiveness that could easily and quickly be reversed. Experience gained from unresponsive adults suggests that all unresponsive infants and children should be immediately checked for hypoglycemia. Infants are susceptible to hypoglycemia because of relatively reduced glycogen storage and a higher metabolic rate. The blood glucose level can be checked quickly with use of a glucose reagent strip and abnormalities can be treated immediately with a bolus of D10W or D25W.

An overdose of narcotics should be considered in older children and adolescents. Particularly if the history and physical findings suggest narcotic ingestion, a trial of naloxone is warranted.

Seizures should always be considered, especially when the cause of coma is undetermined. Seizures should be treated immediately because prolonged status epilepticus has a high mortality rate and has been shown to cause neuronal necrosis. An extensive discussion of seizures and their treatment is provided in Chapter 60.

Rapidly Progressive Reversible Lesions

Space-occupying lesions frequently result in increased ICP, and this situation must be addressed immediately to avoid further damage and death. Therapy must be directed toward limiting the extent of secondary damage and preventing herniation by reversing the rapid rise in ICP and/or surgically addressing the lesion or hydrocephalus if present. When signs of central or uncal herniation are noted, the physician must respond rapidly and attempt to decrease ICP by altering the volume of one of the three intracranial constituents: brain, blood, or CSF. Interventions include elevating the head 30 degrees, keeping the head in midline position, hyperventilation, and administration of mannitol and/or hypertonic saline solution to rapidly decrease intracranial volume and ICP.[18,19] A complete discussion of treatment of ICP is presented in Chapters 59 and 61.

States Amenable to Prolonged Therapy

Certain brain insults are not readily reversible and require prolonged treatment to obtain the best possible outcome. Although the primary insult may not be reversible or may require extended care, secondary injury such as hypoxia and raised ICP can occur and cause further deterioration, despite the fact that the initial injury may not progress. Examples of primary insults that can have major secondary changes include encephalitis, meningitis, hypoxic-ischemic insults, and certain metabolic abnormalities such as hepatic failure and renal failure. Thus broad-spectrum antibiotics and antiviral therapy should be empirically started when meningitis or encephalitis is suspected, even if the lumbar puncture is deferred. Electrolyte imbalance, especially related to serum sodium either as an underlying cause or as a result of CNS insult due to inappropriate antidiuretic hormone secretion or diabetes insipidus, also should be appropriately corrected. It may be preferable to keep the serum sodium level around 150 mEq/L for first 72 hours. Hypoglycemia and/or hyperglycemia and variation in glucose level are associated with increased morbidity and mortality. These potential developments should be monitored and prevented, and hypoglycemia should be immediately treated.[20] Adequate blood pressure to maintain cerebral perfusion pressure is immensely important and can be ensured with appropriate fluid resuscitation and/or inotropic support. Untreated hypotension in patients with TBI is associated with increased morbidity and mortality.[17] It is important to maintain a mean arterial pressure of at least 50 mm Hg or higher for older pediatric patients. Although therapeutic hypothermia for the initial 24 to 48 hours following an anoxic-ischemic reperfusion event is helpful among adults following cardiac arrest or depressed newborns,[21,22] normal body temperature may be necessary for resolution of acidosis. Agitated patients may require sedation to prevent elevations in ICP. Patients should be adequately sedated for comfort and prevention of complications related to ventilation. Analgesia/anxiolysis titration using a standard scoring system can be helpful. Patients at risk of or demonstrating overt or subclinical seizures should be treated appropriately.

Outcome

The major causes of pediatric coma involve HIE and trauma. These conditions are serious and are common reasons for admission to the pediatric intensive care unit. Coma is associated with high morbidity and mortality. It also is hard to predict outcome early in the course. In children, improvement can continue over a very protracted time, even several years, long beyond the time when most adult patients will have reached their plateau of recovery.[23] Thus it is important to provide accurate and timely prognostic information if possible so that appropriate levels of care can be provided. The combination of physical signs, EEG, evoked potentials, and MRI provide useful prognostic information after 24 hours of HIE and can help in predicting outcome. These tests may need to be delayed to rule out compounding factors, and/or multiple tests may be required to provide the best prognostic information to families.[15,16]

TBI is a leading cause of death and disability in the pediatric age group. Neuropsychological and behavioral outcomes depend not only on the severity and type of injury and age at injury but also on premorbid conditions and the families' socioeconomic status.[24-26] Hypotension alone and hypoxemia associated with hypotension are significant predictors of disability and death in patients admitted with moderate to severe TBI. Early fluid resuscitation for hypotension, oxygen supplementation for hypoxemia, and ventilation for apnea in patients with TBI can have a significant impact on outcome.[17] Also, the presence of vascular injury, refractory ICP, elevated ICP, and cisternal effacement at presentation had the highest correlation with subsequent mortality and morbidity. Controlling elevated ICP is an important factor associated with survival following severe pediatric TBI.[27]

The outcome of coma following cardiopulmonary arrest is associated with greater than 80% mortality. Patients with out-of-hospital arrests have a worse outcome than those with inhospital arrests. Factors associated with 100% mortality were duration of asystole more than 15 minutes and administration of more than 1 dose of epinephrine.[22] Patients who were alert before resuscitation had better survival beyond 24 hours versus those who were comatose.

The precise prognosis of children with severe submersion injuries is difficult to determine within the first few hours of injury. In general, prolonged cardiopulmonary resuscitation, fixed and dilated pupils, and a GCS score of 3 portend a poor outcome.[28,29] Orlowski[16] developed a scoring system for evaluating prognosis in submersion injury based on five unfavorable prognostic factors: age less than 3 years, estimated submersion longer than 5 minutes, no attempts at resuscitation for 10 minutes, coma on admission to the emergency department, and severe acidosis with arterial blood pH 7.10 or less. A total score of 2 or less was associated with 90% chance of recovery, but a score of 3 or greater was associated with only

a 5% chance of recovery.[30] Coma following cerebral edema in patients with diabetic ketoacidosis is unpredictable, and outcomes are variable and may not be related to any specific management strategy.[31]

Ethical Considerations

The main purpose of coma prognostication is not merely to satisfy a parent's anxiety to know what the future holds but primarily to assist with difficult management decisions.[32] If within the acute period there is a high probability of death without regaining consciousness, decisions to withdraw life-sustaining technologies often are made. By contrast, a decision to withdraw support based on a high probability of survival with severe motor or mental disability is ultimately a judgment about quality of life, with the implication that "life with severe disability is worse than no life at all." Currently it is not possible to precisely predict outcome in patients in persistent vegetative states,[33] as distinct from death on the one hand or severe disability on the other. Life and death judgments based on quality of life appear more complex in pediatric versus adult patients. There are age-specific differences in coping and adapting to injuries that cause physical or mental disability. Younger children adapt better to physical and mental disability, and those adaptations may be better incorporated in family life.

Terms such as "mild," "moderate," or "severe" disability can subjectively describe levels of neurologic dysfunction. Categories such as "favorable" or "unfavorable" convey value judgments. Thus it is important to use appropriate terminology for coma prognosis. Parents of disabled children tend to strongly disagree with subjective and judgmental terminology, such as life with a "poor" or "unfavorable" outcome even if at a time after brain insult that they might feel utterly incapable of ever learning to cope with such an outcome. Thus with respect to ethical implications as well as the neurobiology of coma prognosis, the adage holds true: "children are not miniature adults."

IV Chapter 59

Intracranial Hypertension and Brain Monitoring

Robert C. Tasker and Marek Czosnyka

PEARLS

- As intracranial hypertension progresses, changes may occur in the vital signs, with an elevation of blood pressure, a decrease or an increase in pulse, and irregularity in the respiratory rhythm. These signs, sometimes associated with episodes of decerebrate rigidity, indicate the occurrence of transtentorial herniation or "coning" and imply the possibility of impending death if the process cannot be reversed.
- The continuous measurement of intracranial pressure is an essential modality in most brain monitoring systems. After a decade of enthusiastic attempts to introduce newer modalities for brain monitoring (e.g., tissue oxygenation, microdialysis, cortical blood flow, transcranial Doppler ultrasonography, and jugular bulb oxygen saturation), the measurement of intracranial pressure has become increasingly noticeable as a robust and only moderately invasive modality, and it can be realistically conducted in most critical care units.

In most organs in the human body, the environmental pressure for blood perfusion is either low or coupled to atmospheric pressure. The environmental pressure for the brain differs in this respect because the brain is surrounded and protected by a stiff skull. Thus a rise in environmental pressure—intracranial pressure (ICP)—may impede blood flow and cause ischemia. In pediatric critical care, ICP may be of acute significance in a number of instances (e.g., traumatic brain injury, bacterial meningitis, and the Fontan circulation). In this chapter we discuss how information from ICP monitoring helps our understanding and treatment of brain disorders.

Clinical Background

In critical illness, the early recognition and treatment of intracranial hypertension is important because it is a major cause of mortality and morbidity. Therefore an attempt should be made to collate the clinical evidence for and against its presence. The early symptoms and signs of this complication, however, which are invariably subtle and nonspecific (Table 59-1), make this form of assessment somewhat limited. As will be discussed later, as intracranial hypertension progresses, changes may occur in the vital signs, with an elevation of blood pressure, a decrease or an increase in pulse, and irregularity in the respiratory rhythm. These signs, sometimes associated with episodes of decerebrate rigidity, indicate the occurrence of transtentorial herniation or "coning" and imply the possibility of impending death if the process cannot be reversed. Unfortunately recognition at this stage is often too late to prevent death.

Brain tissue shifts may produce various "syndromes." First, transtentorial or cerebellar herniation may result in midbrain or medullary compression. Many of the clinical signs observed in association with herniation result from direct compression of structures by the impacted tissue or are due to angulation of nerves or arteries against normal structures in the area. These herniations can cause increasing coma, with distortion of the brainstem leading to midbrain and pontine hemorrhages. Cerebellar herniation is likely to occur when the increase in ICP is maximal in the posterior fossa. Such herniation occurs more commonly downward, squeezing one or more of the cerebellar tonsils through the foramen magnum; compressing the medulla; and leading to neck stiffness, head tilt, lower cranial nerve palsies, respiratory irregularities, or sudden cardiorespiratory arrest. Cerebellar herniation may occur upward through the tentorial notch, causing midbrain compression and leading to paralysis of upward gaze, dilated

Table 59–1 Early, Subtle Symptoms and Signs of Raised Intracranial Pressure

	Infant	Child
General state	Poor feeding	Anorexia and nausea
	Vomiting	Vomiting

Table 59–2 Clinical Features of Central Syndrome or Rostrocaudal Deterioration

Stage	Level of Consciousness	Respiration	Pupil Size and Reactivity	Oculocephalic and Oculovestibular Responses	Posture and Tone
Diencephalic (early to late) ↓	Agitation Drowsiness Stupor	Deep sighs or yawns Occasional pauses Cheyne-stokes or periodic breathing	Small (1–3 mm) with brisk reaction to light	Conjugate at rest and respond quickly	Normval or slightly increased Generalized muscular hypertonus
Midbrain to upper pontine ↓	Coma	Central hyperventilation	Midpositon (3–5 mm) with sluggish reaction to light	Dysconjugate	Decorticate posturing and increased tone
Lower pontine to upper medullary ↓	Deep coma		Midposition and fixed	Absent	Flaccid: (1) retained bilateral extensor plantars, (2) occasional flexor responses in the lower limbs
Medullary (terminal)	Deep coma	Irregular breathing interrupted by deep sighs, gasps, and then terminal apnea	May be unequal	Absent	Flaccid

Modified from Plum F, Posner JB: *Diagnosis of stupor and coma,* Philadelphia, 1966, FA Davis.

and fixed pupils, and respiratory abnormalities, although this type of cerebellar herniation is uncommon.

When intracranial hypertension is more marked in the supratentorial compartment, for instance, with acute intracerebral hematoma, the temporal lobe on the affected side may be displaced into the tentorial notch and result in unilateral transtentorial herniation. The herniation may be more marked anteriorly (uncal) or posteriorly (hippocampal) and is usually accompanied by displacement of the ipsilateral cingulate gyrus under the falx (cingulate herniation). Clinical manifestations of this condition may include ipsilateral third nerve palsy, contralateral hemiparesis, respiratory irregularities, deepening coma with decerebrate posturing, and ultimately cardiorespiratory arrest.

Finally, when bilateral or a general increase in ICP in the supratentorial compartment occurs, as in diffuse cerebral edema, central transtentorial herniation may occur. This condition leads to impairment of upward gaze, pupillary constriction, hypertonus, and decerebrate posturing. Temperature irregularities and diabetes insipidus may develop, and cardiorespiratory arrest may occur eventually. A summary of the clinical features of "central syndrome" is given in Table 59-2.

Physiology of the Intracranial Vault

A physiologic process underlies the clinical picture of intracranial hypertension, and in this section of the chapter our intention is to familiarize the pediatric intensivist with new approaches to understanding the hydrodynamic function of the intracranial vault. In other words, what happens before brain tissue shifts occur? Most of the developments in this field have occurred in the setting of adult neurosurgery and critical care. In common with any aspect of physiology, the tasks have been straightforward: Can it be measured? Can it be modeled? How do the models help in the understanding of the underlying homeostasis and the mechanism of derangement and perturbation? We highlight these topics and hope you will see the obvious application to pediatric critical care; that is, use of this form of cerebral monitoring and potential approaches to ICP assessment. In many specific conditions, however, knowledge is still lacking with regard to which parts of the adult-generated theory may be fully applicable to children.

Intracranial Pressure

The brain is an expansile structure that expands and contracts with each beat of the heart. Because there are no valves within the venous drainage from the brain, any changes in intrathoracic pressure are transmitted to ICP. Such phenomena can be seen and palpated simply through the examination of a baby's fontanelle and quantified with cerebrospinal fluid (CSF) pressure recording. Once the cranial sutures have fused, any change in cerebral blood volume (CBV) on the arterial-to-arteriolar side of the cerebral circulation must be compensated by either reduction in cerebral venous volume or by phasic movement of CSF out of the intracranial vault through the foramen magnum. Such expansion of the cerebral mantle with compression of the lateral ventricles during systole and movement of CSF through the aqueduct of Sylvius and to and fro through the foramen magnum was first visualized with pneumoencephalography. These changes now can be seen more easily with dynamic magnetic resonance imaging (MRI). Inevitably a lag phase exists between the systolic increase in CBV and the effect of the compensatory mechanisms so that CSF pressure increases to reflect, in part, the systolic waveform. The CSF pressure waveform is not an exact replica of the arterial waveform because it has been "filtered" by the combined effects of arterial wall compliance of the cerebral arteries, cerebrovascular resistance, and intracranial compliance (Figure 59-1).[1]

Hydrodynamic Model of Intracranial Pressure

ICP is a function of the circulation of cerebral blood and CSF in which ICP is related to a vascular component ($ICP_{vascular}$) and a CSF component (ICP_{CSF}). There is considerable interest

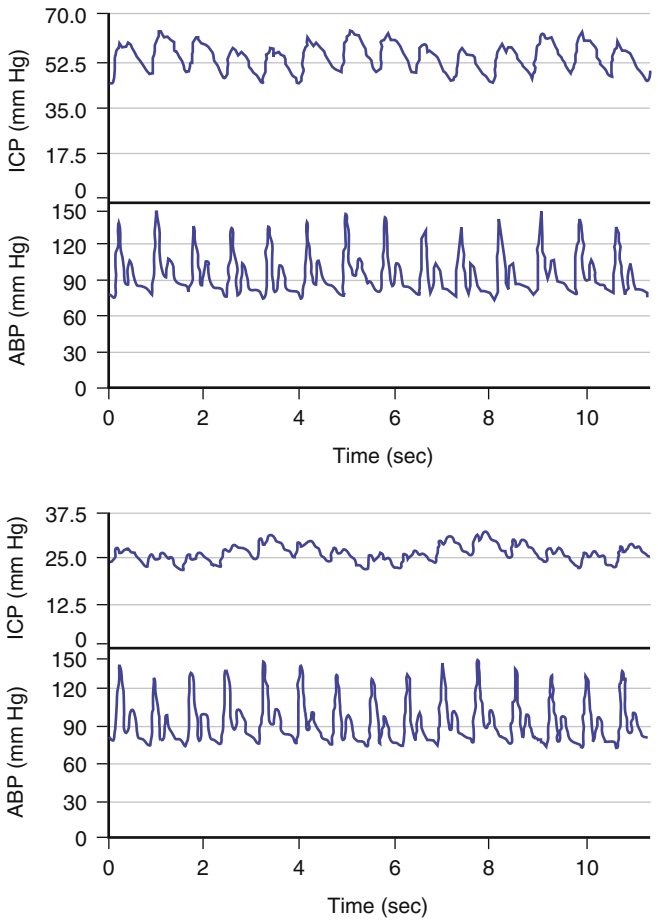

Figure 59–1. Examples of waveforms of intracranial pressure *(ICP)* and arterial blood pressure *(ABP)* recorded at a high level of ICP (*upper plots*) and a lower level of ICP (*lower plots*). Note that the pattern of ABP waveform is relatively invariant, but ICP changes its shape considerably.[1]

in modeling these relationships as an aid to understanding some of the complex phenomena seen in critically ill patients. The vascular component is difficult to express quantitatively.[2] It is probably derived from the pulsation of CBV that is detected and averaged by nonlinear mechanisms of regulation of CBV. More generally, multiple variables such as the arterial blood pressure (ABP), autoregulation, and cerebral venous outflow all contribute to the vascular component. In regard to the other component, circulation of CSF, 80% of CSF is the product of active secretion by the choroid plexus, and movement of interstitial fluid into the ventricles and subarachnoid space contributes the remainder. Drainage is largely passive via arachnoid villi and granulations into the superior sagittal sinus and spinal root sleeve venous drainage. Some drainage, which is currently unquantifiable, occurs through the olfactory bulb and mucosa into the deep cervical lymphatics. The equation by Davson and colleagues[3] shows the immediate relationships controlling CSF pressure, in which ICP_{CSF} = (Resistance to CSF outflow) × (CSF formation) + (Pressure in sagittal sinus). With these two components—vascular and CSF—taken together, Figure 59-2 shows the hydrodynamic model of cerebral blood flow (CBF) and CSF circulation and the equivalent electrical circuit.[4] This model can be used to interrogate CSF dynamics clinically (described later in this chapter).

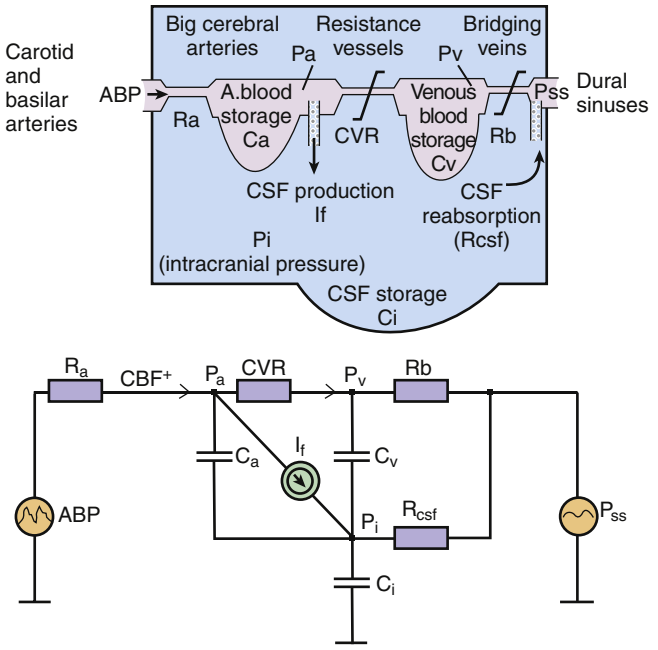

Figure 59–2. Hydrodynamic model of cerebral blood and cerebrospinal fluid (CSF) circulation (*upper plot*) and its electrical equivalent (*lower plot*).[4] *ABP,* Arterial blood pressure; *CBF,* cerebral blood flow.

Cerebral Vasodilation and Cerebrospinal Fluid Pressure

Three major factors regulate CBF: cerebral perfusion pressure (CPP), partial pressure of arterial carbon dioxide ($Paco_2$), and partial pressure of arterial oxygen (Pao_2). Hypercapnia causes cerebral vasodilatation, increases CBF, and increases ICP. Hypoxia also causes cerebral vasodilatation and a rise in ICP. CPP is taken as the difference between mean ABP and ICP and represents the pressure gradient acting across the cerebrovascular bed; therefore it is an important factor in regulation of CBF.[5] Under normal circumstances, over a wide range of CPP, CBF is autoregulated (i.e., it remains constant when CPP varies). Thus in regard to the effect of this phenomenon on ICP, active cerebral arteriolar constriction occurs and ICP consequently falls to maintain CBF when ABP is increased (i.e., hypertension). At the other extreme, systemic hypotension (within the autoregulatory range) provokes cerebral vasodilatation and an increase in ICP. When autoregulation is defective, ICP increases and decreases with ABP (Figures 59-3 and 59-4).[4]

In practice, measurement of ICP can be used to estimate the CPP when it is the most significant "downstream" pressure acting on vascular perfusion. However, in some instances, venous pressure may be of more significance, such as critical Fontan circulation.

Cerebral Perfusion Pressure and Autoregulation

In adults, the lower limit for CPP is taken as a threshold of 60 to 70 mm Hg. In children, however, it is evident from measurement of normal ABP that the lower limit for CPP must be lower than this adult level for much of childhood (Figure 59-5).[6] A new concept that has arisen in the adult critical care

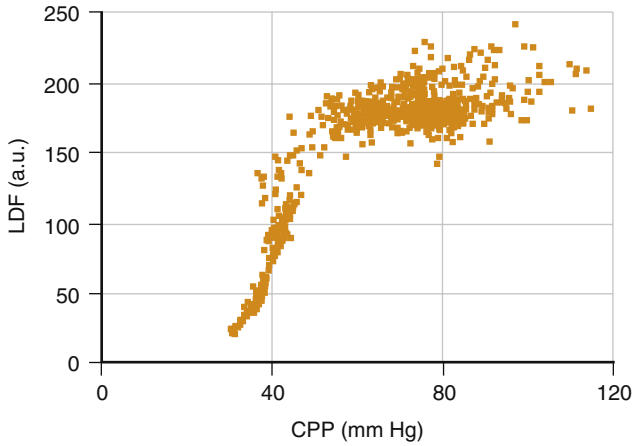

Figure 59–3. Pressure autoregulation where cerebral blood flow *(CBF)* stays constant. CBF is measured with laser Doppler flowmetry *(LDF)* (*y axis*). During changes in cerebral perfusion pressure *(CPP) (x axis),* CBF remains constant until a critical threshold is reached, below which CBF falls passively with decreasing CPP.

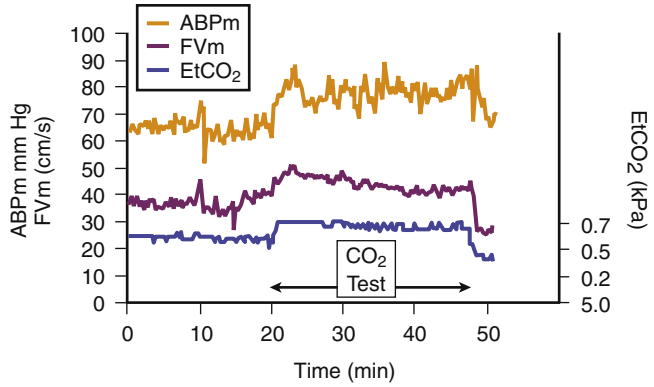

Figure 59–4. Cerebral vessels dilate when arterial content of carbon dioxide (here measured with end-tidal carbon dioxide [E_tCo_2]) increases. A rise in cerebral blood flow (here assessed with transcranial Doppler velocity [FVm]) also increases.[5] *ABPm,* Mean blood pressure.

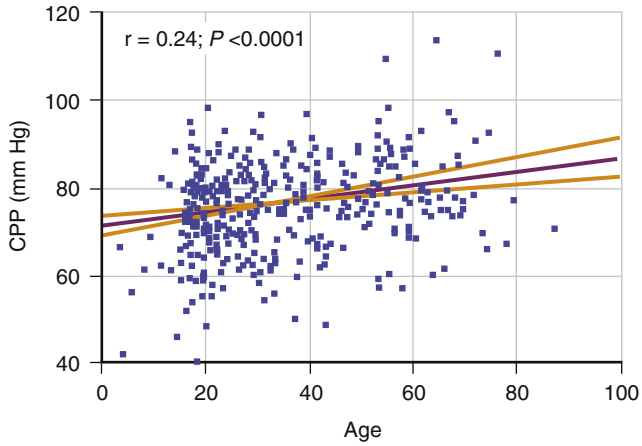

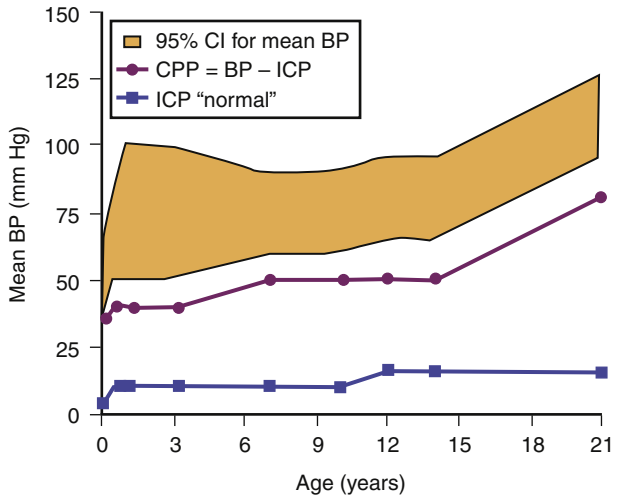

Figure 59–5. *Top panel,* The empiric relation between cerebral perfusion pressure *(CPP)* and age in nearly 400 adults after head injury. *Bottom panel,* Estimated lower limit of CPP by age in the pediatric range on the basis of normal blood pressure *(BP)* and intracranial pressure *(ICP)* data.[6]

literature is worth considering in this context. The idea is that a autoregulatory reserve exists that is considered to be the difference between current mean CPP and the lower limit of autoregulation.[7] This reserve may become exhausted. Alternatively, it may change over time, and it has been argued that the border between adequate and nonadequate CPP should be assessed individually and frequently.

How is this assessment performed? Autoregulation of CBF may be assessed by artificial manipulation of ABP with medication, but only at infrequent intervals and with the risk that the drugs used may have a direct cerebrovascular effect. Alternatively, transient hyperemia after transient carotid compression has been used as an all-or-none index of whether autoregulation is intact. A more sophisticated approach is to examine the effect of natural variation in ABP; however, this technique requires precise signal processing. For example, to date, the most robust clinical method is to monitor the slow fluctuations in ABP that last from 30 seconds to a few minutes and are almost always present in patients who undergo ventilation[8-9]; the rate of change observed is usually sufficient to provoke a noticeable vasomotor response. Figure 59-6 shows that continuous monitoring of cerebrovascular reactivity is possible with this method even during large spontaneous ICP waves (B and plateau waves; discussed later in this chapter).[10]

Measurement of Intracranial Pressure

Monitoring Devices

ICP monitoring devices can be categorized according to the anatomic site of placement and the manner in which the pressure record is transduced. For example, in babies, surface tonometry, applied to the anterior fontanelle, was an early method used for noninvasive transduction of the ICP waveform. This method, however, is limited because the force of applanation influences the pressure record. More standard approaches for the measurement of ICP rely on manometry of catheters placed in the ventricular system or in other CSF space. Alternatively, pressure sensors may be placed within the brain.

The complications of ICP monitoring include infection, hemorrhage, CSF overdrainage, and monitor malfunction. The overall incidence of infection for the various forms of ICP monitors is not significantly different regardless of their location, but the severity of infection may differ slightly depending on the anatomic site of the device. Hemorrhage is a rare

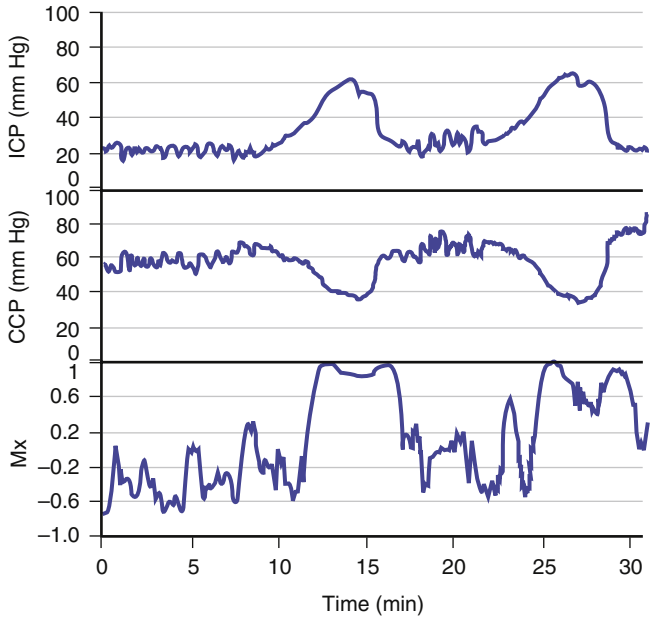

Figure 59–6. Continuous monitoring of cerebral autoregulation during plateau waves of raised intracranial pressure *(ICP)*. Positive values of the autoregulation index *(Mx)* indicate faulty autoregulation.[9] Autoregulation fails during the waves, when cerebral vasodilation occurs.[10] *CPP,* Cerebral perfusion pressure.

complication of ICP monitoring and is a direct result of surgical placement of the device. Overdrainage of ventricular catheters can result in rapid emptying of the ventricular system and accumulation of subdural hematomas. Close attention must be made to prevent drainage systems from being placed too low or falling to the floor. This complication is most serious when intraventricular pressure is monitored in children with hydrocephalus. Overdrainage also may result in pneumocephalus.

Overall, an intraventricular drain connected to an external pressure transducer is still considered the gold standard for measuring ICP.[11,12] ICP can be controlled by CSF drainage, and the transducer can be adjusted to zero externally. After 5 days of monitoring, however, the risk of infection starts to increase, with an overall risk estimated to be about 5%.[13] Insertion of the ventricular catheter may be difficult or impossible in cases of advanced brain swelling. As an alternative, modern catheter-tipped ventricular, subdural, or intraparenchymal microtransducers have been used (the most popular types are the Camino ICP Bolt, Camino Laboratories, San Diego, Calif., and Codman MicroSensor, Johnson and Johnson Professional Inc, Raynham, Mass.). These microtransducers are said to reduce the infection rate and risk of hemorrhage[13] and have excellent metrologic properties.[14] One disadvantage of microtransducer systems is that they cannot, in general, be readjusted to zero after insertion, and considerable zero drift sometimes can occur in long-term monitoring.[15]

Regarding other forms of monitoring, contemporary epidural sensors are much more reliable now than they were 10 years ago. Nevertheless, the question as to whether epidural pressure can express ICP with confidence and under all circumstances is still unanswered. Lumbar CSF pressure is seldom measured in patients receiving neurointensive care. This form of assessment of craniospinal dynamics is more often used in the assessment of hydrocephalus and benign intracranial hypertension. It is unreliable if the instantaneous value of the fluid column pressure is recorded; at least 30 minutes averaging in resting conditions (with a period of overnight monitoring as the gold standard) is the desired requirement. Finally, attempts to monitor ICP noninvasively are still in a phase of technical evaluation,[16] with the most promising methods based on transcranial ultrasonography.[17,18]

Noninvasive Inference of Intracranial Pressure

It would be helpful to measure ICP or CPP without invasive transducers. To this end, transcranial Doppler (TCD) examination,[19] tympanic membrane displacement,[20] and ultrasound "time of flight"[18] techniques have been suggested. The description of TCD sonography by Aaslid, Markwalder, and Nornes[21] permitted bedside monitoring of one index of CBF noninvasively, repeatedly, and even continuously. The problem has been that it is a "big tube technique" that measures flow velocity in branches of the circle of Willis, most commonly the middle cerebral artery (MCA). Compliant branches of the MCA can be compared with two physiologic pressure transducers. The pattern of blood flow within these tubes is certainly modulated by transmural pressure, that is, CPP and the distal vascular resistance (also modulated by CPP). What is the calibration factor, and how should we compensate for unknown nonlinear distortion?

Reasonable correlation exists between the pulsatility index of MCA velocity and CPP after head injury, but absolute measurements of CPP cannot be extrapolated.[22] Other investigators have suggested that "critical closing pressure" derived from flow velocity and arterial pressure waveform approximated the value of ICP.[23] The accuracy of this method, however, has never been satisfactory.[24] Aaslid et al.[25] suggested that an index of CPP could be derived from the ratio of the amplitudes of the first harmonics of the ABP and the MCA velocity (detected with TCD sonography) multiplied by mean flow velocity. Recently, a method for the noninvasive assessment of CPP has been reported, derived from mean ABP multiplied by the ratio of diastolic to mean flow velocity.[26] This estimator can predict real CPP—in the adult range (60 to 100 mm Hg)—with an error of less than 10 mm Hg for more than 80% of measurements. This method is of potential benefit for the continuous monitoring of changes in real CPP over time in situations where direct measurement of CPP is not readily available. Finally, a more complex method aimed at the noninvasive assessment of ICP has been introduced and tested by Schmidt et al.[27] The method is based on the presumed linear transformation between ABP and ICP waveforms. All of these techniques still require validation in pediatric series.

Last, there is one other potential method for predicting increased ICP that has emerged from the adult literature and is now being tested in children. Optic nerve sonography can be used to assess enlargement of the optic nerve sheath, and it is sheath diameter that appears to be directly related to the level of ICP.[28] A recent study by Le et al[29] included 64 children, 24 (37%) of whom had a confirmed diagnosis of increased ICP. An optic nerve sheath diameter greater than 4.0 mm in subjects younger than 1 year and greater than 4.5 mm in older children was considered abnormal. The sensitivity of optic nerve sheath diameter as a screening test for increased ICP was 83% (95% confidence interval [CI], 0.60 to 0.94); specificity

was 38% (95% CI, 0.23 to 0.54); positive likelihood ratio was 1.32 (95% CI, 0.97 to 1.79); and negative likelihood ratio was 0.46 (95% confidence interval, 0.18 to 1.23). Taken together, it is clear that this technique may be useful, but currently it is inadequate as an aid to decision making about whether raised ICP is present in a particular child.

Pressure Compartments

In a fluid-filled container, pressure is the same wherever one chooses to measure it within that space. Generally, uniformly distributed ICP can be seen only when CSF is circulating freely among all of its natural pools, equilibrating pressure everywhere. When little or no CSF volume is left (because of brain swelling), the assumption of one uniform value of ICP is questionable. (It is for this reason that brain tissue shift and herniation occur: they move down tissue pressure gradients.) It is worth remembering that with the commonly used catheter-tipped, intraparenchymal probes, the measurement of pressure is at a particular point, an area of cortex within a hemisphere, and the ICP may merely reflect pressure in that compartment rather than be representative of pressure within the ventricular system (i.e., real CSF pressure).[30]

Analysis of Intracranial Pressure

Normal Values in Intracranial Pressure Monitoring

Establishing a universal "normal value" for ICP is difficult because it depends on age, body posture, and clinical condition. In the horizontal position, a normal ICP value in healthy adults was reported to be within the range of 7 to 15 mm Hg.[31] In the upright position ICP is a negative value, with a mean of around ~10 mm Hg but not exceeding ~15 mm Hg.[32] In infants and children, normal values for ICP, usually taken at the time of a "negative" diagnostic lumbar puncture, are lower than the adult values and are probably between 5 and 10 mm Hg.

The definition of a raised ICP value depends on the specific disease. In hydrocephalus, a pressure above 15 mm Hg can be regarded as elevated. After head injury, any pressure above 20 mm Hg is considered abnormal, and aggressive treatment is usually started with values above 25 mm Hg.[33] Also, in most cases, ICP varies with time. Decent averaging for at least 30 minutes is needed to calculate "mean ICP." The patient should be in a horizontal position during the measurement, and movement should be avoided.

Normal Trends in Intracranial Pressure and Waveform Analysis

Overnight monitoring, during natural sleep, provides a "grand average" with a good description of the dynamics of ICP. When monitored continuously in acute states (e.g., in the presence of head injury, poor-grade subarachnoid hemorrhage, and intracerebral hematoma), changes in the time-averaged mean ICP may be classified into relatively few patterns (Figure 59-7).[34] The first pattern, low and stable ICP (below 20 mm Hg) is seen after uncomplicated head injury (Figure 59-7, *A*). Such a pattern also is seen commonly in the initial period after brain trauma before brain swelling evolves. The second pattern, high and stable ICP (above 20 mm Hg), is the most common pattern to follow head injury (Figure 59-7, *B*). The third pattern is vasogenic waves, that is, B waves (Figure 59-7, *C*) and plateau waves (Figure 59-7, *D*). The fourth pattern is ICP waves related to changes in ABP and hyperemic events (Figure 59-7, *E* to *G*). The final pattern, refractory intracranial hypertension (Figure 59-7, *H*), usually leads to death unless surgical decompression is undertaken.

In addition to these patterns, more information can be gained from analyzing the ICP waveform. The ICP waveform consists of three components, which overlap in the time domain but can be separated in the frequency domain (Figure 59-8).[34,35] The pulse waveform has several harmonic components; of these, the fundamental component has a frequency equal to the heart rate. The amplitude of this component (AMP) is useful for the evaluation of various indices. The respiratory waveform is related to the frequency of the respiratory cycle (8 to 20 cycles/min). "Slow waves" are usually not as precisely defined as in Lundberg's original work[36]; that is, all components that have a spectral representation within the frequency limits of 0.05 to 0.0055 Hz (20-second to 3-minute period) are considered slow waves. The magnitude of these waves can be calculated as the square root of the power of the signal, of the passband, or of the equivalent frequency range at the output of the digital filter.

Assessment of Pressure-Volume Compensatory Reserve and Cerebrovascular Pressure Reactivity

Theoretically, the compensatory reserve in intracranial hydrodynamics can be studied through the relation between ICP and changes in volume of the intracerebral space, known as the pressure-volume curve.[37,38] For example, the RAP index, an index of reserve based on the correlation coefficient (R) between AMP amplitude (A) and mean pressure (P), can be derived. This calculation can be done in real time with bedside computing to calculate the linear correlation between consecutive, time-averaged data points of AMP and ICP (usually 40 such samples) acquired over a reasonably long period to average over respiratory and pulse waves (usually 6- to 10-second epochs). The RAP index indicates the degree of correlation between AMP and mean ICP over short periods (~4 minutes). An RAP index close to zero indicates lack of synchronization between changes in AMP and mean ICP. This index denotes good pressure-volume compensatory reserve at low ICP (i.e., a change in volume produces little or no change in pressure) (Figure 59-9).[39] When the RAP index rises to +1, AMP varies directly with ICP and indicates that the "working point" of the intracranial space shifts to the right toward the steep part of the pressure-volume curve. Here compensatory reserve is low; therefore any further rise in volume may produce a rapid increase in ICP. After head injury and subsequent brain swelling, the RAP index is usually close to +1. With any further increase in ICP, AMP decreases and RAP values fall below zero. This phenomenon occurs when cerebral autoregulatory capacity is exhausted; the pressure-volume curve bends to the right, the capacity of cerebral arterioles to dilate in response to a fall in CPP is exhausted, and the arterioles tend to collapse passively. This phenomenon indicates terminal

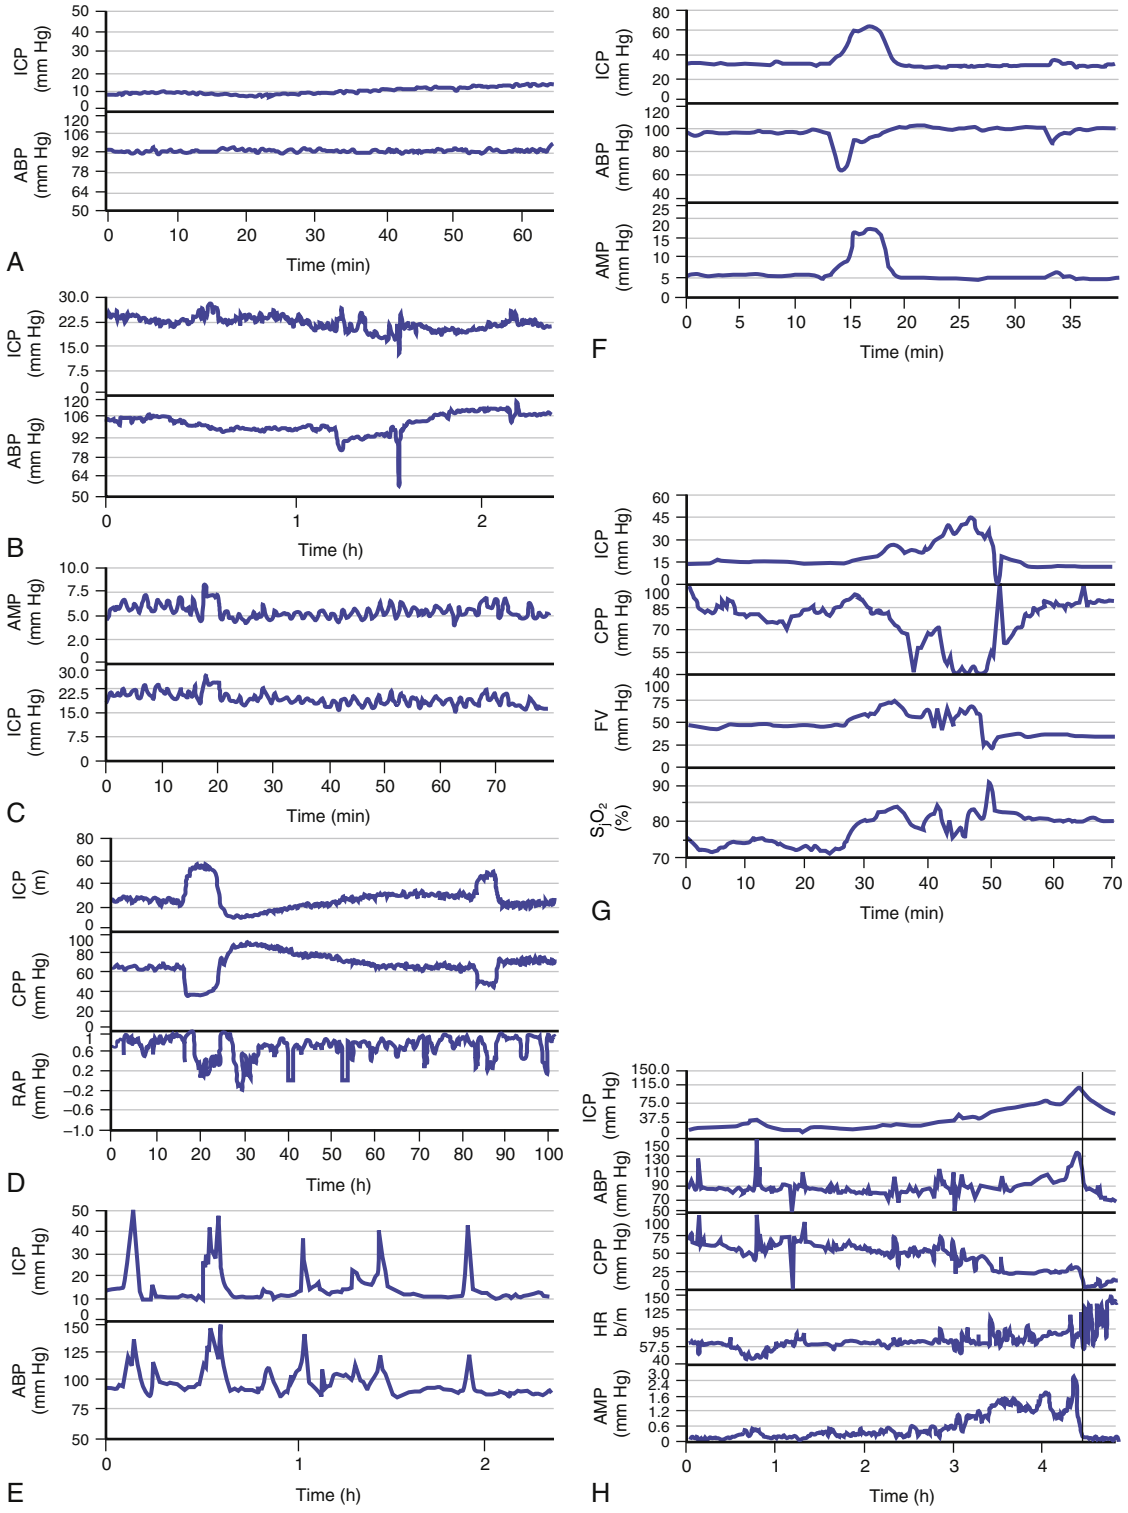

Figure 59–7. Examples of intracranial pressure *(ICP)* recording in various clinical scenarios after head trauma[34]; note the different scales. **A,** Low and stable ICP: mean arterial blood pressure *(ABP)* is plotted in the *bottom panel*. **B,** Stable and elevated ICP: such a picture can be seen most of the time in patients with head injuries. **C,** B waves of ICP: these are seen both in mean ICP and spectrally resolved pulse amplitude of ICP *(AMP)*. They also are usually seen in a plot of time-averaged ABP, but not always. **D,** Plateau waves of ICP: cerebrospinal compensatory reserve is usually low when waves are recorded (the correlation coefficient between AMP and mean ABP, RAP, is close to +1). At the top of the waves, during maximal vasodilatation, integration between pulse amplitude and mean ICP fails, as indicated by afall in RAP. After the plateau wave, ICP usually falls below the baseline level and cerebrospinal compensatory reserve becomes better. *CPP,* Cerebral perfusion pressure. **E,** High, spiky waves of ICP caused by sudden increases in ABP. **F,** Increase in ICP caused by temporary decrease in ABP. **G,** Increase in ICP of hyperemic nature: both blood flow velocity *(FV)* and jugular bulb oxygen saturation *(Sjo_2)* increase in parallel with ICP. **H,** Refractory intracranial hypertension: ICP increases within a few hours to 100 mm Hg. The *vertical line* denotes the likely moment when the vasomotor centers in the brainstem became ischemic. At this point the heart rate *(HR)* increased and CPP decreased abruptly. Note that pulse amplitude of ICP *(AMP)* disappeared around 10 minutes before this terminal event.

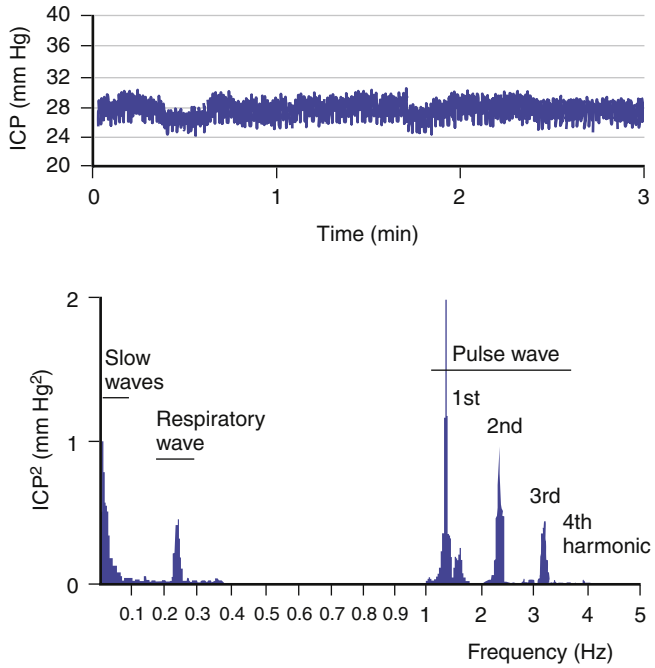

Figure 59–8. Example of intracranial pressure *(ICP)* recording showing pulse, respiratory waves, and "slow waves" overlapped in the time domain (*top panel*) and separated in the frequency domain (*bottom panel*).[35]

cerebrovascular derangement with a decrease in pulse pressure transmission from the arterial bed to the intracranial compartment.

Another ICP-derived index is the pressure-reactivity index (PRx), which incorporates the idea of assessing cerebrovascular reaction by observing the response of ICP to slow spontaneous changes in ABP (discussed previously).[40] For example, when the cerebrovascular bed is normally reactive, any change in ABP produces an inverse change in CBV and thus ICP. When cerebrovascular reactivity is disturbed, changes in ABP are transmitted passively to ICP. Again, with the use of computational methods similar to those used for the calculation of the RAP index, PRx is determined with the calculation of the correlation coefficient between 40 consecutive, time-averaged data points of ICP and ABP. A positive PRx signifies a positive gradient of the regression line between the slow components of ABP and ICP, which is suggested as being associated with passive behavior of a nonreactive vascular bed (Figure 59-10, *A*).[8] A negative value of PRx reflects a normally reactive vascular bed, because ABP waves provoke inversely correlated waves in ICP (Figure 59-10, *B*). In practice, this index correlates well with TCD ultrasonography indices of autoregulation.[8] Also, abnormal values of both PRx and RAP, which are indicative, respectively, of poor autoregulation or deranged cerebrospinal compensatory reserve, have been shown to be predictive of a poor outcome in adults after head injury.[7]

To date, there are few data on the use of these hydrodynamic indices in children. One report in 32 hydrocephalic children, however, examined maximum ICP, RAP index, magnitude of slow waves, and AMP in individuals presenting with possible ventriculoperitoneal shunt dysfunction.[41] The authors concluded that, because of the association between abnormalities in the parameters studied and improvement in symptoms in patients undergoing shunt revision, such computerized ICP assessments are beneficial. In another study of 21 children with head injuries, Brady et al.[42] used continuous monitoring of the PRx and found this parameter to be associated with outcome. In addition, they found that impaired cerebrovascular pressure reactivity was evident at low levels of CPP. The implication is that PRx may be useful for defining age-specific and possibly patient-specific optimal targets for CPP (see the following section).

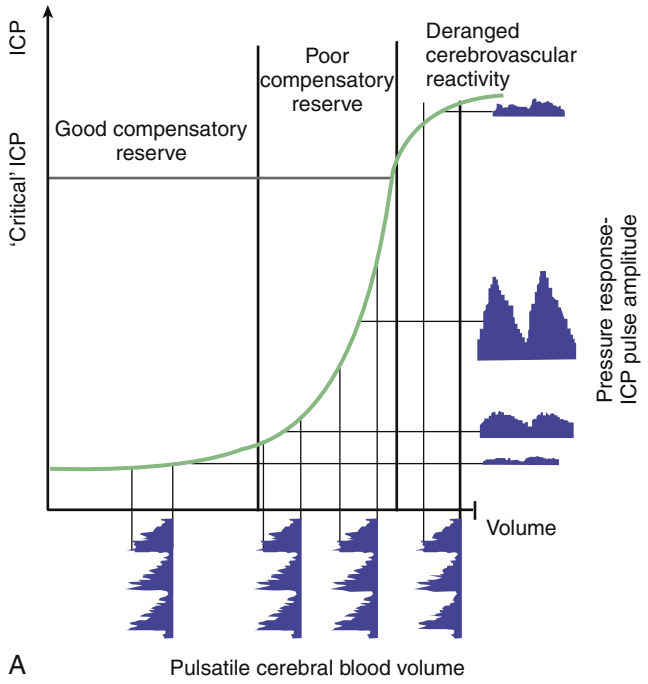
Monitoring Optimal Cerebral Perfusion Pressure Derived from Intracranial Pressure Parameters

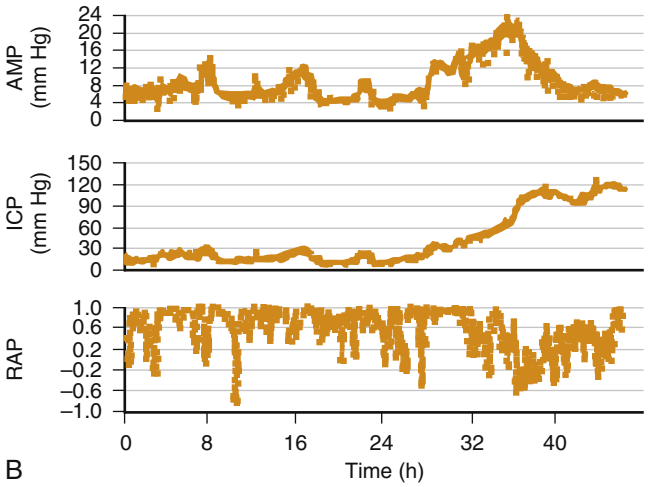
Both the PRx and the RAP index can be used to evaluate secondary variables that combine the value of absolute ICP and CPP with information about the state of autoregulatory and compensatory reserves. In adults with head trauma, PRx plotted against CPP gives a U-shape curve that indicates, for most patients, a value of CPP for which pressure-reactivity is optimal.[7] This optimal pressure can be estimated with the plotting and analyzing of the PRx-CPP curve in sequential 6-hour periods; the greater the distance between the current and the "optimal" CPP, the more likely outcome will be poor. This potentially useful method attempts to refine the current approach to CPP-oriented therapy: levels of CPP that are either too low (ischemia) or too high (hyperemia and a resulting increase in ICP) are detrimental. It has been suggested that CPP in adults should be optimized to maintain CPP in the most favorable global state.[7]

Quantifying the Cumulative Intracranial Pressure/Cerebral Perfusion Pressure Insult to the Brain

In adults with severe head injury, the cumulative insult to the brain can be quantified in a number of ways. For example, an average ICP above 25 mm Hg during the entire period of monitoring doubles the risk of death.[7] Averaged values of the RAP index and the PRx also are strong predictors of fatal outcome. Both these indices suggest that good vascular reactivity is an important element of brain homeostasis, which enables the brain to protect itself against an uncontrollable rise in intracerebral volume. Also, a low value of slow waves of ICP also is indicative of a fatal outcome after head injury. Because each of these parameters—ICP, PRx, and the power of ICP slow waves—is an independent predictor of outcome, these three variables, although mutually correlated, should be considered jointly in any analysis.

With regard to mean CPP, it is now one of the variables that is actively targeted with treatment; therefore, it may have lost its predictive power for outcome. This fact does not mean that short-term decreases in CPP ("CPP insults") have become any more benign. Reductions in CPP below specific threshold values are associated with poor outcome. In cases of severe pediatric head injury, studies have defined the CPP associated with poor outcome as between 40 and 65 mm Hg. For example, Downard et al[43] studied 118 children (mean age, 7 years) with an overall mortality rate of 28% and found that the CPP associated with survival was greater than 40 mm Hg. No further improvement in outcome was seen with mean CPP in deciles from 40 to 70 mm





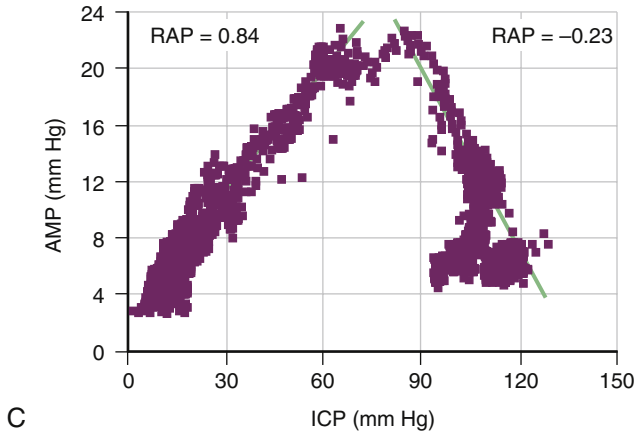


Figure 59–9. **A,** In a simple model, pulse amplitude of intracranial pressure *(ICP)* (AMP, expressed along the *y* axis on the right side of the panel) results from pulsatile changes in cerebral blood volume (expressed along the *x* axis) transformed by the pressure-volume curve. This curve has three zones: a flat zone, expressing good compensatory reserve; an exponential zone, depicting poor compensatory reserve; and a flat zone again, seen at very high ICP (above the "critical" ICP), depicting derangement of normal cerebrovascular responses. The pulse amplitude of ICP is low and does not depend on mean ICP in the first zone. The pulse amplitude increases linearly with mean ICP in the zone of poor compensatory reserve. In the third zone, the pulse amplitude starts to decrease with rising ICP. **B,** Example of the relation between AMP and mean ICP recorded during a 46-hour period, during which terminal intracranial hypertension developed. Pulse amplitude increased first proportionally to the change in ICP but started to decrease when ICP increased above 80 mm Hg. **C,** The regression plot between AMP and ICP indicates a biphasic relation of positive and negative slopes. The correlation coefficient between AMP and ICP *(RAP)* was positive before 32 hours but negative after that; this indicated terminal cerebrovascular deterioration.[39]

Hg. The pediatric guideline for severe head injury is that "CPP greater than 40 mm Hg should be maintained."[33] A modification of this recommendation is to titrate the CPP threshold according to age: a threshold of 40 to 50 mm Hg in infants and toddlers, 50 to 60 mm Hg in children, and greater than 60 mm Hg in adolescents.

Clinical Utility of Intracranial Pressure Monitoring with Other Monitoring Modalities

The continuous measurement of ICP is an essential modality in most brain monitoring systems. After a decade of enthusiastic attempts to introduce newer modalities for brain monitoring (e.g., tissue oxygenation, microdialysis, cortical blood flow, TCD ultrasonography, and jugular bulb oxygen saturation), it is becoming increasingly obvious that ICP is robust, only moderately invasive, and can be realistically conducted in most critical care units. In previous sections of this chapter we noted that ICP measurement is a complex modality that contains information about compensatory mechanisms intrinsic to the brain and regulation of CBF. Thus continuous monitoring is required to control raised ICP. For example, most authors agree that ICP should be measured in patients with acute states such as head injury, poor-grade subarachnoid hemorrhage, and intracerebral hematoma and that monitoring should be linked with therapy. CPP-oriented protocols,[44] osmotherapy, and the Lund protocol[45] cannot be conducted correctly without guidance from real-time ICP recording. Similarly, a decision about performing a surgical intervention such as decompressive craniectomy should be supported by the close inspection of the trend of ICP and, preferably, by information derived from its waveform (see previous discussion).[46]

Newer modalities, however, may provide supplementary information about the state of the injured brain in a comatose patient. We now discuss the role of these modalities, but first, by way of context, some consideration should be given to the mechanisms underlying brain injury.

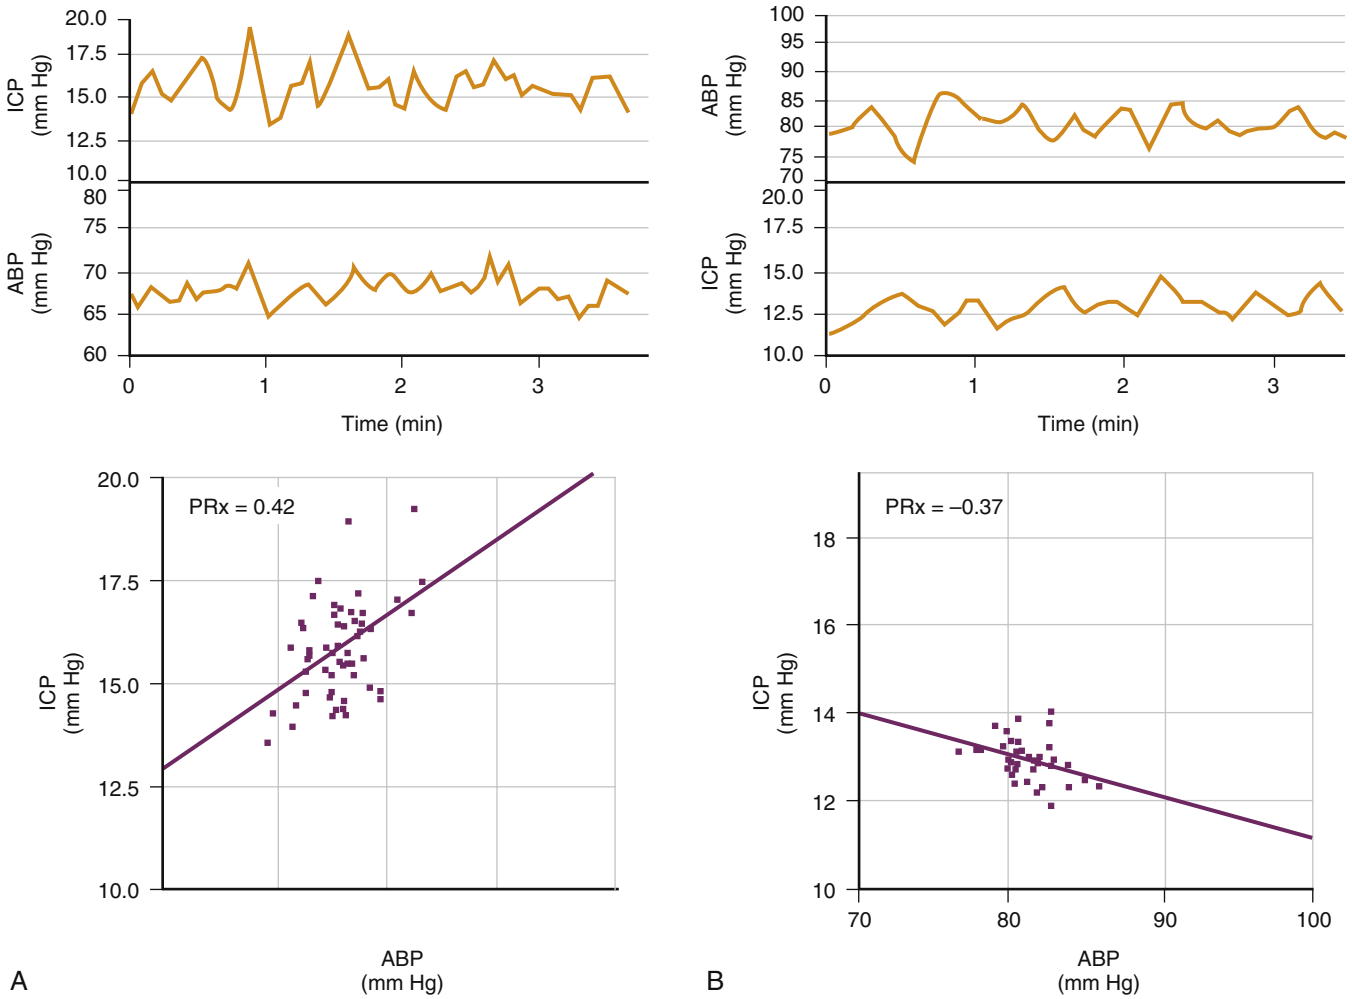

Figure 59–10. Relation between slow waves of arterial pressure *(ABP)* and intracranial pressure *(ICP)*. **A,** Slow waves in ICP and ABP produce a positive correlation (*lower left panel*), giving a positive value of the pressure-reactivity index *(PRx),* which indicates loss of cerebrovascular reserve. **B,** Coherent waves both in ABP and ICP produced a negative correlation coefficient when plotted on the regression graph (*lower right*), giving values of PRx that were clearly negative.

Mechanism of Brain Injury Where Intracranial Hypertension Occurs

In patients with a head injury, MRI commonly reveals focal lesions within the frontal and temporal lobes, the temporal poles, and the limbic system, including its connections with the orbitofrontal surface of the frontal cortex.[47,48] Pathologic change may occur by means of several injurious mechanisms in these regions. In the temporal lobes or its connections, manifestations of the following conditions may be found:

1. Direct high-speed impact injury with or without acceleration-deceleration forces. In this instance, the medial temporal lobe is vulnerable to mechanical deformation and contusion.[49]
2. Metabolic perturbation resulting from vascular or systemic factors such as hypoxia, ischemia, hypoglycemia, and seizures. In these head injury–related insults, there is a predilection for vulnerability within a structure in the temporal limbic system, the hippocampus.[50]
3. Diffuse axonal injury as a consequence of rotational forces at the time of injury affecting axonal integrity; thereafter, secondary or postacute deafferentation or deafferentation of structures such as the hippocampus occurs.[51,52]
4. Raised ICP with brain swelling resulting in pressure necrosis of the main cortical input to the hippocampus, to the parahippocampal gyrus, and against the free edge of the tentorium cerebelli.[53]

Each of these four mechanisms may result in injuries that, in the long term, induce deficits in neuropsychologic function.[54] However, only the fourth mechanism (pressure necrosis of the parahippocampal gyrus) depends on the development and presence of brain swelling.[53] A fifth injurious mechanism, which is important in regard to morbidity, is best shown by the disease to the frontal lobes. Recent research in children suggests that emerging or developing executive functions may be particularly vulnerable when the frontal lobes are injured in childhood.[55] In the context of head injury, such an insult is not excluded by the absence of focal brain lesions detected with MRI. For example, Slawik et al.[54] used MRI-volumetric analysis to study pediatric survivors of severe head injury. On follow-up 4 years after the accident, a decrease in the frontal gray and white matter volume was found in those with raised ICP, even when there had been no focal areas of abnormal signal in the frontal lobes during the acute episode. The substrate for this change

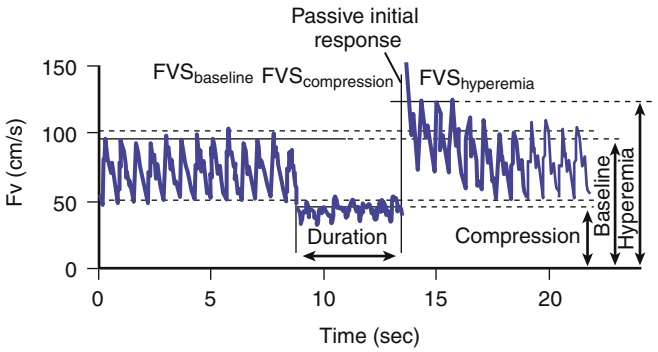

Figure 59–11. Transient hyperemic response used test to assess autoregulation: middle cerebral artery blood flow velocity *(Fv)* is measured with transcranial Doppler ultrasonography before, during, and after a 6-second compression of the carotid artery. Hyperemia after release of compression signifies properly functioning vascular reactivity. *FVS*, Flow velocities.

in the frontal lobes is most likely compromised perfusion to the frontal or anterior cranial compartment[56,57] that may well represent a "frontal compartment syndrome."[54] Another potentially remediable physiology is posttraumatic vasospasm.[58,59] Thus in this final pathophysiologic mechanism, a manifestation of the following condition may occur:

5. Frontal hemodynamic perfusion failure as a consequence of inadequate local CBF, failed local cerebral autoregulation, raised ICP, or anterior compartment syndrome (Figure 59-11).

When consideration is given to monitoring other modalities besides ICP, two problems are encountered. The first problem is understanding the extent to which these mechanisms contribute to the physiologic derangements that can be followed in the intensive care unit. The second problem is making a difference in patient assessment and outcomes, provided these mechanisms can be influenced.

Monitoring and the Postinsult Natural History

In a patient with a severe head injury, the value and utility of monitoring may serve a spectrum of functions. Given the five potential mechanisms outlined in the previous section (i.e., direct mechanical effect, metabolic perturbation, axonal injury, brain swelling, and hemodynamic perfusion failure), specific foci, whether for assessment or treatment, can be identified for monitoring. The potential for treatment rather than for assessment, however, will be limited by the time course over which the pathophysiologic monitoring is enacted. For example, the following need to be considered: What processes occur at the time of injury, what are the subsequent epiphenomena of these events, and what are the secondary factors that are amenable to treatment and altered outcome? Mechanisms 1 and 3 occur at the time of injury, and mechanism 2 starts during the interval between the accident and arrival in the intensive care unit, although this mechanism may, in part, be avoidable with attention to emergency care and life support. Mechanisms 4 and 5 are processes in which treatment that is directed by intensive care monitoring presumably has the potential for altered outcome (i.e., focal brain tissue shifts and hemodynamic perfusion failure). One important issue, therefore, is the natural history of brain swelling and local compartment syndrome after severe head injury.

In persons with a traumatic head injury, intracranial hypertension occurs when there is brain swelling or a hematoma that occupies significant space. In persons with severe traumatic injury and abnormalities shown with computed tomography (CT) scans on admission, a greater than 50% chance of raised ICP exists.[60] In adults, this complication may occur in persons whose CT scans appear normal, particularly if two of the following three features are present: age older than 40 years, unilateral or bilateral motor posturing, or systolic ABP below 90 mm Hg. In children, the occurrence of this complication has been analyzed in a United Kingdom national data set of all 501 children receiving critical care after sustaining a severe head injury. Forsyth et al[61] found that by modeling demographic, acute physiologic, and cranial imaging variables they could derive an empiric decision rule that predicted the development of raised ICP at any point during intensive care unit admission with a sensitivity of 73% and a specificity of 74% (positive predictive value, 82%; negative predictive value, 63%). Overall raised ICP was present in 25% of those undergoing invasive monitoring. Importantly, the decision rule predicted raised ICP in 20% of children not undergoing ICP monitoring. Natale et al.[62] have shown that the natural history of raised ICP in children not requiring surgery after head injury can be as short as 3 days, but not infrequently it lasts for 7 to 10 days. Thus in regard to brain tissue shifts and frontal compartment perfusion failure, the potential of a postinsult "therapeutic window" exists, which also implies a goal for therapy directed by monitoring.

Newer Modalities: Supplementary Monitoring of Intracranial Pressure

Many of the supplementary, often research-based modalities that are used in monitoring have only been tested in patients with a head injury, because this is the most common reason for instituting ICP monitoring.

Neurochemical Protein Markers of Injury

Interest has been growing in markers that are concerned with broadly assessing tissue integrity and cell-specific injury. The clinical measurement of two proteins may serve this purpose.[63] Neuron-specific enolase (NSE), an enzyme involved in glycolysis that is localized in neurons and axonal processes, potentially escapes into the blood and CSF at the time of neural injury. (This enzyme is also found in erythrocytes.) S-100B protein, a calcium-binding protein localized to astroglia, also may be released from cells at the time of cerebral damage.

A number of clinical monitoring studies of these proteins have been undertaken in patients with head injury. For example, in patients with mild traumatic brain injury, de Kruijk et al[64] found that in blood samples taken shortly after trauma, the median and range of NSE levels were similar in patients (n = 104) and control subjects (n = 92). They found, however, that S-100B levels were significantly higher, particularly in patients with trauma who were also vomiting. Ingebrigtsen et al.[65] selected a similar group of 50 patients (i.e., those with a Glasgow Coma Scale (GCS) score of 13 to 15 and a CT scan showing no abnormalities). They found that serum S-100B protein levels were highest immediately after the trauma and then declined each hour thereafter so that the level was undetectable 6 hours after injury. Four of the five patients

with an MRI-detectable brain contusion had detectable levels of S-100B. In patients with more severe injuries (GCS score = 8), Raabe et al.[66] found that the level of S-100B in venous blood was higher in nonsurvivors, and on logistic regression, the S-100B level was an independent predictor of outcome along with age, GCS score, ICP, and CT scan findings. These authors also reported that persistent elevation of S-100B for 3 to 5 days occurred even in patients with favorable outcome and no signs of secondary insults.[35,67] Finally, in this class of patient, venous NSE appears to perform poorly as a diagnostic marker of severity.[67] Its level rises acutely in patients with both favorable and unfavorable outcome. With a cut-off level of more than 100 μg/L, the likelihood ratio for positively identifying an unfavorable outcome is approximately 2 (i.e., specificity 0.96 and sensitivity 0.09), which is of indeterminate diagnostic impact.

As with the studies in adults, the pediatric studies are somewhat inconclusive, and it may be that age and mechanism of injury—hypoxic-ischemic versus trauma—are important factors. For example, Berger et al.[68] followed the levels of S-100B and NSE in CSF samples from patients with inflicted and noninflicted trauma. Of note, these authors found that in both mechanisms of trauma a single peak in S-100B occurred at approximately 27 hours after injury, but a difference existed in the profile for NSE. After an initial or transient peak in NSE (~11 hours after injury) in both forms of insult, inflicted trauma had the additional feature of a sustained and delayed peak at around 63 hours after injury. In a more recent study of serum biomarkers, Berger et al.[69] assessed whether serum biomarkers concentrations obtained at the time of injury are associated with outcome in 152 children with acute head injury. For all biomarkers and time points, higher biomarker concentrations were associated with worse outcome. Initial and peak NSE concentrations and initial myelin basic protein concentrations were more strongly correlated with outcome in children younger than, or equal to, 4 years compared with those older than 4 years. The authors concluded that obtaining serum biomarkers at the time of injury "may be useful in predicting outcome." In less severe forms of head injury in children, other investigators have found that serum S-100B and NSE do not discriminate between those who do and do not have symptoms.[70]

Taking both the adult and pediatric studies together, a dilemma still exists. Does the very nature of sustaining a head injury initiate a normal yet insignificant transient release (albeit marked in CSF) of NSE and S-100B into the circulation, or are patterns of injury with varying mechanisms such as cerebral contusion in the case of S-100B and unappreciated hypoxia-ischemia or diffuse neuroaxonal injury in the case of NSE unable to be identified?

Brain Oxygenation

Jugular bulb oxygen saturation is commonly used to assess cerebral oxygenation. However, this form of monitoring has several shortcomings, not the least of which is that it is a global measure that is insensitive to small, though important, regional changes. The relatively recent development of implantable tissue oxygen and pH microsensors has meant that more direct regional assessments are now being made. The questions, though, are: What is normal tissue oxygen tension, and what does it mean? Recent reports in adults indicate that the threshold for abnormality is around 10 mm Hg,[71-73] although the validity and appropriateness of using such an exact measure has been questioned by Gupta et al.[74] These investigators used positron emission tomography scanning in 19 adults with head injuries to validate the reading of brain tissue oxygen pressure (P_tO_2) from a NeuroTrend sensor inserted into the frontal region. End-capillary oxygen tension (P_vO_2) was calculated from oxygen extraction fraction in a 20-mm region of interest around the sensor and compared with P_tO_2. No correlation was found between the absolute values of P_tO_2 and P_vO_2. In contrast, a significant correlation was obtained between the change in P_tO_2 and the change in P_vO_2 produced by a decrease in arterial carbon dioxide by approximately 1 kPa (7.5 mm Hg). Therefore these authors could only conclude that such monitoring should be used to assess, in real time, the changes attributable to a particular intervention.

Ushewokunze and Sgouros[75] have reported on five children with head trauma for whom this monitoring has been used. In common with findings in adults, the low P_tO_2 levels that occur during the first 24 hours following head injury do not correlate necessarily with poor outcome, and an increase in ICP may be accompanied by a decrease in P_tO_2.

Microdialysis and Brain Tissue Biochemistry

Tissue biochemical metabolic markers—rather than serum or cerebrospinal biomarkers (see previous discussion)—can be assessed continuously using cerebral microdialysis; essentially, one is potentially sampling cerebral extracellular fluid and using changes to make inferences about cell homeostasis and perturbation. Currently, this approach is used predominantly for research purposes. The technology enables bedside measurement (usually hourly in the case of head injury) of levels of cerebral dialysate glucose, lactate, pyruvate, glutamate, and glycerol. Typically, glucose level and lactate-pyruvate ratio (LPR) are used as indices of inadequate substrate delivery, altered metabolism, and ischemia. The use of a ratio (i.e., LPR), rather than absolute concentrations, means that an alteration in dialysate recovery rate does not result in spurious changes in LPR. A ratio less than 20 suggests uncomplicated cerebral metabolism,[76] and an increase in ratio is a sensitive indicator of a decrease in P_tO_2.[77] Dialysate increases in glutamate and glycerol are used as indices of cumulative tissue responses to secondary ischemic events such as intracranial hypertension, systemic hypotension, seizures, and contusions.

In adults with head injury, an increased ratio results from a tenfold to 100-fold reduction in pyruvate concentration in association with a twofold to fivefold increase in lactate concentration.[78] Two recent studies in adults with head injuries, however, suggest that the LPR (and levels of the components that make up the ratio) might be telling us more about other forms of cerebral metabolic perturbation besides ischemic crisis. Hlatky et al[79] found that in the first few hours after injury—at a time when P_tO_2 was normal (i.e., nonischemic)—the LPR was increased because of low pyruvate concentration and not raised levels of lactate. Later when the P_tO_2 was at its lowest level, signifying "hypoxia/ischemia," increased LPR was due to a combination of increased lactate and decreased pyruvate levels. Vespa et al.[80] found that even though a raised lactate level or LPR was present in 25% of cerebral microdialysis samples, the occurrence of cerebral ischemia—defined as a

raised lactate level, LPR, and a low glucose level—was much less frequent (~3%). Furthermore, upon combining these studies with positron emission tomography for assessing the metabolism of oxygen, the incidence of a high oxygen extraction fraction (i.e., ischemia) was rare, at approximately 1%. Hillered et al.[81] has commented on these clinical reports in adults and suggested that the findings represent two metabolic states:

- Type 1, classical cerebral ischemia, is characterized by reduced microdialysis pyruvate and an increased level of lactate, leading to increased LPR (in association with depressed P_tO_2). This state is a result of an overt lack of oxygen and glucose at the mitochondria.
- Type 2, cerebral metabolic perturbation, occurs when P_tO_2 is normal (i.e., nonischemic) and a reduction in pyruvate is the sole change in dialysis metabolites. The rise in LPR in this state is "perhaps reflecting a limited glucose supply or an impairment of the glycolytic pathway."

However, the mechanism of these early type 1 and type 2 changes are not fully understood, and there is an important difference between the study by Hlatky et al.[79] and that reported by Vespa et al.[80]: in the first study the microdialysis probes were placed perilesional or pericontusional; in the second study the microdialysis probes were cited as being placed in the nondominant, normal-appearing frontal lobe tissue. This difference is likely to be significant because, as Engstrom et al.[82] reported, microdialysis monitoring of normal-appearing tissue is not representative of perilesional tissue. Raised LPR persisted for at least 72 hours in perilesional tissue. In the first 36 hours this rise was associated with raised lactate levels and raised pyruvate concentrations. After that time, raised LPR was a reflection of raised lactate levels with normal pyruvate concentrations. All microdialysis parameters were in the normal range in normal-appearing tissue. These observations suggest that perilesional tissue has features of type 1 cerebral metabolic crisis, but the absence of depressed P_tO_2 suggests that increased lactate occurs as a consequence of increased glycolytic activity, which may be due to perilesional depolarizations.[83] Such hyperglycolysis is marked by increased metabolism relative to utilization and, after trauma, it represents an uncoupling between predominantly glycolytic and oxidative metabolism.[84]

In the broader context of managing intracranial hypertension, one needs to consider whether microdialysis and monitoring brain tissue biochemistry will have a role beyond the physiologic insights previously described. For example, if measurements are made hourly—dialysate flow rate of 0.3 μL/min is the most common—then what does a change represent: a concurrent acute event, a prolonged ongoing event, or an acute event that has now resolved but with abnormal tissue biochemistry? Belli et al.[85] have addressed this issue by examining whether metabolic impairments preceded rises in ICP. The authors found that an abnormal LPR could predict an ICP rise in 89% of cases. An LPR above 25 was associated with an odds ratio of 9.8 (95% CI, 5.8 to 16.1) of imminent intracranial hypertension. With regard to the utility of this form of monitoring in children, we know that in the United Kingdom national data set of critical care for severe traumatic brain injury less than 1% of children undergo such monitoring.[86] To date, a case series of only nine children has been reported.[87,88]

Transcranial Doppler Ultrasonography and Assessment of Autoregulation

TCD ultrasonography has a number of uses in the assessment of cerebrovascular health. In the field of adult neurocritical care, much progress has been made in applying this technology to head injury practice. The following discussion highlights the key issues.

TCD ultrasonography provides noninvasive measurement of blood flow velocity in basal cerebral arteries.[21] Most data have been derived from the MCA. This vessel is readily accessible to the ultrasonographer; it is the most convenient for probe fixation and long-term monitoring, and it delivers the largest percentage of supratentorial blood. Although the blood flow velocity cannot express a baseline volume of flow, dynamic changes of CBF are usually reflected in the TCD readings.[21,89] The response of blood flow velocity to a critical decrease in CPP is sensitive and usually immediate (see Figure 59-11). It is this high-dynamic resolution and close correlation with other hemodynamic modalities that has encouraged the development of the technique in clinical practice.

Increased baseline flow velocity (>100 cm/sec) may indicate cerebral vasospasm or hyperemia.[90,91] Uncoupling between CBF and flow velocity in vasospasm has been documented both experimentally and clinically.[92] For example, if the ratio of flow velocity in the insonated artery to the velocity in the ipsilateral internal carotid artery is greater than 3, vasospasm is likely. A ratio lower than 2 indicates hyperemia as the cause for accelerated blood flow.[89] After a severe head injury is sustained, cerebral autoregulation is frequently disturbed, although the extent of this disturbance may fluctuate with time.[7,8] The range of assessments that can be conducted at the bedside are:

1. **Static test of autoregulation:** Methods for the static assessment of autoregulation rely on measurement of MCA blood flow velocity during changes in mean ABP induced by a vasopressor infusion. The static rate of autoregulation (SoR) can be calculated as the percentage increase in vascular resistance divided by the percentage rise in ABP. An SoR of 100% indicates fully intact autoregulation, whereas an SoR of 0% indicates fully depleted autoregulation.
2. **TCD reactivity to changes in carbon dioxide concentration:** Testing for carbon dioxide cerebrovascular reactivity has been shown to have an important application in the assessment of severe head injuries and other cerebrovascular conditions. Many authors have shown that cerebral vessels are reactive to changes in carbon dioxide when cerebral autoregulation had been impaired.[93] Carbon dioxide reactivity correlates significantly with outcome after a head injury.[94] In patients with an exhausted cerebral compensatory reserve, however, hypercapnia may provoke substantial changes in ICP. Therefore this method cannot be used without consideration of patient safety, particularly if baseline ICP is already elevated.
3. **Dynamic test of autoregulation:** Aaslid et al.[95] have described a method in which a step decrease in ABP is achieved by the deflation of compressed leg cuffs while TCD flow velocity in the MCA is simultaneously monitored. An index called the dynamic rate of autoregulation describes how quickly cerebral vessels react to the sudden fall in blood pressure. The dynamic rate of autoregulation

is thought to express the autoregulatory reserve and, in adult volunteers, has been shown to correlate with blood carbon dioxide concentration in volunteers.[96]

4. **Transient hyperemic response test:** Short-term compression of the common carotid artery produces a marked decrease in MCA blood flow velocity in the ipsilateral hemisphere. During compression, the distal cerebrovascular bed dilates if autoregulation is intact. On release of the compression, transient hyperemia, which lasts for a few seconds, occurs until the distal cerebrovascular bed constricts to its former diameter. This sequence of events, which underlies the transient hyperemic response test, indicates a positive autoregulatory response (see Figure 59-11). In persons with a head injury, preliminary results show a positive correlation between the presence of a hyperemic response and outcome.[97]
5. **Continuous analysis of TCD ultrasonography with respiratory waves:** An interesting method of deriving the autoregulatory status from natural fluctuations in MCA blood flow velocity involves the assessment of phase shift between the superimposed respiratory and ABP waves during deep breathing.[98] A 0-degree phase shift indicates absent autoregulation, whereas a phase shift of 90 degrees indicates intact autoregulation. Such an approach may allow for the continuous assessment of autoregulation without performing potentially hazardous test maneuvers on arterial pressure.
6. **Continuous analysis of TCD flow velocity waveform:** In patients with severe head injuries, CPP monitoring can be correlated with mean blood flow velocity continuously. For example, consecutive CPP samples (averaged over 5-second periods) can be assessed with average flow velocity (collected over 5-minute epochs). The correlation coefficient (named mean index) may be positive or negative, and the regression line describing the relationship between the systolic-, mean-, and diastolic-flow velocity and the CPP may be used for assessment. A positive correlation coefficient signifies positive association of flow velocity with CPP; a negative correlation coefficient signifies a negative association. In persons with a head injury, group analysis has shown that clinical outcome depends on the averaged autoregulation indices.[9] Furthermore, time analysis has shown that failure of autoregulation is a strong independent predictor of fatal outcome after a head injury.[99]

Some data on TCD assessments of cerebral autoregulation in children with traumatic brain injury are now available. For example, in a series of 36 children, the incidence of impaired cerebral autoregulation was greatest following moderate to severe traumatic brain injury.[100] Impaired autoregulation was associated with poor outcome, and hyperemia was associated with both impaired autoregulation and poor outcome. In severe cases, cerebral autoregulation often changes over the course of a critical illness, with worsening autoregulation mirroring progression of worsening injury.[101] Importantly, in children, bilateral assessment of cerebral autoregulation is required because hemisphere differences are common in those with an isolated focal injury.[102] Finally, inflicted traumatic brain injury probably should be considered a special case: in a small case series, Vavilala et al.[103] found that none of their critically ill cases had intact autoregulation.

Clinical Neurophysiology

In comparison with the other categories already discussed, clinical neurophysiology data are unique in that they can provide some assessment of what the brain produces— activity. This assessment may take the form of its global integrity (e.g., general brain activity) or of some specific electrophysiologic function (e.g., dysrhythmic or seizure activity and sensory pathway performance).

In comatose states, the electroencephalogram (EEG) can provide useful information about the severity and distribution of altered function of the cerebral cortex. Multiple factors, however, may affect the level of such activity, and in the context of pediatric head injury, the signals reflect the summed effects of brain temperature, cerebral perfusion, metabolic state, anesthesia, and drug action on the normal background activity expected for age or stage of brain development. Thus while the technique itself is sensitive, the changes observed generally are not that specific, particularly when one considers the range of variables that will lead to altered EEG activity. Serial EEGs, however, can provide important, albeit intermittent, assessment of changes in cerebral function.[104] Alternatively, automated, signal-processed, continuous EEG can be used for uninterrupted surveillance of brain function. Various methods of displaying modified EEG data in an understandable and interpretable form have been developed and reported upon,[105-107] although the value of these methods in identifying persons who likely have a poor prognosis has been questioned. For example, in adults with severe head injury (n = 103, GCS score = 8), Moulton et al.[108] reported that signal-processed EEG data could not be relied upon as a basis for critical management decisions. In contrast, Thielen et al.[109] found that in a group of 32 adults with head injuries (GCS score <8), a cut-off of EEG-silence ratio (which was derived from a mathematically processed EEG) at 20% was of high diagnostic impact in the identification of the Glasgow Outcome Scale (GOS) category at 6 months (GOS 4-5 compared with GOS 1-3). (The sensitivity was 0.91, the specificity was 0.91, and the likelihood ratio was <0.1.) Finally, Murdoch-Eaton et al.[107] have reported a similar experience with continuous monitoring in 108 children with a variety of brain insults, although the presence of seizure activity featured highly in the prognostication.

In addition to the identification of background EEG activity (which, as discussed, has limited specificity) in the patient with a head injury, identifying seizure activity may be more pertinent because its presence will result in a change in therapy. In this regard, Vespa et al.[110] undertook continuous EEG monitoring in 94 adults with moderate to severe brain injuries. Convulsive and nonconvulsive seizures occurred in 22% of the patients, with six persons displaying electrical status epilepticus. In more than half of the patients, the seizures were diagnosed solely on the EEG monitoring. Of particular concern was the finding that these seizures occurred despite the unit's use of prophylactic anticonvulsant therapy. In another EEG study of comatose patients (n = 236), including children, Towne et al.[111] also found that nonconvulsive status epilepticus was underrecognized, occurring in 8% of their comatose patients without signs of seizure activity. Finally, in children with a head injury, Chiaretti et al.[112] reviewed their clinical experience in 125 patients, 12% of whom had seizures within 24 hours of trauma. Taken together with the adult EEG studies, there certainly appears to be some merit in characterizing the

role of seizure monitoring in children with head injuries, particularly because anticonvulsant prophylaxis seems to be failing to confer protection, and we can easily provide a remedy.

Somatosensory evoked potentials (SEPs) are widely used to assess neurophysiologic function in patients with severe head injury.[108] The strong predictive value of these potentials in comatose patients has been demonstrated in a number of pediatric series. The bilateral absence of the cortical components of the SEP is usually regarded as an ominous sign, invariably indicating a poor outcome. For example, Carter et al.[113] reported a series of 105 children with severe brain injury for whom they had long-term (5 years) functional and health status outcomes. For children with bilaterally absent SEP responses, the positive likelihood ratio of identifying unfavorable functional outcome was approximately 15 (specificity, 0.96; sensitivity, 0.57; and high diagnostic impact). The results for health status were of equally high diagnostic impact. The question that arises, however, is this: Are these data sufficient for influencing practice, or should such assessment merely be used for stratifying patient prognosis at an early stage?

In 1997, Pohlmann-Eden et al.[114] reviewed 18 studies in which the predictive value of SEPs in 758 comatose patients was analyzed. These investigators identified 300 reports of patients with bilateral loss of cortical SEP responses, and of these patients, 286 died or remained in a vegetative state. Two of the remaining 16 surviving patients had a good outcome with functional independence; both were children.[115,116] In 1999, Schwarz et al.[117] reported on four adults who survived despite bilateral loss of the cortical SEP; three of these patients had an excellent outcome. Wohlrab et al.[118] reviewed 53 children with bilateral absent cortical SEP, 13 of whom had sustained a severe head injury. Thirty (57%) of 53 children died within the first 4 weeks, and another eight children died within 4 years of the event (i.e., a total of 72%). Of the 15 surviving children (six of whom had a severe head injury), two children remained in a persistent vegetative state, nine children had severe deficits (two of these children had head injuries), and four children had mild or moderate deficits (all of these children had head injuries). Interestingly, 30 of the 53 children underwent repeated examinations, and in eight of these children, unilateral or bilateral cortical responses reappeared. Taken together, the poor prognostic implications of bilateral loss of SEPs are indisputable. Nevertheless, the occurrence of recovery from, in the main, transiently absent cortical responses indicates that this finding alone does not imply irreversible dysfunction of the somatosensory pathway in the child with a severe head injury. Absent SEPs should be interpreted carefully, particularly in conjunction with hypothermia, deep sedation, intoxication, or decompressive craniectomy.[119]

Status Epilepticus

Cecil D. Hahn, Sam D. Shemie, and Elizabeth J. Donner

PEARLS

- Prolonged convulsive and nonconvulsive seizures cause neuronal injury by excitotoxic and hypoxic-ischemic mechanisms related to the intense metabolic demands of seizures and associated cardiorespiratory compromise.
- The longer seizures continue, the more difficult they are to abort with medications. Early diagnosis and aggressive intervention for both convulsive or nonconvulsive seizures is essential for their successful treatment.
- Outcomes following status epilepticus are primarily related to the underlying cause of the seizures and are generally more favorable in children than in adults.
- Clinically subtle or nonconvulsive seizures are common among patients in the intensive care unit, particularly following prolonged convulsive seizures. Postictal stupor or coma due to the sedative effects of medications are often difficult to distinguish from continued nonconvulsive seizures without the aid of continuous electroencephalographic (EEG) monitoring. Treatment of refractory status epilepticus requires continuous EEG monitoring because pharmacologic therapy is titrated to EEG seizure suppression or burst-suppression.
- The dose limitations of traditional high-dose suppressive therapies (barbiturates or benzodiazepines) generally are related to cardiovascular toxicity rather than to any predefined upper limit of dosing.

Definition

Status epilepticus (SE) is a life-threatening medical emergency. In children, SE often necessitates urgent treatment and monitoring in the pediatric intensive care unit (PICU) and requires that the pediatric intensivist be comfortable with the diagnosis and management of this common condition.

The International League Against Epilepsy defines SE as a seizure that persists for a sufficient length of time or is repeated enough to produce a fixed and enduring epileptic condition.[1] From the practical perspective of the treating physician, this definition is difficult to apply. A more commonly used clinical definition includes duration of seizure activity, specifying SE as seizures lasting 30 minutes or longer, which is based on the theory that neuronal damage may begin after 30 minutes of continuous seizures. No clinical data support the 30-minute rule, however, and more recent definitions of SE include a shorter duration of seizure activity. An operational definition has been proposed, in which generalized convulsive SE in adults and children older than 5 years is "greater than or equal to 5 minutes of continuous seizures or two or more discrete seizures between which there is incomplete recovery of consciousness."[2] This definition has been supported by clinical studies showing that most secondarily generalized convulsive seizures in adults last less than 5 minutes[3]; these results suggest that seizures lasting more than 5 minutes should be regarded as more significant. Similar data in children have shown that new-onset seizures cluster by duration; most seizures (76%) last less than 5 minutes and 24% last longer, with a mean duration of 31 minutes.[4] The shorter duration definition of SE remains controversial, however, because although it is less common for seizures to persist beyond 5 minutes, it also has been shown that seizures lasting 10 to 29 minutes that stop spontaneously are associated with a significantly lower mortality rate than seizures lasting beyond 30 minutes.[5] Thus before the definition of SE includes a seizure duration of less than 30 minutes, further study and discussion are required.

Regardless of the definition of SE, there is a consensus in the medical community that continuous or prolonged seizures require urgent intervention. Children with prolonged seizures should receive prompt and aggressive treatment with the aim of stopping seizures as soon as possible.

Classification of Status Epilepticus

SE should be classified with the same terminology used for seizure classification. The International League Against Epilepsy Task Force on Classification and Terminology identifies two major categories that may be applied to both self-limited and continuous seizures.[6] *Generalized seizures* refer to seizures involving both cerebral hemispheres, which are believed to originate within, and rapidly engage, bilaterally distributed neuronal networks. Consciousness is usually impaired. Generalized seizures include seizures with motor movements as well as absence seizures during which no convulsive signs may be present. Electroencephalography (EEG) indicates seizure activity involving both cerebral hemispheres. *Focal seizures*, previously referred to as partial seizures, are those in which the first clinical and EEG changes indicate seizures that originate within one cerebral hemisphere. Generalized seizures that begin as focal seizures are termed secondarily generalized seizures. Complex focal seizures are associated with an impairment of consciousness. Simple focal seizures have no impairment of consciousness. When simple focal seizures are prolonged and have a

focal motor component, the term *epilepsia partialis continua* is used.[7] These same terms are also used to describe continuous seizures and SE. SE also may be defined more specifically by seizure type, including myoclonic status, tonic status, and absence status.[6] Although these distinctions are helpful to predict the cause and outcomes of SE, the differentiation may require EEG and has limited utility in the acute clinical situation.

A more clinically useful classification scheme involves categorizing SE by the presence of motor movements (Box 60-1). *Convulsive SE* (CSE) consists of continuous clonic or tonic motor activity with bilateral epileptiform discharges on the EEG. As CSE progresses, the motor movements are reduced and may be characterized only by subtle twitching of the limbs, face, or trunk. This condition is termed *subtle CSE.*

Nonconvulsive SE consists of continuous electrographic seizures with no motor movements. This type of seizure may occur after prolonged generalized CSE. Nonconvulsive SE also refers to SE consisting of absence seizures or focal onset seizures that do not produce motor movements.

In children, an additional category, febrile SE, may be considered. SE occurring in association with fever represents one form of complex febrile convulsions.

Finally, SE also may be classified with respect to cause. Symptomatic implies a known cause for SE and can be further divided into *acute symptomatic* and *remote symptomatic* on the basis of cause. Examples of acute symptomatic causes include toxins and acute infections. Remote symptomatic SE is most often associated with a long-standing history of epilepsy or remote central nervous system (CNS) insult. The term *idiopathic SE* is used when there is no known or suspected cause for the seizures.

Nonepileptic seizures, also known as *nonepileptic events,* also may present as SE. Patients with and without a prior history of epileptic seizures may have nonepileptic SE. In this situation, EEG may be necessary for diagnosis to confirm the absence of abnormal electrical discharges in the brain.

Epidemiology of Status Epilepticus

Incidence

Two population-based studies have examined the incidence of SE in the United States. The incidence of SE in Richmond, Va.,[8] was determined to be 41 per 100,000 population, and in Rochester, Minn.,[9] the incidence was 18 per 100,000 population. The difference may reflect a different racial composition in the communities studied; in the Richmond study, the incidence of SE was higher in the nonwhite population.

Box 60–1 Classification of Status Epilepticus

Generalized Convulsive
Overt
Subtle

Nonconvulsive
Associated with coma or paralysis
Following prolonged convulsive seizures
Absence status epilepticus

Focal
Simple: without altered consciousness
Complex: with altered consciousness

A population-based United Kingdom study determined the incidence of CSE in children to be 17 to 23 per 100,000 per year. The incidence of CSE was highest in children younger than 1 year (51 per 100,000 per year) falling to only 2 per 100,00 per year in 10- to 15-year-olds. The incidence of CSE was similar in girls and boys.[10] Lower socioeconomic status, independent of ethnicity, was associated with prolonged febrile seizures and acute symptomatic CSE.[11] SE was found to be the admission diagnosis of 1.6% of children admitted to a pediatric intensive care unit.[12]

Cause

One of the largest series of SE in children was published in 1970. This review of 239 cases of SE in children identified 47% of cases to be symptomatic (26% acute symptomatic and 21% remote symptomatic) and the remaining 53% of cases to be idiopathic, including febrile SE.[13] The cause of SE is age dependent; infection plays a larger role in the cause of SE in children than in adults. In a 1996 study in Richmond, Va., the three major causes of SE in children were infection with fever, remote symptomatic cause, and low anticonvulsant drug levels (Table 60-1).[8] The three major causes in adults were low antiepileptic drug (AED) levels, remote symptomatic cause, and stroke.[8] The cause also differs among younger and older children. Febrile and acute symptomatic SE are more common in children younger than 2 years, whereas idiopathic and remote symptomatic causes are most common in children older than 4 years.[12,14]

A recent prospective population-based study found that more than half of children with a first event of CSE were previously neurologically healthy. One third were identified as having prolonged febrile seizures, 17% as having acute symptomatic seizures, and 16% as having remote symptomatic seizures, and the remaining 12% had cryptogenic or idiopathic epilepsy.[10] A retrospective case series of SE in children report similar results.[15] Prolonged febrile seizures represent a significant burden in the PICU. A report of 119 prolonged febrile seizures, defined as lasting longer than 30 minutes, found that the seizures lasted a median of 68 minutes, and 24% lasted more than 2 hours. Analysis suggested that the longer a seizure lasts, the less likely it is to spontaneously remit.[16]

Table 60–1 Causes of SE in Children from the Richmond, Va., SE Database

Cause	% of SE
Non-CNS infection	52
Remote symptomatic	38
Low AED level	21
Cerebrovascular disease	10
Metabolic	7
Hypoxia	5
Idiopathic	5

From DeLorenzo RJ, Hauser WA, Towne AR, et al: A prospective, population based epidemiologic study of status epilepticus in Richmond, Virginia, *Neurology* 46:1029, 1996.

In children with a first seizure, 12% present in SE.[17] In a report of 613 children with newly diagnosed epilepsy, 9.1% had provoked or unprovoked SE before the diagnosis of epilepsy and a nearly equal number, 9.5%, had an episode of SE following the diagnosis of epilepsy (8-year median follow-up).[18,19] Children who had SE before a diagnosis of epilepsy were most likely to have remote symptomatic epilepsy. Younger age of epilepsy onset and symptomatic epilepsy increased the risk of SE.[19]

Outcome

Mortality

Status epilepticus is a clinical expression of potentially severe brain disease and may threaten life through impairment of airway control and respiratory function. Once intubation and mechanical ventilation are established, the outcome is primarily related to the underlying brain disease and the ability to control seizures. Age and etiology are strong predictors of outcome in SE, reflecting the fact that morbidity and mortality are more related to the underlying disorder than to the seizures. Mortality rates as high as 23% have been reported in SE in adults[20,21]; however, such high rates have not been reported in children. Case fatality was 3% in a prospective population-based study of first episodes of CSE in children. Death was associated with bacterial meningitis, underlying metabolic disease, and progressive neurodegenerative disorders.[10] In a study of 193 children with SE, 3.6% died within 3 months of the SE; the etiology of SE was the strongest predictor of death. All deaths that occurred were associated with an acute CNS insult or progressive encephalopathy, and no children with unprovoked or febrile SE died.[22] Similar findings were documented in a study of 40 cases of pediatric SE, in which mortality rate was 10% and the cause of SE in all children who died was acutely life-threatening.[23] Refractory SE carries higher risks of significant morbidity and mortality (see the section on Refractory SE later in this chapter).

Subsequent Development of Epilepsy

Epilepsy, which is defined as recurrent unprovoked seizures, is a potential long-term complication of SE. In children, the risk that epilepsy will develop after SE ranges from 26% to 36%.[23,24] This risk is not significantly different from rates of epilepsy following a brief first unprovoked seizure.[25] As with mortality, the development of epilepsy after SE is strongly related to the etiology of SE. In children with acute symptomatic SE, the risk for development of subsequent epilepsy was found to be 41%, three times higher than that for children with self-limited acute symptomatic seizures. This risk was highest in children with anoxic encephalopathy, followed by structural and then metabolic causes.[26]

In contrast, children with a first unprovoked seizure presenting as SE were not more likely than children with self-limited first unprovoked seizures to have recurrent seizures.[17] Furthermore, the increased risk of the development of epilepsy after febrile SE is generally reported to be small to none.[22-24,27]

Pathophysiology

The exact mechanism that permits a seizure to become sustained is not known. Theoretically, either a failure of physiologic neuronal inhibition or an excess of excitation is required. Much of the research in this area has focused on the failure of neuronal inhibition by the major inhibitory neurotransmitter in the CNS, γ-aminobutyric acid (GABA). Prolonged seizures have been associated with deficits in GABA-mediated neuronal inhibition because of the rapid internalization of synaptic $GABA_A$ receptors. Clinically this phenomenon may be demonstrated by the poor response of prolonged seizures to the GABA agonists benzodiazepines and barbiturates,[28] a phenomenon known as time-dependent pharmacoresistance.[29-31]

SE causes neuronal injury by both hypoxic-ischemic and excitotoxic mechanisms. The pathophysiology of SE-induced hypoxic-ischemic injury is illustrated in Figure 60-1.[32] Early in SE, an increase in neuronal metabolic demand occurs with a compensatory increase in cerebral blood flow (CBF) and brain oxygenation. Later in SE, these homeostatic mechanisms are unable to keep up with the sustained increase in cerebral metabolic demand. Autoregulation of CBF fails, and consequently a higher mean arterial pressure is required to maintain adequate brain perfusion. As systemic blood pressure falls, a subsequent reduction in brain parenchymal oxygenation occurs. In the face of increased neuronal metabolic demand, uncontrolled muscular contractions, hyperthermia, and impaired airway control, both impaired oxygenation and ventilation contribute to the mismatch between metabolic supply and demand. However, neuropathologic injury occurs even when these systemic factors are controlled and before CBF is reduced, presumably because of unmet neuronal metabolic demands alone.

Excitotoxicity is the second major mechanism for neuronal injury in SE. Glutamate is the major excitatory neurotransmitter in the CNS, and glutamate agonists are used to induce seizures in experimental animal models of SE. Studies have implicated both the *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) glutamate receptors in the pathophysiology of SE.[33] The NMDA receptor may have a dual function in the pathophysiology of SE. Magnesium blocks the NMDA channel when it is in its normal state. With depolarization, magnesium no longer blocks the channel, and calcium, which is allowed to flow into the cell, produces further depolarization. Thus the NMDA receptor is activated when the cell is depolarized and responds by further depolarizing the cell, sustaining the excitation. This process also has been implicated in SE-induced neuronal injury, as the accumulation of intracellular calcium activates pathologic processes resulting in both necrotic and apoptotic cell death.[34,35]

Diagnosis

The clinical presentation of SE is variable, depending on seizure type and the baseline developmental and medical status of the child. Diagnosis depends on the identification of continuous or repetitive seizures, which is usually straightforward in the presence of convulsive seizures. However, after prolonged convulsive seizures the motor manifestations often diminish, and the seizures may become subtle or even nonconvulsive. Differentiating between such nonconvulsive seizures and a postictal state can be challenging. Patients with nonconvulsive SE, including absence SE, may be difficult to identify by history and physical examination alone. These patients can have intermittent altered awareness and continuous lethargy or unresponsiveness with or without subtle myoclonic jerks

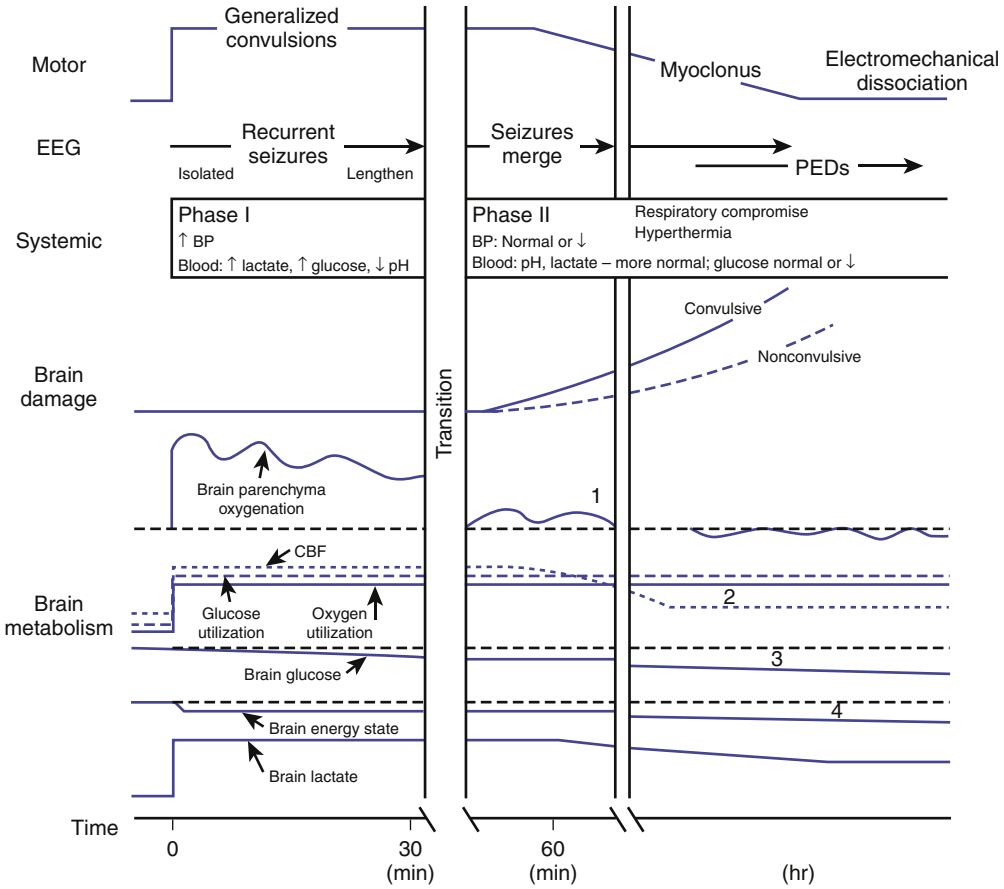

Figure 60–1. Pathophysiology of hypoxic-ischemic brain injury in status epilepticus. *(Modified from Lothman E: The biochemical basis and pathophysiology of status epilepticus,* Neurology *40(5 suppl 2):13-23, 1990.)*

of the face or limbs. In such cases, continuous EEG monitoring is critical for diagnosis. EEG monitoring also can be used to identify nonepileptic (psychogenic) SE. Although uncommon, prolonged delays in the EEG-based diagnosis of nonepileptic SE can lead to unnecessary medical intervention.[36]

EEG measures extracellular electrical activity generated by cortical neurons. Data are collected with a standard array of scalp electrodes and presented for visual display onto a paper or digital record.

Because EEG provides real-time information regarding brain activity, it is invaluable in the evaluation of patients with SE, permitting direct correlation between patient behavior and neuronal activity. EEG interpretation should be performed with the assistance of a trained neurologist or neurophysiologist to reduce the potential for both over- and under-identification of seizures.

Recent advances in computing and networking technology have facilitated the remote interpretation of continuous EEG recordings. Regular communication between ICU staff and the neurology team remains essential to optimizing the care of SE patients. Quantitative EEG trending tools such as amplitude-integrated EEG and color density spectral array are increasingly being incorporated into portable EEG systems and bedside monitors (Figure 60-2). These tools may be applied to visualize single or multiple channels of EEG, providing a time-compressed overview of cerebral function that is simpler to interpret than conventional EEG. However, because these displays are generally less sensitive and specific for the identification of seizures, they should be used judiciously, with corroboration by careful analysis of the underlying raw EEG tracing.

Abnormal waveforms on EEG can be divided into two categories: epileptiform abnormalities and nonepileptiform abnormalities. Epileptiform abnormalities are abnormal discharges associated with an increased risk of seizures, including sharp waves, spikes, polyspikes, and spike and slow wave discharges (Figure 60-3). When present between seizures, these waveforms are termed "interictal" abnormalities. Seizures are defined electrographically by the presence of "ictal" EEG abnormalities, whose hallmark is their rhythmicity and their evolution in frequency or distribution over the course of a seizure. Generalized seizures are characterized by widespread bilateral rhythmic epileptiform discharges (Figure 60-4, *A*). Focal seizures are characterized by rhythmic epileptiform discharges that are confined to one brain region (Figure 60-4, *B*). Focal seizures may spread to involve both cerebral hemispheres, a process termed secondary generalization.

Nonepileptiform abnormalities are not necessarily associated with a risk of seizure but suggest CNS dysfunction. Slow waves are a nonspecific finding, suggesting a structural or functional abnormality, and often are seen after a seizure or SE. The location of slow waves after a seizure may aid in the differentiation between generalized and focal seizures. Generalized slow waves are associated with a diffuse encephalopathy such as due to metabolic disturbance, hypoxia-ischemia, or a postictal state.

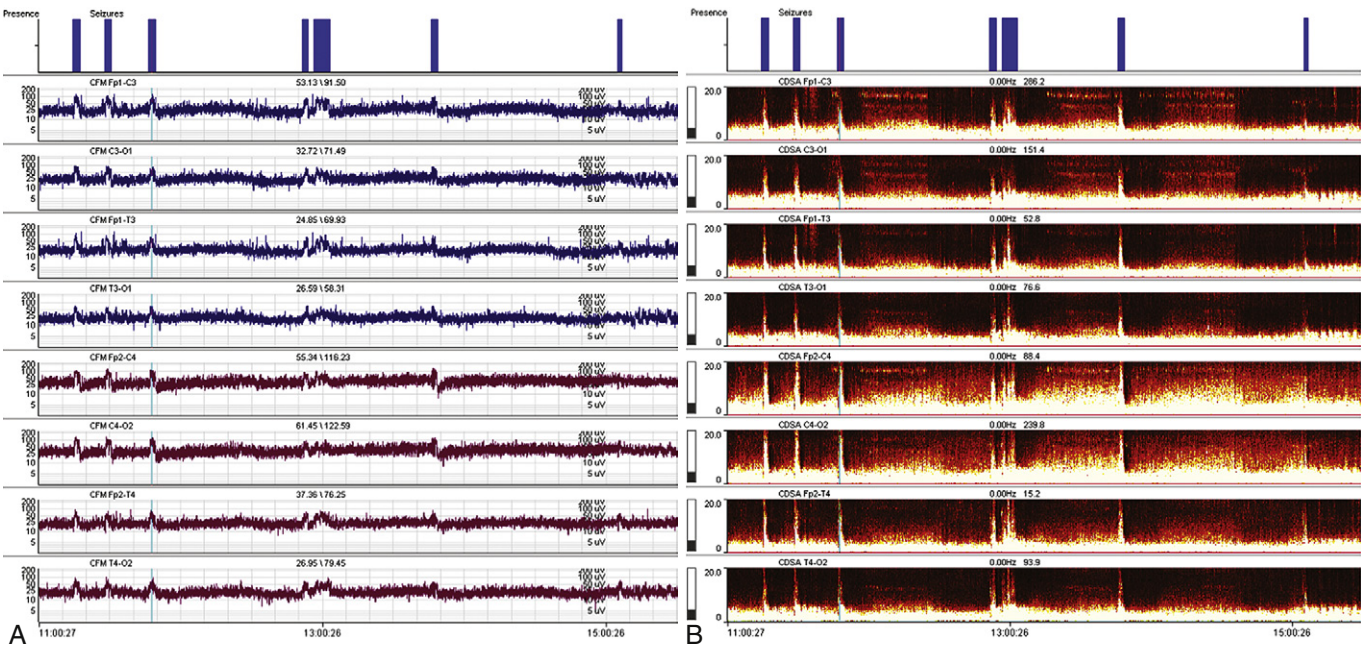

Figure 60–2. Examplesof 8-channel quantitative electroencephalographic (EEG) displays depicting 4 hours of raw EEG containing several generalized seizures. The timing of seizures is indicated at the top of each display. **A,** On an amplitude-integrated EEG display, seizures are characterized by elevations in the upper and lower margins of the tracing. **B,** On a color density spectral array display, seizures are characterized by bright bands of color.

Two further EEG patterns are of particular relevance to the treatment of prolonged seizures. Burst-suppression is characterized by brief bursts containing a mixture of spikes, sharp waves, and slow waves alternating with periods of very low voltage (Figure 60-4, *C*). An isoelectric EEG pattern refers to a continuous low voltage record without any discernable cortical activity. Both burst-suppression and isoelectric EEG patterns can be seen in persons in a coma and may carry a poor prognosis in certain clinical situations. However, in the context of refractory SE, these patterns are often the desired endpoint for treatment with high-dose barbiturates or benzodiazepines (see section on Treatment of Refractory Status Epilepticus).

Refractory Status Epilepticus

Refractory status epilepticus (RSE) is characterized by seizures that persist beyond 60 minutes and fail to respond to first- and second-line therapy. In adults, SE may be refractory in 9% to 31% of patients and carries increased rates of morbidity and mortality.[37] In children, the incidence of RSE has not been well documented; however, in a large series of children with SE, 26% of the children had seizures lasting more than 60 minutes.[22] Pediatric mortality rates from RSE have been reported to be 16% to 32%.[38,39] As with all cases of SE, outcome appears to be related to cause, with deaths occurring predominantly in acute symptomatic cases.[38,39]

A group of patients who are particularly severely affected have seizures that persist for more than 24 hours; this condition has been termed *sustained* RSE. Prolonged therapy for days or weeks may be required for patients with sustained RSE. Although it is virtually always possible to control the seizures with high-dose seizure-suppressive medications, continued seizure remission is not always possible when these high-dose medications are withdrawn.

The outcome of acute symptomatic RSE in seven children who received long-term high-dose seizure suppressive medication was reported to be uniformly poor, with all children having medically intractable epilepsy and developmental deterioration.[40] We have reviewed seven cases of acute symptomatic sustained RSE. In these cases, sustained RSE is most often associated with viral encephalitis or a postinfectious process. This experience shows that SE persisting longer than 24 hours identifies a prolonged course, with our patients requiring high-dose seizure suppressive medication for up to 108 days. Outcome was consistently poor, with a 57% mortality rate and severe disability in the surviving children.

Treatment of Status Epilepticus

The principal goal of therapy in SE is to abort the seizure before irreversible neuronal injury occurs. In experimental models of SE, irreversible neuronal injury begins after 20 minutes to 1 hour of continuous seizure activity, despite the maintenance of adequate brain oxygenation and perfusion. Furthermore, evidence indicates that SE becomes more difficult to control as its duration increases.[29,41-43] Therefore prompt and aggressive pharmacologic management is paramount, for which the formulation of institutional guidelines is invaluable. Figure 60-5 illustrates guidelines for the treatment of prolonged seizures and **SE** in use at The Hospital for Sick Children in Toronto, Canada.[44]

General Supportive Measures

The initial approach to therapy should always focus on securing the airway and maintaining adequate ventilation and circulation. Patients should be positioned on their side with the head below the torso to minimize the risk of aspiration. An oral or nasopharyngeal airway should be inserted. If oxygenation is inadequate, early intubation may be required, in

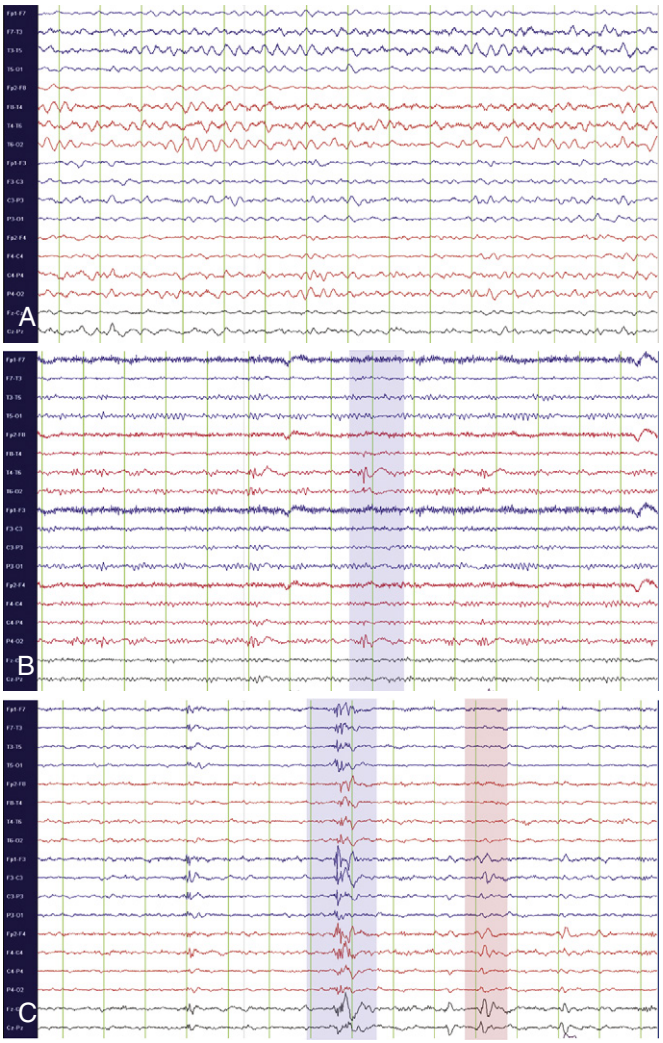

Figure 60–3. Examples of normal electroencephalographic (EEG) background and interictal epileptiform discharges. **A,** Normal 3- to 4-Hz awake background rhythm in a 7-month-old boy. **B,** Normal 9-Hz awake background rhythm in a 4-year-old girl, with a right temporo-occipital spike-wave discharge highlighted in blue. **C,** Normal sleep background in an 8-year-old girl, with a vertex sleep wave highlighted in red and a generalized polyspike discharge highlighted in blue.

which case only short-acting neuromuscular blocking agents and sedatives should be used to avoid compromising the neurologic assessment. Vital signs should be checked at frequent intervals, including the patient's heart rate, blood pressure, and temperature. A cardiac monitor and transcutaneous oxygen saturation monitor should be applied. A rapid test of blood glucose should be performed, and hypoglycemia should be treated with intravenous dextrose. In parallel with the efforts to abort the seizure, investigations into the cause should be undertaken as soon as the patient's medical condition permits (see the section on Investigations later in this chapter).

Initial Management

Most AEDs used to treat SE have the potential to compromise airway control and respiratory drive and therefore should be used with necessary precautions. Table 60-2 provides details of drugs that may be used in the treatment of SE.

Figure 60–4. Electroencephalography in status epilepticus (SE). **A,** Generalized seizure. **B,** Left focal seizure. **C,** Burst-suppression pattern in a patient treated with a midazolam infusion for refractory SE.

Benzodiazepines

Benzodiazepines are considered the first-line agents for the initial therapy of prolonged seizures and SE. Benzodiazepines enhance inhibitory neurotransmission by binding to a specific benzodiazepine site on the $GABA_A$ receptor. Lorazepam and diazepam have been shown to be equally effective at aborting seizures.[45] However, seizure recurrence is higher with diazepam because of rapid protein binding,[46] leading to an abrupt fall in the unbound (and pharmacologically active) serum diazepam concentration. For these reasons, lorazepam has become the drug of choice in many centers for the initial management of SE.[29] Intravenous administration of benzodiazepines is the preferred route because of its rapid onset of action, but alternatives include

buccal administration of the sublingual preparation and rectal administration of the liquid form. Diazepam may be rectally administered in a commercially available gel preparation. Buccal midazolam may be an equally effective and more socially acceptable alternative to rectally administered diazepam.[47]

Barbiturates

Phenobarbital and other barbiturates enhance inhibitory neurotransmission by binding to a specific barbiturate site on the $GABA_A$ receptor. Phenobarbital is generally considered a second-line agent for the treatment of SE and is usually administered when benzodiazepines do not promptly abort the seizure. Advantages of phenobarbital include a relatively rapid infusion time and efficacy against a wide spectrum of seizure types, including generalized tonic-clonic, absence, myoclonic, and focal seizures. The main drawbacks of phenobarbital are sedation, respiratory depression, and hypotension. Phenobarbital is the primary AED used for neonatal seizures, although phenytoin appears to be equally effective.[48]

Phenytoin

Phenytoin blocks the fast repetitive firing of neurons through the use-dependent inhibition of voltage-gated sodium channels. Advantages of phenytoin include minimal sedation and respiratory depression at therapeutic levels. The main disadvantage of phenytoin is that it must be infused relatively slowly to minimize the risk of cardiac arrhythmia, infusion site pain, and thrombophlebitis. The maximum recommended infusion rate is 1 mg/kg/min (maximum, 50 mg/min); therefore an infusion of 20 mg/kg requires 20 minutes. Extravasation of phenytoin at the infusion site has been associated with a "purple glove syndrome," which consists of localized extremity edema and discoloration that occasionally requires fasciotomy or amputation. Purple glove syndrome, as well as the more common adverse effects of hypotension and cardiac arrhythmia, is attributed to the fact that phenytoin is dissolved in a solution of propylene glycol and ethanol with a pH of 12.

Fosphenytoin

Fosphenytoin, a water-soluble phenytoin pro-drug, has several advantages over phenytoin and has been widely adopted in the United States. Fosphenytoin may be administered intramuscularly or intravenously. The maximal recommended infusion rate is 150 mg phenytoin equivalents per minute, and the pro-drug has a 7-minute half-life of conversion to phenytoin.[49] Although it remains to be proved that the greater speed of administration of fosphenytoin results in improved seizure control compared with phenytoin, fosphenytoin often is preferred because it is better tolerated at the infusion site, carries a lower risk for cardiac arrhythmia and hypotension, and has not been associated with the purple glove syndrome.[50] The higher cost of fosphenytoin and the lack of definitive evidence for superior efficacy, however, may limit its widespread use, despite the suggestion by phamacoeconomic analysis that fosphenytoin is cost effective.[51]

Paraldehyde

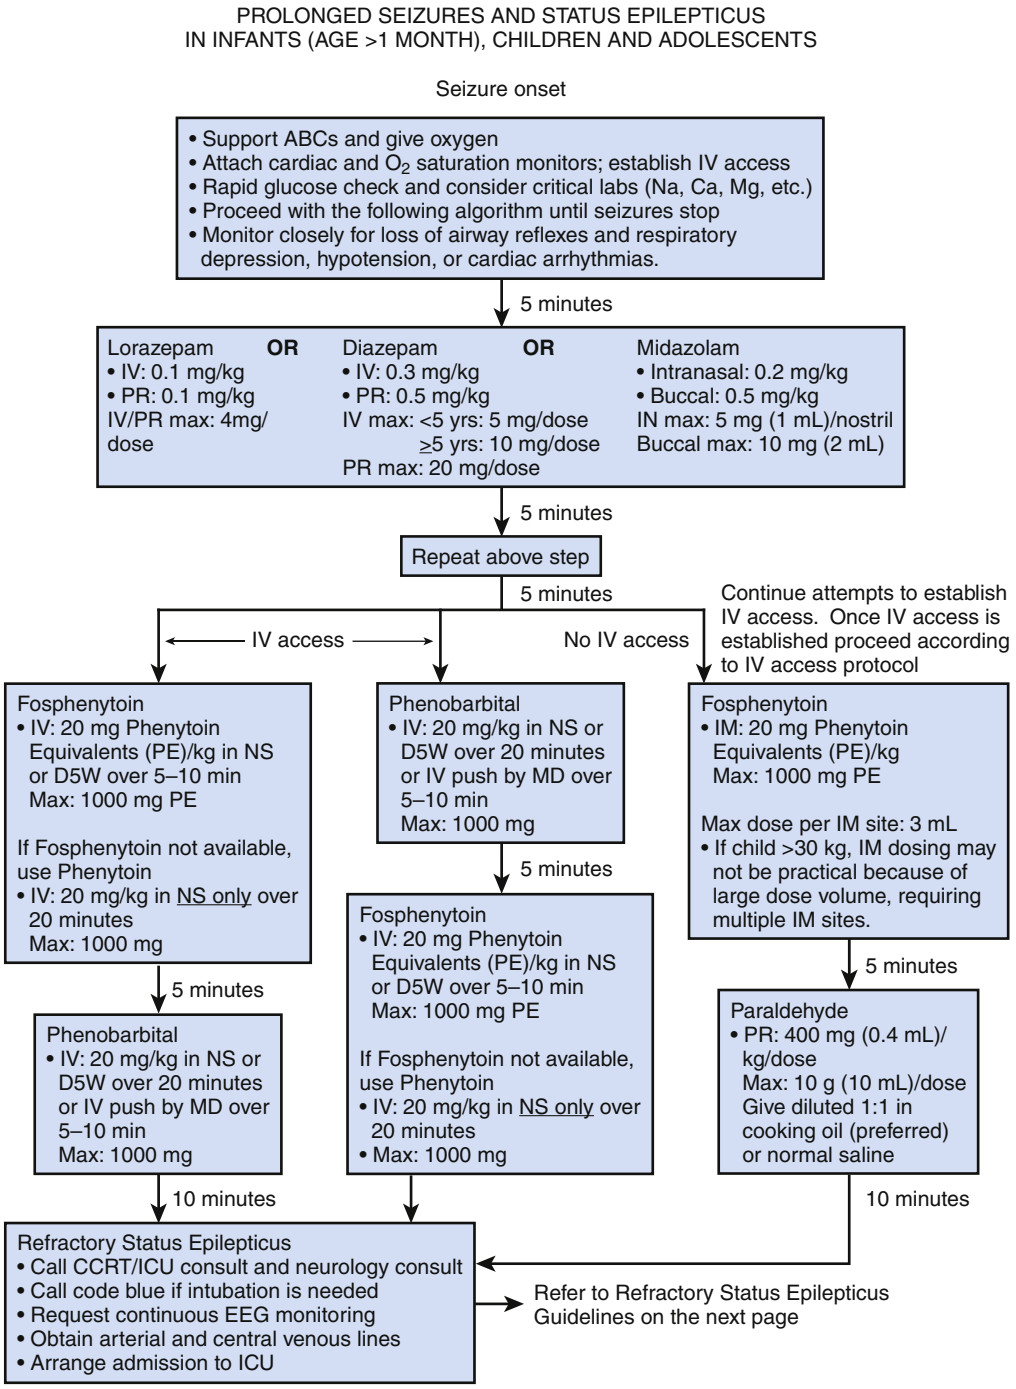
Paraldehyde is an alternative to phenytoin and phenobarbital for the treatment of early SE and also may be used for RSE. The primary advantages of paraldehyde are its wide spectrum of efficacy for different seizure types and relatively modest respiratory depressant effect. Disadvantages of paraldehyde include limited availability, its irritant effect on the rectal mucosa, and its unpleasant pungent odor. Paraldehyde is usually administered rectally, diluted in an equal volume of mineral or cooking oil at a dose of 200 to 400 mg/kg. Intravenous administration is possible but difficult because paraldehyde may dissolve plastic intravenous tubing and decompose into acetaldehyde and acetic acid when exposed to air and light. Plastic syringes may be used safely for rectal administration if the injection is performed promptly. Pulmonary toxicity, which is likely due to the partial excretion of paraldehyde through the lungs, has been reported; therefore the drug should be used with caution in patients with significant pulmonary disease.[49]

Treatment of Refractory Status Epilepticus

SE that persists beyond 1 hour despite AED therapy is considered refractory. Conventional AEDs have low efficacy in RSE, and although conventional AEDs (e.g., topiramate, levetiracetam, and carbamazepine) should be continued during this treatment phase, higher dose or higher potency agents are required to abort RSE. Therapeutic options include high-dose benzodiazepines, barbiturates, propofol, valproic acid, ketamine, lidocaine, and inhalational anesthetic agents. Currently, insufficient evidence exists to conclude which of these high-dose suppressive medications, either alone or in combination, has superior efficacy in the treatment of RSE.[38] High-dose midazolam is the preferred initial approach at The Hospital for Sick Children, Toronto because of an accumulated historic experience of profound cardiovascular depression with high-dose barbiturates.

Goals of Therapy

In the treatment of RSE, as in SE, the goal is termination of all clinical and electrographic seizure activity, and thus continuous EEG monitoring is required. ICU practitioners should resist the temptation to assess seizure control on the basis of clinical signs alone because the clinical expression of seizures can be very subtle and the examination is often confounded by the use of sedative medications. Therefore treatment of RSE should be guided by EEG monitoring. However, the exact target of EEG-guided therapy remains controversial. In addition to achieving seizure suppression, it is generally recommended to escalate therapy to achieve a burst-suppression pattern on EEG. The rationale for achieving burst-suppression is that profound suppression of brain activity may have a protective effect and "break the cycle" of seizures, thus reducing the chance of seizure recurrence upon tapering of medications.[52] Debate continues regarding the recommended length of the periods of EEG suppression (the interburst interval) and how long the burst suppression pattern should be maintained. Furthermore, because of a concern that seizures may persist even when the EEG is interspersed with a burst-suppression pattern, some experts recommend achieving complete EEG suppression, in other words an isoelectric EEG pattern.[41] As a general approach, once seizure control or a burst-suppression pattern has been achieved, a suggested practice is to maintain the burst-suppression pattern for at least 12 hours before a medication taper is attempted. If seizures recur when medication is tapered, then therapy is reinstated to achieve a burst-suppression pattern for at least another 48 hours.



Continued

In parallel with high-dose suppressive therapies described in detail in the following sections, conventional AEDs (i.e., topiramate, levetiracetam, and carbamazepine) should be titrated to high-therapeutic doses, both to assist in aborting RSE and to provide continued anticonvulsant coverage following tapering of high-dose suppressive therapies.

High-Dose Barbiturates

Barbiturates including pentobarbital, thiopental, and phenobarbital are widely used medications for RSE that also may have neuroprotective effects.[53] Pentobarbital is the best-studied drug, and the most data are available on its use. Pentobarbital is administered as an intravenous loading dose of 5 to 12 mg/kg, followed by a continuous infusion of 1 mg/kg/h, increasing as needed to a maximum rate of 10 mg/kg/h. Breakthrough seizures may be treated with additional boluses of 3 to 5 mg/kg.[49] High-dose phenobarbital is an alternative to pentobarbital. Phenobarbital may be given in incremental boluses of 10 mg/kg, without reference to a predetermined maximum level or dose, until seizures are suppressed. There appears to be no maximum dose beyond which further doses are ineffective, and serum levels of up to 344 mg/mL (1490 mmol/L) have been reported.[54] The main drawback of all of the barbiturates in high doses is

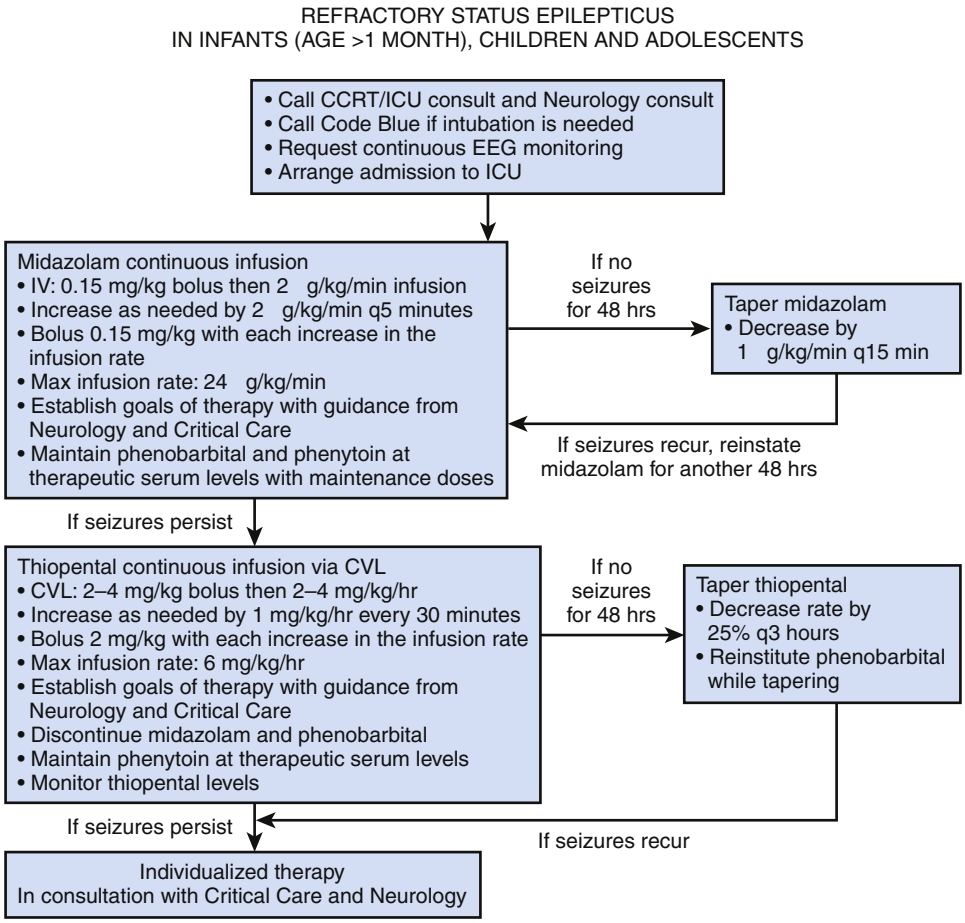


Figure 60–5. Guidelines for the treatment of prolonged seizures and status epilepticus in infants (age >1 month), children, and adolescents *(From The Hospital for Sick Children Toronto, Canada.)*

the high risk of cardiovascular depression and hypotension. This situation frequently requires inotropic and vasopressor therapy and, in rare instances, cardiopulmonary resuscitation. In addition, the need for mechanical ventilation and the time to regain consciousness are also greater with barbiturates than with benzodiazepines.[38] Among the barbiturates, phenobarbital probably carries the lowest risk of hypotension and respiratory depression.[54] Finally, evidence indicates that high-dose, prolonged barbiturate therapy is immunosuppressive, and thus particular vigilance for nosocomial infections is indicated.[55,56]

High-Dose Benzodiazepines

Midazolam is a short-acting benzodiazepine with an efficacy equal to pentobarbital in controlling RSE.[57] It is administered as a loading dose of 0.15 mg/kg, followed by a continuous infusion beginning at 1 μg/kg/min. The infusion rate may be increased as tolerated to a maximum of 24 μg/kg/min, although even higher infusion rates have been reported. The advantages of midazolam include a rapid onset of action, a short half-life, and a lower incidence of cardiovascular depression and need for vasopressors than with pentobarbital.[38,58] The major disadvantage of midazolam is the need for escalating doses because of tachyphylaxis. High-dose infusions of diazepam and lorazepam represent other alternatives.[59,60]

Propofol

The $GABA_A$ agonist propofol is an anesthetic agent with potent anticonvulsant properties that has been widely used for the treatment of RSE, particularly in adults. The advantage of propofol is its rapid onset of action and short half-life; however, rapidly tapering propofol can precipitate seizures.[61] The main adverse effects of propofol are respiratory depression and hypotension due to myocardial depression. Early concerns about a possible proconvulsant effect of propofol have been largely allayed.[62,63] The use of propofol, particularly at high doses and with prolonged infusions, has been associated with a "propofol infusion syndrome" characterized by metabolic acidosis, lipemia, rhabdomyolysis, bradyarrhythmias, and death.[64,65] A recent retrospective series of 31 adults treated with propofol for RSE found a 6% mortality rate and 10% rate of cardiorespiratory arrest directly attributable to the propofol infusion syndrome. In addition, 39% of patients developed one or more features of the syndrome.[66] Therefore propofol infusions should be used with caution and should be limited to short duration with careful monitoring for adverse effects. Few data have been published on pediatric dosing of propofol for RSE. One recent case series reported safety and efficacy using a bolus dose of 1 to 2 mg/kg, followed by a continuous infusion of 1 to 2 mg/kg/h.[67]

Table 60–2 Drugs Used in the Treatment of Status Epilepticus

Drug	Initial Dose	Maximum Single Dose	IV Administration	Onset of Action	Half Life	Principal Adverse Effects in Short-Term Use
Lorazepam	0.05–0.1 mg/kg IV	4 mg	0.5 mg/min bolus	1–3 min	Neonates: 40 h Children: 10 h	Sedation, hypotension, bradycardia, respiratory depression, paradoxical hyperactivity
Diazepam	0.05–0.3 mg/kg IV	<5 y: 5 mg ≥5 y: 10 mg	0.1 mg/kg/min bolus	1–3 min	Neonates: 50–95 h Infants: 40–50 h Children: 15–20 h	Sedation, hypotension, bradycardia, respiratory depression, paradoxical hyperactivity, thrombophlebitis
Phenobarbital	15–20 mg/kg IV	1 g	1 mg/kg/min bolus to max. 60 mg/min	5 min	Neonates: 45–200 h Infants: 20–133 h Children: 37–73 h	Hypotension, sedation, respiratory depression, paradoxical hyperactivity, immunosuppression
Pentobarbital	5–12 mg/kg	100 mg	1 mg/kg/h infusion, then titrate	1 min	25 h	Sedation, bradycardia, hypotension, cardiac arrhythmia, respiratory depression, laryngospasm, extravasation causes skin necrosis
Phenytoin	15–20 mg/kg IV	1 g	1 mg/kg/min bolus, to max. 50 mg/min		7–42 h (first-order kinetics do not apply)	Dysarthria, ataxia, sedation, hypotension, cardiac arrhythmia, thrombophlebitis, extravasation causes "purple glove syndrome"
Fosphenytoin	15–20 mg PE/kg IV	1 g PE	3 mg PE/kg/min bolus to max. 150 mg PE/min		12–29 h (first-order kinetics do not apply)	Dysarthria, ataxia, sedation, hypotension, bradycardia, tachycardia
Valproic acid	10–30 mg/kg IV	30 mg/kg	5 mg/kg/min bolus		Children >2 mo: 7–13 h Children 2–14 y: 3.5–20 h	Hypotension, cardiac arrhythmia, hepatitis, pancreatitis
Paraldehyde	200–400 mg/kg PR	10 g	NA		4–10 h	Rectal irritation, lung toxicity
Midazolam	0.15 mg/kg IV	0.15 mg/kg	1 μg/kg/min infusion, titrate to max. 24 μg/kg/min	1-5 min	Neonates: 4–12 h Children: 3–4 h	Sedation, hypotension, bradycardia, respiratory depression, apnea, laryngospasm, paradoxical hyperactivity
Propofol	1–2 mg/kg IV		1–2 mg/kg/h infusion		1.5–12 h	Sedation, hypotension, bradycardia, respiratory depression, bronchospasm, hallucinations, pain when injected, propofol infusion syndrome: metabolic acidosis, rhabdomyolysis, lipemia, cardiac bradyarrhythmias, death
Ketamine	0.5–2 mg/kg IV		2–7 mg/kg/h*	30 sec	2.5 h	Hypertension, increased intracranial pressure, hallucinations, vomiting, emergence reactions, laryngospasm
Thiopental	2–4 mg/kg IV		2–4 mg/kg/h infusion	30–60 sec	14–34 h	Sedation, hypotension, respiratory depression, accumulation due to lipid solubility, extravasation causes skin necrosis
Isoflurane	0.5% –1% v/v		NA			Respiratory depression, hypotension, arrhythmias, malignant hyperthermia, laryngospasm, coughing (due to pungent odor)
Lidocaine	2–3 mg/kg IV		2–6 mg/kg/h		1.5–2 h in adults	Sedation, cardiac arrhythmias

IV, Intravenous; *NA,* not applicable; *PE,* phenytoin equivalents; *PR,* rectal; *v/v,* volume per volume.
*Continuous infusion rates for ketamine are not well established in children; refer to institutional guidelines and experience.

Valproic Acid

Intravenous valproic acid may have a useful role in RSE, but relatively little evidence exists to support its use.[68] In one case series, the authors reported on the efficacy of intravenous valproic acid for generalized convulsive and nonconvulsive seizures in children. They recommended a loading dose of 20 mg/kg followed by an infusion at 1 to 4 mg/kg/h, depending on the patient's state of hepatic induction (1 mg/kg/h for noninduced, 2 mg/kg/h in the presence of polyanticonvulsant therapy, and 4 mg/kg/h for high-dose pentobarbital).[69] In a subsequent retrospective review of 40 children (18 with SE), the researchers reported on the safety and efficacy of valproic acid when administered at loading doses of 25 mg/kg (in valproate-naive patients) and infused at rates of 2 to 3 mg/kg/min.[70] No significant changes were noted in heart rate or rhythm, blood pressure, or liver enzymes. One patient reported a transient tremor after the infusion.

Inhalational Anesthetics

The efficacy of inhalational anesthetics for SE that is refractory to high-dose benzodiazepines and barbiturates is described in several reports.[71,72] Inhalational anesthetics have the advantage of being easily titratable; however, prolonged use (particularly of halothane) may cause organotoxicity. Hemodynamic compromise is seen with all of these agents, particularly halothane, and all patients in reported studies required vasopressors. In adults, achieving isoelectric EEGs has required isoflurane concentrations of 1.5% to 2%.[73] The use of inhalational anesthetics in the ICU setting is complicated by the need for a proper gas scavenging system and supervision by staff trained in the administration of anesthesia.

Ketamine and Lidocaine

Ketamine is a unique NMDA antagonist reported to have both anticonvulsant and neuroprotective properties. Because of its unique mechanism of action on NMDA receptors, ketamine is an attractive therapeutic option for refractory SE that has failed to respond to high-dose benzodiazepines and barbiturates.[74] Ketamine is commonly used for procedural sedation, but there is no consensus on its dosing for SE, particularly when given as a continuous infusion. Lidocaine, which is given as an intravenous bolus or a continuous infusion, is another treatment option, although it is not widely used in North America.[75]

Pyridoxine

Pyridoxine (vitamin B_6) is a cofactor for both glutamic acid decarboxylase and GABA transaminase, the enzymes required for the synthesis and metabolism of GABA in the brain. Pyridoxine dependency and pyridoxine deficiency are rare disorders (with a prevalence of ~1/300,000 in the United Kingdom) that usually present in the neonatal or infantile period but may present as late as age 2.5 years.[76] Patients with these disorders have intractable seizures that are refractory to conventional anticonvulsant medications but respond promptly to pyridoxine. Therefore a trial of pyridoxine should be considered in any child who is seen before age 3 years with recurrent seizures or SE, particularly if the seizures are refractory to conventional anticonvulsant agents.[76] Isoniazid poisoning is another clinical scenario in which pyridoxine may be the only effective anticonvulsant therapy.[77]

Surgical Treatment

When SE is refractory to multiple medical treatments, including high-dose barbiturates and benzodiazepines, surgical intervention can be considered by centers with experience in pediatric epilepsy surgery. This approach is most easily considered for but not limited to children with a large cortical malformation.[78] Focal cortical resections may be indicated if a focal structural abnormality can be identified on neuroimaging; however, the presence of a lesion on MRI is not sufficient to ensure that seizures are arising from that region. Seizures also may arise from regions remote from a lesion visualized by MRI. Furthermore, in children with prolonged RSE, secondary epileptogenic foci may develop. Typically, multiple investigations will be undertaken to ensure that seizures are arising from the area of potential surgical resection. At a minimum, there should be concordance between the structural lesion and the location of ictal and interictal EEG discharges. If the patient is medically stable, fluorodeoxyglucose positron emission tomography may be used to demonstrate interictal hypometabolism or ictal hypermetabolism of the epileptogenic focus, and magnetoencephalography may be used to support the identification of the epileptogenic focus.[79] Implantation of subdural electrodes allows for the most precise localization of the epileptogenic focus; however, this procedure usually is not feasible in the setting of RSE. The evidence for such surgical approaches is limited to case reports and smaller series.[78,80-82]

Corpus callosotomy also has been attempted for SE that is generalized or cannot be localized. Implantation of a vagal nerve stimulator may be another therapeutic option, although it is rarely considered in the acute situation.[83,84]

Investigations

Investigation of the cause of SE should proceed in parallel with treatment because the optimal treatment, including prevention of recurrent SE, requires an understanding of the underlying cause. A 2006 evidence-based practice parameter identified the lack of high-level evidence for many of the recommendations that are generally regarded as standard of care for children with SE.[85]

Box 60-2 outlines the spectrum of investigations that should be considered in patients with SE and their rationale.

Acknowledgment

We thank Angela Trope, MSc, RPh, for her contribution to Table 60-2.

Box 60–2 Investigation of the Patient with Status Epilepticus

To Be Performed in All Patients with Status Epilepticus

Serum glucose, electrolytes, calcium, magnesium
Blood gas, serum osmolality
Toxicology screen (serum and urine)
Antiepileptic drug levels
Complete blood count (RBC, differential WBC, platelet count)
Liver enzymes, serum ammonium
Blood culture
Lumbar puncture, including
- Opening pressure
- Cell count, Gram stain, smear for acid-fast bacilli
- Viral and bacterial cultures
- PCR for herpesvirus

EEG, preferably continuous monitoring with video
- To monitor for subtle or subclinical seizures
- To guide antiepileptic drug therapy
- To localize the epileptogenic brain region (focal slowing or epileptiform activity)

To Be Considered in Patients with Status Epilepticus

Structural neuroimaging (CT, MRI)
- To diagnose acute infarction, hemorrhage, vascular malformation, encephalitis, abscess, neurocysticercosis, neoplasm
- In nonlesional cases, may localize the epileptogenic zone by evidence of focal edema in the affected cortical region
- To assess the degree of cerebral edema and diagnose impending uncal or transtentorial herniation
- MR angiography may identify CNS vasculitis, especially in medium or large vessel disease

Functional neuroimaging (PET, SPECT)
- In nonlesional cases, may identify the epileptogenic zone

Cerebral angiography
- To identify small vessel CNS vasculitis, which may not be visible on MR angiography

Rheumatological workup for vasculitides
ESR, C-reactive protein, rheumatoid factor, serum complement levels, antineutrophil cytoplasmic antibodies
Brain biopsy
- To diagnose cerebral vasculitis (granulomatous compared with nongranulomatous)
- To identify malformations of cortical development

CNS, Central nervous system; *CT*, computed tomography; *EEG*, electroencephalography; *ESR*, erythrocyte sedimentation rate; *MRI*, magnetic resonance imaging; *PCR*, polymerase chain reaction; *PET*, positron emission tomography; *RBC*, red blood cell; *SPECT*; single-photon emission computed tomography; *WBC,* white blood cell.

Severe Traumatic Brain Injury in Infants and Children

Patrick M. Kochanek, Michael J. Bell, Hülya Bayir, Michael J. Forbes, Randall Ruppel, P. David Adelson, and Robert S.B. Clark

PEARLS

- Complete and rapid physiologic resuscitation is essential to the initial treatment of infants and children with severe traumatic brain injury.
- Recent data have begun to support age-dependent targets for cerebral perfusion pressure–directed therapy in the treatment of infants and children with severe traumatic brain injury.
- Monitoring and control of intracranial hypertension should begin with first-tier therapies and progress to less well established second-tier therapies in refractory cases.
- The choice of second-tier therapy is based in part on an in-depth knowledge of the physiologic derangements involved and the preferences of the treating team.
- Advanced neuromonitoring is providing additional insight into pathophysiology-guided treatment.
- Because pediatric patients with traumatic brain injury often sustain multiple insults, appropriate correction of physiologic derangements and complications in other organ systems is also important in creating an optimal environment for recovery.

The topic of severe traumatic brain injury (TBI) in infants and children has been the focus of many chapters and reviews, but it has been the focus of few clinical reports and even fewer randomized controlled trials (RCTs). The paucity of clinical trials in infants and children with severe TBI became apparent when a group of physicians and scientists (pediatric critical care medicine specialists, pediatric neurologic surgeons, pediatric emergency medicine specialists, and experts in the methodology of evidence-based medicine) met and published an evidence-based document outlining "Guidelines for the Management of Severe TBI in Infants, Children, and Adolescents" (henceforth referred to as "the pediatric guidelines" in this chapter).[1] While the document focused on evidence from pediatric studies, small controlled studies or even uncontrolled case series of specific therapies for severe pediatric TBI were scarce. Studies focused on the age-related effects of therapies in the pediatric population were largely absent, and therapeutic trials in key pediatric subgroups, such as victims of inflicted childhood neurotrauma (child abuse), were rare. Based on the existing literature, few recommendations at the guideline level could be made. Subsequent to these guidelines and the last edition of this textbook, a number of studies have contributed to improving evidence-based care of children with severe TBI, and this information is incorporated into this chapter. This chapter addresses a practical and contemporary approach to the management of patients with TBI based on several sources of information: (1) the pediatric data presented in the pediatric guidelines, (2) data from studies in adults with severe TBI, and (3) accepted principles of the physiology and pathophysiology of the cerebral circulation and cranial vault.

This chapter focuses on severe TBI, specifically on management in the pediatric intensive care unit (PICU). The evolution of PICU management has progressed from exclusively supportive care to strategies attempting to (1) optimize substrate delivery and cerebral metabolism, (2) minimize secondary insults that might worsen secondary damage and outcome, (3) prevent severe or intractable intracranial hypertension and/or herniation, and (4) target specific mechanisms involved in the evolution of secondary injury with novel therapies. The goal of contemporary neurointensive care is the prevention and/or amelioration of secondary injury. The role of newer technologies and the differences between adults and children are highlighted. For information on mild or moderate TBI, outcomes, or rehabilitation of pediatric patients with TBI, the reader is referred to other materials on these topics.[2,3]

Epidemiology

Traumatic brain injury remains a significant pediatric health problem, with an estimated incidence of approximately 230 cases per 100,000.[4] About 475,000 new cases of pediatric TBI are reported each year,[5] which corresponds to a frequency of approximately one case every 2 to 3 minutes.[6] TBI is the most important cause of death and disability in children.[6,7] Specifically, 3000 to 4000 pediatric deaths resulting from TBI are reported annually.[8] About 10% to 15% of TBI cases in infants and children are severe (Glasgow

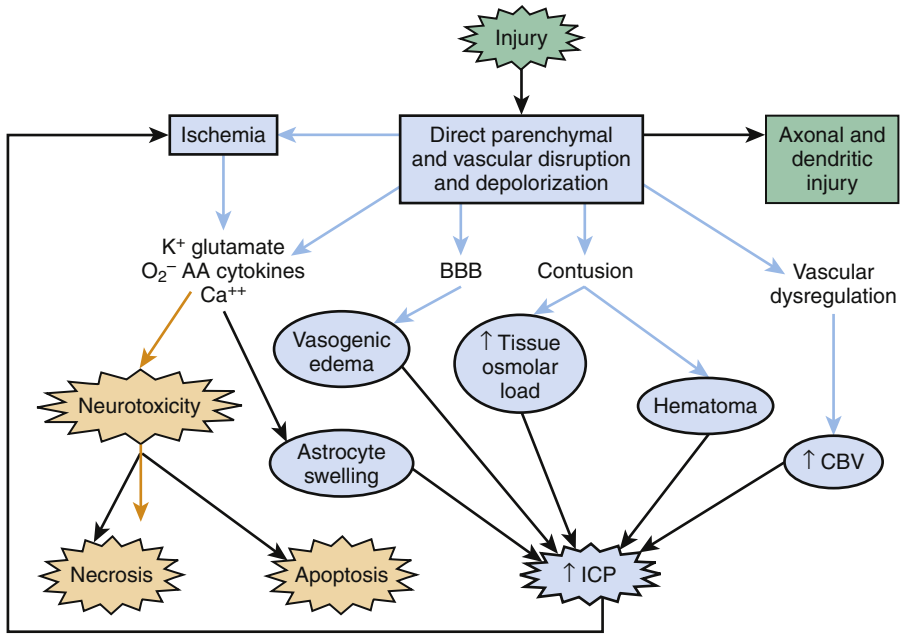

Figure 61–1. Categories of mechanisms proposed to be involved in the evolution of secondary damage after severe traumatic brain injury in infants and children. Three major categories for these secondary mechanisms are (1) ischemia, excitotoxicity, energy failure, and cell death cascades; (2) cerebral swelling; and (3) axonal injury.

Coma Scale [GCS] score <8), and these cases contribute most of the deaths or permanent brain damage observed.[9] The incidence of pediatric TBI is distributed evenly within three age groups (0 to 4 years, 5 to 10 years, and 11 to 15 years) based on data from the Traumatic Coma Data Bank.[10] Although children 5 to 15 years of age generally have favorable outcomes compared with adults, children aged 4 years or younger—particularly those younger than 2 years—have a worse outcome than older children and adults. Inflicted childhood neurotrauma is the leading cause of severe TBI in infants and is believed to be the key contributor to poor outcome in this younger subgroup, although other factors may play a role.[10,11] Penetrating injuries such as gunshot wounds, although not as common as either motor vehicle accidents or child abuse, also contribute significant morbidity and mortality in the pediatric population.[12]

Pathophysiology

Severe TBI involves a primary injury that includes direct and immediate disruption of brain parenchyma. However, not all of the effects of the primary injury are immediately apparent because damage also evolves over time and results from a cascade of biochemical, cellular, and molecular events involved in the evolution of the injury. In this chapter we define only the key factors involved. For detailed information on this topic, the reader is referred to other reviews.[13-15] Secondary injuries also result from extracerebral and intracerebral insults (e.g., hypotension, hypoxemia, ischemia, and refractory intracranial hypertension) at the injury scene and in the PICU. Three basic categories of secondary mechanisms can be defined (Figure 61-1): those associated with (1) ischemia, excitotoxicity, energy failure, and resultant cell death cascades; (2) secondary cerebral swelling; and (3) axonal injury. A constellation of mediators of secondary damage and repair are involved within each category. The contribution of each mediator to outcome and the interplay among them remain poorly defined. The biochemical and molecular responses to severe TBI resulting from child abuse often are unique and generally severe.[14]

Posttraumatic Ischemia

The early studies of Pickels[15] and Bruce et al.[16] on cerebral blood flow (CBF) in pediatric TBI focused on the role of hyperemia in secondary brain swelling. However, clinical studies in adults showed that CBF is reduced early after injury and suggested that early posttraumatic ischemia might be of special importance.[17,18] The devastating consequences of secondary extracerebral insults (i.e., hypotension and hypoxemia) early after TBI are consistent with this possibility, that is, contributing to an already compromised system. Adelson et al.[19] assessed CBF in 30 infants and children after severe TBI. Early posttraumatic hypoperfusion was common, and a global CBF less than 20 mL/100 g/min was associated with a poor outcome. After the initial 24 hours, CBF often recovered, in some cases to high levels. However, delayed increases in CBF were not associated with poor outcome. This finding shifted the emphasis toward the recognition and possible treatment of hypoperfusion early after TBI to avert secondary damage.

Numerous mechanisms may contribute to early posttraumatic hypoperfusion, including (1) an attenuated vasodilatory response to nitric oxide (NO), cyclic guanosine monophosphate, cyclic adenosine monophosphate, and/or prostanoids; (2) loss of endothelial NO production; (3) elaboration of endothelin-1[14]; and (4) production of other vasoconstrictor mediators.[20] Early after injury, increases in metabolic demands resulting from uptake of glutamate are reported.[21,22] Thus reduced metabolic demands coupled with CBF reduction in severely injured brain regions are an unlikely explanation for hypoperfusion. Work by Vavilala et al.[11] that was published after the pediatric guidelines identified a potentially

critical factor, that is, age at the time of injury, that could increase the importance of ischemic brain injury in pediatric TBI, particularly in infants and young children. These investigators reported that no difference exists in the lower limit of blood pressure autoregulation of CBF in children younger than versus older than 2 years.[11] This finding led them to conclude that the autoregulatory reserve (i.e., the difference between baseline mean arterial blood pressure [MAP] and the lower limit of autoregulation) is smaller in infants than in older children or adults; even modest MAP reductions may exacerbate ischemia in infants. The contribution of this finding to secondary ischemia in pediatric TBI will become apparent later in this chapter.

Excitotoxicity

Excitotoxicity is the process by which glutamate and other excitatory amino acids cause neuronal damage. Glutamate is the most abundant neurotransmitter in the brain, but exposure to toxic levels produces neuronal death.[23] Glutamate exposure produces neuronal injury in two phases. Sodium-dependent neuronal swelling quickly occurs,[24] followed by delayed, calcium-dependent degeneration. These effects are mediated through both ionophore-linked receptors, labeled according to specific agonists (*N*-methyl-D-aspartate [NMDA], kainite, and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), and receptors linked to second messenger systems (i.e., metabotropic receptors). Activation of these receptors leads to calcium accumulation via receptor-gated or voltage-gated channels or through release of intracellular stores. Increased intracellular calcium concentration triggers a number of processes that can lead to cell death. One mechanism involves activation of constitutive NO synthase, leading to NO production, peroxynitrite formation, and resultant deoxyribonucleic acid (DNA) damage. Poly(ADP-ribose) polymerase is an enzyme operative in DNA repair. In the face of excessive DNA damage, poly(ADP-ribose) polymerase activation leads to adenosine triphosphate (ATP) depletion, metabolic failure, and necrotic cell death.[25]

In cerebrospinal fluid (CSF) from adults with TBI, glutamate levels were about fivefold greater than in control patients (up to 7 μm/L).[26] These levels are sufficient to cause neuronal death in cell culture. Increased levels of glutamate also are seen in CSF of infants and children with TBI and correlate with poor outcome and child abuse as an injury mechanism.[27] Antiexcitotoxic therapies improve outcome after experimental TBI; pretreatment with NMDA antagonists (e.g., MK-801) attenuate behavioral deficits.[28] Other therapies that modify glutamate-NMDA receptor interaction and improve outcome after experimental TBI are magnesium, glycine site antagonists, hypothermia, and pentobarbital.[14] Despite this benefit, clinical trials with antiexcitotoxic therapies have been unsuccessful in adults, perhaps because of adverse effects of these drugs, delayed treatment, or the antiexcitotoxic effects of many current therapies (e.g., barbiturates, hypothermia, and sedatives).[29] Developing neurons are more susceptible to excitotoxic injury than are mature cells; however, concerns have been raised about use of NMDA antagonists in infants because these drugs may induce apoptotic neurodegeneration.[30] Investigating which specific NMDA receptor subunits may need to be targeted to produce antiexcitotic effects without triggering apoptosis is a key area for future research.

Apoptosis Cascades

Cells that die after TBI can be categorized on a morphologic continuum ranging from necrosis to apoptosis.[31,32] Apoptosis is a morphologic description of cell death defined by cell shrinkage and nuclear condensation, internucleosomal DNA fragmentation, and formation of apoptotic bodies.[33] In contrast, cells that die of necrosis display cellular and nuclear swelling with dissolution of membranes (see also Chapter 100).

Because apoptosis requires a cascade of intracellular events for completion of cell death, "programmed cell death" is the currently accepted term for the process that leads to apoptosis. In diseases with complex and multiple mechanisms, such as TBI, distinguishing clinical apoptotic from necrotic cell death as classically defined may be difficult,[34] and some cells have mixed phenotypes. In mature tissues, programmed cell death requires initiation via either intracellular or extracellular signals (Figure 61-2). Intracellular signaling appears to be initiated in mitochondria, triggered by disturbances in cellular homeostasis such as ATP depletion, oxidative stress, or calcium fluxes.[35] Mitochondrial dysfunction leads to egress of cytochrome c into the cytosol. Oxidation of the mitochondrial lipid cardiolipin may play a central role in cytochrome c release.[36] Cytochrome c release can be blocked by antiapoptotic members of the Bcl-2 family (e.g., Bcl-2, Bcl-xL, Bcl-w, and Mcl-1) and promoted by proapoptotic members of the Bcl-2 family (e.g., Bax, Bcl-xS, Bad, and Bid).[37] Cytochrome c in the presence of dATP and a specific apoptotic-protease activating factor in cytosol activates the initiator cysteine protease caspase-9.[38] Caspase-9 then activates the effector cysteine protease caspase-3, which cleaves cytoskeletal proteins, DNA repair proteins, and activators of endonucleases.[39] Extracellular signaling of apoptosis occurs via the tumor necrosis factor (TNF) superfamily of cell surface death receptors, which includes TNFR-1 and Fas/Apo1/CD95.[40] Receptor-ligand binding of TNFR-1–TNF-α or Fas-FasL promotes formation of a trimeric complex of TNF- or Fas-associated death domains. These death domains contain caspase recruitment domains, ultimately leading to caspase-3 activation, where the mitochondrial and cell death receptor pathways converge (see Figure 61-2). Both the intrinsic and extrinsic pathways may contribute to the evolution of cell death after severe TBI in infants and children. CSF levels of the anti-apoptotic protein Bcl-2 in pediatric patients after TBI were increased approximately fourfold in patients with TBI versus control subjects.[41] Similarly, CSF levels of sFas receptor and sFas ligand are increased in patients with TBI versus control subjects.[42] Apoptosis may be an important therapeutic target for new therapies in infants with severe TBI. Finally, current therapies likely attenuate both necrotic and apoptotic injury cascades.

Taken together, the currently available data strongly suggest that early after injury, severe TBI produces a state of hypoperfusion with simultaneous increased metabolic demands from excitotoxicity. This is a state of enhanced vulnerability to secondary insults (i.e., hypotension and hypoxemia). These processes are intimately linked with the evolution of neuronal death by either necrosis or apoptosis.

Cerebral Swelling

After the initial minutes to hours of posttraumatic hypoperfusion and hypermetabolism, a phase of metabolic depression occurs. Cerebral metabolic rate of oxygen ($CMRO_2$) decreases

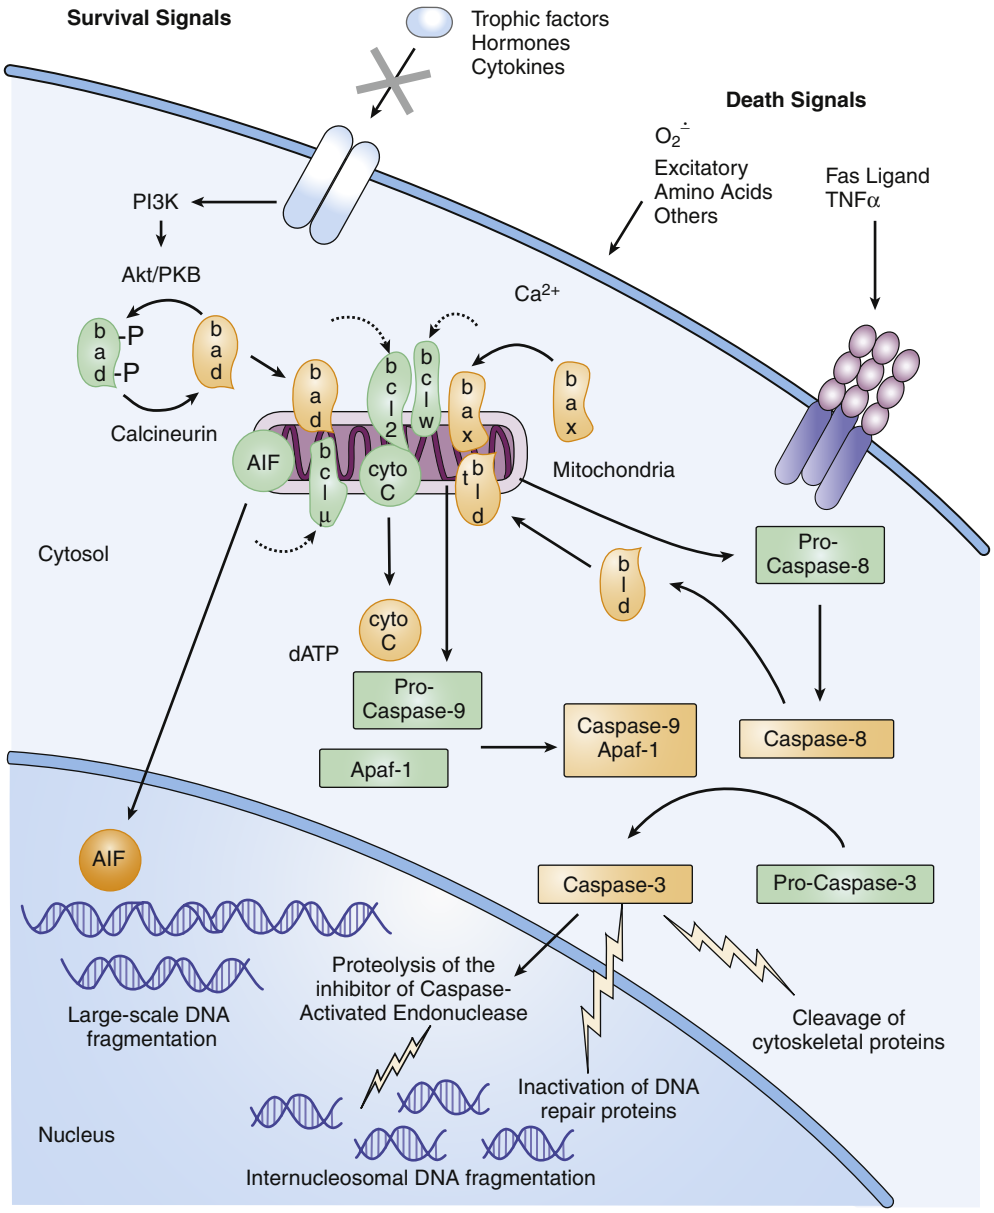

Figure 61–2. Cell death cascades involved in delayed neuronal death after severe traumatic brain injury. *AIF*, Apoptosis-inducing factor; *dATP*, deoxyadenosinemonophosphate; *DNA*, deoxyribonucleic acid; *PI3K*, phosphoinositide 3-kinase; *PKB*, protein kinase B; *TNF*, tumor necrosis factor.

to approximately one third of normal[43,44] and is maintained at that level for the duration of coma, unless perturbed by second insults such as seizures or spreading depression.[45] The exact etiology of this state remains to be defined; however, contributions from reduced synaptic activity and mitochondrial failure may be important.[46] Sustained increases in glycolysis are reported in some cases, possibly related to seizure activity or sustained increases in glutamate levels.[22] During the PICU phase, cerebral swelling develops and generally peaks between 24 and 72 hours after injury, although sustained increases in intracranial pressure (ICP) for 1 week or longer occasionally are observed.

Cerebral Blood Volume

Several mechanisms may contribute to intracranial hypertension in infants and children after severe TBI (see Figure 61-1). Brain swelling and accompanying intracranial hypertension contribute to secondary damage in two ways. Intracranial hypertension can compromise cerebral perfusion leading to secondary ischemia, and it can produce the devastating consequences of deformation through herniation syndromes. Bruce et al.[16] described the phenomenon of "malignant posttraumatic cerebral swelling" in children. CBF was measured in six children, and hyperemia was believed to be the major culprit. Muizelaar et al.,[47] in a series of 32 children, and Beyda[48] suggested similar findings. However, Sharples et al[49,50] suggested that hyperemia was uncommon after severe TBI in children; rather, reduced $CMRO_2$ was associated with poor outcome.

Suzuki[51] measured CBF in 80 normal children. He showed an age dependence of CBF, with rather high values in children ages 2 to 9 years, levels previously suggested to represent posttraumatic hyperemia. Nevertheless, in patients with TBI, after resolution of the aforementioned early posttraumatic hypoperfusion, CBF may increase to levels greater than metabolic demands in some children, producing a state of relative hyperemia.[14]

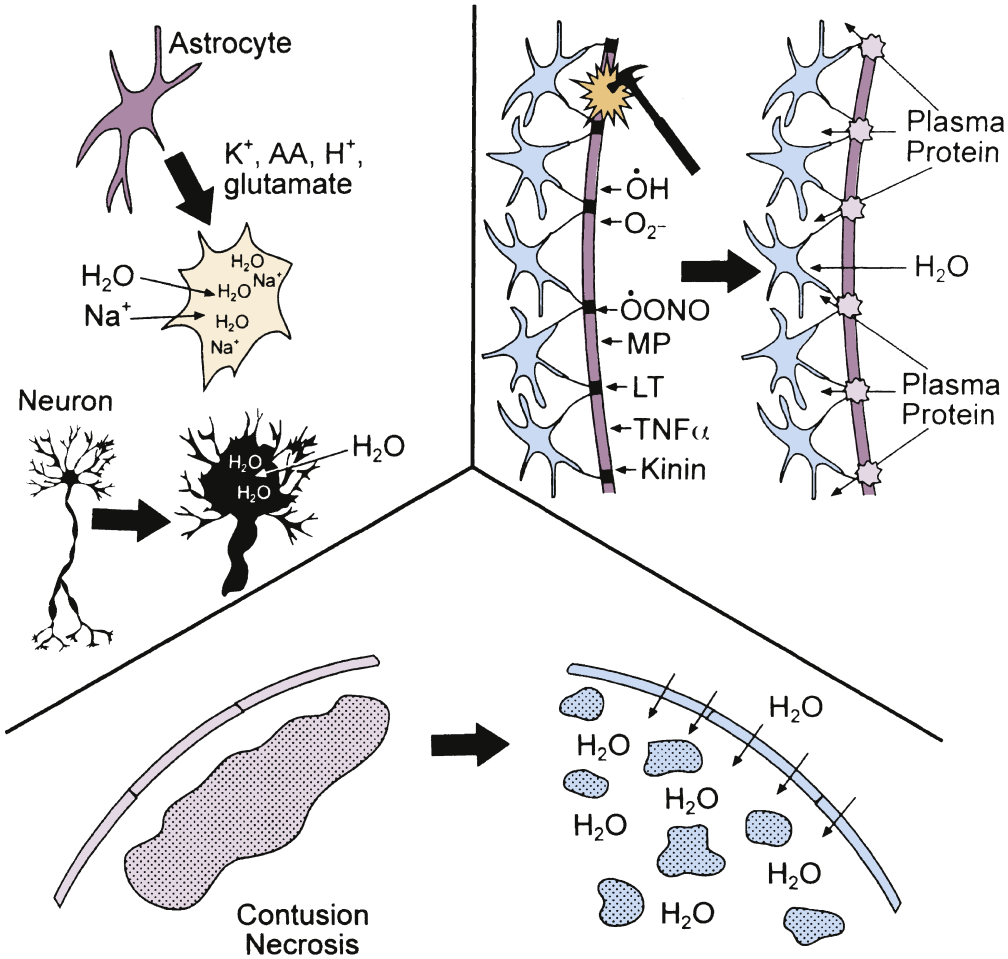

Figure 61–3. Schematic of three cascades leading to cerebral edema. *Top left*, Cellular swelling is predominantly seen in astrocytes and is stimulated by potassium, acidosis, glutamate, arachidonic acid *(AA),* and other factors. This key pathway is less representative of a toxic process and more consistent with a homeostatic or mediator-driven process. Neuronal swelling from pump leak probably is less important. *Bottom*, Osmolar swelling from contusion necrosis. In the hours after injury, reconstitution of the BBB or development of an osmolar barrier around a contusion sets the stage for marked local swelling as macromolecules in the contusion break down, increasing local osmolality. *Top right*, Vasogenic edema results from protein and water accumulation across the damaged BBB, which is formed by tight junctions (astrocyte foot processes). Direct vascular disruption by trauma, reactive oxygen species such as hydroxyl radical *(OH),* superoxide anion *(O_2^-),* and peroxynitrite *(ONOO),* metalloproteases *(MP),* kinins, leukotrienes *(LT),* cytokines, and other mediators contribute to BBB damage. *TNF,* Tumor necrosis factor.

Bergsneider et al.[22] posed the alternative hypothesis of "hyperglycolysis" to explain the increases in CBF in patients with severe TBI whose CBF is uncoupled from $CMRO_2$. Cerebral glutamate uptake is coupled to glucose utilization by glycolysis in astrocytes. Recent studies suggest two other potential contributors to increased glycolysis after TBI even in the absence of low CBF, namely mitochondrial falure[52] and nitration and inactivation of the enzyme pyruvate dehydrogenase, which is critical to the production of acetyl-CoA and thus oxidative metabolism.[53] Thus in injured brain regions with reduced $CMRO_2$, increases in CBF may be coupled to local increases in glucose utilization even in the absence of ischemia.

Local or global increases in glycolysis occur in adults with severe TBI.[22] The incidence and/or importance of secondary "hyperemia" or hyperglycolysis in pediatric TBI remains to be determined. It may occur in select cases, but secondary increases in CBF probably are not the major contributor to raised ICP. Increases in CBF were not associated with raised ICP in adults,[54] and hyperemia was not associated with poor outcome in children.[4] The contribution of hyperemia (increased cerebral blood volume [CBV]) to the development of raised ICP has been studied in adults with TBI.[55] Increased CBV was seen in only a small number of patients. These studies suggest that the importance of posttraumatic hyperemia may have been overstated, and edema rather than hyperemia may be the predominant contributor to brain swelling after TBI.[56]

Edema

Both cytotoxic and vasogenic edema may play important roles in cerebral swelling (Figure 61-3). However, the traditional concept of cytotoxic and vasogenic edema is evolving. There appear to be four mechanisms for edema formation in the injured brain. First, vasogenic edema may form in the extracellular space as a result of blood-brain barrier (BBB) disruption. Second, cellular swelling can be produced in two ways. Astrocyte swelling can occur as part of the homeostatic uptake of substances such as glutamate. Glutamate uptake is coupled

to glucose utilization via a sodium/potassium adenosine triphosphatase, with sodium and water accumulation in astrocytes. Swelling of both neurons and other cells in the neuropil can result from ischemia- or trauma-induced ionic pump failure. Finally, osmolar swelling may contribute to edema formation in the extracellular space, particularly in contusions. Osmolar swelling actually is dependent on an intact BBB or an alternative solute barrier. Cellular swelling may be of greatest importance.

Using a model of diffuse TBI in rats, Barzo et al.[57] applied diffusion-weighted magnetic resonance imaging to localize the increase in brain water. A decrease in the apparent diffuse coefficient after injury suggested largely cellular swelling rather than vasogenic edema in the development of raised ICP. Katayama et al.[58] also suggested that the role of BBB in the development of posttraumatic edema may have been overstated, even in the setting of cerebral contusion. An intriguing possibility is that as macromolecules are degraded within injured brain regions, the osmolar load in the contused tissue increases. As the BBB reconstitutes (or as other osmolar barriers form), a large osmolar driving force for local accumulation of water develops, resulting in the marked swelling so often seen in and around cerebral contusions. Thus in either diffuse injury or focal contusion, BBB permeability may play only a limited role in the development of cerebral swelling. If these results can be generalized, then hypertonic saline solution or mannitol seem to represent optimal therapies. This suggestion is in contrast to traditional recommendations, in which hyperventilation is suggested.[59,60] However, a role for BBB permeability in cases of severe TBI should not be dismissed. A recent study in adults with severe TBI by Polderman et al.[61] reported that prolonged use (>48 hours) of mannitol (a large molecule that does not cross the intact BBB) was associated with a progressive accumulation of mannitol in CSF, and in some cases, a reverse osmotic gradient was even established. This finding suggests that breaching of the BBB is important and that prolonged use of mannitol might create an iatrogenic secondary insult. Studies of the extent of BBB injury and the contribution of cellular swelling to intracranial hypertension in pediatric TBI are needed.

Axonal Injury

Traumatic axonal injury (TAI) encompasses the spectrum from mild to severe TBI.[62,63] The extent and distribution of TAI depend on injury severity and category (focal vs. diffuse). Its incidence and nature appear to be age independent,[64] but its consequences may be particularly devastating in children.[65] The effects of TAI in children during a period of developmental axonal connectivity remain unknown but likely are considerable. During development, numerous signaling molecules can function as attractants or repellents.[66] Clinical data on TAI after pediatric TBI are limited. However, strongly supporting the role for TAI in pediatric TBI, after publication of the guidelines, Berger et al.[67] reported that serum levels of myelin basic protein are markedly increased in infants and children after either accidental or inflicted TBI—in contrast to hypoxic-ischemic encephalopathy (Figure 61-4). In children affected by shaken baby syndrome, TAI may be highly prevalent.[68] The classic view that TAI occurs because of immediate physical shearing is represented primarily in patients with severe injury in whom frank axonal tears occur. Experimental studies suggest that TAI occurs by a delayed process termed *secondary axotomy*, which results from either calcium accumulation or altered axoplasmic flow.[69] What remains to be determined is how much of TAI results from a reversible evolution of damage to axons versus Wallerian degeneration of disconnected axons. The former but not the latter would be amenable to treatment. Nevertheless, TAI contributes to the morbidity after TBI.[69] Laboratory studies suggest that hypothermia, calpain antagonists, and cyclosporine A can attenuate TAI, but clinical data are lacking.

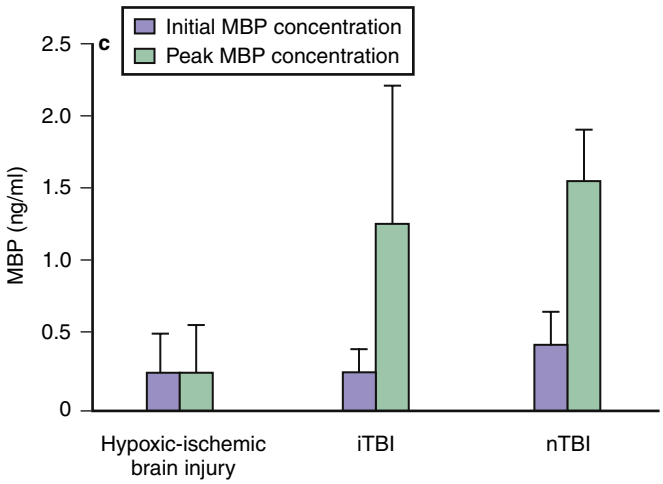

Figure 61–4. Initial (*solid bars*) and peak (*open bars*) serum levels of myelin basic protein (MBP) in infants and children after hypoxic ischemic insult from cardiorespiratory arrest, inflicted traumatic brain injury (*iTBI,* child abuse) or noninflicted TBI (*nTBI,* accidental). Axonal injury, reflected by increases in serum MBP levels, was seen only in the two forms of TBI, and in both cases the increase was delayed because it was not seen on initial presentation. *(Modified from Berger RP, Adelson PD, Richichi R et al: Serum biomarkers after traumatic and hypoxemic brain injuries: insight into the biochemical response of the pediatric brain to inflicted brain injury,* Dev Neurosci *28:327-335, 2006.)*

History

Unlike in adult TBI, where the history is generally straightforward, the special case of inflicted childhood neurotrauma contributes to increased importance of the history in pediatric TBI. For a discussion of the topic, the reader is referred to Duhaime[70] (see also Chapter 113). In cases of severe TBI resulting from child abuse, a history that is incompatible with the observed injury is often given.[71] Occult presentations of inflicted childhood neurotrauma can be particularly important because they may be recognized as cases of severe TBI relatively late in their treatment course.[72] In this setting, brain edema already may have evolved to life-threatening levels, and other superimposed secondary insults (e.g., seizures and apnea) may complicate management and worsen outcome.

Signs and Symptoms

The GCS score[73] (Table 61-1), first described in 1974, remains a valuable tool for grading and communicating severity of neurologic injury after TBI, although limitations remain with pediatric use. The verbal and motor components of the GCS score have been modified for assessment of infants,[74] but this modification has not been validated in infants and

Table 61–1 Coma Scales

Glasgow Coma Scale	Modified Coma Scale	Point Scale
EYE OPENING		
Spontaneous	Spontaneous	4
To speech	To speech	3
To pain	To pain	2
None	None	1

Abnormal extension	Abnormal extension	2
Flaccid	Flaccid	1

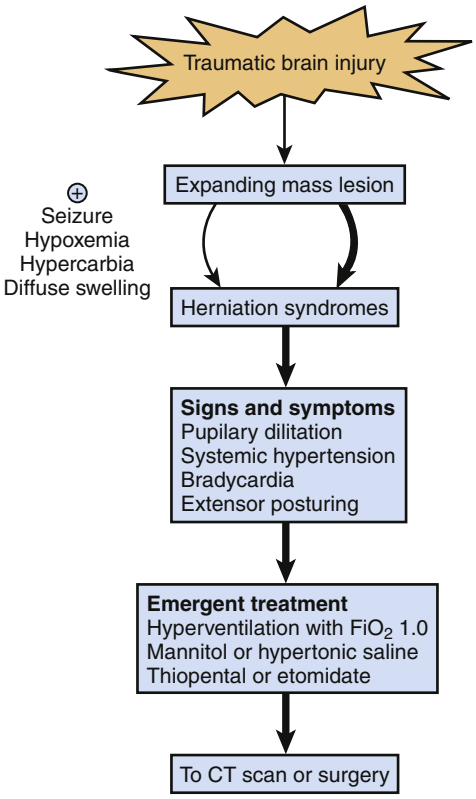

Figure 61–5. Treatment paradigm for management of signs and symptoms of acute herniation after severe traumatic brain injury in infants and children.

young children. The motor score has probably become the most important component of the GCS. A rapid "mini-neuroassessment" that allows evaluation of the patient's level of consciousness, pupillary size and light response, the fundi, extraocular movements, response of extremities to pain, deep tendon reflexes, and brainstem reflexes should all be part of the initial evaluation.[75] Until proven otherwise, an altered level of consciousness, pupillary dysfunction, and lateralizing extremity weakness in an infant or child should raise suspicion of a mass lesion that may require surgery.[76] These signs of impending herniation require an immediate response, as outlined in Figure 61-5.

Initial Resuscitation

The identification and correction of airway obstruction, inadequate ventilation, and shock take priority over a detailed neurologic assessment.[77] Thus the first step in managing a patient with a head injury patient is complete, rapid physiologic resuscitation.[1] Although raised ICP and cerebral herniation are the major complications, brain-specific interventions in the absence of signs of herniation or other neurologic deterioration currently are not recommended. Mannitol may be counterproductive for the management of malignant intracranial hypertension during initial resuscitative efforts. In the acute TBI resuscitation setting, hypertonic saline solution may be a better alternative (discussed later in this chapter). Studies have consistently shown that increased morbidity and mortality are associated with the secondary insults of hypotension and hypoxemia.[78,79] Gentleman[79] reported that the increased use of tracheal intubation and ventilation produced a concomitant reduction in episodes of hypoxemia and mortality rate and an increase in favorable outcomes. Although the basis for this improvement may be multifactorial, early correction of hypoxemia and hypovolemia must be the initial objective. However, specific recommendations for intubation at the scene are complex and likely are influenced by the expertise of caregivers in the field and by the transport distance, among other factors.[1]

Trauma patients with supraclavicular injury should be assumed to have cranial and cervical spine injuries until proven otherwise. The initial evaluation of a child after severe TBI begins by demonstrating the presence of a patent, maintainable airway; the patient must be conscious, alert, and breathing spontaneously. Unconscious patients must be assumed to have an obstructed airway requiring immediate evaluation. The relatively large head, occiput, and tongue and the short narrow epiglottis of the infant facilitate airway obstruction if the child's sensorium has been clouded. The rescuer must alleviate this situation (while protecting the cervical spine) to minimize secondary injury from hypoxia.

We previously outlined the use of the mnemonic SOAP to define the components for optimal preparation for securing the airway in the case of severe TBI requiring intubation in the emergency department or the PICU.[80] "S" represents suction; for most patients, a flexible 10 Fr catheter suffices. However, for school-age children (older than 5 years), we recommend the Yankauer rigid plastic suction catheter, which allows direct oropharyngeal suctioning. "O" represents oxygen; oxygen (a fraction of inspired oxygen [F_{IO_2}] of 1.0) should be delivered to the patient by face mask immediately before intubation. Optimal positioning of the patient requires immobilization of the neck to stabilize the cervical

Box 61–1 Criteria for Intubation of the Head-Injured Child

GCS score ≤10
Decrease in GCS of >3, independent of the initial GCS score

spine. Delivery of 100% oxygen facilitates nitrogen washout from the functional residual capacity, maximizing alveolar oxygenation. "A" represents airway; once the patient is positioned and ventilation and oxygenation are controlled, an age-appropriate laryngoscope blade and tracheal tube are selected. The tube is secured with adhesive tape that should not pass circumferentially around the neck because cerebral venous return may be reduced. "P" represents pharmacology; the medications chosen must be potent and rapid in their onset of action. The goals of analgesia, amnesia, and neuromuscular blockade must be met rapidly. Ideally, the patient never receives a preintubation positive-pressure breath.

Tracheal intubation of the child with severe TBI requires a cerebroprotective, rapid-sequence technique when possible (see also Chapter 42). Bag-valve-mask positive-pressure ventilation should be avoided. However, in cases of hypoxemia or impending herniation, positive-pressure ventilation should be instituted immediately.[81] Because the bag-valve-mask technique may cause unintentional cervical spine manipulation, care is advised.[82]

If a person who has sustained TBI meets any of the criteria listed in Box 61-1, assisted ventilation is indicated.[81,83] In children, the recommended route of initial airway control is orotracheal intubation under direct vision.[84] Nasotracheal intubation should be avoided. Blind passage of the endotracheal tube around the acute nasopharyngeal angle makes this procedure an unnecessary obstacle to rapid, physiologic resuscitation. Orotracheal intubation can be accomplished using a two-person strategy that protects the cervical spine from injury. A normal lateral cervical spine roentgenogram is reassuring but does not rule out cervical spine injury.[85] Spinal immobilization must be maintained,[86] which is accomplished via in-line cervical immobilization by one operator while the second intubates the trachea. Care must be taken to avoid pressing into the soft tissues of the submental region and strap muscles because inadvertent airway obstruction may ensue.

Rapid-Sequence Induction and Intubation

Tracheal intubation, although lifesaving, is a noxious stimulus. The technique of rapid-sequence induction and intubation secures the airway of an unprepared patient, who is at risk for aspiration of gastric contents, in an immediate and safe manner. No resistance is provided to direct laryngoscopy, and the normal responses to intentional placement of a foreign body into the trachea are eliminated. Rapid-sequence induction is documented to be a safer technique than either nasotracheal intubation or orotracheal intubation without neuromuscular blockade.[87,88]

Table 61–2 Drugs for Intubation of the Head-Injured Child

Situation	Drugs
Cardiopulmonary arrest	Resuscitation drugs
Hemodynamically unstable	Fentanyl 2–4 μg/kg
	Lidocaine 1 mg/kg
	Rocuronium 1 mg/kg or vecuronium 0.3 mg/kg
Hemodynamically stable	Fentanyl 2–4 μg/kg
	Lidocaine 1 mg/kg
	Midazolam 0.1–0.2 mg/kg
	Rocuronium 1 mg/kg or vecuronium 0.3 mg/kg
	or
	Thiopental 4–5 mg/kg
	Lidocaine 1 mg/kg
	Rocuronium 1 mg/kg or vecuronium 0.3 mg/kg

In the pediatric patient with TBI, a cerebroprotective rapid-sequence induction strategy should be used. The sequence involves preparation, preoxygenation, sedation, neuromuscular blockade, and orotracheal intubation. Pharmacologic adjuncts are used to prevent morbidity associated with hypotension, hypoxemia, intracranial hypertension, and gastric aspiration. The neurologic and hemodynamic status of the patient directs the choice of adjunctive pharmacologic strategy.

For a victim in cardiac arrest, cardiopulmonary resuscitation should begin immediately, accompanied by direct orotracheal intubation. No pharmacologic adjuncts are necessary to secure the airway. For a hemodynamically unstable patient, the combination of fentanyl, lidocaine, and rocuronium bromide is the first choice (Table 61-2). At Pittsburgh Children's Hospital use of etomidate has been eliminated in children with TBI because of concerns about adrenal suppression.[89] Either of these same sequences of drugs can be used in hemodynamically stable patients, for whom a rapidly acting benzodiazepine (midazolam) can be added.

An alternative in the hemodynamically stable patient is thiopental. Thiopental rapidly reduces cerebral metabolism,[90-93] which in turn blunts the ICP rise associated with laryngoscopy. The rapid cerebral uptake of these agents is matched by rapid washout. Thus these agents must be followed with another sedative or analgesic. Fentanyl, in combination with lidocaine, reduces the catecholamine surge associated with direct laryngoscopy.[81]

Circulatory Stabilization

Assessment of circulatory function after trauma involves the rapid determination of heart rate, blood pressure, central and peripheral pulse quality, capillary refill, and cerebral perfusion.[94] Posttraumatic hypoperfusion must be assumed to be hypovolemic (i.e., hemorrhagic) in nature, but it also

may have a secondary component of myocardial depression resulting from cardiac contusion. However, cardiac contusion is less common in children than in adults. In patients with severe TBI, fluid therapy for hypovolemic shock entails rapid replacement of vascular volume (see also Chapter 29). The choice of resuscitation fluid is controversial. The current recommendation is 20 mL/kg isotonic crystalloid (0.9% NaCl solution) given as soon as vascular access is obtained. Hypotonic fluid should not be used in the initial resuscitation of a patient with a brain injury. Subsequent doses of fluid should be isotonic crystalloid, colloid, or packed red blood cells and titrated based on serial assessment of blood pressure, perfusion, and hematocrit. Although concerns exist regarding the relative hypotonicity of lactated Ringer's solution,[95] evidence from studies in laboratory animals supports the safety of the use of lactated Ringer solution in patients with TBI.[96] Fisher et al.[97] reported the successful use of 3% saline solution as a maintenance fluid in children with TBI. Titration of 3% saline solution as an infusion to prevent development of intracranial hypertension is an acceptable first-tier strategy. Although its efficacy has yet to be proved in a clinical trial, inclusion of hypertonic saline solution should be considered in the setting of volume resuscitation of a child with TBI who has initial signs or symptoms of intracranial hypertension. Details of the approach to osmotherapy are discussed later in this chapter.

Herniation

The need to simultaneously address airway control, cardiovascular assessment and stabilization, treatment of extracerebral insults (hemorrhage and multiple trauma), and initial trauma survey in the field and emergency department makes management challenging. Although mass lesions are less common in children than in adults, they still occur in about 30% of children with severe TBI.[6] Although it happens infrequently, some of these patients, particularly those with rapidly expanding mass lesions (e.g., epidural hematoma), can present with signs and symptoms of herniation (i.e., pupillary dilatation, systemic hypertension, bradycardia, and extensor posturing). Because the devastating complications of herniation sometimes can be prevented or treated in the initial minutes of their progression, the importance of aggressively and presumptively treating signs and symptoms of herniation, which is a medical emergency, cannot be overemphasized until these signs and symptoms are proved not to represent herniation.

Appropriately, there has been a move away from prophylactic application of aggressive hyperventilation for the management of severe TBI. However, it is important to recognize that temporary use of hyperventilation with an F_{IO_2} of 1.0 is a therapy that can be immediately applied and can be life saving in the setting of impending herniation until other therapies can be instituted. Intubating doses of thiopental or pentobarbital and mannitol (0.25 to 1.0 g/kg) or hypertonic saline solution[97] also should be given emergently. One must recognize that factors other than a focal mass lesion may lead to herniation and that these situations may arise more commonly in children than in adults. Diffuse swelling is more common in children than in adults, and in this setting, inadvertent hypercarbia or hypoxemia, iatrogenic excessive fluid administration, or status epilepticus can precipitate herniation. Although discussed in this chapter in the context of acute therapy, herniation can occur at any time in the PICU course, and this approach to treatment also applies (see Figure 61-5).

Transition from the Emergency Department to the Pediatric Intensive Care Unit: Computed Tomographic Scan and Intracranial Pressure Monitoring

The transition of patients with severe TBI from the emergency department to the PICU includes computed tomographic (CT) evaluation of the head (and other anatomic regions, when clinically indicated) followed by placement of an ICP monitor, transport to the operating suite for surgical intervention, or both. In the initial resuscitation, sedation must be carefully titrated, maintaining the difficult balance that produces stability, analgesia, and anxiolysis during transport and scanning while allowing for rapid emergence for clinical assessment (as indicated) until a decision is made regarding surgery or ICP monitoring. Because the early period after injury generally reflects a state of increased vulnerability of the brain to second insults because of the brain's increased metabolic demands and compromised perfusion, providing adequate sedation and maintaining stable hemodynamics are important. An end-tidal CO_2 monitor also should be considered to avoid iatrogenic hyperventilation or hypoventilation. Clinical trials supporting definitive recommendations are not available. Nevertheless, the risks of intrahospital transport are well described;[98] therefore, when possible, a physician should accompany the infant or child upon transport to the scanner to direct care because serial assessment to titrate therapy is needed during the acute phase of injury.

Diagnostic Studies and Monitoring Modalities

Computed Tomography

Since becoming commercially available in 1973, CT has been of enormous benefit to neurointensive care.[99] Examples of classic findings in severe pediatric TBI are shown in Figure 61-6. Comprehensive classifications of CT findings in adults with severe TBI are reported. The Marshall classification is the most commonly used (Table 61-3).[100] A similar system specifically for pediatric TBI is not described, although several reviews characterize the spectrum of injury in infants and children as defined by CT.[101,102] Ewing-Cobbs et al.[101] compared acute CT findings in infants and children with inflicted and noninflicted injuries. Subdural interhemispheric and convexity hemorrhages and preexisting lesions were two to three times more common in the group with inflicted TBI. Epidural hematomas were more common in the group with noninflicted TBI.

Timing of repeat cranial CT scans has been investigated, including studies in children. Routine reimaging at 24 or 48 hours after injury has been suggested.[103] However, Tabori et al.[104] evaluated the impact of routine reimaging on 67 children after severe TBI and noted that although some new lesions were identified, reimaging did not lead to surgical or medical changes in therapy in any patient. A decision to reimage based on changes in ICP or clinical examination was

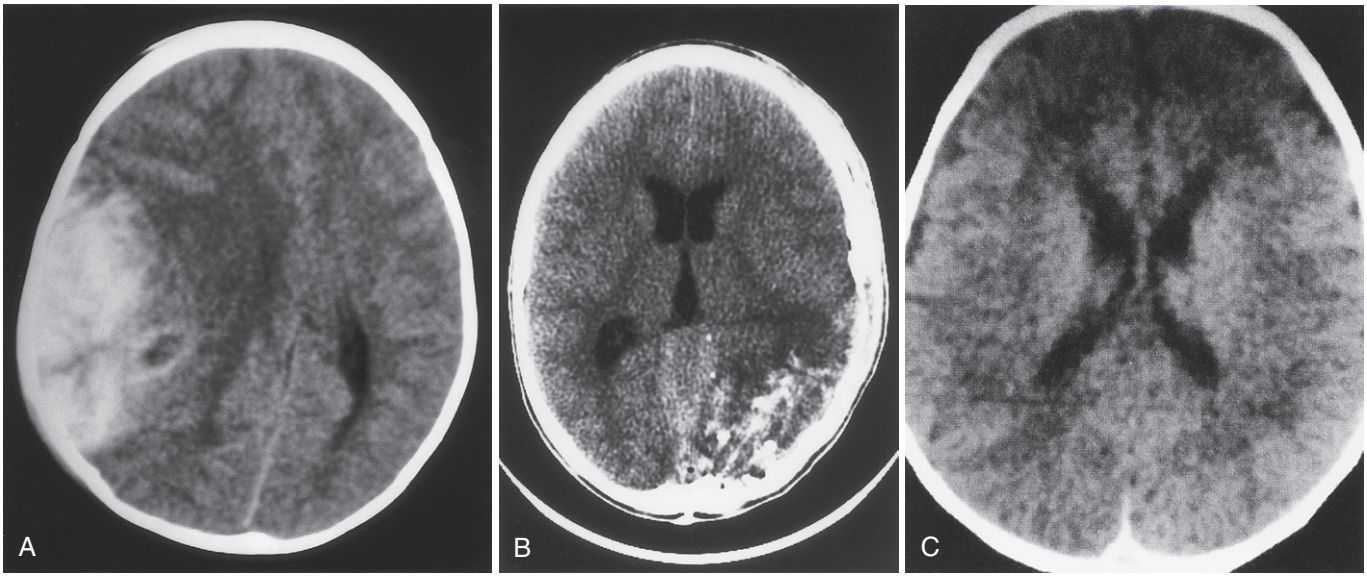

Figure 61–6. Axial cranial CT images of important lesions in pediatric traumatic brain injury including (**A**) acute epidural hematoma (**B**), penetrating brain injury resulting from a gunshot wound (with bullet fragments), and (**C**) inflicted childhood neurotrauma (shaken baby syndrome) with a subtle posterior subdural hematoma.

Table 61–3 Marshall Classification of Cranial Computed Tomographic Scans

Classification	Findings on Scan
Diffuse injury I (no visible pathologic change)	No visible intracranial pathologic change seen on computed tomography
Diffuse injury II	Cisterns are present with shift 0–5 mm and/or lesion densities present
	No high or mixed density lesion >25 mL
	May include bone fragments and foreign bodies
Diffuse injury III	Cisterns compressed or absent (swelling) with shift 0–5 mm
	No high or mixed density lesion >25 mL
Diffuse injury IV (shift)	Shift >5 mm
	No high or mixed density lesion >25 mL
Evacuated mass lesion	Any surgically evacuated lesion
Nonevacuated mass	High or mixed density lesion >25 mL, not surgically evacuated
Brain dead	No brainstem reflexes
	Flaccidity
	Fixed and nonreactive pupils
	No spontaneous respirations with a normal $Paco_2$
	Spinal reflexes permitted

recommended. Such an approach also is recommended in published pediatric guidelines.[1]

Studies in adults and children indicate that CT scans are not without limitations and must be used as only one, albeit important, piece of information. After severe TBI, in about 15% of adults with a normal CT scan, clinically significant intracranial hypertension develops. In contrast, in a study in 65 children, Hirsch et al.[105] reported that CT scans had a high false-positive rate in defining increased ICP. Finally, patients with normal initial head CT scans who also have hypotension or abnormal posturing have the same propensity to the development of intracranial hypertension as do their counterparts with an abnormal scan.[32,33]

Magnetic Resonance Imaging

MRI may have future applications salient to acute management in persons with TBI. The application of diffusion-weighted MRI for studying the evolution of cerebral edema,[55] the use of novel MRI methods for quantifying CBF,[106] and new methods such as susceptibility-weighted imaging to assess white matter damage increasingly are being applied (Figure 61-7).[107] The potential ability to couple these techniques with MR spectroscopy and functional MRI are beginning to yield unprecedented advances in our understanding of the brain's response to injury. However, MRI suites in most institutions are remote from the emergency department and PICU, introducing the risk of transport. Currently, hardware incompatibilities (e.g., ventilators and intravenous pumps) and long data acquisition times (relative to CT) limit the utility of this important tool.

Intracranial Pressure Monitoring

Unfortunately, clinical signs such as pupillary size, light response, and papilledema fail as early indicators of intracranial hypertension. Although the most reliable clinical signs are those associated with herniation, the introduction of ICP monitoring devices has allowed detection of intracranial hypertension before such changes are observed.[108,109] In the pediatric guidelines,[1] ICP monitoring was suggested as appropriate in children with an abnormal admission head CT scan and initial GCS score between 3 and 8. Also, ICP monitoring

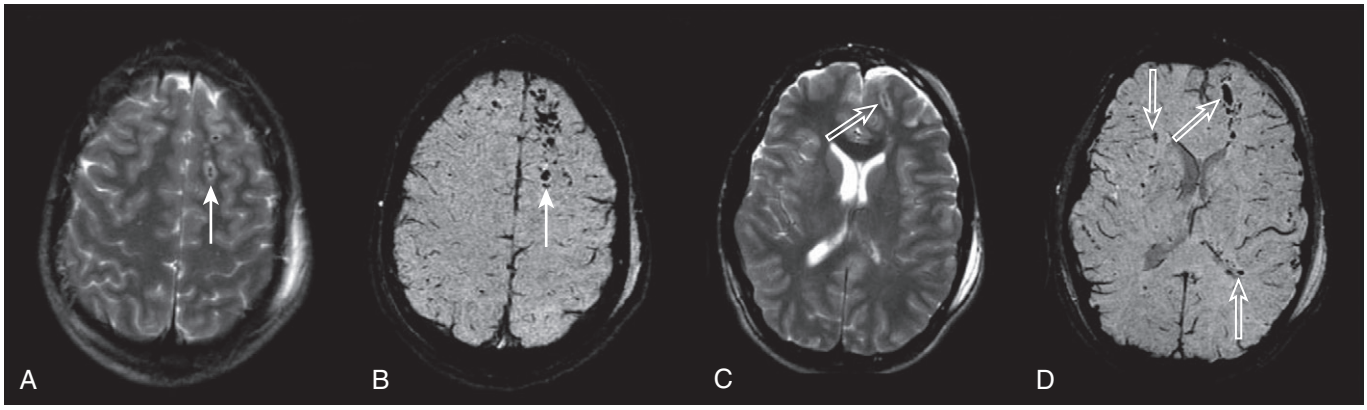

Figure 61–7. Detection of diffuse axonal injury is enhanced by susceptibility-weighted magnetic resonance imaging (SWI). **A,** Subtle hemorrhage in white matter is seen with conventional axial T2-weighted imaging. **B,** The diffuse white matter hemorrhages are much more readily detectible on SWI. *(From Tong KA, Ashwal S, Obenaus A et al: Susceptibility-weighted MR imaging: a review of clinical applications in children,* AJNR Am J Neuroradiol *29:9-17, 2008.)*

was suggested to be appropriate in adults with severe TBI and a normal head CT scan if the clinical course was complicated by hypotension or motor posturing. This modality is essential to implementation of a physiologically guided approach to management of cerebral perfusion pressure (CPP) in the infant or child with severe TBI.[110]

ICP monitoring has not been studied in an RCT to establish its efficacy in altering outcome after severe TBI in either adults or children. Since publication of the pediatric guidelines, however, several studies have contributed new insight. Forsyth et al.[111] recently examined the United Kingdom multicenter database of more than 500 cases of pediatric TBI and reported that both ICP >20 mm Hg and lack of ICP monitoring were independently associated with death before discharge. Given that raised ICP correlates with poor outcome, there is a strong rationale for identifying and treating this problem (see also Chapter 59).[112,113] As discussed in the section on CT, although CT is useful for identifying patients at high risk for the development of raised ICP (e.g., those with mass lesions), the finding of a "normal" cranial CT scan does not rule out the potential for raised ICP.[114] Despite this evidence, ICP monitoring in children with TBI, particularly in infants, is still not rigorously performed in clinical practice. Keenan et al.[115] surprisingly reported in 2005 that only 33% of infants and young toddlers (younger than 2 years) with severe TBI underwent ICP monitoring in the state of North Carolina. Consideration of risk versus benefit for ICP monitoring must be involved in the clinical decision in cases in which the complication rate is high, such as in patients with coagulopathy.

Currently, ICP monitoring by ventricular catheter is considered the most accurate, low-cost, reliable method.[1] The ventricular catheter also affords a key therapeutic option—CSF drainage. Other acceptable methods include parenchymal fiberoptic and microtransducer systems; subarachnoid, subdural, and epidural monitors of any type are less reliable.[116] The type of monitor (ventricular catheter or fiberoptic pressure transducer) used is dependent on the local preference of the neurosurgical staff.

The location of monitors in the hospital varies among centers and includes the emergency department/trauma bay, operating room, or PICU. Despite the flurry of activity that often surrounds the stabilization of a critically injured child with severe TBI, it is important to provide adequate anesthesia during placement of the monitor to prevent pain-induced spikes in ICP and/or herniation.

Monitoring and treatment of ICP are essential to contemporary management. Use of a ventricular catheter affords the added opportunity of CSF drainage as a therapy. Adult patients who have severe TBI with an ICP higher than 20 mm Hg have a poorer outcome than do those without increased ICP.[116] Similarly, although a large prospective RCT of children with and without both ICP monitoring and CPP management has not been performed, a prospective cohort study suggested a better outcome in adults monitored and treated with CSF drainage compared with those who did not undergo ICP monitoring.[117] However, this topic is controversial in the adult TBI literature,[118] and further study is needed.

Advanced Monitoring Techniques

Several techniques for assessing CBF, autoregulation of CBF, or metabolism can provide additional insight into the occurrence of cerebral ischemia during management and help guide therapy. However, information on the use of these techniques and their impact on outcome in infants and children with severe TBI is limited. Often, these methods are used only in clinical research or specialized trauma centers with particular interest in pediatric neurointensive care.

Techniques for measuring CBF after severe TBI include (1) stable xenon (Xe)-enhanced CT, (2) radioactive (inhaled or injected) ^{133}Xe methods, and (3) transcranial Doppler (TCD) methods. Stable Xe CT CBF measurement can aid in clinical decision making in children with TBI.[80,119,120] Although not a "monitor" in the sense that it does not provide bedside assessment of changes, stable Xe CT CBF measurement provides important information about regional CBF and its relationship to anatomic disturbances (Figure 61-8). This technique can be coupled to nearly all CT scans obtained in evaluation and follow-up, including the initial scan.[19,80,119,120] The procedure can be completed in less than 30 minutes. It is complicated when F_{IO_2} or MAP is high (because of the need for inhalation of 50% Xe gas and the effect of its inherently increased density) or if ICP is markedly increased. In those settings, careful monitoring of the patient is needed during the study. Serial stable Xe CT CBF measurements can be coupled to a physiologic manipulation, such as alteration of MAP or

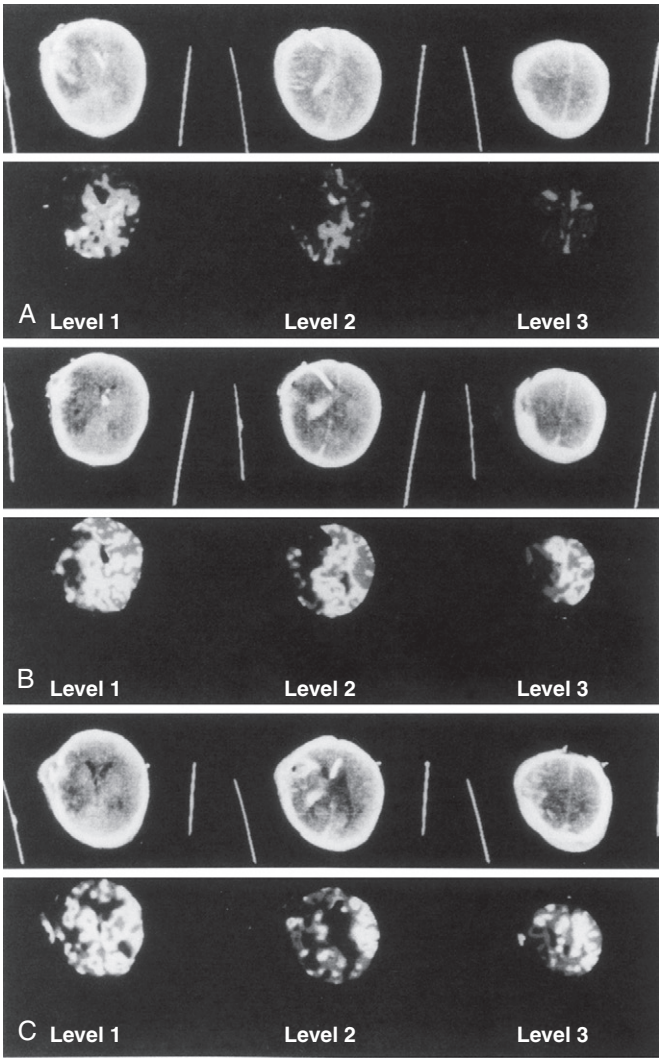

Figure 61–8. Time course of CBF measured by Xe-enhanced CT in a 2-month-old infant after severe traumatic brain injury from a motor vehicle accident. Standard CT images (*upper row*) and Xe-enhanced CBF maps (*lower row*) are shown from studies performed on admission (**A**) and at 2 days (**B**) and 5 days (**C**) after injury. Flow is severely reduced (*black*) on admission. Some recovery of CBF is seen at 2 days and 5 days after injury. CBF ranges from lowest (*darkest image*) to highest (*brightest image*).

$Paco_2$ (Figure 61-9).[80,121,122] These dynamic "pre and post" studies often provide additional insight into the optimal titration of bedside care such as $Paco_2$ levels and additional prognostic information.

Although titration of therapy to ICP or CPP is important, this technique shows that the response of the brain to an intervention such as manipulation of blood pressure or $Paco_2$ or administration of a specific drug often is not homogeneous and may be unpredictable. The response may be reflected by a change in ICP or CPP, as seen with focal losses of blood pressure, autoregulation of CBF, or reactivity to changes in $Paco_2$.

Stable Xe technique is a research tool in pediatric TBI. The ^{133}Xe method for assessment of patients with TBI was pioneered by Obrist et al.[123] By using multiple detectors, it can provide information on regional CBF, and it can be used in dynamic studies. The advantage of the ^{133}Xe method over the stable Xe CT method is that the ^{133}Xe method is a bedside technique. It has been used in children with TBI to define the time course and magnitude of changes in CBF and its regulation.[16,47-50] However, its inability to correlate flow with anatomic disturbances and radiation use is a limitation.

TCD is a method gaining acceptance in pediatric neurocritical care because it is noninvasive and is readily repeated at the bedside.[124,125] It can serve as an early warning monitor of the development of an unfavorable trend in cerebral perfusion; in addition, it can serve to assess autoregulation, define major alterations, identify vasospasm, and contribute prognostic information.[11,124-127] This method measures velocity rather than flow and usually is applied to assess the middle cerebral artery distribution. However, the inability of TCD to acquire regional information limits its utility in titrating care in TBI.[128]

Recently Brady et al.[129] have spearheaded considerable interest in continuous monitoring of blood pressure autoregulation of CBF with use of a pressure reactivity index that is calculated as a linear correlation between ICP and blood pressure. With use of this noninvasive adjunct to ICP monitoring, intact autoregulation was shown to be associated with survival in a study of 21 children with severe TBI. This method also may contribute to better definition of optimal CPP; further study is needed.

Monitoring Cerebral Metabolism

Jugular venous saturation has been used to monitor cerebral oxygen delivery in adults, but limited information on the utility of this technique in children is available.[47-50] Studies in adults suggest that therapies such as barbiturates and hyperventilation can be titrated according to jugular venous saturation.[128,130] Desaturations below the threshold value of 50% are associated with mortality in adults.[131] However, jugular venous desaturation below this level was rarely the sole indication that urgent intervention was needed, and false desaturations occurred. Nevertheless, this tool can assist in clinical decision making, and some persons have questioned its ability to monitor regional effects.[132]

Several other modes of monitoring cerebral metabolic rate may be helpful. Near-infrared spectroscopy has been used to track the oxidative state of cytochromes in brain. It reportedly aided in clinical decision making during treatment of brain-injured adults, warning of reduced cerebral oxygenation, sometimes with greater sensitivity than jugular venous saturation.[125] Near-infrared spectroscopy has been used to assess cerebral metabolic status in hypoxemic-ischemic neonates[133,134] and is beginning to be used in pediatric TBI.[135] Although its exact role remains unclear, it may prove valuable as a trend monitor.[136] Limitations with topographic resolution and the dominance of the superficial brain tissue in generating the signal are concerns.

Monitoring partial pressure of oxygen (PO_2) in brain parenchyma ($Pbto_2$) with a microelectrode implanted in the frontal lobe is feasible in adults.[137] A threshold value of about 8.5 mm Hg was associated with a reduction in CPP below 60 mm Hg, although in adults, thresholds anywhere from 10 to 30 mm Hg have been recommended. Stiefel et al.[138] recently reported on the utility of $Pbto_2$ monitoring in children and suggested a threshold of 20 mm Hg. We routinely use $Pbto_2$ in children with TBI, targeting a threshold of 20 mm Hg. Therapy is first targeted to optimize ICP and CPP. However, in some cases, $Pbto_2$ is less than 20 mm Hg despite control of ICP and it is necessary to evaluate other potential factors that might be affecting brain oxygenation.

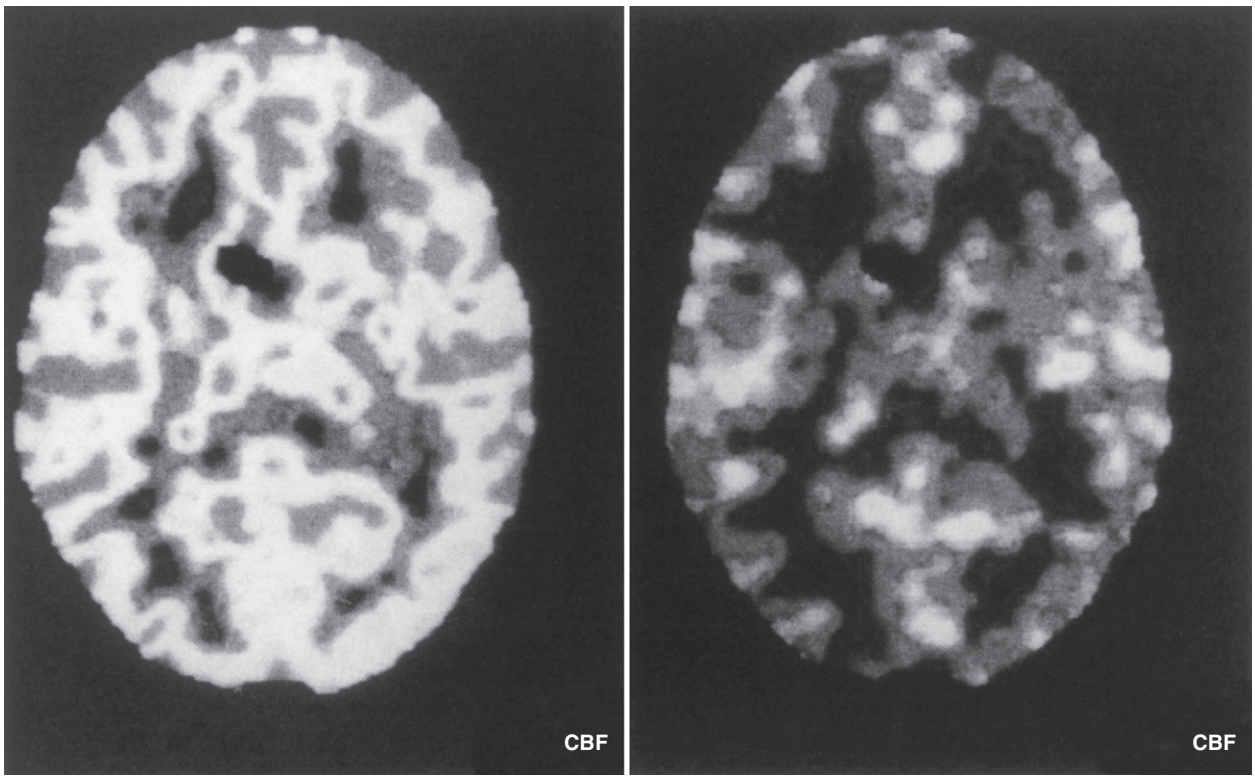

Figure 61–9. Xe-enhanced CBF maps from a child with severe traumatic brain injury before (*left*) and after (*right*) escalation of hyperventilation in the scanner. Intact reactivity of CBF to change in $Paco_2$ is demonstrated by an obvious reduction in flow. CBF ranges from lowest (*darkest image*) to highest (*brightest image*).

These factors could include inadvertant hyperventilation due to a ventilator change or a decline in Pao_2 due to lung disease—that should be addressed. If there is no extracerebral complication affecting $Pbto_2$, interventions such as increasing FIO_2 or raising $Paco_2$ or MAP/CPP to improve CBF may further augment $Pbto_2$. The major limitations of $Pbto_2$ are its invasiveness and provision of only focal data. In adults, $Pbto_2$ measurement has been coupled to cerebral microdialysis to provide metabolic data (i.e., glutamate levels).[139,140]

Finally, positron emission tomography (PET) has been used in adults with severe TBI.[22] Although limited by long acquisition times and the risk of intrahospital transport of critically ill patients, the metabolic maps generated provide much insight, particularly into cerebral glucose utilization after TBI. Diringer et al.[141] used PET to provide important insight into the effect of hyperventilation on $CMRO_2$ in adults with severe TBI (see the section on hyperventilation). Both PET and advanced MRI can provide insight into regional brain disturbances and the effect of therapy (Figure 61-10).

Treatment in the Pediatric Intensive Care Unit

Once the initial resuscitation is completed and evacuable intracranial masses have been addressed, maintenance of physiologic stability and recognition and management of raised ICP are the priorities. A flow diagram illustrating a general approach to first-tier treatments of the child with severe TBI was provided in the pediatric guidelines (Figure 61-11). The injured brain has complex metabolic requirements that are poorly understood.[142] Autoregulation of CBF may be disturbed, and metabolic demands may be either decreased or increased.[14,22,47-50,123] It is clear, however, that evidence of neuronal death from cerebral ischemia is a common finding on autopsy in patients who die after severe TBI. Control of ICP and maintenance of adequate CPP and $Pbto_2$ may limit the risk of developing secondary ischemia.[110,112,113] The goals of management are thus to optimize ICP, CPP, and brain oxygenation/perfusion, avoid secondary insults, and create the best possible environment for brain recovery.

Intracranial Pressure and Cerebral Perfusion Pressure Thresholds

Adult patients with severe TBI who have an ICP of 20 mm Hg have a poorer outcome than do those without increased ICP.[110,112,113,143] Although a prospective RCT in patients with and without both ICP monitoring and targeted management has not been performed, a prospective cohort study by Ghajar et al.[117] suggested better outcome in adults monitored and treated with CSF drainage versus those without ICP monitoring. Several studies suggest that optimal outcome is achieved when even more modest levels of ICP (i.e.,15 mm Hg) are the target.[117] Although no pediatric study has prospectively compared ICP treatment thresholds and their effect on outcome using a specific treatment regimen, review of the pediatric literature provides clues on the optimal ICP treatment threshold. Four of five major studies published before the guidelines, including a total of more than 230 cases of severe pediatric TBI, reported that poor outcome was associated with ICP higher than 20 mm Hg.[49,144-147] In a more recent study by Chambers et al.[148] in 99 children with head injuries (0-13 years of age) in the United Kingdom, an

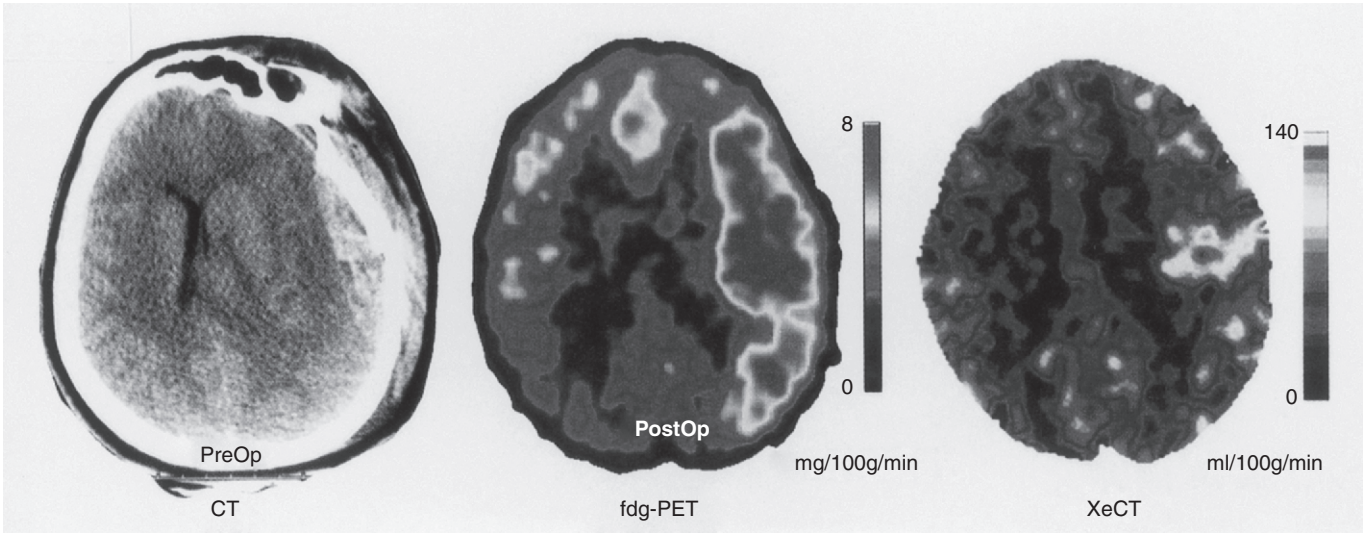

Figure 61–10. CT image (*left*) of an acute subdural hematoma with mass effect that was treated with surgical evacuation. ^{18}F-flurodexoyglucose positron emission tomographic (*PET*) map (*center*) obtained at 5 days after surgery shows marked local increases in cerebral glucose utilization in the brain regions underlying the hematoma. Stable Xe-enhanced CT CBF map also obtained at 5 days after surgery shows increased CBF in the same region, indicating that the increase in glucose utilization is not the result of hypoperfusion. This phenomenon, termed *hyperglycolysis*, is suggested to represent increased glucose utilization by astrocytes coupled to glutamate uptake and other mediator-driven processes. This highlights the complex regional metabolic demands of the traumatically injured brain.

ICP threshold of 15 mm Hg was used. However, it remains to be determined whether a lower ICP threshold is appropriate for infants in whom physiologic MAP is lower than in adults. This issue was viewed as one of the important unanswered questions in a recent survey on the pediatric TBI guidelines.[149]

As with ICP, no RCT has been conducted to define the optimal CPP for pediatric TBI, although its importance in patient management is recognized. Reductions in CPP below specific threshold values are associated with poor outcome. The guidelines' recommendation of 40 mm Hg was based on four studies that defined the CPP associated with poor outcome as between 40 and 65 mm Hg.[147,150-152] As discussed in two recent updates of the pediatric TBI guidelines,[153,154] a major limitation in the guidelines was the lack of data on optimal CPP targets. Based on normative data, lower optimal thresholds are likely in infants and young children versus older children and adults. However, because of limited available data, the Guidelines Committee could only conclude, at the guideline level, that a CPP greater than 40 mm Hg be maintained. This value, based largely on the work of Downard et al.[147] was believed to be the minimum acceptable value. This value differs from that indicated by adult data, which suggest a value of 60 mm Hg or possibly even higher. However, it was stated in the guidelines, at an option level, that a CPP between 40 and 65 mm Hg probably represented an age-related continuum for the optimal threshold.[1]

Since publication of the guidelines, Chambers et al.[155] published what is the largest study on this topic in pediatric TBI, and based on data from 235 children, they suggested minimum CPP values of 53, 63 and 66 mm Hg for children between the ages of 2 and 6 years, 7 and 10 years, and 11 and 16 years, respectively (Figure 61-12). However, that study considered only the first 6 hours of monitoring, and CPP and ICP were not addressed for infants younger than 2 years of age. In a follow-up study of 91 children, Chambers et al.[148] used a pressure-time index to determine critical CPP thresholds of 48, 54, and 58 mm Hg in children aged 2 to 6 years, 7 to 10 years, and 11 to 15 years, respectively. Based on these two reports since the guidelines, which are the most definitive work to date, thresholds of approximately 50, 55, and 60 mm Hg would seem reasonable for children in these age ranges.

In adults with severe TBI, the optimal CPP is also controversial.[156] The most definitive study in adults comes from Robertson et al.,[157] who compared CPP thresholds of 50 versus 70 mm Hg. Use of a CPP-directed treatment targeting a threshold of 70 mm Hg reduced the number of episodes of cerebral ischemia but led to an increased incidence of complications, likely associated with the increase in fluid given to raise MAP. This treatment resulted in no net difference in outcome between groups. Thus optimal CPP likely is directly correlated with age and overall is lower in children than in adults. For many years we have used a threshold of greater than 40 to 50 mm Hg in infants and toddlers, 50 to 60 mm Hg in children, and greater than 60 mm Hg in adolescents, which fortuitously are in agreement with the most recent data. Nevertheless, selection of an optimal CPP threshold is difficult in children with TBI.[158-161]

In addition to the methods described later for control of ICP, titration of vasopressor or inotropic support may be necessary to achieve an appropriate level of CPP once adequate filling pressure and hemoglobin are confirmed. In some situations, as with the development of neurogenic pulmonary edema, aggressive cardiovascular monitoring and optimal titration of cardiopulmonary support can be challenging and key determinants of outcome. Finally, not only are the optimal ICP and CPP targets likely to be important, but how one achieves these target values may be very important.

Treatment of Intracranial Hypertension: First-Tier Therapies

Ventricular Cerebrospinal Fluid Drainage

Ventricular CSF drainage has been used to manage raised ICP in adults for more than 40 years. Cerebrospinal fluid drainage for treatment of intracranial hypertension in children

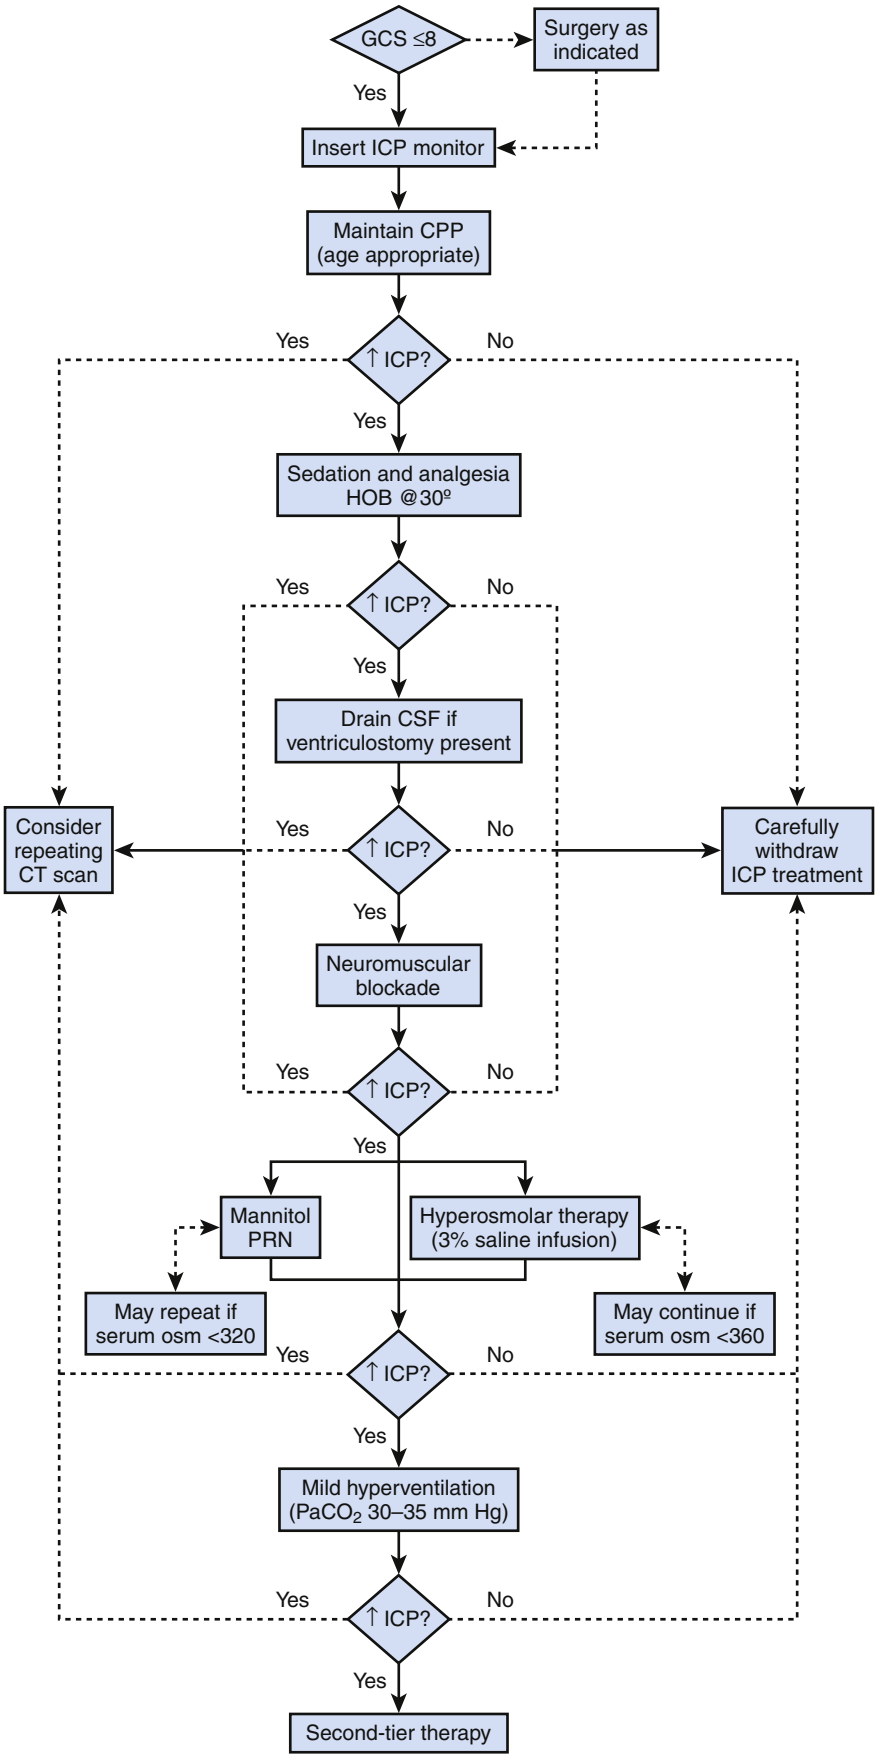

Figure 61–11. First-tier management approach based on the Guidelines for the Management of Severe TBI in Infants, Children, and Adolescents.[1]
HOB, Head of bed.

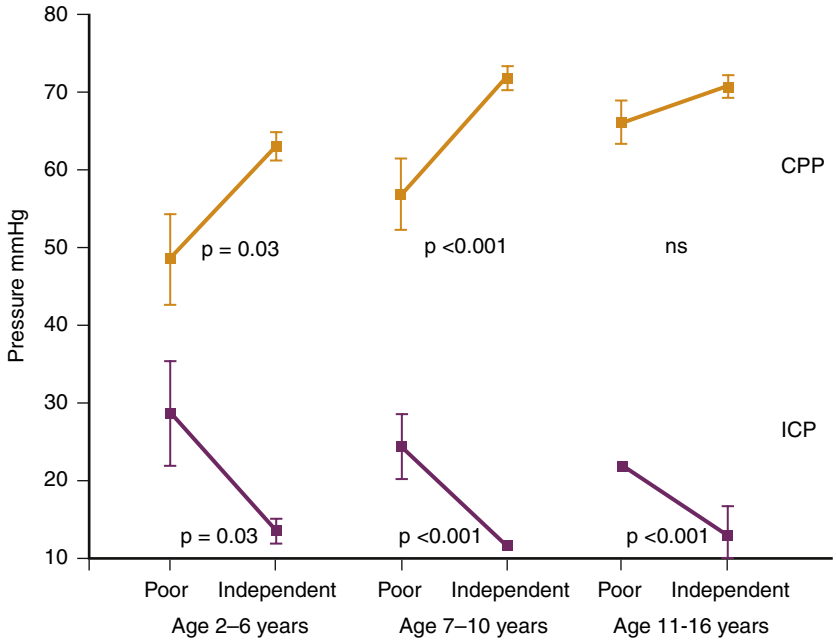

Figure 61–12. Mean ICP and CPP (mm Hg) after TBI for children with poor versus independent outcome for three age groups. Minimum CPP values of 53, 63, and 66 mm Hg were suggested for children between the ages of 2 and 6 years, 7 and 10 years, and 11 and 16 years, respectively. *(Modified from Chambers IR, Stobbart L, Jones PA et al: Age-related differences in intracranial pressure and cerebral perfusion pressure in the first 6 hours of monitoring after children's head injury: association with outcome,* Childs Nerv Syst *21:195-199, 2005.)*

was shown to improve CBF in 1971.[162] Fortune et al.[163] compared the effect of CSF drainage and mannitol in adults after severe TBI and noted similar effects on CBF and ICP. Use of CSF drainage was associated with a greater increase in jugular venous saturation than was mannitol therapy. CSF can be drained intermittently or continuously, with threshold values for drainage determined on the basis of the clinical indication. Since publication of the guidelines, in a small retrospective two-center comparison between continuous and intermittent CSF drainage approaches in children with severe TBI, Shore et al.[164] reported that continuous drainage was associated with removal of a substantially greater amount of CSF, markedly reduced CSF levels of biochemical mediators, and lower ICP. However, the efficacy of CSF drainage versus other treatments of intracranial hypertension remains unclear, and larger studies are needed. It is our clinical impression that CSF drainage reduces requirements for other therapies targeting ICP. However, this has yet to be proved. Recent studies from Pittsburgh Children's Hospital suggest that if continuous drainage is used, inserting a second parenchymal ICP monitor may be of value because continuous drainage limits the ability to continuously monitor ICP, and spikes of intracranial hypertension could be missed.[165] Finally, lumbar CSF drainage can reduce ICP in cases with discernible basal cisterns; this factor is discussed in the section on second-tier therapies.

Osmolar Therapy

Based on the hypothesis that BBB permeability and increases in CBV play only limited roles in the development of cerebral swelling and that tissue osmolar load may be more important, particularly in contusion, osmolar therapies (e.g., mannitol and hypertonic saline solution) seem to be logical. The BBB is nearly impermeable to both mannitol and sodium. This suggestion contrasts with traditional recommendations supporting the use of hyperventilation and avoidance of mannitol.[59,60] Despite its ubiquitous use and studies supporting its use for the management of TBI in adults, mannitol has been subjected to limited investigation in pediatric TBI. Even though mannitol is a cornerstone for management of intracranial hypertension in pediatric and adult TBI,[1,116] it has not been subjected to controlled clinical trials compared with placebo, other osmolar agents, or other mechanism-based therapies in children.

Mannitol reduces ICP by two distinct mechanisms.[116] First, it produces a rapid reduction in ICP by reducing blood viscosity with a resultant decrease in blood vessel diameter and CBV. This mechanism is dependent on intact viscosity autoregulation of CBF that is linked to blood pressure autoregulation of CBF. The effect of mannitol administration on blood viscosity and CBV is transient (lasting ~75 minutes).

The second mechanism by which mannitol administration reduces ICP is via an osmotic effect. This effect develops more slowly (over 15 to 30 minutes) and results from movement of water from parenchyma into the circulation. The effect persists between 1 and 6 hours and depends on an intact BBB. Changes in serum osmolality reduce brain water only in relatively normal brain regions. It has long been suggested that mannitol may accumulate in injured brain regions and a reverse osmotic shift may occur, with fluid moving from the circulation to the parenchyma, possibly exacerbating intracranial hypertension. Since publication of the pediatric guidelines, Polderman et al.[61] showed in adults that after 48 hours of therapy, mannitol levels in CSF increase and in some adults with severe TBI, a reverse osmotic gradient can be seen, explaining the lack of effect of this therapy or the need for escalating doses after several days of administration. They suggested that it might be optimal to measure CSF mannitol levels to guide therapy. Others have suggested titration of mannitol to osmolar gap.[166] Mannitol is excreted unchanged in urine, and a risk for development

of acute tubular necrosis and renal failure has been suggested for mannitol administration with serum osmolarity greater than 320 mOsm in adults. However, the literature supporting this finding dates from the late 1970s and early 1980s, an era when dehydration therapy in combination with mannitol use was common. Hyperosmolar euvolemia is targeted with contemporary mannitol use. High levels of serum osmolarity (365 mOsm) appear to be tolerated in children when induced with hypertonic saline solution, although one small case series suggests the possibility of renal impairment with these high osmolarity levels in children treated with hypertonic saline solution.[167,168]

Few data support the concomitant use of diuretics and mannitol to reduce ICP. James[169] performed a retrospective study of 60 patients (ages 1 to 73 years) treated with mannitol for increased ICP. After bolus mannitol administration, ICP decreased after 116 of 120 doses. The reduction in ICP in response to mannitol administration was dose dependent between 0.18 and 2.5 g/kg. In contrast, Marshall et al.[170] reported equivalence for doses between 0.25 and 1 g/kg in adults. Despite a remarkable track record for controlling ICP in TBI, clinical investigation of mannitol use in infants and children is lacking. Surprisingly, an epidemiologic study suggested that mannitol use was associated with prolonged PICU length of stay but no survival advantage.[156] Nevertheless, it remains a first-tier therapy in severe pediatric TBI.

Use of hypertonic saline for treatment of raised ICP was first described in 1919 but failed to gain clinical acceptance.[171] Interest in this treatment has undergone a resurgence. Penetration of sodium across the BBB is low. Sodium has a reflection coefficient higher than that of mannitol and shares with mannitol both the favorable rheologic effects on CBV and osmolar gradient effects. Hypertonic saline exhibits other theoretical benefits, such as restoration of cell resting membrane potential, stimulation of atrial natriuretic peptide release, inhibition of inflammation, and enhancement of cardiac performance.

Hypertonic saline was studied in more than 130 pediatric patients with severe TBI. There are two types of studies: (1) treatment of refractory intracranial hypertension and (2) comparison of hypertonic saline solution to maintenance fluid as a continuous infusion. Fisher et al.[97] compared 3% saline solution and 0.9% saline solution in children with severe TBI. During the 2-hour trial, hypertonic saline solution was associated with a lower ICP. The serum sodium level increased about 7 mEq/L after administration of 3% saline solution. Khanna et al.[172] reported a prospective study of 3% saline solution (514 mEq/L) given on a sliding scale to maintain ICP less than 20 mm Hg in children with resistant intracranial hypertension. A reduction in ICP and an increase in CPP were noted with 3% saline solution. The mean highest serum sodium level and osmolarity were approximately 170 mEq/L and approximately 365 mOsm/L, respectively. Sustained hypernatremia and hyperosmolarity were generally tolerated. Acute renal failure developed in two patients.

Peterson et al.[167] reported a retrospective study on the use of a 3% saline solution infusion titrated to reduce ICP to less than or equal to 20 mm Hg in infants and children with TBI. The mean daily doses of hypertonic saline solution ranged from between 11 and 27 mL/kg/day. A control group was not used, but only three patients died of uncontrolled ICP, and 73% of patients had a good or moderate outcome. Rebound in ICP or other adverse effects were not seen.

Theoretic concerns associated with use of hypertonic saline solution include development of extrapontine myelinolysis (EPM), rapid shrinking of the brain associated with mechanical tearing of bridging vessels leading to subarachnoid hemorrhage, renal failure, and rebound intracranial hypertension.[173] EPM is related to central pontine myelinolysis (CPM) but occurs with hypernatremia and/or its correction. It is characterized by demyelination of the thalamus, basal ganglia, and cerebellum.[174] Neither EPM nor CPM has been reported in human trials of hypertonic saline solution for treatment of TBI. EPM has been reported in dehydrated children with serum sodium levels of 168 to 195 mEq/L, and CPM has been reported with rapid correction of chronic hyponatremia.[162] Peterson et al.[167] performed MRI evaluations in 11 patients in their study, and none had evidence of CPM. However, rats with normal serum sodium levels subjected to increases of 39 mEq/L showed severe demyelinating lesions.[175] Similarly, subarachnoid hemorrhage has been reported with serum sodium concentrations from 149 to 206 mEq/L within 1 hour after injection of 9% hypertonic saline solution in normal kittens.[176]

Renal failure is a concern with use of hyperosmolar therapies. Use of hypertonic saline solution (vs. lactated Ringer solution) in the resuscitation of burn patients is associated with a fourfold increase in renal failure,[177] but this complication seems uncommon with hypertonic saline solution use in children after TBI.[167,168] Rebound intracranial hypertension has been described with use of hypertonic saline solution bolus therapy or after cessation of continuous infusion.[167,178] As with mannitol therapy, if the BBB is breached, one would also expect that CSF levels of sodium would gradually increase with prolonged therapy. Patients may require progressive increases in infusion rates to control ICP. Hypertonic saline solution, mannitol, and CSF drainage are first-tier therapies for raised ICP.

Sedation Analgesia and Neuromuscular Blockade

Sedation and neuromuscular blockade should be used as needed in the setting of raised ICP once appropriate monitoring has been established and thus are integrated into first-tier treatment. Narcotics, benzodiazepines, or small doses of barbiturates are generally recommended for routine use. To our knowledge, no controlled trial of varying sedation regimens has been performed in pediatric patients with severe TBI. Hsiang et al.[179] reported on 514 adults with severe TBI and suggested that prophylactic neuromuscular blockade was associated with increased length of ICU stay and nosocomial pneumonia. However, the study was not prospective and should not preclude the use of neuromuscular blockade in pediatric TBI. As with most therapies in this setting, careful assessment of indication and titration of therapy are essential. Finally, intermittent doses of barbiturates and/or lidocaine may be needed to blunt excessive rises in ICP resulting from routine patient care maneuvers such as suctioning. Additional studies are badly needed.

Head Position

Head position is an area of controversy. Feldman et al.[180] conducted a prospective RCT of the effect of head position on ICP, CPP, and CBF in 22 adults after severe TBI. Both ICP and mean carotid pressure were reduced in the 30-degree position versus the 0-degree position. CPP and CBF did not

change with this intervention. Thus, in general, the 30-degree head elevated position reduced ICP without deleterious effects on CPP and is preferred. Head elevation and midline position improve jugular venous and possibly CSF drainage and decrease the contributions of these components to ICP.

Treatment of Intracranial Hypertension: Second-Tier Therapies

Refractory intracranial hypertension occurs in 20% to 40% of cases of severe pediatric TBI and is associated with mortality rates of 30% to 100%.[144-147,150-152,156,157,181-183] Several second-tier therapies are available for treatment of refractory intracranial hypertension. These therapies were presented in the pediatric guidelines and are shown in Figure 61-13. Second-tier therapies include barbiturates, hyperventilation, hypothermia, decompressive craniectomy, and lumbar CSF drainage.

Barbiturates

Barbiturates produce a reduction in ICP via a decrease in cerebral metabolic rate. Although an RCT of barbiturate therapy for treatment of severe TBI in adults did not show an outcome benefit,[184] it can be effective in the setting of refractory raised ICP.[185] Goodman et al.[186] reported an improvement in brain interstitial concentration of lactate and glutamate accompanying a reduction of ICP in seven adults treated with barbiturates for refractory intracranial hypertension. In contrast, Cruz[128] reported that about one third of adults given barbiturates experience a deterioration (rather than improvement) in jugular venous saturation. If either frequent dosing or barbiturate infusion is used, an electroencephalogram (EEG) should be used to assess the response to treatment. The endpoint of barbiturate coma is generally burst suppression. Pentobarbital or thiopental often is infused to achieve a burst suppression response on EEG. However, that goal should only represent the maximal barbiturate dose used for ICP control because (1) smaller doses—those still associated with EEG activity—may be adequate to control ICP, and (2) indiscriminate use can be associated with undesirable adverse effects such as hypotension.[187] A lack of ICP response to barbiturates is associated with poor outcome. When barbiturates are used, hypotension should be avoided. Patients should be carefully monitored for reduced cardiac output or inadequate systemic perfusion, as clinically indicated. As the use of hyperventilation for the management of children with refractory ICP has waned, alternative therapies such as barbiturates appear to be increasingly used.

Hyperventilation

Hyperventilation has been used to manage pediatric patients with severe TBI since the 1950s.[188] Bruce et al.[16] suggested that hyperemia was the predominant mechanism involved in the development of raised ICP in children. Thus hyperventilation was recommended as first-line therapy. Until the mid 1980s, prophylactic hyperventilation was the standard of care. In addition to reducing postinjury hyperemia, hyperventilation was suggested to reduce brain acidosis and restore CBF autoregulation. Subsequently, studies in experimental models suggested hyperventilation had deleterious effects. Prophylactic hyperventilation depletes brain interstitial bicarbonate buffering capacity and is accompanied by gradual loss of local vasoconstrictor effects.[189]

In an RCT in adults after severe TBI, prophylactic hyperventilation for 5 days to a $Paco_2$ of about 25 mm Hg versus about 35 mm Hg was associated with worse outcome.[190] Skippen et al.[191] reported that hyperventilation to a $Paco_2$ of about 25 mm Hg reduced CBF to levels less than 18 mL/100 g/min in 73% of infants and children with severe TBI. Coles et al.[132] found similar results in adults. However, neither of these studies assessed the effect of hyperventilation on either regional cerebral metabolism or neurologic outcome. In experimental TBI in rats, aggressive hyperventilation ($Paco_2$ ~20 mm Hg) early after injury enhanced hippocampal cell death. The pediatric guidelines recommend that prophylactic hyperventilation not be used.[1] A $Paco_2$ of about 35 mm Hg was recommended.

Supporting this approach in infants and children, early after severe TBI, hypoperfusion rather than hyperemia was shown to be associated with poor outcome.[19] Zwienenberg and Muizelaar[56] questioned the occurrence of hyperemia in children after severe TBI, suggesting instead that normal CBF values previously were underestimated and are higher in children than in adults. However, the risks of hyperventilation are still somewhat controversial. Diringer et al.[141] reported that at between 8 and 14 hours after severe TBI in adults, hyperventilation ($Paco_2$ ~30 mm Hg) reduced CBF but did not further reduce cerebral metabolic rate for oxygen as assessed using PET. This finding suggests that in TBI, after the acute hypermetabolic phase, hypometabolism follows and hyperventilation may be a relatively safe means to reduce ICP in the PICU. This study did not evaluate outcome. In contrast, several reports in adults suggest deleterious effects of hyperventilation after TBI, including increases in brain interstitial levels of glutamate and lactate[192] and higher ischemic brain volumes.[193]

Based on these data, there is waning support for the use of hyperventilation. At Pittsburgh Children's Hospital, with the addition of $Pbto_2$ monitoring, when ICP is controlled but $Pbto_2$ is <20 mm Hg, we have found that careful limitation of even mild hyperventilation can, in some cases, promptly increase $Pbto_2$. Nevertheless, despite these concerns, hyperventilation surprisingly seems to remain a mainstay of care in pediatric TBI. Specifically, Curry et al.,[194] in a study of 375 children with severe TBI, reported a 52% to 60% incidence of substantial hypocarbia ($Paco_2$ <30 mm Hg) in the initial 48 hours that was significantly associated with poor outcome. This incidence was seen despite ICP levels less than 20 mm Hg in many cases. High frequency of hyperventilation also was reported by Morris et al.[195] in the United Kingdom database and, surprisingly, in the recent RCT of therapeutic hypothermia by the Canadian multicenter trials group (44%).[196] Some investigators have suggested that it may be time to set the alarm threshold for $Paco_2$ in management of severe TBI in children or for a practice bundle in TBI.[153] Nevertheless, its use as adjunct treatment of refractory raised ICP, particularly during the delayed postinjury phase, was supported as a second-tier therapy in the guidelines. Based on the current state of knowledge, if hyperventilation ($Paco_2$ ~30 mm Hg) is used to manage refractory ICP, advanced neuromonitoring such as assessment of $Pbto_2$, CBF, or jugular venous oxygen saturation is recommended to prevent iatrogenic ischemia. Finally, in the absence of signs and symptoms of herniation, there is no physiologic rationale for applying prophylactic hyperventilation.

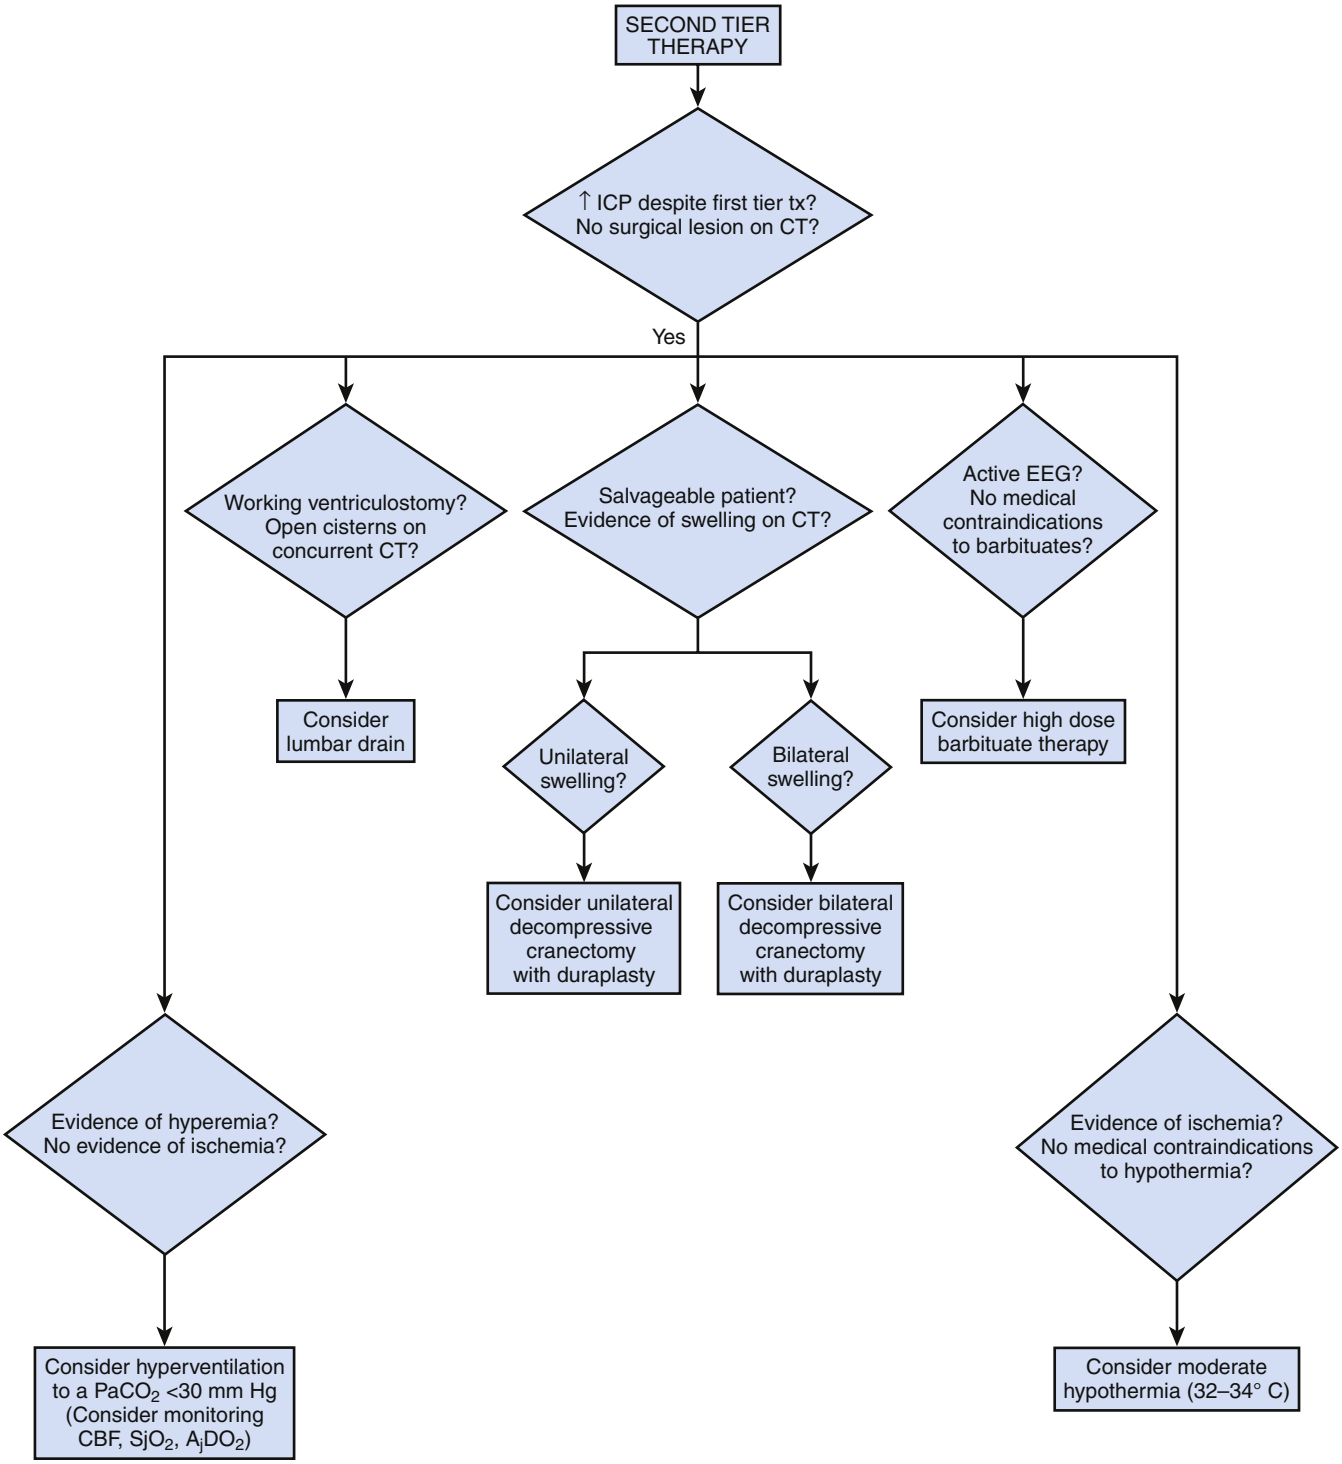

Figure 61–13. Second-tier therapies for the management of refractory intracranial hypertension based on the Guidelines for the Management of Severe TBI in Infants, Children, and Adolescents.[1] A_jDO_2, Arteriojugular venous oxygen content difference; Sjo_2, jugular vein oxygen saturation.

Hypothermia

In experimental models of TBI and in some clinical trials in adults after TBI, hypothermia improved outcome, presumably via multiple mechanisms, and meta-analyses supported its use in adults with severe TBI.[197-199] However, unlike the case in either cardiac arrest in adults or hypoxic ischemic encephalopathy (HIE) in newborns, RCTs of hypothermia targeting a temperature of about 33° C for 24 hours in adults[35] and more recently in children[196] failed to show benefit. Indeed, since publication of the pediatric guidelines, the most important published study is the work of Hutchison et al.[196] In that study, 225 children were randomly assigned to hypothermia versus normothermia for 24 hours with a mean time to target temperature of 6.3 hours. Surprisingly, there was a trend

toward worse outcome and increased mortality with hypothermia treatment. Delays in onset of cooling, short duration of therapy, frequent use of hyperventilation, and a rapid and unstable rewarming phase were suggested to represent limitations. However, this important trial certainly removes the prophylactic use of hypothermia from consideration as a first-tier therapy for severe TBI in infants and children. One might think that it even questions its use as a second-tier therapy; however, as evident in this chapter, other second-tier options also have important limitations.

Several important features of the trial may provide additional clues to the treatment of pediatric TBI. First, patients treated with hypothermia received less hypertonic saline solution than did those in the normothermia group. This protocol suggests a "trading of therapies" that is quite different from cardiac arrest and HIE where no other neurodirected therapies are generally used. It also suggests the possibility that hypertonic saline solution may represent a highly beneficial therapy (discussed previously). In addition, the major adverse effect observed was hypotension during rewarming. This complication, some persons have suggested, should have been prevented. However, hypotension was also seen in the recent RCT of magnesium in adults with TBI and was similarly associated with mortality.[200] Given the aforementioned narrow autoregulatory reserve in infants after TBI,[11] hypotension might represent an even greater concern in pediatric than in adult trials.

In contrast, hypothermia may still be useful for the management of refractory intracranial hypertension after severe TBI.[201,202] Unlike studies showing benefit from transient use (12-24 hours) of mild hypothermia (33° C) in adults after cardiac arrest,[203,204] a variety of temperature ranges are necessary to control ICP; thus a titrated approach to use of hypothermia in this setting is suggested.[201,202] Rewarming should be carried out carefully, at a rate no faster that 1° C every 4 hours—or even more slowly—and great care should be taken to monitor and treat hypotension that can occur with peripheral vasodilation during rewarming. Finally, hyperthermia is extremely deleterious in experimental models of TBI, exacerbating neuronal death. This effect is seen even when a brief 3-hour period of clinically relevant hyperthermia (39° C) is applied. Natale et al.[205] supported the clinical relevance of this work by showing that early hyperthermia (38.5° C within the first 24 hours of admission) occurred in 29.9% of pediatric TBI patients and was associated with poor outcome and increased length of stay. The most definitive clinical study on this matter is in the area of perinatal HIE, where just 1° C of hyperthermia after HIE was associated with a deleterious effect on long-term outcome.[206] Care should be taken to treat or prevent hyperthermia after severe TBI.

Decompressive Craniectomy

Another controversial area in the management of both adults and children with refractory intracranial hypertension is the use of decompressive craniectomy. Controlled studies on this modality are limited. Cushing[207] initially described this modality in 1905. There has been a resurgence of interest in this approach based on several case series and several small clinical trials, often involving children or young adults. Decompressive craniectomy is a controversial therapy that is based on the complex metabolic demands of the brain and the equally complex but poorly understood adverse effects of many of the therapies used to treat refractory intracranial hypertension (ischemia, hyperosmolality, metabolic suppression, and hypotension). However, this simplistic approach may have merit.

Several contemporary pediatric studies have been performed. Cho et al.[208] reported on the use of decompressive craniectomy versus medical management for treatment of infant victims of the shaken baby syndrome with refractory intracranial hypertension. Although the series was small, they reported an improved outcome compared with medical therapy, with some survivors showing good outcome. This study is one of the few specifically examining treatment of patients with severe TBI in whom child abuse is the injury mechanism. Polin et al.[209] reported on the use of extensive bifrontal decompressive craniectomy for the management of 35 adults and children with severe TBI and either refractory intracranial hypertension or diffuse edema on CT scan. They reported a favorable percentage of survivors with good or moderate disability (improved outcome vs. retrospectively matched cases from the Traumatic Coma Data Bank) and suggested a 48-hour time window for successful use. However, the patients in this report generally were not treated with either CSF drainage or barbiturates. Nevertheless, the best results were seen in the children in this study. Taylor et al.[210] reported on an RCT of early decompressive craniectomy versus standardized medical management alone. Although the sample size was limited (n = 27 children), strong trends toward reduction in ICP and improvement in long-term outcome were seen with decompressive craniectomy. More recently, Jagannathan et al.[211] reported 81% favorable outcome in 23 children with severe TBI treated with decompressive craniectomy.

Decompressive craniectomy is a second-tier therapy that is used with varying frequency depending on local experience and the discretion of the management team. Currently a large RCT (The RESCUEicp study) is underway in the United Kingdom.[212] This trial should contain a substantial pediatric component given that the entry criteria include children aged 10 years and older.

Lumbar Cerebrospinal Fluid Drainage

Lumbar CSF drainage can be effective in treating refractory intracranial hypertension in children. Levy et al.[213] reported that controlled lumbar CSF draining reduced refractory ICP in 14 of 16 pediatric patients and eliminated the need for barbiturates in their series. In adults with severe TBI, Munch et al.[214] reported an immediate and lasting reduction in ICP in 23 patients with very refractory intracranial hypertension. This modality is also a second-tier treatment option, but to avoid the risks of herniation, the patient must have open basal cisterns and no important mass effect or shift, and a functional ventriculostomy must already be in place.

Controlled Arterial Hypertension

Induced arterial hypertension is a controversial approach to the management of refractory raised ICP. Whether pressure autoregulation of CBF is intact or defective, arterial hypotension or inadequate CPP must be avoided. If pressure autoregulation is impaired, CBF is directly related to CPP and hypotension reduces flow. If pressure autoregulation is intact, then as CPP is reduced, reflex cerebral vasodilatation occurs (to maintain flow), which increases CBV and ICP.[215] This latter phenomenon occurs as CPP is reduced within the

autoregulatory range. Based on the relationship among CPP, vessel diameter, CBV, and ICP in selected adults with refractory intracranial hypertension, induced arterial hypertension (CPP increased to between 100 and 140 mm Hg via infusion of phenylephrine) produced a reduction in ICP.[215] However, arterial hypertension reduces ICP only when pressure autoregulation of CBF is intact because hypertension-mediated reduction in vessel caliber produces the reduction in CBV (to maintain a constant flow) and resultant reduction in ICP

Use of this intervention is complex in pediatric TBI because a single general threshold value of CPP is not applicable. Management must be tailored to each individual patient. It is possible that the aforementioned pressure reactivity index approach could help guide this intervention.[129] Also, the short-term and long-term effects of the greater hydrostatic pressure on the development of cerebral edema are unclear. Optimal management of blood pressure after severe TBI requires both monitoring of the involved factors and an in-depth understanding of the mechanisms.[215] Induced hypertension is a controversial "last-ditch" therapy that is not addressed in the pediatric guidelines.[1]

Finally, a few groups managing adults with severe TBI have adopted a very different therapeutic approach to blood pressure and ICP management termed the Lund Concept. This approach includes aggressive control of ICP with the unusual combination of β-blockade, α_2 receptor agonists, ergotamine, and barbiturates, with avoidance of systemic hypertension.[216] In some sense, this represents a form of chemical hyperventilation, that is, a pharmacologically controlled reduction in CBV. Remarkably, this approach has produced good outcome data and no exacerbation of ischemia, as assessed using intracerebral microdialysis in adults.[217] One report of this approach to ICP control in children with meningitis is available,[218] along with a recent report in children with TBI.[219] For additional insight into this approach, the reader is referred to the work of Stahl et al.[217] This approach merits additional study.

Is Rigorous Intracranial Pressure Control the Common Denominator in Studies with Exceptionally Good Outcome?

Whatever approach is selected to control ICP after severe TBI, the potentially deleterious and sometimes preventable consequences of secondary ischemia and herniation must be targeted. Interestingly, some of the best outcomes reported in clinical series of either adults or children with severe TBI have come from extremely divergent (albeit aggressive and protocol-based) approaches, namely, aggressive hyperventilation reported by Bruce et al.,[220] aggressive use of hyperosmolar therapy reported by Peterson et al.,[167] rigorous application of hypothermia with tightly controlled hemodynamics as reported by Marion et al.,[197] aggressive CPP management as described by Robertson et al.[157] and Rosner et al.,[221] and aggressive control of ICP using the Lund concept.[216] Perhaps the common denominator in these reports is the aggressive, meticulous, and protocol-driven control of ICP.

Miscellaneous

Seizures should be treated aggressively because excessive metabolic demands in the setting of hypoperfusion could result in a second insult to an already compromised brain. A recent study by Vespa et al.[222] in 20 adults with severe TBI showed that posttraumatic subclinical status epilepticus was associated with a considerable burden in raised ICP and long-lasting increases in brain interstitial lactate/pyruvate ratio—a marker of ischemia. This finding has heightened interest in this area and suggests the consideration of continuous EEG monitoring in pediatric TBI. However, the pediatric guidelines suggested use of prophylactic phenytoin only as a treatment option to prevent early posttraumatic seizures in severe TBI because it has not been shown to improve outcome either acutely or in the prevention of the late development of epilepsy.[1] Additional anticonvulsants are recommended to be given as needed to treat seizures. Finally, despite the fact that phenytoin has been the most commonly used anticonvulsant for acute seizure prophylaxis in pediatric TBI, recent studies in experimental TBI suggest that levetiracetam may be much more neuroprotective than fosphenytoin.[223] Clinical studies are needed.

Even if hypertonic saline solution is not used as a therapy, careful attention should be paid to the serum sodium level. It should be monitored at least twice daily in children with severe TBI. To prevent the development of hyponatremia, we recommend using 0.9% normal saline solution as the initial intravenous fluid for children with severe TBI. For infants, D_5 (5% dextrose) normal saline solution can be used. Hyponatremia that develops while only isotonic fluids are being administered generally can be attributed to either syndrome of inappropriate antidiuretic hormone secretion or cerebral salt wasting.[224] Care should be taken to determine the correct cause of hyponatremia because the management of syndrome of inappropriate antidiuretic hormone secretion involves fluid restriction, while that of cerebral salt wasting involves the administration of isotonic or hypertonic saline solution.

It has long been known that hyperglycemia exacerbates experimental ischemic brain injury, and threshold values greater than 200 mg/dL are generally considered as the target. Similarly, countless studies have shown associations between hyperglycemia and poor clinical outcome after various CNS insults, and most textbooks of adult neurocritical care recommend withholding glucose in intravenous fluids for at least 24 hours unless hypoglycemia is seen. Supporting this concept, Van den Berghe et al.[225] reported that insulin administration to control blood glucose at less than 110 mg/dL in 63 adults with isolated brain injury from various causes produced benefits with regard to ICP, CPP, and seizures. In contrast, Vespa et al.,[226] using intracerebral microdialysis in adults with severe TBI, reported that tight glucose control (serum glucose 90 to 120 mg/dL) produced a metabolic crisis in the brain (increases in glutamate and lactate/pyruvate ration) versus less rigorous glucose control (serum glucose 120 to 150 mg/dL). Great controversy remains as to the optimal management strategy for glucose administration and control after severe TBI.

The provision of adequate nutrition is essential during the catabolic response to critical illness, and beneficial effects of early feeding (either enteral or parenteral) in the critically ill or injured patient are well described. In critically ill adults, a cumulative deficit of 10,000 kcal was associated with increased mortality, and in the PICU this amount can be easily surpassed in less than 1 week.[227] Data in pediatric TBI, however, are lacking. In adults with severe TBI, Hadley et al.[228] reported that jejunal feeding within 36 hours of admission reduced septic complications and ICU days by 50% compared with delayed feeding (when gastric atony had resolved). Care must be taken to prevent the complications

of overfeeding (hyperglycemia with parenteral nutrition or hypoosmolality with enteral feedings). Frequent monitoring of blood glucose, electrolytes, and calorimetry may be useful.[229] Hyperalimentation formulations containing glutamate have been shown to increase glutamate levels, possibly exacerbating excitotoxicity.[230] Curiously, studies in experimental brain injury suggest that starvation for 48 hours dramatically reduces ultimate damage.[231] Ketosis is suggested to confer this benefit. The optimal nutritional approach in severe TBI needs to be addressed.

Routine use of glucocorticoids for treatment of patients with severe TBI is not recommended.[1] However, hypotension in the setting of severe TBI in rare cases is associated with pituitary failure, possibly from vascular disruption.[232]

Outcomes

Outcome from severe TBI generally has been assessed as a function of age at the time of injury and in relationship to three diagnostic categories: noninflicted (accidental) closed head injuries, inflicted childhood neurotrauma (child abuse), and penetrating injury (predominantly gunshot wounds). Accurate assessment of long-term outcome has been somewhat hampered in infants and children by the lack of validated outcome assessment tools. Application of modifications of adult outcome tools (e.g., the Glasgow Outcome Scale) has been the general approach; however, these tools have limitations when applied across the pediatric age spectrum.[233] In an important paper on pediatric outcomes, Levin et al.[10] highlighted the dramatic effect of age on outcome. About two thirds of children between the ages of 5 and 10 years had good outcome (i.e., normal or moderate disability), whereas more than 60% of children age 4 years or younger died. Rates of good outcome as high as 73% have been reported in clinical trials in pediatric TBI.[167] Specific studies of inflicted childhood neurotrauma and gunshot wounds generally have reported poorer outcome than results of series of accidental closed head injury. However, even within these two high-risk diagnostic categories, good outcome in some series has been as high as 35% in patients with severe TBI resulting from inflicted childhood neurotrauma and 24% in patients with severe TBI resulting from gunshot wounds.[208,234] Rehabilitation can have dramatic effects after a severe TBI is sustained, particularly in the setting of focal injury. Successful rehabilitation may require prolonged therapy (months or even years).[235]

Conclusion

Optimal care of the infant or child with severe TBI requires a multidisciplinary approach. Prompt and vigorous resuscitation, including stabilization and control of ventilation, is essential. After initial evaluation and surgical intervention, where appropriate, monitoring and carefully titrated management of raised ICP is essential to optimize cerebral perfusion and facilitate metabolic homeostasis. Meticulous and optimal neurointensive care is the basis on which future targeted therapies will be delivered as additional information on the evolution of secondary neuronal damage becomes available. The goal of contemporary pediatric neurointensive care is the prevention of secondary injury. Much of that care focuses on preventing secondary insults. The goal of future pediatric neurointensive case will be to overlay, on this therapeutic plan, strategies manipulating tissue injury in the evolution of secondary damage at a cellular level, along with strategies to foster regeneration and rehabilitation.

PEARLS

- Cardiac arrest in adult patients differs from cardiac arrest in pediatric patients in at least two important aspects: (1) cardiac arrest in pediatric patients is predominantly from asphyxial arrest, in contrast to adult patients, where it is predominantly from ventricular dysrhythmias, and (2) developmental differences exist between pediatric and adult patients including, ongoing synaptogenesis, lower cerebral blood flow in neonates and higher cerebral blood flow in toddlers and children compared with adults, neurotransmitter receptor maturation, and higher energy expenditure in pediatric patients.
- Although a multicenter, randomized clinical trial evaluating 48 hours of controlled hypothermia versus normothermia is ongoing, the International Liaison Committee on Resuscitation recommends consideration of 12 to 24 hours of moderate (32° to 34° C) hypothermia for comatose children after ventricular tachycardia/fibrillation cardiac arrest.[1]
- At present, there is no cure for hypoxic ischemic encephalopathy. It is likely that targeted therapies, spanning field interventions, intensive care, and rehabilitation, will be required to successfully prevent and treat hypoxic ischemic encephalopathy in infants and children after cardiac arrest.

In the past decade, important clinical trials demonstrating neuroprotective effects of therapeutic hypothermia in adults with cardiac arrest and neonates at risk for hypoxic ischemic encephalopathy (HIE) make this an exciting era for pediatric intensivists.[2-5] These trials (discussed later in this chapter) showing that induced hypothermia can prevent neurologic damage after cardiac arrest provide a window of opportunity for the application of pharmacologic or other interventions in what remains an important clinical problem with exceedingly high mortality and disappointingly high morbidity—cardiac arrest in children. At minimum, these trials have spurred renewed interest in determining whether therapeutic hypothermia is efficacious in infants and children after cardiopulmonary arrest, and were crucial in the implementation of a National Institutes of Health-funded multicenter clinical trial of therapeutic hypothermia after pediatric cardiac arrest in the United States. Although these "breakthroughs" and increasing depth and breadth of the understanding of mechanisms of HIE provide hope, challenges remain as by and large the likelihood of intact neurologic survival in children who suffer cardiopulmonary arrest remains unacceptably small.[6,7] A proven effective treatment protocol that reliably prevents HIE and improves neurologic recovery after cardiopulmonary arrest in infants and children remains elusive. Despite numerous advances in critical care medicine, the optimal supportive care to maintain neuronal function and maximize recovery after cardiorespiratory arrest is in and of itself controversial.

This uncertainty arises from the pathobiologic complexity of cerebral injury and from the limitations in our clinical ability to monitor key metabolic and physiologic parameters in the brain. Clinical stumbling blocks in the history of "brain resuscitation" have also slowed progress in our understanding of HIE after cardiopulmonary arrest. Historically, this entity was largely ignored as a specific disease process. Brain resuscitation was dealt with as a single therapeutic paradigm regardless of the etiology.[8] This resulted in the misguided application of results from studies of traumatic brain injury (TBI), stroke, Reye syndrome, and cerebral protection to patients suffering cardiopulmonary arrest. Second, within cardiopulmonary arrest etiologies and patient-relevant biologic factors such as genetic influences and comorbidities are lumped together. Factors influencing neurologic damage and recovery are clearly different depending on the cause (asphyxia, arrhythmia, hemorrhage, trauma, sepsis, etc.), age of the patient, interval between arrest and return of spontaneous circulation (ROSC), and effectiveness of cardiopulmonary resuscitation (CPR). Finally, the frustration encountered in dealing with the poor neurologic outcomes that often occur in this syndrome

has reduced the enthusiasm for clinical studies involving novel treatments or those with proven efficacy for other indications.

In this chapter, the pathobiology of HIE is reviewed with emphasis on cellular mechanisms, pathophysiology, and histopathology. Differences between the most prevalent etiologies of cardiopulmonary arrest in children (asphyxia vs. cardiac arrhythmia) are examined, and an appraisal of traditional and novel therapies is presented, including the reemergence of the potential for therapeutic hypothermia in children after cardiopulmonary arrest. Finally, any discussion of HIE in children is complicated not only by the specific mode of arrest in children but also by the unique nature of these young patients. The child's brain is still developing, adding another layer of variability in terms of age-specific pathological and reparative mechanisms, potential for therapies to afford benefit, evaluation of therapeutic effectiveness, and neurologic outcome. Thus the effect of the host's immaturity on the pathobiology of postarrest encephalopathy also is examined.

Epidemiology

In the United States, cardiac arrest occurs in 8 to 20/100,000 children per year in the out-of-hospital setting and in 1.06 of every 1000 pediatric hospital admissions.[6,9,10] Males have an increased frequency of cardiac arrest (~60 vs. 40% for females) but there are no sex differences in mortality.[7] Half of children with cardiac arrest have underlying comorbidities.[7,11]

Asphyxia is the most prevalent cause of cardiac arrests and the principal cause of HIE in children.[12,13] In asphyxial arrest, asystole or pulseless electrical activity is preceded and precipitated by a period of hypoxemic or anoxic perfusion.[14] Hypoxia most commonly results from submersion accidents, airway obstruction, pulmonary aspiration, severe asthma or pneumonia, inhalation injury, or apnea syndromes.[6,7,15] In contrast, ventricular fibrillation (VF) is the most frequent cause of out-of-hospital cardiopulmonary arrest in adults.[16] In VF-induced cardiac arrest, respiration ceases shortly after loss of perfusion pressure. VF also occurs in children, but at an estimated incidence of less than 10% of pediatric victims of cardiac arrest overall, more commonly in the in-hospital setting.[7]

Cellular and Molecular Pathobiology

Mechanisms of Hypoxic-Ischemic Brain Injury

Cerebral neurons in culture can tolerate hours of extreme hypoxia. Although it takes about 160 minutes of exposure to an anoxic gas mixture for oxygen tension in the culture medium to reach 1 mm Hg, cortical neurons tolerate 1 to 3 additional hours with little histologic change.[17] If 1 mmol/L sodium cyanide is used to simulate immediate anoxia, hippocampal neurons become swollen and vacuolated within 20 to 60 minutes and begin to disintegrate in 4 hours. Similarly, even 1 hour of complete global brain ischemia in monkeys is followed by electrophysiologic recovery of many neurons and significant recovery of some aspects of brain metabolism, such as protein synthesis.[18] Although the time limit for consistently normal outcome after normothermic primary cardiac arrest is unknown, it is certainly closer to 5 to 10 minutes than 1 to 3 hours. Restoration of integrated brain function, that is, "neurologic recovery," differs markedly from physiologic or metabolic brain recovery. In contrast to the relative cellular homogeneity in other organs, the functional specificity and interactions of neurons and glia in brain make patchy areas of cell death potentially devastating. This is evident in the neuropathology of dogs in persistent coma 1 week after a 10- to 15-minute cardiopulmonary arrest. Scattered neuronal death is evident, but the vast majority of neurons appear normal.[19]

Energy Failure

The brain depends on large amounts of substrate (glucose and lactate) because of its tremendous metabolic demands and paltry energy stores. Interruption of cerebral blood flow (CBF) results in loss of consciousness and electroencephalographic silence within seconds. Within 5 to 7 minutes, energy failure occurs, accompanied by disturbances of ion homeostasis in neurons and glial cells. Clinically this rapid depletion of brain high-energy phosphates has been demonstrated after hypoxia-ischemia in neonates using phosphorus magnetic resonance spectroscopy.[20] Influx of sodium and water and efflux of potassium occur because the cells cannot maintain their energy-dependent electrochemical gradients. When the extracellular potassium concentration reaches 10 to 15 mmol/L, voltage-gated channels open and extracellular calcium influx occurs.[21]

If CBF remains inadequate and energy failure persists, calcium-mediated events such as phospholipase and protease activation can lead to irreversible injury and neuronal cell death. Cerebral acidosis occurs, and intracellular pH decreases from 7 to 6.4.[22] If CBF is restored, however, recovery of basal cellular metabolism (ATP levels, protein synthesis, and oxygen consumption) and pH occurs. This has been shown in brain tissue samples and intact brain measurements after global ischemic insults that result in persistent vegetative coma.[18]

After anoxia or ischemia, the recovery of aerobic metabolism is essential for recovery, but is not in and of itself sufficient. The imbalance between aerobic and anaerobic metabolism and overdependence of neurons on lactate as a substrate[23] must be restored. Despite global metabolic recovery, certain neurons progress to cell death. After restitution of CBF and oxidative metabolism after energy failure in the brain cellular and molecular dysfunction progresses and cells may die via immediate necrosis (complete energy failure), programmed cell death (apoptosis, autophagic stress, or delayed necrosis), or a spectrum of these processes.[24-26] Brain magnetic resonance spectroscopy demonstrates early (during ischemia) and late (48 hours after reperfusion) depletion of high-energy phosphorous compounds and a corresponding lactate peak occurring in the face of normal vital signs, serum glucose, and arterial oxygen saturation after experimental hypoxia-ischemia.[27,28]

Selective Vulnerability

Certain neurons, such as those in the CA_1 region of the hippocampus; basal ganglia; cerebral cortical layers III and V; portions of the amygdaloid nucleus; the cerebellar Purkinje cells; and in infants, periventricular white matter regions and some brainstem nuclei, are known to be especially vulnerable to hypoxia-ischemia.[29,30] Five minutes of complete global brain ischemia produces cell death in these regions that begins to

appear between 48 and 72 hours, without apparent histological damage in other brain areas.

Transient calcium accumulation occurs in all cells during ischemia, but secondary irreversible accumulation occurs in the selectively vulnerable zones many hours later.[31] Electrophysiologic studies show that delayed neuronal death is preceded by neuronal hyperactivity. It is hypothesized that ischemic and early postischemic calcium accumulation leads to a complex sequence of derangements in cellular metabolism such as protease activation and oxygen-derived free radical formation.[32] These conditions, in concert with excessive release of excitatory neurotransmitters (glutamate, glycine, and aspartate) in these areas, lead to excitotoxicity and cell death. These findings are supported by work in neuronal culture showing that calcium influx accompanies cell death in the presence of anoxia or supraphysiologic levels of excitatory amino acids such as glutamate,[17,33] and that CA_1 cells are the most sensitive to glutamate-mediated injury.[34] Finally, delayed energy depletion, mitochondrial dysfunction, and infarction occur in concert, but are regionally distinct, suggesting that metabolic characteristics of brain regions affect recovery from ischemia.[35,36]

Of particular interest is that these intrinsically vulnerable cells do not have a unique vascular distribution.[37] They represent neither vascular watersheds nor hypoperfused zones. Death of these neurons after a threshold ischemic insult occurs in a delayed fashion after reperfusion and thus may be preventable, at least in part, by treatment.

Cell Death Mechanisms

Cell death can occur by at least three distinct pathways, necrosis, apoptosis or autophagy.[24,38] Cell death can also occur via a combination of one or all three of these pathways (see also Chapter 100). Necrosis, which is characterized by denaturing and coagulation of cellular proteins, is the basic pattern of pathological cell death that results from progressive reduction in the cellular content of adenosine triphosphate.[39] Necrosis involves progressive derangements in energy and substrate metabolism that are followed by a series of morphologic alterations, including swelling of cells and organelles, subsurface cellular blebbing, amorphous deposits in mitochondria, condensation of nuclear chromatin, and finally, breaks in plasma and organellar membranes.[39] Whereas necrotic cell death was traditionally felt to be entirely irreversible, recent studies showing that some degree of necrotic cell death responds to treatment after hypoxia-ischemia implicate "programmed necrosis," also termed "necroptosis."[40]

Cell death after hypoxic-ischemic insults can also occur by apoptosis.[41] Development of apoptosis usually requires new protein synthesis and the activation of endonucleases. Two distinct types of characteristic cleavage of DNA have been described. The most well described, *caspase-dependent* apoptosis, involves cleavage by caspase activated deoxyribonuclease at linkage regions between nucleosomes to form fragments of double-stranded DNA.[42] This produces a pattern of DNA cleavage observed on Southern blot analysis termed "DNA laddering." In contrast, *caspase-independent* apoptosis results in large-scale DNA fragmentation induced by the mitochondrial flavoprotein apoptosis-inducing factor.[43,44] The stimuli triggering apoptosis are complex and multifactorial, involving extracellular surface receptors, cell signaling pathways, protease cascades, and mitochondrial and other organelle

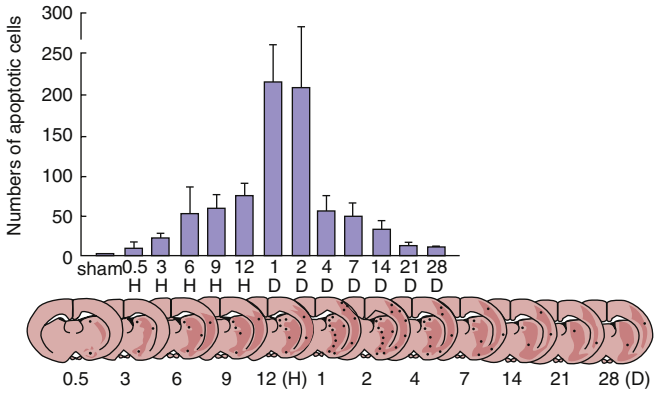

Figure 62–1. Apoptotic cells in coronal brain sections in rats subjected to 2 hours of middle cerebral artery occlusion and between 0.5 and 28 days of reperfusion. *Top,* Progressive increase in the numbers of apoptotic cells occurs with increasing reperfusion time to peak at 24 hours. However, apoptotic cells are still detectable even after 1 week of reperfusion. *Bottom,* Distribution of apoptosis (*dots*) and necrotic neurons (*hatched areas*). Apoptotic cells are localized predominately to inner boundary zone of infarction. *(From Li Y, Chopp M, Jiang N, et al: Temporal profile of in situ DNA fragmentation after transient middle cerebral artery occlusion in the rat,* J Cereb Blood Flow Metab *15:389, 1995.)*

dysfunction. Selective vulnerable cell death in brain regions such as the CA_1 region of the hippocampus after transient global brain ischemia appears to occur by apoptosis.[45] DNA extracted from the hippocampus of gerbils at 4 days after a threshold global ischemic insult exhibits a characteristic laddering pattern consistent with apoptotic cell death. Thus after a threshold ischemic insult, selective neuronal death in the highly vulnerably CA_1 region of the hippocampus occurs by apoptosis. Thalamic-delayed neuronal death was caused by Fas-mediated apoptosis in a model of neonatal hypoxia-ischemia.[46] Li et al.[47] reported that apoptosis in the postischemic brain is not limited to scattered neuronal death in what have been traditionally deemed to be "selectively vulnerable regions," but is seen even in penumbral regions around evolving cerebral infarcts (Figure 62-1). Finally, the proportion of apoptosis in the developing brain after ischemia appears to be a sex-dependent, because females but not males respond to antiapoptotic agents after neonatal hypoxia-ischemia.[48]

Recently, a new mode of cell death after brain ischemia has been implicated—autophagy. Autophagy is a homeostatic process that recycles cell resources during periods of nutrient stress.[49] Autophagy is upregulated after experimental brain ischemia,[50,51] which can be considered profound nutrient stress.[52] Studies show that blocking autophagy after hypoxia-ischemia can be protective or detrimental.[38,53,54] As such, autophagy's role after acute brain injury is controversial, and it may depend on stage of brain development and sex of the patient, animal, or cell.[52,55] Mouse pups lacking Atg7 (a necessary component for autophagy) or rat pups treated with an inhibitor of autophagy (3-methyladenine) are protected from focal hypoxia-ischemia.[50,51]

The proportion of neuronal cell death that occurs via apoptosis, necrosis, or autophagy after cerebral ischemia remains undetermined.[56,57] Moreover, it remains possible that treatments inhibiting apoptosis may simply convert cell death to necrosis or autophagy.[58,59] Although speculative, it is quite possible that after cardiopulmonary arrest and resuscitation, a continuum exists in neurons from recovery to necrosis[60] that

depends on the duration of the insult, the local milieu, and the given brain region.[61-63]

Nevertheless, in any given brain region, whether neuronal death is produced by necrosis, apoptosis, or autophagy, a highly complex series of events appears to be involved during the arrest and after ROSC. A theoretical scheme of the mechanisms involved is given in Figure 62-2, a scheme that remains remarkably contemporary despite being conceptualized almost two decades ago by Bellamy, Safar, and others.[64] Importantly, several molecular and pharmacological interventions that interrupt apoptosis have been reported to improve outcome after cerebral ischemia, including "pediatric" models. Although studies showing improved functional recovery with treatments inhibiting apoptosis after cerebral ischemia suggest that some salvaged neurons regain their integrative properties, it is also possible that some of the delayed apoptosis represents appropriate pruning of neurons that have lost their targets. These processes, coupled with the need to restore highly integrated function, explain the unfortunate clinical scenario of the persistent vegetative state despite restoration of normal function in other organ systems. The relationship of these distinct forms of cell death to selective vulnerability of neurons in brain is beginning to emerge.

Reperfusion Injury

Reoxygenation and reperfusion are essential to recovery of any organ after ischemia. Experimental evidence suggests, however, that certain aspects of reperfusion result in tissue injury.[65,66] Reperfusion injury is a complex series of interactions between parenchyma and microcirculatory elements, resulting in detrimental effects that negate some fraction of the benefits of reperfusion. The magnitude of reperfusion injury varies with the organ in question, the duration and type of hypoxic-ischemic insult, as well as the timing, duration and magnitude of reperfusion.[67,68]

In many organs and in the brain after focal insults, progressive microcirculatory failure is thought to be an important aspect of reperfusion injury.[69] However, as suggested by the nonspecific vascular distribution of selectively vulnerable neurons, the brain may display a second unique setting for the evolution of reperfusion injury, the evolution of selectively vulnerable cell death. Four key mechanisms hypothesized to be important to reperfusion injury in the brain include: (1) excitotoxicity and calcium accumulation, (2) protease activation, (3) oxygen radical formation, and (4) membrane phospholipid hydrolysis and mediator formation.

Excitotoxicity and Calcium Accumulation

Glutamate and aspartate are the major excitatory amino acid neurotransmitters in the mammalian central nervous system, but both also have neurotoxic properties. Pioneering studies by Rothman et al.[70] demonstrated in vitro that hypoxia-induced neuronal death is mediated by synaptic activity. Inhibition of synaptic glutamate release or blockade of glutamate receptors prevented hypoxia-induced neuronal injury. Glutamate is the major neurotransmitter in the selectively vulnerable zones and accumulates extracellularly at supraphysiologic levels in these regions after hypoxic or ischemic insults.[31]

Glutamate is released at the presynaptic terminal in response to neuronal stimulation and acts by binding to postsynaptic dendritic receptors. Two main classes of excitatory neurotransmitter receptors have been identified. One class consists of the ligand-gated ion channels ("ionotropic" receptors) and includes NMDA (*N*-methyl-D-aspartate), AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) or quisqualate, and kainate receptor subtypes. Toxicity caused by NMDA receptor activation is usually rapid, whereas AMPA or kainate receptor-mediated cell death is somewhat slower to develop.[71] The other class of excitatory neurotransmitter receptors includes the "metabotropic" receptors. These receptors are coupled with G proteins and modulate intracellular second messengers such as calcium, cyclic nucleotides, and inositol triphosphate.[72] When activated, the ionotropic glutamate receptors open sodium channels and may also have an important role in initiation and propagation of membrane depolarization and spreading depression.[73] With ionotropic receptor activation, rapid excitatory amino acid-mediated calcium accumulation occurs. In the face of ischemia this calcium accumulation is exacerbated by cellular energy failure, that disables the Na^+/K^+-ATPase membrane pump and results in further calcium accumulation.[31] Reestablishment of the energy supply can reverse these changes. Delayed glutamate-related neuronal injury is most likely the result of activation of ionotropic receptors and subsequent calcium influx. Calcium influx causes death of neurons in culture under anoxic conditions or in the presence of glutamate.[31] The intracellular accumulation of calcium: (1) activates proteases, lipases, and endonucleases resulting in the breakdown of membrane phospholipids; (2) activates neuronal nitric oxide synthase (nNOS), resulting in nitric oxide (NO) production and, in the presence of superoxide, peroxynitrite formation; (3) damages mitochondria; (4) disrupts nucleic acid sequences; and (5) ultimately mediates cell death via necrosis, apoptosis or autophagy (see Figure 62-2). The disturbance of the finely regulated intracellular calcium homeostasis is now recognized as a possible final common pathway of neuronal death.[25,31,64,72] NMDA receptor activation has also been shown to stimulate superoxide anion production, which may contribute to cellular injury.[74] The NMDA and AMPA-receptor subtypes have been suggested to play key roles in ischemic brain injury. The potential implications of these mechanisms in regard to therapeutic manipulation of glutamate receptors, as well as calcium and sodium channels, are discussed later.

Protease Activation

One of the candidates for a critical role in neuronal injury as a result of increases in intracellular calcium concentration is protease activation. Protease activation plays a central role in mediating both necrosis and apoptosis. With regard to necrosis, numerous calcium-dependent enzymes can become activated during ischemia and produce important structural injury to neurons. One class of calcium-dependent proteases, calpains, are cytosolic cysteine proteases that have a homeostatic role in cell-cycle regulation, differentiation, cell migration, and signal transduction.[75] After injury, calpain-mediated proteolysis of cytoskeletal proteins as well as activate protein kinase C and phospholipases can occur.[75] Calpains also hydrolyze the major plasma membrane sodium/calcium exchanger in neurons during excitotoxicity, allowing enormous secondary influx of calcium into the cell following NMDA receptor activation and creating a positive feedback environment.[76] In a model of oxygen-glucose deprivation in

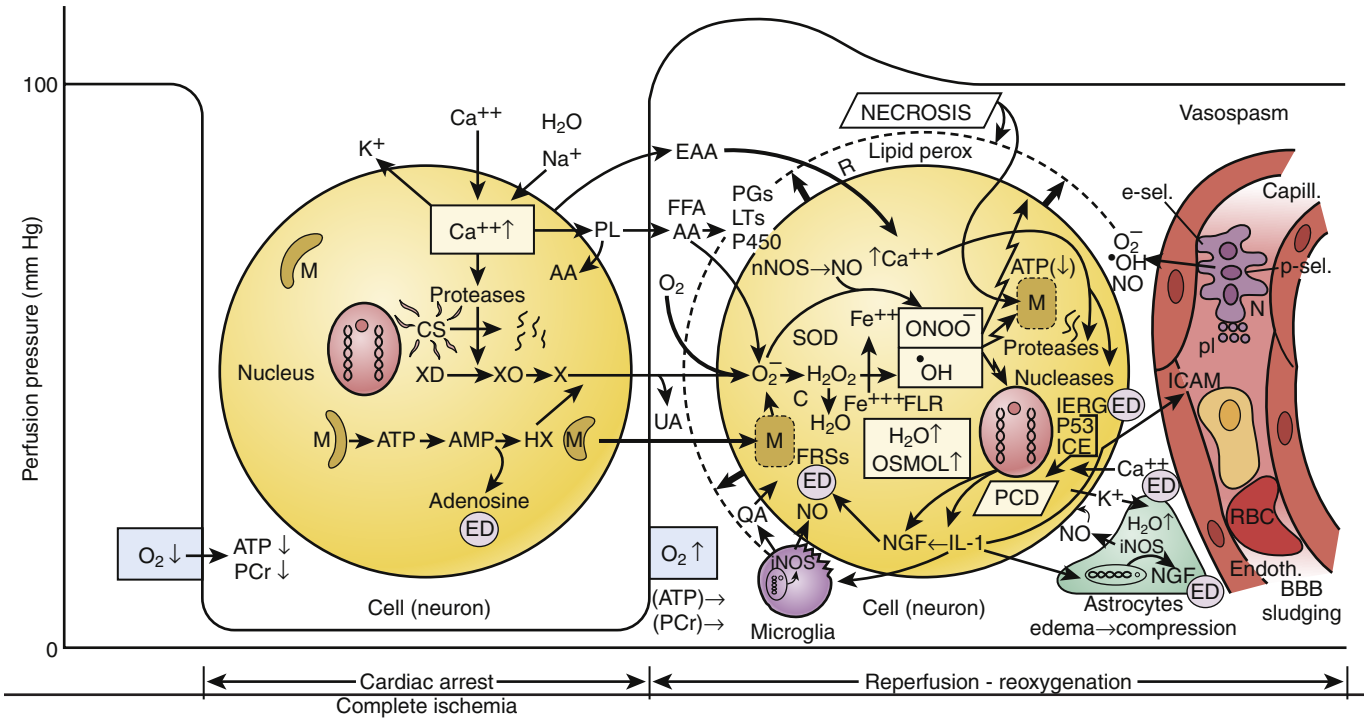

Figure 62–2. Death of cells after temporary ischemia. Diagram of complex, partially hypothesized biochemical cascades in neurons during and after cardiac arrest.[64] Normally intracellular ([Ca^{2++}]*i*) to extracellular ([Ca^{2++}]*e*) calcium gradient is 1:10,000. Calcium regulators include calcium/magnesium adenosine triphosphatase, the endoplasmic reticulum (ER), mitochondria, and arachidonic acid (*AA*). With stimulation, different cell types respond with an increase in [Ca^{2++}]*i* because of release of bound Ca^{2++} in the ER and influx of [Ca^{2++}]*e,* or both. During complete ischemic anoxia (cardiac arrest) *(left),* the level of energy (phosphocreatinine [*Pcr*] and adenosine triphosphate [*ATP*]) decreases to near zero in all tissues at different rates, depending on stores of oxygen and substrate; it is fastest in the brain (~5 minutes) and slower in the heart and other vital organs. This energy loss causes membrane pump failure, which causes a shift of sodium *(Na^+)* ions, water *(H_2O),* and calcium ions *(Ca^{2++})* from the extracellular into the intracellular space (cytosolic edema), and potassium *(K^{++})* leakage from the intracellular into the extracellular space. Increase in [Ca^{2++}]*i* activates phospholipase A_2, which breaks down membrane phospholipids (*PL*) into free fatty acids *(FFA),* particularly *AA*. Increase in [Ca^{2++}]*i* also activates proteolytic enzymes, such as calpain, which may disrupt the cytoskeleton (*CS*) and possibly the nucleus. In mitochondria (*M*) hydrolysis of ATP to adenosine monophosphate (*AMP*) leads to an accumulation of hypoxanthine (*HX*). Increased [Ca^{2++}]*i* may enhance conversion of xanthine dehydrogenase (*XD*) to xanthine oxidase (*XO*), priming the neuron for the production of the oxygen free radical superoxide anion (O_2) although this pathway is of questionable importance in neurons (*X,* xanthine; *UA,* uric acid). Excitatory amino acid neurotransmitters (*EAA*), particularly glutamate and aspartate, increase in extracellular fluid. Increased [EAA]*e* activates *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors (*R*), thereby increasing calcium and sodium influx and mobilizing stores of [Ca^{2++}]*i.* Increased extracellular potassium activates EAA receptors by membrane depolarization. Glycolysis during hypoxia results in anaerobic metabolism and lactic acidosis, until all glucose is used (in the brain, during anoxia after ~20 minutes). This lactic acidosis, plus inability to wash out CO_2, results in mixed tissue acidosis that adversely influences neuronal viability. The net effect of acidosis on the cascades during and after ischemia is not clear. Mild acidosis may actually attenuate NMDA-mediated [Ca^{2++}]*i* accumulation. Without reoxygenation, cells progress via first reversible, later irreversible structural damage, to necrosis at specific rates for different cell types. During reperfusion and reoxygenation (*right*), lactate and molecular breakdown products can create osmotic edema and rupture of organelles and mitochondria. Recovery of ATP and Pcr and of the ionic membrane pump may be hampered by hypoperfusion as a result of vasospasm, cell sludging, adhesion of neutrophils (granulocytes) (*N*), and capillary compression by swollen astrocytes, which also help to protect neurons by absorbing extracellular potassium. Capillary (blood-brain barrier [*BBB*]) leakage results in interstitial (vasogenic) edema. Increased concentrations of at least four oxyradical species that break down membranes and proteins, worsen the microcirculation, and possibly also damage the nucleus may be formed: Superoxide anion ($O_2.-$) leading to hydroxyl radical (⁻OH) (via the iron-catalyzed $Fe^{+++} \rightarrow Fe^{++}$, Haber-Weiss/Fenton reaction); free lipid radicals (*FLR*) and peroxynitrite (*OONO⁻*). O_2 may be formed from several sources: (1) directly from eicosanoid metabolism; (2) by the previously described XO system; (3) via quinone-mediated reactions within and outside the electron transport chain (from mitochondria [*M*]); and (4) by activation of NADPH-oxidase in accumulated neutrophils in the microvasculature or after diapedesis into tissue. Increased O_2 leads to increased hydrogen peroxide (H_2O_2) production as a result of intracellular action of superoxide dismutase (*SOD*). [H_2O_2] is controlled by intracellular catalase. Increased O_2 further leads to increased ·OH, because of conversion of H_2O_2 to ⁻OH via the Haber-Weiss/Fenton reaction, with iron liberated from mitochondria. This reaction is promoted by acidosis. ·OH and OONO⁻ damage cellular lipids, proteins, and nucleic acids. Also, AA is metabolized by the cyclooxygenase pathways to prostaglandins (*PGs*) including thromboxane A_2, or by the lipoxygenase pathway to produce leukotrienes (*LTs*); and by the cytochrome P-450 pathway. These products can act as neurotransmitters and signal transducers in neuronal and glial cells and can activate thrombotic and inflammatory pathways in the microcirculation. Inflammatory reactions after ischemia have been shown to occur in extracerebral organs, focal brain ischemia, or brain trauma; to date, they have not been demonstrated after temporary complete global brain ischemia. Neuronal injury can signal interleukin-1 and other cytokines to be produced and trigger endogenous activation of microglia, with additional injury (*QA,* quinolinic acid). In addition, tissue or endothelial injury—particularly associated with necrosis—can signal the endothelium to produce adhesion molecules (intercellular [*ICAM*], e-selectin [e-sel], p-selectin [p-sel]), cytokines, chemokines, and other mediators, triggering local involvement of systemic inflammatory cells in an interaction between blood and damaged tissue. Reoxygenation restores ATP through oxidative phosphorylation, which may result in massive uptake of [Ca^{2++}]*i* into mitochondria, which are swollen from increased osmolality. Thus mitochondria loaded with bound [Ca^{2++}] may self-destruct by rupturing and releasing additional free radicals. Increased [Ca^{2++}]*i* by itself and by triggering free radical reactions may result in lipid peroxidation, leaky membranes, and cell death. Neuronal damage can be caused, in part, by increased [EAA]*e* (excitotoxicity). During reperfusion, [Ca^{2+}]*i* and increased [EAAs]c normalize. Their contribution to ultimate death of neurons is more likely through the cascades they have triggered during ischemia. During ischemia and subsequent reperfusion, loading of cells and calcium maldistribution in cells are believed to be the key trigger common to the development of cell death. This calcium loading signals a wide variety of pathological processes. Proteases, lipases, and nucleases are activated, which may contribute to activation of genes or gene products (i.e., interleukin-converting enzyme, [*ICE*] or *P53*) critical to the development of programmed cell death (*PCD,* i.e., apoptosis, autophagy or necroptosis), or inactivation of genes or gene products normally inhibiting this process. Activation of nNOS by calcium can lead to production of NO·, which can combine with superoxide to generate peroxynitrite (*OONO⁻*). OONO⁻ and ⁻OH both can lead to DNA injury and PCD, or protein and membrane peroxidation and necrosis, respectively. Nerve growth factor (*NGF*), nuclear immediate early response genes (*IERG*) such as heat-shock protein, free radical scavengers (*FRSs*), adenosine, and other endogenous defenses (*ED*) may modulate the damage. *(Courtesy P. Safar, MD, and P. Kochanek, MD, with input from N. Bircher, MD, and J. Severinghaus, MD.)*

neuronal cell culture that mimics transient ischemia, calpains induced mitochondrial release of apoptosis-inducing factor, that translocates to the nucleus to initiate caspase-independent apoptosis.[77]

With regard to apoptosis, the caspase family of cysteine proteases plays an important role after cerebral ischemia, and may have a more prominent role in the developing versus mature mammalian brain.[78,79] After unilateral hypoxic-ischemic brain injury, neonatal rats had increased cytochrome c release and caspase-3 activation versus juvenile and adult rats.[55] Regulation of apoptotic machinery also appears to be sex dependent after neonatal hypoxic-ischemic brain injury.[80] Comparatively, female rats had more caspase-mediated apoptosis while male rats had more caspase-independent, apoptosis-inducing factor-mediated apoptosis.

Oxygen Radical Formation

Toxic oxygen radical species produced during postischemic reperfusion have been implicated as important contributors to reperfusion injury and delayed cell death.[66] The primary species of interest include superoxide anion, hydrogen peroxide, hydroxyl radical, and the reactive nitrogen species peroxynitrite.

The potential sources of oxygen radicals are many. Superoxide anion is produced by the electron transport chain during normal mitochondrial respiration. Mitochondrial dysfunction, as may occur under conditions of ischemia, produces increased generation of free radicals that may extend beyond the capacity of local endogenous antioxidants leading to oxidative stress. Metabolism of arachidonic acid via the cyclooxygenase pathway to form prostaglandins also produces superoxide anion as an enzymatic byproduct, and this also occurs to a lesser extent in the lipoxygenase and cytochrome P-450 pathways.[66,81] Accumulated neutrophils also can contribute superoxide anion via neutrophil reduced nicotinamide adenine dinucleotide (NADPH)-oxidase. Yet another potential oxygen radical source is xanthine oxidase (XO)-xanthine dehydrogenase (XD). Energy depletion is associated with conversion of ATP to adenosine diphosphate (ADP) and eventually to hypoxanthine. This ischemia- or anoxia-induced energy deprivation also causes conversion of XD to XO via calcium-activated proteases. In the presence of hypoxanthine and oxygen, that become available during reperfusion, XO produces superoxide anion. These XO-mediated reactions may occur in cerebral vascular endothelial cells, that are rich in XO.[66] However, the importance of XO in contribution to the generation of free radicals in human beings has been challenged.[82,83] Autooxidation of circulating catecholamines or of neurotransmitter catecholamines may represent another potential source of oxygen radicals.

Another possible contributor to free radical generation is delocalized iron. Iron is normally transported in the blood tightly bound to transferrin and stored inside the cell bound to ferritin. In ischemic conditions with accompanying acidosis, however, iron may be displaced from its normal binding sites and can catalyze reactions that promote oxygen radical formation.[84,85] Most commonly implicated is the Haber-Weiss/Fenton reaction, whereby the very potent hydroxyl radical is produced from superoxide anion and hydrogen peroxide in the presence of free iron. The iron-chelator, deferoxamine, has been shown to reduce neurologic injury after experimental neonatal hypoxia-ischemia.[86,87] Finally, NO is another free radical that contributes to both nitrosative and oxidative stress. NO increases during ischemia via increased NMDA receptor stimulation, mediated by release of excitatory amino acids and subsequent calcium-mediated activation of nNOS.[88] NO in the presence of superoxide produces peroxynitrite.[89] Free radicals have also been associated directly with an increase release of excitatory amino acids and vice versa.[74,90] Not only do they participate in each other's release and formation, but they also may act synergistically in causing tissue damage.

The brain may be particularly vulnerable to free radical injury for several reasons. One is the high concentration of polyunsaturated fatty acids, especially arachidonic acid. Release of free fatty acids (FFA) occurs throughout ischemia. On exposure to oxygen radical species, these FFA are vulnerable to autocatalytic lipid peroxidation.[91] Cerebrospinal fluid (CSF) has low concentrations of iron-binding proteins; therefore, iron released from injured neurons or glia is likely to contribute to these peroxidation reactions. Byproducts of these reactions, for example, malondialdehyde and conjugated dienes, have been used as markers of the extent of lipid peroxidation after brain injury (e.g., the thiobarbiturate assay). Lipid peroxides accumulate in the selectively vulnerable zones during reperfusion after transient forebrain ischemia.[84,92] The peroxides do not accumulate during the ischemic period itself or in areas that are not reperfused and thus are implicated in reperfusion injury.[93]

Investigators have also detected oxidative damage to brain proteins after reperfusion.[93] Pyruvate dehydrogenase, a key mitochondrial matrix enzyme that converts pyruvate into acetyl coenzyme A, undergoes oxidative protein modification after ischemia that impairs enzyme activity, possibly contributing to neuronal cell death.[94] However, others have argued that oxidized proteins detected in previous studies were oxidized during sampling and not as a result of ischemia.[91] Other investigators were also unable to detect oxidized nuclear material or mitochondrial DNA during cerebral ischemia.[95] These results were expected because of the compact structure of DNA and the presence of histones, which provide increased resistance to oxidative damage. However, there are two problems with these findings: (1) damage caused by oxidative stress can occur in the absence of lipid peroxidation[96] and (2) work investigating apoptosis suggests that oxidation of regulatory proteins of transcription and translation of DNA may be an important intermediate step in propagation of neuronal cell death.[97,98] Application of contemporary techniques to quantify oxidative stress should help clarify this issue,[99] and may assist in the evaluation of therapies to prevent oxidative stress-mediated brain damage produced during ischemia and reperfusion.

Developmental and sex differences exist in terms of the degree of oxidative stress and amount and function of antioxidant enzymes after brain injury. In mice, glutathione and catalase activity in brain is higher in adult female versus male mice, and discrepancies become more exaggerated with age.[100] Furthermore, neurons from male rats have less capacity to replenish glutathione levels after cytotoxic stress in vitro, and in vivo after asphyxial cardiac arrest.[101] A similar pattern occurs in adult patients after severe TBI with males demonstrating increased lipid peroxidation products in CSF compared with females.[102]

Membrane Phospholipid Hydrolysis and Mediator Formation

Membrane phospholipids modulate signaling cascades, affecting the development, differentiation, function, and repair of the nervous system, functions that become dysregulated with ischemia and oxidative stress.[103] FFAs are released from neuronal membranes during ischemia, and the amount of FFA released are proportional to the duration of ischemia. FFA release continues to change in proportion to duration of ischemia after the completion of energy failure.[104] FFA are released by two distinct but related processes. First, phosphatidyl inositol is hydrolyzed by phospholipase C with the production of diacylglycerol (DAG) and inositol phosphates.[105,106] Phospholipase C-mediated hydrolysis begins during the initial moments of the ischemic insult and is related to neurotransmitter receptor stimulation. DAG is then hydrolyzed by lipases to FFA, predominantly arachidonic and stearic acid. Second, other brain glycerophospholipids are hydrolyzed by phospholipase A_2, which is activated by increases in intracellular calcium concentration. FFA release and metabolism is not a generalized process in the neuronal membrane, but is concentrated in the synaptic regions and is thus related to excitotoxicity.[107]

The FFAs released then have potential detrimental effects during the postischemic period by three mechanisms: (1) arachidonic acid metabolism via the cyclooxygenase pathway contributes to oxygen radical production during reperfusion[81]; (2) FFA and DAG directly increase membrane fluidity, inhibit ATPases, increase neurotransmitter release, and uncouple oxidative phosphorylation; and (3) enzymatic oxidation of arachidonic acid during reperfusion by cyclooxygenase, lipoxygenase, or cytochrome P-450 produces a large number of bioactive lipids, including prostaglandins, thromboxanes, leukotrienes, and hydroxy fatty acids, many of which have detrimental effects (see Figure 62-2).

Endogenous Defenses

In response to the complex sequence of pathobiological events that evolve after brain injury, several endogenous neuroprotectants are produced, induced, or activated after ischemia, and their postulated or proven functions improve cell (specifically neuronal) survival in in vivo and in vitro models.

The heat-shock proteins are one family of candidate neuroprotectants that are highly conserved among biological species and are induced in cells after a variety of stimuli. Thermal stress is the classic example; however, any insult that damages protein structure, including ischemic[108] and TBI,[109] can produce a heat shock protein response. Simon et al.[108] showed that after global ischemia the 72-kDa heat shock protein (Hsp72) is temporally expressed in a pattern that mirrors the pattern of selective vulnerability in the model, seen first in the CA_1 region of the hippocampus, followed by CA_3, cortex, and thalamus, and finally in the dentate granule cells. Hsp72 is also induced in both gray and white matter of piglets after mild and severe hypoxia.[110] The heat shock proteins have generated major interest as potential neuroprotectants because their prior induction by a sublethal stress can afford protection from subsequent injury. Transient whole-body hyperthermia reduces subsequent ischemic brain injury in both adult[111] and neonatal rats.[112] Furthermore, exogenous Hsp72 reduces glutamate toxicity in neuronal cell cultures.[113] Importantly, overexpression of Hsp72 reduces ischemic damage and apoptosis after experimental stroke and global ischemia in vivo.[114-116]

Another potential mechanism for endogenous neuroprotection is the upregulation of genes that inhibit apoptosis and augment neurogenesis. The mammalian gene *bcl-2,* a proto-oncogene, can block apoptosis[97] and perhaps necrosis as well.[117] The *bcl-2* gene is expressed in neurons surviving both focal and global ischemia[118,119] and is reduced in degenerating neurons after cardiopulmonary arrest in rats.[120] Viral transfection of *bcl-2* reduces infarction after focal ischemia,[121] and upregulation of *bcl-2* via ceramide administered 30 minutes after hypoxia-ischemia reduced the number of cells with DNA damage in immature rat brain.[122] Forced overexpression of the *bcl-2* family member *bcl-xL* also reduces tissue damage after focal cerebral ischemia in adult rats.[123] After TBI in infants and children, CSF levels of *bcl-2* are increased in patients who survive compared with those who die.[124] Finally, *bcl-2* overexpression promotes neurogenesis in adult mice with and without ischemic injury.[125]

Adenosine is an endogenous biochemical mediator that may serve a protective role after cerebral ischemia, particularly early after injury. Adenosine is increased in brain tissue after experimental ischemia,[126] and in response to hypoxia,[127] hypotension,[128] and hypoglycemia.[129] The release of adenosine after ischemia could afford neuroprotection by a combination of several mechanisms. When bound to A2-receptors, adenosine is a potent cerebrovasodilator and inhibits platelet activation and neutrophil function.[130] Bound to A1-receptors, adenosine reduces neuronal metabolism and excitatory amino acid release and stabilizes postsynaptic membranes.[130] Thus the beneficial effects of adenosine after cerebral ischemia include improved regional blood flow, reduced local oxygen demand, attenuation of both excitotoxicity and calcium accumulation, and antiinflammatory and rheologic effects. Finally, adenosine agonists have been shown to improve survival of selectively vulnerable neurons after ischemia in many studies (reviewed in Rudolphi et al.[131]).

Clinical Pathophysiology

Cerebral Blood Flow and Metabolism After Resuscitation

The pioneering studies in which global CBF and cerebral metabolic rate for oxygen ($CMRO_2$) were measured in animal models of global ischemia or cardiac arrest focused on the early post-resuscitation period. In their classic study, Snyder et al.[132] showed that after 15 minutes of global brain ischemia in dogs, CBF transiently increased to levels well above baseline (Figure 62-3). Then, after 15 to 30 minutes, CBF progressively decreased to a level below normal for the remainder of the monitoring period (90 minutes). This pattern of early transient postischemic hyperemia and subsequent delayed postischemic hypoperfusion has been observed in many global cerebral ischemia models, including both VF and asphyxial arrest.[133,134] The level of hyperemia and subsequent hypoperfusion vary in relation to the duration of the insult.[135] Although these phases of increased and decreased CBF characterize the net global effect, regional CBF is often inhomogeneous, particularly during postischemic hypoperfusion, when areas of decreased and increased perfusion may coexist.[136]

Recently, the heterogeneous and duration dependent nature of post-arrest CBF was characterized using contemporary

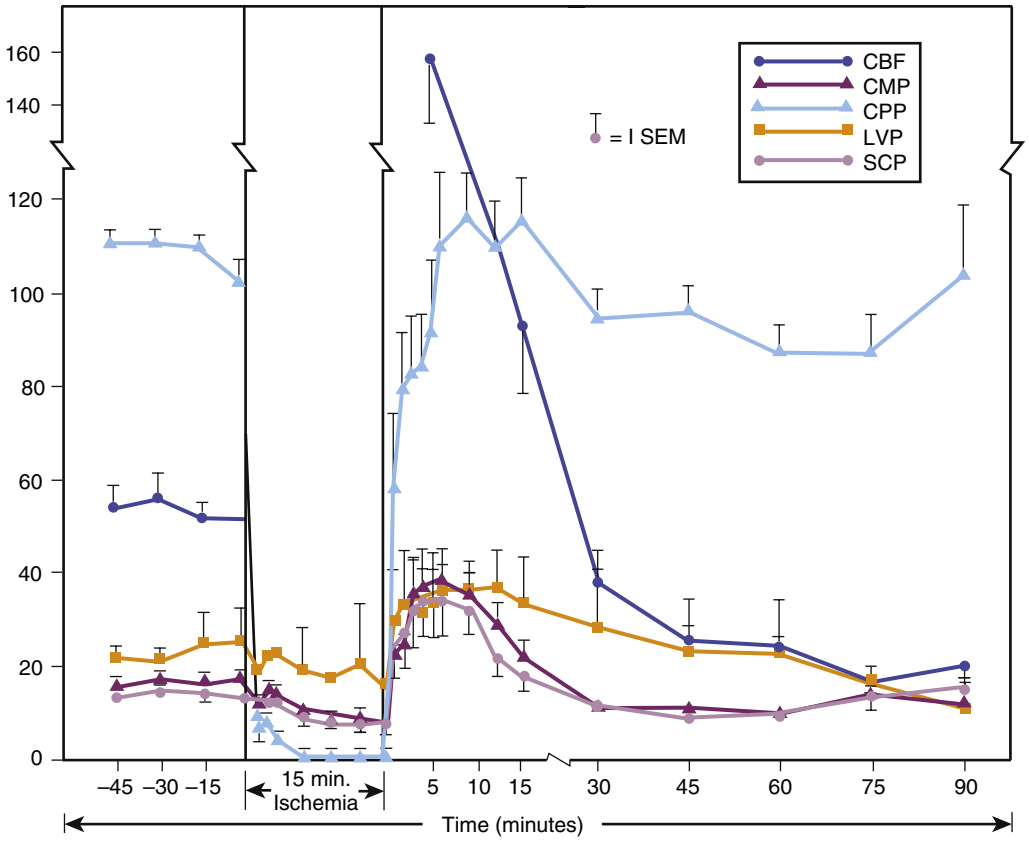

Figure 62–3. Global cerebral blood flow *(CBF),* cisterna magna pressure *(CMP),* cerebral perfusion pressure *(CPP),* lateral ventricular pressure *(LVP),* and supracortical pressure *(SCP)* measured before, during, and for 90 minutes after a 15-minute circulatory arrest in dogs. CBF data demonstrate that early postresuscitation hyperemia occurs, followed by hypoperfusion. *(Modified from Snyder JV, Nemoto EM, Carroll RG, et al: Global ischemia in dogs: intracranial pressures, brain blood flow and metabolism,* Stroke *6:21, 1975.)*

imaging techniques allowing for regional assessment and a clinically relevant model of pediatric asphyxial cardiac arrest.[137] Using arterial spin labeling magnetic resonance imaging, CBF was measured for the first 3 hours after 8.5, 9, or 12 minutes of asphyxial cardiac arrest in postnatal day 17 rats—approximating a 1- to 4-year-old human in terms of brain development (see also Chapter 57). Although the pattern of early global hyperemia followed by hypoperfusion similar to that observed by Snyder et al.[132] was seen after asphyxial arrests lasting 8.5 and 9 minutes, a pattern of global and persistent hypoperfusion was observed after a 12-minute arrest (Figure 62-4). Remarkably, CBF disturbances were also found to be region-dependent after asphyxial arrests lasting 8.5 and 9 minutes, with subcortical hyperemia but cortical hypoperfusion. After a 12-minute asphyxial arrest hypoperfusion was observed in both cortical and subcortical regions, and CBF was pressure passive, perhaps indicating loss of autoregulation after a prolonged arrest.

In patients with good outcomes, global CBF recovers over the subsequent 24 to 72 hours and CO_2 reactivity remains intact. Patients who do not regain consciousness or progress to brain death develop absolute or relative CBF hyperemia with impaired CO_2 reactivity.[138,139] A theoretical scheme of postarrest global CBF and its relation to neurologic outcome is presented in Figure 62-5. Most studies in experimental animal models of asphyxial arrest suggest a similar pattern of CBF and $CMRO_2$ to that observed after VF cardiac arrest and global ischemia in the early post-resuscitation period in humans.[134,138] However, there are some exceptions.[140] Results from clinical studies of pediatric asphyxial arrest are scarce and somewhat conflicting with regard to the prognostic implications of high or low values of postarrest CBF based on a single measurement; however, loss of CO_2 reactivity appears to be associated with poor outcome in all studies. In studies of children between 24 and 48 hours after near-drowning, Ashwal et al.[141] observed low CBF in the seven nonsurvivors and no relationship between CBF and $PaCO_2$ in these patients—again suggesting loss of CBF reactivity to changes in $Paco_2$. In this study, hyperemia was not routinely observed in either survivors in a persistent vegetative state or children who died, but only a single CBF measurement was made in these patients. Beyda[142] obtained serial measurements of postarrest ^{133}Xenon in a series of children who suffered asphyxial arrest from submersion accidents. Children with good neurologic outcomes had slightly decreased CBF values at 12 hours that increased to normal during the subsequent 24 to 60 hours. In these children, CBF reactivity to CO_2 was intact. Children with eventual vegetative outcome or brain death exhibited hyperemia with loss or attenuation of CO_2 reactivity. This hyperemia progressed to low or normal flow over the following 12 to 72 hours in children with vegetative outcome and progressed to low and then no flow with the development of brain death.

Brain metabolism, as assessed by $CMRO_2$, is reduced during the early postischemic period and then progressively recovers to a level that varies, depending on the model used

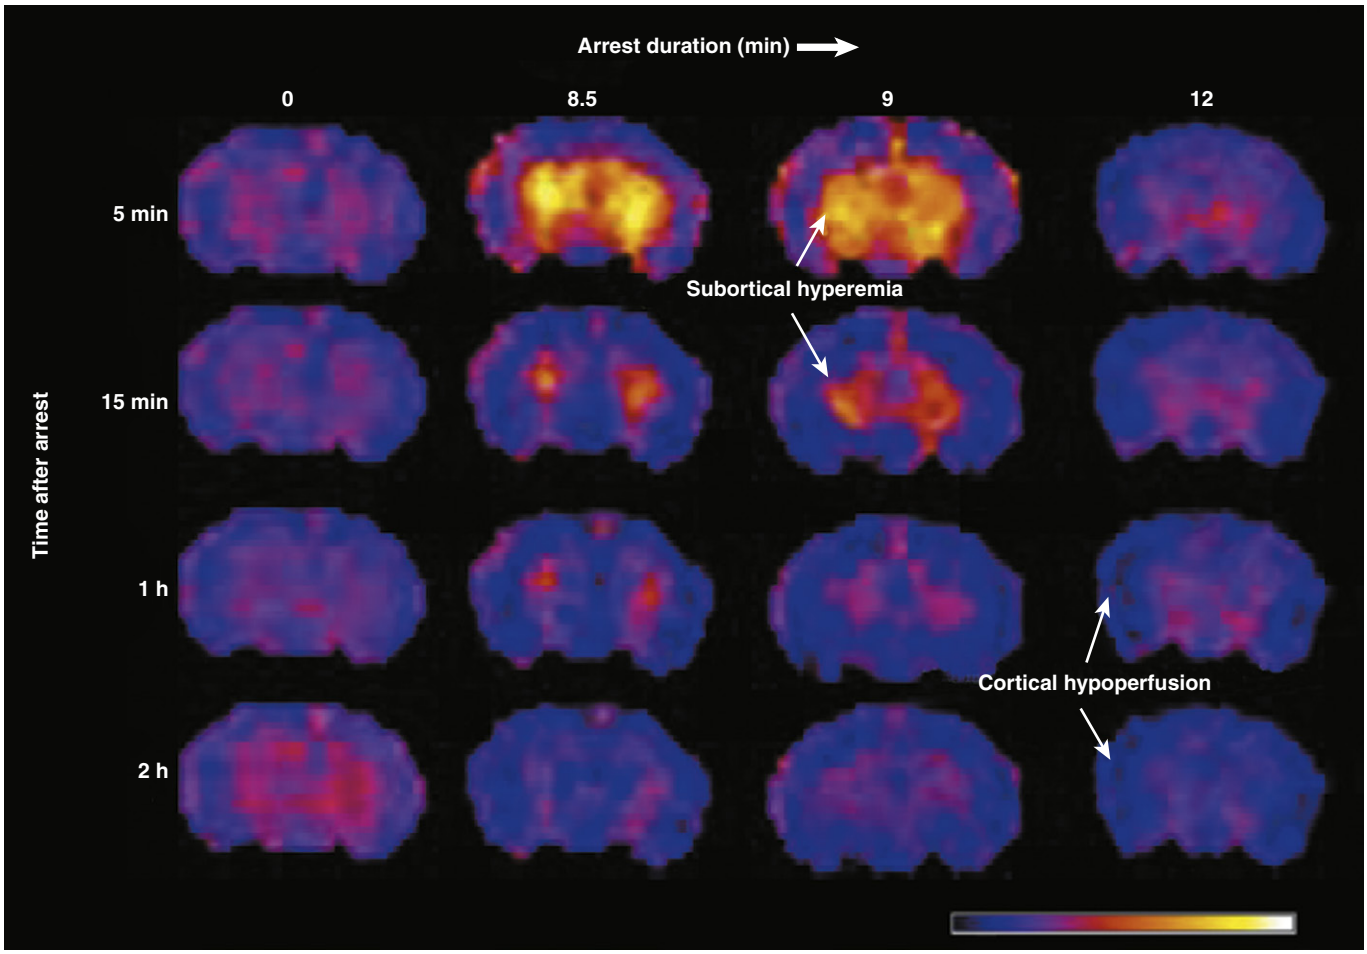

Figure 62–4. Duration and regional dependency of cerebral blood flow (CBF) disturbances acutely after asphyxial cardiac arrest in postnatal day 17 rats. CBF data demonstrate that early postresuscitation hyperemia occurs in subcortical regions after an 8.5- and 9-minute but not a 12-minute asphyxial cardiac arrest, and that duration-dependent hypoperfusion occurs in cortical regions. *(Modified from Manole MD, Foley LM, Hitchens TK, et al. Magnetic resonance imaging assessment of regional cerebral blood flow after asphyxial cardiac arrest in immature rats.* J Cereb Blood Flow Metab *29:197, 2009.)*

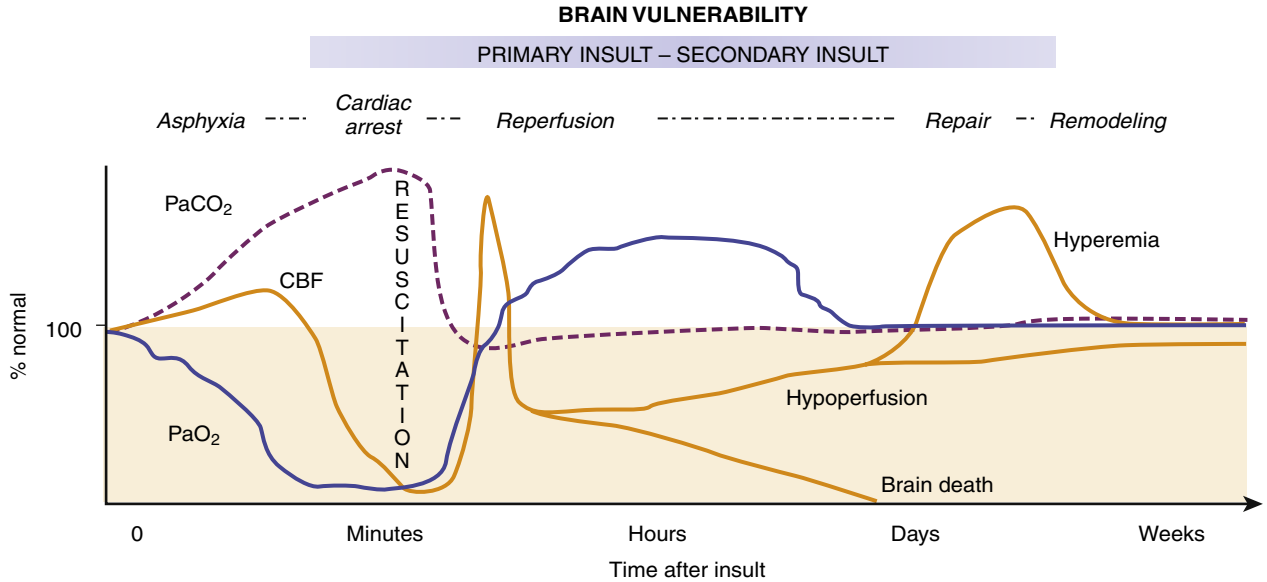

Figure 62–5. Hypothetical diagram illustrating the patterns of *global* cerebral blood flow (CBF) during and after cardiopulmonary arrest of moderate duration in humans. Immediately after resuscitation, "early postischemic hyperemia" occurs for about 15 minutes in subcortical brain regions. This is followed by patchy multifocal "delayed postischemic hypoperfusion" in cortical brain regions lasting from a few hours to days. Progressive return of CBF to normal is seen in patients with intact neurological outcome. In contrast, "delayed postischemic hyperemia" can be observed hours to days postarrest in patients with more severe insults.[139,142] This delayed hyperemia appears to be associated with disabled or vegetative outcome (where CBF gradually decreases to near normal or below normal) or brain death (where CBF decreases to no flow). It is unclear, however, if all patients with vegetative outcome or eventual brain death develop delayed hyperemia.

and on the duration of ischemia.[135,143] In some models, including VF arrest in dogs, significant recovery of $CMRO_2$ may occur during the first few hours, despite persistent postischemic hypoperfusion—creating the potential for a secondary ischemic insult during reperfusion. Whether this increase in $CMRO_2$ represents appropriate synaptic activity, seizures, or basal metabolism is not certain. In other models, global CBF and $CMRO_2$ are matched during the first few hours after ischemia.

It must be recognized that the measurements of metabolism in the studies have traditionally been $CMRO_2$. However, Bergsneider et al[144] used positron emission tomography in patients after TBI and reported the occurrence of delayed hyperglycolysis in some comatose patients, suggesting a shift to anaerobic metabolism in injured brain in some patients. Using microdialysis in a porcine model of cardiac arrest, increased lactate/pyruvate ratios were found during arrest, and again in a delayed fashion especially if kept normothermic versus hypothermic.[145] This same group found increased lactate/pyruvate ratios and glutamate using microdialysis in adult survivors after cardiac arrest, all of whom were treated with hypothermia.[146] Prolonged increases in brain lactate detected using proton magnetic resonance spectroscopy after global hypoxia-ischemia in children have also been reported.[28,147,148] Oxidative stress decreases the function of the pyruvate dehydrogenase complex, a key enzyme in oxidative metabolism, possibly contributing to the shift to anaerobic metabolism.[149] Although routine monitoring of CBF or CMR has not been applied extensively to the post-arrest setting in children, their routine assessment using contemporary methods would likely lead to an improved understanding of pathophysiology.

Drugs such as nimodipine can increase CBF during the early postischemic hypoperfusion phase after global cerebral ischemia. $CMRO_2$ recovery generally is not increased by treatment.[150] Although nimodipine has been shown to be beneficial in patients after subarachnoid hemorrhage,[151] but not ischemic stroke,[152] the testing of strategies targeting early post-arrest hypoperfusion deserves further study. Safar et al.[153] have reported that a multifaceted treatment strategy to increase CBF ("flow promotion") and reduce CMR or $CMRO_2$ early after VF in dogs improved outcome. This was accomplished by use of cardiopulmonary bypass (CPB), mild hypothermia, hemodilution, and transient hypertension.

Histopathology of Hypoxic-Ischemic Encephalopathy

Ischemic neuronal change (Figure 62-6), as first described by Sommer in 1880 and later by Spielmeyer, involves a progression from extensive cellular microvacuolation to a cell that resembles a naked shrunken nucleus.[18] As described by Brierley et al.,[37] "this type of neuronal damage is neither ubiquitous nor randomly distributed but is found in regions which exhibit selective vulnerability to hypoxic stress." As discussed previously, death of selectively vulnerable neurons (e.g., hippocampal CA_1) cannot be explained by vascular distribution. Remarkably, these clinical descriptions of cell shrinkage were consistent with apoptosis rather than necrosis. However, the connection between selective vulnerability and apoptosis was made 100 years later.[45] Neuronal death after cardiopulmonary arrest is seen not only in the selectively vulnerable neurons but also as a subtle histopathological finding in the arterial boundary zones. These neurons (not otherwise selectively vulnerable) are in the most poorly perfused areas during or after resuscitation.[34] Neuronal death in the arterial boundary zones was elegantly described by Nemoto et al. in a monkey model of 16 minutes of complete global brain ischemia followed by 7 days of intensive care.[154] Maximal damage appeared to be in the classically described selectively vulnerable zones, but neuronal death was also observed in the most distal distribution of the posterior cerebral artery and in the watershed zones of the anterior and middle cerebral arteries (Figure 62-7). With sufficient injury in the arterial boundary zone, more severe findings such as microinfarction or laminar necrosis can be seen.[19,154] As previously discussed, even in stroke, neuronal death in an ischemic penumbra can occur either by necrosis or apoptosis. Thus it appears that there may be a continuum between apoptosis and necrosis that may depend on a large number of factors, such as duration of the insult and brain region in question.[60] Whereas apoptosis in a given area often affects only a select percentage of neurons, infarction affects all neurons and glia. Obviously, if the arrest time is long or if the postischemic conditions are sufficiently poor, infarction of the entire brain can occur.

Vaagenes studied neuropathology after primary VF arrest of 10 minutes in dogs.[19] Despite vegetative outcome at

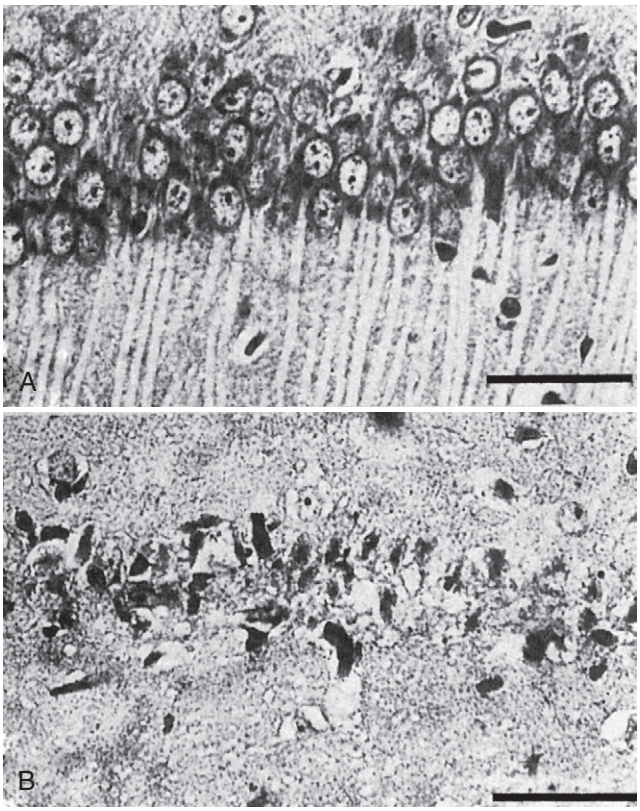

Figure 62–6. Light micrograph of dorsal hippocampus in gerbils 7 days after 5 minutes of sham ischemia (**A**) or global ischemia by carotid occlusion (**B**). Ischemic neuronal change is seen with CA_1 neurons appearing as dark, shrunken nuclei without cytoplasm (**B**) by contrast with the normal-appearing nonischemic neurons (**A**). Investigations by Nitatori et al.[45] indicate that neuronal death in selective areas, after threshold ischemia insults, occurs via apoptosis. *(From Kuroiwa T, Bonnekoh P, Hossmann KA: Therapeutic window of CA1 neuronal damage defined by an ultrashort-acting barbiturate after brain ischemia in gerbils,* Stroke *21:1489, 1990.)*

96 hours, only scattered ischemic neuronal changes in the selectively vulnerable neurons and to a much lesser extent in the vascular watersheds were observed. Microinfarct formation was seen in only 5 of 18 dogs, suggesting that patchy ischemic neuronal change is sufficient for vegetative outcome. They then compared this 10-minute VF arrest with an asphyxial episode (airway occlusion) resulting in cardiac arrest with 7 minutes of no flow. Related either to differences in the initial insult or to postischemic events, asphyxial arrest resulted not only in ischemic neuronal change in the selectively vulnerable regions but also in marked microinfarct formation (30 of 32 dogs) and scattered petechial hemorrhages. This more severe histological injury was seen despite significantly *easier* ROSC in the asphyxial arrest group (Figure 62-8). In addition, unlike VF arrest, asphyxial arrest caused some ischemic neuronal changes even after no flow of only 2 minutes. These findings may explain the poor outcome generally observed in cardiopulmonary arrest in children (usually asphyxial arrest) compared with that in adult series (VF arrest). After asphyxial cardiac arrest that results in long-term survival in both adult and pediatric-aged animals,[155-157] the pattern of neuronal death produced is similar to that reported in human studies[158] including that of the young victim of asphyxial cardiac arrest, Karen Ann Quinlan,[159] in which a predilection for basal ganglia injury resulting in a persistent vegetative state is observed.

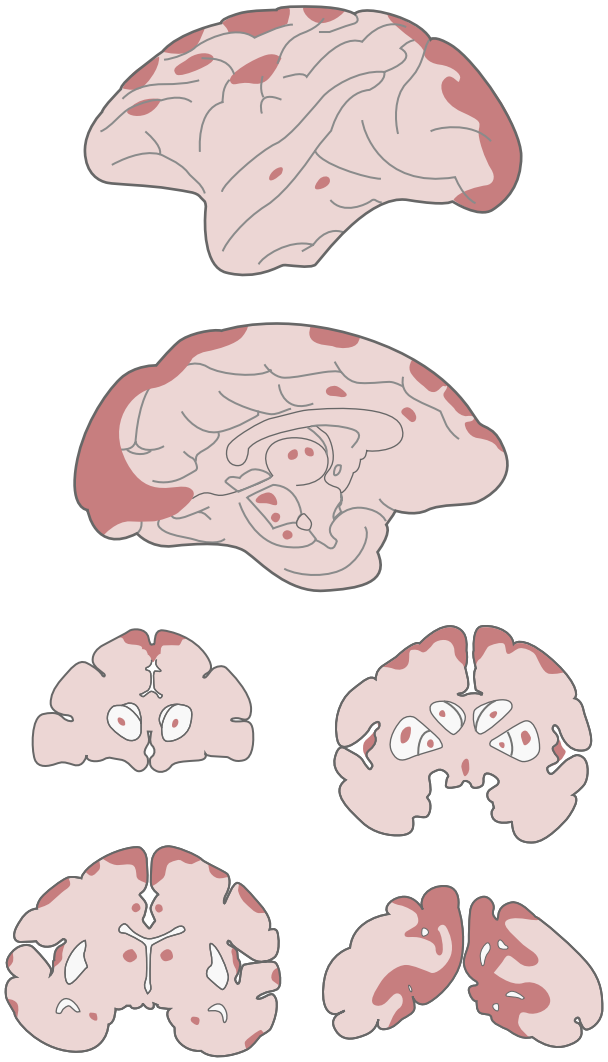

Figure 62–7. Topographic distribution of cortical lesions 7 days after 16 minutes of global brain ischemia in rhesus monkeys. Neuronal death in areas with intrinsic selective vulnerability was most apparent in the distal distribution of the posterior cerebral artery. Damage in the watershed distributions of the anterior and middle cerebral arteries was less consistent. *(Modified from Nemoto EM, Bleyaert AL, Stezoski SW, et al: Global brain ischemia: a reproducible monkey model,* Stroke *8:558, 1977.)*

Clinical Outcome After Pediatric Cardiopulmonary Arrest

Compared with results in adult series, survival and neurologic outcome after cardiopulmonary arrest in infants and children are remarkably poor.[6] Most published data examining out-of-hospital cardiopulmonary arrest in adults reveal about 11% to 12% "good" neurologic outcome at 6 months after arrest, with good outcome generally defined as the ability to function independently.[160] One review summarizing the results from 44 studies totaling 3094 pediatric patients after cardiopulmonary arrest showed favorable outcome at hospital discharge (generally defined as nonvegetative) in only about 6% of patients.[13] In addition, after asphyxial arrest in children, clinical outcomes somewhere between vegetative and good, such as moderate disability or severe disability, are uncommon.[141,161] Survival to hospital discharge after out-of-hospital arrest ranges from 8% to 25% and after in-patient arrest is 24% to 51% in several studies, with an overall survival of 13%.[7,9,10,13,15] However, if the child had a pulse by hospital arrival after out-of-hospital cardiac arrest, survival increases to 38%.[7] The most common cause of death is neurologic injury for out-of-hospital arrests and cardiovascular failure for in-hospital arrests.[7] Good neurologic outcome in pediatric patients surviving cardiac arrest is often overestimated using traditional categorical outcome measures such as the Glasgow Outcome Score and Pediatric Cerebral Performance Category Scale.[162-164] Furthermore,

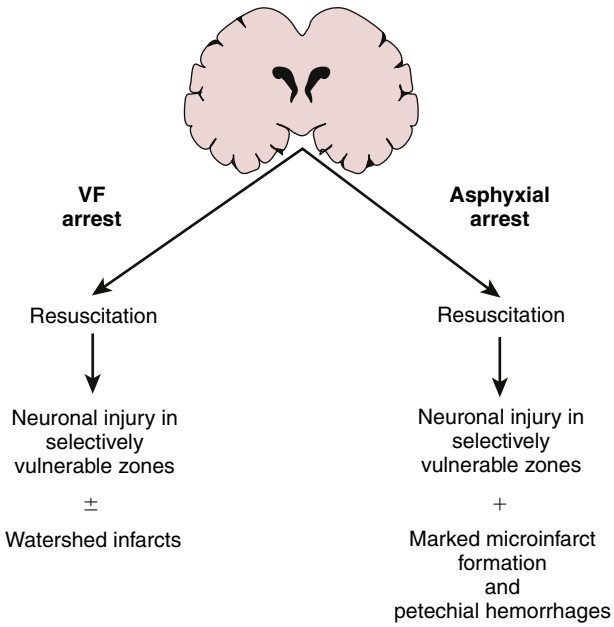

Figure 62–8. Schematic diagram based on the work of Vaagenes et al.[19] comparing the histologic outcome of VF cardiac (adult) and asphyxial (pediatric) arrest. *(From Holbrook P [ed]:* Critical care clinics, vol 4, *Philadelphia, 1988, WB Saunders, p 661.)*

contemporary longer-term outcome studies evaluating overall functional status, neuropsychological function, and quality of life do not exist. One observational study focusing on late improvements in functional outcome noted improved mobility in 22% of children after cardiac arrest versus 66% of children after TBI two years after the initial event.[165]

This high mortality and poor outcome after cardiorespiratory arrest in children generally represents out-of-hospital or unwitnessed full arrests. Recovery is much better in children who had witnessed arrests, cold water submersion, or isolated respiratory arrest, after which intact survival rates as high as 44% to 75% have been reported.[7,12,166-168] Nevertheless, these clinical data seem to bear out the severe neuropathology observed in asphyxia-induced arrest in animal models because asphyxial arrest is the most common mode of arrest in all of the clinical pediatric series.[12,13,162,166-168]

Such factors as initial pH, number of epinephrine doses, and arrest duration have been examined in an attempt to predict outcome from cardiopulmonary arrest. Although sometimes predictive, this information can be misleading. For example, the time delay before analysis of the first blood sample can vary, as can estimates of arrest duration. With asphyxial arrest, even controlled experimental animal studies show that the time from asphyxia until cardiac arrest varies considerably. Currently, the most powerful individual predictor of neurologic outcome after cardiorespiratory arrest is the neurologic examination or one of several scoring systems based on selected aspects of the neurologic examination. In 1985, Levy et al.[169] applied multivariate analysis to variables from the neurologic examination in a series of 210 adults in coma studied for at least 6 hours after a hypoxic-ischemic insult. None of the 15 patients who were in a vegetative state at 1 month regained independent function. In this retrospective study, the combination of scores is from 2 weeks. The oculocephalic response and the 3-day motor response were able to identify all patients who gained independent function. This was true even for the 2 of 57 patients who remained in eyes-closed coma for 3 days and then ultimately regained independent function. Edgren et al.[170] applied the Glasgow Coma Score (GCS) to assess outcome in 262 adult comatose survivors of cardiac arrest. GCS less than 6 at 3 days post-arrest predicted poor outcome (at 6 months) with no false-negative results. In a similar study of 216 adults after out-of-hospital cardiac arrest, Mullie et al.[171] found that a best GCS of less than 4 as early as 2 days post-arrest predicted death or vegetative outcome in all but one patient. The one exception progressed from vegetative state to severe disability. The addition of hypothermia as a post-resuscitative therapeutic option may delay attempts at early prognostication.[172]

Although a few patients survive relatively intact despite poor prognosis they likely represent cases of asphyxia without cardiac arrest, coma of an origin other than asphyxial arrest, unrecognized hypothermia, or an associated overdose of a cerebral protective drug. Two prospective trials examining predictors of outcome have been reported after cardiopulmonary arrest in pediatric patients. Robertson et al. in a series of 27 pediatric patients with hypoxic-ischemic encephalopathy found that a GCS of 3 and nonreactive pupils were predictive of adverse outcome.[162] Consistent with asphyxia as the predominant cause of cardiac arrest in infants and children, Sirbaugh et al. found that the only factor that was positively associated with ROSC was endotracheal intubation.[173] This would not support abandonment of the practice of ventilating infants and children found pulseless and apneic, and rather, suggests that it is crucial in this patient population.[174,175] Indeed a recent, prospective multicenter study done in Japan comparing conventional versus chest-compression only CPR for children after out-of-hospital cardiac arrest strongly supports this view.[176] In children requiring resuscitation from non-cardiac causes, conventional CPR resulted in favorable neurologic outcome in 45 of 624 children compared with "hands-only" CPR where favorable neurologic outcome was seen in only 6 of 380 (7.2 vs. 1.6%; odds ratio, 5.54; confidence interval, 2.52 to 16.99). Importantly, in children requiring resuscitation from cardiac causes, favorable neurologic outcome was not different between conventional CPR and compression only CPR, implying that unlike in adults, conventional CPR does not negatively influence outcome in children suffering arrests of cardiac origin.

The electroencephalogram (EEG) can also provide prognostic information for patients after cardiac arrest. Scollo-Lavizzari and Bassetti[177] retrospectively examined the relation between first post-arrest EEG and clinical outcome in 408 cases. A 5-grade classification was used to categorize EEGs. Although permanent severe neurologic damage was observed in some patients with grade I EEG, none of the 208 patients with grade IV or V EEGs had a good neurologic recovery. A recent single-center retrospective case series in children showed that after a 5-grade EEG score was collapsed into three categories, the score was associated with a positive predictive value of 90% and negative predictive value of 91% in determining poor outcome at hospital discharge.[178] Detailed quantitative EEG may also have a role in the prediction of neurologic outcome after cardiac arrest (see also Chapter 34).[179]

Adjunctive prognostic information also can be derived from brain-derived protein levels in serum or CSF. High serum levels of neuron-specific enolase (NSE) in comatose patients at 24 and 48 hours after cardiopulmonary arrest predict poor neurologic outcome.[180] Martens et al. found that serum concentrations of the astrocyte-derived protein S-100B were superior to serum NSE (as well as CSF S-100B and NSE) in predicting which adult patients would regain consciousness after cardiac arrest.[181] A study used a multimodal approach, combining serum concentrations of NSE, the astrocyte-derived protein S-100B, and somatosensory-evoked potentials (SSEPs), prospectively in 27 adult patients after cardiac arrest and were able to predict all patients that did not regain consciousness.[182] Serum NSE is increased in children after cardiac arrest and peaks at 24 hours.[183] NSE and other biomarkers may be useful in determining responsiveness to therapeutic interventions (e.g., it has been reported that decreasing serum NSE occurs mainly in hypothermic [vs. normothermic] adults after cardiac arrest and is predictive of outcome).[184] Other biomarkers showing promise in case series are procalitonin,[185,186] alpha II-spectrin breakdown products,[187] serum glial fibrillary acidic protein,[188] and brain natriuretic peptide.[189]

Studies have used SSEP monitoring in an attempt to provide early prognostic information about outcome after cardiopulmonary resuscitation. Madl et al. tested median nerve SSEPs in 66 adults after successful resuscitation from cardiac arrest. They reported that the presence or absence and the latency of the cortical N70 peak reliably differentiated between bad and favorable outcome with 100% predictive ability.[190] Testing was performed within 48 hours of resuscitation, which is a

clinically relevant time frame. Auditory evoked response testing has been used in children with cardiac arrest after a submersion accident.[191] Normal evoked responses were observed in all children who recovered neurologically intact. Children who recovered with significant handicaps demonstrated reduction in wave V amplitude over time, and prolonged wave I-V inter-peak latencies. In adults, bilaterally absent N20 waves at 24 and 48 hours have a reported specificity of 100% in predicting permanent coma after cardiac arrest.[192]

The utility of computed tomography (CT) of the head and other neuroimaging modalities after cardiac arrest is unknown (Figure 62-9). Head CT takes only a few minutes and is useful for evaluation of intracranial lesions contributing to the cause of arrest, but requires the critically ill subject to be transported out of the ICU and uses ionizing radiation. In a large retrospective case series of children with near-drowning, children with any abnormal CT findings (e.g., loss of gray-white differentiation, infarction) within the first 24 hours of admission died.[193] Ninety-six percent of children with an initially normal CT on the first day that had a subsequent abnormal CT either died or remained in a coma. Using a novel scoring system assessing primarily the cortex and basal ganglia, a good correlation between early magnetic resonance imaging score and neurologic outcome was reported.[194] Using magnetic resonance spectroscopy, decreases in the brain metabolite *N*-acetylaspartate and increases in lactate in the basal ganglia and cortex are can assist in outcome determination in children after near-drowning and cardiac arrest.[147,195,196]

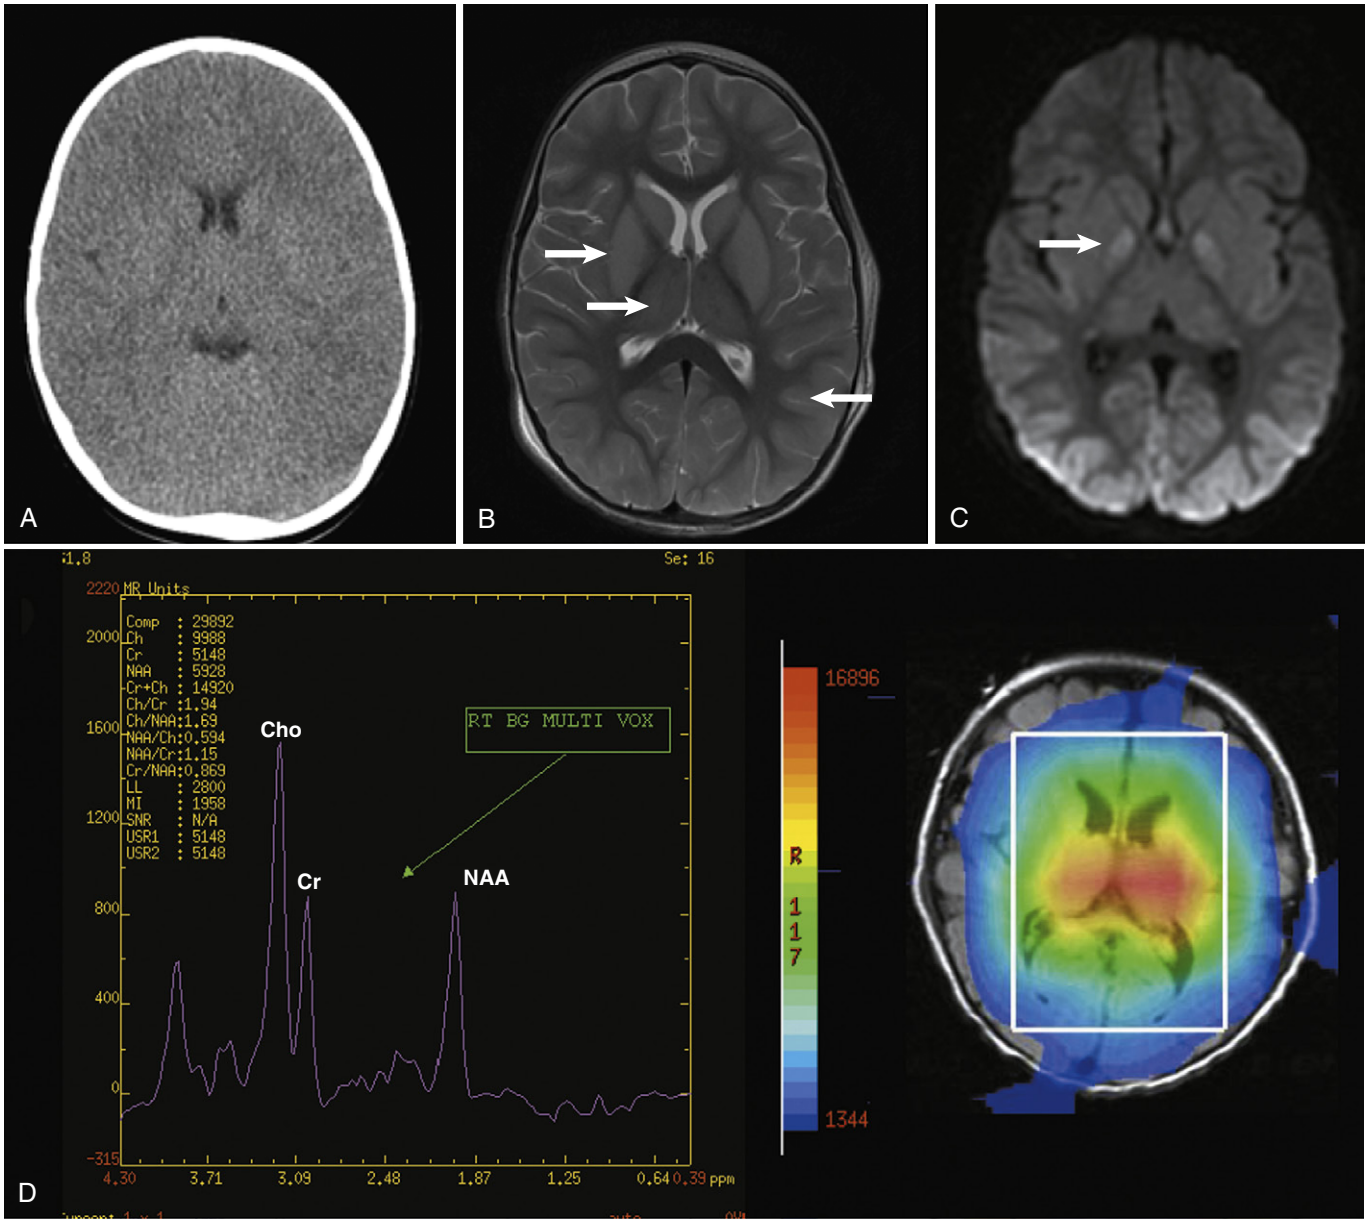

Figure 62–9. Neuroimaging after asphyxial cardiac arrest in children. **A,** Computed tomography scan of the head on day 1 showing decreased gray-white differentiation, consistent with cerebral edema. **B,** T2-weighted magnetic resonance image using a 3-Tesla magnet on day 10 showing enhancement of the basal ganglia, thalamus, and parietal lobes (*arrows*). **C,** Diffusion-weighted imaging shows corresponding edema of the globus pallidus (*arrow*). **D,** Multivoxel magnetic resonance spectroscopy showing the whole brain chemical analysis of N-acetylaspartate (*NAA*), choline (*Cho*) and Creatine (*Cr*). Response of the Immature Brain to Cardiopulmonary Arrest

Clinical and laboratory studies suggest that the neurologic outcome of newborn animals after a hypoxic-ischemic insult is favorable compared with that of adults; although this may be related to the ability of newborn animals to tolerate asphyxia systemically. This is most evident when neonatal and adult experimental models are compared. In newborn monkeys even 12 minutes of asphyxia did not result in cardiac arrest,[197] and in Beagle pups, 15 minutes of asphyxia produced hypotension but not cardiac arrest.[198] Asphyxial arrest in mature animal models generally occurs within 6 to 8 minutes.[19,133] Kirsch et al.[199] showed that newborn piglets had better recovery of SSEPs and less postarrest hypoperfusion than young adult pigs in the 2 hours after global cerebral ischemia. Thus not only does the cardiovascular response during asphyxia appear to be more robust in immature animals, but also the intrinsic sensitivity of the brain to a hypoxic-ischemic insult may be less. Studies suggest a selective vulnerability of the neonatal brain stem sensory nuclei to asphyxia.[197,200] This "selective vulnerability" may more correctly represent a relative lack of vulnerability of neonatal cerebral cortex to asphyxia because anoxic perfusion was tolerated for over 12 minutes in immature monkeys, most of which demonstrated no ischemic neuronal change.[197] However, some mechanisms of secondary damage, such as excitotoxicity, appears to be more injurious in the immature.[201,202] Further complexity is added to processes such as excitoxicity when the immature brain is involved, as some degree of excitatory stimulation is essential for neuronal survival and normal development.[203] Finally, greater plasticity in the immature brain may also allow for improved long-term recovery of function, although this may be more important in focal insults.[204,205]

The poor clinical outcome of infants and children presenting in cardiopulmonary arrest is probably related to specific mechanisms operating in the special setting of the asphyxial arrest. As the asphyxial arrest is developing, cardiac standstill is preceded by a variable period of severe hypoxia with increased CBF. During this period, severely hypoxic perfusion, a form of incomplete ischemia is produced, which can markedly increase cerebral lactate production.[206] The initial phase of asphyxia can also be accompanied by extreme stress during struggling, which could increase $CMRO_2$ and may be accompanied by systemic hyperglycemia.[141] The combination of hypoxic perfusion or incomplete hypoxia-ischemia and hyperglycemia can increase cerebral lactate concentration to 30 to 35 μmol/g tissue and decrease tissue pH to levels as low as 6.05.[207-209] These lactate levels are much higher than those observed during even 30 minutes of complete ischemia (11 to 14 μmol/g tissue) and are above the threshold of 20 to 25 μmol/g tissue, at which lactic acid can produce local coagulation necrosis.[210] As suggested by the histopathological outcome studies previously discussed,[19] cardiac arrest or reperfusion may be particularly devastating to the brain in this milieu. Also, because of the relative resistance of the immature myocardium to asphyxia, it is easier to restore cardiovascular function in younger patients after longer durations of cardiac arrest than would be possible in adults. Total insult time (hypoxia plus anoxia plus cardiac arrest) is often very long. In adults with asystole or a pulseless bradycardia rather than VF, outcome is also poor.[211] Thus although pediatric intensivists have the apparent luxury of dealing with a somewhat resistant brain with more plasticity for functional recovery, this advantage is often trivial compared to the devastating pathobiology of the asphyxial arrest.[157,212]

Treatment of Cardiopulmonary Arrest

Adequate understanding of the pathobiology of HIE after cardiopulmonary arrest in children is possible given the development of contemporary models of pediatric asphyxial arrest. These models in juvenile rodents and piglets will hopefully lead to more etiology-specific evaluation of the post-resuscitation syndrome in terms of mechanisms and relevant therapies.[156,157]

Field Interventions

Pediatric cardiac arrests are usually not sudden in onset as in adults and thus a window of opportunity exists during which interventions could potentially prevent cardiac arrest and subsequent poor outcome. As discussed, children sustaining isolated respiratory arrest have a mortality rate as low as 25%, whereas patients with cardiac arrests as a result of hypoxia have a high mortality rate.[6,13] Thus, the sooner the recognition and interventions, the better are the chances for a good outcome. Aside from witnesses with knowledge of CPR or the capacity to follow instructions provided by telephone emergency services, prehospital emergency medical services are capable of providing the earliest medical interventions and hold the greatest promise for improving outcome from prehospital pediatric cardiopulmonary arrest. Emergency medical services have developed sophisticated methods for dispatch and transport, but there are logistical limits to the rapidity with which they can provide basic interventions. Nationwide the average response time is well over 8 minutes, greater than the time required for an infant to progress from apnea to cardiac arrest. As a result, more advanced, traditionally hospital based and investigational interventions must also be administered in the prehospital setting in attempts to optimize outcome. Toward this end, use of medical simulation has greatly improved both the understanding of the mechanics of quality CPR, as well as teaching and training (see also Chapter 34).

High-dose epinephrine therapy has been shown in many animal models to improve resuscitation rates.[213] However, a more recent study in a piglet model of asphyxial cardiac arrest showed no improvement in survival or neurologic outcome when high-dose epinephrine was used for resuscitation versus standard-dose.[214] Vasopressin and terlipressin may also be of value after cardiac arrest in pediatric patients, as vasopressin alone and in combination with epinephrine increases CBF during resuscitation from VF compared with epinephrine alone.[215-217] However, the effects of high-dose epinephrine, vasopressin, or terlipressin on long-term survival and neurologic outcome in pediatric patients have not been firmly established. A small study in children using historical controls demonstrated a beneficial effect on resuscitation and outcome in patients receiving high-dose epinephrine.[218] In contrast, a large multicenter trial with concomitant controls in adults was unable to demonstrate a beneficial effect of high-dose epinephrine.[219] Further, a recent meta-analysis of adult studies favored high-dose epinephrine in terms of ROSC, but a trend toward favoring standard-dose epinephrine in terms of survival to hospital discharge.[220] Recently,

the use of bolus calcium during resuscitation was found to be associated with poor neurologic outcome and mortality.[221] The efficacy of pharmacological therapy during CPR is probably limited by the minimal perfusion provided by standard CPR (see also Chapter 34). Development and implementation of improved perfusion techniques for cardiac arrest victims in the prehospital environment would provide an increased "therapeutic window" and thus a better chance of benefiting from advanced therapeutic techniques.

Controlled experimental or prospective clinical studies of intracranial pressure (ICP) monitoring or treatment after asphyxial arrest have not been performed. It could be predicted that ICP elevation would be more common after asphyxial arrest than after isolated global brain ischemia or VF arrest, given the severe histopathology seen after asphyxial arrest and the long insult times from which the myocardium can recover in children. Sustained elevation of ICP (>20 mm Hg) has been shown uniformly to predict poor outcome in four series of pediatric submersion accidents.[222-225] Unfortunately, as in VF arrest, the threshold for poor outcome from asphyxial arrest appears to be below the threshold for the occurrence of intracranial hypertension because some patients experience poor outcome despite normal ICP.[225] Although anecdotal cases of asphyxial arrest in patients with intact neurologic outcome despite elevated ICP are occasionally discussed, in the series cited previously the ability to control ICP elevation did not result in meaningful survival.[223,225] Routine ICP monitoring and ICP-directed treatment are not currently recommended after asphyxial arrest[161,223,225]; however, studies using ICP-directed therapy in the era of contemporary neurointensive care have yet to be performed.

The blanket use of hyperventilation for cerebral resuscitation after cardiac arrest is currently out of favor. Only one laboratory study of cardiopulmonary arrest has demonstrated a beneficial effect of hyperventilation. Vanicky et al.[226] reported that 8 hours of hyperventilation reduced neuronal damage after cardiac arrest in dogs. However, histology was examined at 3 hours after arrest, and no long-term outcome was studied. The blind application of hyperventilation early after severe TBI in adults worsened outcome.[227] The failure of ICP-directed therapy to improve outcome after cardiopulmonary arrest and the commonly observed period of hypoperfusion in the first hours to days after arrest seriously question the application of an intervention with the potential to further reduce CBF.[228,229] Although irreversible ischemic brain damage has never been demonstrated with hyperventilation,[230] these data suggest that it is probably not wise to intentionally or unintentionally hyperventilate patients routinely after arrest, particularly during the period of postischemic hypoperfusion.[132,142,154] Clinical studies suggest that postischemic hyperemia is accompanied by loss or severe attenuation of CBF response to alterations in $Paco_2$ resulting from severe ischemic insult.[139,142] However, some post-resuscitation patients with delayed hyperemia but intact CBF response to $PaCo_2$ have been observed (Figure 62-10).

The traditional approach to cerebral resuscitation has also recommended the use of hyperosmotic agents in the post-arrest period,[231] although similar to hyperventilation, the blanket use of hyperosmotic agents after cardiac arrest is currently not in favor. Again, studies in the setting of cardiopulmonary arrest are lacking. In dogs subjected to 6 minutes of global ischemia, mannitol (2 g/kg) further reduced CBF during the postischemic hypoperfusion phase.[232] This unwanted effect of mannitol likely represents a result of dehydration because with more conventional doses, decreased blood viscosity after mannitol administration lowers cerebral blood volume but maintains

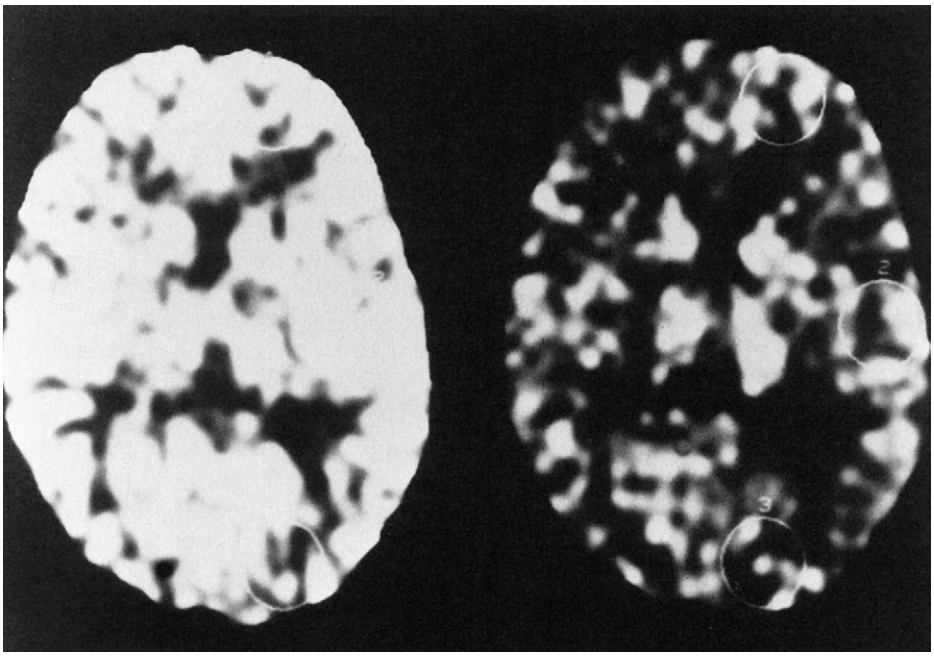

Figure 62–10. Stable-xenon computed tomography (CT) cerebral blood flow study in a comatose 6-year-old 3 days after cold-water submersion accident with asphyxial cardiorespiratory arrest. Delayed CBF hyperemia is represented as high-density white areas through the CT brain section shown on the left ($PaCO_2$ ~40 mm Hg). Flows (calculated from this scan) are in excess of 100 mL/100 g/min throughout the brain. Normal values are ~60 to 70 mL/100 g/min. Despite diffuse hyperemia, CBF reactivity to changes in $Paco_2$ remain intact. CBF values ranged from 50 to 60 mL/100 g/min *(right)* in areas sampled when $Paco_2$ was reduced to 29 mm Hg with hyperventilation. Six months after the arrest, the child was moderately disabled but not in a vegetative state.

CBF.[233] A few anecdotal reports in support of the use of albumin as an osmotic agent after cardiac arrest exist,[234,235] supported by several more recent experimental studies in models of global ischemia.[236] Administration of hypertonic saline improves myocardial blood flow and survival versus standard resuscitation after VF in pigs.[237] These studies suggest that clinical trials examining the effect of hypertonic solutions on outcome after cardiopulmonary arrest are warranted.

In clinical practice, patients are encountered who have been successfully resuscitated from an arrest of unknown etiology, have a clinical history suggestive of trauma, or demonstrate focal pupillary findings. In this setting it is appropriate to hyperventilate and/or to administer mannitol until CT and clinical examination confirm the absence of trauma or a mass lesion.

Supportive Care in the Intensive Care Unit

A hypothetical algorithm for the management of infants and children after cardiopulmonary arrest is provided in Figure 62-11. In addition to maintenance of normal ventilation, arterial oxygenation, and blood pressure, several other aspects of supportive care are important to discuss because suboptimal treatment might adversely affect outcome.

Although transient hyperglycemia commonly occurs after resuscitation from cardiac arrest,[238] the optimal therapy or need for controlling blood glucose after resuscitation has not been established. Current recommendations are for the use of glucose containing solutions during newborn resuscitations[239] because of evidence that hypoglycemia has synergistic deleterious effects coupled with perinatal asphyxia.[240] Glucose containing solutions are generally avoided in the resuscitation of the older child, given the association between hyperglycemia and poorer outcome after near-drowning and TBI in pediatric patients.[141,241] Although a cause and effect relationship between hyperglycemia and outcome in humans has not been established, it is curious to note that in one of the clinical trials showing beneficial effects of hypothermia in adults after cardiac arrest, hyperglycemia was associated with hypothermic treatment.[5] However, reports of tight glucose control versus standard care in adults with VF arrest showed no difference in outcome.[242] The optimal resuscitation fluid has not been established, particularly in pediatric patients beyond the

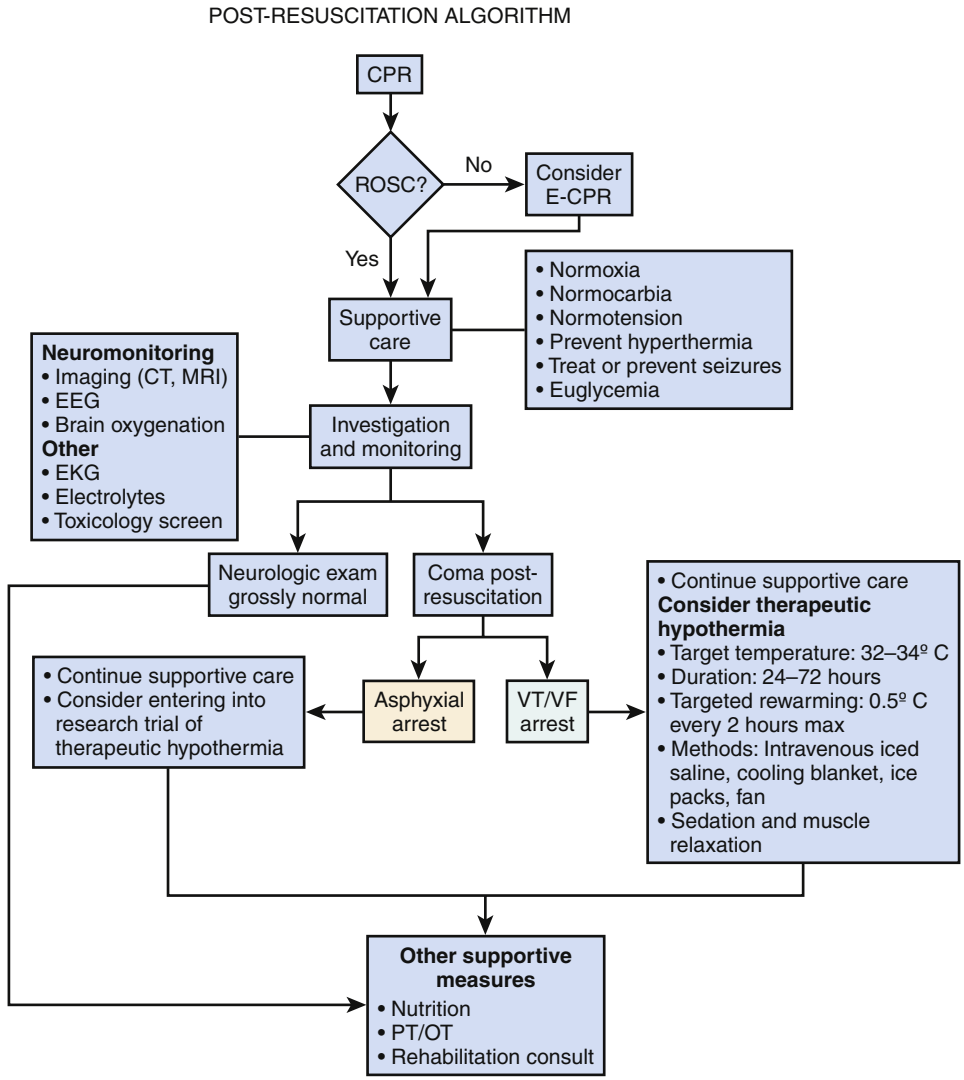

Figure 62–11. A hypothetical algorithm for the management of infants, children, and adolescents after cardiopulmonary arrest.

neonatal period and before adolescence, but is likely to be age- and perhaps mechanism-dependent.

Although the optimal cerebral perfusion pattern for neuronal recovery remains to be defined,[231] blood pressure fluctuations, both high and low, adversely affect outcome. In their classic study of the neuropathology of systemic circulatory arrest in immature monkeys, Miller and Myers[197] found that systolic blood pressures at or below 50 mm Hg during the reperfusion period had devastating effects on survival and neuropathology. This occurred even when the ischemic time was less than the 12-minute minimum that caused brain injury in their model. In contrast, Bleyaert et al.[243] showed that intermittent episodes of hypertension (mean atrial pressure 150 to 190 mm Hg) induced with norepinephrine during the first 24 hours after 16 minutes of global brain ischemia in monkeys worsened neurologic outcome. A beneficial effect of transient hypertension during the immediate postresuscitation period has been suggested,[8] hypothesizing that this improves flow in areas with microvascular sludging. Safar et al.[153] suggested that transient hypertension was beneficial after cardiac arrest in dogs. However, it was applied as part of a multifaceted treatment protocol and its specific benefit remains controversial.

While seizures may be seen in 30% to 50% of children after cardiac arrest, the use of prophylactic antiepileptics is also controversial. A recent prospective study showed that 9 of 19 children who received therapeutic hypothermia and continuous EEG monitoring had seizures, many occurring near or during the rewarming period.[244] A small case series in children surviving cardiac arrest observed how a seven-channel EEG test evolved from the first few hours to days after resuscitation.[245] EEGs were grouped into normal, impaired, grossly impaired, and "death of the brain," and the authors posited that the first EEG may not be valid for outcome prediction. The independent association between poor outcome and the presence and severity of seizures after birth asphyxia is better established.[246] There is strong rationale for treating clinical seizures postarrest; however, whether or not to aggressively treat subclinical seizures and/or use antiepileptics prophylactically remains to be determined.

Current and Novel Therapies

Postresuscitative Hypothermia

The effectiveness of hypothermia as a cerebral protective intervention (i.e., prearrest) is unquestioned. The beneficial effects of hypothermia applied immediately before and during cardiopulmonary arrest are also clearly demonstrated by the clinical experience with cold-water submersion (near-drowning) accident victims.[161] By contrast, complications from the use of moderate hypothermia (30° to 34° C) postarrest and the apparent lack of a beneficial effect led to the abandonment of its routine application in the 1980s.[247] In the last decade, however, two independent randomized clinical trials in adults remaining comatose after resuscitation from ventricular-arrhythmia induced cardiac arrest showed a beneficial effect of mild (30° to 34° C) whole-body hypothermia.[4,5] These studies prompted the International Liaison Committee on Resuscitation to recommend 12 to 24 hours of mild hypothermia (34° C) for adult victims of VF or VT cardiac arrest.[248]

Although hypothermia after cardiac arrest has relatively recently been recommended, therapeutic hypothermia has been used to treat acute brain injury for over a century.[249] Classically, the beneficial effect of hypothermia was thought to be primarily related to a reduction in oxidative metabolism. Rosomoff and Holaday demonstrated that with each decrement of 1° C, brain oxidative metabolism slows by 6.7%,[250] a finding also seen in immature rats.[251] Moderate hypothermia (31° C) during neonatal hypoxia-ischemia maintains brain glucose and ATP concentration and reduces lactate production compared with normothermia (37° C) or mild hypothermic (34° C).[251] Taken together with the well-documented effects of hypothermia on neurologic outcome in experimental models, at least a partial contribution of the effect of hypothermia on cellular energetics in affording neuroprotection after cardiac arrest is supported. However, given that mild hypothermia, which does not significantly lower oxygen consumption, provides some degree of neuroprotection, it seems more likely that hypothermia affects multiple mechanisms that influence outcome after cardiac arrest. These mechanisms include, but are not limited to, excitotoxicity, calcium fluxes, oxidative stress, and inflammation.[252]

Although the composition of mechanisms by which hypothermia confers neuroprotection after cardiopulmonary arrest is still under debate, numerous experimental studies support further preclinical and clinical studies designed to optimize its application in humans. For instance, both applied mild hypothermia, reducing temperature by as little as 2° C,[253] and delayed spontaneous hypothermia[254] reduce neuronal death seen after cerebral ischemia in rats. Leonov et al.[255] reported improved neurologic recovery in dogs subjected to ice-water immersion of the cranium beginning 3 minutes after the onset of 12.5 minutes VF arrest, using CPB to maintain core temperature at 34° C for 1 hour. In this same canine VF arrest model, mild (34° C) or moderate (30° C) hypothermia was found to be protective whereas deep (15° C) hypothermia worsened cerebral and cardiac outcome.[256] Relevant to pediatric cardiopulmonary arrest, posttreatment with brief (1 hour) and prolonged (24 hour) hypothermia improved neurologic outcome in a juvenile rat model and piglet model of asphyxial cardiac arrest, respectively.[156,257]

Raising the question as to the need for further clinical trials in pediatric cardiopulmonary arrest in the era of contemporary intensive care, are the two multicenter, randomized trials demonstrating beneficial effects of hypothermia after cardiac arrest in adult patients.[4,5] In the European study by the Hypothermia After Cardiac Arrest Study Group, 137 of 275 patients were assigned to the hypothermic group. Mild hypothermia (32° to 34° C) was instituted with a median interval to target temperature of 105 minutes after ROSC. Patients were maintained at target temperature for 24 hours. Passive rewarming to a temperature above 36° C occurred over a median of 8 hours. Mortality rate at 6 months after arrest was 41% in the hypothermic group compared with 55% in the control group. The hypothermic group also had more patients with better neurologic outcome assessed by the cerebral performance category (55% vs. 39% in the control group). In the Australian study by Bernard et al.,[5] cooling was initiated in 77 patients in the field after ROSC. Mild hypothermia (33° C) was maintained for 12 hours, followed by active rewarming over 6 hours. Improved survival to discharge was observed in patients in the hypothermic group compared with patients in the normothermic group (49% vs. 26%). Although somewhat different from a pathophysiologic standpoint, studies in neonates at risk for HIE from birth asphyxia have similarly shown that local head or whole-body mild hypothermia applied for 72 hours improves survival and neurologic outcome.[2,3,258]

The main question is whether or not hypothermia will benefit infants (outside the neonatal period) and children with asphyxial cardiac arrest? Lesser questions and a few caveats remain. For instance, the timing, duration and degree of hypothermia warrant further optimization, as well as which patients stand to benefit from treatment. Extrapolating from experimental studies, hypothermia should be initiated as soon as possible after resuscitation. However, even when delayed for a few hours, mild hypothermia has been shown to be beneficial in animal models of cardiac arrest.[254] Consequently, prehospital induction of hypothermia is being implemented in a few centers for emergency services, but barriers exist for its implementation in this setting.[259] Consideration should be paid to proper monitoring of transport patients undergoing hypothermia to prevent overcooling and other known side effects of cooling such as fluid and electrolyte depletion.[260] Current guidelines recommend a duration of 12 to 24 hours of moderate (32° C to 34° C) hypothermia for adult victims of cardiac arrest instituted as quickly as possible.[248] While this duration and degree of hypothermia does not appear to have any untoward effects, more profound depth and duration of hypothermia (28° to 32° C) increase the risk for complications such as arrhythmias, coagulopathy, and infection.[261] Intra-arrest cooling is more neuroprotective than postresuscitative hypothermia in experimental models and may also improve rates of ROSC.[262,263]

Other important issues include the method and rate of cooling. In both the European and Australian studies, mild hypothermia was achieved by surface cooling over a period of hours. Other modalities that achieve target temperatures more rapidly deserve further investigation, such as peritoneal lavage, venovenous or arteriovenous bypass, or novel internal cooling devices.[264,265] There are important differences in cooling rate and precision of temperature maintenance found in cooling devices and also in different patient populations.[266-268] Studies in adults and children demonstrate that caregivers must be cognizant of overcooling below target temperature.[269,270] Bernard et al.[271] reported that administering a bolus of 30 mL/kg of ice-cold (4° C) lactated Ringers solution intravenously safely and effectively decreased core temperature from 35.5° C to 33.8° C in 22 adult patients after cardiac arrest. In a group of healthy volunteers, mild hypothermia (34.9° to 35.5° C) was attained after 40 mL/kg of ice-cold (4° C) normal saline was infused through an antecubital vein.[272] This method of core cooling might be the fastest, most practical way of inducing hypothermia in the field immediately after ROSC. Rapid rewarming and hyperthermia[273,274] should be avoided, and based on available data, active rewarming of patients after cardiac arrest that present with mild-moderate spontaneous hypothermia (33° C-35° C), should be discouraged.

Finally, the efficacy of hypothermia for neuroprotection in neonates with birth asphyxia and in adults with VF arrest prompted some clinicians to treat pediatric victims of asphyxial or arrhythmia-induced cardiac arrest with hypothermia.[275] Two retrospective studies found that clinicians were applying hypothermia to patients with historically poor outcomes—out-of-hospital and unwitnessed arrests that required multiple doses of epinephrine for ROSC.[270,276] Whether or not hypothermia is beneficial, detrimental or has no impact in pediatric cardiac arrest remains to be determined. Currently, a multicenter, randomized prospective trial is underway in the United States (Therapeutic Hypothermia after Pediatric Cardiac Arrest; THAPCA).

Inhibition of Postischemic Excitotoxicity

The observation in animal models that hypermetabolism accompanies postischemic hypoperfusion formed the basis for early clinical cerebroprotective strategies in the postarrest setting. Therapies directed at attenuating active cerebral metabolism ($CMRO_2$ resulting from synaptic transmission) were applied in the hope of reducing this secondary insult of hypoperfusion plus hypermetabolism. The cerebral protective effects of interventions that decrease cerebral metabolic rate *before* the onset of ischemia, such as barbiturates and hypothermia, are well established and clinically important.[277,278] The selective inhibitory effect of barbiturates on active $CMRO_2$ was particularly attractive. However, therapeutic reductions in brain metabolism when applied *after* the insult, as in the "HYPER" therapy of the 1970 and 1980s, did not improve outcome.[247,279] This may have been the result of the relative lack of post-arrest hypermetabolism in human beings.[138] In addition, adverse hemodynamic consequences of barbiturates and the ill effects of sustained hypothermia on immune function and blood rheology may have counteracted any beneficial effects.

Death of selectively vulnerable neurons is mediated by local release of excitatory neurotransmitters with hypermetabolism and calcium accumulation. This has led to attempts to attenuate postischemic excitotoxicity more selectively by administering specific receptor antagonists. The failure of barbiturates to block NMDA-mediated excitotoxicity in vitro emphasized the need to test more specific agents. Many animal models of focal and global brain ischemia have been used to test the efficacy of both competitive and noncompetitive NMDA receptor antagonists. Most studies have demonstrated beneficial effects on histological severity of ischemic damage (especially in the hippocampus) and several have shown benefits in survival.[280] After asphyxial arrest in piglets, alterations in NMDA receptor potentiation within the striatum may participate in striatal neuron degeneration.[281] An important consideration is the finding that beneficial effects of NMDA antagonists in the earlier rodent models of ischemia may have been related to mild systemic hypothermia induced by a central effect of these agents.[282] Blockade of non-NMDA receptors (i.e., AMPA and kainate receptors) with selective receptor-antagonists have shown the most consistent prevention of delayed neuronal cell loss in the hippocampal CA_1 region in models of global cerebral ischemia. However, a report by Brambrink et al.[283] suggests that treatment with the AMPA antagonist NBQX in piglets worsened outcome after asphyxia. The exact role of excitatory neurotransmitter receptor and sodium channel blockade in both the selectively vulnerable zones and other areas of the brain remain to be more clearly defined,[284] particularly in established models of cardiac arrest. Clinical trials using anti-excitotoxic strategies to treat adult stroke patients have been terminated for both futility and the possibility of adverse side effects.[285]

Voltage-Operated Calcium Channel Antagonists

Calcium accumulation in neurons and release of stored intracellular calcium are pivotal events leading to irreversible cellular damage during the reperfusion phase after an ischemic insult. Calcium accumulation occurs via receptor-operated channels such as the NMDA receptor-activated channels,

voltage-operated calcium channels, nonspecific membrane channels, and release of intracellular calcium via the inositol second-messenger pathway. Conflicting results have been obtained regarding the ability of the voltage-operated calcium channel antagonists (lidoflazine, nimodipine, nicardipine) to attenuate calcium accumulation in neurons after ischemia.[286] The contribution of the voltage-gated channels to postischemic calcium accumulation is apparently less than that of the agonist-operated channels in selectively vulnerable zones.

After encouraging animal investigations, Abramson and colleagues conducted a multicenter study of the effect of lidoflazine treatment in a blinded, randomized protocol in 505 adult patients after cardiopulmonary arrest. Lidoflazine did not significantly improve neurologic outcome, which was normal in about 12% of patients.[219] Nimodipine increased CBF in humans at 3 hours after cardiac arrest in a blinded, randomized study.[287] However, a subsequent multicenter, placebo-controlled, randomized, double-blind trial of nimodipine after out-of-hospital cardiac arrest in adults failed to demonstrate a beneficial effect on cognitive function in the survivors.[288] Adults suffering a stroke also did not benefit from nimodipine.[152] Although clinical studies of nimodipine in asphyxial arrest have not been done, Ment et al.[198] observed hypotension and decreased CBF with nimodipine in a perinatal asphyxia model.

A limitation of these studies is that they target only one of several redundant pathways contributing to cell death. Thus some investigators argue for trials targeting multiple mechanisms or final common pathways.

Inhibitors of Oxygen Radical Mediated Injury

As previously noted free radicals can damage membrane lipids, cellular proteins/enzymes and DNA. The importance of damage to each brain component and subsequent contribution to triggering or mediating the final pathway of neuronal death remains to be defined. Studies with superoxide dismutase (SOD) to reduce injury from ischemia have met with mixed results.[289,290] Manipulation of glutathione metabolism has also shown some promise.[291,292] Interestingly, females may have more intrinsic antioxidant activity and benefit less from exogenous treatment.[101,293]

Antioxidant enzymes and water-soluble free radicals scavengers do not easily penetrate the blood-brain barrier.[294] As a result, multiple strategies have been devised to modify these agents to improve availability and efficacy in the brain. Conjugation of polyethylene glycol (PEG) to both SOD and catalase improves drug half-life and reduces cerebral damage caused by ischemia.[295] Liposome-encapsulated SOD has also been shown to be beneficial.[296] Analogs of glutathione, YM737 and γ-glutamylcysteine ethyl ester, have been developed to allow for better penetration of the blood-brain barrier and have been shown to reduces brain injury caused by cerebral ischemia, oxidative stress, and trauma, respectively.[297-299] Ascorbic acid has been combined with α-tocopherol to form the compound EPC-K1. EPC-K1 has both protective and resuscitative effects on the brains of gerbils sustaining cerebral ischemia and reperfusion.[277]

Lipid-soluble agents rapidly cross the blood-brain barrier, a beneficial property for cerebral resuscitation. Administration of α-tocopherol after cerebral ischemia reduces ischemic neuronal damage in gerbils.[300] Lipid-soluble compounds termed "Lazaroids" have been developed to reduce iron-dependent lipid peroxidation after cerebral ischemia. The 21-aminosteroid Trilizad (U74006) has been most extensively investigated and is efficacious in reducing brain damage when given before both focal and global cerebral ischemia.[301] Edaravone is a powerful blood brain barrier-permeable free radical scavenger that that reduces lipid and DNA peroxidation after experimental neonatal hypoxic-ischemic injury.[302-304]

Hydroxyl starch-conjugated deferoxamine that penetrates the blood-brain barrier and chelates transitional metals can reduce free radical production and brain injury.[305] An additional mechanisms of action for deferoxamine is activation of hypoxia-inducible factor-1α, a transcription factor activated by hypoxia that upregulates gene expression including erythropoietin.[306,307] α-phenyl-*N*-tert-butyl-nitrone (PBN), a spin trap commonly used for quantitating free radical production may have therapeutic use during ischemia and reperfusion.[308] However, PBN has been shown to paradoxically increase DNA fragmentation in neurons after TBI.[309] The antioxidant Tempol, provides benefit above and beyond deep hypothermia in a dog model of hemorrhagic shock induced cardiac arrest that produces cerebral ischemia.[310] The antioxidant allopurinol has shown promise in newborns with birth asphyxia,[311,312] and thus may warrant testing in pediatric cardiac arrest.

Although hyperbaric oxygen has been shown to reduce histologic damage after transient forebrain ischemia in rodents,[313] two recent clinical studies have shown that resuscitation outcomes are similar between neonates resuscitated with 100% oxygen versus room air[314,315]; however, in one of these studies, the incidence of cerebral palsy was nonsignificantly higher in the group treated with room air compared with the 100% oxygen group (12% vs. 9%, respectively) as well as the incidence of neurologic abnormalities reported (15% vs. 10%, respectively).[315] Increased oxygen concentration administered during resuscitation also appears to increase the degree of oxidative stress[316-318] Therefore the optimal Fio_2 for resuscitating victims of cardiac arrest needs to be further examined.

Multifaceted antioxidant therapeutic strategies have also been used in experimental asphyxial arrest. Cerchiari et al.[133] produced an asphyxial arrest in mature dogs with a 5- to 8-minute period of airway obstruction followed by 7 minutes of cardiac standstill. Dogs treated with deferoxamine and SOD showed improved recovery of SSEPs, but functional neurologic outcome was not evaluated. Rosenberg et al.[319] showed improved CBF and $CMRO_2$ at 2 hours after prolonged hypoxia (without arrest) in newborn lambs pretreated with PEG-SOD and PEG-catalase. The Thiringer group[320] produced asphyxia in fetal lambs by umbilical cord clamping and studied two insults: severe asphyxia (until asystole) or moderate asphyxia (10 minutes). Treatment with the radical-scavenging compounds methionine and mannitol and the calcium antagonist lidoflazine increased survival and improved postischemic CBF. A pilot randomized clinical trial comparing ascorbic acid plus ibuprofen therapy in neonates with birth asphyxia failed to show neurologic benefit.[321] Long-term follow-up studies with antioxidant therapies in asphyxial arrest models and clinical studies are lacking.

Interventions targeting pathways indirectly related to free radical generation may be beneficial for reducing oxidative stress in the brain. Hypothermia reduces lipid peroxidation and maintains endogenous antioxidant activity during reperfusion from global brain ischemia[322] and is a promising

therapy for improving neurologic outcome after cardiac arrest. Acidosis during ischemia increases free radial production[22] and may inactivate endogenous antioxidants[323]; however, the role of buffer therapy is controversial.

Phospholipid-Derived Mediator Manipulation and Antiinflammatory Therapies

Although many avenues exist for manipulation of phospholipid-derived mediator formation after global cerebral ischemia or cardiorespiratory arrest, most studies have focused on the arachidonic acid cascade. Prostaglandins potentiate the effects of excitatory amino acids, and inhibition of this effect may explain the protection afforded by these agents. Similarly, inhibition of superoxide anion synthesis during the metabolism of arachidonic acid also may be an important mechanism for this effect. Alternatively, cyclooxygenase metabolites of arachidonic acid are important regulators of normal CBF, especially in the immature brain,[324] and cyclooxygenase inhibitors increase CBF after global ischemia.[325] Pretreatment with cyclooxygenase inhibitors (indomethacin, piroxicam, diclofenac, or flurbiprofen) before 5 minutes of global brain ischemia in gerbils attenuated selectively vulnerable cell death.[326] In contrast, inhibition of the lipoxygenase pathway did not prevent selectively vulnerable cell death.[327] However, cyclooxygenase inhibitors (indomethacin or diclofenac) are not protective when given before 10 minutes of global ischemia,[328] and indomethacin administration *after* ischemia does not increase CBF,[329] and the effect of resuscitation with cyclooxygenase inhibitors on CBF after cardiorespiratory arrest has not been studied. A limit to the clinical effectiveness of cyclooxygenase inhibitors may be that a burst of cyclooxygenase product formation occurs within seconds of reperfusion.[330] Nevertheless, Kuhn et al.[331] showed improved 24-hour neurologic outcome in dogs treated with ibuprofen after a 6-minute VF arrest. The 46% mortality rate in vehicle-treated dogs after 6 minutes of VF was excessively high, however, and affected outcome scoring. Jastremski et al.[332] retrospectively assessed the impact of steroid use in the 262 patients who did not receive thiopental in the Brain Resuscitation Clinical Trial I. Four groups (no, low-, medium-, or high-dose steroid) were compared. No effect on mortality or neurologic outcome was seen.

Identification of and agents targeting specific cyclooxygenase isoforms has led to a resurgence of investigation in this area. The inducible form of cyclooxygenase is formed after tissue injury (cyclooxygenase II, COX-2).[333] Thus COX-2 may be a more appropriate therapeutic target, if prostanoids or arachidonic acid metabolites play an important role in ischemic brain injury. Currently, their use as a neuro-resuscitative therapy after cardiopulmonary arrest is unsupported.[328,334] However, recent data suggesting that COX-2 is upregulated after asphyxia in neonates[335] support further testing of more specific and safe agents as they are developed.

Futuristic Approaches

Anti–Cell Death Strategies

Apoptosis occurs over days to weeks after injury and thus may represent an especially important therapeutic target in the developing brain.[46,55,63] Pharmacologic caspase inhibitors have been shown to reduce apoptosis in a sex-dependent manner in a model of neonatal hypoxia-ischemia.[48,336] In a model of VF-induced cardiac arrest in adult rats, intracerebroventricular treatment with a relatively selective caspase-3 inhibitor improved neurologic outcome and reduced apoptosis and histological damage compared with vehicle treatment.[337] Taken together, these studies support testing of antiapoptotic strategies in models of pediatric cardiac arrest.

Minocycline is a blood-brain barrier permeable derivative of the antibiotic tetracycline that has anti-inflammatory properties including inhibition of microglia activation and cytokine production, that also inhibits poly(ADP-ribose) polymerase-1 mediated cell death.[338] Minocycline was effective in reducing microglial activation and CA_1 hippocampal neurodegeneration after asphyxial cardiac arrest in juvenile rats.[339] Of note, preliminary clinical studies suggest that minocycline treatment may benefit adults with acute ischemic stroke.[340]

Statins are 3-hydroxy-3methylglutaryl-coenzyme A reductase inhibitors that act on the endothelium to promote NO release, and have potent antiinflammatory and antioxidant properties. Atorvastatin may protect humans from stroke after transient ischemic attacks.[341] Because Atorvastatin and other statins are currently in clinical trials, timely preclinical testing in models of pediatric cardiac arrest appears warranted.

Erythropoietin (EPO) is a glycoprotein hormone that is upregulated after hypoxia-ischemia. In addition to stimulating erythrocyte production, EPO has neuroprotective effects including preservation of endothelium, inhibition of apoptosis, and prevention of cellular swelling mediated by aquaporin 4.[342-344] Clinically, the efficacy of EPO after adult stroke is mixed and complicated by potential adverse effects of EPO such as hypertension and thrombosis, but neonates with birth asphyxia appear to benefit.[345-347] Similar to the other strategies discussed above, urgent preclinical studies in clinically relevant models and timely clinical trials appear warranted.

Neuronal Regeneration and Replacement

Several trophic factors are synthesized by neurons and other parenchymal cells and are critical to cellular maintenance and regeneration. Nerve growth factor,[348] brain-derived neurotrophic factor,[349] and neurotrophin-3[350] have all been shown to be neuroprotective in models of neonatal hypoxia ischemia. Many others, including vascular endothelial growth factor, have been found to be upregulated after cerebral ischemia.[351] D'Cruz et al.[352] found that hypothermia increases brain-derived neurotrophic factor after asphyxial cardiac arrest in adult rats, implicating enhancement of trophic factors as one possible mechanism behind the protective effects of hypothermia seen in this model. Several of these trophic factors are now commercially available. Augmentation of neuronal regeneration either via trophic factor replacement or augmentation via other means after cardiopulmonary arrest is an unexplored area for future research.

Transplantation of specialized cells to improve neurologic outcome after cerebral ischemia is under investigation. Embryonic, mesenchymal, and cord blood stem cells have been tested in various experimental models of brain injury using systemic (intravenous, intraarterial) and local

(intracerebroventricular) delivery.[353-355] Other groups are looking to enhance the natural production of neural stem cells that occurs after insult by supplementing key growth factors or signaling molecules.[356,357] Phase I clinical trials administering mesenchymal stem cells to patients with stroke have begun and early findings are promising.[358]

Extracorporeal Support

As previously suggested, CPB initiated immediately after VF arrest in dogs (with cannulae already in place) improves outcome when compared to standard ACLS-guided resuscitation.[359] CPB produced 64% survival after even 20 minutes of VF arrest, although all dogs were neurologically impaired. This supports the concept that cerebral and coronary perfusion during CPR extends tolerated insult time, although studies with vascular cannulation during resuscitation have not been reported. These studies would be important in light of the difficulty in obtaining this type of vascular access during arrest in children. Nevertheless, extracorporeal support allows control of postarrest blood flow and temperature, and the cardiovascular support provided might allow use of otherwise contraindicated therapies. Chen et al.[360] reported a 32% survival rate in adult patients rescued with extracorporeal membrane oxygenation (ECMO) or "E-CPR" after prolonged cardiac arrest. A strikingly favorable 5.6% incidence of severe neurologic deficit was reported in survivors within this study. Analysis of 682 pediatric patients placed on ECMO during CPR from the Extracorporeal Life Support Organization registry found that overall survival to discharge was 38%, but there were no data on neurologic outcomes for survivors.[361] The number of reported E-CPR cases increased each year. A meta-analysis of studies in children found a 40% survival rate (total 288 patients).[362] Complications were common after E-CPR and the presence of complication(s) increased risk of mortality. These included neurologic complications (27%), renal failure (25%), and sepsis (17%). Given the enormous resources required for quality E-CPR, institutions providing this service may benefit from having guidelines for inclusion and exclusion patient criteria. Obviously, a highly skilled and dedicated team prepared to provide the service at a moment's notice is also required (see also Chapter 53).

A multimodality approach, combining hypothermia with extracorporeal modalities in pediatric patients after cardiopulmonary arrest, particularly refractory or prolonged arrest, appears to be the next logical step. This is not a new concept. In 1984, Dr. Peter Safar and colleagues recommended research into "suspended animation for delayed resuscitation" for situations where conventional resuscitation attempts were not successful. Recently, they reported survival without brain damage after clinical death of 1 to 2 hours in dogs using suspended animation.[363] In their canine exsanguinations-cardiac arrest model, deep hypothermia (10° to 20° C) was induced by infusion of ice-cold saline via abdominal aorta. Postarrest resuscitation and hemodynamic support was provided by CPB. Mild hypothermia was subsequently maintained at 34° C. Using this protocol, they reported good neurologic outcome based on overall performance category score, neurologic deficit score and brain histologic damage score. The histological differences between groups were striking, with little evidence of neuronal damage in dogs treated with the suspended animation strategy (Figure 62-12). The use of CPB allows ROSC after a prolonged down time, as well as control of postarrest blood flow and temperature, providing the cardiovascular support that many patients might require, particularly under conditions of more profound hypothermia. Nagao et al.[364] reported a 92% ROSC in 50 adult patients that failed standard CPR, rescued with CPB followed by mild hypothermia (34° C) for a minimum of 2 days. These investigators also reported "good outcome" in 12 of the 23 long-term survivors. In the study by Chen et al.,[360] hypothermia was not used with ECMO. Interestingly, much of the mortality was attributed to multiple-organ failure (MOF) in this study. After a prolonged cardiopulmonary arrest, MOF is a common finding, sometimes ignored as the focus is generally on neurologic status. Treatment of MOF will likely become necessary in the

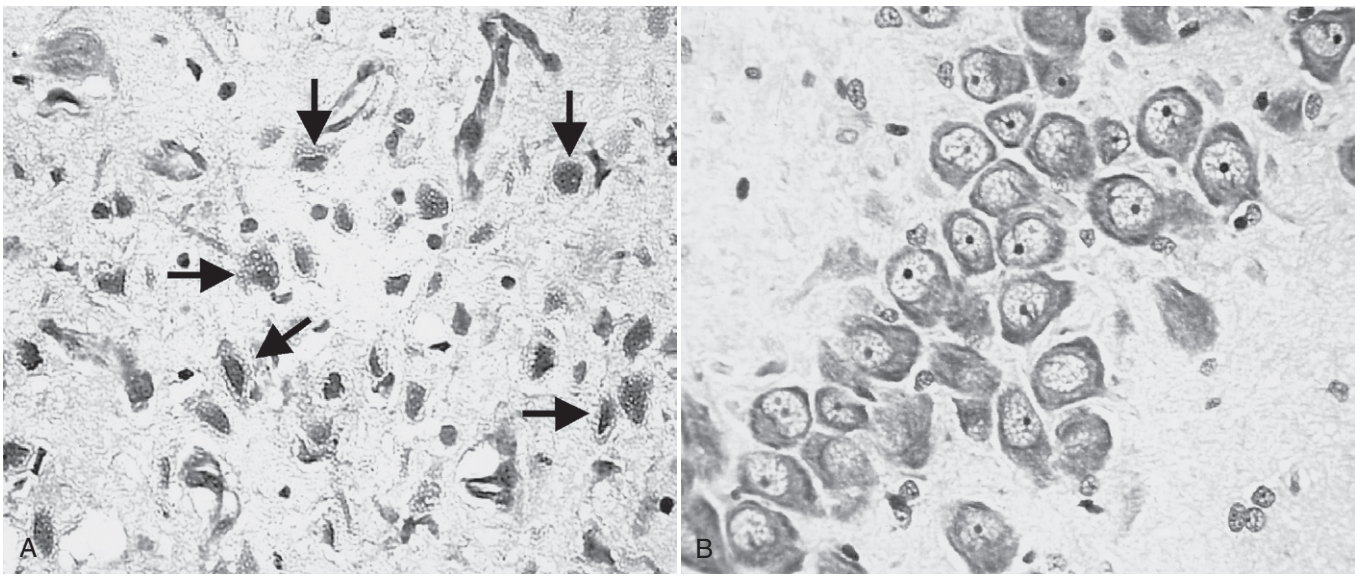

Figure 62–12. Using a "suspended animation" paradigm envisioned by Dr. Peter Safar, neuropathologic damage typically produced by 60 minutes of no flow is dramatically reduced. The hippocampal region of dogs treated without (**A**) versus with hypothermic intraaortic flush (**B**) are shown. Note extensive neuronal damage with evidence of DNA fragmentation (*arrows*) in **A**.

post-resuscitation phase, particularly as effective cerebroprotective strategies are developed.

For patients at risk for the development of HIE with MOF and coagulopathy, plasma exchange might be beneficial. Plasma exchange has been shown to reverse sepsis-induced MOF and effectively correct coagulopathy be removing cytokines and inflammatory mediators and restoring clotting homeostasis.[365] Granted, further clinical studies are needed; however, combining CPB, mild hypothermia, and plasma exchange would provide maximum therapeutic support after cardiopulmonary arrest, and all of these therapies are clinically utilized in pediatric patients. This concept of "therapeutic hibernation and plasma exchange" (HIBERPLEX) was introduced for recalcitrant shock in the pediatric population.[366] This approach could potentially provide neuroprotection, hemodynamic support, and reversal of MOF, thus targeting the major management challenges after prolonged cardiopulmonary arrest.

Summary

The social and economic impact of children left with persistent neurologic injury after cardiopulmonary arrest is unacceptable. Preventive approaches to this problem are unlikely to reduce significantly the occurrence of these multifactorial and largely unanticipated events. However, it is worthwhile for the general public to become more knowledgeable of child CPR and safety measures (e.g., pool and road safety), enormous benefit of quality CPR,[176] and to consider implementation of systems that recognize a hospitalized child in distress before an arrest is imminent, such as pediatric medical emergency teams.[367] Improvements in prognostication after cardiopulmonary arrest are on the horizon with a more concerted application of existing methods and new techniques. The successful application of novel brain-oriented therapeutic approaches is somewhat more speculative, but is likely to require intervention beginning in the prehospital setting or emergency department. Improved, pathophysiologic guided stratification of post-arrest patients is essential to determine which patients have resuscitable insults and, with optimal supportive care and prevention of secondary neuronal deterioration, potential for good rather than vegetative outcome. Unfortunately, this group is unlikely to include most patients with prolonged asphyxial arrest and in any single institution represents a small number of cases per year. Biochemically and physiologically guided, multifaceted pharmacological and mechanical approaches will almost certainly be required, with their application based on the temporal sequence of pathological events.

Stroke and Intracerebral Hemorrhage

Stuart Friess and Rebecca Ichord

PEARLS

- Childhood stroke encompasses a wide spectrum of disease that can be categorized into three groups: arterial ischemic stroke, cerebral venous sinus thrombosis, and intracranial hemorrhage.
- The adult classification of arterial ischemic stroke (AIS), which is based on mechanism, is not applicable to childhood stroke. Dividing AIS into broad pathophysiologic groups of cardiac-aortic embolism, vascular disease, and coagulation disorders is more appropriate.
- Regardless of the etiology of AIS, management should focus on optimizing perfusion and oxygenation, neuroprotection (minimizing the ischemic core and rescuing the penumbra), rehabilitation, and prevention of recurrence.
- In children who have had a stroke, endotracheal intubation and mechanical ventilation should be performed in patients with severe hypoxemia, loss of respiratory drive, or respiratory insufficiency, or to facilitate advanced neuroimaging.

Stroke and intracerebral hemorrhage are significant causes of morbidity and mortality in children. In recent years, childhood stroke has become more commonly recognized. Because of the heterogeneous etiologies, risk factors, and presentations in children, the diagnosis, treatment, and management of stroke present many challenges compared with the adult population. Previous studies have found the incidence of pediatric stroke to be between 2.3 and 13 per 100,000 children per year.[1-4] Boys have been observed to be at higher risk than girls, and children of African descent are at higher risk than white or Asian children.[5] Peak incidence of stroke and intracerebral hemorrhage occurs during the first year of life except in the case of subarachnoid hemorrhage, which peaks in adolescence.[5] Childhood stroke encompasses a wide spectrum of disease and can be categorized into three groups: arterial ischemic stroke, cerebral venous sinus thrombosis, and intracranial hemorrhage. The pediatric intensivist must be familiar with the various etiologies of childhood stroke and be facile in integrating a complete diagnostic and treatment approach to prevent further brain injury and minimize morbidity and mortality.

Arterial Ischemic Stroke

Arterial ischemic stroke (AIS) can be defined as an acute-onset neurologic deficit conforming to an arterial distribution associated with infarction in a vascular territory corresponding to the clinical deficit. AIS can be the result of a myriad of mechanisms and risk factors, and the presentation of pediatric AIS can be subtle. Pediatric AIS requires extensive diagnostic investigation to determine the cause, and in most thoroughly investigated cases outside the neonatal period, one or more risk factors can be identified.

Pathophysiology

The pathophysiology of ischemic stroke is initiated when circulating blood supply to the brain is decreased or absent, resulting in the deprivation of necessary substrates for metabolism (see also Chapter 62). The brain does not have extensive glucose stores, which results in a fairly rapid pathologic cascade after the onset of ischemia.[6] Brain tissue has limited capacity for anaerobic metabolism, which exacerbates substrate deprivation. The decrease in arterial blood supply is the result of thrombus formation, embolus, arterial stenosis, or in many cases a combination of these factors.

The extent and progression of ischemic injury is related to a multitude of factors (Box 63-1). Cerebral perfusion pressure plays a major role, and the maintenance of a steady and adequate cerebral perfusion pressure is critical to minimizing the extent of ischemia. The extent of collateral circulation in the area of affected brain and the duration of the ischemia influences outcome as well. Ischemia of shorter duration or slower onset is better tolerated by the brain, and regions with extensive collateral circulation are at less risk for infarction. Hypercoagulable states can increase the rate of progression and size of thrombus formation, and elevated temperature following brain injury has been associated with poorer outcomes in animal models and humans.[7-10] Disturbances in serum glucose levels (hyperglycemia or hypoglycemia) can increase the extent of ischemic injury.[11]

Cerebral blood flow (CBF) is coupled to the cerebral metabolic rate, which changes with age in the immature brain. Infants have similar CBF rates compared with adults (50 to 60 mL/100 g brain tissue/min). CBF rises in children and peaks between the ages of 3 to 8 years at 80 mL/100 g/min.[12]

It then decreases to the adult level by mid to late adolescence. In response to ischemia, cerebral autoregulation mechanisms increase CBF by local vasodilation (in collateral vessels), and brain tissue responds by increasing the oxygen extraction rate.

Following a decrease in CBF, energy failure at the cellular level leads to a phase of neuronal hyperexcitability. The loss of membrane ion gradients and the failure of glutamate reuptake with widespread neuronal depolarization results in further increases in extracellular glutamate and excitotoxicity. Excitotoxicity results in a cascade of oxidative stress, failure of cellular systems, and ultimately cell death. The perfusion threshold below which infarction occurs has been reported to be 5 to 8 mL/100 g/min within the first few hours of onset.[13,14] In regions of focal ischemia, the central area of lowest perfusion is defined as the ischemic core and is beyond therapeutic rescue when ischemia is of sufficient severity and duration to cause cell death. Surrounding the ischemic core is an area of decreased perfusion above the threshold of ion pump failure and irreversible damage but below the threshold of functional impairment, known as the ischemic penumbra, first described in experimental models.[14] The ischemic penumbra varies with duration of the interruption of blood flow, and the threshold for infarction in the penumbra rises with time, which emphasizes the need for timely intervention to promote recovery. Interventions that promptly restore flow at the site of vascular occlusion and optimize reperfusion of the ischemic penumbra are currently the most effective therapies for stroke in adults.[15]

Epidemiology

The incidence of pediatric AIS has been estimated at two to three per 100,000 children per year in the United States, but it has been reported to be as high as 13 per 100,000 children in France.[1,4,5,16]

A classification system based on mechanism has been developed for adult AIS, but this system is not applicable for neonatal strokes or for the vast majority of childhood strokes. An alternative conceptual framework for classifying stroke in childhood begins by separating neonatal from childhood stroke, and then subdividing the causes into broad pathophysiologic groups: cardiac-aortic embolism, vascular disease, and coagulation disorders (Figure 63-1). About half of children with first-time stroke have conditions known to be associated with risk of stroke (symptomatic AIS), and about half are previously healthy children at the time of stroke presentation (cryptogenic stroke). After completion of a comprehensive risk factor evaluation, 80% to 90% of children are found to have at least one risk factor, and many children have multiple risk factors.[18,19] Risk factors for neonatal stroke differ significantly from those for childhood stroke. For a detailed review of neonatal stroke, including a discussion of definitions and risk factors, the reader is referred to a recently published summary of a National Institute of Health workshop on this topic.[18] The risk of recurrent AIS in children has been reported to be from 6% to 14%.[19,20] In a study from the United Kingdom, moyamoya syndrome and low birth weight

were found to be the most important predictors of recurrent pediatric stoke.[19]

Etiologies and Risk Factors

Sickle Cell Disease

Incidence of stroke in children with sickle cell disease (SCD) has been reported to be 200 times higher than in the general pediatric population.[21] High blood flow velocity on transcranial Doppler (TCD), silent brain infarction, low hemoglobin, hypertension, and history of acute chest syndrome all have been identified as stroke risk factors in children with SCD.[22] A familial predisposition to stroke in SCD also has been reported.[23] Approximately 20% of patients will have silent brain infarcts on magnetic resonance imaging (MRI). Stroke in SCD is associated with the development of large vessel stenosis in the middle cerebral or distal internal carotid artery (moyamoya syndrome), the mechanism of which is unclear (also see Chapter 84).[24]

Moyamoya Disease and Syndrome

Moyamoya syndrome is a condition characterized by progressive stenosis of the distal intracranial internal carotid arteries and their proximal branches that predisposes patients to stroke. It was first described in 1957 in Japan. Moyamoya is a term in Japanese meaning "something hazy or a puff of smoke," representing the characteristic finding on angiography (Figure 63-2).[25,26] Patients with no known associated comorbidity are categorized as having moyamoya disease. The highest incidence has been reported in Japan at three cases per 100,000 children, and much lower rates have been reported in Europe and the United States (0.086/100,000).[27,28] Moyamoya syndrome in children usually presents as ischemic stroke or transient ischemic attacks. Ischemic strokes can be repetitive and are commonly found in watershed territories. Presentations can vary from infrequent, intermittent attacks to a rapid and fulminant course.

Arterial Dissection

A spontaneous or traumatic tear in the intimal layer of an arterial vessel can lead to arterial occlusion and artery-to-artery embolism. Arterial dissection is a significant cause of pediatric stroke and has been reported to be the cause for 7.5% of ischemic strokes.[29] Traumatic vertebral artery dissections in children are usually the result of sports injuries, and symptoms may appear quickly or can be delayed up to days (Figure 63-3). In many cases, the precipitating injury does not seem severe enough to result in vertebral artery dissection. Recurrence in cases of arterial dissection is highest in the first 4 to 6 weeks after the initial presentation, and thereafter it falls to less than 1% per year. Factors associated with recurrence are incompletely understood but may include predisposing conditions such as pro-thrombotic conditions, fibromuscular dysplasia, Marfan syndrome, autosomal-dominant polycystic kidney disease, coarctation of the aorta, and Ehlers-Danlos syndrome type IV.[30]

Congenital and Acquired Heart Disease

Among children with cardioembolic causes for stroke, those with complex congenital heart disease with right-to-left shunts are at greatest risk, but stroke has been observed in children with other heart defects. Children with uncorrected congenital heart disease are at highest risk, and emboli can arise at the atrial, ventricular, and arterial level. Prosthetic heart valves increase the risk for endocarditis and stroke. Patients with left-sided endocarditis have neurologic complications rates of 20% to 40%, with half of these events being strokes.[31] Cardiac surgery and catheterization also can be complicated by thromboembolic stroke (Figure 63-4). Stroke secondary to cardiac arrhythmias or acute myocarditis is uncommon in children but has been reported. Cardiomyopathy and congestive heart failure place children at higher risk for stroke and are associated with muscular dystrophy, mitochondrial disorders, and other metabolic disorders.

Focal and "Transient" Cerebral Arteriopathy

Focal cerebral arteriopathy refers to a group of childhood cerebral arteriopathies of uncertain cause; they manifest most typically as arterial ischemic stroke in the middle cerebral artery territory and are associated with findings on vascular imaging of focal stenosis or occlusion in the proximal middle cerebral artery.[32] The natural history is variable, with spontaneous remission and normalization of the vessel in some children, stable chronic partial occlusion in others, and progressive stenosis involving other areas of the circle of Willis in other children. In some children there is a period of progression over months to a year and eventual stabilization, often referred to as "transient cerebral arteriopathy."[33] This pattern is typical of that seen in children with stroke and vasculopathy attributed to prior varicella (postvaricella vasculopathy),[33] and it is among the childhood arteriopathies associated with significant risk of recurrence.[3]

Vasculitis

Vasculitis of intracranial vessels in children can be due various etiologies and affect a wide variety of vessel sizes (Box 63-2). Cerebral vasculitis should be considered in children with stroke and fever, elevated markers of inflammation (c-reactive protein or sedimentation rate), skin findings, or renal dysfunction. Primary vasculitis of the intracranial vessels in children is rare and usually presents with headache and altered mental status but without elevation in the sedimentation rate. Intracranial infections can cause a secondary vasculitis leading to AIS. Bacterial meningitis, mycotic infections, and tuberculous meningitis all have been associated with stroke. Lyme disease and rickettsial infections can involve intracranial vessels, leading to stroke. Varicella infections have been reported to cause a cerebral vasculopathy in children.[34] Takayasu's arteritis should be considered in older children, especially girls of Asian descent. Patients with systemic lupus erythematosus are at higher risk for stroke. Direct intracranial vasculitis in persons with systemic lupus erythematosus is rare, but stroke also can occur as a result of embolism from Libman-Sacks endocarditis and a hypercoagulable state (antiphospholipid antibodies) (also see Chapter 98).[35]

Hypercoagulable States

Various pro-thrombotic states are common in children with stroke, and often are combined with other major stroke risk factors such as congenital heart disease (Box 63-3).[36] Elevated lipoprotein a and deficiencies in antithrombin III, protein C, and protein S have been identified in children with AIS.

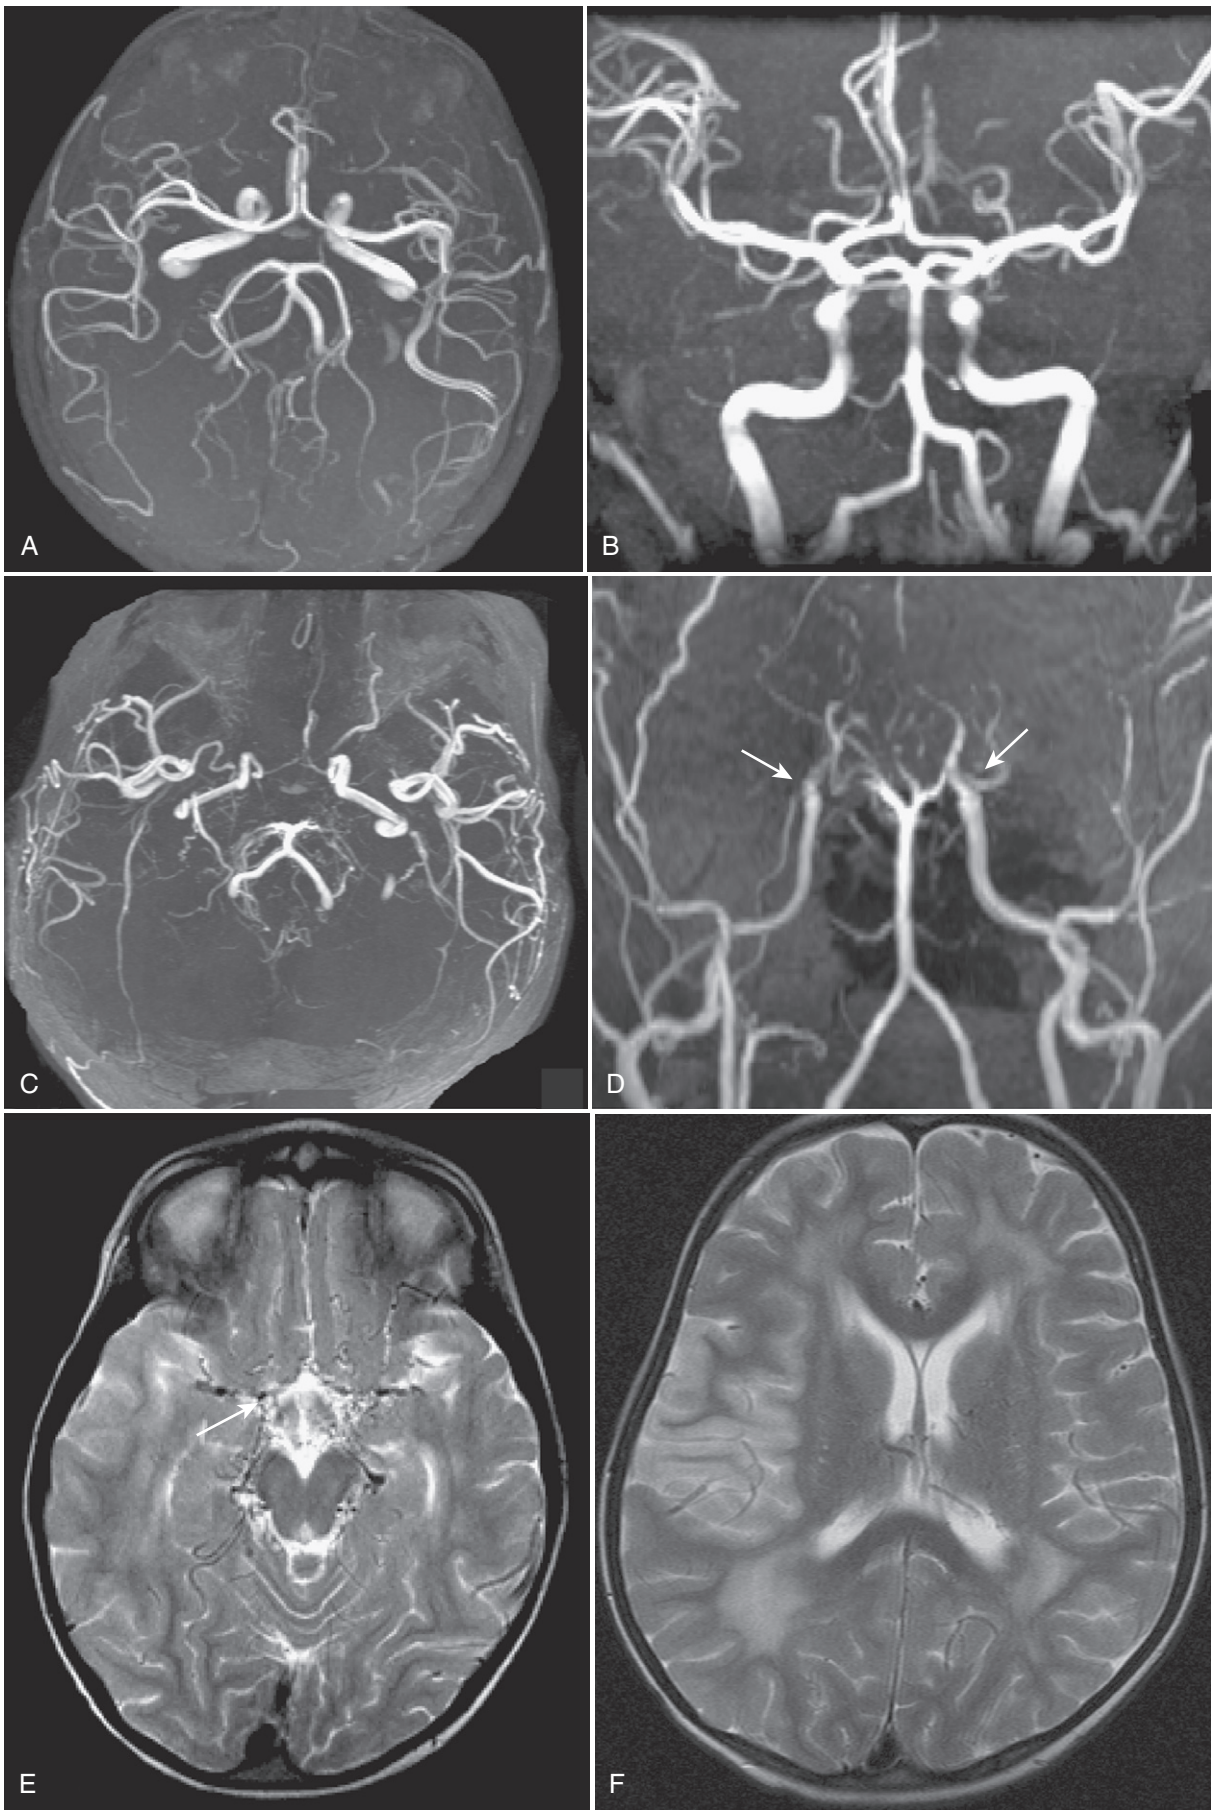

Figure 63–2. Normal MR angiogram, axial (**A**) and coronal (**B**). Bilateral terminal carotid artery occlusion (**C, D,** *arrows*) in a 4-year-old boy presenting with acute left hemiparesis, typical of advanced moyamoya disease. T2 sequence shows multiple small collaterals in basal cisterns (**E**, *arrow*) and large acute right middle cerebral artery infarct and chronic white matter ischemic changes (**F**).

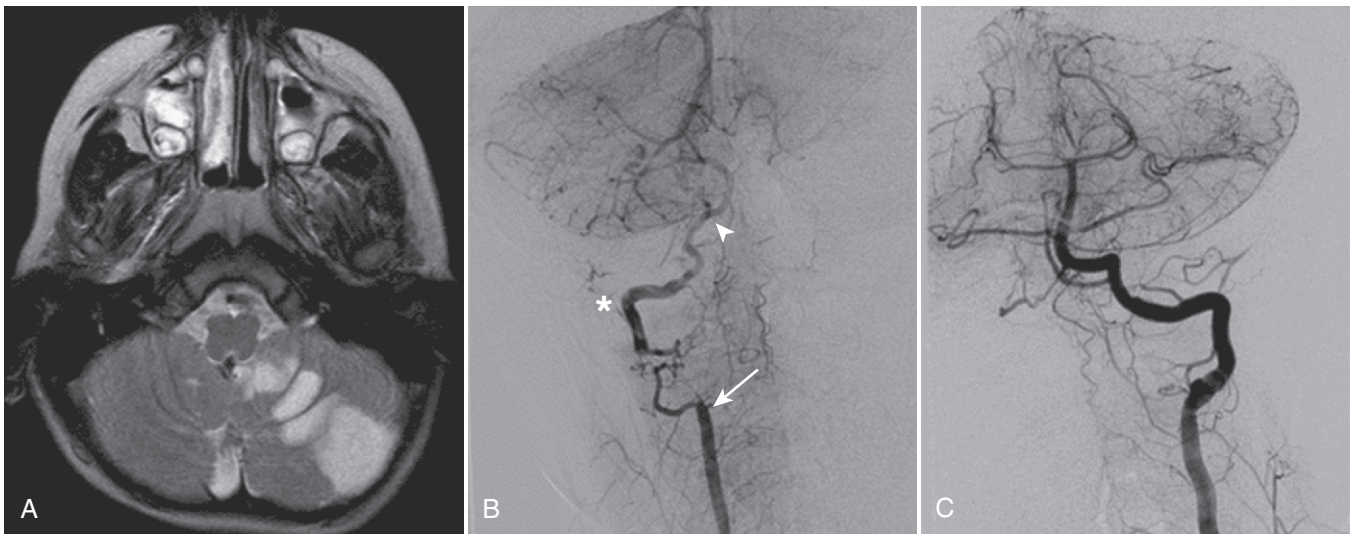

Figure 63–3. Sudden onset of headache, ataxia, and complaint of dizziness developed in a healthy 3-year-old boy after a fall from a slow-moving vehicle. One week later MRI showed cerebellar stroke (**A**). Angiogram shows right cervical vertebral artery occlusion (**B**, *arrow*) with distal reconstitution (*) from collaterals, reocclusion at junction with basilar artery (*arrowhead*). Compare to normal left vertebral artery (**C**).

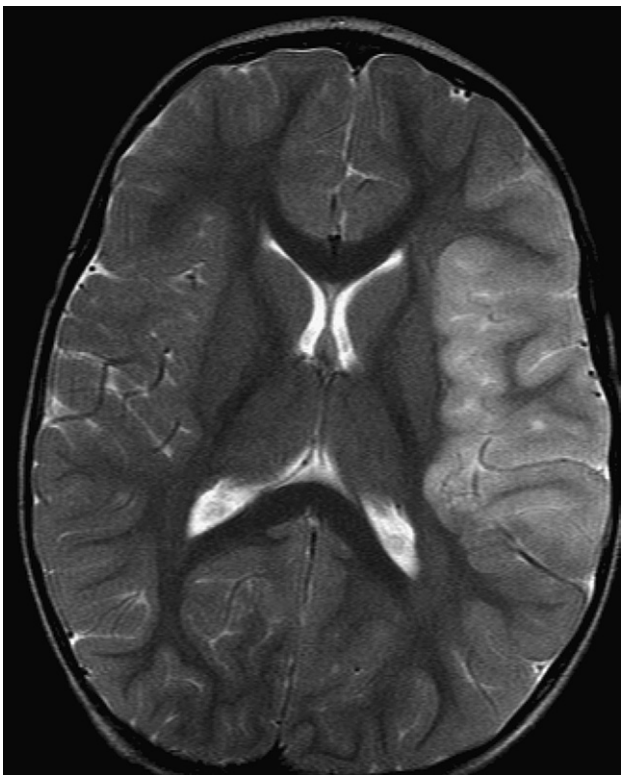

Figure 63–4. Presumed cardioembolic stroke. A 2-year-old with sudden onset of hemiparesis, loss of speech, and seizures 4 days after atrial septal defect closure.

Antiphospholipid antibody syndrome has been associated with recurrent fetal loss, thrombocytopenia, and cardiac valve disturbances, but its association with increased AIS in children is unclear.[37] Homocystinuria is an uncommon condition but can cause arterial ischemic stroke. Clinical manifestations include marfanoid features, mental retardation, seizures, and arteriosclerotic vascular disease. The spectrum of microangiopathic hemolytic anemias including hemolytic-uremic syndrome and thrombotic thrombocytopenia purpura can present with various neurologic manifestations including ischemic infarction. In adolescent girls both pregnancy and use of oral contraceptives must be considered risks factors for AIS.[38] The importance of pro-thrombotic risk factors is further evidenced by the observation that certain pro-thrombotic conditions are associated with higher recurrence risk.[20]

Metabolic Disorders and Toxins

Metabolic disorders are rare causes of stroke-like syndromes or lesions that are not the result of vascular-occlusive infarcts but, for the purposes of this chapter, will be discussed here. Chief among these disorders is MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke).[39] The exact mechanism of ischemia in MELAS is likely multifactorial,

Intravenous immunoglobulin infusion

including direct cytotoxicity from mitochondrial failure and glutamate toxicity, as well as loss of normal coupling of cellular metabolism and CBF.[40] Illicit drug use has been associated with stroke. Cocaine use has been associated with both ischemic and hemorrhagic stroke, and there have been reports of stroke in young adults using amphetamines and ecstasy (3,4-methylenedioxymethamphetamine).[41-43]

Clinical Manifestations

AIS in infants and children can be difficult to correctly diagnose. Stroke typically is not high on the practitioner's differential diagnosis in the pediatric population, and the presenting symptoms are attributed to more common conditions such as a viral syndrome, migraine, or oppositional behavior. Compared with adults, children may not articulate their symptoms well. Infants usually fail to display localized deficits and typically present with seizures or altered mental status. Many stroke "mimics" exist in childhood that require advance imaging for accurate diagnosis, including migraines, demyelinating disorders, tumors, hypertensive encephalopathy, psychogenic, postictal paralysis, infections, and metabolic disorders.[44] These factors can lead to delays in presentation as well as delay in diagnosis.[45]

AIS usually presents with acute neurologic deficits in an arterial distribution and typically conforms to a pattern of ischemia in either the anterior (carotid) or posterior (vertebrobasilar) circulations. Deficits associated with each are related to the regions of brain supplied by the affected artery or arteries. The anterior circulation includes the internal carotid, anterior cerebral, and middle cerebral arteries. Ischemia in anterior circulation produces unilateral motor and sensory deficits.[46] The location of the lesions can influence presentation. Typically cortical infarcts will affect both motor and sensory function in the face and upper extremity more than in the lower extremity. Subcortical infarcts will produce the same density deficits in the face and upper and lower extremities. Many patients will have visual field cuts with a gaze preference. If the stroke occurs in the dominant hemisphere, patients can present with aphasia. Extinction and neglect are seen when the infarction occurs in the nondominant hemisphere. The posterior circulation includes the vertebrobasilar arteries that supply the brainstem, cerebellum, and the occipital lobe.[46] Cerebellar strokes closely resemble acute cerebellitis, typically including severe headache, lethargy, vomiting, ataxic gait, unilateral limb ataxia, and dysarthria.[47,48] Unilateral brainstem deficits include pure motor deficits without cortical symptoms, oculomotor deficits, diplopia, vertigo, tongue deviation, or dysarthria/dysphagia.[49] Infarcts in the distribution of the posterior cerebral artery present typically with visual field deficits and gaze preference. Seizures herald the onset of stroke in 10% to 20% of childhood-onset AIS and in the vast majority of neonatal cases of AIS.

Imaging and Laboratory Evaluation

The goals of initial investigation are to verify the occurrence of AIS and the location to determine the likely causative stroke mechanisms so a specific treatment plan can be initiated.[10] If AIS is suspected, strict attention to maintenance of adequate airway, breathing, and circulation and close monitoring of neurologic status should be performed throughout the acute evaluation process.

Neuroimaging typically starts with a head computerized tomography scan (CT) because it is widely available and can quickly demonstrate hemorrhage as the cause of symptoms. The major disadvantages of CT, in addition to exposure to ionizing radiation, are that it is insensitive and nonspecific and does not provide information about vascular disease. Ischemic changes on CT typically are not visible until 12 to 24 hours after onset and are indistinguishable from lesions that mimic stroke such as tumor and demyelinating disease. MRI with diffusion weighting is far superior for the diagnosis of AIS and the differentiation of stroke from other diagnoses such as acute disseminated encephalomyelitis or methotrexate toxicity.[50] Moreover, vascular imaging can be obtained readily with the initial diagnostic brain imaging using MRI, and it should be obtained for both the head and the neck in all children suspected of having a first ischemic stroke (see Figure 63-3). When a metabolic stroke-like syndrome is suspected, such as MELAS, magnetic resonance spectroscopy may be helpful. If MRI is not available, vascular imaging can be achieved with CT angiogram.[51] Diagnostic imaging can be challenging for the pediatric patient, and care must be taken not to compromise oxygenation, ventilation, and perfusion to at-risk tissues with sedation or general anesthetics. Careful planning and coordination of diagnostic imaging is necessary to obtain optimal imaging in a timely and safe manner. This coordination is best accomplished through direct consultation and dialogue involving the primary team caring for the patient, the sedation team, and the radiology technicians and physicians responsible for specifying and executing the imaging protocol (also see Chapter 56).

Box 63–5 Treatment in Pediatric Arterial Ischemic Stroke*

Perfusion: Restore and Maintain Cerebral Circulation and Energy Substrate Delivery (Glucose, Oxygen)

Maintain circulating volume with intravenous fluids
Eliminate postural perfusion fluctuations (keep head of bed flat)
Respiratory support, oxygenation
Correct anemia (ideal hemoglobin for cerebral perfusion ~10–12 mg/dL)
Blood pressure: aim for upper limit of normal for age, do not overtreat hypertension
Prevent clot propagation—antithrombotic drugs (antiplatelet, anticoagulation)*
Thrombolysis—evidence lacking on safety, dose, efficacy in children; see American Heart Association guidelines*

Neuroprotection: Limit the Extent of Infarction, Salvage the Penumbra

Temperature: target intervention to keep temperature ≤37.5° C
Glucose control: target intervention to keep serum glucose >50, <150 mg/dL
Assess for and treat seizures
Prevent complications: deep venous thrombosis prophylaxis, aspiration precautions

Rehabilitation: Promote Recovery and Plasticity

Start rehabilitation in pediatric intensive care unit or acute care ward
Be aggressive —"time is brain" also during rehabilitation and plasticity is use dependent
Greatest long-term morbidity is neurocognitive and psychosocial—take care of the whole child and the family unit within the family, neighborhood, and school

Secondary Prevention: Prevent Recurrence*

Antiplatelet Agents, Commonly Used for:
Idiopathic stroke (no risk factor after complete evaluation)
Cerebral arteriopathy for low-grade stenosis
Congenital heart disease with no intracardiac thrombus or cardiac failure
Mild pro-thrombotic states

Systemic Anticoagulation, Commonly Used for:
Dissection of cervical/extracranial cerebral arteries
Intra-cardiac thrombus or severe ventricular dysfunction
Stroke or transient ischemic attack while taking antiplatelet agents
High-grade stenosis of cerebral artery
Major pro-thrombotic state

*Use of antithrombotics in neonatal arterial ischemic stroke is not usually recommended because of very low recurrence risk. An exception would be to consider systemic anticoagulation where intracardiac or systemic thrombosis is identified or a major pro-thrombotic defect is identified.

Laboratory evaluation in the early screening stage should include a complete blood cell count, comprehensive metabolic panel, and coagulation profile (Box 63-4). If AIS is confirmed, a thrombophilia workup should be performed and consultation with a hematologist should be considered. It is critical that blood samples be taken for key tests prior to the initiation of anticoagulation therapy (see Box 63-4). If stroke symptoms are associated with an acute febrile illness, a lumbar puncture should be considered as well as serologies for other infectious etiologies (e.g., mycoplasma infection and Lyme disease). Lumbar puncture may need to be delayed if intracranial hypertension as a result of stroke and peri-infarct edema are suspected, particularly for patients with large strokes. When an embolic etiology of AIS is suspected, urgent cardiac evaluation is warranted, including an echocardiogram with a bubble study and an electrocardiogram (ECG). Although uncommon, AIS has been reported in children with cardiac arrhythmia.[52]

Treatment

Regardless of the etiology of AIS, management should focus on optimizing perfusion and oxygenation, neuroprotection (minimizing expansion of the ischemic core and secondary injury and rescuing the penumbra), rehabilitation, and prevention of recurrence (Box 63-5). Specific therapies should be tailored based on the stroke mechanism. Reviews of existing evidence and summaries of evidence-based and consensus-based management guidelines have been published recently.[10,53]

Supportive Measures

Interventions aimed at optimizing perfusion to ensure adequate oxygen delivery and protection of the ischemic penumbra should begin immediately. Evidence for the effectiveness

of supportive measures in childhood AIS is lacking, and thus these measures are largely based on adult trials and consensus guidelines. Airway patency and adequate breathing should be assessed and maintained and supplemental oxygen provided to maintain normal oxygenation. Currently no strong evidence exists to support administration of supplemental oxygen in the absence of hypoxemia.[10] Endotracheal intubation and mechanical ventilation should be performed in children with severe hypoxemia, loss of respiratory drive or respiratory insufficiency, or obtundation with loss of airway protective reflexes. The need for early advanced neuroimaging (e.g., MRI and magnetic resonance spectroscopy) in the pediatric stroke patient raises additional challenges of sedation. Endotracheal intubation and mechanical ventilation may be necessary to ensure adequate oxygenation, ventilation, and perfusion during neuroimaging.

The head of the bed should remain flat to maximize perfusion and eliminate postural fluctuations during the initial 12 to 24 hours until the hemodynamic status and neurologic deficits stabilize. Blood pressure should be monitored closely, and isotonic intravenous fluids should be administered to maintain circulating intravascular volume. Adult stroke guidelines recommend permissive hypertension, and the most recent pediatric guidelines suggest controlling systemic hypertension, but to what degree or how quickly is unclear.[10] Symptomatic hypertension should be controlled, a reduction in blood pressure should be performed slowly, and neurologic status should be monitored closely during this process. Treatment of asymptomatic hypertension in the patient who has had a stroke must be tailored to the specific status of the individual patient, including the perceived risk or demonstrated occurrence of hemorrhagic transformation or infarct progression, presence of anticoagulation, and the potential complications of overtreating or undertreating the hypertension.

Hyperthermia increases metabolic demand and, in the presence of impaired substrate delivery, can increase neuronal injury. It has been demonstrated that fever following brain injury in animal models worsens outcomes.[8,9] In children with traumatic brain injury, hyperthermia has been associated with longer hospital stays, but currently no studies have been performed that assess the role of fever in childhood AIS.[54] Adult stroke guidelines recommend aggressive treatment of fever, and current pediatric consensus statements support the treatment of fever.[7,10] Experimental studies also have demonstrated possible benefits of neuroprotection with therapeutic hypothermia after brain injury, but to date efficacy and safety has not been studied in the pediatric stroke population.[55,56]

Clinical and electrographic seizures should be controlled with antiepileptic medications. In the absence of seizures, little evidence exists that prophylactic antiepileptic medication administration is beneficial.[10] In adult AIS, hyperglycemia and hypoglycemia have been associated with worse outcomes.[57,58] Although hypoglycemia should always be treated, glycemic control after pediatric AIS has not been extensively studied; however, based on adult evidence, pediatric guidelines currently recommend treatment of hyperglycemia.[10]

Thrombolytic Therapy

Randomized controlled trials have demonstrated the efficacy of intravenous and intraarterial thrombolysis in adult patients with AIS.[15,59] Evidence regarding thrombolysis for acute AIS in children is scarce, resulting in a lack of consensus on the role of this therapy for children. Published studies on the use of tissue plasminogen activator (tPA) in children with AIS is limited to only a few case reports and small case series.[60-63] In the largest case series published to date, Amlie-Lefond et al.[64] described the clinical features, dosing and timing, and short-term outcome in all children treated with tPA for acute AIS who were enrolled in the International Pediatric Stroke Study between 2003-2007. Among 677 children in the International Pediatric Stroke Study with acute AIS, 15 (2.2%) received tPA. Time intervals and dosing often deviated from adult guidelines. Intracranial hemorrhage was seen after tPA treatment in four of 15 patients, though none were judged acutely symptomatic, and functional outcome was poor in most patients. Consensus is strong that tPA should not be used in children with neonatal stroke because of uncertainty regarding the stroke onset. In older children and adolescents data on safety and efficacy are very limited, and to date consensus among experts is limited. Lower dose tPA has been reported to be effective in children, but further investigation and clinical trials are needed.[65] The current American Heart Association Guidelines suggest that tPA be used in children (preadolescents) only in the context of a clinical trial,[11] and if it is considered for children or adolescents, its use should adhere strictly to adult guidelines.

Antithrombotic Therapy: General Principles

In some centers it is common practice to begin anticoagulation initially in children with acute AIS while studies of risk factors are undertaken. This approach is based on the assumption that children with AIS may be more likely to benefit from anticoagulation compared with adults because of the greater prevalence of hypercoagulable states and lower incidence of hypertension. Typically, decisions regarding therapy for secondary prevention are finalized at 7 to 10 days after symptom onset, when results of comprehensive risk factor evaluation (cardiac, vascular, and thrombophilia) are available and the clinical course has stabilized (see Box 63-5). Because a significant risk of recurrent ischemic stroke exists, it is reasonable to provide most children with some form of antithrombotic therapy for secondary stroke prevention for 1 to 2 years. The decision to use anticoagulation vs. antiplatelet therapy takes into account stroke mechanism, presence of thrombophilia, and comorbid diseases that may be affected by the use of antithrombotic agents. Anticoagulation is commonly used in patients with presumed cardioembolic stroke, cervical artery dissection, and certain high-risk thrombophilias (such as antiphospholipid antibody syndrome). Antiplatelet therapy, usually with aspirin, is commonly used for all other stroke subtypes or in children with contraindications for chronic anticoagulation therapy. A thorough review of antithrombotic treatment strategies and of the relevant literature can be found in the American Heart Association's Scientific Statement on the Treatment of Childhood Stroke[10] and the *Chest* guidelines for the use of antithrombotic therapies in children.[66]

Antiplatelet Therapy

Aspirin inhibits platelet activity by irreversibly inhibiting cyclooxygenase-1, which results in impaired platelet activation. Two adult multicenter trials examining the role of aspirin administration within 48 hours of onset of stroke symptoms demonstrated an absolute risk reduction for in-hospital AIS recurrence of seven per 1000 patients.[67-69] The

risk of hemorrhagic transformation was only increased by two per 1,000 patients. Currently no studies have been conducted in children with AIS, but pediatric consensus statements recommend initial treatment with aspirin, 3 to 5 mg/kg/day for acute pediatric AIS, excluding patients with sickle cell disease, intracranial hemorrhage, or recent thrombolytic therapy.[10,53]

Aspirin also is used for long-term secondary prevention of stroke. Adult studies have demonstrated no difference in the prevention of stroke recurrence between aspirin and anticoagulation. A nonrandomized single-center prospective study of 135 children with AIS comparing low-molecular weight heparin (LMWH) and aspirin demonstrated no difference in recurrence rates and bleeding risks between the two drugs.[70] Dosing of aspirin is usually 3 to 5 mg/kg/day. Because of the association of aspirin use and Reye syndrome, patients taking aspirin for secondary stroke prevention need to be monitored closely during flu-like illnesses.[10] Varicella and annual influenza vaccination is recommended for these patients as well.

Anticoagulant Therapy

Heparins are the mainstay of acute anticoagulation for AIS. By enhancing the activity of antithrombin, they effectively inhibit thrombin, a key player in the coagulation cascade. Antithrombin levels vary with age. Infants have lower levels of antithrombin, and as a result they require higher doses of heparin to achieve anticoagulants effects that are similar to those in adults.[71] LMWH offers both advantages and disadvantages for acute coagulation compared with unfractionated heparin (UFH). LMWH offers more predictable pharmacokinetics, fewer blood tests to ensure therapeutic dosing, and subcutaneous administration, but it is cleared renally, which may pose problems for patients with renal insufficiency or failure. UFH advantages over LMWH include rapid reversibility with protamine sulfate or fresh frozen plasma and the fact that kidney dysfunction does not alter clearance. For long-term anticoagulation, the practitioner has the choice of LMWH or oral vitamin K antagonists such as warfarin. LMWH can be administered in doses of 1 mg/kg every 12 hours through a subcutaneous catheter that is replaced weekly to minimize needle injections.[72] Therapy is monitored with anti-factor Xa levels sampled 4 to 6 hours after injection with a therapeutic range of 0.5 to 1 U/mL. Dosage of warfarin is tailored to target an international normalized ratio between 2 and 3. The risk of major hemorrhage in children with AIS being treated with warfarin has not been studied but has been reported to be less than 3.2% in children receiving warfarin for mechanical heart valves.[66]

Special Circumstances

Sickle Cell Disease. The primary acute treatments for AIS in patients with sickle cell disease are hydration and exchange transfusion. Exchange transfusion avoids the risk of increasing blood viscosity that may occur with increases in hematocrit with simple transfusions.[73] Typically, sickle hemoglobin reduction to less than 30% is targeted during exchange transfusion therapy. A randomized trial comparing periodic blood transfusions with standard treatment in children with sickle cell disease and high risk for stroke determined by TCD demonstrated a reduction in stroke risk from 10% to less than 1% per year.[74] Periodic transfusions are now recommended for children ages 2 to 16 years with sickle cell disease and abnormal TCD results.[10]

Moyamoya Syndrome. Moyamoya syndrome affects the internal carotid artery and its branches while leaving the external carotid artery unaffected. Surgical revascularization using the external carotid artery as a new blood supply to the affected hemisphere has become a viable option for pediatric patients with moyamoya syndrome.[75,76] There are two general approaches to surgical revascularization: direct and indirect. Direct revascularization involves taking a branch of the external carotid artery and directly anastomosing it to a cortical artery.[77] This technique can be technically difficult in the pediatric population because of the small size of the vessels that need to be manipulated.

Indirect revascularization such as pial synangiosis involves placement of external carotid artery branch or vascularized tissue in direct contact with the brain, leading to growth of new blood vessels to the underlying brain tissue (Figure 63-5). A review of 143 pediatric patients with moyamoya syndrome treated with pial synangiosis demonstrated marked reduction in stroke rate from 67% before surgery to 3.2% in the first year of follow-up.[78] Forty-six patients who had 5 years or more of follow-up had a stroke rate of only 4%. Pediatric patients with moyamoya syndrome undergoing revascularization procedures have additional challenges in the immediate postoperative period of ischemic events. Crying and hyperventilation can reduce partial pressure of carbon dioxide, inducing cerebral vasoconstriction and ischemia. Adequate pain control and sedation during the postoperative period as well as avoidance of hypotension and hypovolemia is warranted.[79]

Rehabilitation

Introduction of rehabilitation relatively early in the stroke course has the potential to reduce long-term morbidity. A multidisciplinary approach to rehabilitation including physical medicine and rehabilitation physicians, occupational, speech, and physical therapists, child life specialists, and psychologists has been recommended.[80] Constraint-induced movement therapy (CIMT) has been introduced to improve recovery from pediatric stoke.[81] CIMT is based on the theory of forced use that was originally investigated with primate models.[82,83] Forced use theorizes that the affected or paretic arm can be retrained by restricting movement of the unaffected or less affected arm. A trial in adults with subacute AIS randomly assigned to a 2-week period of intensive physical therapy with or without CIMT demonstrated a significantly greater improvement in function of the affected arm in the CIMT group compared with the control group at 1 year.[84] Observational studies in pediatric stroke patients and patients with hemiplegic cerebral palsy have reported mixed results.[85-87] A randomized controlled trial in children with cerebral palsy who had asymmetric motor impairment reported improvement in acquisition and quality of motor skills following CIMT.[88]

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis (CVST) is a relatively rare disease in the overall pediatric population, but with advances in neuroimaging, recognition of this condition has increased.

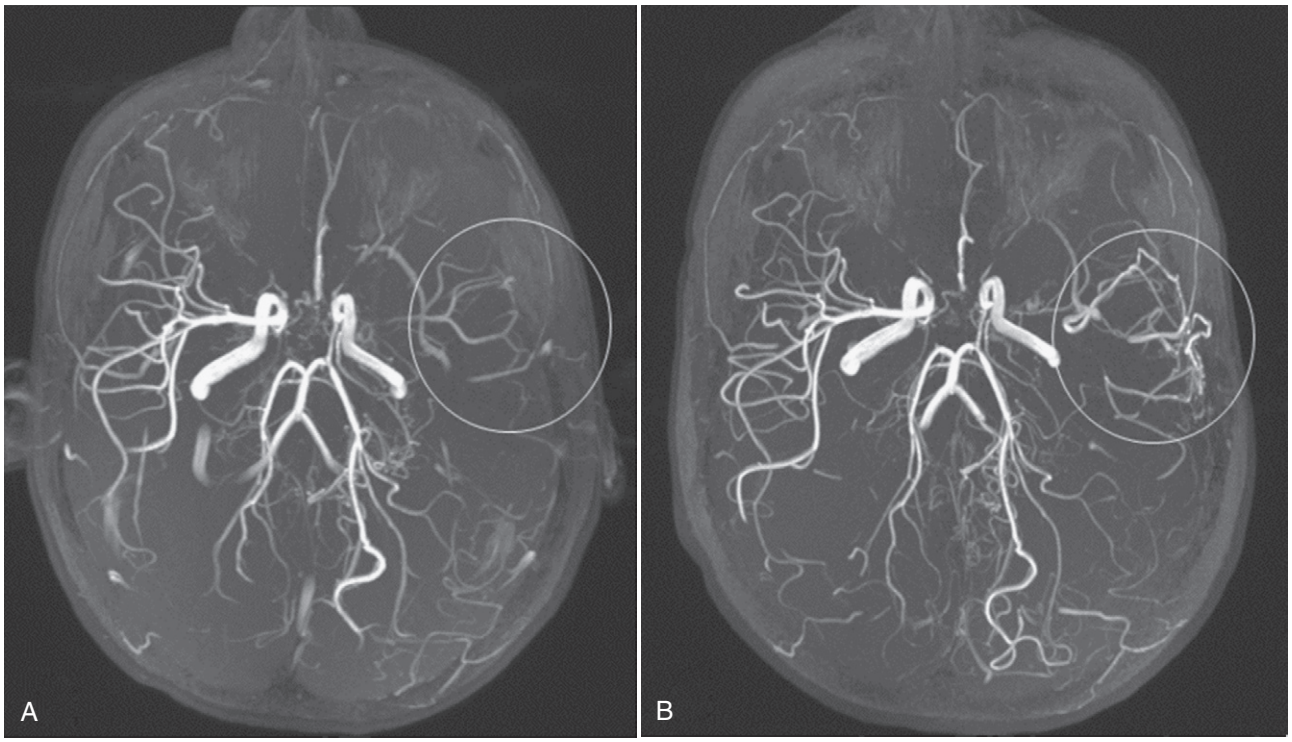

Figure 63–5. A 16–year-old with unilateral moyamoya syndrome presenting with left carotid territory transient ischemic attack (right face, arm, and hand weakness and numbness with headache). MR angiogram at onset (**A**) and 1 year after pial synangiosis (**B**). Note increased vascularity in middle cerebral artery territory at site of surgery (*circle*).

CVST can be the result of a variety etiologies, and the presentation can be nonspecific and subtle, making early diagnosis challenging.

Pathophysiology

Thrombosis of the cerebral venous sinuses can be the result of various processes. Venous stasis, hypercoagulable states, dehydration, hyperosmolality, and disruption of the vessel wall due to regional pathology (such as infection or trauma) all can result in CVST. The lower velocity of blood flow in the venous sinus system provides optimal conditions for thrombus propagation. Venous infarction may occur if the venous sinus system pressure rises above the arterial perfusion pressure resulting in venous congestion, leakage of fluid and blood into the brain parenchyma, and hemorrhagic infarction. In the most severe cases of venous outflow obstruction from thrombotic occlusion, extensive venous infarction, hemorrhage, and cerebral edema progress to herniation and death. Occlusion of the venous sinuses with thrombosis may impede cerebrospinal fluid absorption and produce intracranial hypertension without ventricular enlargement via a process resembling pseudotumor cerebri. If untreated, intracranial hypertension can lead to papilledema and vision loss.

Epidemiology

CVST is rare in the pediatric population, with an estimated incidence of 0.67 per 100,000 children per year.[89] Neonates have the highest incidence of CVST. The majority of neonates (84%) are observed to have a systemic illness, most commonly dehydration or perinatal complications (e.g., hypoxia at birth, premature rupture of membranes, or maternal infection).[89] Other disorders in neonates known to be associated with CVST include bacterial sepsis, meningitis, and hypercoagulable states.

In infants with CVST, head and neck disorders are common, with otitis media and mastoiditis being the most frequent pathology. Chronic systemic illnesses (e.g., malignancy, inflammatory bowel disease, and nephrotic syndrome, among others) are frequently found (40% to 60%) in older children with CVST. CVST in older children also has been associated with anemia and hemoglobinopathies, including iron deficiency, hemolytic anemia, sickle cell disease, and β-thalassemia.[90-93] Pro-thrombotic disorders have been observed in one third to two thirds of children with CVST, which can be congenital or acquired.[89-90]

Clinical Manifestations

Presenting symptoms of CVST in children can be variable and nonspecific. Infants may present with a wide spectrum of clinical manifestation from nonspecific findings such as irritability and a decrease in feeding to lethargy and coma. Older children may present with the triad of unremitting headache, vomiting, and altered level of consciousness.[94] Commonly associated findings include seizures and signs and symptoms of increased intracranial pressure (papilledema and sixth nerve palsy).[89,94] Because of the association with meningitis, mastoiditis, and otitis media, the presence of these signs and symptoms should prompt the practitioner to pursue further laboratory evaluation of CVST.

Imaging and Laboratory Evaluation

When CVST is suspected, strict attention to maintenance of adequate airway, breathing, circulation, and close monitoring of neurologic status should be performed

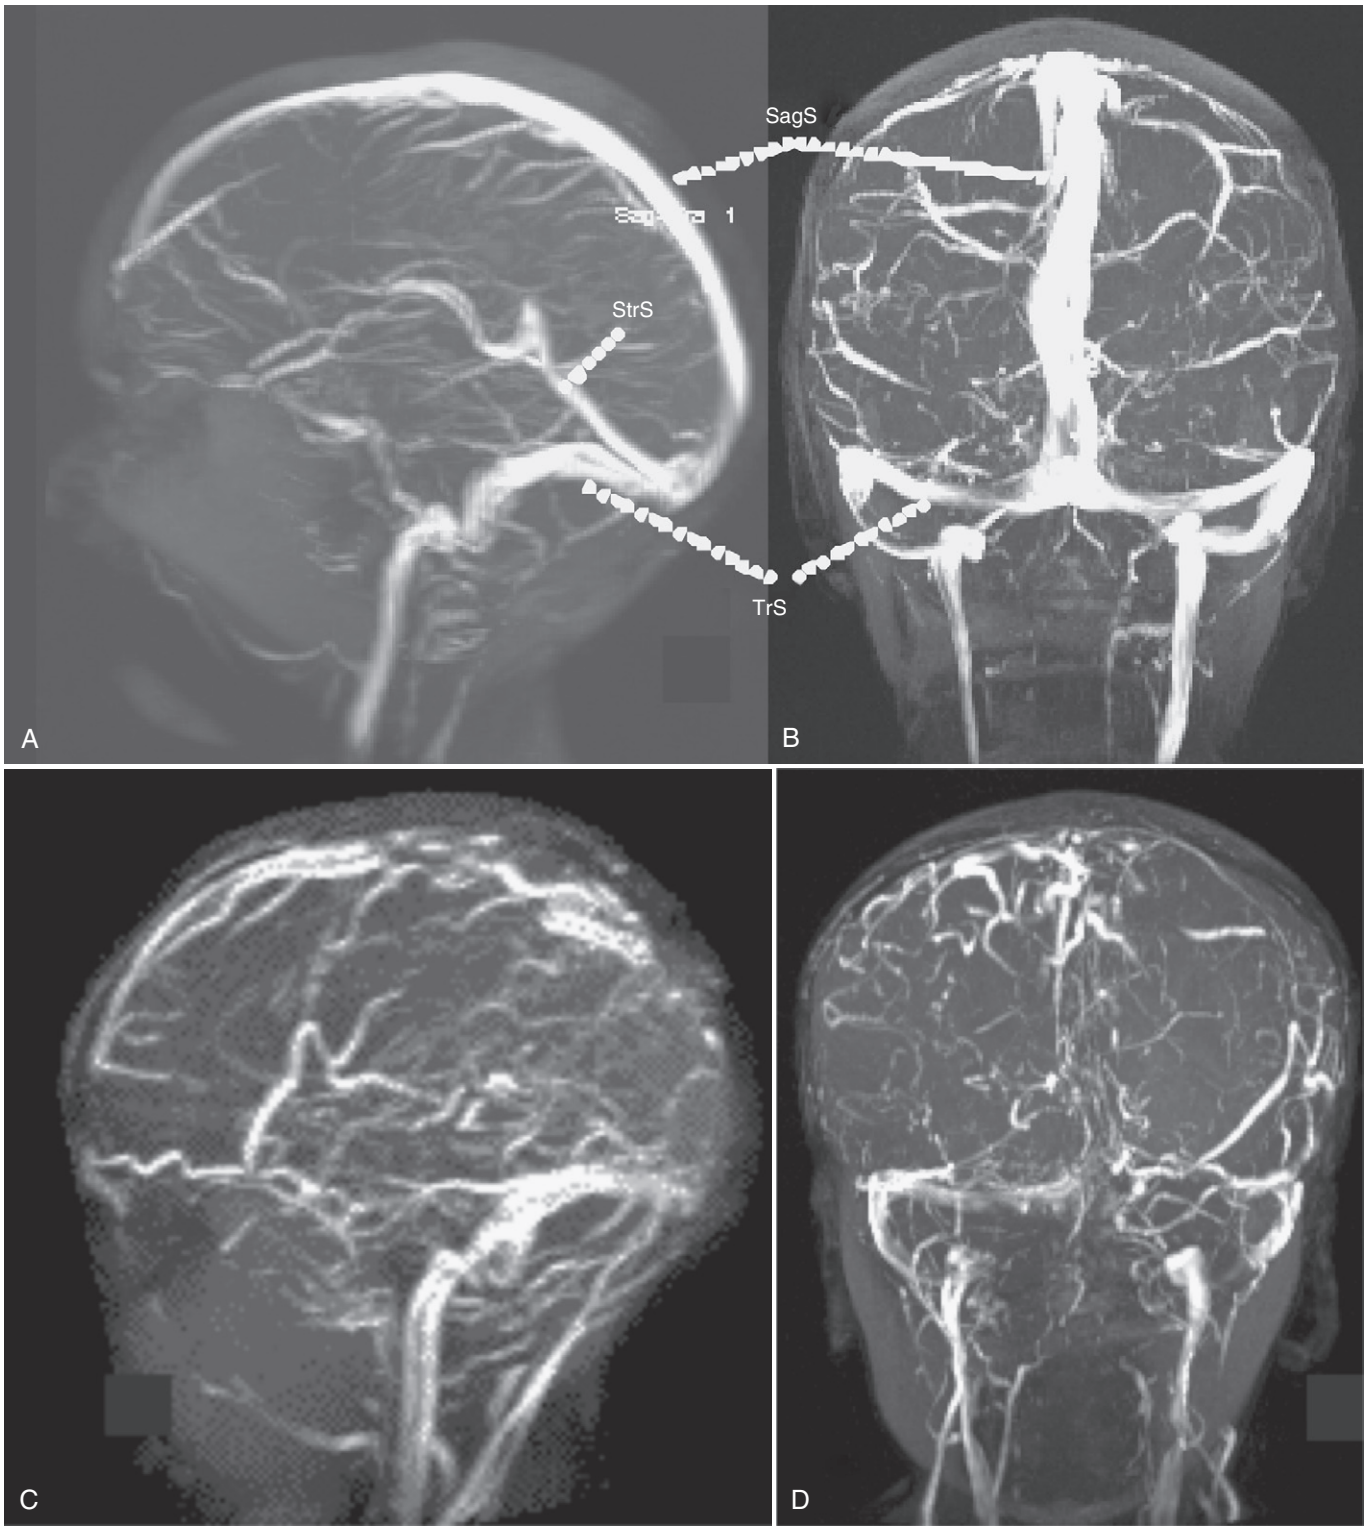

Figure 63–6. Normal MR venogram in a child, sagittal (**A**) and coronal (**B**) views. MR venogram (**C, D**) in an 18-month-old boy with iron deficiency anemia presenting with lethargy, vomiting, and quadriparesis shows absence of flow-related signal in sagittal sinus (*SagS*), straight sinus (*StrS*), and both transverse sinuses (*TrS*).

throughout the acute evaluation process because there is risk of rapid progression and death.[90] With the advent of contrast-enhanced CT and MRI, early diagnosis of CVST in children has become possible. Nonenhanced CT imaging commonly discloses hyperdense venous sinuses, whereas contrast-enhanced CT may demonstrate filling defects in the sagittal sinus. Imaging via head CT alone, however, is associated with a high rate of false positives, and CVST may be missed in up to 40% of patients.[89,95,96] MRI with magnetic resonance venography is more sensitive but may require the use of sedation in younger patients (Figure 63-6). CT venography is a sensitive and specific alternative to

MRI, but it has the disadvantage of radiation exposure. Laboratory evaluation for CVST should include a complete blood cell count and thrombophilia studies. In one cohort of children with CVST, 52% were found to be anemic.[10,90] If a bacterial etiology is suspected, cultures should be taken and appropriate imaging should be performed. Previous studies have observed pro-thrombotic abnormalities in a significant number of children with CVST (32% to 45%).[10,89,90]

Treatment

Supportive measures should be started immediately. Airway patency, oxygenation, and ventilation need to be maintained at all times. If endotracheal intubation is indicated, it should be performed with caution because there maybe on going intracranial hypertension. Dehydration should be treated with intravenous fluids and anticonvulsants should be administered for control of seizures.[97] If a bacterial etiology is suspected, appropriate broad-spectrum antibiotics should be administered as soon as possible.

Anticoagulation in adult patients with CVST has been shown to be safe and provide clinical benefit.[98,99] Smaller studies in children with CVST have demonstrated that anticoagulation with heparin can be safely administered with monitoring of activated partial thromboplastin time when using UFH or anti-factor Xa levels when using LMWH.[90,100] In a small prospective study of 30 children with CVST, three of the eight children who did not receive anticoagulation therapy died compared with no deaths in the 22 children who did receive anticoagulation therapy.[90] In patients with CVST, venous infarcts with hemorrhage may develop, and small studies in adults have shown that anticoagulation for CVST in the presence of intracerebral hemorrhage is safe.[99,101] The pediatric literature is sparse, with case reports of anticoagulation with intracerebral hemorrhage, but consensus statements conclude that anticoagulation is reasonable in these cases.[10,90,102] Close monitoring in the intensive care unit during initial anticoagulation in these patients would seem to be prudent. Thrombolysis, thrombectomy, and surgical decompression have been reported to be successful in small case series of severely affected adults and children.[103-106] The duration of anticoagulation can vary, but 3 to 6 months is recommended.[10]

Prognosis

In the Canadian Pediatric Ischemic Stroke Registry study, the mortality rate for children with CVST was 8%.[89] Other studies have reported higher mortality rates (13%), with neonates having the highest death rates (25%).[97] Seizures at presentation and the presence of infarcts (nonhemorrhagic or hemorrhagic) have been observed to be predictors of adverse neurologic outcome.[89] In a prospective study of 42 patients, older age, lack of parenchymal abnormalities, anticoagulation, and lateral and/or sigmoid sinus involvement were all independent predictors of good outcome.[90] Long-term follow-up of children with CVST has found that they may have residual mild cognitive deficits.[107] Children with CVST are at risk for recurrence, and one multicenter database reported that in 6% of children recurrent thrombosis developed during an average of 36 months of follow-up.[108] Half of these children's recurrent thrombosis was intracranial.

Spontaneous Intracranial Hemorrhage

Spontaneous intracranial hemorrhage (ICH) is customarily broadly defined to include intraparenchymal hemorrhage, hemorrhagic transformation of ischemic stroke, and intraventricular and subarachnoid hemorrhage (SAH) of nontraumatic origin. Each of these subtypes of ICH differs in terms of underlying causes, treatment approaches, and prognosis. A variety of conditions and risk factors predispose children to ICH and carry a variable risk of recurrence. Many of these patients can present with a sudden and rapidly deteriorating clinical picture, requiring emergent stabilization by the intensivist and rapid diagnosis to implement lifesaving treatment.

Epidemiology

The incidence of spontaneous intracranial hemorrhage in children has been reported to be equal if not higher than AIS, at 1.1 to 1.5 per 100,000 children per year.[1,2,4] The peak age for incidence is in the first year of life with the exception of SAH, which peaks in adolescence.[5] Arteriovenous malformations (AVMs) account for 14% to 46% of hemorrhagic stroke and almost 50% of intraparenchymal hemorrhages.[2,109-111] More than 75% of symptomatic AVMs present with hemorrhage, and the majority of them are supratentorial in location. The risk of hemorrhage in children with known AVMs is 2% to 4% per year, and 25% of these hemorrhages will be fatal.[112,113] Cavernous malformations are reported to be the cause of up to 25% of cases of pediatric intraparenchymal hemorrhage.[111] They may increase in size over time because of repeated bleeding and calcification, producing a typical "bull's eye" appearance on MRI (Figure 63-7).[114] For untreated cavernous malformations, the risk of recurrent hemorrhage has been reported at 4% to 5% per year.[115-117]

Congenital and acquired coagulation disorders are also risk factors for spontaneous ICH. In one series of 68 children, 10 children had coagulation disorders including factor VIII deficiency, coagulopathy due to hepatic failure, or vitamin K deficiency.[118] In this same series, an additional eight children were found to have thrombocytopenia. The risk of spontaneous (nontraumatic) ICH correlates with the severity of the coagulation disorder or thrombocytopenia.[119,120] Platelet counts higher than 20,000 appear to minimize the risk of nontraumatic ICH with thrombocytopenia.[121,122] Systemic hypertension, a common cause of spontaneous ICH in adults, has rarely been observed to be a risk factor in children.[118]

Intracranial aneurysms causing ICH are relatively rare in the pediatric population. Symptoms are most common before the age of 2 years or after the age of 10 years. Like adults, children with ruptured aneurysms usually present with SAH, but they also may present with intraparenchymal or intraventricular hemorrhage. Children are more likely to have giant aneurysms and posterior circulation involvement compared with adult patients. Up to 20% of adult patients with an aneurysm will be found to have more than one aneurysm, compared with 5% of pediatric patients. Pediatric aneurysms can be associated with various congenital conditions including

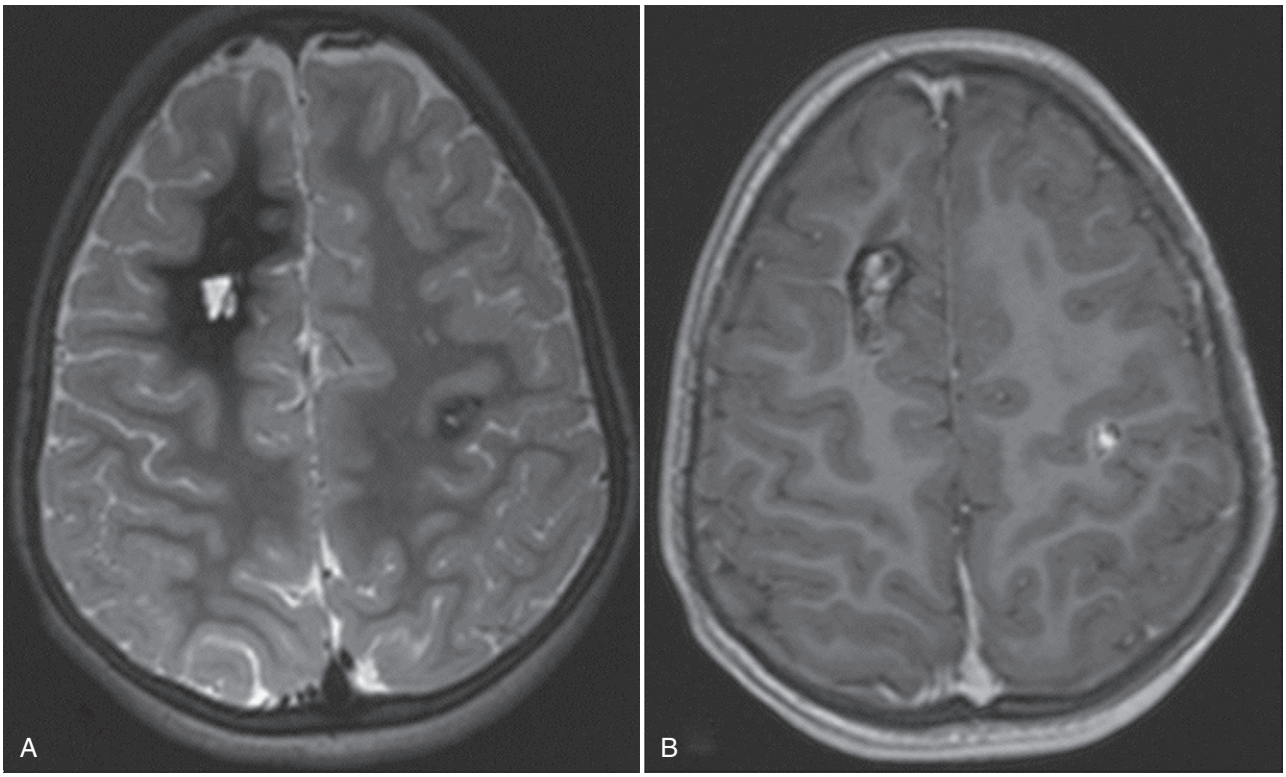

Figure 63–7. T2 (**A**) and T1 (**B**) MR images of a large right frontal cavernous hemangioma and an additional small cavernous hemangioma in the left perisylvian region.

coarctation of the aorta, Ehlers-Danlos syndrome, autosomal dominant polycystic kidney disease, and fibromuscular dysplasia.[123-127]

Clinical Manifestations

ICH in the infant can present with subtle and nonspecific findings unless the hemorrhage involves the motor pathways or the brainstem.[10] Infants with arterioventricular fistula or vein of Galen malformation may present with high output cardiac failure or hydrocephalus.[128] If a vein of Galen malformation is suspected, a bruit maybe auscultated by placing the bell of stethoscope on the child's head. Older children with ICH have a presentation similar to that of adults, with repeated forceful vomiting and sudden headache, often described as the worst headache the patient has ever experienced. They also can present with seizures (focal or generalized), hemiparesis, and coma.[118] Signs and symptoms can progress quickly with rapid deterioration in neurologic status to coma, herniation, and death unless promptly recognized and treated.

Evaluation

Rapid stabilization and diagnostic imaging to determine the presence of ICH and its etiology is essential. Unenhanced CT has good sensitivity and specificity in identifying the presence and location of ICH (intraventricular and intraparenchymal vs. SAH) and associated mass effect and shift, such as subfalcine and uncal herniation. A complete blood cell count and a coagulation profile should be ordered to evaluate for hematologic risk factors. Vascular imaging is usually necessary to determine the etiology of intraparenchymal hemorrhage. MR angiography, brain MRI, and CT angiography are often performed and can provide specific and complementary information in identifying underlying lesions. MRI is the most specific and sensitive modality for identifying cavernous malformations. In cases where an AVM or aneurysm is suspected, catheter angiography is necessary for diagnosis and surgical planning. Repeat catheter angiogram is typically performed in the immediate postoperative period and again at 1- to 5-year intervals through late adolescence in children with ICH due to AVMs, because these lesions are known to recur and cause recurrent hemorrhage (Figure 63-8).

Treatment

Initial treatment should include optimization of oxygenation and ventilation. Systemic hypertension should be controlled to prevent further intracranial bleeding. Seizures should be controlled with antiepileptic drugs, and fever should be treated aggressively. Intracranial hypertension should be managed with hyperosmolar therapy (i.e., mannitol or hypertonic saline solution), titration of $Paco_2$ to 35 to 40 mm Hg, and elevation of the head of the bed to 30 degrees. Ventriculostomy drain placement can be both diagnostic and therapeutic. It allows for the drainage of fluid to relieve intracranial pressure due to intraventricular hemorrhage and hydrocephalus as well as intracranial pressure monitoring. If central venous access is needed for hyperosmolar therapy or circulatory stabilization, care should be taken in choice of insertion site, because cerebral angiography and endovascular interventions may be necessary.

Children with ICH should have treatable hematologic abnormalities corrected to prevent further bleeding. The

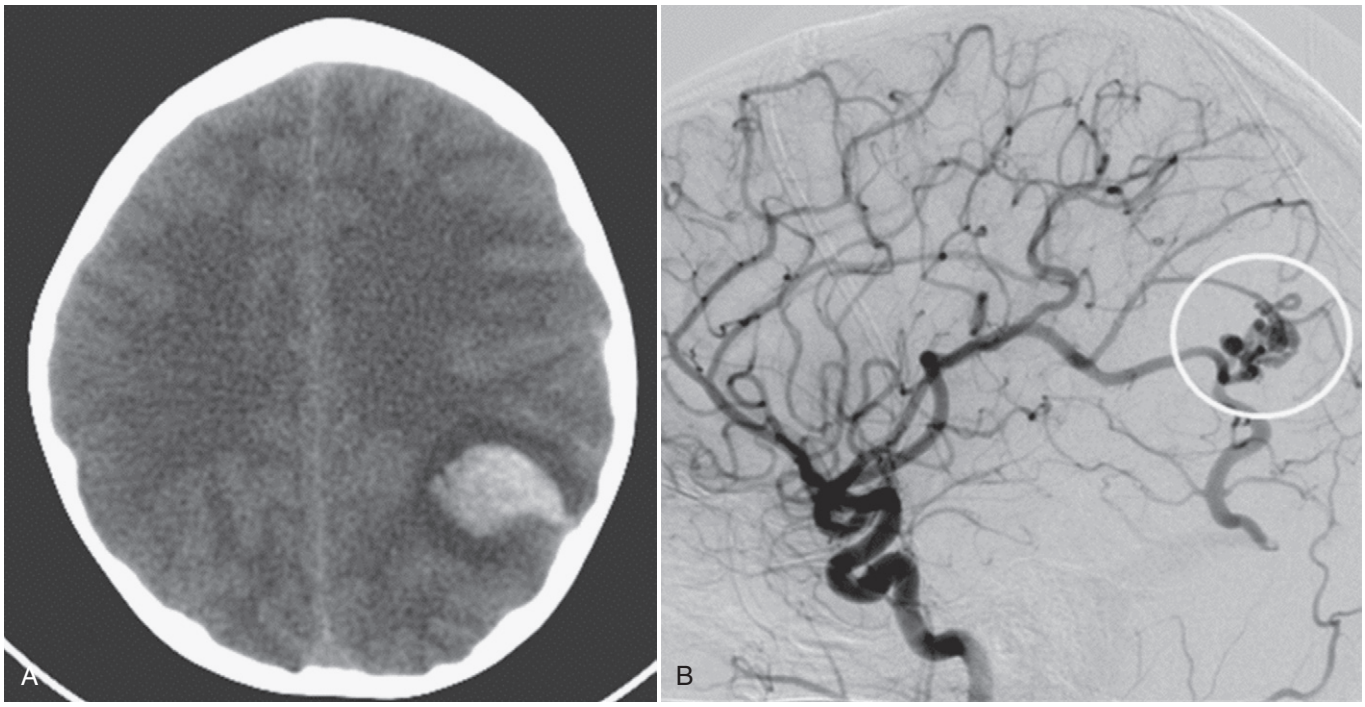

Figure 63–8. Severe headache, vomiting, and confusion develops in a 9-year-old healthy boy. **A,** A head CT scan shows left parietal parenchymal hemorrhage. **B,** An angiogram shows arteriovenous malformation (*circle*) being supplied by the left middle cerebral artery in nidus of hemorrhage.

efficacy of recombinant activated factor VII (rFVIIa) administration in adults with acute hemorrhagic stroke is unclear. A phase IIb trial in adults demonstrated reduction in ICH growth and improvements in mortality and functional outcomes when rFVIIa was administered within 4 hours of onset.[129] A larger follow-up study did not reproduce the improvements in survival and function.[130] The role of rFVIIa in children with ICH has not been determined, and currently it is only recommended in children with severe factor VII deficiency.[10]

Because of the years of cumulative risk of hemorrhage in children with AVMs, removal and/or embolization of the lesion with endovascular embolization, surgery, stereotactic radiotherapy, or a combination of these procedures is usually performed. Cavernous malformations have similar cumulative risk for hemorrhage in children and have been successfully treated with surgical removal or stereotactic radiotherapy.[131-133] Although clinical trials in adults have not proved a benefit for early hematoma evacuation, this approach has not been well evaluated in children. It is widely accepted that acute hematoma evacuation, sometimes combined with decompressive craniectomy, may be life saving in selected children with large lesions in the cerebral hemisphere and cerebellum resulting in impending herniation.[134-136] Intracranial aneurysms are treated with both surgical microvascular and endovascular techniques.[137,138]

Prognosis

Overall prognosis is heterogeneous and is highly dependent on the etiology of the hemorrhagic stroke and the risk of recurrence. The mortality rate for children with cerebral aneurysms is 20%, and poor outcomes are related to delay in diagnosis and rebleeding prior to endovascular or microsurgical treatment.[137,139] Approximately two thirds of patients will have good outcomes (Glasgow Outcome Score of 5) following treatment.[139] A long-term follow-up of 56 children with hemorrhagic stroke of all etiologies found that 13 children died during the initial phase and seven additional children died during long-term follow-up.[140] Of the remaining survivors, only 25% were without physical or cognitive deficits, but almost all were functionally independent.

  - Oral potassium is preferred unless there is an inability to swallow or there are cardiac symptoms
  - Avoid intravenous fluids with dextrose or physiologic saline solution
  - Vigilant cardiac monitoring
  - Serial potassium levels
  - Serial muscle strength examinations
- **Botulism symptoms**
  - Weak cry
  - Poor suck and swallow
  - Decreased tone
  - Decreased reflexes
  - Weakness in descending pattern
  - Constipation
  - Autonomic symptoms
  - Tachycardia
  - Fluctuating blood pressure
  - Urinary retention
  - Decreased tears and saliva
  - Flushed skin or pallor

Neuromuscular diseases, which encompass the entire motor unit, may have similar presentations initially and must be deciphered in a methodical manner. The motor unit consists of the anterior horn cell, which is located in the spinal cord and terminates in a motor nerve; the myelin associated with the nerve; the neuromuscular junction; and the muscle that the nerve innervates. Any disruption of function in this pathway may produce weakness of some variety. Neuropathies and myopathies have similar clinical findings, including weakness and decreased or absent reflexes. These disease processes may be distinguished, however, by sensory abnormalities and the distribution of the weakness. Neuromuscular junction defects may have reflexes present, as in myasthenia gravis, or absent, as seen in tick paralysis. The clinician can narrow the etiologic possibilities by considering the clinical presentation, family history, recent illness, travel history, inciting factors, and the clinical course.

This chapter is devoted to acute neuromuscular diseases that may be seen in a pediatric intensive care unit (PICU). Although

clinicians may encounter a variety of neuromuscular illnesses, this chapter begins with the most common disorders seen in the PICU. Weakness due to spinal cord or other central nervous system abnormalities are discussed in a separate chapter.

Guillain-Barré Syndrome

The most common acute neuromuscular disease seen in the intensive care unit is Guillain-Barré syndrome (GBS). When given the history of an ascending paralysis, a clinician can easily place GBS in the differential diagnosis; however, this history may be difficult to obtain, particularly if the patient is a small child or an infant. GBS is the most common cause of acute flaccid paralysis in children. The incidence is estimated to be 0.38 to 1.1 per 100,000 in a population younger than 15 years.[1,2] A prodromal respiratory or gastrointestinal illness is commonly found in the history. The prodromal illnesses may include *Campylobacter jejuni* and cytomegalovirus. In one study, 70% of patients reported an illness before the onset of symptoms, with 26% having documented cytomegalovirus.[3]

The neurologic symptoms typically present with progressive paralysis that is relatively symmetrical and may evolve to all extremities. Other symptoms include varying degrees of hyporeflexia or areflexia, or even respiratory embarrassment. Other presentations may include acute ataxia, pain, or cranial neuropathies.[4,5] In one study, risk factors for patients requiring ventilation included cranial nerve involvement, elevated cerebrospinal fluid (CSF) protein during the first week of illness, and a short period between antecedent illness and onset of symptoms.[6]

Autonomic symptoms, which may be overlooked, also are present in some cases. Autonomic instability, particularly cardiac arrhythmias, increase the morbidity of this disease. Cardiac monitoring of the R-R interval with reduction of beat-to-beat variability may possibly identify patients at risk for fatal arrhythmia.[7] Cardiac arrhythmias induced by tracheal tube manipulation have been reported.[8]

Asbury and Cornblath[9] have established criteria for the diagnosis of GBS. Per their criteria, the features that are required for the diagnosis include progressive motor weakness of more than one limb and areflexia. Symptoms that are strongly supportive of GBS include the relative symmetry of symptoms, mild sensory symptoms, cranial nerve involvement, autonomic symptoms, and recovery that usually begins 2 to 4 weeks after symptom progression discontinues. Sphincter disturbances rarely occur early in the course of GBS and are usually transient.[10]

Diagnostic studies include examination of the CSF and nerve conduction studies. The CSF reveals elevated protein amid a relative paucity of white blood cells, usually less than 10 cells/mL, with the protein increasing after the first week of symptoms.[9] Electrodiagnostic testing reveals motor conduction velocities in the demyelinating range, conduction block, temporal dispersion, and prolonged F waves. Bradshaw and Jones[4] reported that conduction block and temporal dispersion occurred in 74% of patients.

If the symptoms are severe, treatment options for GBS include plasmapheresis and administration of intravenous immunoglobulin (IVIg). In 2003 the American Academy of Neurology published a practice parameter after reviewing the adult literature and made several recommendations.[11] First, plasmapheresis and IVIg both hasten recovery, and neither is more efficacious. Using these two treatments sequentially is not superior to using either treatment alone. Finally, steroids do not seem to help. The decision of which therapy to apply to children is controversial because a large randomized study has not been performed. Plasmapheresis may be technically difficult to perform in young or very small children; therefore immunoglobulin may be used with more ease. Results from one adult study in which the two methods were compared showed that 53% of the patients treated with immunoglobulin improved by one or more grades on the functional scale at 4 weeks compared with 34% of the patients treated with plasmapheresis.[12] Favorable improvement in pediatric patients treated with immunoglobulin has been reported in several small series.[13-16] More recently, a randomized trial in children showed that fewer relapses occurred if 2 g/kg of IVIg were divided over 5 days instead of 2 days.[17] If additional courses of IVIg are necessary, a 2-day protocol is often well tolerated.

Several GBS variants exist. The best known are the Miller-Fisher variant and acute inflammatory axonal polyneuropathy, the axonal form of GBS. The neurologic triad found in the Miller-Fisher syndrome includes ataxia, areflexia, and ophthalmoparesis. Miller-Fisher syndrome has been linked to immunoglobulin G antibodies against ganglioside GQ1b.[18] In some *C. jejuni* strains, molecular mimicry exists between the surface epitopes and ganglioside GQ1b.[19] The GQ1b ganglioside is thought to cross-react in the brainstem area of the ophthalmic cranial nerves.[20] The axonal form of GBS has been associated with a more prolonged recovery than the classic form of GBS, which is attributed to axonal involvement. Early research suggests that CSF levels of neurofilament correspond to levels of axonal damage on electromyographic (EMG) testing and may help complement EMG studies to help predict patients who will have more prolonged recoveries.[21,22]

Myasthenia Gravis

Myasthenia gravis (MG) has many forms that may present in the pediatric population. The juvenile form of MG is the most common and is clinically identical to the autoimmune adult form of MG. Overall, however, juvenile MG is rare and comprises 10% of all cases of MG in Western populations. Antibodies directed toward the acetylcholine receptor (AchR) at the postsynaptic neuromuscular junction cause this form of the disease. These antibodies result in blockade of the AchR, increase the degradation of the AchR, and also result in complement damage to the AchR.[23] Fenichel[24] reported that 75% of cases occur after age 10 years; however, this age of onset has been debated in recent years.[25,26] AchR antibodies are found less frequently in juvenile MG compared with adult autoimmune MG and are more easily shown in the postpubertal patient population.[27] Anticholinesterase antibody levels should be determined, however, in all patients with suspected MG. Newer assays are finding antibodies previously missed in older anticholinesterase antibody assays, including binding, blocking, and modulating, but these assays may need to be ordered separately.[28-30]

The most common heralding symptoms of weakness in MG include ptosis (with pupillary sparing) and diplopia (from restricted eye movements). These symptoms wax and wane, and the weakness may generalize to the extremities. The two clinical forms of juvenile MG are ocular and generalized. In

ocular MG, symptoms include ptosis and diplopia, but the weakness does not progress to other areas of the body. Generalized MG may begin with ocular symptoms and progress to generalized weakness, usually within 1 year of onset; however, generalized weakness may be the initial presentation. The exact prevalence of generalized compared with ocular forms of juvenile MG is disputed. As in adults with MG, pediatric patients have the fewest symptoms in the morning or after rest, with increasing fatigability with exercise being a hallmark of this disease. The most troublesome symptoms seen in generalized MG are those involving bulbar and respiratory muscles, which may result in difficulty chewing or swallowing and exercise intolerance.

When a patient is suspected to have MG, the classic diagnostic bedside test is the edrophonium (Tensilon) challenge. Edrophonium is an intravenous short-acting anticholinesterase preparation that is no longer available in many hospitals. The dosing is 0.15 mg/kg in infants and 0.20 mg/kg in older children. Only 10% of the entire dose is given initially so that the clinician can observe for muscarinic adverse effects. Atropine (0.015 to 0.040 mg/kg) should be available for these possible adverse effects, which include bradycardia and respiratory distress resulting from bronchial secretions and bronchospasm. After the trial dose is tolerated, the entire dose is then given. In lieu of edrophonium, neostigmine is given at a dose of 0.025 to 0.050 mg/kg intramuscularly. The patient should be observed during the trial for changes in ptosis or fatigability. The onset of action with edrophonium is approximately 30 to 90 seconds after intravenous delivery and remains for approximately 5 minutes. Neostigmine has an onset of action within 15 minutes, and effects may last for 1 hour. Many clinicians also perform a blinded placebo trial of normal saline solution.

The neurodiagnostic study used in patients with suspected MG is repetitive nerve stimulation. This study is best performed on proximal muscles, although distal muscles are often studied. The confirmatory finding on repetitive nerve stimulation is a 10% decrement in amplitude of the compound muscle action potential.

Antibodies have been found that can block, bind, or modulate AChR. Approximately 80% of patients will have antibodies to AChR found in standard assays. Antibodies directed against muscle specific kinase (MuSK) appear to account for some of the remaining 20%.[28] Newer, more sensitive assays can also find antibodies with low affinity for AChR.[30] Clinically, MuSK-positive patients tend to have more frequent bulbar involvement and respiratory crises than do AChR-positive patients and require larger doses of maintenance corticosteroids, although there is no clear difference in clinical outcomes.[31] Seronegative (AChR-negative and MuSK-negative) patients have a disease severity between the other two groups but appear to have better clinical outcomes.[31]

Treatment of MG begins with anticholinesterase medications. The symptoms of MG usually respond to pyridostigmine bromide (Mestinon), the most common oral form of anticholinesterase medication. The dosage of pyridostigmine bromide is 7 mg/kg/day divided four to six times daily as needed for symptoms. Immunosuppressant agents, including prednisone, azathioprine, cyclophosphamide, and tacrolimus, may be added to the regimen for pyridostigmine nonresponders.[32] Mycophenolate also may be prescribed, although it has not proved more efficacious than placebo in two randomized trials of patients already taking prednisone.[33,34] Prednisone is usually initiated at 1 to 2 mg/kg/day. Clinicians must be careful when using prednisone because it may exacerbate weakness on initiation.

Many studies have suggested that the beneficial effects of thymectomy are best when it is performed early in the course of MG.[27,35,36] Because of the spontaneous remission rate of 22.4 per 1000 person-years reported by Rodriguez et al.,[37] as however, many clinicians are reluctant to proceed with early thymectomy, particularly with young children.

Myasthenic crisis is an exacerbation of myasthenic symptoms requiring ventilatory assistance. In adults with MG, myasthenic crisis has been reported to occur in 15% to 20% of patients, with 74% having their first crisis within 2 years of disease presentation.[38,39] Anlar et al.[40] reported that one third of patients with juvenile MG had at least one episode of crisis. Crisis duration in adults has been reported as having a median duration of 13 days by Thomas et al.[39] Initial therapy during crisis includes mechanical ventilation, which provides rest for the weakened patient. Two retrospective studies suggest that the use of biphasic positive airway pressure) may prevent intubation and shorten hospital stay.[41,42] In each study, hypercapnia was a predictor of biphasic positive airway pressure failure.[41,42]

Anticholinesterase medications should be discontinued because they increase secretions that could lead to mucous plugging. Myasthenic crisis is most commonly heralded by infection in 38% of patients; however, 30% of patients have no obvious trigger for their crisis other than respiratory or bulbar weakness.[39] A thorough investigation for the cause of the crisis should be undertaken. The mortality rate has fallen with improvements in health care; however, Thomas et al.[39] recently reported a 10% mortality rate in patients with myasthenic crisis.

Plasmapheresis and IVIg (2 g/kg over 2 to 5 days) also play a role in the treatment of myasthenic crisis and acute exacerbations of myasthenic symptoms. In cases of adult crisis, plasmapheresis has been shown to be more efficacious than IVIg; however, plasmapheresis has more deleterious adverse effects, including cardiovascular and infectious complications.[43] In the first randomized adult trial between plasmapheresis and IVIg, no significant difference was found between the two treatments; however, this study also included myasthenic exacerbations, as well as crisis.[44] Only small numbers of juvenile MG exacerbations or crisis treated with IVIg have been reported.[45,46] These reports have been favorable for IVIg in acute exacerbations of MG.[45,46] IVIg has been shown to be superior to placebo in a randomized controlled trial, with significant improvements seen as early as 14 days after infusion and lasting through 28 days.[47] Several dosing regimens have been used. The previous study used 2 g/kg divided over 2 days; another study failed to find a difference between a 1 g/kg dosage of IVIg given over 1 day and a 2 g/kg dosage given over 2 days.[48] Evidence supports the use of IVIg to treat patients experiencing myasthenic crisis or to treat an exacerbation in patients in whom plasmapheresis is not feasible.

Cholinergic crisis must also be a consideration in a patient with an MG exacerbation. Cholinergic crisis occurs with an overdose of anticholinesterase drugs in patients with MG. The overdose causes depolarization of skeletal muscles and muscarinic adverse effects, including increased secretions, diarrhea, lacrimation, sweating, and bradycardia. These symptoms will

improve upon withdrawal of the anticholinesterase medications. Some authors argue that cholinergic crisis is rarely the cause for worsening myasthenic symptoms.[38,49]

The clinician must always be cautious when initiating new medications in patients with MG. Many drugs interfere with the neuromuscular junction; the drugs best known for doing so are the aminoglycoside medications. Steroids can exacerbate weakness in a patient with MG, although this potential is not well recognized. For this reason one must be cautious when initiating the use of prednisone in a patient with refractory MG; it is necessary to observe the patient closely for any initial increased weakness. Antibiotics that have been implicated in the worsening of myasthenic symptoms include ampicillin, ciprofloxacin, clindamycin, erythromycin, sulfonamide, tetracycline, and the peptide antibiotics (polymyxin A and B and colistin). Cardiovascular medications including antiarrhythmic agents (e.g., quinidine, procainamide, and lidocaine) and β-blockers (e.g., propranolol, timolol, and others) also have been reported to worsen symptoms. Thyroid replacement medications and phenytoin also may cause problems. The neuromuscular junction blockers, including vecuronium, rocuronium, and pancuronium, as well as succinylcholine, should be used with caution because the effects of these medications are prolonged in patients with MG.[49,50] The Myasthenia Gravis Foundation of America maintains a list of medications to avoid and to use with caution on their Web site at www.myasthenia.org.

Additional immune diseases have been associated in approximately 16% of patients with juvenile MG.[37] The autoimmune diseases may include asthma, rheumatoid arthritis, juvenile diabetes mellitus, hyperthyroidism, chronic inflammatory demyelinating polyneuropathy, and central nervous system demyelination.[25,37,51,52] Seizures have occurred in 4% to 12% of patients with juvenile MG, although the exact cause is not known.[25,37]

Congenital and Transient Neonatal Myasthenia Gravis

The other forms of MG are congenital MG and neonatal transient MG. Neonatal transient MG is unique in neonates who are born to mothers with autoimmune MG. Neonates can manifest symptoms of neonatal transient MG even if the mothers were symptom free during pregnancy and delivery. Neonatal transient MG occurs in approximately 12% of infants born to mothers with MG.[53] If a mother with MG gives birth to an infant with neonatal MG, her subsequent neonates are also at increased risk of having this transient disorder. Neonatal MG usually resolves in the first few weeks after birth, when the maternally derived antibody level diminishes in the neonate. Results from several studies have shown that even symptom-free infants born to mothers with MG have elevated titers of AchR antibodies.[54] Additionally, the same phenomenon has been reported in infants born to mothers with anti-MuSK.[40] It is not known why some infants appear to be more susceptible than others for having transient neonatal MG. The antibody concentration of the symptom-free neonate rapidly decreases when compared with the antibody concentration of a neonate with symptoms.[55] The symptoms of neonatal transient MG usually include hypotonia, feeding problems (particularly fatigue), weak cry, and respiratory difficulty. These symptoms are treated with supportive care, and anticholinesterase medications are used for severe symptoms.

Congenital MG usually presents in childhood, with symptoms similar to those of juvenile MG. Many defects are responsible for causing symptoms in congenital MG, including congenital abnormalities resulting in presynaptic, synaptic, or postsynaptic defects of the neuromuscular junction.[56] Congenital MG is always negative for Ach antibody, and a family history of congenital MG may or may not be present. The inheritance of congenital MG may be autosomal recessive or dominant, or sporadic.[56] Treatment of congenital MG is different from the treatment of juvenile MG because immunosuppression obviously does not play a role. Symptoms of congenital MG may or may not respond to anticholinesterase medications.

Tick Paralysis

The clinician must always entertain the possibility of tick paralysis in the differential diagnosis of acute flaccid paralysis in children. On presentation, patients with tick paralysis may be mistakenly diagnosed with GBS. The treatment of the two diseases is distinct; therefore a high index of suspicion for tick paralysis should be maintained.

Affected patients are usually between the ages of 1 and 5 years. A review of 33 patients with tick paralysis reported that 82% were younger than 10 years, and 76% were female patients.[57] Longer hairstyles have been speculated to be the cause of this female preponderance. A thorough search of the patient should ensue because more than one tick may be attached. The ticks most commonly implicated in North America are *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick)[58]; however, other types of ticks have been documented. In Australia, the most common tick variety to cause paralysis is *Ixodes holocyclus*.[58] The cause of the weakness is a neurotoxin that is secreted in the saliva of the gravid female tick. The neurotoxin is produced during the engorgement phase of feeding after mating. The neurotoxin inhibits the release of acetylcholine at the presynaptic terminal.[58]

The symptoms in North American hosts begin with vague complaints of fatigue, irritability, and pain. Vague symptoms may not begin until approximately 5 days after tick attachment, but they progress rapidly.[59] Symptoms may include cerebellar signs, such as ataxia.[59] If the tick remains attached, a symmetrical ascending flaccid paralysis with areflexia develops. Subsequently, bulbar and facial weakness as well as respiratory involvement occur. No systemic features are seen in tick paralysis. Patients are afebrile with normal vital signs, erythrocyte sedimentation rate, CSF, and mental status. The removal of the tick results in the rapid reversal of symptoms, usually within 24 hours.

Upon discovery, the tick needs to be promptly removed. Removal of the tick is performed with blunt curved forceps or tweezers. The tick should be grasped at the point of attachment, as close to the skin as possible. The tick should be pulled upward with steady pressure. Twisting or jerking motions may cause parts of the tick to break off, particularly the mouth parts. The tick should not be handled with bare hands. Needham[60] evaluated various methods of tick removal including fingernail polish, petroleum jelly, 70% isopropyl alcohol, and a hot kitchen match. None of these passive techniques induced tick detachment.

Tick paralysis is more severe in Australia than in North America. The presenting symptoms are similar to those in

the North American cases; however, ocular involvement with nonreactive pupils has been described.[61] Flaccid paralysis may take days to evolve, unlike in North American hosts. The major difference in Australian tick paralysis occurs after the tick is removed. Australian patients must be carefully observed because maximal weakness may not occur until 48 hours after tick removal.[61] Another distinguishing feature of Australian tick paralysis is the possible use of an antitoxin for treatment. The antitoxin, a canine hyperimmune serum, is used cautiously in humans because of potential reactions, including serum sickness.[61] Efficacy of the antitoxin remains uncertain because no controlled studies have been performed.[61]

Periodic Paralyses

Clinicians may encounter several forms of periodic paralysis (PP), including hypokalemic, hyperkalemic, and normokalemic. Persons with most forms of the periodic paralyses have a family history of the disease. The weakness, which eventually results in paralysis, is associated with potassium response as demonstrated in hyperkalemic PP (HyperPP) or potassium serum levels in hypokalemic PP (HypoPP). PP also may be accompanied by cardiac abnormalities, as in Andersen-Tawil syndrome, and thus checking an electrocardiogram may be prudent, regardless of the serum potassium level.[62]

Hypokalemic Periodic Paralysis

HypoPP is the most common form of the periodic paralyses. The presentation of HypoPP usually occurs within the second decade of life. The number of attacks, which may be frequent, usually decrease as patients get older. The rate of occurrence of HypoPP is 1 in 100,000 people. The inheritance pattern of HypoPP is autosomal dominant, with boys/men more frequently affected, but one third of cases are sporadic.[63,64] The most common mutation in familial HypoPP is the dihydropyridine receptor in the voltage sensitive Ca channel, located on chromosome 1q.[65] Another common mutation is a voltage-sensitive sodium channel, SCN4A.[64,66] In a minority of cases no mutation is found.[67]

The onset of symptoms in persons with HypoPP usually occurs after the consumption of a high-carbohydrate meal or after vigorous exercise followed by rest. Other provoking factors include cold temperature, emotional stress, menses, and pregnancy.[64,66,68] In one study of a large affected family, Chinese food was specifically cited as a specific provocative factor.[68] Weakness usually begins during sleep with the patient noticing weakness upon awakening. The weakness usually begins proximally in the legs and then progresses distally before the upper extremities become involved; it may progress to flaccid paralysis of all limbs with areflexia and normal sensation. Cranial nerve function remains normal, and swallowing and respiratory function are rarely affected. The patient remains alert with a normal mental status during the attack, and sensation remains intact. Weakness usually lasts a few hours but may last several days. Upon noticing the initial symptoms of mild muscle cramping or "heaviness," however, some patients are able to abort an attack with light exercise.[69] Sudden death from cardiac arrhythmias or respiratory failure has been reported.[70,71] During paralytic attacks, patients have minimal urine output, with decreased potassium excretion and absent defecation.[68,72] In persons with HypoPP, myotonia confined to the eyelids has been described.[73] Before this report, myotonia was described as occurring only with hyperkalemic periodic paralysis.

Diagnosis of HypoPP can be confirmed with the identification of hypokalemia during an attack. Laboratory testing during HypoPP reveals a markedly diminished potassium level. Although serum potassium levels are decreased, the total body amount of potassium remains normal. The decreased potassium level is due to a shift of the potassium into the muscle cells, resulting in inexcitable muscle cells.[74] During an attack, potassium levels usually fall below 3, but levels below 2 have been reported.[75] Secondary causes of hypokalemia such as Bartter's syndrome, use of corticosteroids and diuretics, hyperaldosteronism, ingestion of laxatives and licorice, renal tubular acidosis, amphotericin B, p-aminosalicylic acid, alcoholism, and villous adenoma must be ruled out.[76]

The paralytic attack may be reversed with normalization of the potassium level. The clinician must be careful when correcting the potassium level, remembering that the total body amount of potassium remains normal. Correction with orally administered potassium (0.2 to 0.4 mmol/kg every 15 to 30 minutes) should be considered. Patients with cardiac symptoms or an inability to swallow, however, require parentally administered potassium.[63] While the potassium level is corrected, vigilant cardiac monitoring, monitoring of serial potassium levels, and muscle strength examinations should be used. Administration of intravenous fluids with dextrose or physiological saline solution should be avoided because they may prolong an attack or even induce cardiac arrhythmias.[76,77] Griggs, Resnick, and Engel[76] reported that a 5% mannitol solution should be considered as a diluent for intravenous potassium replacement.

Links et al.[68] studied a large kindred with HypoPP and showed that all family members older than 50 years had permanent muscle weakness. Muscle biopsy specimens from patients with HypoPP reveal vacuoles in the muscle fibers.[71] Vacuolar changes in the muscle also have been shown in family members of persons with HypoPP who have not had any paralytic attacks.[68] Links et al.[68] concluded from their study that all patients eventually exhibit permanent muscle weakness but that only 60% may have paralytic attacks.

Once a patient is known to have HypoPP, prophylactic medications should be initiated. Acetazolamide has been shown to prevent future attacks in patients with and without a family history of the disease when they take daily doses of 250 to 750 mg.[78] Some patients, however, have been reported to have an exacerbation of attacks when taking acetazolamide.[79] Another report revealed that acetazolamide prophylaxis improved strength between attacks in 80% of patients who displayed persistent weakness between paralytic attacks.[78] Daily oral ingestion of potassium chloride shortens the duration of the attacks but does not appear to prevent attacks.[78] Other medications used for prophylaxis of attacks include triamterene and spironolactone in patients who are not responsive to acetazolamide.[78,79] Other considerations for the prevention of attacks include avoidance of high-sodium, high-carbohydrate meals as well as arduous exercise followed by prolonged rest.

Thyrotoxic periodic paralysis is another entity of weakness with concomitant hypokalemia. As the name implies, a thyrotoxic state is the impetus of this disease. It is mostly found in adult Asian boys/men, although it has been reported in the Asian-American pediatric population.[80] The purpose of

treatment of this disease is to alleviate the hyperthyroid state (also see Chapter 77).

Hyperkalemic Periodic Paralysis

The term *hyperkalemic periodic paralysis* (HyperPP) may be misleading because high, normal, and low levels of potassium have been reported in these attacks.[81] The name "HyperPP" actually correlates to the response these patients have to potassium. HyperPP is also referred to as potassium-sensitive PP, a term that may be more appropriate and less confusing. HyperPP is autosomal dominant with a common gene located on chromosome 17q, affecting the alpha subunit of the sodium channel, but other sodium channels also may be affected.[64,82,83] Sporadic cases have been reported.[64,84] HyperPP usually presents in the first decade of life.

Rest after exercise is the most common provoking feature of HyperPP. Other provoking factors include cold temperatures and skipping meals. The pattern of weakness is similar to that of HypoPP: the legs are usually affected before the arms, with symmetrical weakness. The sensory examination is normal during an attack. Weakness during the attacks varies from mild to flaccid quadriplegia with areflexia, but respiratory weakness rarely occurs. The usual length of attacks is shorter than that of HypoPP attacks; HyperPP attacks usually resolve in a few hours, but they may persist for days. Myotonia and Chvostek's sign are often found in these patients.

Light exercise can prevent an attack. Attacks may be provoked by potassium intake and relieved by glucose intake. Most attacks do not require treatment. In the rare severe attack, however, glucose can be administered intravenously.[85] Cardiac monitoring is important if medical intervention is needed because cardiac arrhythmias may occur.[86] Prophylactic therapy should be considered in these patients because permanent muscle weakness develops over time.[87] Muscle biopsy specimens reveal vacuoles in the muscle cells.[81] Acetazolamide and thiazide agents have been used for prophylaxis of this disease.[88]

Normokalemic Periodic Paralysis

Normokalemic periodic paralysis (NormPP) is a disputed phenomenon. Patients with NormPP have normal potassium levels during an attack and have been shown to be sensitive to potassium.[89] Provoking factors include cold temperatures, alcohol intake, and stress.[89] The kindred described by Poskanzer and Kerr[89] also displayed autosomal dominant inheritance. Therefore it has been argued that this is actually HyperPP, which also is known to display normal values of potassium during an attack. Molecular testing has revealed NormPP mutations in genes associated with HyperPP and HypoPP.[90,91] Treatment of this disease is similar to the treatment of HyperPP.

Botulism

Infantile botulism is a syndrome predominately found in infants ages 6 days to 12 months.[92] In infantile botulism, *Clostridium botulinum* enters the body as a spore through ingestion, germination occurs, and the organism begins to produce the neurotoxin that is the cause of the symptoms.[93] Infant botulism differs from foodborne botulism, in which the preformed toxin is actually ingested. In mouse models, the relationship of the gut and the spores are important, with the pH of the gut and the transient lack of competitive intestinal flora being essential in allowing the spores to germinate.[92] Infants appear to be susceptible, as are adults who have abnormal intestinal flora from abdominal surgery, gut abnormalities, or antibiotic use.[94-97]

Most cases of infantile botulism occur in California, Pennsylvania, and Utah. In one report, more than 75% of the patients with botulism had *C. botulinum* in their home environment.[98] Other sources include soil disruption from cultivation or construction and parental occupations that involve soil exposure.[99] The consumption of honey and corn syrup is a risk factor; these products should not be fed to children who are younger than 12 months. The role of breast-feeding in botulism remains controversial.[100] In one study of 44 patients with botulism, 100% of the patients were breast-fed.[99] Nevertheless, breast milk has been cited as a protective influence against botulism. Arnon et al.[101] reported that of the 10 patients who died of sudden infant death syndrome that was linked to *C. botulinum* infection, eight were fed formula exclusively, and the remaining two patients had not received breast milk 10 weeks before their death. They concluded that breast-fed infants are not completely protected from botulism but appear to have diminished severity of the disease at onset.[101]

The botulinum toxin irreversibly binds at the presynaptic segment of the neuromuscular junction, inhibiting acetylcholine release and causing neuromuscular weakness. The autonomic system is also affected because the toxin binds the acetylcholine-mediated preganglionic parasympathetic and sympathetic synapses, as well as the postganglionic parasympathetic synapse.[102]

The most common symptoms include weak cry, poor suck and feeding, decreased tone with decreased reflexes, weakness in a descending pattern, and constipation.[102] Autonomic symptoms, which often are the first to appear, include constipation, tachycardia, fluctuating blood pressure, urinary retention, decreased tears and saliva, and flushed skin or pallor.[92,103] L'Hommedieu and Polin[103] proposed an algorithm of symptoms beginning with tachycardia and constipation progressing to loss of head control, difficulty feeding, and weak cry. A depressed gag reflex is followed by peripheral muscle weakness and, finally, diaphragmatic weakness. Because of the combination of autonomic and neuromuscular symptoms, the infant with botulism may mistakenly be thought to be septic or dehydrated. Enlarged, sluggishly reactive pupils also may be present but are less common than the other autonomic symptoms.[104]

The consequence of botulism that is of greatest cause for concern is respiratory embarrassment. Schreiner, Field, and Ruddy[102] reported that only 24% of the patients reviewed did not require ventilation or an artificial airway. Patients with botulism also have become apneic during certain procedures, including lumbar puncture and placement of an intravenous catheter.[102] Hypoxic ischemic encephalopathy resulting from respiratory arrest also has been described.[104] Other complications that have been described include syndrome of inappropriate secretion of antidiuretic hormone, urinary tract infections, pneumonia, and autonomic instability.[102] Aminoglycosides exacerbate the neuromuscular blockade and should be avoided in persons with botulism.[105] L'Hommedieu et al.[105] reported that in five patients with

botulism who received aminoglycosides, clinical deterioration was apparent in all of them.

The diagnosis of botulism is clinical but confirmed by isolation of the organism or toxin in stool. EMG in patients with botulism reveals decreased compound motor action potential amplitude and facilitation of the compound motor action potential amplitude with high-frequency repetitive motor nerve stimulation.[106]

The management of patients with botulism has advanced in recent years. Previously, clinicians could offer only supportive care until axonal sprouting could reestablish the neuromuscular junction. The median length of hospital stay was 27 to 37 days, and patients typically required mechanical ventilation for a median of 13 to 16 days.[98,104,107] In patients with respiratory compromise, mechanical ventilation should be instituted until the patient regains protective reflexes and respiratory strength. If patients are unable to tolerate eating orally, nasogastric or nasojejunal feeding should be initiated. Human botulism immune globulin (BIG) has provided the first direct pharmacologic treatment. A randomized, controlled trial has shown that BIG decreased mean hospital stay (5.7 weeks to 2.6 weeks), mean duration of mechanical ventilation, mean duration of feeding through a tube or intravenously, and mean hospital charges with no adverse effects related to BIG.[108] A retrospective article spanning 30 years complemented the randomized trial.[109] Resolution of symptoms occurs in the reverse pattern of presentation, with return of head control appearing to be a reliable measure of improving muscle function.[103]

Diphtheria

Although diphtheria was the leading killer of children in the early 20th century, the United States currently reports fewer than 10 cases of diphtheria annually. Epidemics have occurred in developing countries. Recently the former Soviet Union had a dramatic resurgence of diphtheria, with approximately 48,000 cases reported in 1994.[110]

Although several forms of diphtheria exist, the most common in children is the upper respiratory tract infection. Initial mild infection of the pharyngeal area is followed by tonsillar pseudomembrane formation. The pseudomembrane consists of necrotic epithelium and fibrin, as well as numerous colonies of the bacterium, and may cover the airways and pharynx to the main bronchi down into the smaller bronchi. It can lead to aspiration and ultimately complete obstruction of the airway. Extensive soft tissue edema and lymph node enlargement occur.[111]

Toxic myocardiopathy is estimated to occur in 10% to 25% of patients and is responsible for 50% to 60% of the deaths.[112] Toxic myocardiopathy often arises in the second to third week of illness when the affected individual is improving. Abnormalities of the myocardium, the conductive system, and the pericardium occur. The conductive disturbances are in response to the toxin.[113] Cardiac ectopy is 100% sensitive and specific to predict fatal outcome in children with severe diphtheria.[112]

When severe disease is present, neuropathy is seen in approximately three fourths of the patients.[111] In a classic case of diphtheria, local paralysis of the soft palate occurs 2 to 3 weeks after the beginning of the oropharyngeal infection. Weaknesses of the pharyngeal, facial, and ocular nerves follow. The symmetrical polyneuropathy has a varied onset from 10 days to 3 months following the oropharyngeal infection. The axonal and demyelinating neuropathies are based on the circulating toxins and range from motor weakness to sensory abnormalities in a stocking-glove distribution.[111,112]

The distal ascending weakness and spinal fluid findings are described as being "indistinguishable" from GBS.[112] Additionally, dysfunction of the autonomic function may occur with associated hypertension and cardiac failure, although this phenomenon is rare. Typically the patient recovers completely.

Diagnostically, cultures should be obtained from the nose, throat, and the infected mucocutaneous area. Giving the antitoxin is critical even when there is only a presumptive diagnosis. If the antitoxin is administered on the first day, the mortality rate is 1% compared with a rate of 20% if administration is delayed until the fourth day.[112] Immunoglobulin preparations also have been hypothesized as helpful. The only antimicrobial agents that have been the subject of prospective studies proving efficacy are penicillin and erythromycin.[112]

Airway complications should be anticipated, as should the probability of congestive heart failure and, ultimately, malnutrition. Studies have revealed no difference in the occurrence of carditis, neuritis, or death in patients receiving steroids. Additionally, use of digitalis is associated with an increased occurrence of arrhythmias. Overall prognosis depends on multiple variables, including the delay in the administration of the antitoxin along with the immunization status and age of the individual. The fatality rate of 10% for respiratory tract diphtheria has not changed in 50 years.[112]

Acute Intermittent Porphyria

The most common of the four types of porphyria is acute intermittent porphyria (AIP). Clinical symptoms in acute attacks span multiple medical subspecialties and may be precipitated by numerous medications, hormonal variations, calorie restrictions, and alcohol. AIP most commonly occurs in girls/women with the age of onset between 15 and 40 years, and it rarely occurs before puberty.[114]

An acute neuropathy is found in approximately 40% of acute AIP attacks.[115-117] The neuropathy typically follows the onset of the attack by 1 to 4 weeks but may do so as late as 11 weeks afterward. Although paresthesias and distal sensory changes may be a prodromal finding, the motor signs are much more prominent. Typically the patient has proximally symmetrical upper extremity weakness, but it may advance to involve the lower extremities. Generalized weakness is documented in approximately 42% of patients.[115] In AIP's most dramatic setting, the patient can have a rapid progression of weakness that leads to a flaccid involvement of all four extremities and respiratory compromise. When cranial nerves are involved, nerves VII and X are the most frequently affected. Vascular compromise has been documented in persons with vision loss, which may be monocular or total. Although this vision loss is usually transient, it can be permanent.[115]

AIP is often difficult to diagnose. The patient's chief complaints are typically nonspecific abdominal and back pain. This colicky pain often leads to the consideration of surgical intervention. Notably, AIP is not associated with temperature elevation, leukocytosis, or rebound tenderness.[115] Neurologic and psychiatric symptoms often accompany the onset of attack.

Another important issue is significant hyponatremia and associated seizures, which may be further precipitated by the use of intravenous fluids containing dextrose and water. Cardiovascular complications include hypertension and tachycardia. In its most extreme case, significant hypertension may be present with associated hypertensive encephalopathy and ischemic changes. Intravenous infusion of magnesium sulfate may be helpful.[114] Nutritional support is important to avoid a catabolic state, which will further complicate the clinical picture. In the event that nutrition is required intravenously, high-glucose solutions with dextrose are recommended. Enteral feeding is preferred, with carbohydrates providing 50% to 60% of the energy needs.[114]

Diagnostically in persons with AIP, urine and stool can be tested for alpha aminolevulinic acid. In addition, a marked elevation of urinary porphobilinogen (PBG) is seen. Checking PBG deaminase levels in the blood is helpful because they are abnormal even between the acute attacks.[114]AIP should be a consideration in the differential diagnosis of progressive weakness. It is most often confused with GBS. The ascending qualities, which are classic in GBS, are rare in acute porphyria. Additionally, persons with acute porphyria do not have elevation of the CSF protein or abnormalities of the cellular contents. The associated abdominal discomfort and tachycardia that are seen in porphyria would not be anticipated in GBS. Differential considerations should include lead intoxication and hereditary tyrosinemia as well.[115]

Elder and Hift[114] provided a review of AIP therapy. The two recommended approaches are carbohydrate loading and administration of heme. If the patient has severe symptoms such as seizures, hyponatremia, and initial signs of neuropathy, aggressive therapy is begun as early in the crisis as possible. In mild attacks it may be possible to wait 24 hours to determine if the attack will spontaneously reverse. Carbohydrate loading is delivered as a 20% glucose solution provided via a central venous catheter. Studies that support the use of heme are primarily noncontrolled and have difficulty reaching statistical significance, but the overall consensus is that it does provide benefit. Daily measurements of urinary alpha aminolevulinic acid or PBG may be a helpful monitor.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA), a disease of the anterior horn cell, is most commonly inherited in an autosomal recessive manner. The responsible gene is the survivor motor neuron gene on chromosome 5q13.[118,119] SMA has three subtypes that present in childhood, and both autosomal dominant and X-linked inheritance have been reported. The combined incidence of all forms of SMA has been estimated as 1 case in 6000 to 25,700 live births.[120,121] After cystic fibrosis, SMA is the next most common fatal disease with an autosomal recessive pattern of inheritance.[120] The most severe form is previously known as Werdnig-Hoffmann disease but is now more commonly referred to as SMA type I. It usually presents shortly after birth but should be apparent before age 6 months and is defined by the patient never being able to achieve independent sitting. SMA type II usually presents between ages 6 and 18 months and is characterized by the patient sitting but never standing or walking. In SMA type III, patients do stand independently and walk.

In SMA type I, the examination reveals a floppy baby with proximal weakness greater than distal weakness. The lower extremities are more affected than the upper extremities, and the only spontaneous movement in these infants may be in the hands and feet. When supine, the infant will assume a frog-legged position. Polyminimyoclonus, a fine tremor most easily visualized in the hands, also may be present in these patients. Areflexia, tongue fasciculations, facial weakness, and normal sensation are also found.[122,123] Retrospectively, some mothers will report decreased fetal movement during the pregnancy with the affected infant. Death usually occurs before age 2 years as a result of respiratory problems.[120] In patients with clinical symptoms within the first day of life, life expectancy was between 2 and 6 months, with a mean age at death slightly before 4 months.[124]

Patients with SMA type II usually have delayed motor milestones after having normal motor development in infancy. Polyminimyoclonus is also present in these patients. Life expectancy is variable, with many patients not surviving past adolescence.[120] Life expectancy can be enhanced, however, with fastidious respiratory care.[125] Not surprising was the correlation that patients with an earlier onset of the disease had an earlier death.[126]

In SMA type III, weakness is again more proximal than distal, with the lower extremities being more severely affected. The gait exhibited in these patients has a waddling quality, and lumbar lordosis is also prominent. Once the patient loses the ability to ambulate, the inability to raise the hands above the head also occurs.[127] If symptoms begin after age 2 years, ambulation may continue to a median age of 44 years.[127] If symptoms begin before age 2 years, ambulation continues to a median age of 12 years.[127] Life expectancy for patients with SMA type III may be the same as in the normal population because muscle weakness appears to stabilize in these patients.

Electrodiagnostic studies on these patients reveal normal motor conduction velocities. Over time, the amplitude of the compound muscle action potential may be decreased. Results from sensory nerve conduction studies are normal. EMG reveals evidence of acute denervation with spontaneous activity and chronic denervative changes with polyphasic motor units. Muscle biopsy specimens reveal angulated fibers suggestive of denervation. The creatine phosphokinase (CPK) level may or may not be increased. Genetic testing may be performed to confirm the diagnosis.

Respiratory complications are the most aspect of this disease that cause the most concern and include aspiration, pneumonia, and respiratory failure. Respiratory failure may even be the presenting symptom in SMA type I.[128] Respiratory muscle weakness results in restrictive lung disease with a weak cough and hypoventilation.[123] Hypercapnia is also a consequence of restrictive lung disease, so supplemental oxygen may have devastating consequences, including apnea and death.[123] If supplemental oxygen is needed, conventional ventilation or noninvasive ventilation should be instituted.

Other complications may occur over time. Scoliosis complicates pulmonary function over time because of chest wall alterations. Contractures, particularly in the lower extremities, are also common. In addition, feeding difficulties play a prominent role, particularly in the developing infant with SMA type I. If concerns arise, a feeding evaluation should be performed to rule out aspiration. Supplemental feeding through a nasogastric tube or gastrostomy may be necessary.

Aggressive symptomatic treatment, including more frequent use of ventilation and gastrostomy, has been associated with longer life spans. Specific pharmacologic treatments have not been successful.[129] Phenylbutyrate was ineffective in a randomized, controlled trial.[130] Although riluzole (which blocks glutamatergic neurotransmission in the central nervous system) is effective in persons with amyotrophic lateral sclerosis, it has not been adequately tested in children.[131]

Poliomyelitis

The paralytic form of polio represents only 1% to 2% of the actual infections. Aseptic meningitis represents less than 10% of infections and is often thought to be a nonspecific illness. The remaining 90% to 95% of those affected have no apparent infection. Patients who will have paralytic disorder show very high fevers and significant muscle pain with the lack of reflexes. Paralysis rapidly progresses to complete loss of motor use asymmetrically in one or more extremities over a few hours. The distribution of weakness is classically proximal and in the lower extremities. Cranial nerve abnormalities have been reported in 5% to 35% of the patients. Loss of function peaks at 5 days. The disorder can be associated with bowel and bladder problems over the initial 3 days. Sensory abnormalities are rare. Physical examination reveals meningeal findings with changes in the reflexes both superficially and deep. One of the classic signs described in the early reports is the "head drop." As the examiner lifts the patient's shoulders and raises the trunk, the head often falls backward in a limp fashion. It is thought that this phenomenon is not due to paralysis of the neck muscles because it can occur in the nonparalytic form. The clinical course may include significant respiratory muscle weakness. Involvement of the bulbar muscles, brainstem, the respiratory center, and cranial nerve pose difficulties in breathing and paralysis of the pharynx and vocal cords. Respiratory compromise leads to most deaths in the paralytic form.[132] Typically, 50% of patients with any paralysis exhibit some degree of residual deficits, although most do improve. A 10% mortality rate is now reported in the patients with the paralytic from. Before the use of mechanical ventilation, 60% died.[132]

A throat and stool culture may reveal the poliovirus, which is shed early in the course of pharyngeal infection and later from the stool. It is difficult to isolate from the spinal fluid in affected patients. Usually the results of routine laboratory tests are unremarkable. CSF findings are characteristic of aseptic meningitis. A white blood cell count between 20 and 300 cells is expected with a predominance of lymphocytes and a normal glucose level. Normal or slightly elevated levels of protein may be found. In the first few hours after the onset of symptoms, polymorphonuclear leukocytes may predominate, but within 12 hours the predominance of lymphocytes is seen.[132]

This disorder has numerous clinical manifestations. In the viral myocarditis, the heart is extremely sensitive, and thus very small doses of digoxin have been suggested. Hypertension is well recognized and can be severe enough to cause encephalopathy. In the child with poliomyelitis, analgesics, including opiates, may be required for pain relief. Hot packs have been noted to be effective when applied every 2 to 4 hours. Constipation and bladder paralysis are major issues early in the course and should be monitored closely. Because of the risk of aspiration and airway compromise, a high level of vigilance must be maintained. If the patient demonstrates respiratory compromise, then a tracheostomy is indicated with accompanying mechanical ventilation.[132] Use of antiviral agents is debated. Additionally, some authors argue that steroids are not indicated in enteroviral infections.[132]

Children who experience mild weakness generally have a full recovery. If paralysis is present, the recovery is ongoing for 2 years, with 80% realized by 6 months.[132] Adults may have new symptoms later in life after paralytic poliomyelitis, including weakness and muscle atrophy that is related to continued normal attrition of anterior horn cells.[133]

Polio-like Syndromes

Polio-like syndromes have been reported, and antiviral intervention has been advocated.[134] Interferon-α therapy within 24 hours of admission has been recommended on the basis of information from small case studies. The authors thought that this intervention altered the course and that improvement was evident within 1 to 2 days. West Nile Virus is now recognized as a possible etiologic agent for a polio-like syndrome.[135] Magnetic resonance imaging and proton magnetic resolution spectroscopy have been recommended to monitor the functional activity of the neurons. It is difficult to determine without further study whether the natural course would have been almost complete recovery or if it was in the fact the interferon-α intervention that was responsible.[136] Overall prognosis in patients with nonpolio enteroviral infections is very good.[132]

Organophosphate and Carbamate Poisoning

The clinician must always maintain a high index of suspicion and consider poisoning in the differential diagnosis in patients with altered mental status, respiratory symptoms, or weakness (also see Chapter 105). In their study of 37 children with organophosphate or carbamate poisonings, Zweiner and Ginsburg[137] reported that 43% of these patients were evaluated by their primary care doctor, and pesticide toxicity was not suspected. Patients commonly do not have a known history of exposure. Exposure to these substances may occur as inhalation, ingestion, or dermal contact. In one study of 37 infants and children with organophosphate and carbamate poisonings, 76% of these patients ingested these substances (which were improperly stored), 16% had transcutaneous exposure (through contact with treated carpets, linens, and lawns), and 8% were poisoned by an unknown etiology.[137] Cholinesterase, which is present in the neuromuscular junction, is irreversibly inhibited by organophosphates and reversibly inhibited by carbamate compounds. Therefore, a constellation of muscarinic, nicotinic, and central nervous system symptoms may occur.

Symptoms may originate from various systems. Muscarinic symptoms include miosis, excessive salivation, sweating, lacrimation, diarrhea, urination, and bradycardia. In severe poisonings, flaccid paralysis with areflexia is common. In moderate poisonings, muscle fasciculations may be present. Central nervous system symptoms include coma and seizures; however, seizures are less common in persons with carbamate toxicity.[138] Pulmonary symptoms including bronchoconstriction, increased pulmonary secretions, and wheezing have been reported.[139] In one study of 52 children with organophosphate or carbamate poisoning, 100% of these patients exhibited hypotonia, stupor, or coma.[140] With further analysis

of the 16 patients with organophosphate poisoning, the other common symptoms included miosis (56%), salivation (37%), pulmonary edema (37%), diarrhea (30%), and bradycardia (25%).[140] Various cardiac rhythms may occur with pathologic signs of cardiotoxicity.[141] Overall, carbamate poisonings are usually less severe and shorter in duration, although the symptoms are essentially the same as those found in organophosphate poisonings.[142]

If organophosphate and carbamate compounds are ingested, gastric lavage and activated charcoal should be initiated. If contaminated, the patient's skin and hair should be rinsed and cleansed thoroughly with soap, and the clothes should be changed to reduce further exposure.[138]

In both forms of poisonings, atropine is used as an antidote for the muscarinic symptoms. Treatment with atropine, however, does not reverse the nicotinic symptoms, which include muscle weakness and respiratory failure. Atropine should be administered as quickly as possible and in adequate doses. In children older than 12 years, the dosing is 1 to 2 mg intravenously every 10 to 30 minutes.[139] In children younger than 12 years, the initial dose is 0.05 mg/kg with maintenance doses of 0.02 to 0.05 mg/kg over 10 to 30 minutes.[139] In organophosphate and carbamate poisonings, the atropine dose is 5 to 10 times greater than conventional atropine dosing.[139] Atropine should be continued until the muscarinic symptoms begin to abate. The signs of atropinization include mydriasis, tachycardia, and xerostomia, and they help provide parameters for adequate dosing.[143] Atropine should be continued for at least 24 hours after severe exposures and then tapered if symptoms are improving.[139]

Pralidoxime chloride, the only cholinesterase reactivator in the United States, is an antidote for only the nicotinic symptoms of organophosphate poisonings; therefore atropine must be used concomitantly. Pralidoxime chloride does not help in carbamate exposures. Various doses have been reported for pralidoxime in patients older than 12 years. A conservative dose is 0.5 to 1 g administered intravenously over 15 to 30 minutes, repeated every 10 to 12 hours, beginning 1 to 2 hours after the initial dose. More recently, another study suggests a 2 g loading dose with a continuous infusion of 1g/h for 48 hours.[144] These doses have not been directly compared with each other. In patients younger than 12 years, the dose is 25 to 50 mg/kg administered intravenously over 15 to 30 minutes, repeated every 10 to 12 hours, beginning 1 to 2 hours after the initial dose.[139] Further studies appear warranted because a meta-analysis showed either no benefit or possible harm of pralidoxime compared with best medical therapy.[145]

After the antidotes are given, the mainstay of treatment is supportive. If necessary, ventilation should be provided until the patient regains respiratory strength. Suctioning of secretions in both the oropharynx and in the respiratory tree is essential. Seizures should be treated with diazepam or lorazepam. Cardiac monitoring should be implemented because complex ventricular arrhythmias may occur.[146,141] Early feeding may prolong the hospital stay.[147] Death usually occurs as a result of respiratory arrest and pulmonary complications, including excessive secretions, edema, and bronchoconstriction.[139]

Diagnosis is based on clinical findings and response to antidote medications. Serum and red blood cell cholinesterase levels should be obtained to assist in the diagnosis of organophosphate poisoning. Treatment should be initiated immediately and not be delayed while waiting for cholinesterase level results. Cholinesterase levels do not assist in the diagnosis of carbamate exposure because the reversal of the enzyme occurs too rapidly to be quantified.

Rhabdomyolysis

Rhabdomyolysis refers to a process in which myoglobin is liberated from injured or damaged skeletal muscle into the blood and urine, resulting in myoblobinemia and myoglobinuria. Evidence of chronic rhabdomyolysis, the most common form in children, may be discovered incidentally during routine blood laboratory workups that include CPK levels.[148] Acute episodes of rhabdomyolysis also may result from a myriad of causes. The history of the patient is extremely important in determining the exact cause. Acute episodes of rhabdomyolysis may be fatal because of electrolyte abnormalities, cardiac arrhythmias, and renal damage, which occur during this process.

Potential causes of rhabdomyolysis include environmental factors (extreme cold or heat); viral and bacterial infections; and metabolic abnormalities, including hypokalemia, hypernatremia, nonketotic hyperosmolar coma, and diabetic ketoacidosis.[149,150] Less common causes include excessive muscle activity as seen in convulsive seizures, extreme exertion, drugs, toxins, venoms, physical trauma, malignant hyperthermia, and metabolic myopathies.

Muscle-related symptoms found in rhabdomyolysis include severe weakness, hypoactive reflexes, tenderness, edema, cramps, and localized pain.[150,151] Muscle symptoms make the diagnosis more obvious; however, if the patient has decreased level of consciousness from metabolic abnormalities, trauma, drugs, or seizures, these muscle symptoms may be obscured.

Abnormal laboratory results include myoglobinuria and profound elevation of serum CPK. Muscle cell destruction results in the release of potassium and phosphorous into the blood, with consequential hyperkalemia, hyperphosphatemia, and eventually hypocalcemia.[151,152] Elevations of aldolase, uric acid, lactic dehydrogenase, and transaminase (serum glutamate oxaloacetate transaminase and serum glutamate pyruvate transaminase) levels also occur.[151,152]

Complications from rhabdomyolysis may affect the heart, kidneys, and ventilation. The severe myoglobinuria in rhabdomyolysis may result in acute tubular necrosis, which can be fatal. Alkalinization of the urine, hydration, and osmotic diuresis have been used to prevent renal damage.[152] Hypocalcemia, which results from the elevated potassium and phosphorous levels, may lead to cardiac arrhythmias. In the review by Robotham and Haddow,[151] several types of cardiac disturbances were reported, including ventricular arrhythmias, intraventricular conduction delays, abnormal axis deviation, sinus bradycardias and tachycardias, ischemic changes, nonspecific ST segment and T wave changes, and T wave changes associated with hyperkalemia. Compartment syndrome also may occur because of severe muscle edema, and fasciotomy may be required to prevent neurovascular compression.[152] If the diaphragm and intercostal muscles are affected, mechanical ventilation may be required. Bulbar weakness necessitating mechanical ventilation in rhabdomyolysis is rare.[152] Overall, it is unusual for muscle weakness to be permanent, with full muscle strength usually returning in 1 to 6 weeks.[152]

Several diseases may result in recurrent rhabdomyolysis. McArdle's disease, a metabolic myopathy that also goes by the names type V glycogenosis and myophosphorylase deficiency,

is predominantly autosomal recessive. Patients with this disease exhibit exercise intolerance, muscle stiffness, and myalgia.[153] Vigorous activity, including squatting, sprinting, and carrying heavy objects, may precipitate an episode of muscle rigidity with cramping and myoglobinuria resulting in rhabdomyolysis. Recognition of these symptoms will help achieve a timely diagnosis, prevent morbidity, and avoid recurrent rhabdomyolysis. Tarui's disease, also known as glycogenosis type VII and phosphofructokinase deficiency, is also autosomal recessive. The clinical picture is similar to that found in McArdle's disease and may also result in rhabdomyolysis.[153] Carnitine palmitoyltransferase deficiency is an autosomal recessive disease that also may lead to rhabdomyolysis. Carnitine palmitoyltransferase catalyzes carnitine and fatty acid for transfer into the mitochondria. Rhabdomyolysis may be precipitated by prolonged exercise and fasting and may be prevented by eating frequent meals of low-fat, carbohydrate-rich foods with avoidance of both fasting and prolonged exercise.[153]

Malignant Hyperthermia

Malignant hyperthermia (MH) is a disease that is associated with certain anesthetic agents, including inhalation anesthesia such as halothane and depolarizing muscle relaxant agents such as succinylcholine (also see Chapter 12). MH occurs in approximately 1 in 12,000 children with anesthesia.[154] MH has a variable clinical presentation as described by Kaus and Rockoff.[155] In classic MH, the symptoms include tachypnea, tachycardia, blood pressure abnormalities, cyanosis, mottling, and diaphoresis. Hypoxia, hypercapnia, metabolic acidosis, and muscle rigidity resulting in severe rhabdomyolysis also occur. The severe hyperthermia, which denotes the disease, may exceed more than 42° C. A second presentation of MH occurs after the administration of succinylcholine and results in an abrupt onset of generalized muscle rigidity, cardiac arrest, and rhabdomyolysis. An additional presentation is masseter muscle spasm, which occurs after the administration of halothane and succinylcholine, and results in severe contracture of the jaw that lasts 5 to 20 minutes.[155]

Recent advances have been made in understanding the genetics of MH. The ryanodine receptor appears to be involved, and first- and second-degree family members of patients who have or are suspected of having MH should be considered at risk for MH until a gene test or muscle biopsy is performed.[154,156] As more causative mutations are found, fewer patients will have unexplained causes of their MH. In addition to cases caused by mutations of the ryanodine receptor, some muscle diseases have been associated with MH, including Duchenne muscular dystrophy, Becker muscular dystrophy, central core disease, myotonia congenita, King-Denborough syndrome, Schwartz-Jampel syndrome, and other muscular dystrophies.[155]

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome occurs in 0.5% to 1.4% of patients exposed to antipsychotic medications.[157,158] Neuroleptic malignant syndrome has a constellation of signs and symptoms including hyperthermia, muscle rigidity, autonomic instability, tachycardia, tachypnea, diaphoresis, hypertension, and altered mental status (also see Chapter 124).[159] Rhabdomyolysis may be a component of this syndrome, which includes elevated CPK levels and myoglobinuria; therefore, MH may be in the differential diagnosis of severe acute-onset weakness.

Inflammatory Myopathies

Dermatomyositis and Polymyositis

Dermatomyositis and polymyositis are inflammatory myopathies with symmetrical proximal muscle weakness that progresses over weeks to months (see also Chapter 98, Autoimmune Diseases and Their Treatment). The incidence ranges from 2.5 to 4.1 per million children in the United States and comprised 5% of all rheumatologic referrals in one review.[160,161] Five major criteria exist for the diagnosis of polymyositis/dermatomyositis as described by Bohan and Peter.[162] Of the five criteria, one clinical criterion is symmetrical proximal weakness that may include respiratory muscles. Another clinical criterion is dermatological, which includes the heliotrope rash and Gottron's sign. In addition, a scaly erythematous rash of the face, neck, upper torso, knees, elbows, and median malleoli is also present. The two laboratory criteria include elevation of skeletal muscle enzymes, including CPK and adolase, and a muscle biopsy specimen with evidence of necrosis of type I and II fibers, phagocytosis, and inflammatory exudates. The electrodiagnostic criterion includes EMG findings of spontaneous activity, myopathic motor units, and bizarre high-frequency repetitive discharges. Definitive diagnosis must include three or four criteria and the rash for dermatomyositis, and four criteria without the rash for polymyositis.

Systemic symptoms such as fatigue, lethargy, irritability, arthralgias, myalgias, weight loss, gastrointestinal discomfort, and low-grade fever may herald the onset of weakness.[163] Complications of dermatomyositis and polymyositis include respiratory problems such as chronic interstitial pulmonary fibrosis and pneumothorax; gastrointestinal involvement with decreased esophageal motility, gastric ulceration, and bleeding; and cardiac problems such as arrhythmias, abnormal electrocardiograms, and pericarditis.[163,164] The initial treatment of polymyositis and dermatomyositis is corticosteroids. The mortality of juvenile dermatomyositis is 3% in the United States.[165]

Benign Acute Childhood Myositis

Benign acute childhood myositis (BACM) is a self-limited process that usually affects boys more often than girls.[166] The presentation of muscular symptoms occurs after a prodrome of viral upper respiratory illness. An acute onset of severe muscle pain usually involving the calf muscles, difficulty walking, and increased CPK levels usually follow the prodrome. Mackay et al.[168] describe the prodromal symptoms of fever, cough, headache, rhinorrhea, sore throat, and vomiting as being the most common symptoms. In the 41 episodes of BACM that Mackay et al.[166] reported, 42% of those tested were confirmed to be caused by a virus, with 50% of those cases confirmed as being caused by influenza B. The mean CPK level was 14 times normal, but resolution of symptoms occurred within 1 week. BACM resolves rapidly. Bed rest may be necessary until the pain resolves; otherwise, no treatment is needed. This disease process rarely progresses into a severe life-threatening form.

IV Chapter 65

Central Nervous System Infections Presenting to the Pediatric Intensive Care Unit

Mark E. Rowin, Erin P. Reade, and John C. Christenson

PEARLS

- While the term *meningitis* implies that the meninges are primarily involved, *encephalitis* indicates brain parenchymal involvement. The presence or absence of normal brain function is important in distinguishing between meningitis and encephalitis.
- An exception is when intracranial hypertension develops in a patient with meningitis. Prompt administration of an effective bactericidal antimicrobial regimen potentially reduces neurologic sequelae.
- The diagnosis of primary amebic menigoencephalitis should be considered in southern-tier states in the United States.
- The most common origin of central nervous system abscesses in children is direct or indirect extension from the middle ear, paranasal sinus, or dental abscesses, which occurs in up to 10% of untreated cases.

Life-threatening infections in the pediatric population are an all too common occurrence in the pediatric intensive care unit (PICU). These infections can come from a myriad of sources and can affect any organ system. Extremely young age, poor nutritional status, incomplete development of both innate and adaptive immune responses, and underlying disease processes all contribute to the increased risk for severe infections in the pediatric population. Infections of the central nervous system (CNS) are frequently encountered by the pediatric intensivist and often pose life-threatening challenges to the individual.

Understanding infections of the CNS entails more than a comprehension of the appropriate antimicrobial agents and laboratory tests. Recently it has become clear that CNS infections in childhood may have long-term consequences. Earlier studies focused on risk exposures of congenital infections of the CNS acquired during the fetal period. However, the human brain continues to develop well into early adulthood, and infections of the CNS during infancy and childhood may increase the risk of neuropsychiatric problems later in life. A study from South America of persons who had "epidemic meningitis" during childhood (mainly of bacterial origin) demonstrated a fivefold increase in the prevalence of psychotic disorders.[1] Additionally, in a recent Swedish study of over 1 million pediatric patients, serious viral CNS infections during childhood, specifically mumps virus and cytomegalovirus (CMV), appeared to be associated with the later development of schizophrenia and other psychoses.[2] The exact pathophysiology of these long-term insults is currently the focus of clinical interest. Use of new immunohistochemical staining, such as amyloid precursor protein (β-APP), along with biomarkers of axonal injury such as c-tau and α-II spectrin, may offer insight into the axonal and neuronal injury that occur both with and following CNS infections.[3,4]

Bacterial Meningitis

Bacterial meningitis remains a common cause of morbidity and mortality in the pediatric population. It is not infrequent for many children with bacterial meningitis to be admitted to a PICU for initial supportive care.

Many microorganisms have the ability to cause meningitis. Most microorganisms are acquired through a hematogenous route, and others through direct extension from nasal cavities, paranasal sinuses, mastoids, or the middle ear. Other microorganisms are associated with trauma or surgery with or without the placement of foreign materials. In certain instances, the age and the immune status of the host, the exposure history, and the virulent characteristics of the organism directly influence the likelihood of the development of meningitis.

Epidemiology

The use of conjugate vaccines against *Haemophilus influenzae* type b (Hib) and *Streptococcus pneumoniae* have significantly decreased the incidence of Hib as a meningeal pathogen and *S. pneumoniae* as a cause of invasive disease.[5] Even as nonvaccine serotypes have emerged as "newly recognized" pathogens, *S. pneumoniae* remains an important adversary.[6,7] The isolation of nonvaccine serotypes such as 19A, 22F, and 35B has increased since the introduction of the seven-valent vaccine. It is of great therapeutic concern that approximately 28% of these invasive isolates are resistant to penicillin and 11.8% are resistant to cefotaxime. *Neisseria meningitidis* is the second most common cause of sepsis and meningitis beyond the neonatal period. In a recent study of children with bacterial

meningitis, one third of cases were by *S. pneumoniae*, while *N. meningitidis* was responsible for 28% of cases. Sixty-two percent of typed pneumococcal isolates were caused nonvaccine serotypes.[8]

In young infants in the first few months of life, *Escherichia coli* has become the main cause of sepsis and meningitis and is responsible for 22% of cases. Because of the use of intrapartum prophylaxis, *Streptococcus agalactiae* (group B *Streptococcus* [GBS]) is being observed less frequently.[9] Other organisms such as *Klebsiella pneumoniae*, *Enterobacter cloacae*, *Cronobacter* spp. (formerly known as *Enterobacter sakazakii*),[10] and *Citrobacter koseri* (formerly known as *C. diversus*) have been reported as causes of meningitis in young infants.

Listeria monocytogenes continues to be listed as a cause of sepsis and meningitis in the newborn. However, because the frequency of its occurrence in this age group is so low, most clinicians have never seen a case. A known association with specific dietary habits in the mother such as the consumption of unpasteurized soft cheeses, dairy products, and cold meat cuts has been recognized for years.

Children with asplenia, humoral immunodeficiencies, cochlear implants, human immunodeficiency virus (HIV), and cerebrospinal fluid (CSF) leakage resulting from trauma are at high risk of pneumococcal meningitis. Asplenic children and those with complement deficiencies are at risk for meningococcal meningitis. On rare occasions, *Streptococcus pyogenes* has been responsible for meningitis, with concurrent otitis media being a major risk factor.[11] *S. pyogenes* was responsible for close to 2% of cases. Less frequent meningeal pathogens in young infants are *Salmonella* species and *Capnocytophaga canimorsus*, an organism associated with exposure of the mucous membranes to dog saliva.[12]

Rare causes of pediatric meningitis, such as *Cryptococcus neoformans*, *Coccidioides* spp., rickettsiae, ehrlichiosis, *Mycobacterium tuberculosis*, and *Baylisascaris procyonis* (raccoon roundworm) are well recognized for their high degree of morbidity and mortality. Meningoencephalitis also can result from tick bite–associated transmission of rickettsial pathogens such as *Rickettsia rickettsii* and ehrlichia. Infections by *Staphylococcus aureus* and coagulase-negative staphylococci are generally associated with neurosurgical surgery and trauma.

Pathogenesis

Prior to bloodstream invasion, intravascular multiplication, and penetration of pathogenic bacteria through the blood-brain barrier (BBB), in most instances the nasopharynx becomes colonized. Organisms in the nasopharynx penetrate through or between respiratory epithelial cells as a preamble to disease. A lack of immune defenses in the subarachnoid space allows for the rapid multiplication of bacteria in the CNS.

Clinical Manifestations

The classic features of bacterial meningitis such as fever, nuchal rigidity, and altered mental status may not always be observed in young infants and children. Seizures, irritability, decreased appetite, vomiting, poor perfusion, hypotension, coma, and respiratory distress may indicate a serious bacterial infection. Paleness and skin mottling may be observed in severely ill infants. Nuchal rigidity and bulging fontanelle are usually late manifestations of meningitis. Kernig and Brudzinski signs are frequently unrecognized or are absent. The presence of petechiae and purpura may suggest meningococcus as the causative agent. However, similar findings have been observed in children with *S. pneumoniae* and *H. influenzae* (type a) sepsis.[13] Anisocoria, poorly reactive pupils, bulging fontanelle, diplopia, papilledema, and uncontrollable vomiting are signs of increased intracranial pressure (ICP) (see also Chapter 59, Intracranial Hypertension and Brain Monitoring).

Diagnosis

When clinically feasible, the diagnosis of meningitis requires the examination of CSF. In most cases of bacterial meningitis, the diagnosis relies on the isolation of bacteria from a CSF specimen. Cell count and differential, along with protein and glucose determinations, Gram stain, and cultures, are essential tests to be performed. The use of blood cultures alone as an initial screening test is not appropriate. Approximately 80% of patients with bacterial meningitis will have a positive blood culture. This approach alone would result in a large number of cases being missed.

Lumbar puncture should be postponed in children with an ongoing coagulopathy, elevated ICP, or cardiorespiratory difficulty, and in patients with suspected mass-occupying lesions as demonstrated by focal neurologic signs. However, it is critical to remember that antimicrobial therapy and other supportive measures should not be delayed while waiting for results of CSF analysis. Routine end-of-treatment lumbar punctures are no longer recommended.[14] Patients with multidrug resistant *S. pneumoniae* or Gram-negative bacilli meningitis should have a repeat lumbar puncture at 48 hours after initiation of therapy to document sterilization.

Although a computed tomography (CT) scan is not required in all children with suspected meningitis, it is indicated prior to lumbar puncture in patients with focal neurologic findings and signs of ICP. It is important to remember that even when CT scans are normal, herniation may still occur.[15] Similar findings have been confirmed in adults with meningitis.[16]

CSF with pleocytosis (usually greater than 1000/μL) and a predominance of polymorphonuclear leukocytes is highly suggestive of bacterial meningitis. High protein and low glucose (usually < ½ serum value) concentrations also support the diagnosis. A predominance of lymphocytes and monocytes suggests a viral pathogen. A predominance of lymphocytes and monocytes also can be observed in patients with rickettsial and tuberculous meningitis. CSF eosinophils are frequently observed in patients with CSF shunt devices, but this also can be observed in persons with parasitic infections that result in meningoencephalitis, such as baylisascariasis and infections by *Angiostrongylus* species.

Clinicians must remember that a polymorphonuclear leukocyte predominance may be observed early in the course of enteroviral meningitis as well. Frequently, patients with this disease have normal CSF protein and glucose concentrations. However, hypoglycorrachia can be observed with certain viral pathogens such as enterovirus and mumps virus. On occasion, a small percentage of patients may have an initial "normal appearing" CSF analysis, especially with *N. meningitidis*.

Gram stains have been reported to demonstrate organisms in 50% to 75% of specimens. The impression of most clinicians is that it is not that high. The clinician is cautioned not to

make significant changes in antimicrobial therapy based solely on a Gram stain result. CSF cultures remain the ultimate gold standard.

In most instances, prior oral antimicrobial therapy will not significantly alter CSF cell counts, differential, and chemistries in children with bacterial meningitis. In contrast, Gram stain and culture positivity are greatly reduced. Clinicians frequently are faced with the question of how to treat these patients and/or if there is a need for prophylaxis of household members if the infection happens to be caused by *N. meningitidis*.

Routine use of rapid bacterial antigen detection assays have been shown to be of limited clinical relevance because on most occasions therapy typically is not altered based on the result.[17] However, in a multisite study from Asia and Africa, an immunochromatographic test for pneumococcal antigen was found to have high sensitivity and specificity. This assay may be useful in previously treated children with a negative CSF Gram stain and culture.[18]

Real-time fluorescent quantitative polymerase chain reaction (PCR) amplification of the bacterial 16S ribosomal ribonucleic acid (RNA) gene may become a useful clinical tool for the rapid diagnosis of bacterial meningitis. It would be particularly beneficial in patients who have taken antibiotics prior to undergoing a lumbar puncture. Compared with bacterial culture controls, sensitivity was 100% in one study; in another study it was 86% overall.[19,20] This assay also may be useful for the prompt identification of *S. pneumoniae* and *N. meningitidis* as the etiologic agents.[21] In a clinical setting, a real-time PCR for *N. meningitidis* was found to have a high sensitivity, specificity, and predictive values.[22]

Serum procalcitonin assays have been used to differentiate between bacterial and aseptic meningitis. In a small study, procalcitonin determination had 99% sensitivity and 83% specificity.[23] A larger prospective study will be needed to assess the ultimate clinical role for this assay.

Susceptibility testing of most bacterial isolates is of clinical importance. In certain pathogens, however, it may not be required. Unless penicillin G is being considered for the treatment of meningococcal meningitis, susceptibility testing for this pathogen is not required. Similarly, penicillin or cephalosporin resistance is not currently recognized for *S. pyogenes*.

Treatment

An effective antimicrobial agent for the treatment of bacterial meningitis must be bactericidal and must achieve high concentrations in the CSF. In addition, initial empiric therapy should take into consideration antimicrobial resistance among the most likely meningeal pathogens. Once meningitis is suspected, antimicrobial therapy must be initiated promptly.

The Infectious Disease Society of America has published practice guidelines for the management of bacterial meningitis. All critical care clinicians should be familiar with their recommendations.[24] Tables 65-1, 65-2, and 65-3 provide a listing of most frequent meningeal pathogens and recommended antimicrobial regimens along with dosage information.

In the neonate with meningitis, empiric antimicrobial agents used initially should consist of ampicillin, an aminoglycoside, and cefotaxime. In infants older than 1 month, vancomycin and a third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended. Alterations to these regimens may be influenced by Gram stain, culture, and drug susceptibility results. Additional empiric agents could be added according to epidemiologic exposures, underlying conditions, and the presence of resistant organisms in the community or hospital.

Table 65–1 Initial Empiric Antimicrobial Therapy for Bacterial Meningitis Based on Presumptive Pathogen(s)

Age and/or Predisposing Condition	Pathogen	Antimicrobial Therapy
<1 mo	*Escherichia coli, Streptococcus agalactiae, Klebsiella* spp., *Listeria monocytogenes*	Ampicillin + cefotaxime ± aminoglycoside
1–2 mo	*Streptococcus pneumoniae, Neisseria meningitidis, S. agalactiae, Haemophilus influenzae, E. coli*	Vancomycin + third-generation cephalosporin*
2 mo–5 y	*S. pneumoniae, N. meningitidis, H. influenzae*	Vancomycin + third-generation cephalosporin*
>5 y	*S. pneumoniae, N. meningitidis*	Vancomycin + third-generation cephalosporin*
Humoral immunodeficiency, human immunodeficiency virus, asplenia	*S. pneumoniae, N. meningitidis, H. influenzae, Salmonella* spp.	Vancomycin + third-generation cephalosporin*
Complement deficiencies	*N. meningitidis, S. pneumoniae*	Vancomycin + third-generation cephalosporin*
Basilar skull fractures	*S. pneumoniae, N. meningitidis, Streptococcus pyogenes*	Vancomycin + third-generation cephalosporin*
Cerebrospinal fluid, shunt related	Coagulase-negative staphylococci, *Staphylococcus aureus* (methicillin-susceptible, methicillin-resistant), aerobic gram-negative bacilli (including *Pseudomonas aeruginosa*), *Propionibacterium acnes*	Vancomycin + ceftazidime or vancomycin + cefepime or vancomycin + meropenem†
After neurosurgery	Coagulase-negative staphylococci, *S. aureus* (methicillin-susceptible, methicillin-resistant), aerobic gram-negative bacilli (including *P. aeruginosa*), *P. acnes*	Vancomycin + ceftazidime or vancomycin + cefepime or vancomycin + meropenem†
Cochlear implants	*S. pneumoniae*	Vancomycin + third-generation cephalosporin*

*Cefotaxime or ceftriaxone.
†The choice of anti–gram-negative bacillary agent should be based on the institution's susceptibility patterns.

Once a specific pathogen has been identified and susceptibility data are available, antimicrobial therapy could be "narrowed" to specifically target the offending pathogen. It is the opinion of many clinicians that ampicillin or penicillin G plus gentamicin are the agents of choice for GBS meningitis in the young infant. Unless susceptibility is provided for penicillin, a third-generation cephalosporin is the agent of choice for patients with *N. meningitidis*. Because drug-resistant *S. pneumoniae* (DRSP) has become a problem in the United States, vancomycin plus cefotaxime or ceftriaxone, possibly with rifampin, may be indicated for the full course.

The duration of antimicrobial therapy will vary according to causative pathogen. Neonates with group B streptococcal meningitis require 14 to 21 days of antimicrobial therapy, and those with *S. pneumoniae* require 10 to 14 days; for neonates with *N. meningitidis*, most clinicians prescribe therapy for 7 days, and for those with *H. influenzae*, 7 to 10 days of therapy is required. Children with Gram-negative bacillary meningitis require a minimum of 3 weeks of antimicrobial therapy.

Table 65–2 Antimicrobial Therapy for Specific Meningeal Pathogens

Pathogen	Antimicrobial Therapy
Streptococcus agalactiae	Penicillin G ± gentamicin or ampicillin ± gentamicin
Hemophilus influenzae, β-lactamase–negative	Ampicillin
H. influenzae, β-lactamase–positive	Third-generation cephalosporin*
Streptococcus pneumoniae, penicillin-susceptible	Penicillin G or ampicillin†
S. pneumoniae, penicillin-resistant, cephalosporin-susceptible	Third-generation cephalosporin*
S. pneumoniae, drug resistant (multiply resistant)	Vancomycin + rifampin
Neisseria meningitidis	Third-generation cephalosporin*
N. meningitidis, penicillin-susceptible	Penicillin G or ampicillin†
Escherichia coli, other aerobic enteric gram-negative bacilli (not including *Pseudomonas aeruginosa*)	Cefotaxime or ceftriaxone (if >1 mo of age) + aminoglycoside‡§
P. aeruginosa	Meropenem + aminoglycoside or cefepime + aminoglycoside or ceftazidime + aminoglycoside§
Coagulase-negative staphylococci, methicillin-resistant *Staphylococcus aureus*	Vancomycin ± rifampin
Methicillin-susceptible *S. aureus*	Nafcillin

*Cefotaxime or ceftriaxone.
†Some clinicians prefer ampicillin because of less frequent dosing.
‡The choice of aminoglycoside will depend on the institution's susceptibility patterns.
§The choice of antipseudomonal regimen is influenced by the institution's susceptibility patterns.

Supportive Care

The correction of hyponatremia and hypotension (which is key to maintaining adequate cerebral perfusion) and the treatment of ICP are just as important as the selection of an effective antimicrobial regimen. The presence of hyponatremia, hypotension, or ICP along with a delay in CSF sterilization is associated with poor outcomes and neurologic sequelae.

In the patient who is dehydrated or in shock, administration of intravenous fluids is critical for the maintenance of normal blood pressure and proper perfusion; in addition, it potentially reduces the risk of central venous or sagittal sinus thrombosis. Some patients may require vasoactive-inotropic agents such as dopamine and dobutamine. Routinely restricting fluids in patients with CNS infection as a way to prevent inappropriate antidiuretic hormone secretion should be limited. Patients may have elevated ICP as a consequence of CNS inflammation or obstruction by purulent debris of their lateral, third, or fourth ventricles. Treatment of elevated ICP is discussed in Chapter 59, Intracranial Hypertension and Brain Monitoring. Anticonvulsant therapy is indicated in patients with seizures. Generalized seizures are present in ~20% to 30% of patients in the first 3 to 4 days of illness. The presence of focal seizures and an onset past the third day of illness are associated with long-term neurologic sequelae.

Table 65–3 Dosages of Commonly Used Antimicrobial Agents for Bacterial Meningitis*

Antibiotic	Neonates 0–7 Days, >2000 g†	Neonates >7 Days, >2000 g	Infants and Children	Maximum Daily Adult Dose
Ampicillin	150 (8)	200 (6)	300–400 (6)	12 g
Cefepime	–	–	150 (8)	6 g
Cefotaxime	150 (8)	200 (6)	200-300 (6)	12 g
Ceftriaxone	–	–	100 (12–24)	4 g
Gentamicin	5	7.5	7.5	5 mg/kg
Meropenem	–	–	120 (8)	6 g
Penicillin G	150,000	200,000	300,000	24 million units
Rifampin	–	10–20 (12–24)	10–20 (12–24)	600 mg
Vancomycin	30 (12)	45 (8)	60 (6)	45 mg/kg

*Total daily dose based on mg/kg/day. Exception: penicillin G is expressed as units/kg/day. Numbers in parenthesis represent dosing intervals.
†Dosages of agents for neonates <2000 g can be obtained from Lexi-Comp, Inc. online or from Bradley JS, Nelson JD: *2008-2009 Nelson's pocket book of pediatric antimicrobial therapy*, ed 17, Buenos Aires, Argentina, 2009, AWWE.

Adjunctive Therapy

Two agents, glycerol and dexamethasone, have been evaluated as candidates for possible adjuvant therapy in persons with meningitis. In various studies, orally administered glycerol had been shown to reduce neurologic sequelae in children with bacterial meningitis. It has been postulated that through an increase in serum osmolality, enhanced movement of water back into plasma would result in a reduction of CSF volume and an increase in cerebral blood flow.[25,26] However, in a recently published multicenter trial, it was found that glycerol did not prevent hearing loss, which is a frequent neurologic sequelae.[27]

Corticosteroids such as dexamethasone (DXM) have a discernible effect on inflammatory markers in the CSF in persons with bacterial meningitis.[28] Use of DXM in children remains a topic of controversy among clinicians. In adults with pneumococcal meningitis, the early administration of DXM (15 to 20 minutes before or with the first dose of an antibiotic) was associated with a reduction in mortality and unfavorable outcomes.[29]

In early studies in children with Hib meningitis, children treated with DXM had a lower incidence of moderate-to-severe hearing deficits when compared with placebo.[30] However, one of the antimicrobial agents used in the study, cefuroxime, was later shown to be associated with increased neurologic sequelae. This single factor may have influenced the results for the placebo group. In a study by Peltola and Roine, DXM did not prevent neurologic sequelae in children with Hib meningitis; however, glycerol performed in a favorable manner.[31] On the other hand, in a recently published multicenter study, neither agent was found to prevent hearing loss.[27]

In children with pneumococcal meningitis, DXM has not demonstrated the same magnitude of benefit as in adults. In one study, DXM use was associated with an increase in moderate or severe hearing loss and other neurologic deficits.[32] As a consequence, some clinicians may elect not to administer DXM. However, many experts would agree to administer DXM if Hib meningitis was suspected (e.g., in an unimmunized child, in a child living in an endemic region with known Hib transmission, or in a child whose Gram stain shows pleomorphic gram-negative bacilli).[33]

In summary, studies of adjuvant corticosteroid therapy in children have not unequivocally demonstrated beneficial effects. Study design flaws and the fact that most studies were done in the era of Hib disease bring into question the applicability of these results to today's practice. Meta-analysis and retrospective studies have demonstrated beneficial effects in persons with Hib and pneumococcal meningitis. However, these effects were demonstrated at a time when DRSP was not a serious problem. The data could support a beneficial effect in persons with Hib meningitis, but because this organism is an uncommon pathogen at this time, empiric therapy would not be warranted in most cases. In the era of DRSP, when an isolate may be resistant to the third-generation cephalosporin, it has been suggested that DXM may impair the diffusion of vancomycin through the BBB, delaying CSF sterilization. Thus the use of caution has merit. Some clinicians recommend the addition of rifampin under these circumstances. Further studies are needed in this patient population. Lastly, because maximal beneficial effect would be gained by administering DXM prior to antibiotic therapy, infants and children previously treated with antibiotics should not receive DXM.

There is no evidence that corticosteroids are beneficial in patients with viral or meningococcal or neonatal meningitis.[34,35] In contrast, patients with tuberculous meningitis who are treated with steroids have an improved survival rate compared with those who are not treated with steroids. However, the severity of disability commonly observed in those with tuberculous meningitis is not altered.[36]

Prevention

Persons such as household members, caregivers, and day care center playmates who have significant prolonged and close exposures to children with *N. meningitidis* meningitis should receive antimicrobial prophylaxis with either ceftriaxone, ciprofloxacin, or rifampin.[37] Recently ciprofloxacin resistance was reported in Minnesota and North Dakota. Clinicians should be familiar with resistance rates in their communities.[38] Young children exposed to a person with Hib meningitis also may require prophylaxis with rifampin to eradicate potential nasopharyngeal colonization and prevent secondary infections.[39]

A quadrivalent conjugate meningococcal vaccine is now recommended for all children at 11 to 12 years of age and for high-risk individuals as young as 2 years of age. *N. meningitidis* groups B, C, and Y account for most cases in the United States, with group B being responsible for most *N. meningitidis* disease in young infants.

Outcomes

With aggressive support and appropriate antimicrobial therapy, the mortality rate of bacterial meningitis remains low. Unfortunately, neurological sequelae still occur. When compared with other pathogens, pneumococcal, tuberculous, and Gram-negative bacillary meningitis are commonly associated with neurological sequelae. Seizures, hearing deficits, hydrocephalus, and motor and intellectual deficits are the most common sequelae reported.

No single laboratory factor is entirely predictive of outcome in children with meningitis. In pneumococcal meningitis, antimicrobial resistance was not associated with death, ICU admission, need for mechanical ventilation, focal neurologic deficits, seizures, secondary fevers, or duration of hospital stay.[40] However, the presence of shock, hyponatremia, or coma upon admission to the ICU was associated with a higher use of invasive medical devices and higher mortality.[41,42] The presence of low leukocyte blood cell and platelet counts also was associated with increased mortality.[43] In another study, no child with a leukocyte blood cell count greater than 16,000/μL died.[44]

Subdural Empyema

Subdural collections complicating meningitis are common in young infants, and they occur in 40% of infants with proven pyogenic meningitis.[45] However, these fluid collections are typically sterile and cause no long-term sequelae. Subdural empyemas (SDE) are serious CNS infections defined as purulent fluid collections outside the brain parenchyma but contained under the dura. They usually are encapsulated and often loculated. Historically, otorhinolaryngeal infections were an important predisposing factor to SDE in older children. However, a recent study demonstrated that only 10% of episodes

were related to otorhinolaryngeal infections. The decrease in the incidence of SDE after sinus infections is presumed to be from increased antibiotic use for this disease process. Meningitis, head trauma, or neurosurgeries are now more common predisposing conditions for SDE.[46]

In adolescents and adults, subdural empyemas usually result from infection of the paranasal sinuses, middle ear, and face or, less frequently, from a penetrating skull fracture. In young infants, SDE is rare and is usually a complication of purulent meningitis wherein the infection extends through the arachnoid and into the subdural space.[47] The sequelae of SDE may be more severe in young infants than in any other age group.[48] The clinical symptoms can mimic mild meningitis, followed several days later by rapidly progressive drowsiness, neurologic deficits, and seizures. Prolonged fever (90%), seizures (70%), and focal neurologic signs (60%) are the most common clinical signs noted in the pediatric population.[46]

In children, SDE is commonly secondary to Hib *or S. pneumoniae* meningitis. SDE also occurs with *Salmonella, N. meningitidis, E. coli,* and neurotuberculosis. The most common pathogen in infants younger than 4 months of age is GBS.[46]

The diagnosis is often made with radiologic assistance and evaluation of the subdural fluid collection. Distinguishing an SDE from a sterile reactive subdural effusion (RSE). is often difficult.[49] The differentiation of SDE from sterile RSE may not be possible if contrast enhancement of the inner membrane is not seen at CT. Magnetic resonance imaging (MRI) is superior to CT in the demonstration of both the extra-axial fluid and the enhancement of the inner membrane with a paramagnetic contrast medium. Still, there are no MRI characteristics that are specific for SDE compared with a nonpurulent RSE. Analysis of the subdural fluid often is required to establish the diagnosis of SDE. Serial cranial ultrasounds may be the modality of choice for the evaluation of response to medical management.[48]

The goal of treatment is evacuation of pus and eradication of the source of infection. Management choice should be related to the clinical condition. Medical treatment may be adequate if the empyema is small. A surgical approach is suggested in patients who are not responding well to medical treatment or in those who have large subdural pus accumulation with evidence of midline shift or elevated ICP. In infants whose anterior fontanelles are still wide open, transcutaneous subdural tapping may be another option but should be performed by an experienced clinician.

The keys to an optimal outcome in SDE are early, accurate diagnosis, timely intervention, and appropriate antibiotic therapy. The reported mortality rate of SDE is approximately 10%.[46] Age, level of consciousness, timing and aggressiveness of treatment, and the rapidity of disease progression all influence outcome.

Meningoencephalitis

As more children are successfully immunized with vaccines to prevent bacterial meningitis, a greater proportion of children with CNS infections present to the PICU with viral meningoencephalitis. The initial signs and symptoms are often indistinguishable from bacterial meningitis, and a diagnosis of a viral rather than bacterial CNS infection does not decrease the chance of a patient becoming critically ill.

While the term *meningitis* implies that the meninges are primarily involved, *encephalitis* indicates brain parenchymal involvement. The presence or absence of normal brain function is important in distinguishing between aseptic meningitis and encephalitis. Patients with meningitis have fever, meningeal symptoms, and CSF pleocytosis but no evidence of bacterial or fungal infection and no associated neurologic dysfunction.[50] Abnormal neurologic function, such as focal neurologic signs, cranial nerve involvement, motor deficits, sensory deficits, or speech difficulties, implies brain parenchymal involvement and encephalitis. Both meningitis and encephalitis may result in increased ICP, and patients may present with coma as a result of increased ICP or partial or complete brainstem herniation. Patients presenting with seizures may have meningitis or encephalitis. Making the distinction between meningitis and encephalitis is often difficult, and patients may present with both a parenchymal and meningeal process. Therefore, some clinicians prefer the term *meningoencephalitis* to recognize the inherent overlap between the two clinical entities.

Epidemiology

A survey of hospital discharge records from 1988 to 1997 showed approximately 19,000 hospitalizations per year (7.3 hospitalizations per 100,000 population), 230,000 hospital days, and 1400 deaths annually due to viral encephalitis in the United States.[51] Children younger than 1 year had the highest risk for hospitalization as a result of encephalitis. Between the years 1989 to 1998, approximately 1100 deaths were attributed to encephalitis in children younger than 19 years in the United States. The highest rate of death occurred in children younger than 1 year (9.3 per 100,000 population).[52] Nonviral causes of encephalitis are extremely rare.

Although the causative agent in many cases of encephalitis can be difficult to isolate, most cases are attributed to enteroviruses, herpesviruses, and arboviruses. Table 65-4 lists some of the common pathogens associated with meningoencephalitis. The enteroviruses and arboviruses in particular display seasonality in infection, being seen most frequently in the summer and autumn months. Herpesviruses, CMV, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV) often show a predilection for the winter and spring. Herpes simplex virus (HSV), on the other hand, does not demonstrate any seasonality. With this epidemiology in mind, the evaluation of children with suspected viral meningoencephalitis is guided by many factors, including age, geographic location, season of the year, vaccination status, chronic conditions or immunosuppression, history of tick or mosquito exposure, and travel history.

Pathophysiology/Pathogenesis of Viral Meningoencephalitis

The current understanding of how viral pathogens infect the CNS holds that most neurotropic viruses initially multiply at the port of entry (mucosal surfaces of the skin, gastrointestinal tract, or respiratory tract) and then travel to extraneural sites in the body. They then migrate to vascular tissue, further multiply, and finally infect the CNS. Viruses may reach the CNS by several mechanisms. Whereas most directly invade across cerebral capillary endothelial cells that comprise the

Table 65–4 Causes of Meningoencephalitis and Available Laboratory Testing and Treatment

Virus	Available Laboratory Testing	Treatment
COMMON CAUSES		
Enterovirus		No specific therapy
Poliovirus (three serotypes)	Cell culture; isolates sent to CDC via state laboratories	
Nonpoliovirus	CSF PCR	
Echovirus (28 serotypes)	Cell culture, CSF PCR	
Coxsackievirus A (23 serotypes)	CSF PCR	
Coxsackievirus B (six serotypes)	Cell culture, PCR	
Parechovirus (six serotypes)	None	
Herpesvirus		
Herpes simplex virus-1, -2	CSF PCR	Acyclovir, foscarnet (if resistant to acyclovir in immunocompromised patients)
Cytomegalovirus	CSF PCR	Ganciclovir, Foscarnet
Ebstein-Barr virus	CSF PCR	
Varicella zoster	CSF PCR	Acyclovir
Human herpesvirus-6	CSF PCR	
Arbovirus	Viral isolation, serology done by state and research laboratories, detection of virus-specific IgM in CSF + Ab in serum specimen; CSF PCR in reference laboratories	
Flavivirus		
St. Louis encephalitis		
West Nile virus		
Togavirus		
Eastern equine encephalitis virus		
Western equine encephalitis virus		
Bunyavirus		
California encephalitis virus		
La Crosse virus		
Jamestown virus		
Snowshoe virus		
LESS COMMON CAUSES		
Mumps	Cell culture, mumps-specific IgM Ab, PCR	
Adenovirus	CSF PCR, cell culture	None
Respiratory syncytial virus	Viral isolation from nasopharyngeal secretion in cell culture, PCR	
Influenza A and B	Viral culture, PCR	Oseltamivir, zanamivir, amantadine or rimantadine if susceptible
HIV	HIV-1 nucleic acid detection by PCR	Multiple drug regimens
Lymphocytic choriomeningitis virus	Viral isolation from CSF, virus-specific IgM Ab in serum or CSF	
Rabies	Antemortem diagnosis via fluorescent microscopy of skin biopsy specimen, isolation of virus from saliva, detection of Ab in CSF or serum, detection of viral Ag and nucleic acid in infected tissue; postmortem diagnosis by immunofluorescent or immunohistochemical examination of brain	None

Ab, Antibody; *Ag,* antigen; *CDC,* Centers for Disease Control and Prevention; *CSF,* cerebrospinal fluid; *DNA,* deoxyribonucleic acid; *IgM,* immunoglobulin M; *PCR,* polymerase chain reaction.

BBB, they also may: (1) directly infect cerebral microvascular endothelial cells before infection of adjacent glia and neurons; (2) be carried between cerebral endothelial cells in infected leukocytes after BBB disruption; (3) initially infect glia without evidence of endothelial cell infection; (4) enter the choroid plexus epithelium; or (5) spread along olfactory nerve or peripheral nerve pathways.[53] Once a virus has invaded the CNS, it attaches within susceptible cells and induces the cellular changes and inflammatory responses that manifest as meningitis or encephalitis.

Clinical Evaluation

Bacterial and other causes of meningoencephalitis as well as other causes of encephalopathy such as trauma, hepatic failure, electrolyte abnormalities, and toxic ingestions must be ruled out before viral encephalitis is diagnosed. A careful history will yield important information such as immunization status, recent viral or other infections, history of immune diseases, travel history, tick or mosquito exposure, and the history of maternal herpes infection in the case of neonates. Physical examination should focus on evaluation of the mucous membranes and skin as well as a complete neurologic examination including the funduscopic examination. A high level of suspicion and vigilance along with serial neurologic examinations is essential because viral injury may result in the development of cerebral edema and even brainstem herniation. As in the case of meningitis, antibiotics and/or antiviral medications should not be withheld while the laboratory and imaging workup of encephalitis is pursued.

Laboratory Manifestations

Lumbar puncture with an opening pressure is essential in the evaluation of the patient with suspected meningoencephalitis. Initial evaluation of cerebrospinal fluid includes blood cell count, protein, glucose, culture, HSV PCR, enteroviral PCR, and oligoclonal bands.[54] CSF findings in viral encephalitis include pleocytosis with CSF white blood cell counts in the 100 to 1000 cells/μL range. Polymorphonuclear cells often are predominant in early infection and even up to 48 hours of infection; lymphocytes typically become more predominant later in the time course.[55] At least a mild elevation in CSF protein is usually seen, and mildly decreased levels of glucose may be present; however, the glucose level is often normal. Elevated levels of red blood cells often are seen in persons with herpesvirus meningitis. In addition to CSF, blood should be obtained for a complete blood cell count and culture, erythrocyte sedimentation rate or C-reactive protein, and electrolytes. If suggested by the history, additional samples for viral studies should be obtained. These samples often include CSF and serum arboviral titers and serum, urine, and/or nasal specimens to test for viruses such as HSV, varicella, EBV, CMV, adenovirus, influenza, and parainfluenza.

As a more rapid alternative to tissue culture, PCR techniques allow for relatively sensitive and specific diagnosis of enteroviruses, herpesviruses, and arboviruses in the clinical setting. For enteroviruses, PCR is directed at genomic RNA in the highly conserved regions of the 5' noncoding region. PCR allows for accurate diagnosis of enteroviruses in a few hours and sensitivity has been shown to be approximately 98%.[56] Specific virologic diagnosis of enteroviruses requires recovery of virus from CSF or tissue culture, with a sensitivity of 65% to 75%.[57] For HSV, CSF PCR is the test of choice, with approximately 98% sensitivity and 94% specificity.[58,59] PCR for varicella-zoster deoxyribonucleic acid (DNA) has been found to be 95% specific but only 30% sensitive. Therefore it is recommended that in cases of suspected VZV encephalitis the CSF be tested for intrathecal synthesis of VZV-specific antibody (IgM and CSF-to-serum immunoglobulin [Ig] G ratio).[60,61] PCR testing is also available for EBV and CMV from the CSF. For human herpesvirus-6 (HHV) infection, which may cause a severe encephalitis in immunocompromised patients, PCR has been shown to be somewhat sensitive; however, it may unreliably detect the virus, and viral isolation may be required.[62,63] Arboviruses in the CSF and serum are detected by IgG and IgM antibody testing. According to Centers for Disease Control and Prevention (CDC) criteria, confirmed cases of arboviral disease must demonstrate either: (1) a fourfold or greater change in virus-specific antibody titer; (2) isolation of virus from or demonstration of specific viral antigen or genomic sequences in tissue, blood, or CSF; (3) virus-specific IgM in CSF by antibody-capture enzyme immunoassay; or (4) virus-specific antibodies demonstrated in serum by antibody-capture enzyme immunoassay and confirmed by IgG antibodies in either the same or a later specimen.[64] Many states have epidemiological programs to provide surveillance of arboviral infections, and consultation with local and state health departments will help guide serologic testing.

In some rare cases, despite a thorough laboratory evaluation, a brain biopsy is required for definitive diagnosis and remains the gold standard to diagnose viral infections of the CNS.[65-67]

Neuroimaging

The initial noncontrast head CT scan may be normal in patients with meningoencephalitis. While most patients will require a CT scan in the early period of illness, MRI is most sensitive for detecting inflammation, edema, and hemorrhage in viral encephalitis. If there is concern for spinal cord involvement (e.g., transverse myelitis or enterovirus), then the MRI should also include the spine.[54] Depending on disease severity, patients with viral encephalitis may show focal or diffuse cerebral edema and even uncal or transtentorial herniation on either CT or MRI.

Specific infections often show characteristic MRI findings that may be helpful in formulating a diagnosis. The MRI appearance of viral encephalitis is generally that of diffuse scattered or confluent areas of T2-weighted hyperintensity. A variable degree of mass effect and edema is seen. Inflammation often involves meninges, and gadolinium enhancement is diffuse. The classic finding in HSV and HHV-6 encephalitis is hemorrhagic inflammation, often bilateral, of the temporal lobe, which manifests as T2-weighted hyperintensity on MRI and usually spares the deep nuclear structures (Figure 65-1).[68,69] Neonates with HSV encephalitis may demonstrate less defined areas of inflammation on MRI and may have a loss of gray-white matter distinction only.[54] Among other herpesviruses, varicella-zoster encephalitis may demonstrate multifocal ischemia and infarction as well as demyelinating lesions in the white matter and at gray-white junctions. CMV often shows characteristic enhancement in the ependyma around the lateral ventricles.[69] Togaviruses, including West Nile Virus, St. Louis encephalitis virus, Japanese encephalitis virus, and Eastern

Figure 65–1. A magnetic resonance image of a pediatric patient with herpes simplex encephalitis. The image demonstrates the attenuation of the white matter of the right temporal lobe.

and Western equine encephalitis viruses, show involvement in the subcortical white matter, thalami, and substantia nigra.[69] In particular, Eastern equine encephalitis has been shown to produce focal lesions in the basal ganglia, thalami, and brainstem.[70] MRI findings in enterovirus encephalitis are less clearly defined and may be highly variable. However, patients with enterovirus 71 infection have demonstrated increased T2 and fluid-attenuated inversion recovery signal intensity in the midbrain, pons, medulla, and even the spinal cord.[71]

Clinical Presentation and Course

The clinical course of viral meningoencephalitis is highly variable, ranging from mild disease to death. Children with viral meningoencephalitis or encephalitis usually present with a prodrome of fever, headache, irritability, malaise, decreased oral intake, nausea, and possibly neck pain and/or nuchal rigidity. These signs and symptoms are essentially identical to the presentation of viral meningitis. However, a child with encephalitis also shows a decline in the level of consciousness and may demonstrate confusion, ataxia, seizures, aphasia, visual changes, and focal motor deficits or sensory deficits corresponding to the affected areas of the brain. In general, the most common focal neurologic deficits seen in encephalitis are hemiparesis, aphasia, ataxia, cranial nerve palsies, seizures, and myoclonus. Patients may also demonstrate autonomic dysregulation or hypothalamic dysfunction resulting in diabetes insipidus or syndrome of inappropriate antidiuretic hormone. Seizures are possible, especially in infants and children with herpes encephalitis. At the most extreme end of the encephalitis spectrum, focal or diffuse cerebral edema and even brainstem herniation may occur.

HSV remains the most common cause of fatal sporadic encephalitis in humans, despite specific antiviral therapy.[72] This may be either a new infection or latent reinfection.[72] HSV encephalitis is particularly severe in children with an immunocompromised status due to chemotherapeutic regimens, genetic immune defects, or HIV infection. Children and adolescents with HSV encephalitis present with nonspecific neurologic signs and often have seizures. Support for the diagnosis of HSV encephalitis may be bolstered by findings of temporal lobe involvement on MRI as well as spike and slow-wave activity on electroencephalogram (EEG).[73] Adults and children typically present with HSV-1 infection. In neonates, the majority of encephalitis cases are caused by HSV-2 due to perinatal transmission and shedding of virus in the maternal genital tract. Neonates presenting with encephalitis attributed to HSV often do not demonstrate fever. The most common presenting signs for neonates with HSV CNS disease are seizures and lethargy.[74] Skin lesion findings are variable. Infants with HSV infection also may have disseminated disease, which increases the morbidity and mortality significantly.

Enteroviral encephalitis may be highly variable in its presentation. The majority of cases are self-limited, but a large proportion of patients experience at least short-term morbidity. While HSV has predilection for the temporal lobes in many cases, the enteroviral infections in general are more global in nature. Patients with enteroviral encephalitis often present with fever, headache, nausea, vomiting, and nuchal rigidity. They also may demonstrate confusion or delirium and have seizures or focal neurologic signs.[75]

Enterovirus 71, a cause of hand-foot-mouth disease/herpangina, usually causes flu-like symptoms and a characteristic rash on hands, feet, and buttocks along with oral ulcers. It also can cause flaccid paralysis, inflammation, necrosis of the tissues of the brainstem, and death in about 16% of cases.[76] In addition, myocarditis and heart failure also have been reported with enterovirus 71 infection. Severe enterovirus 71 outbreaks were originally described in Asia. They have since been reported in other areas of the world, including the United States, Australia, Sweden, Bulgaria, and Hungary. This virus may represent an important emerging pathogen.[77] Unfortunately, the neurodevelopmental follow-up of children with severe enterovirus 71 brainstem encephalitis reveals significant long-term cognitive and motor deficits.[78]

Neuroinvasive arboviral infections include the California serogroup viruses, Eastern and Western equine encephalitis viruses, Powassan virus, St. Louis encephalitis virus, and West Nile virus. Their incidence increases when mosquito vectors are most active, usually in the summer months, and incidence varies significantly based on geographic region. This group of viruses causes encephalitis as well as myelitis. In fact, West Nile virus infection has been misdiagnosed as Guillain-Barre syndrome because of the flaccid paralysis that accompanies it. According to the 2004 CDC case definition, arboviral encephalitis is characterized by fever, headache, and altered mental status ranging from confusion to coma, with or without additional signs of brain dysfunction. Arboviral myelitis causes acute bulbar or limb paresis or a flaccid paralysis.[64]

Other zoonotic pathogens can cause encephalitis. Exposure to tick populations may suggest infection with Colorado tick fever in the western United States or nonviral etiologies such as Lyme disease or Rocky Mountain spotted fever. Nipah virus encephalitis has been seen in Malaysia, Singapore, and

Bangladesh and may be associated with exposure to bats or pigs.[65-67] Lymphocytic choriomeningitis virus is caused by a rodent-borne arenavirus and is transmitted via mice, rat, and hamster secretions. Rabies, although rare in the United States, should be suspected in patients with prodromal symptoms of encephalitis followed by hydrophobia and pharyngeal spasms as well as exposure to bats or other reservoirs. The incubation period is typically 20 to 60 days but can be in the 5-day to 6-month range.[72] In the developing world, canine rabies transmission to humans remains a significant public health problem, with an estimated (but probably severely underestimated) 55,000 deaths annually in Africa and Asia.[79]

Influenza virus infection has been associated with a number of neurologic complications such as seizures and mild encephalopathy.[80] The neuroimaging of many of these patients demonstrates a distinct pattern of bilateral, multifocal lesions of the thalami that have been described as acute necrotizing encephalopathy.[81-83] In addition, many patients with influenza-associated encephalitis and necrotizing encephalitis progress to multisystem organ failure. In a survey of more than 140 cases in Japan during the 1998-1999 influenza A (H3N2) outbreak, 31.8% of patients with influenza-associated encephalitis or encephalopathy died and another 27.7% experienced either short-term or long-term disability.[82] Brain CT revealed abnormalities in 66% of patients, with the most frequent findings being cerebral edema and hypodensities in the thalamus, brainstem, and brain parenchyma. Approximately 10% of the patients in the 1998-1999 case series showed the characteristic findings of acute necrotizing encephalopathy.[82] Only a small number of these patients have had influenza RNA isolated from CSF, and autopsies demonstrate a lack of direct viral invasion in the CNS. Many of the cases have been described in Japan and other parts of Asia, leading to speculation that some people may have a genetic susceptibility to the development of influenza-associated encephalitis/encephalopathy, but cases also have been described in Europe and North America.[82,84-86]

Treatment

With the exception of patients with herpesviruses, therapy for patients with viral encephalitis is largely supportive. Patients with severe neurologic dysfunction and/or status epilepticus may require airway, respiratory, and circulatory support. Clinicians should maintain careful attention to fluid and electrolyte status because of the risk of diabetes insipidus, syndrome of inappropriate antidiuretic hormone, and cerebral salt wasting. ICP monitoring has been used at some centers, and therapies to decrease ICP may be required.[87-90] Several small case series and case reports have discussed the use of decompressive craniotomy or craniectomy in the setting of severe encephalitis-induced intracranial hypertension in both adults and children.[91-93] However, to date no large studies have been conducted on the outcomes of children with severe viral encephalitis and increased ICP who have been treated with ICP monitoring and/or decompressive craniectomy. Seizures, both clinical and subclinical, should be treated and prevented as often as possible. Continuous EEG monitoring and induction of a barbiturate coma has been used in selected cases; however, the literature suggests that patients with refractory status epilepticus and viral encephalitis have extremely poor outcomes.[94-97]

Medical treatment of viral encephalitis is most effective in the treatment of herpes virus. In neonates with HSV encephalitis, antiviral therapy has significantly improved survival and decreased disease progression. The current recommended treatment for patients with HSV encephalitis from infancy to age 12 years is "high-dose" intravenously administered acyclovir (20 mg/kg every 8 hours) given for 21 days for both encephalitis and disseminated disease.[98] Patients older than 12 years should receive acyclovir at 30 mg/kg per day in three divided doses for 21 days.[98] Acyclovir-resistant HSV infections, while rare, have been reported and are best treated with foscarnet.[99]

Infants born to mothers who contract primary varicella infection from 5 days prior to delivery until 2 days after delivery are at increased risk for severe varicella encephalitis. Exposed newborns may be candidates for varicella-zoster specific immunoglobulin (variZIG) or intravenous immunoglobulin prophylaxis if the mother has severe skin involvement. Data are scarce, but the use of intravenous acyclovir at doses identical to treatment for HSV infection is recommended for neonates with clinical signs of varicella because of the risk of severe disease.[99] Intravenous acyclovir therapy is also recommended for other pediatric patients with encephalitis as well as immunocompromised patients with any form of varicella disease. Children with varicella should not receive salicylate agents because of the increased risk for Reye syndrome, and administration of salicylate drugs should be stopped in patients receiving chronic salicylate therapy for other conditions. Like HSV, acyclovir-resistant varicella has been treated with foscarnet.[99]

Case reports of immunocompromised patients with HHV-6 encephalitis suggest that this may be an emerging pathogen, particularly among transplant recipients.[100] Encephalitis may be caused either by a new infection or by reactivation of latent HHV-6. Isolation of HHV-6 from the blood or detection of viral DNA in serum or plasma via PCR indicates active viral infection. Serology is considered unreliable, particularly in immunocompromised patients. Foscarnet, ganciclovir, and cidofovir have been shown to have efficacy against HHV-6, and the International Herpes Management Forum recommends foscarnet and ganciclovir, either alone or in combination, for treatment of HHV-6–related CNS illness.[101]

CMV has caused encephalitis in immunocompromised patients and is particularly fatal in HIV disease. Foscarnet-ganciclovir combination therapy has been used with limited success.

Influenza encephalitis remains a challenge because often the virus is not detected in the CSF or even in autopsy brain specimens. The neuraminidase inhibitor oseltamivir as well as the ion channel blocker amantadine were both used in the largest prospective study of acute encephalitis/encephalopathy and influenza. It is currently unknown whether these agents change the outcome of this particularly clinically diverse and evolving entity.[102]

Prognosis

The prognosis of patients with meningoencephalitis is extremely variable and depends on the causative agent and the degree of CNS injury. Some patients with relatively mild disease may experience only short-term sequelae of their infection. Although antiviral therapy has significantly improved mortality for HSV encephalitis in neonates, studies suggest

that the long-term cognitive and neurodevelopmental consequences for survivors of HSV encephalitis and disseminated HSV disease include static encephalopathy, mental retardation, autism, cortical blindness, and epilepsy.[103] Focal signs on neurologic examination, multiple seizures or status epilepticus on admission, leukopenia, and focal slow waves or continuous generalized delta waves on EEG are all associated with poor neurologic outcomes.[104-105] Serial neuroimaging studies and close neurologic follow-up may aid in counseling families regarding prognosis for individual patients, but predicting neurologic functional outcomes in this group of patients remains a challenge for clinicians.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is a demyelinating disorder most common in childhood and adolescence. The median age of onset is 6.5 years. The incidence of ADEM is estimated to be 0.8/100,000 patients annually.[106]

ADEM is believed to have an immune pathogenesis. This belief comes from the observation that ADEM typically develops in a post- or parainfectious time period. The diagnosis often is made in the setting of a defined viral illness or vaccination in the month preceding the onset of neurologic symptoms and signs. A recent pediatric study from the United States showed that the most common risk factor was not a vaccination or infection but rather exposure to an ill sibling in the month before the onset of symptoms.[107] Neurologic symptoms can begin as early as 1 to 2 weeks following a febrile event. Documented prodromal viral illness or vaccination occur in only 50% to 75% of patients with childhood ADEM, and half of the patients in these studies were well past the age of the standard childhood immunizations.[108] Serologic studies for viral or bacterial pathogens causing antecedent or coincident infections are documented in less than 20% of cases.[107] In countries where immunizations against measles, mumps, rubella, and varicella were not commonly given, these agents were most commonly associated with ADEM.[109] For most vaccines, incidence rates are approximately 0.1 to 0.2 per 100,000 vaccinated individuals.[106] Of note, the incidence of measles vaccination–associated ADEM is 0.1/100,000. This incidence is considerably lower than the incidence of ADEM after wild-type measles, which is associated with ADEM in approximately 100 per 100,000 cases.[110] Two specific vaccines against Japanese B encephalitis and rabies are associated with ADEM, with incidence rates as high as 1/600.[110] Interestingly, in populations that routinely receive vaccinations, nonspecific upper respiratory tract illnesses are cited as the most common cause of childhood cases of ADEM.[111]

Although the exact pathophysiologic mechanism of ADEM is uncertain, the concept of molecular mimicry is one of the most prevalent theories.[112] It is believed that certain amino-acid sequence homologies and antigenic epitopes are shared between an invading pathogen or inoculated vaccine and the host CNS protein. The pathogen is neither recognized as "foreign" in order to be eliminated nor as "self," which would result in immune tolerance. Initially the pathogenic material is processed at the site of infection or inoculation. The adaptive immune response causes T cell activation and ultimately production of antigen-specific B cells. These autoreactive T cells and B cells are capable of entering the CNS. During routine immune surveillance, they may encounter the homologous myelin protein. Following local reactivation by antigen-presenting cells, an inflammatory immune reaction against the presumed foreign antigen is elicited. Thus a physiologic immune response causes detrimental autoimmunity distant from the original site of infection or inoculation.

Another theory on the pathogenesis of ADEM concerns release of CNS autoantigens following encephalitis.[113] After a direct CNS infection with a neurotropic pathogen (such as measles), CNS tissue may be damaged and the BBB disrupted. This phenomenon may result in systemic leakage of CNS-confined autoantigens into the systemic circulation, where they are processed in systemic lymphatic organs, causing breakdown of tolerance with subsequent emergence of a self-reactive T cell response. Subsequent expression of proinflammatory cytokines may perpetuate CNS inflammation even further. However, although there appears to be an immune response component to the pathophysiology of ADEM, the CSF of these patients has significantly less interferon-γ and interleukin (IL)-10 concentrations when compared with patients with CNS enteroviral infections but similar IL-12 values.[107]

From a histological perspective, the lesions of ADEM often can be confused with those found in patients with multiple sclerosis (MS). However, both ADEM and MS lesions have unique histopathological findings. MS lesions are heterogeneous in terms of lesion age and composition of the cellular components. In contrast, ADEM lesions are almost always of similar age and consist of mostly one distinct pattern.[114] The inflammation tends to cluster around small vessels (particularly veins) in both white and gray matter. Lesions are infiltrated by lymphocytes, macrophages, and, to a lesser extent, neutrophils. In addition, perivascular edema, endothelial swelling, and vascular endothelial infiltrations are present. Demyelination may not be present in the acute lesions but tends to develop later in the lesion's evolution, often in a "sleevelike" pattern confined to the area of inflammation. Damage to the axon itself is rare.

Although most episodes of ADEM are solitary with no further clinical relapse or new radiographic findings, recurrences have been reported.[108] In other patients additional areas of demyelination develop with localizations that differ from those of the initial episode. In these patients, the diagnosis of MS is often considered once they reach adulthood. Some patients have recurrent episodes in temporal proximity to or with the same localizations as the initial presentation. These very early temporally circumscribed relapses are thought to represent part of the same acute monophasic immune process, and the terms *monophasic disseminated encephalomyelitis* or *relapsed ADEM* are used occasionally to describe these cases.[115] Monophasic disseminated encephalomyelitis is characterized by older age of patients at onset (typically >10 years), more severe and prolonged local neurologic symptoms, marked extrapyramidal signs, and distinct demyelination patterns on MRI.[116]

A combination of altered consciousness or behavior and multifocal neurologic deficits, especially in close relation to an infection, should raise the clinician's suspicion of ADEM. The initial clinical presentation is often of nonspecific complaints. Patients may experience headaches, vomiting, lethargy, and low-grade fevers. Distinct functional neurologic or cognitive defects develop gradually, with most patients demonstrating

findings at the time of admission. Clinical deterioration and development of new neurologic abnormalities are prominent features of the hospital course of many patients. The majority of patients exhibit multiple abnormalities including ataxia, inability to walk, slurred speech, or decreased speech output. Cranial neuropathies (especially of extraocular movements) and abnormal reflexes (typically hyperreflexia) are common findings. Altered mental status, including agitation, delirium, nonresponsiveness, and inability to recognize parents or siblings, is noted in up to two thirds of patients.[107]

No specific laboratory criteria exist for the diagnosis of ADEM. CSF examination is commonly performed at the time of clinical presentation in most patients with ADEM, and often it is normal. Abnormalities generally include moderate elevation in the numbers of leukocytes, typically lymphocytes or monocytes, and moderately elevated protein levels. Oligoclonal bands are rare in patients with ADEM, occurring in 3% to 29% of the samples studied.[115] Oligoclonal bands may only be present transiently, which is in sharp contrast to MS. EEGs typically show diffuse slowing, especially when the patient exhibits an altered level of consciousness. Focal epileptiform activity is noted in 2% of patients with ADEM.[108]

A CT scan usually does not detect the lesions noted in most patients with ADEM. The radiologic study of choice for diagnosing ADEM is the MRI scan. Abnormalities are most frequently identified on T2-weighted and fluid-attenuated inversion recovery sequences. ADEM-associated MRI lesions are often multiple and asymmetric. They frequently involve the subcortical and central white matter, cortical gray-white junction, and gray matter of the thalamus and basal ganglia (Figure 65-2). One third of MRI abnormalities completely resolve, while a partial resolution is noted in 35% to 50% of patients.[108,111,115] In addition, the MRI may have a role in the clinical prognosis of patients with ADEM. Delayed development of MRI lesions in deep gray matter and brainstem may herald a prolonged clinical course and lack of response to glucocorticoid therapy.[117]

Because there is no single radiologic study or serologic test to confirm ADEM, a differential diagnosis must be entertained in all suspected cases. Meningoencephalitis, HIV encephalopathy, Behçet's disease, CNS vasculitis, CNS neoplasia or metastases, and mitochondrial encephalopathies are a few diseases that can potentially present with clinical symptoms similar to those of ADEM. However, the most important and most common differential diagnosis with regard to therapeutic options and prognosis is MS. In a recent study from Germany, the authors noted that the incidence of MS was fivefold higher than ADEM in the pediatric population.[118] While the diagnosis rates of ADEM and MS were virtually identical during childhood, MS was more prevalent in adolescence. The clinical picture of MS is often indistinguishable from that of ADEM, although CSF findings are much more likely to show oligoclonal banding in persons with MS. Cerebellar and brainstem clinical signs are the most frequent initial presentation of pediatric-onset MS, occurring far more frequently than adult-aged control subjects with MS.[118]

A recent study indicated that initial MRI findings might be helpful in distinguishing MS from ADEM in children. Although the total lesion number did not differentiate ADEM from MS, periventricular lesions were more frequently found in children with MS. Further, the authors noted that the presence of two or more periventricular lesions combined with

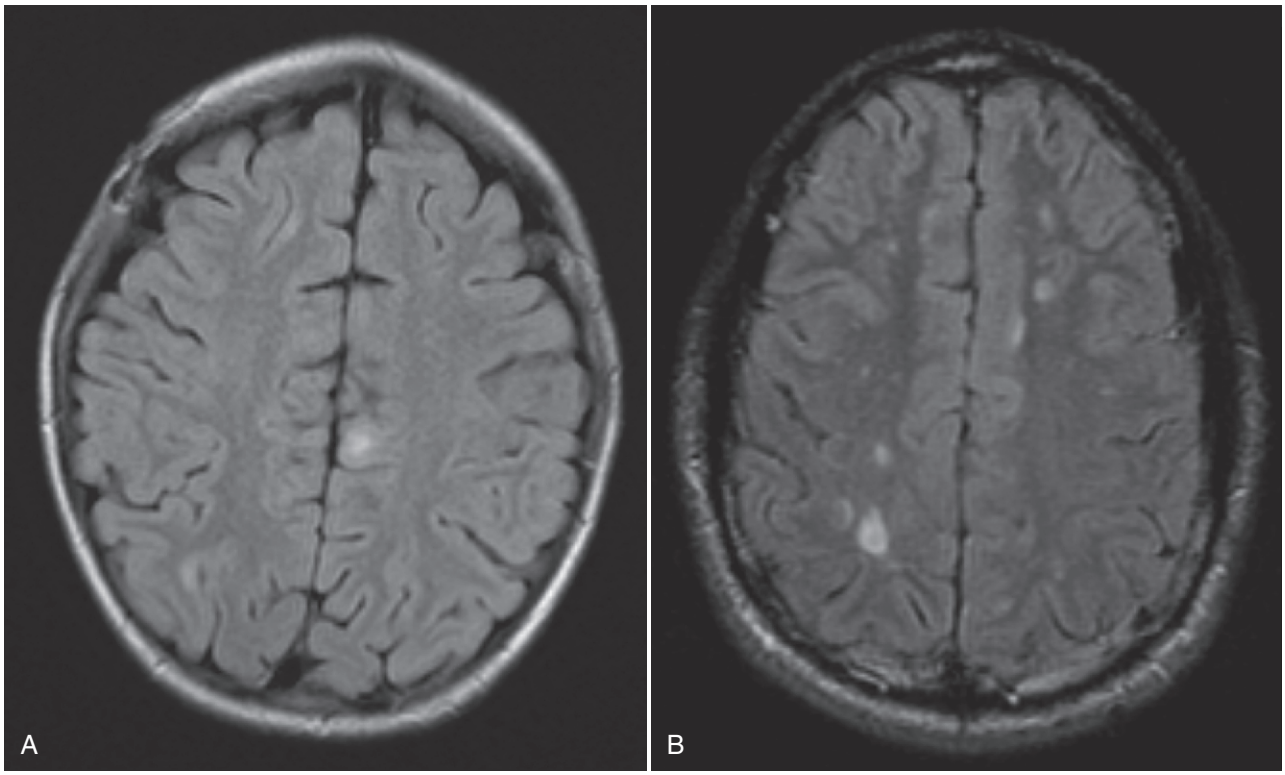

Figure 65–2. Radiographic overlap between multiple sclerosis (MS) and acute disseminated encephalomyelitis (ADEM). **A,** ADEM tends to have a single area of demyelination, often involving the cortical gray-white junction. This T2 fluid-attenuated inversion recovery (FLAIR) image shows involvement of the subcortical white matter. **B,** MS tends to involve the deep white matter and corpus callosum. This T2 FLAIR image demonstrates lesions in these areas.

either the absence of a diffuse bilateral lesion pattern or the presence of nonenhancing lesions on T1-weighted images (black holes) was highly sensitive and specific for MS in children.[119]

Given the presumed autoimmune nature of ADEM, high-dose steroid therapy remains the mainstay of treatment. Therapies such as intravenous immunoglobulin or cyclophosphamide do not appear to offer clinical benefit. Methylprednisolone appears to have clinical benefit over other high-dose steroids.[111] Clinical improvement is generally noted with 24 hours of initiation of therapy. Although the duration of therapy lacks consensus, most clinicians recommend a 3- to 5-day course of methylprednisolone. Relapses are common, occurring in 25% to 35% of patients. Some authors advocate administration of intravenous immunoglobulin or use of plasmapheresis as treatment options for patients with ADEM, especially when the course is aggressive or the patient has severe disease that has not responded to use of corticosteroids.[117]

Most pediatric patients recover from ADEM. More than 70% of children with ADEM, including many with significant neurologic deterioration upon admission to the PICU, recover completely from their initial attack, generally within 6 months after the initial presentation.[120] Residual disability appears to be more common in patients with large or bithalamic lesions on MRI.

Brain Abscesses

The brain parenchyma is remarkably resistant to microbial infections. Despite the relative frequency of occult bacteremia in the pediatric age patient, cerebral abscess formation is a rare occurrence. The incidence of brain abscesses in children is 4 cases per million, with a peak age of presentation between 4 and 7 years of age.[121] Certain medical conditions, especially those that impair the immune response, predispose patients to brain abscess formation. These conditions include prolonged steroid use, diabetes mellitus, alcoholism, and primary immunodeficiencies.[122] A brain abscess is a focal intracerebral infection that begins as a localized area of cerebritis and matures into a collection of pus surrounded by a well vascularized capsule. Although it is a rare occurrence, its presence is often serious and life threatening.

Brain abscesses are usually classified according to their likely point of entry. The most common origin of CNS abscesses in children is direct or indirect extension from the middle ear or paranasal sinus or dental abscesses.[123] Brain abscesses are sequelae in 6% to 8% of untreated sinusitis cases and up to 10% of mastoiditis cases.[121] Abscesses in the temporal lobe or cerebellum typically are linked to ear or mastoid air cell points of entry. Frontal lobe abscesses often are due to sinus or dental infections. Metastatic lesions often are noted in the CNS parenchymal area, especially in the middle cerebral artery distributions, including the parietal and occipital regions (Figure 65-3). The etiology is often from distant foci in children with cardiac or pulmonary right-to-left shunts.

Extensions from cranial osteomyelitis, scalp infections, endocarditis, and meningitis are rare causes of CNS abscess formation. Historically, penetrating head trauma and neurosurgery represent a small proportion of the predisposing causes of CNS abscess, but the proportion is increasing, possibly as other predisposing factors such as middle ear infection become less important. Cyanotic congenital heart disease also has been reported to increase the risk of brain abscess.[121,124] Of pediatric patients diagnosed with brain abscesses, one third have an underlying cardiac defect. This increased predisposition may be due to the presence of areas of brain ischemia caused by decreased arterial oxygen saturation and increased hemoglobin that may act as a focus for infection to develop. Right-to-left shunting also may predispose a person to a brain abscess, as the removal of organisms from the systemic circulation by the lungs is bypassed. In roughly one quarter of brain abscess cases, no identifiable route or predisposing factors are identified.[123]

In the first few days of a developing abscess, cerebritis with a focal area of acute inflammation, vascular dilation, microthrombus formation, and rupture of small vessels are all noted. After 4 to 9 days, the center of the lesion undergoes liquefaction necrosis. By 10 to 14 days, a well-vascularized collagenous capsule with peripheral gliosis or fibrosis is typically present.

The clinical presentation varies, depending on the size, multiplicity, and location of the lesion. Most patients are symptomatic within a week of the onset of abscess formation. Symptoms in adults are nonspecific and include headache (70%), fever (60%), vomiting (50%), focal neurologic deficits (45%), and seizures (40%).[125] However, in pediatric patients the classic triad of fever, headache, and focal deficits occurs in less than 30% and meningeal signs in less than 25% of cases.[126] More than half of the cases will feature papilledema. The sudden worsening of a preexisting headache can indicate rupture of the brain abscess into the ventricular space or impending herniation from the lesion's mass effect. A significant alteration in mental status is an ominous clinical finding. Children with abscesses located within their brainstem typically present with fever, headaches, hemiparesis, and often have palsies of cranial nerves III, VI, and VII.

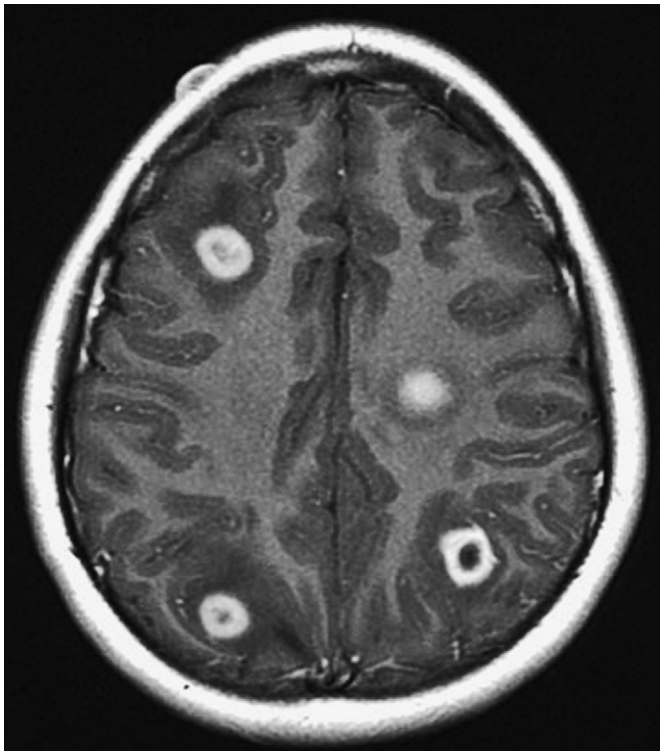

Figure 65–3. This magnetic resonance image demonstrates multiple brain abscesses in a pediatric patient with chronic granulomatous disease. A culture of the abscess material grew aspergillus.

The most important microbiological investigation in the management of patients with brain abscess is culture of the abscess fluid. CT-guided stereotactic aspiration of brain abscesses, a minimally invasive procedure with low morbidity and mortality, is often indicated. This procedure allows both rapid and effective drainage of the brain abscess and obtains material for culture. A lumbar puncture to obtain CSF may be contraindicated in a patient with a brain abscess. Raised ICP may lead to brainstem herniation in these patients. Additionally, CSF culture does not contribute significantly to the identification of the organism. Blood cultures can be helpful in a small percentage of patients, especially in those in whom the abscess is thought to be the result of hematogenous spread.

The microorganisms cultured from the brain abscess are variable and often depend on the original source. *S. aureus*, multiple species of aerobic, anaerobic, and α-hemolytic *Streptococcus*, and Gram-negative anaerobic bacilli tend to predominate. *Citrobacter* and *Cronobacter* spp. are frequently associated with brain abscesses in neonates. In children with impaired host defenses, fungi and uncommon pathogens such as *Toxoplasma, Nocardia*, and *Mycobacterium* organisms can be identified. Mixed aerobic and anaerobic flora are isolated in up to one third of patients, especially in children with chronic otitis and sinusitis.[127] One quarter of samples may demonstrate no bacterial growth.

The clinical presentation of brain abscess is often nonspecific. As such, the diagnosis often is made through radiographic means. Without imaging, it may be difficult to differentiate between a brain abscess and other intracerebral pathologic processes. The advent of CT, and more recently MRI, has altered the prognosis of brain abscess by improving diagnosis. In addition, both CT and MRI are able to locate the position of the abscess accurately, thus enabling a more focused surgical intervention. MRI may have a diagnostic advantage over CT by better differentiation of edema from liquefaction necrosis, greater sensitivity for early satellite lesions, and more sensitivity in the detection of early cerebritis.[128] Serial CT scanning may provide additional information about response to treatment.

Stereotactic CT-guided drainage of the abscess is the treatment of choice in most patients, followed by antibiotic therapy. Even in the critically ill ICU patient, a stereotactic procedure is minimally invasive and the risk-benefit profile will often support its use. Aspiration of the abscess allows both removal of infected nidus and likely identification of the causative organism. Endoscopic drainage may be useful in lesions located in a periventricular distribution. Few indications exist for the nonoperative management of brain abscesses. Typically, abscesses >2.5 cm require surgical drainage.[129] Occasionally the abscess is inaccessible or there are multiple abscesses. In specific cases where there is a small lesion and the infecting organism is known, medical treatment alone may be considered appropriate. Craniotomy and direct surgical drainage is required in some cases of fungal, helminthic, or multiloculated abscesses or after failed stereotactic drainage. Also, brain abscesses resulting from traumatic head injury should be considered strongly for surgical excision because of the possibility of retained foreign bodies or bone fragments. Lastly, primary excision should be chosen over stereotactic aspiration for lesions located in the cerebellum because this approach demonstrates a lower mortality, lower incidence of the development of obstructive hydrocephalus, and an overall shorter hospital stay.[130]

A combination of a third-generation cephalosporin and metronidazole is a reasonable combination for initial antibiotic therapy in persons with brain abscesses. Vancomycin can be added if *S. aureus* is identified or suspected as the causative organism. Vancomycin also is a reasonable choice if the abscess is believed to have occurred as a consequence of a neurosurgical procedure, because in these circumstances, *Staphylococcus* is frequently a pathogen. No prospective studies in children are available to guide antibiotic therapy. Duration of treatment is best based on clinical response. Duration of treatment can be as short as 1 to 2 weeks of intravenous antibiotic therapy followed by 2 to 4 weeks of an oral antibiotic after surgical drainage. Some clinicians recommend that intravenous therapy be continued as long as 4 to 6 weeks.[128] If antibiotics alone are utilized, the duration of intravenous therapy is typically longer, with some clinicians recommending a treatment period of up to 6 to 8 weeks.[129]

Mortality attributed to brain abscess was 60% prior to 1970. Since the advent of newer radiologic procedures such has high-resolution head CT or MRI, detection of brain abscesses is more efficient. With earlier detection, mortality has dropped and currently is about 10% to 15%.[125-126] Long-term neurologic morbidity attributed to the abscess and therapy ranges from 10% to 30% depending on both the size and location of the lesion as well as the response to therapy. The patient's neurologic status at presentation is a significant predictor of outcome, with an increased mortality rate in those who present to the PICU with an altered mental status or rapid neurologic deterioration.[131] Brain abscesses resulting from a contiguous focus of infection and those developing after a traumatic injury tend to have a good prognosis. Those resulting from neurosurgery for neoplasia or where there is a medical or cardiac predisposing factor are more likely to have a poorer outcome.

Primary and Granulomatous Amoebic Central Nervous System Infections

Primary amebic meningoencephalitis (PAM) is a rare, often fatal disease caused by infection with *Naegleria fowleri*, a thermophilic, free-living amoeba found in freshwater environments. In 2007, six cases of PAM in the United States were reported to the CDC, five of which involved pediatric patients. All of the patients reported to the CDC died.[132]

Naegleria fowleri is the causal agent of most PAM infections, but other species of *Naegleria* with pathogenic potential have been described (e.g., *Naegleria australiensis* and *Naegleria italica*). Currently, more than a dozen species of *Naegleria* have been recognized based on small subunit ribosomal DNA.[133] The habitat for *N. fowleri* is natural or man-made fresh water lakes or an inadequately chlorinated swimming pool where the amoebas can feed upon bacteria and proliferate. In the United States, *N. fowleri* is commonly found in warm freshwater environments in 15 southern-tier states (Arizona, Arkansas, California, Florida, Georgia, Louisiana, Mississippi, Missouri, Nevada, New Mexico, North Carolina, Oklahoma, South Carolina, Texas, and Virginia).

In 2007, the CDC and the Council of State and Territorial Epidemiologists formed the *Naegleria* Workgroup. They used multiple resources to conduct a review of all PAM cases reported in the United States from 1937 to 2007. Preliminary

results indicate that a total of 121 cases (range: 0 to 8 cases per year) occurred in the United States from 1937 to 2007. The six cases of PAM reported to the CDC in 2007 were among the highest during the study period. From 1937 to 2007, the median age of the patients was 12 years (range: 8 months to 66 years). Among the 119 cases for which the sex of the patient was known, male patients accounted for 93 (78%) of the cases. Only one survivor was reported. Among the 112 cases for which the month of exposure was known, 95 (85%) occurred during July to September.[132]

Naegleria species typically cause PAM in children and healthy adults who have been swimming in infested water. *N. fowleri* enter through the olfactory neuroepithelium at the level of the cribriform plate and invade the submucosal nervous plexus. Symptoms begin after a 3- to 7-day incubation period. PAM presents in a manner very similar to acute bacterial meningitis, but physicians often miss the diagnosis initially. History is vital for making the diagnosis. Residence in or travel to a southern-tier state in the United States must be verified. Recent exposure to diving, swimming, or splashing in warm fresh water should suggest the possibility of amoebic meningoencephalitis, and the CSF should be promptly examined for *N. fowleri*. The onset of PAM is abrupt, with sore throat, headache, nausea, vomiting, malaise, and fever. Early findings also may include irritability, hallucinations, meningismus, cerebellar ataxia, and cranial nerve palsies, although focal neurologic defects are usually absent. Alterations in taste and smell may occur, likely due to involvement of the olfactory nerve.[134]

Differential diagnosis includes acute bacterial meningitis, HSV-1 encephalitis, and viral or fungal meningitis. With immunosuppressed patients, amoebic meningitis might be confused with toxoplasmosis, CMV infection, and other opportunistic pathogens. The diagnosis is made by examination of CSF wet mounts for motile trophozoites; however, failure to visualize these amoebae does not exclude PAM. The diagnosis is often missed when *Naegleria* organisms are mistaken for atypical monocytes or lymphocytes.

Currently, the most effective therapy is amphotericin B, given both intravenously and intrathecally. Miconazole, rifampin, and doxycycline are often used in conjunction with amphotericin B.[134] Given the difficulty in making a diagnosis, early infectious diseases consultation should be considered for any patient with a history of stagnant warm water exposure, clinical signs of early meningoencephalitis, CSF findings consistent with meningitis, and a CSF Gram stain showing no bacterial organisms.

PAM infections tend to be fulminant, with seizures progressing to coma and death within 4 to 6 days. Autopsy findings typically demonstrate acute hemorrhagic necrotizing meningoencephalitis with purulent exudates in the brain, brainstem, and cerebellum.

The extremely low incidence of PAM makes epidemiologic study difficult. It is unknown why certain individuals become infected with the amoebae when many others who are exposed to the same freshwater sources do not become infected. Attempts are under way to determine what concentration of *N. fowleri* in the environment poses an unacceptable risk, how a standard might be set to protect human health, and how regulators might measure and enforce such a standard.

Another amoebic organism, *Acanthamoeba* spp., causes a subacute CNS infection known as granulomatous amoebic encephalitis. More so than the *Naegleria* organism, *Acanthamoeba* is ubiquitous in the environment, with amoebas widely disseminated in soil and water. Unlike the healthy individuals acquiring *Naegleria* infections, *Acanthamoeba* infections of the CNS are typically in found in compromised hosts who have concurrent diseases such as acquired immunodeficiency disorder or IgA deficiency or those undergoing suppressive therapy for organ transplantation. The portal of entry of this species of ameba can vary. It may be intranasal, allowing amoebas to migrate directly to the CNS, via a break in the skin or through the respiratory tract, with subsequent spread of amoebas to the CNS by a hematogenous route. The disease assumes a chronic status, leading to slow deterioration. Gadolinium-enhanced T1-weighted MRI of the brain show multiple punctate focal areas of enhancement bilaterally throughout the cerebellar hemispheres, with some scattered foci supratentorially.[135] These lesions may represent focal cerebritis or microabscesses. Diagnosis is most often made by postmortem examination of brain tissue showing patchy, chronic granulomatous encephalitis with trophozoites and cysts in the lesions.

Conclusions

Acute infections of the CNS are common in childhood and can be associated with significant morbidity and mortality. The field of pediatric CNS infections is ever changing with the advent of new conjugate vaccinations for bacterial meningitis and the emergence of new pathogens. Further, pressure in the community to prescribe antibiotics has led to the development of drug-resistant organisms, thereby causing infections that are increasingly difficult to control. The best approach for management of CNS infections in the PICU continues to rely on successful integration of treatment strategies designed to correct the systemic and intracranial pathophysiologic issues. A thorough knowledge of the pathophysiology, screening laboratory tests and radiographic studies, and best treatment options is mandatory in the training of all pediatric intensivists. Insight into the etiologies and nuances of CNS infections remains a crucial component for therapeutic success.

Renal Structure and Function

Maury N. Pinsk and Victoria F. Norwood

PEARLS

- The efferent blood supply from a single glomerulus will contribute to the capillary vascular supply of tubules from different nephrons. This arrangement of the vascular supply explains the patchy distribution of tubular damage after ischemic injury.
- Combinations of angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs result in inhibition of afferent arteriolar vasodilation and inhibition of efferent arteriolar vasoconstriction. In low flow states, these agents can cause precipitous loss of glomerular filtration pressure and kidney function
- Tubular dysfunction in the setting of acute tubular necrosis results in the inability to transport sodium into the medulla to establish concentration gradients, impairing the concentration of urine and resulting in diuresis. Furosemide and other loop diuretics, which also impair sodium transport into the medulla, are often ineffective at increasing urine output in this setting.

Renal Development

The human kidneys begin development in the third week of gestation, at which time they are primitive organs called pronephroi. These early kidneys are functional but regress as development unfolds. As gestation continues in the fourth week, the secondary kidney elements, the mesonephroi, form from parallel strips of mesoderm along the paravertebral axis. The mesonephroi begin functioning between the sixth and tenth week of gestation before involution in a cranial-caudal direction beginning at 10 weeks' gestation. The definitive kidney, or metanephros, begins development at the fifth week of gestation and begins functioning between the tenth and fourteenth week. This kidney develops in the pelvis as the branching ureteric bud and undifferentiated metanephric mesenchyme interact in a complex series of reciprocal inductions.[1-3] These interactions lead to the formation of glomeruli, whereas vessels and tubules form from mesenchymal precursors, and distal tubules and collecting ducts derive from ureteric bud epithelium. This process occurs in a centrifugal fashion so that deeper corticomedullary nephrons form earliest in organogenesis, whereas the more peripheral cortical nephrons form later. As the metanephros develops, the maturing kidney ascends into the retroperitoneal space to its final location with the upper poles at the T12 vertebra. During the ascent, the systemic blood supply is derived from more cranial aspects of the aorta and from the lumbar renal arteries at the final position of the kidney. The ureters elongate and canalize during the ascent to maintain drainage to the bladder. By the time human nephrogenesis is complete at 34 to 36 weeks of gestation, repeated cycles of mesenchymal induction, ureteric branching, and morphogenesis result in approximately 1 million nephrons per kidney.

Renal Anatomy

Normal human kidneys reside in the retroperitoneal space at the level of the T12 vertebra. The liver is superior to the right kidney and thus displaces it lower than the kidney on the left side. The spleen and stomach overlie the superior aspect of the left kidney. Kidneys, however, can be found in a variety of other locations and have altered morphologies as a result of alterations of the normal developmental program (reviewed by Schedl[4]). For example, failure of the kidney to ascend normally results in a pelvic kidney that has abnormal vascular supplies from the aorta and iliac vessels. Mesenchymal regions of the two kidneys coming in contact during early development likely cause fused kidneys, most commonly the horseshoe kidney. Partial or complete renal duplications comprise a variety of abnormalities that may arise from aberrant branching of the ureteric bud into the developing mesenchyme. Unilateral agenesis likely results from failure of ureteric bud development or abnormal mesenchymal induction, leading to regression of the metanephric mesenchyme and failed renal development.

Renal Vasculature

Vascular Development

Markers of early vascular development are expressed in undifferentiated metanephric mesenchyme, which suggests that the blood supply to the nephron develops at least partially from precursors inherent to the maturing kidney.[5] Migration of committed endothelial cells into the developing glomerulus occurs in response to secreted factors such as vascular endothelial growth factor, which is secreted under the transcriptional regulation of the oxygen-sensitive hypoxic inducible factor.[6] Control of the corresponding branching of extraglomerular vessels is an area of active study and may involve branching from existing vessels, de novo vessel formation, or both processes. These actions appear to be regulated in part by the renin-angiotensin system.[7]

Vascular Anatomy

The arterial supply of the kidney branches from the main renal artery and enters the kidney in a series of rays called interlobar arteries. The interlobar vessels branch at the corticomedullary junction to run parallel to the surface of the kidney as arcuate arteries. Arcuate arteries penetrate the cortex as interlobular arteries, which ascend into the cortex in a radial pattern. It is from the interlobular arteries that afferent arterioles of the glomeruli arise. After filtration across the glomerular tuft, blood exits the glomerulus by efferent arterioles, which travel to the surface of the cortex and eventually feed the peritubular capillary vascular beds, the vasa rectae. The efferent arteriole of a single nephron can supply blood to multiple vasa rectae. The postglomerular vasculature of the cortex is supplied by efferent arterioles from midcortical and superficial cortical nephrons, whereas the blood supply to the medulla is entirely derived from juxtamedullary efferent arterioles. The vasa rectae of the medulla branch as they descend toward the papilla of the kidney and form the complex meshwork of the medullary capillary vascular beds. Only a few vessels of the vasa rectae eventually reach the papillary tip.

Venous drainage of the vasa rectae is divided into two types: the vessels of the deep medulla ascend to join the arcuate veins at the corticomedullary junction, and those of the superficial medulla ascend into the cortex to join the cortical capillary network and ultimately the interlobular and arcuate veins (Figure 66-1). The arcuate veins join with the interlobar veins via the interlobular veins and finally drain into the main renal vein to join the main circulation.

Vascular Function

The kidneys are extraordinarily vascular organs; they receive 15% to 18% of cardiac output in the neonate and up to 20% of cardiac output in the adult.[8] Blood flow to the kidney is tightly regulated to ensure continued renal function over a range of blood pressures. Sympathetic α_1-receptors, myogenic contraction, and vasoactive mediators control vascular resistance and provide autoregulation of renal blood flow. Maintenance of glomerular filtration rate at the level of the glomerulus occurs by vasoconstriction of efferent arterioles in response to pressors such as angiotensin II, whereas afferent arterioles relax in response to vasodilators such as prostacyclin. Circulating angiotensin II is elevated in the neonate,[9] as are corresponding vasodilators.[10,11] Therefore infants have a decreased capacity to regulate renal blood flow, which explains their increased susceptibility to renal ischemia in hypotensive states.

Arterial supply (*left*): The arcuate artery (*arrow*) travels parallel to the surface of the kidney, branching into interlobular arteries that travel toward the kidney surface, and further branches into afferent arterioles supplying each glomerulus. The efferent arterioles travel to the medulla forming the vasa rectae. Venous drainage (*right*): Interlobular veins receive blood from the vasa rectae of the medulla and superficial cortex. Interlobular veins drain into arcuate veins and ultimately rejoin the systemic circulation via the renal vein. *C,* Cortex; *IM,* inner medulla; *IS,* inner stripe; *OS,* outer stripe. *(Modified from Kriz W, Lever AF: Renal countercurrent mechanisms: structure and function,* Am Heart J *78:101-118, 1969; and Rollhäuser H, Kriz W, Heinke W: Das Gefässsystem der Rattenniere,* Z Zellforsch *64:381-403, 1964.)*

The Nephron Unit

The nephron unit consists of a glomerular tuft, proximal tubule, loop of Henle, distal tubule, and collecting duct (Figure 66-2). The proximal tubule is an extension of the urinary space of the glomerulus and courses into the loop of Henle. Two types of nephrons are characterized on the basis of the location of the glomerulus and the path of the loop of Henle: the juxtamedullary nephrons and the cortical nephrons. Most nephrons are cortical in location, have short loops of Henle that extend into the superficial medulla, and have a relatively low capacity to reabsorb solute and water. Juxtamedullary nephrons are fewer in number but have longer loops of Henle that extend deep into the medulla. Consequently, these nephrons absorb larger amounts of salt and water, generate steep osmotic gradients, and produce highly concentrated urine. Regardless of the location of the nephron, the loop of Henle returns to the cortex to become a distal tubule. The distal tubule then continues on to form the collecting duct, the final common pathway for several nephrons draining into the renal papilla.

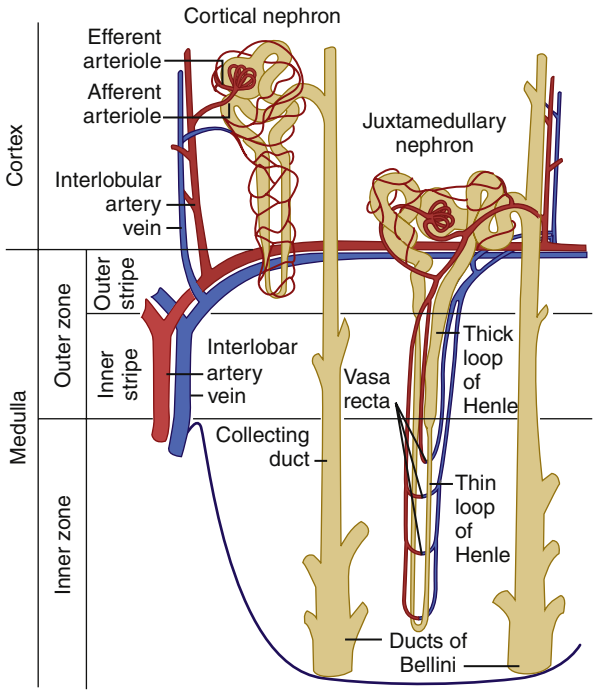

Figure 66–2. The nephron structure. *(From Guyton A: Formation of urine by the kidney: I. Renal blood flow, glomerular filtration, and their control. In Wonsiewicz M, editor:* Textbook of medical physiology, *ed 8, Philadelphia, 1991, WB Saunders.)*

Nephron Development

Nephron development occurs through a complex, interactive series of processes that remains to be completely understood.[1-3] Nephron development begins with the outpouching of the ureteric epithelium, the ureteric bud. This precursor to the collecting duct encroaches on undifferentiated mesenchyme in the caudal retroperitoneal space and induces the development of an epithelial cell condensate, the precursor to the future glomerulus and tubule (Figure 66-3). Simultaneously, factors within the metanephric mesenchyme induce the ureteric bud to continue branching. The epithelial condensate forms a vesicle that convolutes progressively into a comma-shaped body and then an S-shaped body, signifying the development of the urinary space and early tubule segments. The terminal portion of the tubule is contributed by the ureteric bud derivatives and forms the collecting duct. The mechanisms by which the ureteric bud epithelial derivatives link to the corresponding mesenchymal derivatives in the distal nephron remain unknown. The glomerular capillary loops appear to form through the angiogenic processes of committed endothelial cells,[5] and supporting mesangial cells develop from committed metanephric mesenchyme with myoblastic characteristics.[12] Nephrogenesis in the human is essentially complete by the thirty-fourth week of gestation, but functional maturation continues into the second year of life.[1-3]

Glomerular Anatomy

The glomerular tuft consists of endothelial cells, specialized epithelial cells (podocytes), and supporting mesangial cells. Epithelial cells form the urinary compartment into which ultrafiltrate passes (Bowman's space). Endothelial cells and podocytes sit on opposite sides of the glomerular basement membrane, the entirety of which forms the filtration apparatus. The epithelial side is characterized by fingerlike extensions of the podocyte cell membrane that interdigitate to form a mesh on the glomerular basement membrane. Glomerular endothelial cells on the blood side of the filtration barrier are highly fenestrated, thereby enhancing solute and fluid transfer. Mesangial cells form the supporting network of the glomerular structure, provide some phagocytic function, and participate in control of glomerular filtration.

Glomerular Function

Filtration is the primary function of the glomerulus. For filtration to occur, there must be a gradient across the glomerular basement membrane favoring the movement of filtrate to a low-pressure area. There are generally four factors that determine the quantity of filtrate obtained across the glomerular basement membrane (Figure 66-4). First, hydrostatic pressure in the glomerular capillary drives filtration of fluid across the glomerular basement membrane. If the blood flow to the glomerulus decreases, the hydrostatic pressure also drops, which necessitates an increase in efferent vascular resistance to maintain glomerular perfusion pressure. Hormones, predominantly angiotensin II and prostaglandins, and renal sympathetic activity control afferent and efferent vascular tone to carefully regulate glomerular vascular resistance.

The second factor controlling filtration is the oncotic pressure of the blood entering the glomerulus. As blood is filtered and water leaves the vascular compartment to enter the urinary space, the oncotic pressure in the blood compartment rises, retarding the further passage of fluid across the glomerular basement membrane. In situations of low oncotic pressure, such as nephrotic syndrome, the initial rate of ultrafiltrate formation is increased because of low oncotic pressure. Low oncotic pressure, however, also causes a concomitant redistribution of intravascular volume into peripheral tissue spaces, resulting in decreased vascular hydrostatic pressure, thus causing ultrafiltrate production to finally drop. Lower hydrostatic pressure therefore balances the low oncotic pressure.

The third factor determining the efficiency of ultrafiltrate formation is tubular hydrostatic pressure, or the resistance within the urinary space. Tubular hydrostatic pressure is an important factor limiting ultrafiltrate generation in the setting of urinary obstruction because it can rise above the hydrostatic pressure of the blood compartment and arrest ultrafiltrate generation.

The last important factor in the determination of ultrafiltrate formation relates to the intrinsic properties of the glomerular basement membrane. Both the area of available membrane surface and the efficiency of the membrane to filter affect the generation of ultrafiltrate. Physiologically, the "size" of the glomerular basement membrane can be determined at the whole kidney level or at the glomerular level. At the whole kidney level, the number of nephrons receiving adequate blood supply determines glomerular basement membrane area available for filtration. For example, shunting of blood from the cortex into the medulla, as seen in persons with hepatorenal syndrome, effectively decreases the available glomerular basement membrane area by reducing the number of actively filtering nephrons. At the glomerular level, glomerular basement membrane area can be altered

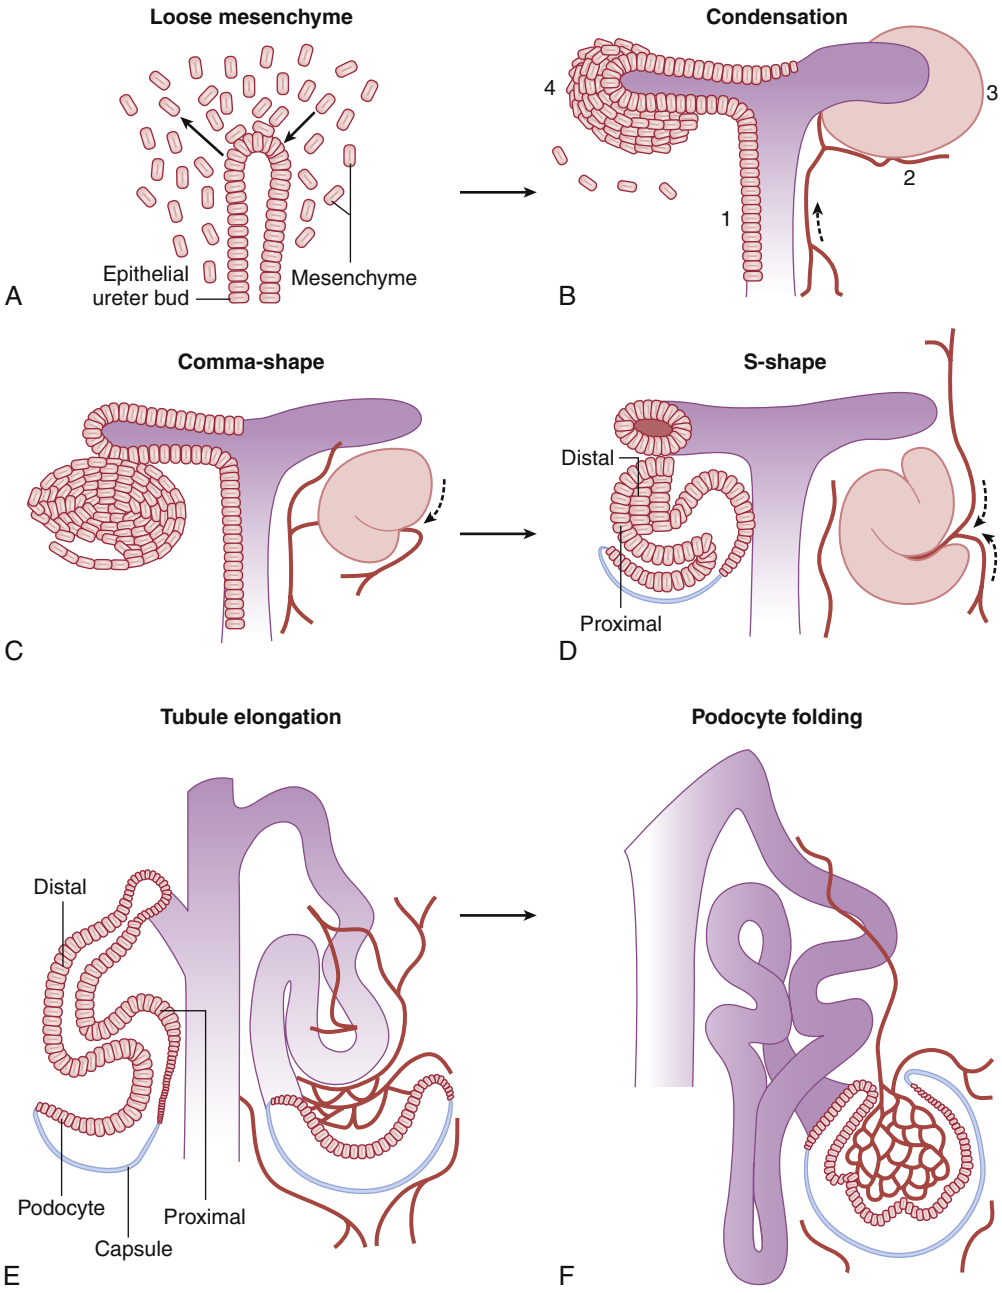

Figure 66–3. Branching morphogenesis of the developing kidney. **A** and **B,** The ureteric epithelium interacts with the metanephric mesenchyme, inducing condensation of the mesenchyme (*1* = ureteric epithelium, *2* = vasculature, *3* = undifferentiated mesenchyme, *4* = condensed mesenchyme [precursor to epithelium]). **C** and **D,** Infolding of the glomerular epithelium forms a comma-shaped body, followed by development of an S-shaped body. **E** and **F,** Infolding of the glomerular epithelium and vascular structures and elongation of the tubular elements form the completed nephron. by mesangial cell function. In hypovolemic states, mesangial cell contraction is thought to decrease glomerular basement membrane area in response to hormonal mediators, resulting in decreased filtration and preservation of intravascular volume.[13] The efficiency of basement membrane filtration also can be affected by disease states including immune complex deposition, fibrosis, or complement activation, which disrupt the integrity and efficiency of the membrane.

Finally, selectivity of the filtration barrier is determined by the ability of the basement membrane to permit some materials to pass into the urine while restricting others to stay in the blood compartment. Selectivity appears to be the result of both size discrimination of the glomerular basement membrane and the orientation of podocyte foot processes on the glomerular basement membrane. Disruption of the normal podocyte physiology results in nephrotic range proteinuria.[14,15]

Tubular Anatomy

Proximal Tubule

The proximal tubule consists of polarized epithelia with a distinctive apical brush border not seen in other parts of the tubule (Figure 66-5). The brush border functions to increase the surface area of the luminal side of the cell so that maximal contact of the cell with the ultrafiltrate is made. Increased surface area facilitates reabsorption of solute and water, which occurs through an abundant variety of sodium-coupled transport proteins. Also on the brush border membrane are ion channels and ion exchange proteins that maintain electrochemical gradients across the apical membrane. On the basolateral aspect of the proximal tubular cells are located sodium-potassium adenosine triphosphatase (Na/K-ATPase) proteins and a high density of mitochondria. It is through the Na/K-ATPase that favorable sodium and electrochemical gradients are generated to facilitate transcellular and paracellular transport of solutes and water. The lateral membranes of the proximal tubule cells are characterized by the presence of cell-cell adhesion complexes called tight junctions. Tight junctions maintain the polarity of the proximal tubule cells by separating transport proteins on the apical side from the gradient-generating basolateral membrane proteins.

Loop of Henle

The cortical and juxtamedullary nephrons are defined by their position within the cortex but also by the length of the loop of Henle. The juxtamedullary nephrons have loops of Henle that extend deep into the hyperosmolar medulla, whereas most nephrons are cortical and have loops that reach only the mildly hyperosmolar outer medulla. The properties of the epithelial cells change throughout the length of the loop of Henle. The proximal portions have cells with prominent microvilli and permeable cell junctions that permit passage of fluid via aquaporin type 1 channels.[16] The distal sections of the loop of Henle consist of flat epithelia lacking microvilli and are devoid of aquaporin-1 channels. Thus the thin ascending limb of the loop of Henle is impermeable to water and urea but transports other solutes, particularly chloride, and is important in assisting with the establishment of medullary gradients.[17]

An abrupt transition occurs at the beginning of the thick ascending limb of the loop of Henle (TALH). The TALH is impermeable to water but transports solute in an active, adenosine triphosphate (ATP)-dependent manner. These cells do not have prominent microvilli but do have dense tight junctions. These tight junctions allow solute, but not water, to move among cells into the basolateral space. TALH cells are characterized by the dense localization of mitochondria and Na/K-ATPase at the basolateral membrane that generate gradients for solute transport across the luminal surface. Compared with the proximal tubule, the TALH basolateral surface is larger than the luminal surface, accommodates a larger number of Na/K-ATPase pumps, and is more metabolically active than the proximal tubular epithelium.[18] At the distal end of the TALH, the tubule courses back toward its originating glomerulus. Here a small plaque of tall, narrow cells, the macula densa, contacts the vascular pole and extraglomerular mesangial cells (Figure 66-6). The primary function of the macula densa cells appears to be the detection of tubular chloride content and the regulation of glomerular filtration.

Distal Nephron

The distal nephron segment from the TALH to the beginning of the collecting duct is marked by the presence of three distinct morphological regions. The first region is the distal

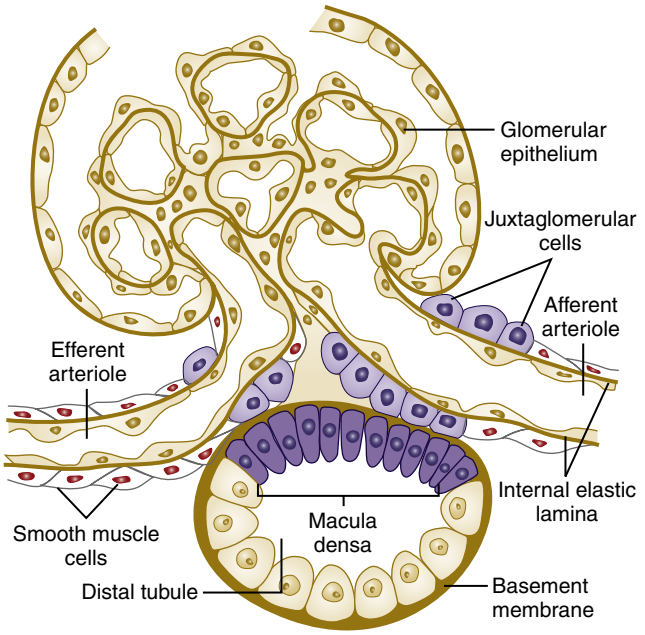

Figure 66–6. Structure of the juxtaglomerular apparatus. *(From Guyton A: Formation of urine by the kidney: I. Renal blood flow, glomerular filtration, and their control. In Wonsiewicz M, editor:* Textbook of medical physiology, *ed 8, Philadelphia, 1991, WB Saunders.)*

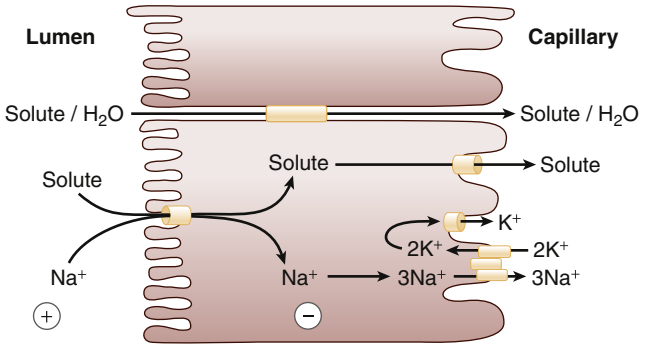

Figure 66–7. Proximal tubule transport of solute and water. Apical solute reabsorption (glucose, amino acids, phosphate, and organic acids) is sodium coupled and follows an electrochemical gradient generated by basolateral sodium-potassium adenosine triphosphatase (Na/K-ATPase) activity.

convoluted tubule, the cells of which contain the luminal sodium chloride transporter (NCC2, or thiazide-sensitive transporter) and the highest density of mitochondria in the nephron. The basolateral membrane of this segment is composed of interdigitating membranes from adjacent cells, giving the appearance of membranous convolutions. This composition maximizes the basolateral surface area to accommodate the high density of mitochondria and allow for high levels of Na/K-ATPase function. Moving distally, the tubule contains transitional cells that have a smaller basolateral surface area and fewer mitochondria at the basolateral membrane. Transitional cells express both the NCC2 channel and the luminal epithelial sodium channel (ENaC), with the quantities of ENaC increasing and NCC2 decreasing with distal progression along the segment.

The next segment is the connecting tubule, where cells show even fewer mitochondria and smaller basolateral membranes. These cells are distinguished by a more flattened appearance, an expression of ENaC, and a luminal potassium channel (ROMK), but not NCC2. The basolateral membrane is expanded to some degree by infoldings of the basal membrane, but there is no interdigitation from neighboring cells. Because of the presence of magnesium transporters (TRPM6) and calcium transporters (TRPV6), there is also a role for divalent cation regulation.[19,20]

The last segment in the distal nephron is the collecting duct. The primary cells of this segment, the principal cells, are characterized by apical vacuoles, some of which store aquaporin-2 channels. They also contain mineralocorticoid receptors and apical sodium channels that function in sodium and potassium balance. The basolateral membrane is infolded but to a lesser degree than other cells in the region. These infolds diminish in cells of the medullary collecting duct compared with those in the cortical collecting duct. In the medullary portions of the collecting duct, urea transporters again appear.

Two forms of intercalated cells, "type A" and "non–type A," exist as single cells interspersed throughout the distal nephron. These cells have prominent microfolds in the apical membrane, have high densities of mitochondria, and express several important membrane proteins such as the luminal H^+-ATPase and H^+/K^+-ATPase, as well as cytoplasmic carbonic anhydrase, serving an integral role in acid-base balance. The essential difference between type A and non–type A intercalated cells is that cell polarity is opposite in the two cell types. In "type A" intercalated cells, the apical membrane contains an H^+/K^+-ATPase, whereas the basolateral membrane contains AE1, a bicarbonate/chloride exchanger that provides a mechanism for proton secretion. The non–type A intercalated cell has vacuolar H+-ATPase on the basolateral and apical surfaces and a chloride bicarbonate exchanger, pendrin, on the apical surface, allowing for both bicarbonate secretion and proton reabsorption.[21] Generally, the number of type A and non–type A intercalated cells can vary to accommodate the acid base status in the blood.[22]

Tubular Function

While the function of the glomerulus is filtration, the function of the tubule is to modify the ultrafiltrate to maintain metabolic balance. This task is accomplished through the mechanisms outlined in the following section but includes the reabsorption of water and solutes and excretion of waste products generated from daily metabolism.

Proximal Tubule

Solute and water are transported in the proximal tubule via both paracellular and transcellular routes (Figure 66-7). Paracellular transport is a high-flux means of moving water and solute between cells along chemical or electrical gradients generated by the basolateral Na/K-ATPase. The mechanism for high flux movement of sodium out of the lumen is explained by a net luminal positive charge generated by the basolateral Na/K-ATPase and net anion reabsorption. The bulk of the sodium therefore follows an electrochemical gradient through paracellular pathways into the blood space. The same principle applies to other cations, such as calcium, which are passively reabsorbed down electrochemical gradients in the proximal tubule. Neutrally charged solutes, such as glucose, move between cells following concentration gradients, the transport

becoming less effective more distally as the gradient dissipates. Water movement generally follows sodium movement and is facilitated by the high oncotic pressure of the peritubular capillary network. This favorable osmotic gradient allows for reabsorption of approximately 70% of the filtered water in the adult proximal tubule.

Transcellular movement of solute is a high-resistance method of sodium-coupled transport that results from electrochemical and concentration gradients established by the basolateral Na/K-ATPase (see Figure 66-7). The Na/K-ATPase pumps three sodium molecules into the basolateral extracellular milieu against a concentration gradient and imports two potassium molecules into the cell against a concentration gradient. The process, which is ATP dependent, establishes a low intracellular sodium concentration and permits luminal sodium entry along a concentration gradient coupled with solutes such as phosphate, glucose, amino acids, and organic acids. In a similar fashion, protons are exported from the luminal membrane by an Na/H+ exchanger that exploits the intracellular movement of sodium to facilitate the export of protons. Bicarbonate is indirectly absorbed through the activity of luminal carbonic anhydrase and the Na/H+ exchanger. The high oncotic pressure of the blood in the arterioles and early vasa recta drives transcellular water reabsorption in the proximal tubular cells via constitutively expressed aquaporin-1 channels that permit water to flow from lumen to vasculature.[23] Some proximal solute reabsorption is modifiable by hormone activity. Parathyroid hormone binding to the proximal tubule receptors activates several second messenger systems that ultimately result in decreased sodium-phosphate transporter activity and phosphate excretion.[24] The proximal tubule is also a site of hormone production, with 1α-hydroxylase activity converting 25-hydroxyvitamin D to the active 1,25-dihydroxy form. This conversion permits vitamin D to act in calcium and phosphate metabolism.[24]

Maturational development of the proximal tubule imparts functional differences in neonatal proximal tubules compared with those in adult kidneys. The relatively low outer cortical nephron blood flow in infancy results in a generalized decrease in proximal tubule resorptive capacity because fewer nephrons participate in active solute and water reabsorption. In the neonate, the proximal tubule also expresses specific neonatal isoforms of the Na/H+ exchanger, has decreased chloride permeability, and expresses different permeability proteins (claudins) in the transcellular space. As a result, neonatal reabsorptive capacity is reduced compared with adults.[25] In addition, hormone receptors are expressed in fewer numbers or may have higher thresholds for activation in the neonate. For example, isoforms of sodium-phosphate transporters of the premature neonate exhibit a relatively low sensitivity to parathyroid hormone but a high transport capacity for phosphate, resulting in lower urinary excretion of phosphate and higher serum phosphate levels than those seen in adults.[26]

Loop of Henle

The loop of Henle plays an important role in establishing the osmotic gradients facilitating water reabsorption in the kidney. In the descending limb of the loop of Henle, the tubular epithelium is impermeable to solute but not water. Therefore as ultrafiltrate passes down the descending loop of Henle, ultrafiltrate becomes increasingly hyperosmolar as water

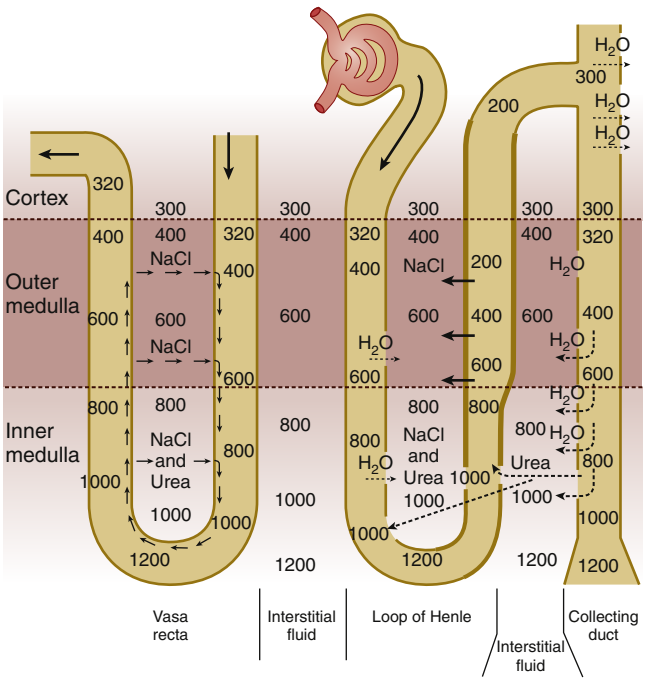

Figure 66–8. The countercurrent amplification mechanism permitting urinary concentration. *(From Guyton A: Renal and associated mechanisms for controlling extracellular fluid osmolality and sodium. In Wonsiewicz M, editor:* Textbook of medical physiology, *ed 8, Philadelphia, 1991, WB Saunders.)*

leaves the luminal space. Water permeability decreases, however, in the ascending loop, and solute transporters become more prevalent, allowing the filtrate to become hypoosmolar by the time it reaches the outer cortex.

The thick ascending loop of Henle is responsible for roughly 25% of the total sodium reclamation in the kidney, primarily by the NKCC2 channel, that allows one sodium, one potassium, and two chloride ions to move from the tubular lumen into the cell.[27] Potassium subsequently leaks back into the lumen via the ROMK potassium channel, causing the lumen to become positively charged. This electrochemical gradient permits paracellular reabsorption of cations such as calcium and magnesium as they are propelled out of the tubular lumen.

The reabsorption of sodium in the TALH also helps establish osmotic gradients in the renal interstitium by the countercurrent amplification mechanism (Figure 66-8). Although sodium, potassium, and chloride are absorbed into the interstitium, back leak of ions occurs into the descending limb of the loop of Henle, thereby increasing the concentration of solute in the descending limb tubular fluid. As this fluid passes into the ascending loop of Henle, the higher sodium content is also reabsorbed into the interstitium, augmenting the osmotic gradient in the medulla. Under normal conditions, ultrafiltrate leaving the ascending loop of Henle is more dilute than that entering the descending loop because of the proficient solute reabsorption in the late ascending limb. Loop diuretics such as bumetanide or furosemide block the NKCC2 channel function and impair the ability both to establish osmotic gradients and to reabsorb solute. The result is the production of large volumes of urine that is isotonic to plasma.

In the immature kidney, the loop of Henle is relatively short and impedes the ability to set up steep osmotic gradients. In the setting of stable vasopressin levels, neonatal

urinary concentrating ability is relatively weak compared with that of the mature adult kidney.[28] The thick ascending loop of Henle returns to its glomerulus of origin where the tubular epithelium is attached to the triangle between the efferent and afferent arteriole. The tubular epithelium in contact with the glomerulus contains about 15 to 20 cells in the form of a plaque, called the macula densa (see Figure 66-6). The macula densa actively reabsorbs sodium, potassium, and chloride through the NKCC2 channel and, in doing so, acts as a sensor of tubular chloride concentration.[29] This sensing mechanism is integral to the functioning of the juxtaglomerular apparatus, which consists of the macula densa, the afferent arteriole containing renin-producing granular cells, the efferent arteriole, and the extraglomerular mesangium. In response to low tubular chloride, such as in hypovolemia, the macula densa secretes chemical mediators (prostaglandins, nitric oxide, adenosine, and ATP) that trigger renin release from the granular cells in the afferent arteriole.[30] Similar effects can be induced by sympathetic nervous system stimulation and arteriolar baroreceptor activation.[31]

Renin activity ultimately leads to the production of the potent vasoconstrictor angiotensin II, vascular smooth muscle contraction in the efferent arteriole, increased efferent arteriolar vascular resistance, and a rise in glomerular perfusion pressure.[31] The macula densa also signals the mesangial cells and neighboring smooth muscle cells to contract through a process that involves gap junction signaling and calcium flux. This contraction results in increased vascular tone and decreased effective filtration area of the glomerular basement membrane.[32,33]

Distal Tubule

The distal convoluted tubule is also a site of active sodium reabsorption and functions to help fine-tune the urinary filtrate. When tubular fluid enters the distal convoluted tubule, it is relatively dilute because of active solute reabsorption in the TALH. Thus reabsorption of sodium and chloride in this segment occurs against a concentration gradient. Sodium and chloride are actively reabsorbed through the luminal thiazide-sensitive cotransporter (NCCT) following electrochemical gradients generated by the basolateral Na/K-ATPase. However, regulation of the NCCT, and hence sodium flux, is modifiable through a series of modulator kinases (WNK-1 and WNK-4).[34] Approximately 10% of filtered calcium is also reabsorbed from the luminal space in the distal convoluted tubule through parathyroid hormone activation of ATP-dependent TRPV5 calcium channels.[35] Once inside the cell, calcium is sequestered by calbindin-D28k, a protein that facilitates the transport of calcium to the basolateral membrane. Calcium exits the cell through either a basolateral Na-Ca exchanger, NCX1, or the plasma membrane Ca efflux ATPase.[35]

Collecting Duct

The collecting duct also functions to fine-tune the final composition of the renal ultrafiltrate adjusting sodium, potassium, and water content and acid-base balance. Approximately 5% of the filtered sodium is reabsorbed at this location and occurs through active transport. Sodium enters the cell through apical epithelial sodium channels (ENaC) and generates a luminal electronegative gradient.[36] Consequently, the excretion of cations such as potassium (principal cell) or protons (a-type intercalated cell) is favored (Figure 66-9). Because relatively little potassium is in the tubular fluid when it reaches this segment, potassium excretion down a concentration gradient is facilitated. As potassium is excreted, urine flow keeps the concentration in the tubular fluid low, and the favorable gradient is maintained. In states of low urine flow the tubular potassium concentration rises, the gradient is reduced, and potassium excretion decreases.

Potassium excretion and sodium reabsorption are also enhanced by the presence of aldosterone. Binding of aldosterone to its receptor and subsequent translocation to the cell nucleus induces transcription of the luminal sodium channel and basolateral Na/K-ATPase.[37] Increased efficiency and numbers of ENaCs on the luminal membrane tend to increase cell permeability to sodium, and this increase allows the tubular fluid to become more negatively charged after the influx of sodium. This process is facilitated by the increased activity and number of Na/K-ATPase pumps at the basolateral membrane, which creates larger electrical gradients. The net result is an increased capacity to excrete potassium or, in the hypokalemic state, an increased capacity to excrete protons.

The electrical gradient in the collecting duct also favors proton secretion into the tubular lumen, but the chemical gradient does not; the pH in the lumen can be as low as 5, whereas that of the intracellular space is 7.3. Excretion of protons occurs through an apical H-ATPase in the a-type intercalated cells and is also increased by aldosterone action in principal cells, as previously described. Protons secreted into the lumen are bound by ammonia to form NH_4 or are bound by other titratable acids such as phosphate or sulfate. This sequestration lowers the concentration of free protons in the ultrafiltrate, prevents diffusion of protons back into the intracellular space, and ultimately promotes acid secretion.

The collecting duct is also responsible for establishing the final concentration of the urine by controlling water reabsorption. At the beginning of the medullary collecting duct, the ultrafiltrate remains relatively dilute and the cells are relatively impermeable to water and solute (see Figure 66-8). In the setting of hypovolemia or hyperosmolarity, however, arginine vasopressin binds to V2 vasopressin receptors on the basolateral membrane of the medullary collecting duct cell. V2 receptor signaling results in aquaporin-2 channel migration from intracellular vesicles to the apical surface, and this migration increases tubular permeability to water. Because of the high interstitial osmolality, water is reabsorbed through the aquaporin channels along an osmotic gradient into the blood space; thus the urine is concentrated.[38]

Although largely established by active sodium reabsorption in the TALH, the medullary osmotic gradient is also maintained by the presence of urea gradients generated in the collecting tubule (see Figure 66-8). As tubular fluid moves down the collecting duct, the water entering the interstitium allows the urine to become more concentrated and the urea concentration to rise. The interstitium, however, becomes less hyperosmolar with the influx of water. As the distal tubular permeability to urea increases distally, urea moves from an area of high concentration (the lumen) into an area of lower urea concentration (the interstitium) via the UT-1 urea transporters.[39] The interstitium becomes more hypertonic with the influx of urea, and the concentrating mechanism of the interstitium is partially restored.

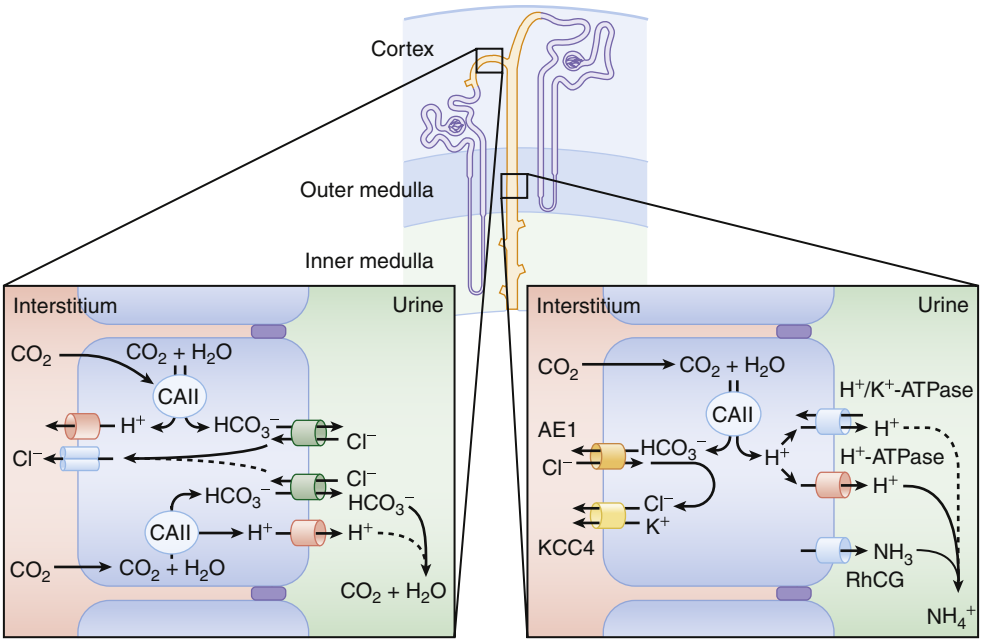

Figure 66–9. Two types of intercalated cells. Intercalated cells are expressed from the late distal convoluted tubule to the initial third of the inner medullary collecting duct *(shaded red). Left,* Cell model of non–type A intercalated cell. These cells express on the luminal membrane the chloride/bicarbonate exchanger pendrin mediating bicarbonate excretion and chloride absorption. Bicarbonate is produced from CO_2 and H_2O catalyzed by carbonic anhydrase II (CAII). Non–type A intercalated cells express also V-type H^+-adenosine triphosphatases (ATPases), which can be found on the basolateral and/or luminal membrane and may drive pendrin transport activity. Chloride is released across the basolateral membrane through chloride channels that consist of ClC-kb and Barttin subunits. *Right,* Cell model of type a intercalated cell. Bicarbonate and proton generation is catalyzed by CAII, providing protons for luminal V-type H^+-ATPases and bicarbonate for basolateral chloride/bicarbonate exchangers, including AE1. Type A intercalated cells also express basolateral KCC4 KCl-cotransporters, which may function in maintaining in low intracellular chloride. Type A intercalated cells also express on their luminal membrane H^+/K^+-ATPases that are not further discussed in this review and serve mostly for preservation of potassium during potassium deficiency. Moreover, both type A and non–type A intercalated cells participate in ammonium excretion. *(Adapted from Wagner CA, Devuyst O, Bourgeois S et al: Regulated acid-base transport in the collecting duct,* Pflugers Arch *458[1]:137-156, 2009.)*

The Interstitium

Development

The tubular interstitium remains a poorly understood region of the kidney, both from developmental and functional standpoints. From a developmental perspective, the interstitium arises from cells that surround the ureteric bud and condensing mesenchyme and are possibly of mesenchymal origin. As the metanephros develops, the primordial insterstitium differentiates to form the larger inner and outer medullary interstitium and the smaller cortical interstitium. In the inner medulla, the interstitium is involved in growth and branching of the collecting duct. In the outer medulla, the interstitium is involved in the elongation of the Loops of Henle of the corticomedullary nephrons. Although the mechanisms for both processes remain unclear, the role of the interstitium appears to be in the promotion of growth/branching and attachment, respectively occuring through the secretion of growth factors and matrix proteins.[40]

Structure and Function

The interstitium is a composite of cells, fluid, matrix proteins, and fibrils that form a network supporting the function of tubules. In the cortex, the interstitium contains two dominant components: fibroblasts and dendritic cells. Cortical interstitial fibroblasts provide both structural support of the kidney and a synthetic role in the synthesis of erythropoietin.[41] The dendritic cells appear to originate from bone marrow and function largely in an immune capacity, presenting antigen in MHC class II molecules to surveying cells of the immune system.[40,41] In the medulla, the interstitium is the site where the steep osmotic gradients are maintained. Additionally, some evidence supports a role for medullary intersitium in the secretion of vasodepressors. The role of these depressors, on either a local or systemic effect, requires further study.[40]

The interstitium is also a target of disease, with the result often being interstitial fibrosis. The development of interstitial fibrosis in response to injury is modulated by dendritic cell activity and subsequent cytokine release, as well as the synthesis of matrix by fibroblasts, most notably transforming growth factor β. A number of chronic inflammatory processes may induce chronic renal insufficiency through development of interstitial fibrosis, a phenomenon that remains an area of active study.[41]

Summary

Structural development of the human kidney support the observation that renal physiological processes change with maturation. Perfusion, tubular function, and hormonal responses are unique in young patients and affect the renal response in health and disease. Understanding the functions of the pediatric kidney at various stages of development is important in predicting therapeutic responsiveness in the critically ill child and in monitoring recovery from illness.

Chapter 67

Fluid and Electrolyte Issues in Pediatric Critical Illness

Robert E. Lynch and Ellen G. Wood

PEARLS

- Distinguishing the syndrome of inappropriate antidiuretic hormone secretion from cerebral salt wasting may be intellectually challenging, particularly when one is faced with a severely hyponatremic, obtunded, or seizing patient. Save the patient now and save the argument for later. The immediate need is the same: raise the serum osmolality 5 to 10 mOsm/L with 3% saline solution, repair any marked intravascular volume deficit, and then analyze the etiology while continuing to stabilize the patient.
- In several case reports, patients diagnosed with prolonged cerebral salt wasting resistant to resolution have stabilized when treated with fludrocortisone, a potent synthetic mineralocorticoid. The evidence is not strong, but some cases are very reminiscent of mineralocorticoid deficiency.
- Calcium infusion for hyperkalemia is indicated when electrocardiographic changes are present. In the absence of electrocardiographic changes, other choices such as glucose/insulin and inhaled β-agonist have a better risk/benefit ratio. If digoxin toxicity is a possible cause of the hyperkalemia, calcium infusion is inappropriate as initial therapy because the arrhythmogenic potential of the digoxin will be enhanced by intravenously administered calcium.
- New antitumor treatments are producing tumor lysis syndrome somewhat unexpectedly, because monoclonal antibodies, enzyme inhibitors, and tumor embolization or catheter-delivered chemotherapy can produce dramatic, sometimes disturbing results.
- Seizures in a recent recipient of a solid organ transplant should provoke a search for hypomagnesemia. Calcineurin inhibitors are everywhere and are associated with this scenario.
- Acute changes in Ca^{++} binding equilibrium or chelation are the most frequent causes of hypocalcemia in the intensive care setting.
- Acidic pH decreases calcium binding and increases ionized calcium (Ca^{++}), whereas alkalosis increases binding and reduces Ca^{++}.

Fluid and electrolyte management is a basic tool used for every critically ill patient. A grasp of the physiology and its serious disturbances is valuable both for crisis management and for recognition of the underlying processes resulting in the fluid and electrolyte abnormality. The body of fluid and electrolyte knowledge pertinent to pediatric critical care continues to evolve. Sodium homeostasis has been reconsidered in light of the influence of postoperative hypotonic intravenous fluids and mild hyponatremia. Cerebral salt wasting, perhaps more appropriately labeled cerebral-renal salt wasting (CRSW), continues to have conceptual challenges. Arginine vasopressin receptor antagonism is now available in the pharmacy, and use of 3% saline solution is increasing. Human albumin may be safe, but is it effective? What is the role for extravascular lung water measurement in pediatrics? New approaches to tumor management occasionally provoke unexpected episodes of life-threatening tumor lysis syndrome. The challenges of our patients demand our continuing attention to the changes in science and expert opinion pertinent to their care.

Fluids Update

Fluid management in the intensive care unit (ICU) is conceptually simple. One provides maintenance fluid plus any extra losses and minus any unexpected retention. Complexities arise, however, in patients with abnormal critical organ function, disturbed fluid distribution among internal spaces, and gross abnormalities of humoral function or metabolic and caloric needs. Many of these issues are addressed in basic texts or in organ-specific sources in this text or others. Here, we provide a few comments on current issues.

Albumin

Several specific concerns about the safety of the use of human albumin in critical care resulted in a large, prospective, randomized, stratified, and very convincing[1] study that demonstrated no difference in mortality or in the number of days spent in the ICU in the hospital undergoing ventilation, or undergoing dialysis between those receiving 4% albumin for volume replacement versus those receiving normal saline solution. While this study provides strong evidence for the safety of albumin administration, its use in some specific patient populations will require further studies of adequate power and design. Evidence of efficacy in patients with certain clinical problems needs to be strengthened and must be weighed against its large cost disadvantage. Developing guidelines in individual ICUs may be useful.[2] Recombinant[3] and pegylated[4] albumin preparations are under study.

Starch

Synthetic colloid solutions are less expensive than human albumin and continue to be of interest. Hydroxyethyl starch 6%, 130/0.4 appears to have an improved safety profile compared with earlier products,[5] has Food and Drug Administration approval, and may be safe in limited doses and circumstances. Significant questions about safety remain, however.[6]

Fluid Balance

In pediatric ICU (PICU) patients with significant cardiopulmonary disease, fluid administration requires judgments about volume as well as content. The evolving area of extravascular fluid volume measurement appears to have value in adults[7] and has been extended to the pediatric population.[8] Its efficacy in pediatrics remains to be determined.

Diabetic Ketoacidosis/Cerebral Edema

Various regimens for limiting hydration fluids during the first 24 hours of diabetic ketoacidosis (DKA) treatment have been utilized and seem to have had some effect in decreasing the incidence of cerebral edema. Knowledgeable observers are aware that cerebral edema has developed in some patients receiving less than the fluid limit and has not developed in many patients who exceeded the limit. Evidence now suggests that cerebral edema occurs when a significant increase in the permeability of the blood-brain barrier allows excessive transudation of intravascular fluid.[9] This degree of this change may be associated with the severity of acidosis, and the overall risk of edema would be multifactorial, consistent with clinical observations. Although not primary or universally sufficient, continuing limitation of initial hydration fluids given adequate hemodynamics is certainly a rational aspect of a DKA protocol (also see Chapter 78).[10]

Sodium

Sodium distribution is 90% extracellular. With its associated anions, it largely determines the osmotic condition of the extracellular fluid (ECF). Disturbance of ECF osmolality affects cell volume with particularly dramatic clinical significance in the central nervous system (CNS). Mild disturbance of sodium concentration has limited clinical danger but may serve as a warning of an ongoing process of greater significance. More severe hyponatremia or hypernatremia or simply a rapid change in sodium concentration may be life threatening. These disturbances may result from the gain or loss of either sodium or water. Pathological sodium retention may occur in disorders such as congestive heart failure (CHF), cirrhosis, and nephrosis without causing a significant change in ECF concentration, but the induced expansion of the ECF volume may be damaging.

Hyponatremia

Sudden, severe hyponatremia is life threatening and its management demands prompt, measured action and ongoing monitoring and therapeutic adjustment. The syndromes of inappropriate antidiuretic hormone (ADH) secretion (SIADH) and CRSW are the most common causes for severe hyponatremia, although a gross feeding or iatrogenic misadventure also should be considered. Severe hyponatremia is uncommon and usually associated with known risk factors such as pulmonary or central system disease or injury or the use of certain drugs.

Mild hyponatremia is common in patients with some renal, hepatic, or cardiac issues and occurs predictably in postoperative patients, particularly those with prolonged general anesthesia. The use of isotonic intravenous fluids postoperatively may decrease the frequency of mild hyponatremia,[11,12] but severe SIADH or CRSW may lead to profound hyponatremia despite the use of isotonic intravenous (IV) fluid.[13-15] Appropriate monitoring of electrolytes in patients at risk will allow an early and specific response to evolving hyponatremia, whether related to water retention or sodium excretion. Even knowing the underlying diagnosis in severe, acute hyponatremia may not be as important as prompt, careful osmolality management with a continuing cycle of monitoring and therapeutic adjustment.[16]

Pathophysiology and Etiology

Hyponatremia may occur in the presence of decreased, increased, or normal amounts of total body sodium.

Decreased Total Body Sodium. Loss of total body sodium results in hyponatremia if total body water is retained in relative excess of the sodium loss. Hypovolemic stimulation of ADH release may overwhelm osmotic ADH control, maintaining water retention despite hyponatremia and hypoosmolality. Sodium deficit may occur through extrarenal or renal losses. In children, extrarenal losses most often occur from vomiting and diarrhea. In critically ill patients, large extrarenal losses may result from fluid sequestration occurring with septicemia, peritonitis, pancreatitis, ileus, rhabdomyolysis, and burns. Various skin conditions including burns may cause large transcutaneous losses. Renal losses include diuretic use, osmotic diuresis, various salt-losing renal diseases, CRSW, and adrenal insufficiency.[17] If renal function is preserved, these conditions, especially with concurrent thiazide or loop diuretics, may result in hyponatremia with hypovolemia and generally are associated with hypokalemic metabolic alkalosis.[18] Concentrated urine is produced by the equilibration of fluid in the collecting tubules with the hyperosmotic medullary interstitium, which in turn is generated by sodium chloride (NaCl) reabsorption without water in the ascending limb of the loop of Henle. Thiazides act in the cortical distal tubule and do not impair the ability of ADH to increase water reabsorption in the collecting tubules and collecting duct,[18] resulting in thiazide-associated hyponatremia. Osmotic sodium and water losses occur in a child with uncontrolled hyperglycemia with glucosuria, with mannitol use, and during urea diuresis following relief of urinary tract obstruction. Sodium wasting is greater in the presence of massive ketonuria because the keto acids are anions obligating cation losses. Hyperglycemia and mannitol, in addition to inducing urinary sodium and water losses, produce osmotic water movement from the intracellular fluid (ICF) to the extracellular fluid (ECF), further lowering serum sodium. Sodium levels drop about 1.5 mEq/L for every 100 mg/dL rise in blood glucose level. Significant salt wasting may occur with several intrinsic renal diseases and may result in hyponatremia when associated with decreased access to water and sodium (Box 67-1).

In the absence of these causes, adrenal insufficiency must be considered. Generally it is associated with hyperkalemia

Box 67–1 Causes of Hyponatremia

Decreased Total Body Sodium Level

Extrarenal

Vomiting/diarrhea
Fluid sequestration
Septicemia, peritonitis, pancreatitis, ileus, burns, rhabdomyolysis
Cutaneous losses
Burns, cystic fibrosis
Ventriculostomy drainage

Renal

Cerebral-renal salt wasting
Diuretics
- Thiazides > loop agents
- Mannitol, glucose, urea

Tubulointerstitial diseases
Medullary cystic disease, obstructive uropathy, tubulointerstitial nephritis, chronic pyelonephritis, renal tubular acidosis, Kearns-Sayre syndrome
Adrenal insufficiency
Congenital adrenal hyperplasia, Addison disease

Increased Total Body Sodium Level

Congestive heart failure
Cirrhosis
Nephrotic syndrome
Advanced renal failure

Normal Total Body Sodium Level

Syndrome of inappropriate antidiuretic hormone secretion
Glucocorticoid deficiency
Hypothyroidism
Infantile water intoxication
Abusive water intoxication

and decreased urinary potassium excretion. In each of the renal salt wasting states, urinary sodium excretion is generally greater than 20 mEq/L (fractional excretion of sodium more than 1%). Cerebral salt wasting was reported in 1950, was attributed to SIADH in the 1960s and 1970s, and then was rediscovered. Despite lingering skepticism, its clinical identity continues to be supported (Table 67-1).[19-21]

Patients typically have neurologic injury with hemorrhage, infection, or a mass and often undergo surgical procedures. The development of hyponatremia may be attributed to SIADH but appears distinct in that large urine volumes contain very high sodium concentrations that lead to rapid depletion of both sodium and ECF volume. A distinct and otherwise unexplained intravascular contraction is expected for diagnosis, may cause a secondary boost in ADH release, and appears to occur in a variety of CNS disorders. Renal sodium loss is central to this diagnosis. Both atrial natriuretic peptide and brain natriuretic peptide are attractive as mediators, but niether has a proved etiological role.[22,23] Both cerebral and renal components are key, but the connecting link is unknown, thus some favor cerebral-renal (CRSW) terminology.[24] Distinguishing CRSW from complex SIADH may be difficult; however, in severe hyponatremia cases, it may be temporarily unnecessary because the initail therapy is similar.[16] Administration of enough concentrated sodium to result in a small increase in osmolality is appropriate, and support of intravascular volume is required, which may entail administering 5 to 6 mL/kg of 3% NaCl followed by isotonic or hypertonic crystalloid as necessary. The absolutely essential part of therapy is the frequent measurement and evaluation of the results of therapy with treatment adjustments as indicated.

Table 67–1 Cerebral-Renal Salt Wasting Syndrome

Trigger	Subarachnoid hemorrhage or other acute intracranial injury or illness
Onset	Usually a few days after the injury
Signs	Falling serum Na^+, high urine output, high urine Na^+
Course	Without treatment, it proceeds to intravascular volume depletion, hypoperfusion, and hypotension
Treatment	Replace salt and water loss; restoring serum Na^+ may require 3% NaCl, furosemide, rarely fludrocortisone
Resolution	Days to weeks
Differential diagnosis of SIADH, adrenal insufficiency, osmotic diuresis	

Increased Total Body Sodium. Hyponatremia occurs when the increase in total body water exceeds the sodium retention. Four clinical situations are commonly seen: congestive heart failure, cirrhosis, nephrotic syndrome, and advanced renal failure. In all four conditions, hyponatremia tends to be mild, asymptomatic, and nonprogressive. These patients come to ICUs primarily for care of the other aspects of their chronic conditions.

Congestive Heart Failure

Hyponatremia in heart failure is associated with a worse prognosis.[25,26] In a low cardiac output animal model, renal sodium excretion is decreased primarily from the associated decrease in "effective" blood volume.[27] Stimulation of aortic and carotid vasoreceptors and right and left heart volume receptors may result in sodium retention through increased sympathetic activity and stimulation of the renin-angiotensin-aldosterone axis, producing increased renal vascular resistance, decreased glomerular filtration rate (GFR), and resultant decreased urinary sodium excretion. In addition, decreased aldosterone degradation and altered levels of other vasoactive and nonvasoactive substances result in the primary increased tubular sodium reabsorption. Impaired water excretion occurs from both nonosmotic ADH release and decreased distal renal tubular delivery of fluid.[11]

Cirrhosis

Early in cirrhosis, increased intrahepatic pressure may initiate renal sodium retention before ascites formation. Later, peripheral vasodilation mediated with nitric oxide, multiple arteriovenous fistulae, and a decrease in the effective blood volume occur. These decompensated patients have higher levels of renin, aldosterone, vasopressin, and norepinephrine than do compensated patients with cirrhosis.[28]

Nephrotic Syndrome

Humoral factors involved in patients with decreased central volume appear to be similar to decompensated patients with cirrhosis. The cause of hyponatremia in patients reported to have normal central volume status is unclear.

Renal Failure

As a diseased kidney loses nephrons, the remaining nephrons exhibit a dramatically elevated fractional sodium excretion in efforts to maintain sodium balance. Edema develops when larger quantities of sodium are ingested than can be excreted. The ability to excrete water is also impaired, primarily because of the progressive decrease in GFR. Hyponatremia occurs when water intake exceeds insensible losses plus the maximum volume that can be excreted.

Normal Total Body Sodium

Hyponatremia with no evidence of hypovolemia or edema in the pediatric population is almost exclusively associated with SIADH. Renal concentrating and diluting ability ultimately depends on the presence or absence of ADH to modulate water permeability in the collecting duct. Osmoreceptors for ADH reside in the anterior hypothalamus, responding to changes of as little as 1% in plasma osmolality. The nonosmotic stimuli that induce release are generally associated with changes in autonomic neural tone such as those that occur with physical pain, emotional stress, hypoxia, cardiac failure, adrenal insufficiency, and volume depletion. When stimuli for ADH release are competitive, the volume-sensitive pathway appears to rule. Vasopressin synthesized in the hypothalamus is transported in neurosecretory granules to the axonal bulbs in the median eminence and posterior pituitary gland and is released by exocytosis. After release, binding to V2 receptors occurs at the basolateral membrane of the collecting duct, increasing cyclic adenosine 3′, 5′-monophosphate formation, facilitating phosphorylation of aquaporin-2. Incorporation of aquaporin-2–containing vesicles into the apical (luminal) membrane increases cell permeability to reabsorptive water movement.[29]

Several categories of clinical diseases have been associated with SIADH, including CNS and pulmonary disorders, malignancies, glucocorticoid deficiency, hypothyroidism, and adverse effects of numerous drugs (Box 67-2).[30]

Postoperative pediatric ICU patients frequently have increased ADH release and are at risk of (usually mild) hyponatremia.[31,32] The appropriate use of isotonic intravenous fluid in these patients will decrease the incidence of mild hyponatremia. For patients with severe SIADH or CRSW, the use of isotonic fluids alone may not be adequate to prevent life-threatening complications. Monitoring sodium and avoiding large amounts of hypotonic fluid is mandatory. SIADH should be considered when hyponatremia occurs in the absence of hypovolemia, edema, endocrine dysfunction, renal failure, or suspect drugs. Urine osmolality is inappropriately high compared with plasma osmolality. A urine osmolality of 200 to 250 mOsm does not rule out the diagnosis because a decrease of 4 to 5 mEq/L below normal in serum sodium should maximally inhibit ADH secretion with a resultant urine osmolality of less than 100 mOsm. The urinary sodium level is generally more than 20 mEq/L; however, it can be much less than 20 mEq/L in patients who are provided a low sodium intake or in whom some degree of volume depletion occurs concurrently.[33] Urinary sodium may be generous, but the overall amount of sodium excretion should not grossly exceed intake without provoking consideration of a salt-wasting syndrome.

Box 67–2 Conditions Associated with SIADH

Central Nervous System
Meningitis
Encephalitis
Head trauma
Brain tumors
Brain abscess
Guillain-Barré syndrome
Hypoxia (neonatal)
Hydrocephalus
Rocky Mountain spotted fever
Vincristine
Salicylates
Cerebral thrombosis or hemorrhage
Subarachnoid or subdural hemorrhage
Acute psychosis
Peripheral neuropathy
Multiple sclerosis
Hypopituitarism

Pulmonary
Pneumonia
Positive-pressure ventilation
Asthma
Pneumothorax

Tumors
Lymphoma, thymoma
Ewing sarcoma, mesothelioma
Carcinoma (bronchogenic, duodenum pancreas, ureter, bladder, prostate)

Drugs
Antidiuretic hormone analogs
Chlorpropamide
Vincristine
Cyclophosphamide
Carbamazepine
Barbiturates
Colchicine
Haloperidol
Fluphenazine
Tricyclics, selective serotonin reuptake inhibitors
Clofibrate
Salicylates
Indomethacin, nonsteroidal antiinflammatory drugs
Interferon
Ecstasy (MDMA)

Miscellaneous
Infants (0–6 mo) receiving diluted feeding
Marathon runner
Postoperative, postprocedural patients

Signs and Symptoms

The severity of signs and symptoms depends on the rapidity of development. Acute decreases in sodium are associated with lethargy, apathy, and disorientation often accompanied by nausea, vomiting, and muscle cramps. No predictable correlation exists between the degree of hyponatremia and its resulting symptoms. In general, however, most patients exhibit seizures and coma with acute decreases in sodium to less than 120 mEq/L. Other signs include decreased deep tendon reflexes, pathologic reflexes, pseudobulbar palsy, and Cheyne-Stokes respiratory pattern. Signs and symptoms are related

to cellular swelling and resultant cerebral edema, which may be severe enough to result in herniation.[34] Patients in whom hyponatremia develops over several days to weeks may be symptom free or may have nonspecific symptoms of nausea, vomiting, and lethargy.

Treatment

Severe hyponatremia is associated with significant morbidity and mortality. A decrease in the serum sodium concentration would be expected to cause a shift of water from the ECF to the ICF compartment, resulting in generalized cellular edema. When this swelling occurs in the brain, which is limited by the presence of meninges and the cranium, neurologic symptoms are expected. Cerebral edema and transtentorial herniation may result. Hyponatremia developing over a more prolonged period is unlikely to cause herniation. Brain cells prevent massive swelling when gradual hyponatremia is produced by the extrusion of electrolytes and other osmolytes. Total brain amino acid content, particularly taurine, is strikingly decreased in hyponatremic rats with prolonged deficits. Brain water content is also lower in these animals. These data suggest that brain edema develops when the plasma/brain osmotic gradient reaches a critical level before these adaptive processes have been fully developed. Hyponatremia that has been present less than 4 hours can be corrected promptly. However, when adaptation of brain cells has already occurred, a rapid rise in serum sodium concentration may induce a shift of water from the ICF to the ECF compartment, resulting in brain dehydration, brain injury, and the osmotic demyelination syndrome.[35] Originally noted in the pons, both pontine and extrapontine myelinolysis has been reported in children.[36-38] Extrapontine sites have included the cerebellum, thalamus, lateral geniculate body, and hippocampus. Osmotic demyelination can occur without hyponatremia as a starting point.[38,39] Large bolus doses of hypertonic saline solution may place the patient at risk regardless of starting sodium concentration. Electrolyte fluctuations around the time of liver transplantation may account for the risk of myelinolysis noted in these patients.[40] Even rapid correction of hypernatremia is a possible cause of myelinolysis and suggests that pressure effects may be capable of causing damage to myelinated structures. Symptoms of osmotic demyelination may include obtundation, quadriplegia, pseudobulbar palsy, tremor, amnesia, seizures, and coma.[41,42] Approaches to patients with hyponatremia may vary depending on whether the hyponatremia has developed suddenly, that is, in fewer than 4 hours, in which case rapid reversal may be safe. If asymptomatic hyponatremia has developed over many hours, or has developed over a longer period (i.e., chronic hyponatremia), gradual, conservative reversal is likely to be uncomplicated. In planning treatment it is critical to determine the presence or absence of CNS symptoms or imaging suggestive of cerebral edema. Development of CNS cellular swelling and symptoms is more likely with acute hyponatremia or with severe chronic hyponatremia.[43,44] In these patients, an initial small but rapid correction of serum sodium, about 5 mEq/L, should stabilize or begin to reverse cerebral swelling and avoid impending herniation. Subsequently, further correction of the hyponatremia should occur more slowly.

A dose of 3% saline solution at 5 to 6 mL/kg would be expected to initially raise the serum sodium approximately 5 mEq/L. The subsequent correction rate for patients with acute hyponatremia with CNS symptoms or for any patient with chronic hyponatremia should raise the serum sodium no more than 0.5 mEq/L/h. For patients with acute hyponatremia but no CNS symptoms, rates of 0.7 to 1 mEq/L/h have been reported without patient morbidity or mortality. In many patients, a regimen of hypertonic 3% saline solution at 1 to 2 mL/kg/h plus periodic administration of a loop diuretic results in an appropriate correction for those patients for whom "rapid" correction is safe. Further correction may require isotonic fluids or a mixture of isotonic and hypertonic fluids, particularly in patients with CRSW. In resistant, severe CRSW, mineralocorticoid treatment has been helpful in several reports.[45,46] Other protocol approaches are available.[47] CNS symptoms that develop during correction suggest osmotic demyelination and have occurred most frequently in patients or experimental animals that are euvolemic rather than hypovolemic. At least three patients have been reported who had symptoms of osmotic demyelination and whose course was subsequently reversed; their serum sodium level was decreased to its nadir followed by a slower rate of correction resulting in recovery without neurologic sequelae.[48-50] Conivaptan, an ADH V1 and V2 receptor antagonist, is in use as an IV agent in adults for treatment of hyponatremia, particularly in fluid-retaining states.[51,52] This receptor blocker group[53] increases urine volume and reduces urine osmolality. Pediatric usage has been reported,[54] but further study of kinetics, safety, and efficacy will be needed to clarify the clinical role in pediatrics. In the patient in whom less severe hyponatremia occurs (i.e., serum sodium 125 to 130 mEq/L), slow correction through water restriction, occasionally with the use of oral sodium supplements, is all that is required for normalization to occur. In the patient with hypovolemia, volume status clearly must be corrected in addition to the hyponatremia.

Hypernatremia

As with hyponatremia, hypernatremia can develop with low, normal, or high levels of total body sodium. History and weights are particularly important in evaluating the hydration state of patients with hypernatremia because a shift in the ICF to the ECF tends to obscure the physical findings of dehydration. Accurate assessment of total body sodium and water aids considerably in planning management, although the most important management principle is the frequent monitoring of the patient's progress with treatment adjustments as needed.

Low Total Body Sodium Level

Patients with a low total body sodium level have a loss of water in relative excess of sodium losses. Because the ECF space is hyperosmolar, water movement from the ICF occurs with resulting ICF dehydration. Therefore the ECF space is somewhat preserved until extreme degree of hypovolemia has occurred. Losses of sodium and water may be extrarenal or renal (Box 67-3).

In the pediatric patient, extrarenal causes are commonly seen from vomiting and diarrhea, although hospital-acquired hypernatremia from insufficient free water administration is a major concern.[55,56] Excessive sweating with inadequate replacement also may occur. Renal causes of hypernatremia include osmotic diuresis from mannitol, hyperglycemia, or increased urea excretion. Urine is either hypotonic or isotonic,

Box 67–3 Causes of Hypernatremia

Low Total Body Sodium

Extrarenal Losses
Vomiting/diarrhea
Sweating
70% sorbitol

Renal Losses

Chronic renal failure
Renal tubulointerstitial diseases
Hypercalcemia
K^+ depletion
Drugs
- Alcohol, lithium, diuretics, amphotericin B, methoxyflurane, demeclocycline

Sickle cell disease
Dietary abnormalities
- Primary polydipsia, decreased sodium chloride intake, severe protein restriction or depletion

and urine sodium is more than 20 mEq/L. Infants are particularly susceptible to hypernatremic dehydration because their surface area/weight ratio is high and their relative renal immaturity results in greater water losses for excretion of a solute load compared with older children and adults.[57] Insufficient maternal lactation places small infants at risk of hypernatremic dehydration. Infants with prolonged hospitalization because of bronchopulmonary dysplasia seem particularly susceptible to hypernatremic dehydration with intercurrent gastrointestinal illnesses.

Normal Total Body Sodium Level

Loss of water occurs without excessive sodium losses in some conditions. Extrarenal causes include increased respiratory losses as may occur with tachypnea, hyperventilation, or mechanical ventilation with inadequate humidification and increased skin losses associated with fever, burns, extreme prematurity, or use of phototherapy or radiant warmers in the neonate without adequate water replacement. Renal losses result from acquired or congenital diabetes insipidus (DI), either central or nephrogenic. Acquired forms of DI are more commonly seen by the intensivist. Major insults resulting in central DI include head trauma, tumors, infections, hypoxic injury, neurosurgical procedures, and nontraumatic brain death. Often, in experimental animals and in humans, three stages occur: (1) an initial polyuric phase (hours to several days); (2) a period of antidiuresis probably due to ADH release from injured axons (hours to days); and (3) a second period of DI that may or may not resolve.[58,59] Sudden onset of polyuria is characteristic, as is polydipsia (in the conscious patient). In the critically ill patient, lack of access to increased water may result in life-threatening hypernatremia.[60] Patients with the rare congenital nephrogenic DI may have repeated bouts of hypernatremic dehydration, resulting from x-linked alteration of the vasopressin receptor V2 or the autosomal recessive changes in the aquaporin II water channel physiologically regulated by ADH.[61] Acquired forms are much more common, and manifestations are less severe. Causes of DI are shown in Box 67-4.

Increased Total Body Sodium Level

Hypernatremia with an increased total body sodium level is most often an iatrogenic problem. In the critical care unit, administration of hypertonic solutions of sodium bicarbonate during resuscitation efforts or as therapy for intractable metabolic acidosis is often responsible for this condition. Particularly at risk is the patient after cardiac arrest, when renal failure from hypoxic injury may ensue as well. Other causes include excessive hypertonic NaCl administration for treatment of hyponatremia, near drowning in salt water, ingestion by infants of improperly diluted formula, inadvertent intravascular infusion of hypertonic saline solution during a therapeutic abortion, and dialysis against a high sodium concentration. Normonatremic patients with massive edema who undergo a forced diuresis frequently become mildly

hypernatremic because the induced urine may be hypotonic and water loss exceeds sodium loss.

Hypernatremia is purposely induced in patients with head trauma as a form of osmotherapy for control of intracranial hypertension (also see Chapter 59).[62,63] Such patients have tolerated a serum sodium of 175 mEq/L when carefully managed. When the ECF osmolality of these patients is manipulated, the risks involved with rapid changes in either direction must be kept in mind.

Signs and Symptoms

Clinical manifestations of hypernatremia relate predominantly to the CNS. Marked irritability, a high-pitched cry, a decrease in sensorium varying from lethargy to coma, normal or increased muscle tone, and frank seizure activity may occur in children with development of severe hypernatremia over 48 hours or more. Hyperglycemia and hypocalcemia also may occur. In infants with acute hypernatremia, vomiting, fever, respiratory distress, spasticity, tonic-clonic seizure activity, and coma are common.[64] Death from respiratory failure occurred in experimental animals when serum osmolality reached about 430 mOsm/kg.[64] Mortality in children has ranged from 10% to about 45% with chronic and acute hypernatremia, respectively. Morbidity in survivors also may be high.

Anatomic changes seen with the hyperosmolar state include loss of volume of brain cells with resultant tearing of cerebral vessels, capillary and venous congestion, subcortical or subarachnoid bleeding, and venous sinus thrombosis. During the first 4 hours of experimental acute hypernatremia, brain water significantly decreases while the concentration of solutes (electrolytes and glucose) increases. A small portion of increased osmolality is not accounted for by the increase in electrolytes and glucose, termed idiogenic osmoles. By 48 hours, however, brain water has returned to normal with idiogenic osmoles (amino acids, polyhydric alcohols, and urea and trimethylamines) accounting for about 60% of the increased osmoles.[65] The central demyelination syndrome has been seen in patients with hypernatremia. It remains unclear as to whether it results from a rapid rise in serum osmolality or from some other aspect of the clinical course.

Treatment

Whenever possible, therapy of hypernatremia should address correction of the underlying disease process as a primary goal. Correction of dehydration with slow hypernatremia correction is the target. When sodium exceeds 165 mEq/L, isotonic fluid and colloid may be used for correction of shock or circulatory collapse and initial reversal of hypernatremia. Some data are available regarding the ideal rate of correction. Numerous fatal cases of cerebral edema have occurred with correction over a 24-hour period, leading to recommendations for correction over no less than a 48-hour period[66,67] and general agreement that plasma osmolality should not be decreased more rapidly than 2 mOsm/hr (1 mEq/h sodium). Patients with serum sodium levels greater than 165 mEq/L for more than 48 hours deserve particular care, and a correction rate of no more than 1 mOsm/h may be appropriate. Thus corrections from extreme hypernatremia may take several days. This slower rate of correction appears to allow time for dissipation of idiogenic osmoles without development of cerebral edema. Estimated deficits, ongoing maintenance requirements, and additional excessive losses must be accounted for in calculations of amount of fluid replacement. Although it is not frequently required, calculation of tonicity balance may give an accurate analysis of the disturbance.

Central DI is a likely cause of hypernatremia in an ICU patient with high urine volume and low urine osmolality, particularly in patients who have head trauma, cerebral edema, or have undergone a recent intracranial operation. In these patients, a trial of vasopressin is in order. Either aqueous vasopressin given subcutaneously or intravenously (0.5 to 10 mU/kg/h) or 1-deamino-8-D-arginine vasopressin (DDAVP) may be used. An increase in urine osmolality to values exceeding that in serum suggests the diagnosis of central DI. Careful adjustments must be made in fluid administration to avoid iatrogenic hyponatremia. DDAVP is generally begun in a dosage ranging from 0.05 to 0.1 mL by nasal spray once or twice daily.

In patients with an increased total body sodium level (and often hypervolemia), the goal is sodium removal. In patients with intact renal function, sodium removal may be accomplished with diuretics and a decrease in sodium administration. If renal failure is present, dialysis may be required.

Potassium

Hypokalemia is common among ICU patients receiving diuretics and β-agonists. Hypokalemic arrhythmias can be dangerous but are infrequently fatal. Severe hyperkalemia is much less frequent but extremely life threatening. Ninety-eight percent of the potassium total body stores (about 50 mEq/kg) are intracellular. The distribution of potassium between intracellular and extracellular compartments is critical and is maintained by hormonal and nonhormonal factors.

The transcellular distribution of potassium establishes the resting membrane potential of cells, including the myocardium. Factors involved in total body distribution include acid-base status, insulin, catecholamines, magnesium, and aldosterone.[68,69] Acidemia tends to increase the serum potassium, and alkalemia lowers it. The type of acid-base disturbance (metabolic or respiratory), the duration of the disturbance, and the nature of the anion accompanying the hydrogen ion in metabolic acidosis, however, are important in determining what effect a particular acid-base disorder may have on potassium concentration.[70] The greatest effect occurs with mineral acids, where cellular permeability to accompanying anions is low so that hydrogen ions enter cells alone. In this case, potassium must move out of the cells to maintain electrical neutrality. In metabolic acidosis caused by organic acids such as lactate and β-hydroxybutyrate, however, hydrogen ions presumably enter cells with their accompanying anions so that cation exchange with potassium is not required.

Hyperkalemia associated with DKA may reflect the effects of hyperosmolality and decreased circulating insulin rather than the acidemia itself.[71,72] Epinephrine initially causes serum potassium to rise, reflecting release from the liver, and then fall, as potassium moves into cells.[73] This effect is abolished by β-adrenergic blocking drugs. In rats with experimentally induced insulin deficiency, both epinephrine and the peripheral sympathetic nervous system have been shown to regulate cell potassium uptake.[74] Change in intracellular magnesium may affect the sodium-potassium adenosine triphosphatase (ATPase) pump and alter the transcellular distribution. All

of these mechanisms, however, are generally representative of fine-tuning in potassium homeostasis. Ultimately, potassium balance is regulated through excretion by the kidney and to a lesser extent the gastrointestinal (GI) tract. Conditions associated with massive cell lysis require management of the sudden shift of intracellular potassium into the ECF, which occurs frequently in the presence of compromised renal function.

Most of the filtered potassium is absorbed before the distal nephron in normal kidneys.[75] The potassium excreted in the urine then is mainly due to secretion in the distal convoluted tubule and cortical collecting duct. As with sodium, the kidney's capacity to vary potassium excretion is profound, ranging from a low of approximately 5 mEq/L to amounts exceeding 100 mEq/L of urine. Factors influencing renal potassium excretion include mineralocorticoid and glucocorticoid hormones, acid-base balance, anion effects, tubular fluid flow rate, sodium intake, potassium intake, ICF and plasma potassium concentrations, and diuretics.[75] Aldosterone is a major kaliuretic hormone. Metabolic acidosis decreases and metabolic alkalosis increases intracellular potassium activity in cells of the distal tubule, causing enhanced potassium secretion during alkalosis and reabsorption during acidosis. Fluid delivery to the distal tubule probably enhances potassium secretion by two mechanisms: (1) the faster fluid moves past the secretory site, and a greater amount of potassium can be secreted; and (2) because tubular fluid potassium concentration decreases as flow rate increases, a favorable gradient for potassium movement is maintained at high flow rates.[76]

Hypokalemia

Causes of Hypokalemia

Hypokalemia Without Potassium Deficit. The detection of a low serum potassium level may reflect a true deficit in total body stores or an apparent deficit from the shift of this ion from the ECF to the ICF pool. A shift to the ICF pool may occur in patients with alkalemia, exogenous administration and likely endogenous release of β-adrenergic agonists, familial hypokalemic periodic paralysis,[77] barium poisoning,[78] and excess insulin. In the case of alkalemia, potassium moves into the cell in exchange for H^+ in an attempt to maintain extracellular pH. The pediatric patient with alkalemia also may have a true potassium deficit because of decreased potassium intake or increased losses. Numerous studies have confirmed an acute decrease in serum potassium after administration of β_2 agonists, including epinephrine and albuterol, presumably from cellular influx of potassium into skeletal muscle cells. Endogenous levels of epinephrine equal to or greater than levels obtained by exogenous administration have been reported in adults with acute myocardial infarction and in children after near drowning.[79]

Periodic paralysis is a rare autosomal dominant disorder presenting with intermittent episodes of profound muscle weakness associated with a sudden fall in serum potassium concentration precipitated by a high-carbohydrate/low-potassium diet, exercise, infection, stress, or alcohol ingestion.[77,80] Barium poisoning can produce hypokalemic paralysis and weakness probably by competitive blockade of inward rectifying potassium channels. Insulin produces potassium shifts into the liver in association with glycogen formation and into muscle cells.

Hypokalemia with Potassium Deficit. A deficit in total body potassium may occur from decreased intake, from renal losses, or from GI losses. Poor intake coupled with increased GI or renal losses is common. Any history of geophagia in the toddler should be sought because ingested clay binds potassium in the GI tract.[81]

Renal Losses. Major categories that may be seen in the ICU setting include diuretic use, osmotic diuresis, use of various other drugs, renal tubular acidosis, hyperaldosteronism, magnesium deficiency, and recovery from acute renal failure (ARF). Osmotic diuresis from glucosuria is the primary cause of renal potassium wasting in patients with prolonged DKA that can present with ventricular arrhythmia. Primary aldosteronism, congenital adrenal hyperplasia, adrenal adenoma, and familial idiopathic hyperaldosteronism are rare in children and even rarer in the pediatric ICU setting. Secondary hyperaldosteronism is common, however, either from volume depletion or from CHF, cirrhosis, or nephrotic syndrome. Patients with the latter conditions, however, rarely have severe hypokalemia unless they are additionally treated with diuretics. The infant with Bartter's syndrome may initially come to the ICU because of multiple metabolic derangements including hypokalemia, metabolic alkalosis, and often hypomagnesemia and hyperuricemia. Other findings include weakness, polyuria, and failure to thrive, with elevated renin and aldosterone levels in the absence of hypertension.[82] Other conditions associated with elevated renin secretion, secondary hyperaldosteronism, and hypokalemia include renal artery stenosis, malignant hypertension, renin-producing tumor, or Wilms' tumor. Additional mechanisms include secondary hyperaldosteronism and increased distal tubular fluid delivery. The severity of hypokalemia is often masked by the shift of potassium from the ICF to ECF space related to insulin deficiency, metabolic acidosis, and hypertonicity.

If a brisk diuresis is induced by loop, thiazide, or osmotic diuretics, kaliuresis may result, and this may lead to acute hypokalemia. Use of combinations of these diuretics, in particular loop diuretics and metolazone, may accentuate potassium losses. Each agent leads to increased distal delivery of tubular fluid. Other drugs that induce excessive renal losses include amphotericin B (kaliuresis with reduced renal function and tubular injury); aminoglycosides, particularly gentamicin; and high-dose penicillin and carbenicillin, which produce an osmotic load in addition to acting as nonreabsorbable anions.[83] Renal tubular acidosis or hypomagnesemia may cause renal potassium wasting.[84]

Gastrointestinal Losses. Upper GI losses from vomiting or from nasogastric (NG) suction are frequently associated with hypokalemia, although they are rarely responsible for the total depletion seen. The gastric concentration of potassium ranges from 5 to 10 mEq/L.[85] However, concomitant volume depletion and metabolic alkalosis associated with NaCl and hydrogen ion losses often result in secondary aldosteronism and an increased filtered load of bicarbonate with resultant renal potassium losses. Diarrhea, regardless of cause, may result in large potassium losses, the amount lost being related to the volume of fluid lost. Other GI causes are listed in Box 67-5.

Signs and Symptoms

For the intensivist, cardiovascular and neuromuscular effects of potassium deficiency are of particular concern, although metabolic, hormonal, and renal effects also may occur.[68]

Box 67–5 Causes of Hypokalemia

Hypokalemia Without Potassium Deficit

Alkalosis
β-Agonist, exogenous or endogenous
Familial periodic paralysis
Thyrotoxic periodic paralysis
Barium poisoning
Excessive insulin

Hypokalemia with Potassium Deficit

Decrease intake
Renal losses
- Hyperaldosteronism
  - Primary or secondary
  - Barter syndrome
  - Liddle syndrome
  - Laxative and/or diuretic abuse
  - Licorice ingestion
- Osmotic agents
- Drugs
  - Caffeine
  - Diuretics
  - Amphotericin B
  - Aminoglycosides
  - High-dose penicillin, carbenicillin
- Miscellaneous
  - Hypomagnesemia
  - Renal tubular acidosis
  - Toluene toxicity

Extrarenal loses
- Gastrointestinal
  - Vomiting, nasogastric suction
  - Diarrhea
  - Laxative abuse
  - Ureteral sigmoidostomy
  - Obstructed or long ileal loop

Electrocardiographic (ECG) changes include T-wave flattening or inversion, ST depression, and the appearance of a U wave. Atrial and ventricular arrhythmias and conduction disturbances may occur. Resting membrane potential is increased, as are both the duration of the action potential and the refractory period. The decreased conductivity predisposes a patient to arrhythmias. Finally, threshold potential and automaticity are increased, and this increase makes automatic arrhythmias possible.[86]

Hypokalemia diminishes skeletal muscular excitability, which can present as a dynamic ileus or a skeletal muscle weakness resembling Guillain-Barré syndrome. Eventually it can affect the trunk and upper extremities, becoming severe enough to result in quadriplegia and respiratory failure.[81,87-89] Rhabdomyolysis also has been reported from decreased muscle blood flow, decreased glycogen stores, and altered sodium/potassium (Na/K)-ATPase and membrane potential.[90,91] Autonomic insufficiency may also occur, generally manifested as orthostatic hypotension. In patients with severe liver disease, hypokalemia may precipitate or exacerbate encephalopathy. Glucose intolerance in the presence of primary hyperaldosteronism and in certain patients receiving thiazide diuretics has been corrected with potassium repletion. Renal effects of hypokalemia include polyuria and polydipsia, renal structural changes with cellular vacuolization in the proximal tubule, and occasional interstitial fibrosis.

Treatment

Because of the wide spectrum of abnormalities resulting from marked potassium depletion, judicious correction is generally in order. Most PICU patients with cardiovascular disease are given NG or IV potassium supplements at serum levels of 3.0 to 3.5 mEq/L. In the patient without life-threatening complications, the oral route is generally preferred for treatment, if possible, because this route is rarely associated with "overshoot" hyperkalemia if normal renal function exists. Oral dosage is frequently 1 mEq/kg up to a maximum of 20 mEq per dose, repeated if necessary. If, however, depletion is associated with digoxin use or with life-threatening complications, including cardiac arrhythmias, rhabdomyolysis, extreme weakness with quadriplegia, or respiratory distress, then urgent IV therapy is generally needed. Recommendations for IV dosage in the pediatric patient have ranged from infusions of 0.25 mEq/kg/h to those as high as 1 to 2 mEq/kg/h in the face of severe hypokalemia associated with DKA, arrhythmias, or quadriparesis and respiratory insufficiency. Ventricular tachycardia clearly associated with hypokalemia may initially require more rapid administration. Continuous ECG monitoring is essential, along with frequent physical examination and determination of serum potassium levels to avoid hyperkalemic complications. Highly concentrated potassium IV solutions should only be administered centrally. Preoperative potassium repletion of patients with cardiac disease who are treated with diuretics may be beneficial,[86] although some persons would argue against routine screening.[92] Patients who receive albuterol continuously are frequently mildly hypokalemic, but they rarely warrant potassium chloride replacement.

The potential for catastrophic drug error in replacing potassium is real. In most PICUs, patients with cardiovascular disease are given NG or IV supplements at serum levels of 3.0 to 3.5 mEq/L. Steps to decrease the chance of error include satellite pharmacy dosing, use of a mandatory drug request form,[93] NG replacement when possible, use of a single solution concentration for all doses, and small aliquot solution containers. Continuing education regarding this risk for the pediatric ICU staff is essential.[94]

Hyperkalemia

Causes of Hyperkalemia

Hyperkalemia may result from artifactual elevation; from redistribution of potassium from the ICF to the ECF space; or from increased intake, decreased losses, or both. Causes of hyperkalemia are listed in Box 67-6.

Artifactual. Tight, prolonged tourniquet use produces spurious potassium elevation due to potassium release from ischemic muscle.[95] Even more common is hemolysis of red cells with potassium release associated with capillary sampling or aspiration or delivery under pressure through a small needle. Hemolysis may be noted by the laboratory, but artifactual normality or actual elevation should always be considered. Less commonly, in vitro release of potassium occurs from white blood cells (>100,000/μL) or platelets (>1,000,000/μL) and may result in increased levels.[96,97]

Box 67–6 Causes of Hyperkalemia

Artifactual

Ischemic potassium loss from tourniquet use
In vivo red cell injury
In vitro hemolysis, profound leukocytosis, thrombocytosis

Redistribution

Change in pH
Hypertonicity
Drugs
- Digoxin toxicity, β-blockers (β_2-inhibitory activity), succinylcholine, arginine, or lysine hydrochloride, chemotherapeutic agents, sodium fluoride, epsilon-amino caproic acid

True Potassium Excess

Increased Load

Exogenous
- IV infusion, PO supplements, potassium-containing salt substitutes, potassium penicillin, blood transfusion

Endogenous
- Tissue necrosis
  - Burns, trauma, rhabdomyolysis, intravascular coagulation
- Gastrointestinal bleeding
- Tumor cell lysis
- Reabsorption of hematoma

Decreased Excretion

Acute renal failure
Chronic renal failure
Mineralocorticoid deficiency
Addison disease
Adrenal biosynthetic defects
- 21-Hydroxylase deficiency
- Desmolase deficiency
- 3- -OH-dehydrogenase deficiency

Aldosterone deficiency
Diabetes mellitus
Renal tubulointerstitial disease
Drugs
- Indomethacin, converting enzyme inhibitors, heparin, cyclosporine, tacrolimus, trimethoprim, pentamidine, amphotericin B

Renal tubular secretory deficit
- Pseudohypoaldosteronism

Sickle cell disease
Systemic lupus erythematosus
Renal allograft
Urinary tract obstruction
Very low birth weight infants

Inhibition of Tubular Secretion

Drugs
- Spironolactone, triamterene, amiloride

Redistribution. In general, when extracellular pH falls, potassium exits from cells; the result is an increase in serum potassium levels. As mentioned earlier, metabolic acidosis from mineral acids has a more pronounced effect than that of organic acids. Plasma potassium does not change in parallel with the pH change; rather, it gradually rises even as extracellular pH returns to normal after acute acid loading. Respiratory acidosis does not usually cause a marked change in potassium concentration.[98]

Hypertonicity per se produces a shift of potassium from ICF to ECF. Studies of anephric animals show potassium increasing by 0.1 to 0.6 mEq/L for each increment of 10 mOsm/kg H_2O in tonicity. Hypertonicity causes cellular dehydration and therefore an increase in ICF potassium that favors increased passive diffusion out of cells. A very small percentage shift of intracellular potassium delivers a significant potassium load to the ECF. In the hyperkalemic patient in the ICU who has acute oliguria, mannitol should not be used for diuresis because further potassium elevation may result. In the patient with hyperglycemia, hypertonicity is likely only one of several mechanisms resulting in elevated serum levels.

Several commonly used drugs result in net movement of potassium from ICF to ECF. Digoxin inhibits the net uptake of potassium by cells by inhibiting Na/K-ATPase, with hyperkalemia commonly occurring in severe digitalis poisoning.[99] Other drugs include β_2 antagonists and the muscle relaxant succinylcholine. This drug induces a prolonged dose-related increase in the ionic permeability of muscle, with subsequent efflux of potassium from muscle cells. Normal serum potassium concentration rises about 0.5 mEq/L. Succinylcholine should be avoided in patients with burns, muscle trauma, spinal injuries, certain neuromuscular diseases, near drowning, and closed head trauma, because upregulated and new forms of acetylcholine receptors may respond with life-threatening hyperkalemia.[100] New examples of patients at risk will continue to be reported.[101,102] Hyperkalemia may result in nonsuspect patients via rhabdomyolysis or malignant hyperthermia following administration of succinylcholine.[103] Familial hyperkalemic periodic paralysis appears to be related to potassium redistribution related to changes in ion channel function.[77,104] Rebound hyperkalemia may be life threatening after coma-inducing barbiturate is stopped[105] or surgical insulinoma removal.[106]

Increased Potassium Load. Hyperkalemia due to an increased potassium load is unusual as long as renal function is normal. Transient elevations may be seen with inappropriate IV infusion, delivery of large volumes of cold-stored blood,[107] oral potassium supplements, salt substitutes containing potassium, or large doses of potassium penicillin.[108] Strict measures to guard against accidental potassium overdoses are mandatory. Large endogenous loads of potassium are more likely in the patient who is in the ICU. The release of cellular potassium associated with tissue necrosis from burns, trauma, rhabdomyolysis including that from spider bites[109] or the propofol syndrome,[110] massive intravascular coagulopathy, massive hemolysis, or GI bleeding may lead to hyperkalemia.

Tumor lysis syndrome (TLS) is classically associated with drug or radiation treatment of sensitive lymphoid malignancies and results in hyperkalemia often accompanied by hypocalcemia, hyperphosphatemia, acidosis, and compromised renal function (also see Chapter 81). Many fatalities have been reported. The list of TLS-producing events or therapies has been increasing and now must include transcatheter chemical and embolic tumor necrosis,[111,112] monoclonal antibody treatment with rituximab,[113] and newer enzyme-inhibiting agents bortezomib,[114] imatinib,[115,116] and sorafenib.[117] It also seems possible that endogenous corticoids associated with surgical stress[118] or dexamethasone given for potential airway edema could cause severe TLS.

Decreased Excretion. Hyperkalemia in patients with ARF results from a profound reduction in the GFR, decreased distal water and solute delivery limiting Na/K exchange,

and an insufficient time for renal and extrarenal adaptive mechanisms to develop. These conditions often are associated with increased catabolism and metabolic acidosis. Nondiabetic chronic renal failure is rarely associated with hyperkalemia until the GFR falls below 5% to 10% of normal. Progressive, gradual impairment induces excretion of more potassium per the remaining nephron.[119] Other adaptations include increased stool loss and more rapid redistribution of potassium into cells.[120] Decreased mineralocorticoid activity regardless of origin causes hyperkalemia. Addison's disease, although rare in the PICU, may present in crisis with life-threatening hyperkalemia, as may adrenogenital syndromes. Hyporeninemic hypoaldosteronism is commonly seen in adults but may become more common in children; the classic example is the patient with diabetes mellitus and mild to moderate renal insufficiency.[121] Aldosterone production may be suppressed and potassium elevated by heparin, angiotensin-converting enzyme inhibitors, prostaglandin inhibitors, tacrolimus, or cyclosporin.[108]

Renal tubular secretory defects occur in patients with pseudohypoaldosteronism presenting in children with failure to thrive, metabolic acidosis, hyperkalemia, and elevated aldosterone levels, as well as in rare patients with sickle cell disease, systemic lupus erythematosus, urinary tract obstruction, and renal allografts. Premature infants without renal failure, especially those weighing less than 1000 g, may demonstrate life-threatening hyperkalemia and increased sodium excretion in association with decreased potassium excretion.[122] Tubular immaturity with unresponsiveness to aldosterone has been postulated.[123] Finally, potassium-sparing diuretics, trimethoprim, and pentamidine may produce hyperkalemia, particularly when used in combination with other drugs that decrease potassium excretion or in patients with renal insufficiency.[108]

Manifestations of Hyperkalemia

Life-threatening complications are most likely to result from the cardiac changes caused by hyperkalemia. ECG signs include tall, peaked T waves in the precordial leads, followed by a decrease in amplitude of the R wave, bradycardia, widened QRS complexes, prolonged PR intervals, and decreased amplitude and disappearance of the P wave. Finally, the classic sine wave of hyperkalemia from the blending of the QRS complex with the P wave may appear. Recognizing that ventricular arrhythmias or cardiac arrest may occur at any point in this progression and that progression may occur over a matter of minutes is extremely important.

Treatment

Treatment of hyperkalemia depends on the level of plasma potassium and the state of neuromuscular irritability.[124] If the potassium is less than 6.5 mEq/L without ECG changes, discontinuation of exogenous potassium and drugs that decrease its excretion with close follow-up of potassium levels may be all that is necessary. In the patient with renal compromise, extra potassium may be eliminated with use of the potassium-binding agent sodium polystyrene sulfonate (Kayexalate, resonium) (oral, NG, or rectal doses of 1 to 2 g/kg in a sorbitol or dextrose solution). When administered rectally, sorbitol may not be necessary, and it certainly should not be given rectally in a concentration greater than 20%. Highly concentrated sorbitol may cause severe proctitis and colonic injury. Increasing reports of colonic injury, particularly in hemodynamically compromised or premature patients, suggests that caution be exercised in using this preparation. However, when it is needed, having the pharmacy stock a premixed 10% to 20% suspension of sodium polystyrene sulfonate and sorbitol allows either oral or rectal administration on short notice. If the potassium concentration is more than 6.5 mEq/L with associated ECG changes, additional measures are indicated. In the absence of digitalis toxicity, hyperkalemia with ECG changes should be treated with a secure and rapid IV infusion of calcium chloride or calcium gluconate. Hand injection with ECG monitoring is reasonable beginning with the administration of 10 mg/kg of calcium chloride (or gluconate equivalent) over 1 to 5 minutes. Infusion may be stopped if the ECG has normalized or if deterioration of the ECG seems to be precipitated by the calcium, suggesting a clinical scenario more complex than simple hyperkalemia. If the ECG improves but is not normalized by this calcium dose, additional calcium chloride may be given at a lower rate. It should be anticipated that ECG changes will recur in 15 to 30 minutes unless additional measures are taken immediately to treat the hyperkalemia. The effective calcium dose may be repeated as necessary to preserve cardiac function while additional treatments are in progress. Additional, rapidly effective treatments include nebulized albuterol (rapid nebulization or continuous nebulization of 0.3 to 0.5 mg/kg) or salbutamol (IV dose of 4 to 5 μg/kg over 20 minutes and repeated after 2 hours).[125,126]

Insulin and glucose are also rapidly helpful in redistributing potassium to the ICF. Glucose (1 g/kg) and insulin (0.2 units/g glucose) may be given over 15 to 30 minutes and then infused continuously with a similar amount per hour. Blood glucose monitoring is essential because the relative glucose and insulin dosing may need adjustment.

Sodium bicarbonate (1 to 2 mEq/kg IV) has been a part of the classic treatment of hyperkalemia. Its benefit, however, is more difficult to predict and slower in onset than that of the measures mentioned earlier.

Sodium polystyrene sulfonate binds potassium and may be administered while dialysis arrangements are made. Sodium polystyrene sulfonate administered rectally must be retained for 15 to 30 minutes to be effective. If the oral route is available, it is generally more efficient.

In the patient with severely compromised renal function, these measures generally allow stabilization of potassium long enough to institute dialysis. Although hemodialysis is much more efficient for potassium removal than peritoneal dialysis, the latter may be more quickly instituted in many centers, particularly in the small infant in whom vascular access to support reasonable blood flow may be difficult to accomplish. In the absence of renal failure, loop diuretics or thiazide diuretics or both are useful for the increase of renal excretion. If mineralocorticoid activity is deficient, the administration of fludrocortisone may be indicated. In patients with severe hyperglycemia and moderate hyperkalemia, early steps to improve glucose control should decrease ECF potassium shifts from hyperosmolality and decreased insulin.

Magnesium

Magnesium deficiency that leads to overt clinical symptoms and signs is a recognized problem in the ICU setting.[127,128,129] Less than 1% of magnesium is distributed within the ECF

space, with the remainder distributed in the ICF space. More than 50% of ICF magnesium is located in bone; 20% in skeletal muscle; and the remainder in other soft tissues. ECF forms include free ion (Mg^{++}) (55% to 65%), magnesium complexed with anions (phosphate, oxalate, and citrate) (20% to 30%), and protein bound (5% to 20%).[130] Magnesium plays a key role in numerous metabolic processes, including cellular energy production, storage, and utilization involving adenosine triphosphate (ATP); the metabolism of protein, fat, and nucleic acids; and the maintenance of normal cell membrane function. It also is involved in neuromuscular transmission, cardiac excitability, and cardiovascular tone.[131]

Magnesium balance is maintained through intestinal absorption and renal excretion; 25% to 65% of ingested magnesium is absorbed in the ileum. Absorption varies inversely with intake and is also affected by paracellular water reabsorption. Increased bowel water that is due to any cause results in decreased magnesium reabsorption. Regulation of renal excretion occurs by glomerular filtration and reabsorption. The bulk (50% to 70%) of filtered magnesium is reabsorbed in the ascending limb of the loop of Henle[132] resulting from active NaCl reabsorption and is susceptible to loop diuretic inhibition. The threshold value for magnesium excretion varies between 1.5 and 2 mg/dL in different species. Thus if serum magnesium levels fall even slightly, renal excretion dramatically decreases under normal circumstances. Primary factors that increase renal magnesium excretion include ECF volume expansion; hypermagnesemia; hypercalcemia; metabolic acidosis; phosphate depletion; and various drugs, including loop and osmotic diuretics, cisplatin, aminoglycosides, cyclosporin, and digoxin. Decreased excretion occurs with ECF volume depletion, hypomagnesemia, hypocalcemia, hypothyroidism, and metabolic alkalosis, to a lesser extent. Parathyroid hormone (PTH) may decrease magnesium excretion, but that effect may be offset by the opposite effect of causing hypercalcemia.[133]

Hypomagnesemia

Clinically significant magnesium depletion may be present despite normal serum magnesium levels. Serum total magnesium correlates fairly well with bone concentration but may be normal in the presence of low tissue or muscle levels. Free, ionized magnesium is physiologically the most important form, but determination of total magnesium is still generally used. Critically ill children, however, frequently are reported to have low ionized magnesium levels despite having normal total magnesium levels.[129] Evidence supporting obligatory ionized magnesium measurement remains elusive more than a decade after it became feasible.

Magnesium depletion may result in hypocalcemia; the mechanism includes the suppression of parathormone secretion.[134-136] Hypokalemia also occurs in patients with hypomagnesemia. Magnesium deficiency impairs the Na/K pump, allowing potassium loss from the ICF, which in turn is excreted in the urine. Magnesium repletion is important for the resolution of these secondary disturbances.

Causes of Hypomagnesemia

Intensivists deal with hypomagnesemia most often in patients receiving loop diuretics or transplant immunosuppressives. Other causes must be considered.

Magnesium deficiency may be caused by decreased intake or increased losses. Although slight falls in serum magnesium levels may occur after 1 week of a deficient diet, a more sustained period of deprivation is generally necessary for significant hypomagnesemia to occur.[128,137] In children, magnesium deficiency has been particularly common in patients with protein-energy malnutrition and anorexia nervosa. Intestinal malabsorption is a major cause of magnesium deficiency. Isolated familial primary hypomagnesemia occurs from selective malabsorption of magnesium; patients generally have symptoms in infancy. These symptoms often include tetany and convulsions as a result of severe hypomagnesemia with consequent hypocalcemia, and patients respond well to supplemental magnesium. Other causes associated with magnesium malabsorption include regional enteritis, ulcerative colitis, massive small bowel resection, generalized malabsorption syndromes, pancreatic insufficiency, and cystic fibrosis. In some of these cases, the formation of insoluble soaps due to the complexing of magnesium with unabsorbed fat is the postulated mechanism for hypomagnesemia.

Intrinsic renal tubular disorders associated with hypomagnesemia are rare in the ICU setting. Various causes of hypomagnesemia are displayed in Box 67-7.

Drugs that induce renal magnesium wasting are more common causes and include aminoglycosides,[138] cisplatin,[139] amphotericin B,[140] diuretics,[141] cyclosporin A,[142] and

tacrolimus.[142] Furosemide produces greater losses of magnesium than of sodium and calcium.[143] Hypomagnesemia requiring supplementation is common in transplant recipients who receive cyclosporine or tacrolimus. Fractional excretion of magnesium and total excretion are elevated. Patients with DKA also may have marked renal magnesium wasting during the acidotic period, as well as in early treatment. An increased urine calcium level, from whatever cause, is often associated with magnesium wasting from competitive inhibition of renal tubular reabsorption of magnesium in the ascending limb.

Signs and Symptoms

In addition to biochemical derangements associated with hypomagnesemia, a wide spectrum of other clinical disorders have been attributed to its depletion, including cardiac arrhythmias, increased sensitivity to digoxin, coronary spasm, hypertension, seizures, and neuromuscular derangements.

Hypomagnesemic arrhythmias include ventricular premature beats, ventricular tachycardia, torsades de pointes, and ventricular fibrillation.[144,145] Supraventricular arrhythmias are less common. Improvement in resistant ventricular arrhythmias following magnesium infusion has been reported, although other metabolic derangements often coexist in such patients. Magnesium deficiency enhances myocardial cell uptake of digoxin and toxicity. Both inhibit Na/K-ATPase with resultant ICF potassium depletion.

Depletion is thought to contribute to the development or worsening of hypertension by increasing vascular smooth muscle tone and reactivity. Increased cellular influx of calcium and decreased reuptake by sarcoplasmic reticula occur; the result is increased cytosolic calcium for activation of actin-myosin contractile proteins. Similar effects in coronary and cerebral vessels also have been observed.

Seizures may be the first symptom of hypomagnesemia noted in a ICU setting. Other neuromuscular changes may include tremors, fasciculations, spontaneous carpopedal spasm, muscle cramps, paresthesias, seizures, and coma. Personality changes, including apathetic behavior and depression, also have been associated with hypomagnesemia.[146,147]

Treatment

Patients undergoing or at immediate risk of hypomagnesemic malignant ventricular arrhythmias (such as torsades de pointes) or seizures can be given magnesium sulfate intravenously with careful monitoring. An IV infusion of 25 to 50 mg/kg of magnesium sulfate per dose diluted to 10 mg/mL can be administered over 15 to 60 minutes. The rate of infusion should not exceed 150 mg/min. Doses may be repeated as needed depending on patient response. Complications of parenteral magnesium therapy include neuromuscular and respiratory depression, rare arrhythmias, flushing, hypotension, and prolonged bleeding times.[148] Other routes of therapy include intramuscular magnesium sulfate, injections of which are painful, and oral therapy with magnesium oxide or citrate. In situations known to be associated with the development of hypomagnesemia, it seems particularly important to attempt to avoid deficiency through adequate magnesium intake before life-threatening symptoms develop. The use of supplemental magnesium infusions in perinatal asphyxia is intriguing[149] but remains to be fully tested or extended to other hypoxic-ischemic encephalopathies.

Hypermagnesemia

Hypermagnesemia is seen much less commonly than is hypomagnesemia. Magnesium infusions in patients with status asthmaticus have become common, however, and may be associated with hypermagnesemia. Although elevated, the levels achieved are unlikely to cause toxicity.

Causes of Hypermagnesemia

Hypermagnesemia occurs in patients with renal failure and is generally associated with iatrogenic administration of magnesium as antacids, cathartics, or enemas or through total parenteral nutrition (TPN) containing magnesium. In the absence of renal failure, the administration of large quantities of magnesium cathartics in the management of constipation[150] or overdoses[151] and antacid use with increased peritoneal absorption of magnesium in the presence of a perforated viscus[152] are causes of hypermagnesemia. Magnesium levels as high as 10 to 12 mEq/L have been reported. Megadose vitamin-mineral supplementation, including magnesium oxide, has been fatal.[153]

Signs and Symptoms

Acute elevations of magnesium depress the CNS and the peripheral neuromuscular junction. Pseudocoma with fixed, dilated pupils has been reported. Deep tendon reflexes are depressed at levels greater than 4 mEq/L with total disappearance along with flaccid quadriplegia at levels greater than 8 to 10 mEq/L. Hypotension, hypoventilation, and cardiac arrhythmias also may occur.[154-157] Moderate hyperkalemia has resulted from prolonged magnesium infusions in occasional patients.

Treatment

Calcium acts as a direct antagonist to magnesium. In life-threatening situations associated with severe magnesium intoxication, intravenous calcium should be used as the initial therapy. Adults have been treated with 5 to 10 mEq of calcium in either the chloride or gluconate forms over 5 to 10 minutes, with doses repeated if necessary. An initial dose of calcium chloride at 10 mg/kg or an equivalent amount of calcium gluconate has been suggested for infants and children. Medications that contain magnesium obviously should be discontinued. If renal function is normal, IV furosemide may be administered to increase magnesium excretion while urine output is replaced with half-normal saline solution. In patients with renal failure or severe toxicity, dialysis may be necessary for removal of magnesium.

Phosphorus

Virtually all of plasma phosphorus is in the inorganic form, with a small organic component composed entirely of phospholipids bound to protein. Serum levels vary with age; approximate normal values (specific to the analytical instrument) are 4.8 to 8.2 mg/dL for neonates, 3.8 to 6.5 mg/dL for children aged 1 week to 3 years, 3.7 to 5.5 mg/dL for children aged 3 years to 12 years, and 2.9 to 5 mg/dL for adolescents aged 12 to 19 years.[158] Differences are thought to be related to more rapid rates of skeletal growth in the pediatric population. Most total body phosphorus resides in bone. More than 50% to 65% of ingested phosphorus is absorbed, primarily in

the jejunum. Its absorption may be decreased by a high calcium intake or by ingestion of antacids, which binds phosphorus in the bowel. Urinary excretion depends primarily on oral intake. About 80% of the inorganic phosphorus is filtered, with reabsorption occurring predominantly in the proximal tubule by an active mechanism coupled to sodium transfer. Renal phosphorus reabsorption is decreased by parathormone and by calcitonin with resultant phosphaturia. Glucose competitively inhibits phosphorus reabsorption. Glucocorticoids produce phosphaturia by a decrease in sodium-dependent transport in the proximal tubule. Vitamin D may increase or decrease reabsorption, depending on conditions.

Phosphorus plays an important role in cellular structure and function, bone mineralization, and urinary acid excretion. The development of severe phosphorus depletion affects the availability of intracellular ATP for every production; depletes the erythrocyte of 2,3-diphosphoglycerate (2,3-DPG), with resultant tissue hypoxia; and impairs urinary acid excretion. The major acute effect of hyperphosphatemia is hypocalcemia; the long-term consequence is soft tissue calcification.[159]

Hypophosphatemia

Hypophosphatemia as measured by serum or plasma levels may or may not indicate true phosphorus deficiency. Severely depressed levels of serum-measurable phosphorus may occur in the absence of true deficiency after transcellular shifts from the ECF to the ICF, whereas a moderate phosphorus deficiency may be indicated only by slightly decreased serum levels.[160] Moderate hypophosphatemia has been defined as levels between 1.5 and 2.5 mg/dL and severe hypophosphatemia as levels less than 1.5 mg/dL on serum determination. In general, only with severe deficiency of phosphorus do multiple symptoms occur, as well as overt cell dysfunction or necrosis. Risk is greatest when superimposed additional cellular injury exists.

Cause of Severe Hypophosphatemia

Although numerous abnormalities may result in moderate decreases in phosphorus levels, severe hypophosphatemia has been associated with only a handful of clinical syndromes. These syndromes include significant respiratory alkalosis, prolonged use of phosphate-deficient TPN, the nutritional refeeding syndrome, thermal burns, DKA, pharmacologic binding of phosphorus in the gut, and alcohol withdrawal.[160,161] Association with continuous renal replacement therapy and bone recovery after renal transplant also have been reported.[162,163] The increase in the ICF pH associated with acute respiratory alkalosis stimulates the enzymes of glycolysis, with subsequent depletion of ICF phosphorus, which is replaced by an influx from the ECF space. Although carbon dioxide diffuses across membranes much more readily than bicarbonate does, metabolic alkalosis rarely produces a decrease in phosphorus levels, whereas very low levels may be seen with respiratory alkalosis.[164] An absolute deficiency from malnutrition and transcellular shifts from the ECF to the ICF with an anabolic response to increasing caloric intake are the causes associated with TPN use.[165] In the pediatric population, the preterm infant is particularly susceptible. Nearly 80% of calcium-phosphorus assimilation in the fetus occurs in the last trimester of pregnancy. The preterm infant is therefore born deficient in total body phosphorus. When reasonable nutrition has been absent for even short periods or when phosphorus has not been provided in TPN, severe hypophosphatemia has occurred, associated in several cases with the development of hypercalcemia.[166] A similar situation may occur with the refeeding of patients who have significant protein calorie malnutrition.[167] As previously noted, an absolute phosphorus deficiency and transcellular shifts from the ECF to the ICF in the face of an anabolic response are responsible.

Significant hypophosphatemia in burn patients during their recovery phase has been associated with the presence of respiratory alkalosis, diuresis of initially retained sodium and water, and acceleration of glycolysis.[160] As previously described, ECF phosphorus shifts to the ICF compartment when intracellular-free phosphorus has been used in phosphorylation of organic compounds such as occurs during glycolysis, oxidative phosphorylation, glycogenolysis, and synthesis of glycogen, protein, and phosphocreatine. Acidosis decomposes organic compounds within the cell with subsequent movement of inorganic phosphorus from ICF to ECF and excretion in the urine. Osmotic diuresis augments these losses. Decreased intake also commonly occurs. During treatment of DKA, renal phosphorus clearance generally increases with fluid administration. In addition, insulin therapy results in stimulation of glycolysis and anabolism with a shift of phosphorus back to the ICF. If the acidosis has been present for only a few days, then rarely is there a severe phosphorus deficiency. Although levels may decrease, they generally return to normal without extra phosphorus therapy. In the patient whose symptoms have been present for a number of days to weeks, however, severe deficiency may exist at the time of admission. These patients may have life-threatening complications of hypophosphatemia if they are not treated. In general, this subset of patients has low phosphorus levels on admission, whereas phosphorus levels are normal or increased at admission in less severely affected patients.

Signs and Symptoms

Multiple organ systems may be affected by severe hypophosphatemia, including CNS, cardiac, respiratory, musculoskeletal, hematological, renal, and hepatic abnormalities.[168-171] Decreased diaphragmatic contractility in patients with hypophosphatemia with acute respiratory failure significantly improved as measured by transdiaphragmatic pressures during phrenic stimulation with treatment of hypophosphatemia.[172] Respiratory muscle weakness in patients with hypophosphatemia but without respiratory failure also has been documented and shown to normalize with phosphorus repletion.[173]

Neurologic symptoms may initially include irritability and apprehension followed by weakness, peripheral neuropathy with numbness, and paresthesias. Dysarthria, confusion, obtundation, seizures, and coma may occur in more profound cases.[170,174] Reports in the literature include Guillain-Barré–like syndrome,[175] diffuse slowing on electroencephalogram, and congestive cardiomyopathy[176] that significantly improved with correction of phosphorus depletion. In dogs, decreased cardiac output, decreased ventricular ejection velocity, and increased left ventricular end diastolic

pressure reversed with phosphorus repletion. In humans, rhabdomyolysis has been predominantly seen in alcoholic patients, in whom subtle myopathy was likely present, and rarely in patients with DKA or after TPN therapy. Decreased levels of 2,3-DPG in red blood cells (RBCs) may depress P-50 (oxygen half-saturation pressure) values so that the release of molecular oxygen to peripheral tissues is decreased, with resultant tissue hypoxia.[168] Structural defects of RBCs associated with hypophosphatemia have included rigidity and rarely hemolysis and have generally occurred when additional metabolic stresses such as metabolic acidosis or infection were placed on the RBC. Decreased levels of ATP in neutrophils may result in decreased chemotaxis, phagocytosis, and bacterial killing.[177] The mechanisms underlying the development of metabolic acidosis include decreased phosphorus excretion that thereby limits titratable acid excretion and decreased ammonia levels.

Treatment

As with other minerals and electrolytes, when oral therapy is potentially possible, it is the preferable route for administration. In patients with severe hypophosphatemia, IV therapy is often indicated.[178,179] Few data exist in the pediatric literature regarding dosage. Therefore most data are extrapolated from adult literature.[180-182] Reasonable recommendations in children with severe phosphorus depletion are to use 0.15 to 0.33 mmol/kg per dose, given as a continuous infusion over 4 to 6 hours. Subsequent doses are generally calculated on the basis of response to this initial dosage. Either potassium or sodium phosphate may be administered with the attendant potential complications of hypernatremia or hyperkalemia. Other potential complications of therapy include hyperphosphatemia, metastatic deposition of calcium phosphate, hypocalcemia, potential nephrocalcinosis with renal failure, and hypotension. Both sodium and potassium phosphate contain 3 mmol of phosphate per mL and 4 or 4.5 mEq of sodium or potassium, respectively. For oral administration, a combination product of sodium with potassium phosphate (Neutra-Phos) has been used commonly in children. One capsule supplies 8 mmol of phosphorus along with 7.1 mEq of sodium and potassium. Capsules can be reconstituted in water as well. Hypophosphatemia associated with continuous renal replacement therapy provides a special case. IV replacement is required in many such patients.[162]

Hyperphosphatemia

Causes of Hyperphosphatemia

Acute and chronic renal failure with decreased phosphorus excretion are the most common causes of hyperphosphatemia, with elevation in serum phosphorus occurring when the GFR is less than 30 mL/min/1.73 m^2. Extreme hyperphosphatemia associated with several deaths has been reported from the use of sodium phosphate enemas in infants and children.[183-185] Abnormalities of intestinal anatomy or motility predisposing to retention of enemas or renal insufficiency represent risk factors, but no risk factors are identified in 30% of reported patients The administration of IV boluses of sodium or potassium phosphate rather than slow infusion may result in symptomatic hyperphosphatemia. An error in parenteral nutrition resulted in hyperphosphatemia in multiple infants,[186] and severe hyperphosphatemia has been reported related to use of liposomal amphotericin B.[187]

TLS represents an additional cause of hyperphosphatemia along with hyperkalemia, acidosis, hypocalcemia, and renal failure. It results from drug-induced lysis of tumor cells and is always a concern in a child with a lymphoid malignancy and substantial cellular mass, but it can occur in a variety of settings.[111,113,115] Initial chemotherapy or radiation of B-cell lymphoma is particularly likely to produce cell lysis and hyperphosphatemia along with hyperuricemia, acute renal failure (ARF), hyperkalemia, metabolic acidosis, and hypocalcemia. Aggressive hydration and careful initiation of chemotherapy usually will result in a manageable degree of electrolyte abnormality. Urinary alkalinization to increase urate solubility is usually recommended but is being reexamined. Rasburicase is replacing allopurinol in the control of urate levels. Hemodialysis is an essential resource to have available if managing such a patient (Table 67-2).

Table 67–2 Tumor Lysis Syndrome

At risk	Lymphoid malignancies
High risk	Large tumor mass, B-cell lymphoma
	Renal compromise
Initiating event	Cytolytic chemotherapy
	Radiation therapy
	Embolic tumor infarction
Prophylaxis	Hydration, urinary alkalinization, allopurinol
	Gradual chemotherapy initiation, rasburicase
Serious disturbances	Hyperkalemia, hypocalcemia, acidosis, renal failure, hyperuricemia, hyperphosphatemia
Management	Obsessive electrolyte monitoring
	Hemodialysis available stat CVVHD helpful, may not be adequate

CVVHD, Continuous venovenous hemodialysis; *stat,* immediately.

Signs and Symptoms

The major clinical consequence of severe hyperphosphatemia is its associated hypocalcemia, as well as soft tissue deposition of calcium phosphate salts. Seizures, coma, and cardiac arrest have been reported, generally in the presence of both hypocalcemia and hyperphosphatemia. In one case report, however, seizures, malignant ventricular arrhythmias, and cardiac arrest with acute hyperphosphatemia alone were described.[188] Hyperphosphatemia may be a proximate cause of ARF via precipitation in renal tissue.[189,190]

Treatment

In patients with life-threatening complications or multiple additional electrolyte disturbances or in the presence of renal failure, dialysis may be required. Intravenous fluid loading to increase renal phosphorus losses and intravenous calcium may increase excretion. Mannitol diuresis will inhibit proximal phosphorus reabsorption and theoretically should expedite phosphaturia. If oral administration is possible, Sevelamer has been used in patients with TLS to bind

phosphorus and perhaps decrease the need for more invasive therapy.[191]

Disorders of Calcium Homeostasis

The extracellular ionized calcium (Ca^{++}) concentration must be maintained within narrow limits for its vital and ubiquitous role in normal metabolism. Entry of Ca^{++} into cardiac and skeletal muscle cells, facilitated by membrane depolarization and β-adrenergic stimulation, mediates conversion of electrochemical into mechanical energy with resultant muscle contraction. Additionally, several enzyme systems (e.g., adenylate cyclase, phosphodiesterase, and protein kinases) are to be regulated by the interaction of Ca^{++} with calmodulin. A similar interaction stimulates myosin kinase in vascular smooth muscle so that Ca^2 influx (enhanced by α-adrenergic and inhibited by β-adrenergic stimuli) causes vasoconstriction. Ca^{++} also plays a critical role in the clotting system and various membrane transport systems. Alterations in calcium homeostasis occur frequently among critically ill patients.

Extracellular Ca^{++} is monitored by Ca^{++}-sensing receptors.[192] These receptors are plentiful on the surface of the chief cells of the parathyroid glands, on numerous kidney sites (e.g., the juxtaglomerular apparatus, luminal surface of the proximal convoluted tubule, basolateral surface of the cortical thick ascending limb of the loop of Henle, and apical and luminal membrane of the inner medullary collecting duct in the kidneys), in the intestine, parts of the brain, thyroid C cells, breast, and adrenal glands. In classic hormonal negative feedback fashion, binding of Ca^{++} to this receptor activates phospholipase C and accumulation of inositol triphosphate, which secondarily leads to inhibition of the secretion and synthesis of PTH and activation of its proteolysis.

Regulation of Extracellular Calcium

Derangements in calcium homeostasis result from (1) changes in protein binding and chelation (with phosphate [PO_4] or other anions) and (2) excessive or deficient hormonal action. The former scenario is more common in the ICU. A majority of total serum calcium is bound to proteins, and this binding is pH dependent. Acidic pH decreases calcium binding and increases ionized calcium (Ca^{++}), whereas alkalosis increases binding and reduces Ca^{++}. Fortunately, direct measurement of Ca^{++} is now readily available in PICUs.

Hormonal Regulation of Calcium

Hormonal control of calcium homeostasis involves PTH, vitamin D, and calcitonin. Secretion of PTH by the parathyroid chief cell varies inversely with the serum Ca^{++} and is inhibited by hypomagnesemia and $1,25(OH)_2$-vitamin D. Rapid proteolytic degradation of PTH yields a physiologically inactive C-terminal fragment and an active NH_2-terminal fragment. PTH binds to cell surface receptors in bone osteoblasts and kidney and exerts its effects through binding of a subunit of a membrane-associated heterotrimeric protein, which mediates increased formation of cyclic adenosine 3′,5′-monophosphate.

In the kidney, PTH inhibits proximal tubular PO_4 reabsorption and promotes phosphaturia. This loss of PO_4 inhibits bone mineralization and tends to shift the flow of calcium from bone to the ECF. Distal tubular reabsorption of filtered calcium is also increased by PTH. PTH stimulates 1a-hydroxylation of 25(OH)–vitamin D, resulting in production of metabolically active 1,25(OH)2–vitamin D that stimulates intestinal absorption of calcium and PO_4. The overall effect of PTH is to raise serum calcium levels and lower serum PO_4 levels. This characteristic reciprocal relationship is helpful in distinguishing PTH disorders from those involving vitamin D alone.[193]

Hyperphosphatemia lowers Ca^{++} by shifting the equilibrium in calcium flux from ECF toward bone and by inhibiting 1a-hydroxylation activity. Calcitonin is a 32-amino-acid, calcium-lowering hormone elaborated by C cells of the thyroid in response to rising Ca^{++} levels. Although it rapidly reduces the bone resorptive function of osteoclasts and promotes calciuria and phosphaturia, its excess or absence causes no discernible disorder.

Hypocalcemia

Clinical and Laboratory Diagnosis

Hypocalcemia is frequently associated with critical illness in children. In some cases, hypocalcemia is associated with PTH deficiency, whereas in others hypercalcitoninemia or hypermagnesemia is cited. In children with severe burns, hypocalcemia, magnesium depletion, hypoparathyroidism, and renal resistance to PTH may develop. Here a reduced set point for Ca^{++} suppression of PTH secretion, rather than magnesium depletion, appears be the primary cause of low PTH production.[194]

Reduced Ca^{++} inhibits acetylcholine release and impairs effective muscular contraction in both sensory and motor nerves. Accordingly, a variety of peripheral and CNS effects (tetany, convulsions [grand mal, petit mal, or focal], carpopedal spasms, muscle cramps and twitching, paresthesias, laryngeal stridor, and apnea in the newborn) are characteristic features of hypocalcemia. Latent tetany is manifested by Chvostek (provoked facial muscle twitching) and Trousseau (provoked carpopedal spasm) signs. Cardiovascular manifestations of hypocalcemia include hypotension, myocardial depression, CHF, and dysrhythmias. Somatic changes accompanying prolonged hypocalcemia include dry, coarse skin, eczematous dermatitis, brittle hair with areas of alopecia, brittle nails with smooth transverse grooves, and dental enamel hypoplasia.

Determination of the free ionized Ca^{++} level is diagnostic, although the rate of decline also contributes to the development of symptoms. Estimations of Ca^{++} correcting for protein binding (i.e., for every 1 g/dL reduction of serum albumin, the protein-bound calcium fraction is reduced by 0.8 mg/dL) and pH must be interpreted cautiously. Prolongation of the QT interval may be helpful in confirming reduced ionized calcium levels, although the correlation is not strong.

The causes of hypocalcemia are best recalled by reviewing the mediators of normal calcium homeostasis as summarized in Box 67-8.

Reduced PTH effect can result from parathyroid gland failure (e.g., autoimmune or postsurgical hypoparathyroidism), insensitivity to PTH (e.g., pseudohypoparathyroidism), or suppression of PTH release (e.g., hypomagnesemia, maternal hypercalcemia, and burns). Hyperphosphatemia is frequently present, and accompanying clinical features (e.g.,

short stature, mental retardation, and shortened metacarpals in pseudohypoparathyroidism and moniliasis of the nails in hypoparathyroidism)are seen. Measurement of immunoreactive PTH (iPTH) levels distinguishes hormonal deficiency from resistance to hormone action. Reduced vitamin D effect results from vitamin D deficiency (e.g., malabsorption, best detected by low 25(OH) –vitamin D levels), impaired activation of vitamin D (e.g., renal disease, best detected by low 1,25(OH)2–vitamin D levels), or exaggerated losses or metabolism (e.g., phenytoin). Acute changes in Ca^{++} binding equilibrium or chelation are perhaps the most frequent causes of hypocalcemia in the intensive care setting. Respiratory alkalosis or hyperphosphatemia may dramatically reduce total and ionized calcium levels. Infusion of large amounts of citrate-preserved blood and acute phosphorus overload or retention (e.g., in patients with acute renal failure) rapidly deplete ECF calcium levels. Various drugs also contribute to development of hypocalcemia.

Treatment

Correction of hypocalcemia should be preceded by consideration of readily treated factors (such as acute respiratory alkalosis) or confounding factors. Rapid development of hyperphosphatemia suggests acute renal failure, cell lysis, or excessive supply (also see Chapter 81). As appropriate, efforts should be made to reduce serum phosphate levels, because intravenous calcium therapy may cause metastatic deposition of calcium-phosphate salts. Hypomagnesemia impairs PTH release, response to PTH, and, consequently, correction of hypocalcemia. Hypomagnesemia may develop in critically ill patients by several mechanisms as previously discussed.

Urgency of therapy is determined by the child's clinical status. Asymptomatic hypocalcemia is appropriately treated with oral calcium salts. For the seriously ill patient with overt or evolving hypocalcemia, replacement therapy is accomplished with IV calcium chloride, 5 to 20 mg/kg, or an equivalent calcium gluconate infusion. Potential bradycardia and asystole with infusion of calcium should be anticipated, with cardiac monitoring and atropine readily available. Care is required to prevent tissue damage by extravasation, precipitation with concomitantly administered bicarbonate, and untoward cardiac rhythm disturbances in patients receiving digitalis.

Oral administration of calcium salts is efficient for control of persistent hypocalcemia and is preferable to prolonged infusion. Liberal amounts can be administered orally (e.g., calcium 50 mg/kg/day in four to five divided doses), with attention paid to the differing Ca content of various oral preparations. For patients with fat malabsorption, supplementation of calcium therapy with magnesium or vitamin D will be needed for maintenance of normocalcemia. In the setting of hypoparathyroidism secondary to magnesium depletion, magnesium replenishment will need to occur.

Hypercalcemia

Clinical and Laboratory Diagnosis

In contrast to dramatic neuromuscular manifestations of hypocalcemia, the physical effects of hypercalcemia may be subtle and nonspecific. However, a serum total calcium greater than 15 mg/dL represents a medical emergency. Renal,

cardiovascular, and CNS disturbances predominate and reflect both the degree and duration of calcium elevation. Increased filtered load of calcium creates hypercalciuria and accompanying polyuria, reduced urine-concentrating ability, dehydration, and eventual renal lithiasis. Hypertension is common, possibly mediated through increased renin production or direct effects on peripheral vasoconstriction and inotropy. Alterations in the cardiac conduction system include a shortened QT interval and a tendency to dysrhythmias. Impaired nerve conduction resulting from excess calcium creates hypotonia, hyporeflexia, and paresis in severe cases. Alterations in CNS function, including lethargy, confusion, and even coma, can occur. Constipation, anorexia, and abdominal pain resulting from reduced intestinal motility are frequent symptoms of hypercalcemia. Promotion of gastrin release by calcium may account for an increased incidence of peptic ulcer disease. Soft tissue deposition of calcium, usually facilitated by associated hyperphosphatemia, can impair function of the lungs, kidneys, blood vessels, and joints.

In the absence of hyperproteinemia, determination of elevated serum total calcium levels reliably indicates increased Ca^{++} concentrations. Because common causes of hypercalcemia in adults (hyperparathyroidism and malignancies) are less common in children, hypercalcemia is encountered less frequently than is hypocalcemia by the pediatric intensivist. Diagnostic possibilities are best approached by considering the predominant underlying mechanism of hypercalcemia as outlined in Table 67-3.

Increased bone resorption reflects excess PTH effect (e.g., hyperparathyroidism and ectopic PTH), immobilization, or bone lysis by metastatic malignancy (e.g., neuroblastoma). PTH-mediated hypercalcemia is distinguished by a depressed serum phosphate concentration, decreased renal tubular reabsorption of phosphate ($TmPO_4$/GFR), and an iPTH level inappropriately elevated for the simultaneous serum Ca^{++}. In the child with hyperparathyroidism, evaluation for multiple endocrine neoplasia is warranted. Heightened vitamin D effect is manifested by increased intestinal calcium absorption and can be related to vitamin D intoxication, increased sensitivity to vitamin D, or ectopically produced 1,25(OH)2–vitamin D, as seen in sarcoidosis. Serum PO_4 levels and $TmPO_4$/GFR) ratios are normal or increased, and iPTH levels are suppressed in these disorders. Detection of an elevated 25(OH) –vitamin D level (nutritional excess) or 1,25(OH)2–vitamin D level (sarcoidosis, hyperparathyroidism) may be helpful. Decreased excretion of calcium occurs with dehydration or treatment with thiazide diuretics and frequently aggravates the severity of hypercalcemia in patients with unrecognized hyperparathyroidism. Familial hypocalciuric hypercalcemia, an autosomal dominant disorder resulting from partially deactivating mutations in Ca^{++}-sensing receptor, is characterized by normal to slightly elevated iPTH levels and decreased urinary calcium excretion.[195] Thus determination of (a logical combination of) serum Ca^{++}+, PO_4, iPTH, vitamin D metabolites, and urinary calcium and PO_4 excretion allows differentiation of most hypercalcemic disorders.

Treatment

A serum calcium level greater than 15 mg/dL may be life threatening and requires direct Ca-lowering therapy in addition to attention to the underlying disorder. Hydration with isotonic saline solution (200 to 250 mL/kg/day) and furosemide diuresis (1 mg/kg administered every 6 hours) results in calciuresis and amelioration of hypercalcemia in the majority of cases. Excessive losses of sodium, potassium, magnesium, and PO_4 may occur. Thiazide diuretics should not be used because of their hypercalcemic effects.

Adjunct therapy is directed at the specific cause of hypercalcemia. Drugs that inhibit excessive bone resorption include calcitonin (10 U/kg IV every 4 to 6 hours), mithramycin (25 mg/kg IV over 4 hours), and indomethacin (1 mg/kg/day). Calcitonin, now available in human recombinant form, blocks PTH-induced bone resorption, facilitates calciuria, is relatively nontoxic, and has a prompt (but transient) peak effect by 1 hour. Mithramycin is a toxic antibiotic that inhibits osteoclastic activity

	3. Idiopathic infantile hypercalcemia or Williams syndrome	H	N	N	L, N, or H	L	H	N or H
	4. Abrupt glucocorticoid withdrawal or deficiency	H	N or H	N	N	L	H	N or H
Decreased renal excretion of calcium	1. Familial hypocalciuric hypercalcemia	H	N or L	N	N or H	N or H	L	L

H, High; *L,* low; *N,* normal.

within 24 hours but has potential adverse effects, including thrombocytopenia and hepatic and renal toxicity. Indomethacin (or aspirin) is useful when excessive prostaglandin E2 production is suspected (e.g., some tumor-related hypercalcemic syndromes). More recently, bisphosphonates (e.g., pamidronate and etidronate) have been used successfully for treatment of persistent hypercalcemia.[196] Intestinal calcium absorption is reduced by corticosteroids (hydrocortisone 1 mg/kg administered every 6 hours or equivalent). Consequently, corticosteroids are especially useful for treatment of vitamin D–related hypercalcemia. Delayed onset of corticosteroids action, however, limits their use in the acute setting. Phosphates are not recommended because of the likelihood of soft tissue deposition of calcium-phosphate salts.

Acid-Base Balance and Disorders

Hector Carrillo-Lopez, Adrian Chavez, and Alberto Jarillo-Quijada

PEARLS

- The classical acid-base approach states that acidosis is produced by the gain of acids (endogenous or exogenous) that directly release H^+, and/or the loss of bicarbonate. For alkalosis, the opposite must occur. PCO_2, pH, standard base excess (SBE), HCO_3^-, and anion gap are the assessment tools used in this physiological view. However, with the exception of PCO_2, all these variables have a *correlation* with pH but have *no causal* relationship with it.
- According to the physical-chemical approach, water is a virtually inexhaustible source of hydrogen ion, and thus it is water itself that actually provides hydrogen ions through its dissociation or recomposition: $H_2O \leftrightarrow H^+ + OH^-$.
- Blood plasma contains numerous ions. Some of them are fully dissociated, chemically nonreacting in aqueous solutions, and are called "strong ions," such as Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cl^-. Certain organic acids, such as lactate and keto acids, are also considered strong ions.
- The determinants of $[H^+]$ and pH are the determinants of water dissociation, and the quantification of the water dissociation is made through the measurement of the hydrogen ion concentration, i.e., the pH.
- The model of acid-base balance was redefined as a consistent system in an aqueous solution with only three "independent variables" that are *causally* related to the H^+:
  - Partial pressure of carbon dioxide (PCO_2).
  - The strong ion difference (SID). In blood plasma, strong cations outnumber strong anions. The difference between the sum of all strong cations and all the strong anions is called SID; it has a powerful electrochemical effect on water dissociation, and hence on H^+. Sodium and chloride are the two most important plasma strong ions.
  - The most important nonvolatile weak acid—partially dissociated acid—is albumin, with a minor effect from phosphate.
- Normal acid-base status occurs when the independent variables have normal values. Abnormality of one or more of the independent variables underlies all acid-base disturbances. Adjustment of the independent variables is the essence of all therapeutic interventions because none of the dependent variables (e.g., pH, SBE, or HCO_3^-) can be changed primarily or individually; the dependent variables change, all of them simultaneously, if, and only if, one or more of the independent variables changes.
- Since PCO_2 is regulated by ventilation, its changes result in respiratory acid-base disorders. Metabolic acid-base disorders stem from changes in either SID or in total concentration of nonvolatile weak acids.
- Acid-base disorders must be considered more important for what they tell the clinician about the patient than for any harm that is directly provoked by the acid-base imbalance. Mortality is more closely related to the nature of an acid-base disorder, than to the magnitude of the derangement of the pH, whether acidotic or alkalotic.
- The main type of acid-base derangement in the critical care setting is metabolic acidosis. When the origin is lactic acidosis, the correlation with mortality is greatest. It has become evident, however, that iatrogenic hyperchloremic acidosis, related to resuscitation fluids, is much more frequent than previously thought, a fact that should be corrected through a better supervision of the fluids given to the patient and their impact in Cl^- and on SID.
- The clinical approximation to an acid-base disorder should include all the tools of the classical approach, but with some merging concepts from the physical-chemical approach: the anion gap must always be "corrected" for albumin levels, and sodium, chloride, and lactate levels must be checked. If a high volume of resuscitation fluids is given to the patient, or if the presence of unmeasured anions is expected, or if a complex or mixed pattern of acid-base metabolic derangement is suspected, then SID, strong ion gap (SIG), and probably "partitioned" SBE should be calculated.
- For easy bedside calculation of extensive formulas, there is an online free software solution, offering free decision support in complex acid-base scenarios at AcidBase.org [analysis module].

Physics, chemistry, and the physiology of acid-base balance are among the first subjects that are taught at medical school, and are one of the best examples of the close correlation between basic and clinical sciences. However, physicians seem to display only a superficial knowledge of this field. When queried, 70% of medical doctors at a university hospital stated that they needed no help in correctly interpreting arterial blood gases. However, they succeeded in only 40% of the cases presented to them.[1] Similar experiences have been reported more recently, involving both physicians and nurses.[2,3] As a paradox, it is likely that the easily available software for computers and hand-held devices, along with internet-available "primers" for

the interpretation of blood gases and acid-base status, are all contributors to this situation, as they provide physicians, residents and nurses with a fast-track mechanical interpretation of the arterial blood gases and acid-base status, even when all the complexities are not fully understood.[3] Because intensivists spend much of their time managing problems related to fluids, electrolytes, and acid-base balance, every hour making important clinical decisions after interpreting the available acid-base parameters, a thorough but practical understanding of the physiology and pathophysiology of acid-base disorders is a central aspect of the expertise of the critical care practitioner.

Understanding Acid-Base Physiology: Traditional and Newer Approaches

Most of the concepts of acid-base physiology were developed in the early twentieth century,[4,5] and are based mainly on the accepted definition of acid.[5-7] As early as 1887, Arrhenius had defined acid as a substance that, when dissolved in water, produces an increased concentration of hydrogen ions; in other words, it is not mandatory for this given substance to have hydrogen atoms in its molecule, as the water itself can be the source of the hydrogen ions.[5] Accordingly, by 1900, Naunyn and others proposed that the acid-base status was, at least partially, determined by the concentration of some electrolytes, mainly sodium and chloride, that had been formerly described by Faraday as "base-forming cation" and "acid-forming anion," respectively.[5] In the 1920s, Brönsted and Lowry stated that an "acid" is any molecule that contains hydrogen atoms and that is able to release them in a soluble manner; that is, an acid is a "proton-donor substance."[6,7] Thus an acid (HA) may dissociate and donate a proton (H^+) to the solution, forming the conjugate base (or anion) A^- in a reversible manner:

$$[HA] \overset{K_a}{\longleftrightarrow} [H^+] + [A^-] \qquad (1)$$

where K_a is the equilibrium or dissociation constant, particular to every different substance and influenced by the characteristics of the particular solution in which the reaction is taken place. Therefore a base is a molecule with the ability to accept or "trap" free hydrogen ions (proton-acceptor substance).[7] Examples include bicarbonate, hemoglobin, many other proteins, and phosphates.

Whatever definition of acid is used, its validity depends on the situation that one is trying to understand or the event one is attempting to explain. In biologic solutions such as plasma, the situation is a water-based solution with tightly controlled solute concentrations. It is remarkable that, in this scenario, all the former acid definitions are valid[5] because water can supply both hydrogen and hydroxyl ions:

$$H_2O \leftrightarrow H^+ + OH^- \qquad (2)$$

Therefore water must be seen as the major natural reservoir of hydrogen (and hydroxyl) ions; thus the acid-base balance relies on the chemical properties of water, that is, acid-base unbalance can be seen as an alteration of water dissociation. In physiologic conditions, there is little dissociation of water molecules into its components. Electrical charge and temperature represent the main determinants for its eventual dissociation. Electrical neutrality is always held constant; that is, the number of positive charges must equal the number of negative charges. Both extracellular and intracellular fluids are an ionic mix of electrolytes, proteins, and other substances, whose charges tend to modify the electrical balance and then can have an influence on the dissociation of water. In order to keep the electroneutrality, more (or fewer) water molecules will have to dissociate. In other words, the determinants of H^+ are the determinants of water dissociation, and the quantification of the water dissociation is made through the measurement of the hydrogen ion concentration H^+.

Normal concentration of hydrogen ions in the extracellular fluid is extremely low, in the nanoequivalent (nEq) or nanomole (nmol) range (i.e., the order of magnitude of the H^+ is in the millionth of a milliequivalent range [1 nanoequivalent = 10^9 equivalent = 10^6 milliequivalent]). The usual arterial blood H^+ is about 40 nEq/L (or nmol/L) (i.e., 0.000040 mEq/L, with a normal range of 35 to 45 nEq/L [0.000035 to 0.000045 mEq/L or mmol/L]).[4] In other words, serum H^+ is about 3 million times less than the serum sodium concentration.[9] Because hydrogen ion concentration in body fluids and tissues has a strong influence on the function of almost all enzymatic systems of the organism, a tight regulation of its concentration is mandatory for the body. For convenience, the H^+ value is usually expressed as pH units, that are derived as the negative $\log_{10}$ of the hydrogen ion concentration in nanoequivalents per liter.This concept was developed by Sörenson and adapted by Karl Hasselbalch to clinical medicine in 1909. A normal pH of 7.4 corresponds to a blood hydrogen ion concentration of 40 nEq/L, at 37° C. The relationship between pH and serum H^+ is nonlinear, but it is almost linear over the narrow normal range of 7.35 to 7.45 (corresponding to 45 to 35 nEq/L of H^+).[9]

Acids, Bases, Buffers: The Traditional Understanding

An acid is *strong* when it dissociates its hydrogen ion easily because the corresponding base has a low affinity for it (high Ka–dissociation constant value). *Weak* acids only partially dissociate because their corresponding base has high affinity for hydrogen ions (low K_a value). When the latter is the case, both the hydrogen ion and the base form of the parental molecule are present in the resulting solution in equimolar proportions. As a consequence, this solution has the ability to resist changes in acidity (or pH) after the addition of a strong acid or base. This solution, constituted by an acid-base pair, is known as a buffer. The dissociation constant K_a, as in the case of pH, can be expressed as $\log_{10}K_a$, is termed pK_a, and represents a measure of the tendency of the acid-base pair to ionize. Strong acids have a low pK_a (high K_a) and weak acids have high pK_a (low K_a). A weak acid-base pair is more effective as a buffer in living systems when the pK_a is close to physiologic pH.[6,7,10]

Physiologic buffering systems may be classified into two general categories: the bicarbonate/carbonic acid (HCO_3^-/H_2CO_3) buffering system, that acts in both the extracellular space and inside the cells, and the nonbicarbonate buffers, which include hemoglobin and oxyhemoglobin, organic phosphates, inorganic phosphates, and plasma proteins. Extracellular buffers (HCO_3^-, plasma proteins) represent the body's first and immediate line of defense against any alteration of pH of the body fluids. After extracellular buffering occurs, a second intracellular phase takes place, as long as intracellular buffers (intracellular proteins, dibasic phosphates, hemoglobin-oxyhemoglobin, and carbonate in bones) reach

buffering capacity over the next several hours.[10] The buffering systems cannot truly eliminate hydrogen ions from the body, but they tamper sudden changes in $[H^+]$ (or pH) and "buy time" until a new balance can be achieved. Altogether, extracellular and intracellular buffers provide a volume of distribution close to that of the total body water to any exogenous acid load (or deficit). This represents a formidable capacity for resisting changes in pH.

Acid Production in the Body

Acid production in the body occurs in two major ways. The first one involves CO_2 production during oxidative metabolism of carbohydrates, fat, and amino acids. The CO_2 is then hydrated by the cytoplasmic enzyme carbonic anhydrase to produce carbonic acid (H_2CO_3), a weak acid that dissociates in hydrogen ion and bicarbonate.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (3)$$

The second pathway involves nonvolatile metabolic acids that are produced by the normal daily catabolic load (oxidation of sulfur-containing amino acids, hydrolysis of pyrophosphate and orthophosphate esters) or during situations with incomplete catabolism of fat and carbohydrates, such as lactic acidosis or diabetic ketoacidosis (DKA). The free hydrogen ions are neutralized by extracellular and intracellular buffers, but because these acids are not in equilibrium in the normal plasma, they must be metabolized, mainly in the liver, and then excreted by the kidneys.[10]

The major acid-base buffering system in the blood is the bicarbonate/carbonic acid system, which has the tremendous advantage of interconversion of CO_2 with H_2CO_3. Any increase in $[H^+]$ (or drop in pH) will shift the former reaction (Equation 3) to the left through an increase in both alveolar ventilation and elimination rate of CO_2. This respiratory response begins within minutes, but may not reach a steady state for 12 to 24 hours. This method of achieving a rapid decrease of the actual acid component is a unique characteristic of the bicarbonate/carbonic acid buffering system. For the other buffers, the addition or removal of hydrogen ions has the corresponding opposite effect on the buffer components, limiting the maximum buffering capacity. On the contrary, the capacity of the bicarbonate-CO_2 system is greatly increased because the lungs can eliminate a vast amount of CO_2 per day. Similarly, the kidneys can eliminate or regenerate bicarbonate as needed, although this response is slower than that of the lungs.

The Classic Paradigm: H^+ Depends on CO_2, H_2CO_3, and HCO_3^-

The quantitative importance of the bicarbonate/carbonic acid buffering system was clearly noticed by Henderson when he developed his famous equation, which was modified by Hasselbalch shortly after. The Henderson-Hasselbalch equation[4,5] expresses the relationship of the bicarbonate/carbonic acid buffering system to pH:

$$pH = pK_a + \log([HCO_3^-]/[H_2CO_3]) \quad (4)$$

The pH is equal to a constant (pK_a, the $\log_{10}$ of K_a, the first dissociation constant for H_2CO_3, which has a value of 6.1 for human plasma in physiological conditions) plus the log of the ratio of HCO_3^- (proton acceptor) to H_2CO_3 (proton donor). The modified Henderson-Hasselbalch equation takes into consideration that H_2CO_3 is in equilibrium with dissolved CO_2 and is rewritten as[9]:

$$pH = pKa + \log([HCO_3^-]/0.03 \times PCO_2) \quad (5)$$

where *0.03* is the solubility coefficient for carbon dioxide in blood at 37° C.

What the Henderson-Hasselbalch equation tells us is how pH is affected by the change in the ratio of the concentration of nondissociated acid HA (in this case carbonic acid or PCO_2) to the concentration of the conjugated base or anion A^- (in this case HCO3$^-$). When pH is altered as the result of changes in the volatile component (increases or decreases of PCO_2), clinically speaking, the change is referred to as *respiratory*.[9] When pH is modified by changes in nonvolatile acids (e.g., lactic acid, keto acids), or by changes in serum cations and/or anions (e.g., hyperchloremia/hypochloremia), it is referred to as *metabolic in origin*.[5,8,9] The term *acidosis* is used to describe the process that tends to produce an increase in H^+, whether or not there is a change in pH. *Alkalosis* is the opposite; that is, the process that tends to produce a decrease in H^+, with or without changes in pH. *Acidemia* and *alkalemia* are the corresponding terms for those situations in which blood pH actually changes.[9] Thus this equation allows disorders to be classified according to the primary type of acid being increased or decreased. For example, if a patient's pH is low (acidemia), then the patient may have either an increased PCO_2 or a PCO_2 within normal or decreased values. If the PCO_2 is increased (alveolar hypoventilation), the condition is classified as *respiratory acidosis*. If it is not increased, there cannot be a respiratory acidosis. Therefore some nonvolatile acid or anion must be the cause of the acidemia, and this is then referred to as *metabolic acidosis*. If these examples are reversed, then alkalemia can also be classified as resulting from either respiratory or metabolic alkaloses.[9]

The Henderson-Hasselbalch equation is useful but has intrinsic limitations.[5,8] The first one is that it does not quantify the severity of the metabolic derangement as it does for the respiratory component. In a respiratory acidosis, the increase in the PCO_2 quantifies the derangement even when there are mixed disorders. The metabolic component can only be approximated, however, by the change in HCO_3^-. Although the relationship between PCO_2 and HCO_3^- provides a useful clinical guide for uncovering a metabolic origin of a given derangement, this is dampened because PCO_2, H_2CO_3, and HCO_3^- are all interlinked (Equations 3 and 5), so the bicarbonate will also increase if PCO_2 increases.[6,8] The second important characteristic of the Henderson-Hasselbalch equation is that it does not provide information about any acids other than carbonic acid.

Using the Brönsted-Lowry definition of acid as a "proton donor,"[4,6,7,11] many physiologists dismissed defining chloride as an acid and sodium as a base, arguing that there was an insufficient link between these and other electrolytes and the subsequent changes in hydrogen ions. Thus, by accepting only Brönsted-Lowry acids while looking for factors controlling the nonrespiratory component of acid-base balance, many physiologists focused on the plasma bicarbonate concentration and the Henderson-Hasselbalch equation.[5] This was the beginning of the still-dominant concept that plasma bicarbonate is not only the best indicator of acid-base status, but also a main determinant of it. Unfortunately, this way of thinking

overlooked the fact that *all* weak acids in a given aqueous solution such as plasma can be inserted into a Henderson-Hasselbalch type of equation to calculate pH, as Lawrence Henderson himself demonstrated in 1908.[4] The reason is easy to understand: for a single solution containing several weak acids (as human plasma), all the weak acids are equilibrated with a single pool of hydrogen ions. This is called the isohydric principle.[5] Consider two buffer systems: bicarbonate/carbonic acid and phosphate/phosphoric acid:

$$H_2CO_3 \leftrightarrow HCO_3^- + H^+ + HPO_4^{2-} \leftrightarrow H_2PO_4^- \qquad (6)$$

Note that the H^+ that will eventually form both carbonic acid and phosphoric acid actually comes from the single plasmatic pool. Expressing the same concept in the Henderson-Hasselbalch way:

$$pK_{a1} + \log([HCO_3^-]/[H_2CO_3]) = pH = pK_{a2} + \log([HPO_4^{2-}/[H_2PO_4^-]) \qquad (7)$$

Thus according to the isohydric principle, the ratio of *any pair* of conjugate base or anion and its nondissociated acid will be able to describe the H^+ or pH.[5,12] This means that although the ratio of PCO_2 to bicarbonate can describe what the pH and acid-base status is, the system bicarbonate/carbonic acid is not necessarily the primary or underlying mechanism for explaining changes in pH.

Correlation and causation are not the same.[5,8] Immersed in the bicarbonate-centered approach, investigators yielded basically three solutions for analyzing the "metabolic side" of the equation: the base excess method, the six bicarbonate "rules of thumb," and the use of anion gap (AG).[4,5,9,13-15]

Base Excess and Standard Base Excess

The change in pH of a given buffered solution is dependent on both the amount of strong acid (or strong base) that is added, and on the buffering capacity of the system. As acid is added, for every H^+ that is buffered, one molecule of conjugate base of the buffer is consumed. Therefore, quantifying the changes in the concentration of the conjugate base of the buffer is more useful than the degree of change in the pH in estimating the amount of nonvolatile acids present.

Siggaard-Andersen, from Copenhagen, developed the "base excess" method in the late 1950s.[4,14,15] Base excess (BE) is defined as the amount of strong acid (or strong base), in moles per liter (mol/L), that must be added to a whole blood sample to return the pH of the sample to 7.40, while the PCO_2 is maintained at 40 mm Hg.[5,15,16] Therefore if the blood sample is normal (i.e., its pH is 7.4 and its PCO_2 is about 40 mm Hg), the BE will be 0 mmol/L. Positive values mean literally an excess of metabolic bases; negative values mean an excess of metabolic acids.[9,15,16] To apply the BE to the clinical setting, a nomogram was developed that was later mathematically transcribed to allow BE calculation by blood gas analyzers.[17,18] However, several flaws appeared.[19-21] For clinical accuracy, other assumptions had to be incorporated (correction factors, adjusted formulas, nomogram modifications),[5,18,22] and, remarkably, an empiric estimate of hemoglobin concentration throughout the entire extracellular fluid space (whole blood plus interstitial fluid) had to be established, in order to consider the net effect of the intracellular buffers, hemoglobin the main one.[5] A hemoglobin concentration of 50 g/L (5 g/dL)[5,22] was chosen to calculate standard base excess (SBE), a parameter reported nowadays by modern gas analyzers and used in the classical approach to acid-base balance (Table 68-1). Although SBE has good correlation with bicarbonate levels and quantifies the change in metabolic acid-base status in vivo, its accuracy depends on the 5 g/dL of hemoglobin assumption, and it still does not provide information about the origin or mechanisms of the metabolic acid-base derangement because SBE is not a substance that can be regulated, absorbed, or excreted by the body.[8] Perhaps the main pitfall is that the SBE value represents the net effect of all metabolic acid-base abnormalities. Therefore the effects of coexisting metabolic acidoses and alkaloses may cancel each other, and the normal figure of the SBE will mistakenly suggest that no acid-base derangement exists. Actually, 15% to 18% of critically ill adults with acid-base disorders have a normal SBE.[13,23]

Bicarbonate Rules

In a "great transatlantic debate,"[18,21] strong criticism of the SBE from Schwartz and Relman from Boston yielded the six bicarbonate "rules of thumb" (Table 68-2).[18] The Henderson-Hasselbalch equation easily disclosed derangements into "respiratory" and "metabolic," the so-called *simple derangements*.[9] Because the body always seeks to tightly control H^+, however, several physiologic responses become active over time, and then the relationship between PCO_2 and HCO_3^- is modified so pH changes can be minimized. This minimization gives origin to more complex or "mixed" conditions.[9,10,24] Despite this, through careful examination of the changes that occur in PCO_2 and HCO_3^- in relation to each other, it was possible to find patterns and to derive rules (the so-called *six rules of thumb*) for uncovering mixed disorders and to differentiate acute from chronic respiratory unbalances. These rules describe the physiological compensation to acid-base changes to optimize acid-base homeostasis. With the expected physiologic compensation allowed for, residual changes in CO_2 or bicarbonate are then seen as the mechanisms for changes in acid-base status (Tables 68-2 and 68-3). This approach is still the most practical acid-base balance diagnostic tool for the busy clinician.[9]

Anion Gap and Corrected Anion Gap

The AG was introduced as a complementary diagnostic tool for either SBE or bicarbonate rules-of-thumb approaches to metabolic disturbances.[25] It is based on the principle of electroneutrality, which states that there is no electrical charge in plasma. Accordingly, serum positive-charged cations must equal serum negative-charged anions[9] (see Table 68-1):

$$[Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}] + [H^+] = [Cl^-] + [HCO_3^-] + [\text{proteins}^-] + [PO_4^{3-}] + [SO_4^{2-}] + [OH^-] + [CO_3^{2-}] + [XA^-]) \qquad (8)$$

where *[XA⁻]* is the unmeasured acid anions. Sometimes they are abbreviated as UMAs.

The plasma concentrations of SO_4^{2-}, OH^-, CO_3^{2-}, and H^+ are quite small and can be neglected. Concentrations of Na^+, K^+, Cl^-, and HCO_3^- (in the form of total CO_2) are reported in a standard chemistry panel. The sum of the remaining anion

Table 68–1 Classical Acid-Base Parameters

pH	$\log_{10} H^+$. Measured directly by electrode. Normal = 7.35–7.45.
PCO_2	Partial pressure of gaseous CO_2. Measured directly by electrode. Usually expressed in mm Hg. Normal value: 35–45 mm Hg (sea level, arterial blood).
HCO_3^-	Bicarbonate concentration. A calculated parameter, derived from pH and PCO_2 values using a nomogram or the Henderson-Hasselbalch equation, or equal to the difference between serum total CO_2 (CO_{2TOT}) and the dissolved CO_2. ($PCO_2 \times 0.03$). Normal value: 22–28 mEq/L.
Base excess (BE or BE/D)	Also known as base excess/deficit. Defined as the amount of strong base (negative base excess, or "base deficit") or strong acid (positive base excess) in mmol/L that would be needed to restore a pH of 7.4 to a liter of whole blood equilibrated at PCO_2 = 40 mm Hg. It is calculated by a nomogram or equation that was derived from an experimental series of in vitro titrations of strong acid and base in whole blood samples at various PCO_2 levels. It excludes the effect of acute changes in PCO_2, so it loses accuracy if PCO_2 is abnormal. It should not be used in critically ill patients.
Standard base excess (SBE)	An improvement of base excess to allow equilibration across the entire extracellular fluid space (whole blood interstitial fluid) and thus preserve accuracy at variable PCO_2 values. The new equation assumes an "average" concentration of hemoglobin through that space of 5 g/dL. Despite being a somewhat arbitrary figure, it indeed works in vivo.
CO_{2TOT} or CO_2	Total CO_2 or CO_2 concentration. A serum chemistry measured value. Its components include HCO_3^-, dissolved gaseous CO_2, carbonic acid (H_2CO_3), carbamino CO_2, and carbonate (CO_3^{2-}). About 95% exists as HCO_3^-, and 4% to 5% as dissolved gaseous CO_2. Remaining species are negligible. Because the difference between CO_{2TOT} and HCO_3^- is about 1 mEq/L at physiological pH, for clinical purposes they are taken almost as equivalents.
Anion gap (AG)	A calculated value that, taking advantage of the electroneutrality principle that rules plasmatic ions (total amount of cations should be the same as the total amount of anions), indicates the presence of "unmeasured" anions (mostly organic acids). $AG = (Na^+ + K^+) - (Cl^- + HCO_3^-)$. Normal values are 16 mEq/L (if K^+ is included) or 12 mEq/L (without K^+, with variations of ± 2 to 4 mEq/L. These values may be influenced by the way the values of some of the parameters are measured, so it is always better to consult each institution's own expected normal AG.
Corrected anion gap (AG_{CORR})	An improvement in the calculation of AG, that acknowledges that an increase in AG from organic acids may be masked by a decrease in AG from low protein (albumin) levels. AG is corrected for the patient's own albumin concentration as follows: $AG_{CORRECTED} = AG_{OBSERVED} \times 2.5$[normal albumin (g/dL)] – [observed albumin (g/dL)], considering normal albumin from 3.2 to 4.5 g/dL. In order to avoid [lactate$^-$] influence on AG_{CORR} that could mask the detection of other unmeasured anions, it has been suggested that AG should be corrected not only for albumin, but also for lactate. This is simply made by subtracting the serum lactate concentration (in mmol/L) from the already albumin-corrected AG: $AG_{CORRLACT}$ = Albumin-corrected AG – [lactate$^-$ (mmol/L)].
Urinary anion gap (uGap)	The same principle of the anion gap applied to urinary ions, that is, uGap estimates unmeasured urinary ions. It has also been designated by some as urine strong ion difference (uSID), a functionally correct name, as all the involved ions are strong ions: $uGap = uSID = [uNa^+ + uK^+] - [uCl^-]$. The most important unmeasured urinary strong anion (Ur^-) is SO_4^{2-} (derived from the metabolism of sulfur amino acids), whereas the most important unmeasured cation (Ur^+)is ammonium (NH_4^+). In physiologically normal conditions, uSID must equal the plasmatic SID_{APP}, or 38–42 mEq/L.

Table 68–2 Classical Acid-Base Approach: Observational Acid-Base Patterns

Primary Disorder	Expected Changes $[HCO_3^-]$ (mEq/L or mmol/L)	Expected Changes PCO_2 (mm Hg)	Expected Changes SBE (mmol/L)
Metabolic acidosis	<22	$= (1.5 \times HCO_3^-) + (8 \pm 2)$ $= 40 + SBE$	<–5
Metabolic alkalosis	>26	$= (0.7 \times HCO_3^-) + (21 \pm 2)$ $= 40 + (0.6 \times SBE)$	>+5
Acute respiratory acidosis	$= [(PCO_2 - 40)/10] + 24$	>45 or $\Delta pH = 0.008 \times (PCO_2 - 40)$	= 0
Chronic respiratory acidosis	$= [(PCO_2 - 40)/3] + 24$	>45 or $\Delta pH = 0.003 \times (PCO_2 - 40)$	$= 0.4 \times (PCO_2 - 40)$
Acute respiratory alkalosis	$= [(40 - PCO_2)/5] + 24$	<35 or $\Delta pH = 0.008 \times (40 - PCO_2)$	= 0
Chronic respiratory alkalosis	$= [(40 - PCO_2)/10] + 24$	<35 or $\Delta pH = 0.017 \times (40 - PCO_2)$	$= 0.4 \times (PCO_2 - 40)$

Table 68–3 Classical Acid-Base Approach: Additional Clues

1. A metabolic acid-base derangement exists if:
   a. pH is abnormal.
   b. pH and PCO_2 have changed in the same direction (both increased or both decreased).
   c. Respiratory compensation is intact if P_aCO_2 resembles last two digits of pH (e.g. pH 7.23 and P_aCO_2 ≤23 mm Hg).
2. A respiratory acid-base derangement is overlapped if any of the following occurs:
   a. pH is abnormal but PCO_2 is reported within normal limits.
   b. PCO_2 reported is higher than expected PCO_2 (respiratory acidosis overlapped).
   c. PCO_2 reported is lower than expected PCO_2 (respiratory alkalosis overlapped).
3. A respiratory acid-base derangement exists if:
   a. P_aCO_2 is abnormal.
   b. PCO_2 and pH have changed in opposite directions (i.e., raised PCO_2 and decreased pH or vice versa).
4. If the change of pH is … (see formulas in Table 68-2)
   a. 0.008 × change in PCO_2, there is no compensation; then the derangement is acute.
   b. >0.003 but <0.008 × change in PCO_2, there is a partial compensation.
   c. 0.003 × change in PCO_2, there is full compensation; then the derangement is chronic.
   d. >0.008 × change in PCO_2, there is an overlapping metabolic derangement.
5. There is a mixed derangement (acidosis and alkalosis) if any of the following occurs:
   a. P_aCO_2 is abnormal and pH has not changed as expected or is within normal values.
   b. pH is abnormal and P_aCO_2 has not changed as expected or is within normal values.

Modified from Marino PL: Acid-base interpretations. In: *The little ICU book of facts and figures,* Philadelphia, 2009, Lippincott Williams & Wilkins, pp 349-362.

species, proteins$^-$, PO_4^{3-}, and XA^-, is defined as the unmeasured anions (UA), whereas the sum of the remaining cation species, Ca^{2+} and Mg^{2+}, is defined as the unmeasured cations (UC). Thus AG is commonly defined as[9]:

$$AG = UA - UC = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) \quad (9A)$$

Sometimes [K+] and its effect are disregarded[26]:

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \quad (9B)$$

Typically, normal values are 16 mEq/L (if K^+ is included) or 12 mEq/L (without K^+), with variations of ±2 to 4 mEq/L. These values may be influenced by the way the values of some of the parameters—particularly chloride levels—are measured, so it is always better to consult each institution's own expected "normal AG."[26,27]

It must be realized that calculated AG is affected by any change in the concentrations of either the UA or UC. Plasma proteins and phosphate levels can be significantly decreased in the critical care setting. Reduced protein and phosphate levels result in a decreased UA and hence in a decreased AG. Therefore, an increase in AG from organic acids may be masked by a decrease in AG from low protein and phosphate levels and thus it is wise to make the proper corrections.[28] This is particularly true in the pediatric critical care setting, where hypoalbuminemia is nearly ubiquitous.[26,29,30] Phosphate influence is rather small, and so is the effect of globulins, since their pK_a is much greater than plasma pH (they do not easily dissociate) and hence they do not have a significant H^+ contribution.

Figge et al. showed that in most patients, the AG could be corrected (AG_{CORR}) as follows[26]:

$$AG_{CORR} = AG_{OBSERVED} + 0.25 \times [\text{Normal albumin (g/L)}] - [\text{Observed albumin (g/L)}] \quad (10)$$

considering normal albumin from 3.2 to 4.5 g/dL.

The albumin-corrected AG (AG_{CORR}) can unmask an organic acidosis previously undetected in the setting of hypoalbuminemia, and adds sensitivity for detecting unmeasured anions, including lactate, although the specificity for hyperlactatemia is poor.[28,31-33] Thus lactate must be directly determined.

Despite the fact that it is not useful for quantifying the metabolic derangement, AG is a powerful tool for the clinician in the categorization of metabolic acidoses, as not all metabolic acidoses result in an elevated AG.[34] As an hypothetical example, the reader might consider that acid in the form of HCl is added to the circulation. Upon dissociation, Cl^- remains as the conjugate base, while the plasmatic bicarbonate buffer is "consumed" by the hydrogen ion. The result is that an increase in Cl^- is balanced by a decrease in HCO_3^-, that is, there is metabolic acidosis without a change in the AG. Thus through the AG_{CORR} it is possible to differentiate hyperchloremic acidosis (normal AG) from "gap acidoses" (increased AG).[26,34] The last category includes all conditions of metabolic simple acidosis caused by increased concentrations of nonvolatile anions other than chloride, usually unmeasured (or unmeasurable), such as lactate, keto acids, phosphate, sulfates (and other anions in renal failure setting), salicylate, some β-lactam antibiotics, organic acids from congenital errors of metabolism, and acetate from parenteral nutrition (Table 68-4).[31,34] Non-AG hyperchloremic acidoses include excessive infusion of chloride salts (saline or parenteral nutrition) and increased renal or gastrointestinal bicarbonate losses. On the contrary, metabolic alkalosis may stem from hypochloremia from chloride loss or bicarbonate gain, and from hypoalbuminemia.[31] AG performance is not so good in mixed acid-base physiology, despite several attempts to improve it. This represents an important limitation to its use in critical care patients, in whom single metabolic acid-base disorders are more the exception than the rule. In spite of several attempts, the "corrections" and adaptations for the AG that have been proposed in order to detect mixed disorders have not fulfilled the expectations.[24,31]

Water as the Main Source of Hydrogen Ions: The Stewart Approach

It is remarkable that not one of the classic acid-base approaches examined the role of water as a virtually inexhaustible source of hydrogen ion, as Peter Stewart later did.[5,8,35] Although pure water dissociates only slightly into H^+ and OH^- in plasma, the presence of electrolytes, CO_2, and other weak acids produces powerful electrochemical forces influencing water dissociation.[8] In the late 1970s and early 1980s, Peter Stewart proposed that Arrhenius' more general definition of an acid, along with Naunyn's ideas from 1900, was more useful to acid-base physiology than the Brönsted-Lowry definition.[36,37] Applying several basic principles of physical chemistry, particularly

Table 68–4 Causes of Metabolic Acidosis in Critically Ill Patients

I. Accumulation of unmeasured anions: the anion gap acidoses
  A. Endogenous source of acids
    1. Type A hyperlactatemia (decreased tissue O_2 delivery)
    2. Type B hyperlactatemia (not associated with tissue hypoxia)
    3. Ketoacidosis (diabetic, alcoholic, starvation)
    4. Renal failure: accumulation of phosphates, sulfates, and organic ions
    5. Unidentified anions in sepsis other than lactate
    6. Certain organic acids from inborn errors of metabolism
    7. Late metabolic acidosis of prematurity
  B. Exogenous source of acids
    1. Ingested toxins and drugs that directly provoke acidosis
      a. Methanol, formic acid, keto acids, lactate
      b. Ethylene glycol, glycolic acid, oxalic acid, paraldehyde
      c. Ethanol
      d. Salicylate, salicylic acid, acetic acid
      e. Illegal drugs
    2. Total parenteral nutrition*
II. Hyperchloremic acidoses: the non–anion gap acidoses
  A. Exogenous chloride load
    1. Normal saline or hypertonic saline resuscitation
    2. HCl, NH_4Cl, arginine HCl administration
    3. Total parenteral nutrition*
  B. Loss of cations from the lower gastrointestinal tract (postpyloric gastrointestinal fluid losses)†
    1. Infectious secretory diarrhea and dehydration
    2. Short bowel syndrome
    3. Drainage from ostomies, tubes, fistulas (small bowel, pancreatic, or biliary drainage)
    4. Sulfamylon, cholestyramine
  C. Renal causes‡
    1. Chronic renal insufficiency (impaired ammonium [NH_4^+] generation)
    2. Renal tubular acidoses
    3. Hypoaldosteronism
    4. Recovery phase of diabetic ketoacidosis
    5. Urinary tract obstruction
    6. Drug-mediated loss of cations and tubulopathies
      a. Acetazolamide
      b. Amphotericin B
      c. K^+-sparing diuretics
  D. Urinary reconstruction using bowel segments

*Total parenteral nutrition may cause both anion gap and non-anion gap acidosis. In the first case, an excessive amount of exogenous acids is the cause, mainly if liver or renal functions are impaired; in the latter, an unbalanced, excessive chloride content in the formulation provokes the derangement, which is easily produced in the setting of renal failure.
†This class corresponds to the gastrointestinal loss of bicarbonate type of acidosis, according to the classical approach.
‡This class corresponds to the renal loss of bicarbonate type of acidosis, according to the classical approach.

electroneutrality, conservation of mass, and dissociation equilibrium of partially dissociated substances (electrolytes and others),[5,8,13,38] Stewart developed a mathematical model of acid-base balance. He defined the system as an aqueous solution that contains strong ions that are completely dissociated at physiologic pH, weak acids that are partially dissociated at physiologic pH, and carbon dioxide that is in equilibrium with an external partial pressure of carbon dioxide. The main concepts of this approach are summarized in Table 68-5, and a classification of primary acid-base disturbances based in this system is presented in Table 68-6. Thus according to Stewart, there are only three independent controlling variables of H+ concentration[5,8,38-40]:

1. Partial pressure of carbon dioxide (PCO_2).
2. The strong ion difference (SID). Blood plasma contains numerous ions, which may be classified not only in regard to their electrical charge (cations are positive, anions are negative), but also according to their tendency to dissociate. Some ions are fully dissociated and chemically nonreacting in aqueous solutions, and are called "strong ions," such as Na^+, K^+, Ca^{2-}, Mg^{2+}, and Cl^-. Others, such as albumin, phosphate and HCO_3^-, can exist both as charged (i.e., dissociated) and uncharged forms, and are called "weak ions." Certain organic acids, such as lactate and others, are nearly completely dissociated under physiologic conditions, and so are considered strong ions. In blood plasma, strong cations outnumber strong anions. The difference between the sum of all strong cations and all the strong anions is called SID. Sodium and chloride are the two most important plasmatic strong ions.[23,41]
3. The total concentration of nonvolatile weak acids (A_{TOT}), that is, for each of them, the sum of its dissociated and undissociated forms ($A_{TOT} = A^- + HA$).[13,36,38-40] The most important weak acid—partially dissociated acid—is albumin, with a minor effect from phosphate.

"Independent variables" mean that PCO_2, SID, and A_{TOT} are causally related to the hydrogen ion, rather than being merely correlated.[38,39] Normal acid-base status occurs when the independent variables have normal values. Abnormality of one or more of the independent variables underlies all acid-base disturbances. Adjustment of the independent variables is the essence of all therapeutic interventions, because none of the dependent variables (e.g., pH, BE, HCO_3^-) can be changed primarily or individually; the dependent variables change all of them simultaneously if, and only if, one or more of the independent variables changes.[8,13,39] Since PCO_2 is regulated by respiration, its changes result in respiratory acid-base disorders. Metabolic acid-base disorders stem both from changes in either SID or A_{TOT}.

CO_2 and Bicarbonate in Stewart's Approach

In Stewart's approach, CO_2 represents a primary independent determinant of pH, just as in the bicarbonate-BE-centered approaches, that is, there are no changes in the understanding of the respiratory acid-base derangements. However, the role of bicarbonate is reduced from being causative to a mere indicator, as hydrogen ion and bicarbonate concentrations are totally dependent on the three independent controlling variables. Hence, according to Stewart, the major use for the bicarbonate rules of thumb and SBE are to determine the extent of the clinical acid-base disorder, rather than the mechanism.[5,8,39]

The rise of the PCO_2, according to the Henderson-Hasselbalch equation (Equation 5), will increase both H^+ and HCO_3^- concentrations. Therefore the change in HCO_3^- concentration is mediated by chemical equilibrium (Equation 3) and not by any systemic adaptive response.[8] The total CO_2 concentration (and hence the $[HCO_3^-]$) is determined by the PCO_2, which is in turn determined by the balance between alveolar ventilation and CO_2 production at tissue level. Therefore HCO_3^- cannot

Table 68–5 Concepts and Parameters Used in the Quantitative Physical-Chemical Approach to Acid-Base Balance: A Summary

Variable	Comment
Strong ions	Blood plasma contains numerous ions, which may be classified not only in regard to their electrical charge (cations are positive, anions are negative), but also according to their tendency to dissociate. Some ions (such as Na^+, K^+ Ca^{2+}, Mg^{2+}, and Cl^-), are fully dissociated, chemically nonreacting in aqueous solutions, and are called "strong ions." Certain organic acids, such as lactate and other nonvolatile organic acids, are nearly completely dissociated under physiologic conditions, and so they are considered weak ions.
Weak ions	Ions that can exist both as charged (i.e., dissociated) and uncharged forms, such as albumin, phosphate, and HCO_3^-.
Strong ion difference (SID)	In blood plasma, strong cations outnumber strong anions. The difference between the sum of all strong cations and all the strong anions is called SID. Sodium and chloride are the two most important plasmatic strong ions.
Apparent strong ion difference (SID_{APP})	When SID is calculated from direct measurement of serum strong ions, it is termed apparent SID (SID_{APP}): $SID_{APP} = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl^-])$. Ionized concentrations of Mg and Ca are used. If available, lactate should be included: $SID_{APP} = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl^-] + [lactate^-])$. In healthy volunteers, the usual SID_{APP} is 38–42 mEq/L. In stable critical care patients, SID_{APP} is around 33 ± 5.6 mEq/L. If this patient then has metabolic acidosis, SID_{APP} will decrease further. The lower the baseline of the SID_{APP}, the greater the susceptibility to a subsequent acid load.
Effective strong ion difference (SID_{EFF})	According to the principle of electroneutrality, blood plasma cannot be charged, so there should be remaining negative charges balancing the "excess" of plasma strong cations in relation to the strong anions; this is the origin of SID_{APP}. These balancing negative charges come from total CO_2 (~$[HCO_3^-]$) and from albumin and inorganic phosphate. Thus SID can be derived, accounting for electrical neutralitiy, as the sum of $[HCO_3^-]$ plus the negative electric charges contributed by albumin ($[Alb^-]$) and by inorganic phosphate ($[Pi^-]$). This calculation of SID is known as effective SID (SID_{EFF}): $SID_{EFF} = [HCO_3^-] + [Alb^-]$ (g/L) + $[Phosphate^-]$ (mmol/L). The negative electrical charges contributed by serum albumin and phosphate are as follows: [Alb] = [Alb] × (0.123 × pH × –0.631) and [Phosphate] = [Phosphate] × (0.309 × pH × [–0.469]). Taking in account the complexity of the albumin molecule, its charge should be expressed as a linear function of the pH. Thus, a more accurate calculation of SID_{EFF} is: $SID_{EFF} = 2.46 \times 10^{-8} \times PCO_2/10 - pH +$ [albumin (g/dL)] × (0.123 × pH –0.631) + [Phosphate (mg/dL)] × (0.309 × pH – 0.469). For its clinical application, this equation needs access to an Internet-based engine designed for calculating the SID_{EFF} and other physicochemical acid base parameters (consult http://www.acidbase.org).
Strong ion gap (SIG)	In the healthy individual, SID_{APP} and SID_{EFF} are nearly identical. In disease states, this may not be true, as plenty of unmeasured ions not included in equations may be present in plasma (e.g., ketones, sulfates, organic acids from inborn errors of metabolism, certain medications), along with abnormal weak ions (such as proteins). Clearly, this will make both SID_{APP} and SID_{EFF} inaccurate. So, the simplest way to approximate $[XA^-]$ is through the SIG. This term is far from ideal, since the unmeasured anions creating the 'gap' can be either strong or weak. It is calculated as follows: $SIG = SID_{APP} - SID_{EFF}$ with the result expressed in mEq/L. By convention, SIG is positive when unmeasured anions exceed unmeasured cations (acidosis) and negative when unmeasured cations exceed unmeasured anions (alkalosis).
Nonvolatile weak acids (A_{TOT})	These are acids that cannot be eliminated by respiration (unlike H_2CO_3 through its conversion to CO_2), and that have a pKa almost equal to the physiological pH of 7.4. Therefore weak acids, as opposed to strong ions, can exist at physiologic pH as dissociated (A^-) or associate with a proton (AH). Weak acids are often referred to as buffers. The concentration of each one of these weak acids, is the sum of its dissociated and undissociated forms: $A_{TOT} = AH + A^-$ The two nonvolatile weak acids with great enough concentrations in plasma to have an influence on acid-base status are albumin and inorganic phosphate, the latter having a minor effect. They provide the remaining charges to satisfy electroneutrality.
Independent variables	PCO_2, SID, and A_{TOT} are the independent variables that control acid-base status, which means that they are causally related to the hydrogen ion, rather than being merely correlated. Normal acid-base status occurs when the independent variables have normal values. Abnormality of one or more of the independent variables underlies all acid-base disturbances.
Unexplained, or unmeasured, or unidentified acid anions (abbreviated as XA^- or UMA)	Includes organic acids not routinely measured, such as lactate (if not measured), and keto acids. They are the main self-unmeasured acids. Additionally, sulfates and other acids may be high in the chronic renal failure setting, and less common organic acids may appear in other scenarios, as in inborn errors of metabolism. Exogenous UMAs may include salicylate, formate, and other drug or toxic-derived acids that can be responsible for acidosis in some patients. All these (XA^- or UMAs) are strong acids.

Table 68–5 Concepts and Parameters Used in the Quantitative Physical-Chemical Approach to Acid-Base Balance: A Summary—Cont'd

Variable	Comment
Partitioned standard base excess (SBE) or BE gap	It is an attempt to combine the approaches of Siggaard-Andersen and Stewart in a kind of physicochemical adjusted standard base excess (SBE), which seeks to quantify the effect of each individual metabolic component of standard base excess, i.e., each component has its own "adjusted" or "partitioned" SBE. The lab-reported SBE, or total SBE (SBE_{TOTAL}) should equal the sum of the BE for each one of the components. More specifically, $SBE_{TOTAL} = BE_{fw} + BE_{Cl} + BE_{alb} + BE_{XA}$, where the effects of free water (fw), chloride (Cl), albumin (alb), and unexplained or unmeasured anions (XA^- or UMAs) were taken in account. The level of XA^- is, of course, unknown. Hence, the SBE for the unmeasured anions is determined from the others. This is termed by some as the "BE gap": BE_{XA} (also abbreviated as BE_{UMA}) = $SBE_{TOTAL} - BE_{fw} - BE_{Cl} - BE_{alb}$. BE_{fw} and BE_{Cl} (sodium and chloride effects), both being strong ions, were later combined in a single BE due to SID (BE_{SID}): BE_{XA} or $BE_{UMA} = SBE_{TOTAL} - BE_{alb} - BE_{SID}$ in which $BE_{ALB} = (42 - [albumin]) \times 0.25$, and $BE_{SID} = [Na^+] - [Cl^-] - 32$. These values are used to solve the equation: BE_{XA} or $BE_{UMA} = SBE_{TOTAL}$ (blood gas analyzer-derived) – $\{(42 - [albumin]) \times 0.25\} - \{[Na^+] - [Cl^-] - 32\}$.

Table 68–6 Classification of Primary Acid-Base Disturbances: Independent Variables-Oriented Approach

RESPIRATORY		**METABOLIC***					
ALTERATION IN P_aCO_2		**IMBALANCE OF STRONG IONS**				**ABNORMAL NONVOLATILE WEAK ACIDS†**

↑ P_aCO_2	**↓ P_aCO_2**	**↓ SID, ↑ SIG^-**	**↓ SID, ↓SIG**	**↑ SID**	**↑ SID**	**↑ A_{TOT}**	**↓ A_{TOT}**
Central nervous system depression: brain edema from head trauma, from sedation, etc. Neuromuscular function impairment, damage to efferent nerves or to the muscles of respiration Lungs (airway and alveoli)	Inappropriately set mechanical ventilation parameters, central nervous system disorders, and some psychiatric diseases	**Endogenous**: Lactic acid, ketoacids, inborn errors of metabolism, sulfates, late metabolic acidosis of prematurity, etc. **Exogenous**: salicylate, methanol, ethylene glycol, diethylene glycol, propylene glycol, etc.	**Exogenous Cl load**: Sodium chloride resuscitation, TPN, etc. **Loss of cations from postpyloric losses** without proportional losses of chloride: secretory diarrhea, drainage tubes, ostomies, fistulas. **RTA and drug mediated tubulopathies**: amphotericin B, topiramate, acetazolamide, etc. **Urinary reconstruction using bowel segments**	**Cl responsive**: Gastrointestinal losses of Cl^-: Vomiting, gastric drainage, chloride-wasting acute diarrhea Renal losses of Cl^- and K^+: diuretics, posthypercapnea, certain antibiotics **Cl nonresponsive**: Mineralcorticoid excess: Genetic renal tubular defects of electrolyte transport Drug-induced hypokalemic alkalosis Miscellaneous	Na^+ load (as acetate, citrate, lactate) Ringer solution, TPN, blood transfusion, or Na^+ relative excess (water deficit)	Exogenous administration of phosphates	Nephrotic syndrome, hepatic cirrhosis

The most important weak acid—partially dissociated acid—is albumin, with a minor effect from phosphate.

*Metabolic acidoses arise from conditions that cause either a reduction in the plasma SID or increase in A_{TOT}. Conversely, metabolic alkaloses stem from conditions that produce either a primary increase in the plasma SID or a decrease in A_{TOT}. However, whereas there appears to be complex regulation of SID for acid-base purposes, no such mechanisms are known to control A_{TOT} for this purpose. For this reason, there is no agreement as to whether changes in A_{TOT} should be accepted as acid-base disorders or not, despite their influence on pH.

†Excess of acid anions corresponds to the anion gap acidoses. Includes several organic acids, endogenous and exogenous (e.g., lactate, keto acids, salicylate); also sulfate and other anions in chronic renal failure and unknown anions in conditions such as sepsis. Unlike in anion gap, Pi is not included because it is not a strong ion.

‡Hyperchloremic (non-anion gap) acidosis and hypochloremic alkalosis. The hyperchloremic acidosis occurs either as a result of an increase in chloride concentration relative to strong cations (especially sodium) or because of the absolute or relative loss of cations (water excess) with retention of chloride.

§Excess of cations (Na^+)

‖Not a single cause of acidosis, but is a component of metabolic acidosis in severe extracellular volume loss, such as in cholera.

¶This source of alkalosis is clinically insignificant; the normal value of Pi (~1 mmol/L) cannot decrease enough to have an appreciable acid-base effect.

be regulated independently of PCO_2. Plasma bicarbonate concentration will always increase if PCO_2 increases, but this is not an alkalosis. Therefore the increased bicarbonate concentration is not "buffering" the rise of $[H^+]$, and there will be no change in the SBE. As CO_2 easily diffuses through membranes, when PCO_2 increases there is always tissue acidosis. If PCO_2 remains high, the body will attempt to compensate by altering another independent determinant of pH. The kidneys are the main organs involved in this compensation.[8,39]

The Strong Ion Difference

Strong ion difference (SID) is defined as the charge difference between the sum of all strong cations and the sum of all strong anions. When SID is calculated from direct measurement of serum strong ions, it is termed *apparent* SID (SID_{APP}),[8,31,42,43] with the understanding that more unmeasured (or unmeasurable) ions might also be present (see Table 68-5):

$$SID_{APP} = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - [Cl^-] \quad (11A)$$

In the critical care setting, it is wise to include lactate levels if they are available, because the sicker the patient, the higher the chance that lactate or other strong anions are increased:

$$SID_{APP} = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl^-] + [lactate^-]) \quad (11B)$$

From actual measurements in healthy volunteers, the normal range of SID_{APP} has been estimated from 38 to 42 mEq/L.[5,8,13,42,44] In critical illnesses, SID_{APP} may be substantially reduced, even when there is no evidence (by the traditional approach) of a metabolic acid-base derangement.[42,45] Gunnerson et al.[42] found in stable critical care patients a SID_{APP} value of 33 ± 5.6 mEq/L, but others have found different values. Thus, in spite of the lack of consensus about what value of SID_{APP} one should expect in an ICU population, it is clear that their SID_{APP} values are different from healthy volunteers' figures.[23,44,45] The tendency of critical care patients to have a lower SID_{APP} is not surprising, given the fact that the positive charge of the SID_{APP} is balanced by the negative charges of the weak acids, $[A^-]$ (albumin and phosphate), and total CO_2. Because P_{CO_2} is usually modified by the body for other reasons (e.g., hyperventilation in a patient that tends to be hypoxemic) and because hypoalbuminemia is the rule rather than the exception in this setting, $[A^-]$ tends to be reduced, and this decrease leads to a reduction in SID_{APP} to keep the normal pH. Thus a typical critical care patient might have a SID_{APP} around 30 to 35 mEq/L, rather than the "usual" range of 38 to 42 mEq/L. If this patient then has metabolic acidosis, the SID_{APP} will decrease further. The lower the baseline of the SID_{APP}, the greater the susceptibility to a subsequent acid load.[42,44,45]

Additional strong anions may become significative (e.g., hyperlactatemia, sulfate, keto acids, anions from Krebs cycle) or appear de novo in disease states (several organic acids from inborn errors of metabolism), or enter the body as medications or toxic substantes (salicylates, certain β-lactam antibiotics, etc.). They may eventually have an influence on the value of SID_{APP}.[44-47] Because it is usually not possible to have a direct measure of $[XA^-]$ at bedside (with the exception of lactate), it is not always convenient to rely only on SID_{APP} to determine the strong ion status. The more ill the patient, the more accurate is this statement. Then, in critically ill patients, it is better to calculate SID to account for electrical neutrality. According to the principle of electroneutrality (Equation 8), blood plasma cannot be charged, so there should be remaining negative charges balancing the "excess" of plasma strong cations in relation to the strong anions, which is the origin of SID_{APP}. These balancing negative charges come from total CO_2 ($\sim[HCO_3^-]$) and from two substances that act as nonvolatile weak acids, that have concentrations in plasma large enough so that changes in them can produce significant acid disturbances: the weak acids (A^-) albumin and inorganic phosphate. Thus SID can be derived, accounting for electrical neutrality, as the sum of HCO_3^- plus the negative electric charges contributed by albumin (Alb^-) and by inorganic phosphate (Pi^-).[13] This calculation of SID is known as *effective* SID (SID_{EFF})[13,48]:

$$SID_{EFF} = [HCO_3^-] + [Alb^-](g/L) + [P_i^-](mmol/L) \quad (12A)$$

where the negative electrical charges contributed by serum albumin and phosphate are as follows:

$$[Alb^-] = [Alb] \times (0.123 \times pH \times -0.631) \text{ and}$$
$$[P_i^-] = [P_i] \times (0.309 \times pH \times [-0.469]).$$

A less-accurate, simplified version of this formula, which assumes a stable pH of 7.4, appears in some publications[31]:

$$SID_{EFF} = [HCO_3^-] + 0.28 \times [Alb^-](g/L) + 1.8 \times [P_i^-](mmol/L) \quad (12B)$$

where *factors 0.28* and *1.8* are, respectively, the negative electric charges displayed by 1 g albumin and 1 mmol of [Phosphate] in plasma at pH 7.4 (0.6 instead of 1.8 if [Phosphate] is in mg/dL).[48]

Human serum albumin must be treated as a polyproteic macromolecule, exhibiting multiple apparent equilibrium dissociation constants corresponding to different classes of amino acids side chains. Accordingly human albumin charge should be expressed as a linear function of the pH. Thus Eqation 12A from Figge et al.[48] is more useful in sicker patients. Actually, SID was derived from a mathematical model with much more complex nonlinear equations, which might be encountered by the clinician while reviewing certain books and articles.[49-51] Constable and coworkers[42,52] have now developed some adaptations for clinical application, which are claimed to be more accurate:

$$SID_{EFF} = 2.46 \times 10^{-8} \times PCO_2 / 10^{-pH} + [albumin(g/dL)] \times (0.123 \times pH - 0.631) + [P_i(mg/dL)] \times (0.309 \times pH - 0.469) \quad (12C)$$

However, this equation is not very easy for the busy clinician to solve, and therefore its clinical application requires access to an Internet-based engine especially designed for calculating the SID_{EFF} (see the section on Strong Ion Gap in this chapter).

SID has a powerful electrochemical effect on water dissociation, and hence on H^+. Both H^+ and OH^- behave as a weak cation and anion, respectively. Because practically all the cations in plasma are strong ions, except for H^+, only H^+ concentration can vary in response to changes in anions. On the other hand, there are several anions that are weak ions,

and thus there are several "options" for anion molecules that can change their charges if cations change.[8,53] As the SID_{APP} increases (strong cations in excess over strong anions) plasma becomes positively charged. Hence H^+, a weak cation, decreases, and pH increases, to maintain electrical neutrality, and alkalosis is produced. On the other hand, if the SID_{APP} decreases (strong anions in relative excess over strong cations), plasma becomes negatively charged, more water is dissociated producing more H^+ for maintaining electroneutrality, and acidosis is produced.[8,40,51]

Changes in SID result from either a relative or an absolute change in strong ion concentrations. A change in free water content produces an alteration in the relative concentration of the strong ions, and hence a change on SID. If, as a result, Na^+, K^+, and Cl^- decrease, the absolute value for SID will decrease proportionately. Thus an excess of free water lowers SID and results in a tendency towards metabolic acidosis. In a similar manner, a free water deficit causes a metabolic alkalosis by increasing the SID through a relative increase in concentration of all strong ions. Relative and absolute changes in sodium concentration primarily result from osmoregulation, and thus they are reflective of changes in free water. The remaining strong cations, potassium, magnesium, and calcium, as they are tightly regulated by the body for other functions (coagulation, membrane excitability, neuromuscular plates, muscle contraction, etc.) do not vary significantly enough to directly cause alterations in acid-base balance.[13] On the other hand, changes in strong anion concentrations are significant to acid-base status. Traditionally, hypochloremia (from gastrointestinal or renal losses) is associated with metabolic alkalosis, and hyperchloremia (e.g., from resuscitation with saline infusion) is associated with metabolic acidosis. Because chloride concentration can be affected by free water content just as is sodium concentration, according to some authors,[31] it is important to take in account alterations in free water content that might exist, and thus Cl^- would need to be corrected based on the sodium concentration:

$$Cl^-_{CORR} = (140 / [Na^+) \times Cl^- \qquad (13)$$

However, the need for this "correction" is not universally accepted (see the section on Merging Traditional and Newer Approaches).

As the SID requires an actual change in the relative concentrations of strong cations or anions, the kidneys are the primary organs regulating SID. As the kidneys can excrete only small amounts of strong ion into the urine each minute, several minutes to hours are required to achieve a significant change in the SID. The control of the kidney is important and precise because every chloride ion that is filtered and not reabsorbed increases the SID. Acid handling of the kidney has traditionally focused on H^+ excretion and the role of ammonia (NH_3) and ammonium (NH_4^+) as hydrogen ion carriers.[9,10,54] Because water provides an essentially infinite source of H^+, its excretion, *per se,* is possibly not as relevant as formerly taught. In fact, the net H^+ excretion by the kidney as water molecules is larger than the excretion as NH_4^+. Therefore the purpose of renal NH_4^+ production is to allow the excretion of Cl^- without the excretion of Na^+ or K^+. Thus NH_4^+ is important to systemic acid-base balance, not for its role as an H^+ carrier or for its direct action in the plasma (normal $[NH_4^+]$ is ~0.01 mmol/L), but because it allows a "safe" excretion of Cl^-.[8,55]

A urinary anion gap (uGap) was described some time ago.[9] This urinary gap has also been designated by some authors[8] as "urine strong ion difference" (uSID):

$$uGap = uSID = [uNa^+ + uK^+] - [uCL^-] \qquad (14)$$

Certainly, sodium, potassium, and chloride are all strong ions, so the name is, at least, functionally correct. What is the value in measuring the uSID? As its serum analogue, the uSID estimates the unmeasured urinary ions. In terms of its amount, the most important unmeasured urinary strong anion (Ur^-) is SO_4^{2-} (derived from the metabolism of sulfur-containing amino acids), whereas the most important unmeasured cation (Ur^+) is ammonium (NH_4^+). In physiologically "normal" conditions, uSID must equal the plasmatic SID_{APP}, that is, 38 to 42 mEq/L. When a strong ion enters the plasma (e.g., lactate, or a chloride load), plasmatic SID will obviously decrease. Normal kidneys will react by increasing their excretion of chloride, thereby decreasing the plasma chloride concentration, while Na^+ and K^+ must be maintained within normal ranges. This is accomplished by increasing the excretion rate of NH_4^+, which is the more efficient way to increase chloride elimination without losing sodium or potassium. The increased excretion of chloride will decrease the uSID.[55]

In addition to the kidney, both the liver and the gastrointestinal tract may have an influence on SID. In the stomach, Cl^- is pumped out of the plasma and into the lumen, reducing the SID (and pH) of the gastric fluids, but increasing the SID (and pH) in the plasma side (alkaline tide), because of the exit of Cl^- to the stomach. However, only a slight change in plasma pH becomes evident, because Cl^- is reabsorbed in the duodenum just as fast as it was pumped out. However, if gastric secretions are removed, either by vomiting or suction catheter, the SID will progressively increase, as will the pH, as a result of Cl^- loss. Although H^+ is excreted as HCl, it is also lost with every water molecule that exits the body. When the body loses Cl^-, a strong ion, without also losing a strong cation, SID is increased; therefore H^+ is decreased and alkalosis ensues. When H^+ is excreted as H_2O rather than as HCl, there is no change in SID, and consequently there is no change in H^+. At present it is not known whether the gastrointestinal tract, the liver, and the pancreas are capable of compensatory actions to regulate strong ion uptake.[9,39]

Strong Ion Gap

In the healthy individual, SID_{APP} and SID_{EFF} are nearly identical, and therefore are adequate estimates of the "true" SID and of the acid-base status.[8,26,28] However, in disease states, this might not be true, as many unmeasured ions (mainly anions) may be present in plasma. Actually, unexplained anions, and in some case unexplained cations, have been found in the circulation of patients with various diseases and in animal models.[46,47,55-58] Blood samples from certain patients often encountered in the critical care setting may contain unmeasured strong ions (e.g., ketones, sulfates, organic acids from inborn errors of metabolism, certain medications, etc.), making the SID_{APP} an inaccurate estimate of the "true" SID or SID_{EFF}. Similarly, patients of this type may have abnormal weak ions (such as proteins) that can make the SID_{EFF} inaccurate as well. In order to address this situation, Jones[59] and Figge[48] independently proposed a similar scanning tool. Kellum and coworkers coined the term "strong ion gap" (SIG) to

name this new tool[60,61]; however, the term is not ideal, since the unmeasured anions creating the 'gap' can be either strong or weak (see Table 68-5).[46,47,62] Nowadays, a modern clinical lab can easily measure all the components of the SID_{APP} and SID_{EFF} equations, including lactate. As a result, XA^- is easily approximated through SIG, which is calculated as follows:

$$SIG = SID_{APP} - SID_{EFF} \quad (15)$$

By convention, SIG is positive when unmeasured anions exceed unmeasured cations (acidosis) and negative when unmeasured cations exceed unmeasured anions (alkalosis). In ideal theoretical conditions, it would be possible for the sum of strong cations and weak anions to cancel each other out, with a SIG equal to zero. In the real world, most SIGs are positive (anions < cations). The use of SIG is advocated in situations in which SID_{APP} and SID_{EFF} are not equal.[28,60,61] SIG different from zero may also be explained, at least in part, by the difference between *ionic molar concentration* (the basis for SID_{APP}) and *ionic activity* itself (the basis for SID_{EFF}). Ionic molar concentration is a measure of the actual number of ions in solution. In contrast, ionic activity is a measure of the effective concentration of electrolytes that results from the charge interaction on dissociated species. The difference between ionic concentration and ionic activity is important because the molar concentration of any electrolyte will not affect the molar concentration of any other electrolyte, but ionic activities are mutually interactive. The principle of electrical neutrality only refers to the latter.[44] Both SID_{EFF} and SIG have been evaluated as prognostic markers in both children and adults. Both indexes have shown good predictive capability in most publications, but there is no universal agreement regarding their clinical usefulness.[13,30,63-70] If one would like to increase the precision of SIG, one should include as many factors as possible in the calculation of SID_{EFF}. However, a theoretical downside is that each additional analyte may increase imprecision,[62] and the calculations become rather cumbersome in the clinical arena. On the other hand, innovative software solutions have been developed. One is the so-called *strong ion calculator*[71,72] and several similar tools available at http://www.acidbase.org.[73] They can be consulted online through computers and handheld devices. This should be the proper solution for the present time albeit not for the future. The SIG has demonstrated good stability in the setting of severe pH stress (<6.85, >7.55), a clear advantage when compared to AG, which has the tendency to increase steadily as PCO_2 falls and when pH rises. The well-known AG increase parallel with pH has been related to altered albumin and phosphate dissociation in extremes of pH.[60]

Nonvolatile Weak Acids (Albumin and Phosphate)

As already explained, there are normally only two substances that act as nonvolatile weak acids with large enough concentrations to influence H^+: proteins (albumin being the most important by far) and phosphates. They provide the remaining charges to satisfy electroneutrality: $SID - (CO_{2TOT} + [A^-] = 0$ (from Equation 12A): CO_{2TOT} is exchangeable with bicarbonate; A^- is the negative charge of anions, mainly albumin and phosphate). It should be noted that A^- is not an independent variable because it changes with alterations of SID and P_{CO_2}. Rather, $A_{TOT} = ([AH] + [A^-])$ is the independent variable, because its value is not determined by any other. However, mathematical and chemical independence does not necessarily means physiologic independence. Although the loss of weak acid (A_{TOT}) from the plasma space is an alkalinizing process, there is no evidence that the body regulates A_{TOT} directly to maintain acid-base balance, as there is no evidence that clinicians should treat hypoalbuminemia as an acid-base derangement.[8] It is not uncommon that critically ill children develop hypoalbuminemia, and hence their A_{TOT} decreases. However, these patients are not always alkalemic. They usually maintain pH, SBE, and HCO_3^- within normal limits, despite the fact that their SID is also reduced. Because changes in A_{TOT} tend to occur rather slowly, the development of alkalemia would require the kidney to continue with its Cl^- excretion despite an evolving alkalosis; as such, this scenario would probably be considered hypochloremic metabolic alkalosis, and SID would increase as a result of the increased loss of anion (and thus from a net increase in strong cations). However, what is observed in hypoalbuminemic patients is the opposite, that is, the SID tends to be decreased in relation to healthy individuals. This means that the kidney has already compensated the alkalinizing effect of hypoalbuminemia by increasing the reabsorption of Cl^-, then increasing plasma strong anion, then reducing the SID. Thus a hypothetical patient with an albumin around 2 g/dL would have an already "compensated" pH through a SID_{APP} around 30 to 32 mEq/L.[8] It is possible to see that changes in these three independently variable quantities, Alb, Pi, and SID, may have additive or offsetting effects on the metabolic acid-base balance. Such offsetting effects may result in normal values of the dependent variables pH, HCO_3^- and SBE, whereas some independent variables are abnormal. In such a case, the condition could not be considered a normal acid-base status, despite the absence of acidemia or alkalemia.

Merging Traditional and Newer Approaches: Is an Integrated Approach Ready for the Bedside?

Despite the apparent differences between the traditional bicarbonate-centered and the physicochemical approaches to acid base physiology, they are complementary. Through PCO_2 analysis and the Henderson-Hasselbalch equation, it is possible to describe and quantify the respiratory side of the acid-base balance, and to describe the metabolic side, which requires a more complex analysis. The traditional tools for approaching the metabolic side, AG and SBE, now have been supplemented by Stewart's physical-chemical concepts, and their performance has been improved.[29-31,67,74-77] In spite of the apparent differences among these three methods, they all share a common theoretical foundation based on the principle of electroneutrality and the role of plasma weak acids. Prompt identification of unmeasured anions is essential in any acid-base analysis in the critical care setting. This was demonstrated recently in a retrospective study, in which the main finding was that mortality associated with strong ion acidosis, either lactic or nonlactic, was significantly higher than that associated with hyperchloremic acidosis (56%, 39%, and 29%, respectively).[31,42,70] Hence, the presence of an elevated amount of unmeasured anions is a predictor of mortality, and the best diagnostic tool for the early detection of the unmeasured anions XA^- should be preferred. A better correlation

of indicators of unmeasured anions has been found between AG_{CORR} (not AG), SIG, and physicochemical adjusted SBE (also known as *partitioned SBE* or *BE gap*). This has been confirmed in several clinical studies.[31,42,75] Pediatric studies have been made using both SIG and partitioned BE.

Corrected Anion Gap

The correction factor required for the AG to account for hypoalbuminemia improves its performance (see the sections on Anion Gap and Anion Gap Corrected), yet some caveats must be understood by clinicians.[34] For its performance to improve, AG_{CORR} needs additional corrections. For example, the classical AG method does not consider the correction of chloride concentration in the setting of altered free water. Thus, hyperchloremic acidosis may go undetected with the AG_{CORR} method, in the setting of a dilutional alkalosis.[31] Hence a corrected value of chloride would theoretically be needed (see Equation 13). However, the very concept of "corrected chloride" is under criticism by some authors, as no other element of the AG equation (nor of SID or SIGs) is corrected for water excess or deficit,[62,78] and because the sodium correction of the chloride assumes a fixed sodium-chloride relationship that does not occur in vivo, as large transcellular shifts of chloride can occur in exchange for bicarbonate (and thus independently of sodium) in different acid-base states.[67,77,79,80] Hence there is no uniform acceptance of the need to use corrected Cl^- values in calculating AG. It is of much greater importance to be aware of the reference values for chloride that are in use in a given setting. On the other hand, in order to avoid [lactate$^-$] influence on AG_{CORR} that could mask the detection of other unmeasured anions, it has been suggested that AG should be corrected not only for albumin, but also for lactate. This is simply derived by subtracting the serum lactate concentration (in mmol/L) from the already albumin-corrected AG (see Equation 10A):

$$AG_{CORRLACT} = \text{Albumin-corrected AG} - [\text{Lactate(mmol/L)}] \quad (16)$$

This albumin- and lactate-corrected AG ($AG_{CORRLACT}$) seems to correlate well with the SIG, as was found by Moviat et al. in a small but precise study ($r^2 = 0.934$, $P < .001$).[57,64,67] In which case, $AG_{CORRLACT}$ may be an easy bedside measurement that could approximate the SIG in critically ill patients, although more clinical experience is needed. Therefore, using the single, uncorrected value derived for AG in critically ill patients may not represent good practice, given the high prevalence of hypoalbuminemia. If AG needs to be determined, albumin and lactate levels should be taken in account, so the proper correction can be made (AG_{CORR} or $AG_{CORRLACT}$).[28-34,42,74,75]

Partitioned SBE, or BE gap, is an attempt to combine the approaches of Siggaard-Andersen and Stewart in a kind of physicochemical adjusted SBE that seeks to quantify the metabolic component of acid-base disorders. Based on an analysis of Stewart's model, Gilfix[81] proposed that only four conditions may create nonrespiratory acid-base disturbances: (1) free water deficit or excess (BE_{fw}), as determined by changes in sodium concentration; (2) changes in chloride concentration (first corrected for the free water effect) (BE_{Cl}); (3) changes in protein charges, mainly albumin (BE_{alb}); and (4) the presence of organic unmeasured anions (BE_{XA}). Therefore to be precise, SBE needs to be "partitioned" (using abridged Stewart equations)[64,82-84] into four "physicochemical" segments, that is, each one of the four conditions requires its own adjusted or partitioned SBE. Gilfix[81] showed that the lab-reported SBE, or total SBE (SBE_{TOTAL}) should equal the sum of the BE for each one of the four conditions:

$$SBE_{TOTAL} = BE_{fw} + BE_{Cl} + BE_{alb} + BE_{XA} \quad (17A)$$

The concentration of unmeasured anions is, of course, unknown. Hence, the SBE for the unmeasured anions is determined from the others. This is termed by some as the BE gap:

$$BE_{XA}(\text{also abbreviated as } BE_{UMA}) = SBE_{TOTAL} - BE_{fw} - BE_{Cl} - BE_{alb} \quad (17B)$$

BE_{fw} and BE_{Cl} (sodium and chloride effects), both being strong ions, were later combined in a single BE due to SID (BE_{SID}) [77]:

$$BE_{XA}(\text{also abbreviated as } BE_{UMA}) = SBE_{TOTAL} - BE_{alb} - BE_{SID} \quad (17C)$$

This approach has received some criticism for small but potentially important inaccuracies derived from the partition of BE, a whole-blood–derived parameter, into plasma compartments, which may generate discrepancies that magnify as PCO_2 deviates from normal, from the exclusion of phosphate as a part of [A_{TOT}]) and from the lack of uniformity in reference values.[62] In spite of these physiologic and conceptual caveats, this approach was first tested in children in a pediatric intensive care unit in 1999, with apparent success.[64] Reported successful applications in mortality prediction and classification of acidosis in several settings, including sepsis and septic shock, cardiac surgery, diabetic ketoacidosis, and others, soon followed.[70,84,85] Unfortunately, lack of standardization in regard to the formulae used for BE partitioning has been a serious inconvenience for the comparison of these studies.[64,77,81-87] In a recent review,[77] an analysis of the four published methods of partitioning SBE showed large and clinically important discrepancies between them. Of all the documented methods for BE partitioning, the one from Taylor et al., [84] in which $BE_{ALB} = (42 - [\text{Albumin}]) \times 0.25$, and $BE_{SID} = [Na^+] - [Cl^-] - 32$ seems to be the most accurate.[31,64,77] These values must be used to solve Equation 17.

In spite of enthusiastic publications, until a consensus is reached, caution must be applied if the clinician chooses to employ the SBE partitioning approach. Nowadays, certainly an "integrated approach" to the metabolic acid-base disorders is the best advice. This should include the PCO_2/bicarbonate approach for respiratory acid-base disturbances and for the initial appraisal of the metabolic problems (bicarbonate and SBE). For these, AG_{CORR} ($AG_{CORRLACT}$ (if [lactate$^-$] is available) and SIG are the best available tools. SBE partitioning (Taylor's method) could also be employed. The advantage of this approach is that it allows the clinician to detect complex mixed acid-base derangements in the critical care setting, which may result in the identification of more patients with major acid-base disturbances. The physicochemical approach yielded the additional diagnosis of metabolic disorders in 33.7% of patients in one single-center adult study.[88] However, it remains unclear if the identification of these additional acid-base disorders translates to new and otherwise unanticipated therapeutic interventions in these patients. It is important to understand the limitations of all the acid-base assessment tools, to identify when perturbations in AG, SBE, or SIG are significant, and when they are not.[31,75,89]

New Insights for Old Problems

The classical acid-base approach yielded some common sense explanations for some acid-base disturbances often seen in the clinical arena. For example, it is said that the metabolic alkalosis seen with severe emesis or nasogastric tube losses is due to a *loss of* H^+; that the metabolic acidosis seen in persistent postpyloric fluid losses is due to a *loss of bicarbonate*; that an acidosis caused by large volume fluid administration is caused by *dilution of bicarbonate*; and that sodium bicarbonate ($NaHCO_3$) therapy corrects metabolic acidosis by contributing bicarbonate ion (HCO_3^-) to the body. These time-honored explanations have been challenged by the new view of acid-base balance, in which water dissociation represents a core principle.[8,35] According to the water-dissociation principle, pH has no direct relationship with any total body direct loss or gain of H^+ or HCO_3^-, but rather reflects the change of SID_{EFF} and A_{TOT} and their effect on water dissociation, the true antecedent of the resultant pH change and concentrations of H^+ or HCO_3^-, that are then merely effects rather than the cause of the acid-base derangements. For example, it is well-recognized that the acute expansion of extracellular volume with normal saline solution (sodium chloride [NaCl] 0.9%) or with any unbalanced synthetic colloid solution (6% hydroxyethyl starch solution or 4% gelatin) may result in hyperchloremic acidosis.[68,82,87,90-97] The understanding of this condition has improved through the physicochemical comprehension of the acid-base equilibrium: saline causes acidosis not through "dilution" of bicarbonate, but rather by its Cl^- content, which decreases the SID and produces an increase in water dissociation and in H^+.[87,90-94] This occurs despite equal amounts of Na^+ and Cl^- in saline solution, because sodium and chloride concentrations are different in plasma. Therefore when large amounts of NaCl in solution are infused, they will have a proportionally greater effect on total body chloride than on total body sodium. The elevated gastric fluid losses seen with severe emesis or nasogastric drainage are the opposite example: loss of high amounts of chloride lead to an increase in SID and to alkalosis.[98] Sodium bicarbonate, by contributing the strong ion sodium (Na^+), increases the SID and hence pH increases; thus it is the sodium, not the bicarbonate, that actually corrects an acidemia (see Strong Ion Difference in this chapter).[99]

In addition to these examples, the water-dissociation–centered model from Stewart may provide new insight into the molecular biology and transport physiology of the renal tubule. For example, renal tubular acidosis (RTA) and Bartter syndrome may be redefined as "chloride channelopathies," rather than disorders of net acid excretion.[49,100] In spite of the theoretical and mathematical certainties and the experimental and clinical evidence regarding the pertinence of the physicochemical approach, there is still no universal agreement about the clinical validity of these explanations, neither about their clinical relevance.[101-103]

The Clinical Problem: Does Abnormal pH Harm?

The clinician has been taught to fear abnormal pH, in particular acidemia. The rationale for such a fear is that every protein in the body contains areas of both positive and negative charge, and hence it is a fact that they are electrochemically sensitive and thus sensitive to the H^+ concentration of their environment. Therefore a decrease or increase in arterial pH might be expected to have important detrimental effects on a host of bodily functions. In the critical care unit, acid-base disorders are often considered more important for what they tell the clinician about the patient than for any harm that is directly provoked by the acid-base imbalance. Several studies[8,104] have reinforced this concept by showing that mortality was more closely related to the nature of acid-base disorders than to the magnitude of metabolic acidosis (estimated by partitioned SBE). Hyperlactatemia, more than the elevation of unmeasured anions (AG_{CORR}, SID, SIG) or SBE, is predictive of a poor outcome. Despite this reliable data from children with shock, it is generally accepted that acid-base derangement itself may cause harm in certain circumstances.[10,14,105] The obvious examples are the extreme conditions of pH (<7.0 or >7.7). It is also important, however, to consider how fast the acid-base derangement is evolving, along with the specific expected consequences of the alteration in specific patients. For example, in a patient who depends on vasopressors, vasodilation due to alkalosis, either respiratory or iatrogenic in origin (overzealous hand bagging of the patient), or metabolic as a consequence of gastric fluid losses caused by a mechanically obstructed jejunum, can be catastrophic. Another typical example is the spontaneously breathing patient with metabolic acidosis, who tries to compensate by increasing minute ventilation; if the patient gets tired, there is the possibility that hypoxemia will develop along with a respiratory acidosis. In such cases, the underlying disorder must be treated, but one must also provide immediate treatment for the acid-base derangement itself.

The main expected physiologic effects of acidemia and alkalemia are as follows. Acidemia initially causes sympathetic and adrenal stimulation, an effect that is counterbalanced, as the drop in pH becomes more and more severe, by a depressed responsiveness of adrenergic receptors to circulating catecholamines.[14,106,107] In isolated animal heart preparations and in isolated human ventricle muscle, there is no doubt that acidosis reduces contractile function.[108-110] The net influence of acidosis in the whole animal and in real patients, however, is more complicated to discern, and depending on the experimental or clinical model, it has been found that acidosis caused myocardial contractility to remain constant, decrease marginally, or transiently rise and then fall.[111] Hence, the whole-body response to acidosis is much less clearly detrimental in real individuals. In many preclinical and clinical studies of patients undergoing permissive hypercapnia, a pH less than 7.2 was well tolerated,[112,113] as it is in children with diabetic ketoacidosis,[114] children and adults with hypercarbia,[115] and those with grand mal seizures.[116] Thus it is now clear that the effect of acidosis may differ according to type, magnitude, and time of onset.[70,115] Three types of extracellular acidosis—inorganic, respiratory, and lactic—may have disparate effects on left ventricular function, as shown in a model of isolated rabbit hearts.[107,117]

Lactic acidosis caused a significant increase in the time to peak left ventricular pressure, while retarding ventricular relaxation. This reinforced the concept that lactate ions have an independent and deleterious effect on myocardial function.[110,117] These findings make sense (with some reserve) when they are extrapolated to clinical grounds. Despite the frequent coincidence of clinical shock and metabolic acidosis, the striking discordance between the clinical course and

outcome of patients with lactic acidosis compared with those who have ketoacidosis or ventilatory failure, suggests that the low pH itself is important but not crucial for the presentation of the hemodynamic collapse of these patients.[42,107,111] Therefore the net effect on ventricular performance, heart rhythm, and vascular tone depends on the relative effects of many, sometimes competing, influences. In general terms, severe acidemia (pH <7.10 according to most, pH <7.20 according to others)[9,10,14,42,107] is associated with decreased cardiac performance that provokes a drop in cardiac output, along with decreased vascular reactivity that manifests itself as arterial vasodilatation and venous constriction. An important effect in the critical care setting is the marked increase in cerebral blood flow associated with acute respiratory acidemia, and its abrupt decrease with respiratory alkalosis.[118,119] When PCO_2 acutely raises in excess of 70 mm Hg, loss of consciousness and seizures can be seen, probably due to the abrupt lowering of intracellular pH. Cultured lung epithelial cells exposed to cyclic stretch similar to that seen with mechanical ventilation produced a lactic acidosis that markedly enhanced the growth of *Escherichia coli*.[120] In contrast, alkalinizing the pH abolished this effect. The demonstration that clinically relevant levels of metabolic acidosis enhance bacterial growth is of concern. However, in patients with acute respiratory distress syndrome (ARDS) under mechanical ventilation and treated with "permissive hypercapnia," the gradual rise of the PCO_2 and the consequent drop in the pH are well-tolerated in general terms, with no significant negative effects on systemic cardiac output, oxygen delivery, or vascular resistances, both pulmonary and systemic.[112,113] Actually, the hypercapnic acidosis has been shown to provide beneficial effects on pulmonary function by interacting with reactive oxygen species, the immune system, and the alveolar-capillary barrier.[119,120] However, recent evidence showed, through a multivariate analysis, that changes in arterial pH, but not in positive end-expiratory pressure (PEEP) levels, were significantly correlated with impaired right ventricular function, whereas the left ventricle was spared.[121] Thus the net effect of respiratory acidemia to the patient, beneficial or detrimental, may be complex to elucidate and must be carefully assessed in each case. Other potential effects of acidemia include endogenous catecholamine, aldosterone, and parathyroid hormone stimulation; insulin resistance; increased free radical formation; increased protein degradation; gut barrier dysfunction; further respiratory depression; decreased sensorium; hyperkalemia; hypercalcemia; and hyperuricemia.[8,14] In regard to the effect of extracellular acidemia on inflammatory response and immune function, recent research has indicated that different acids produce different effects, despite similar extracellular pH.[105]

When associated with severe alkalemia (pH >7.60), both metabolic and respiratory alkalosis lower blood pressure and cardiac output. The potential deleterious effects of this drop in systemic and regional blood flow may be aggravated by the increased oxygen affinity of hemoglobin (shift to the left of the oxyhemoglobin dissociation curve), particularly in acute alkalosis. In chronic alkalemia this effect is counterbalanced by an increase in the 2,3-diphosphoglyceric acid concentration in red cells.[10] Cerebral circulation responds dramatically to alkalemia with marked vasoconstriction. Cerebral blood flow may drop in response to an acute hyperventilation to about 50% of the basal flow, at a PCO_2 of 20 mm Hg. This effect has been used as an emergency management of an impending rise in intracranial pressure but has the risk of producing an excessive drop of blood flow to the most affected areas of the brain, increasing the possibility of ischemia and subsequent cerebral infarction.[119] Because both metabolic and respiratory alkalemia may provoke abrupt transcellular membrane shifts of several electrolytes, mainly potassium and calcium, the net effect is an increase in neuromuscular irritability and excitability. The occurrence of seizures and severe cardiac arrhythmias has been reported if pH is approaches 7.7.[10,98]

The answer to the question "Does abnormal pH harm?" is therefore quite complex; potential harm always exists, but the occurrence of real damage depends on many factors: clinical setting of the patient; type of derangement (metabolic vs. respiratory); timing of presentation (gradual vs. sudden); renal, lung and liver functional status; type of metabolic acidosis; and magnitude (mild, moderate, or severe), for example. On the basis of available evidence, one more question must be asked: does acid pH confer some advantage? The answer here is also quite complex, but should be a cautious "maybe" for mild-to-moderate acidosis in at least two settings: permissive hypercapnia and cardiopulmonary resuscitation.

Blood Gases: Arterial, Central Venous, or Capillary Samples?

Arterial blood gases (ABG) are the usual gold standard for assessing the acid-base status of a patient. However, once the diversity of microcirculations and tissue metabolism throughout the body is taken into account, clinicians must be aware that the value of a single arterial blood pH as a physiological marker is rather limited, even more so if it is recognized that most functional proteins are intracellular.[107,111] There is significant correlation in pH, PCO_2, partial pressure of oxygen (PO_2), SBE, and HCO_3^- between arterial, central venous (VBG), and capillary blood gases (CBG) in healthy volunteers and in stable patients. However, in the presence of hypotension or shock, there is a very poor or no correlation at all with PO_2 with most acid-base parameters.[122] Thus, capillary and central venous blood gas measurements may be useful alternatives to arterial samples when an arterial line is not in place, in particular for acid-base evaluation, as this good correlation extends also to lactate.[123] However, in the setting of severe circulatory failure, such as in decompensated, catecholamine-resistant septic shock and cardiac arrest, significant widening of the arteriovenous differences in pH, PCO_2, and lactate may occur.[8,10,14] Thus, in the presence of severe hypoperfusion, hypercapnia and acidemia at the level of the tissues are better detected in central venous blood than in arterial blood samples because they directly reflect the average acid-base status of the venous blood returning from the tissues, without the influence of pulmonary function. If this is the case, an apparent improvement in the ABG could be observed as a patient slowly recovers from a cardiac arrest, but a simultaneously obtained VBG may reflect a more severe acidosis for a longer time.[124] On the other hand, in the setting of ARDS, the lungs may become important lactate producers, leading to significant higher levels of lactate in ABGs than in the VBGs (also discussed in *Lactic Acidosis* in this chapter). Therefore both arterial and central venous blood samples are needed to assess acid-base status in patients with severe hemodynamic compromise.

Metabolic Acidosis

The classical approach to metabolic acidosis is to classify the disorders as those with either *elevated AG* or *normal AG*, which continues to be a very practical, although not a pathophysiologically-based, classification (see Table 68-4). Using the more physiological independent variables-oriented approach, metabolic acidosis can be classified as due to an *imbalance of strong ions* (decreased SID) or due to the presence of *abnormal nonvolatile weak acids* (increased A_{TOT}).[42] In turn, decreased SID acidosis can be classified in two categories: excess of unmeasured anions (excess XA^-) (which grossly corresponds to the elevated AG acidosis), and as due to an excess of chloride and/or relative or absolute deficit of sodium-water excess (which corresponds to the non-AG acidosis) (see Table 68-6). There appears to be a complex regulation of SID for acid-base purposes, but no such mechanisms are known to control $[A_{TOT}]$ for this purpose. For this reason, there is no agreement about whether changes in $[A_{TOT}]$ should be accepted as acid-base disorders or not, despite their influence on pH.

The classic approach will be used as the main frame for approaching the metabolic acidoses, with additional information, mainly about pathophysiology, from the physicochemical approach.

Elevated Anion Gap Acidoses

These are a group of disorders in which there is the accumulation of an acidic anion. There are three clinically more relevant examples: lactic acidosis, ketoacidosis, and acidosis secondary to the ingestion or administration of some toxin or drug. In children, most of the "toxins" are actually drugs, and most of them provoke lactic acidosis, and will be mentioned under that subheading. Some interesting miscellaneous disorders will be also mentioned.

Lactic Acidosis

The popular classification of hyperlactatemia as type A (*associated with or caused by* inadequate tissue oxygen delivery) or type B (adequate tissue oxygen delivery) is sustained because of its simplicity, despite the fact that it is not necessarily a reflection of the pathophysiologic mechanism underlying this alteration, as considerable overlap exists between types A and B[125] (Table 68-7). Type B was originally further subdivided into types B1, B2, and B3, with type B1 lactic acidoses being associated with an underlying disease (e.g., diabetes mellitus, asthma, malignancies). B2 includes the lactic acidoses due to drugs or toxins (e.g., cyanide, metformin, epinephrine, etc.), and B3 those due to inborn errors of metabolism. Type A seems to be the most frequent cause of lactic acidosis encountered in critical care patients.[10,14,125,126]

Among all metabolic acidoses, lactic acidosis in the ICU unit signals trouble, regardless of patient age.[10,14,126-131] Depending on the source, hyperlactatemia is defined as a lactate level between 2 and 5 mmol/L, whereas lactic acidosis is said to be present when lactate level exceeds 5 mmol/L and the arterial pH is less than 7.35. Yet these definitions are arbitrary. Blood lactate concentration, both in terms of the magnitude and duration, has been shown to correlate with mortality in pediatric and adult patients in many settings, including septic and hemorrhagic shock, neonates receiving ventilation, and during necrotizing enterocolitis, [70,104,126-131] and has been used for the titration of inotropes and blood cell transfusions during early goal-directed therapy for severe sepsis and septic shock,[132] with a performance not inferior to that of the mixed venous saturation. Hyperlactatemia may also be present in children following cardiac surgery.[133] Therefore lactate measurement has become a common attribute in "point of care" blood gas analyzers used at bedside in modern ICUs.[134]

Lactate represents the end product of anaerobic metabolism (i.e., it is a product of pyruvate reduction via the enzyme lactate dehydrogenase and the reduced nicotinamide hypoxanthine dinucleotide/nicotinamide hypoxanthine dinucleotide

Table 68–7 Causes of Lactic Acidosis

I. Type A: inadequate tissue oxygen delivery*
   A. Hypodynamic shock or inadequate resuscitation
   B. Ischemic tissue (bowel or traumatized tissue)
   C. Severe hypoxemia
   D. Severe anemia
   E. Carbon monoxide poisoning
II. Type B: not associated with tissue hypoxia*
   A. Alterations in cellular metabolism
      1. Hypermetabolism
         a. Increased aerobic glycolysis
         b. Increased protein catabolism
         c. Systemic inflammatory response syndrome, sepsis, and severe sepsis
         d. Huge "tumoral" burden
      2. Postcardiopulmonary bypass
      3. Burn injury
      4. Hematological malignancy
      5. End-organ failure (liver, lungs [ARDS])
      6. Diabetes mellitus
      7. Thiamine deficiency
      8. Mitochondrial myopathies
      9. Severe alkalosis/hyperventilation
   B. Increased oxygen consumption
      1. Strenuous exercise
      2. Grand mal seizure, status epilepticus
      3. Malignant hyperthermia
      4. Neurological malignant syndrome
      5. Severe asthma
      6. Pheochromocytoma
   C. Toxins and drugs or their metabolic byproducts
      1. Epinephrine
      2. Propofol
      3. Terbutaline and other β-agonists
      4. Salicylate
      5. Acetaminophen
      6. Cocaine
      7. Ethanol
      8. Methanol
      9. Cyanide (nitroprusside)
      10. Stavudine and other antiretroviral agents
      11. Biguanides (metformin)
      12. Ethylene glycol, glycolic acid, oxalic acid
      13. Others
   D. Congenital
      1. Glucose-6-phosphate deficiency
      2. Fructuose-1,6-diphosphate deficiency
      3. Pyruvate carboxylase deficiency
      4. Pyruvate dehydrogenase deficiency
      5. Oxidative phosphorylation defects
   E. Decreased lactate clearance
      1. Fulminant hepatic failure
   F. D-Lactate
      1. Short gut syndrome
      2. Antibiotic-induced

*Despite the fact that they are grouped under specific categories, significant overlap exists and one single cause may fit under several categories.

[NADH/NAD] cofactor system (see Chapter 74).[126] It derives primarily from skeletal muscle, gut, brain, and circulating erythrocytes, with a production of about 1 mmol/kg/hr. The healthy liver takes up most lactate and recycles it through three primary options: conversion back to glucose (Cori cycle); oxidation back to pyruvate, which subsequently can be oxidized to CO_2 via the Krebs cycle; or transamination into alanine.[126,135] A decrease in oxygen availability at tissue and cellular levels results in an impairment in oxidative phosphorylation, which results in an increase of the intracellular levels of NADH, the cofactor in the conversion of pyruvate to lactate.[126,135] Because of its close relationship with anaerobic metabolism, increased lactate has been largely considered a dead-end waste product of glycolysis due to hypoxia. This mechanism is clear and easily understandable by the busy clinician seeking prompt explanations for what he or she is facing in the critical care unit. However, using blood lactate concentration as evidence of tissue hypoperfusion, hypoxia, and hyperactive anaerobic glycolysis is, at best, an oversimplification.[124] Strong and compelling evidence from living tissue, animal models of hemorrhagic and septic shock, humans during incremental exercise, and humans in septic shock has demonstrated that stimulation of aerobic glycolysis, that is, glycolysis not attributable to oxygen deficiency, occurs not only in resting, well-oxygenated skeletal muscles, but also in experimental and clinical shock. In this setting, skeletal muscle appears to be a leading source of lactate formation as a result of exaggerated aerobic glycolysis through Na^+K^+ATPase stimulation by circulating epinephrine, both endogenous and exogenous.[136-139] Thus it now appears that increased lactate as a result of hypoxia or dysoxia is more the exception than the rule, at least in the hyperdynamic hypermetabolic phase of sepsis, severe sepsis, and septic shock. As there is evidence that lactate is an important intermediate in the process of wound healing and tissue regeneration, it should no longer be considered just an indicator of damage due to hypoxia/hypoperfusion, but as an important intermediary in numerous metabolic processes, a highly mobile fuel for aerobic metabolism through cell-to-cell "shuttles," allowing the coordination of intermediary metabolism in different tissues, and between cells within those tissues. Therefore, in septic shock patients, a high lactate concentration should be interpreted as a marker of the severity of the disease, but it should not be taken as an irrefutable proof of oxygen debt, requiring increases in systemic or regional perfusion or oxygenation to supranormal values.[136,137]

During systemic hypoperfusion, several tissues are a clear source of lactic acid. For example, underperfused intestine can release lactate but will not do so if mesenteric perfusion is maintained.[56] Causes of hyperlactatemia and lactic acidosis are numerous in the critical care setting[10,14,125,126,129,140] (see Table 68-7). Lactate levels may fluctuate in response to exogenous catecholamines, particularly epinephrine,[135-141] which clearly increases lactate levels through stimulation of glycogenolysis and glycolytic flux with a resultant increase in pyruvate production. This effect does not occur with norepinephrine or dobutamine infusions and is not related to decreased tissue perfusion.[135,141,142] Several studies have shown that the lung is a major source of lactate in severe sepsis/septic shock,[142,143] and that decreased lactate clearance by the liver is also an important component of sepsis-associated hyperlactatemia and lactic acidosis.[142,144] Therefore, instead of being caused by cellular oxygen debt, the persistent lactate elevations often seen in patients with sepsis (and in patients after trauma resuscitation) may be a consequence of a much more complex physiological, inflammatory, and metabolic response, the so-called cytopathic or mitochondriopathic dysoxia (see Chapter 74).[135-144] Thus it is not surprising that lactate levels correlate so well with outcome and survival in several subtypes of shock.

Correlation of lactate levels in terms of rate of increase, magnitude of the increase, and persistence represent well-known prognostic markers in both children and adults,[10,14,70,104,126-131] and are used clinically in gauging the response to treatment.[70,126,128,132] Lactic acidosis, more than just the lactate level, correlates with the severity of sepsis and septic shock.[130] Given the complex and incompletely understood metabolism of lactate in sepsis, however, the belief that lactate levels can be accurately used as a stand-alone marker of outcome and mortality is probably naive.[135,136,138] Although the source and pathophysiological interpretation of lactic acidosis are matters of discussion, no question exists about the ability of lactate accumulation to produce acidemia.

Given its pKa of 3.9, which indicates that more than 3000 molecules are dissociated for every one that is not within clinically encountered pH, lactic acid behaves as a strong ion. Therefore the accumulation of lactate (a strong anion), without the addition of an important strong cation such as sodium, will be expected to lower the SID, increase H^+, and decrease the pH. Lactic acidosis would also be expected to be associated with increased adenosine triphosphate (ATP) hydrolysis, another source of hydrogen ions. Because the body can produce and clear lactate rapidly, it functions as one of the most dynamic components of the SID.[135]

Type B lactic acidoses are probably operative in many clinical circumstances where the so-called type A lactic acidoses have traditionally been invoked. Particularly in the patient with sepsis, lactic acidosis may be associated with a variety of coexisting mechanisms.[135-140,142-145] In addition, there likely exists significant overlap between many of these mechanisms, and hence their categorization is a real challenge. A potentially useful method for distinguishing anaerobically produced lactate from other sources is to measure the whole blood pyruvate concentration. The normal lactate to pyruvate ratio is 10:1. Because pyruvate is reduced to lactate during anaerobic metabolism, the ratio of lactate to pyruvate increases. Therefore if this ratio is higher than 25:1, it is considered evidence of anaerobic metabolism.[141] Unfortunately, pyruvate is unstable in solution, and an accurate measurement in the clinical setting is therefore difficult to obtain. Thus the clinical usefulness of this approach is reduced.[126] In many settings, including septic shock and liver failure, the magnitude of the accumulation of lactate does not always account for the whole of the acid-balance derangement observed.[30,70,104,141,145] In fact, the increase in the AG, SID, and SIG observed in severe sepsis is often substantially greater than the actual lactate concentration. This finding has led to the active search for the so-called unexplained or unmeasured anions (abbreviated XA^- or UMA).[8,56,64,70]

Donnan equilibrium alterations due to sepsis-mediated endothelial damage and a switch from a hepatic anion-uptake state to an anion-release state during endotoxemia have been the main proposals for explaining the fact that as much as 15% to 50% of the increased AG, SID, and SIG is not related to the increased lactate.[8,34,56,142-144] Accumulation

of molecules such as succinate, citrate, and formate has also been implicated.[46,47,57,62]

In addition to epinephrine, numerous drugs and toxins encountered in critical care medicine may cause or contribute to increased lactate, with or without acidemia. Likewise, drugs associated with the release of endogenous catecholamines, such as cocaine, can stimulate lactate production.[146] A similar mechanism is advocated in patients with pheochromocytoma.[147] Sodium nitroprusside remains a key vasodilator drug. Because it is metabolized to cyanide, this toxin may accumulate if excessive drug is administered or impaired cyanide clearance occurs, as in the setting of renal failure. In such cases, mitochondrial respiratory chain activity may be inhibited and lactate production increased.[140] Thus, nitroprusside toxicity is usually heralded by the rise in lactate levels, with or without a drop in the pH.[135,140,144] Similarly, propofol toxicity resulting in lactic acidosis, rhabdomyolysis (including the cardiac muscle), and myocardial, renal, and hepatic failure, seems to involve mitochondrial toxicity, which occurs more often with continuous, high-dose, and prolonged infusion. Hence, its designation as *propofol infusion syndrome*.[148,149] Lactacidemia has also been observed with short-term propofol infusions for general anesthesia. It is a highly lethal complication of propofol use.

There are some other conditions in which lactic acidosis or hyperlactatemia may occur. As noted previously, in acute lung injury (ALI) and ARDS, lactate levels may be high even in the absence of shock or sepsis.[143] In ALI/ARDS the lung is an important source of lactate.[143,150] This was first evidenced by higher lactate levels in arterial blood than in the mixed blood obtained from patients with ALI/ARDS, a phenomenon not seen in patients with other serious lung diseases. It has also been shown that the lung is a source of lactate production in patients receiving mechanical ventilation after cardiopulmonary bypass.[151,152] Potential mechanisms of lactate production by the injured lung may include not only the onset of anaerobic metabolism in hypoxic zones, but also direct cytokine effects on pulmonary cells and a stress-induced enhancement of glycolysis and lactate synthesis by both the parenchymal and nonparenchymal cells (e.g., endothelial cells and inflammatory cells infiltrating lung tissue such as macrophages and neutrophils).[143,150-152]

A similar mechanism is operative in wound tissue, the intestine, and the liver in patients with trauma.[144] Hyperlactatemia, lactic acidosis, or both occur in about 80% of cases of acute liver failure.[153,154] Both decreased hepatic clearance of systemically produced lactic acid and increased hepatic production of lactate are involved.[144,153,154] Hypermetabolism associated with lactate accumulation has been observed in organs rich in mononuclear phagocytes, especially the liver and spleen. Murphy et al.[153] found that, in patients with severe hepatic failure, both the liver and intestine behave as net producers of lactate. After transplantation, the grafted liver became a net consumer of lactate as evidenced by a negative lactate gradient between hepatic and portal venous blood. The intestinal bed, however, continued to produce lactate after transplantation, but arterial blood levels dropped back to normal values. Thus, before transplant, hyperlactatemia and lactic acidosis were due both to defective clearance of lactate by the sick liver and to an increased lactate production resulting from hepatic inflammation, in addition to lactate released from the intestine, the lung, and other organs participating in this multisystem problem.[153,154] Cessation of hepatic lactate release after transplantation was the result not only of improved lactate clearance, but also of the removal of a large body of activated, lactate-producing inflammatory cells.

However, this concept of lactate being produced and not cleared by some "damaged" cells has been challenged. So, the bad reputation of lactate as a waste product of a "defective," inefficient, anaerobic physiology, is about to shift. The key concept is to acknowledge that lactate can be considered a waste product when released from one cell, but it becomes a very useful substrate when taken up by another cell, just as in Murphy's findings. In fact, the rate of lactate turnover in vivo in humans is quite similar in order of magnitude to that of glucose, alanine, or glutamine, indicating that lactate has one of the highest recycling rates in the intermediary metabolism. So, increased lactate levels can be viewed as an organic, adaptive response, by which some lactate-producing cells are providing other group of cells with a highly energetic substrate, the so-called lactate "shuttle."[137-139,155]

In status asthmaticus, 1% of patients admitted to a pediatric ICU demonstrated lactic acidosis.[156] This incidence is lower than that reported in adults with acute severe asthma, which is around 25% to 30%.[157] Pathogenesis of lactic acidosis in this setting seems to be multifactorial and includes contributions from lactate production by overwhelmed respiratory muscles, tissue hypoxia, a hyperadrenergic state, and the metabolic effect of pharmacological β_2 agonists.[158-160] Muscle participation does not seem to be so important, however, because lactic acidosis has been described even in patients with asthma under muscle relaxation.[161] Of interest, nonlactic, non-AG acidosis has been found in adults presenting with status asthmaticus. The hypothetical mechanism is hyperchloremia associated with exacerbated chronic hypocapnia, which would decrease SID in hyperventilating asthmatic patients.[162] In head trauma, it is possible to find lactic acidosis in arterial blood samples, both as an effect of polytrauma and hemorrhagic shock and as a manifestation of severe traumatic brain injury. At the regional level, brain tissue acidosis is associated with increased tissue PCO_2 and lactate concentration. These pathobiochemical changes are more severe in patients who died and in those who remain in a persistent vegetative state.[163]

Salicylate intoxication is a special situation in which lactic acidosis may play an important role (see also Chapter 106) Although salicylate toxicity occurs less frequently now than in the past because of the increased use of alternative antipyretics in young children, it must still be considered in therapeutic situations (e.g., rheumatic diseases), as well as in cases of overdose. Salicylates directly or indirectly affect most organ systems in the body by uncoupling oxidative phosphorylation, inhibiting Krebs cycle enzymes, and inhibiting amino acid synthesis. These derangements can result in variable acid-base patterns: respiratory alkalosis, mixed respiratory alkalosis plus metabolic acidosis, or (less commonly) simple metabolic acidosis. Respiratory alkalosis is caused by direct stimulation of the respiratory center by salicylates, leading to hyperventilation and a compensatory alkaluria, with both potassium and bicarbonate being excreted in the urine.[164,165] This first phase may last for several hours after ingestion in adolescents but may be overlooked in young infants. During the next 12 to 24 hours (or less in younger patients), hypokalemia develops and urinary excretion of hydrogen ion starts. This "paradoxic

aciduria" occurs despite continued respiratory alkalosis and aggravates the clinical manifestations because a higher percentage of salicylate in acidic urine remains in the nonionized form, and is reabsorbed from the glomerular filtrate. Soon after the onset of hypokalemia, dehydration and progressive metabolic acidosis develop. The metabolic acidosis is mainly due to lactic acid, but keto acids and other metabolic acids also participate. As metabolic acidosis ensues, more acidic urine is produced, and the plasma salicylate level may be even higher than in early phases because of the inability to excrete the drug in urine. Chronic salicylate poisoning has been described, in which the patient usually has metabolic acidosis and a "pseudosepsis" syndrome similar to some inborn errors of metabolism, with a high rate of permanent organ dysfunctions and mortality.[166]

Elevation of blood lactate, up to the 5 mmol/L level, may be seen in about 25% of human immunodeficiency virus (HIV)-positive patients who receive nucleoside reverse transcriptase inhibitors (mainly stavudine). Most patients remain asymptomatic, but a small proportion of them may present with dyspnea and abdominal pain, as manifestations of lactic acidosis, 3 to 4 months after starting the treatment. If the drug is discontinued and fluids are replaced, the process is reversible. The mechanism appears to involve uncoupled oxidative phosphorylation due to inhibition of DNA polymerase-γ.[167] As a result of the worldwide problem of overweight and obesity, more school-age children and adolescents must receive some treatment for peripheral resistance to insulin. Thus, metformin, the use of which was formerly limited to adult patients, is now being used with increasing frequency in pediatric patients. The incidence of metformin-associated lactic acidosis is low, but it has a high mortality rate when it presents. There is limited experience in pediatrics, but obese children and adolescents who receive metformin in the setting of intercurrent illnesses that may predispose to accumulation of the drug, such as renal function impairment, are at risk of developing metformin-associated lactic acidosis.[135,168] It also may occur as a consequence of accidental ingestion or suicide attempt. Survival depends on the nadir pH and the peak levels of lactate and drug serum concentration. The mechanism involves uncoupling of oxidative-phosphorylation, with acceleration of the glycolytic flux that increases lactate production.

A curious form of lactic acidosis is the so-called D-lactic acidosis. The lactic acid produced by mammals is a levoisomer; some bowel bacteria produce a dextroisomer.[169] D-lactate derived from bacterial fermentation in the bowel lumina may reach systemic circulation and lead to metabolic acidemia, especially if liver function (and thus lactate clearance) is suboptimal. D-lactic acidosis must be considered in patients with a history of intestinal disease who have neurological findings such as confusion and ataxia along with high-AG metabolic acidosis with normal L-lactate levels. Symptoms worsen after high-carbohydrate meals or tube hyperalimentation. In patients with short bowel syndrome, there is not only an overgrowth of bacteria but also accumulation of carbohydrates in the colon. Therefore the development of the syndrome requires some of the following: (1) carbohydrate malabsorption with increased delivery of these compounds to the colon; (2) colonic bacteria flora producing D-lactic acid; (3) ingestion of large amounts of carbohydrate; (4) diminished colon motility, allowing time for bacterial fermentation; and (5) impaired D-lactate metabolism.[169] Treatment focuses on decreasing gut bacteria overgrowth with antibiotics and the avoidance of high-carbohydrate or lactose feeding. Some studies have advocated the use of probiotics for treating and preventing this problem,[170] but the reports are conflicting, as some cases of encephalopathy associated with D-lactic acidosis have been probably related to their use in patients with short bowel syndrome.[171]

Ketoacidosis

This is another common cause of increased AG acidosis. Ketones are formed by beta oxidation of fatty acids, a process that increases substantially in insulin-deficient states. In the pediatric intensive care setting, this is most often seen in patients with diabetes mellitus with overproduction and underutilization of acetone, β-hydroxybutyric (β-OH-B) and acetoacetic acids (ketone bodies), that accumulate in plasma (see also Chapter 78). This problem is exacerbated because of the glucosuria-mediated diuresis and intravascular volume contraction. Ketoacidosis is also seen in various inborn errors of amino acid and organic acid metabolism, and a mixed ketoacidosis and lactic acidosis is seen with glycogen storage disease type I (glucose-6-phosphate deficiency) (see also Chapter 76). The urinary dipstick for ketones uses a nitroprusside reagent; hence it detects acetoacetate but not β-OH-B. If a patient with DKA develops shock, β-OH-B:acetone may be produced in ratios up to 3:1. Hence, the urine will mistakenly appear to have few ketones, and ketone concentration may paradoxically rise as perfusion improves and the patients gets better.[172-173] The capillary blood determination of β-OH-B is a better alternative for treatment guidance.[173,174] As the renal threshold for the ketone bodies is low, ketones are readily filtered, with no reabsortion mechanism; accordingly the kidneys can eliminate a significant amount of ketones. This loss can shift the AG, which may appear less than expected because of the anions eliminated though the urine, with renal retention of chloride and bicarbonate. The picture can be even more complicated if hypocapnia from hyperventilation is present. Therefore AG (even corrected AG) may not be very useful in severe cases. SIG may provide more information in these more complicated situations.[60] Another form of ketoacidosis, the so-called *alcoholic ketoacidosis,* an uncommon syndrome in acute ethanol drinkers, may be a scenario with which pediatric and adolescent patients occasionally present in the PICU. This presentation is more frequent among patients with chronic ethanol intake and liver disease, and usually occurs after a period of heavy drinking, in association with reduced food intake. Alcoholic ketoacidosis is quickly responsive to fluid administration, with faster resolution when dextrose and saline are infused together.[175]

Toxic Compounds that Directly Provoke Acidosis

Alcohol-related intoxications, including methanol, ethylene glycol, diethylene glycol, and propylene glycol, may present with a high anion gap metabolic acidosis, with a decrease in serum bicarbonate and a rise in the osmolality, with an increased serum osmolar gap (i.e., difference between calculated and measured osmolality) (see also Chapter 106).

The acidosis and cellular dysfunction are direct effects of the metabolites of these substances, while the parent compounds are associated with an increase in serum osmolality. These are rather infrequent problems in the pediatric age group, but adolescents who ingest alcohol or illicit drugs (including inhalants), or who attempt suicide, are potential victims.[175] Younger ages are occasionally affected. Clustering of such cases usually uncovers locally prepared antipyretic (paracetamol elixir) contaminated with diethylene glycol. Similar cases have been reported for propylene glycol. The clinical presentation depends on the total dose of the adulterated medication received, and hence ranges from mild subclinical poisoning to unexpected and rather sudden onset of high anion gap acidosis, renal failure, and encephalopathy, with elevated mortality and a high probability of neurologic sequelae.[176] The intoxication is best treated with supportive critical care including proper alkalinization and early continuous hemofiltration or hemodiafiltration. In some areas a competitive inhibitor of alcohol dehydrogenase (4-methylpyrazole [or fomepizole]) is available for use in ethylene glycol and methanol poisoning, but extracorporeal removal should also be utilized. Fomepizole is possibly useful also in diethylene glycol and propylene glycol intoxications. For methanol and ethylene glycol, ethanol infusion is an alternative competitive inhibitor of the alcohol-dehydrogenase enzyme.[175,177]

Other Forms of Metabolic Acidosis Associated with an Increased Anion Gap

The pediatric critical care physician should be aware of a condition often called *late metabolic acidosis of prematurity*.[178] Although its incidence is greater in the premature infant when compared with that in the term infant (20% compared with 5%), the lesser capacity of not fully developed renal tubules to excrete H^+ and Cl^- and to concentrate urine is a fairly common situation during the first month of life. This level of renal tubular development is adequate for the breastfed infant, but if the protein intake or solute load is excessive, the renal capacity may be exceeded and a metabolic acidosis may develop. This is particularly true during periods of stress. In the setting of renal disease, the clinician must anticipate the occurrence of metabolic derangements. When chronic renal insufficiency develops, hyperchloremic metabolic acidosis—a non–anion gap acidosis—may initially occur because of impaired ammonium (NH_4^+) generation. When the glomerular filtration rate falls below 20 mL/min, the kidneys are incapable of excreting fixed acids. The resulting accumulation of sulfates among other acids may increase the AG. These acidoses are usually mild, producing an excess AG of approximately 10 mEq/L. A mixed metabolic acidosis (high-normal AG mechanism) is not uncommon in this setting.[10,172] If the patient has sepsis or another condition associated with hypermetabolism, however, the rate of acid generation increases and the acidosis may become rather severe. The SID decreases and, because of the lack of renal compensation, some intervention must be taken. Patients who do not yet require dialysis and those who are between their dialytic processes are often administered $NaHCO_3$ (provided there is no hypernatremia) or sodium potassium citrate.[179] In cases where bicarbonate is contraindicated, a dialytic process is in order.

Hyperchloremic Acidoses: The Non–Anion Gap Metabolic Acidoses

In the classical view, hyperchloremia was considered an epiphenomenon of the drop in bicarbonate concentration, due to its *abnormal loss* through urine or stools (see Table 68-4). The rise in chloride concentration is responsible for maintaining a "normal" anion gap, in spite of the drop in bicarbonate levels, i.e., a "non–anion gap" acidosis is produced. When bicarbonate is consumed to buffer an "acid load," hyperchloremia is not produced, because there are other anions emanating from the acid load that will preserve electroneutrality as bicarbonate falls. In this case, the anion gap increases, because of the presence of these "new" (and unmeasured) anions.[9,10,54] As new biological evidence accumulates, this physiological interpretation is increasingly being challenged, and a more central role for chloride is being emphasized.[55,64] Accordingly, the physiological shift is moving from kidneys that directly sense and regulate H^+ to kidneys that react to Cl^- balance, and therefore directly control the independent variable SID in acid-base regulation. This is supported by new insight in the physiology of several ion-transporters of the renal tubules.[51,54,55,100,180-183]

Thus, hyperchloremic acidoses occur either as a result of an increase in chloride concentration relative to strong cations (especially sodium) or because of the loss of cations with retention of chloride (see Table 68-6). When the pH drops, the normal response by the kidney is to increase chloride excretion as ammonium chloride (NH_4Cl), in order to increase the SID and raise back the pH. Thus, the role of the formation of ammonium (NH_4^+) and its eventual tubular excretion, is not for the elimination of H^+, but to allow Cl^- excretion without losing sodium or potassium. Failure to do so identifies the kidney as the problem,[10,49,172] as in renal tubular acidosis.

There are four main causes of non–anion gap acidoses: (1) exogenous chloride loads, such as saline boluses, parenteral nutrition; (2) loss of cations from the lower gastrointestinal tract without proportional losses of chloride, as in secretory diarrhea, also seen in conditions in which loss of alkaline small bowel, biliary, or pancreatic secretions is present (such as drainage from ostomies, tubes, fistulas); (3) renal tubular acidoses and drug-mediated tubulopathies; and (4) urinary reconstruction using bowel segments.

Exogenous Chloride Load

In the critical care unit, mandatory therapeutic interventions are frequently associated with hyperchloremic metabolic acidosis. The more common of such interventions are rapid infusion of isotonic saline (0.9% NaCl) and the infusion of parenteral nutrition. As stated before, the classical explanation for acidosis following saline administration was the so-called *bicarbonate dilution*. This mechanism probably plays a role in certain conditions.[80,101] Healthy, metabolically stable individuals, such as scheduled surgical patients, exhibit plasma SID around 40 mEq/L, while in critically ill patients SID is typically ~30 mEq/L (see Strong Ion Difference in this chapter). On the other hand, the SID of normal saline is 0 mEq/L, because sodium and chloride are both strong ions. Therefore, intravenous administration of 0.9% NaCl will necessarily decrease plasma SID, creating a strong ion acidosis, as long as such an infusion does not cause a change in PCO_2 or albumin or phosphate concentrations. The magnitude of the decrease in plasma SID when 0.9% NaCl is administered

is dependent upon the relative volumes of the extracellular space and the infused normal saline, and the speed of the infusion. Therefore, hyperchloremic acidosis should be expected whenever large volumes of normal saline are rapidly administered, such as in fluid boluses for treating shock, or during surgical procedures under anesthesia.[82,87,93,96] Even the acid-base status of disorders in which one or more unmeasured anions is clearly participating, such as septic shock (lactate) and DKA (ketones), has been shown to be influenced by the chloride supplied through resuscitation fluids,[84,87,92,94] and one recent report warned about hyperchloremic acidosis from saline resuscitation slowing the recovery of children with DKA.[184] This concern is one example of the usefulness of the "partition" of the SBE (see Merging Traditional and Newer Approaches in this chapter).[77,84]

In one study of 81 children with meningococcal sepsis, metabolic acidosis was common and prolonged (persisted for 48 hours), but the pathophysiology changed from one of unmeasured anions at admission to predominantly hyperchloremia-associated by 8 to 12 hours. Thus most of the time the acidosis was iatrogenic.[87] Development of hyperchloremic acidosis was related to the amount of chloride received during intravenous fluid resuscitation. From this and other similar studies, there is little doubt, if any, about the relationship between normal saline resuscitation and the development of hyperchloremia and acidosis (not necessarily acidemia), whatever the underlying mechanism.[87,101,183,185] However, it is not clear whether this hyperchloremic acidosis is really detrimental, implying that hyperchloremic acidosis due to exogenous administration of normal saline might be not an important issue.[65,69,94-97,185] Actually, in a group of 97 children (mean age, 57 months) evaluated in their postoperative period following open cardiac surgery, the occurrence of hyperchloremia was associated with reduced requirement for epinephrine therapy; thus the authors suggested that hyperchloremic metabolic acidosis is a benign finding that should not lead to the escalation of the hemodynamic support, hence the importance of its recognition.[82]

Interestingly, hypoalbuminemia (an alkalinizing force) was associated with prolonged length of stay in the critical care unit. In a recent review of laboratory, animal, human volunteer, and patient investigations focused on the physiological effects of hyperchloremia and acidosis,[95] it was concluded that there is a trend in scientific evidence indicating that both hyperchloremia and hyperchloremic acidosis have subtle, but potentially significant physiological and clinical undesirable effects. Although the acidosis is often quoted as the cause, it is unclear whether this is true or whether the high chloride levels should be of concern. Most of the clinical studies have revealed trends but not statistical significance toward a worse outcome in patients with hyperchloremic acidosis.

Hence, the conclusion so far is that the effects of hyperchloremia, hyperchloremic acidosis, or both are unlikely to influence outcome for most patients. However, given that hyperchloremic acidosis is often iatrogenic and is associated with some proven morbidity (increased length of stay in intensive care, delayed recovery of DKA, higher incidence of nausea/emesis in postoperative period, etc.,[42,184] it should be avoided whenever possible.[42,95,186] How can this task be achieved? Several groups have suggested and assessed the use of the so-called *balanced* fluids, that is, fluids with SID nearer to the SID of human plasma.[42,93,180,186,187] However, the results are still inconclusive. Besides, at least one prospective study in adults has suggested that the amount of fluids administered, rather than the types of fluids, had the stronger effect on the changes in base excess.[188] Meanwhile, the best approach is to keep in mind the potential hazard of hyperchloremic metabolic acidosis, especially in patients with previously known renal or liver dysfunction, with shock, and in surgical patients needing a large amount of intraoperative saline for resuscitation.[189] Intraoperative monitoring of serial chloride determinations has been suggested in order to unmask or exclude hyperchloremia as a cause of acidosis, undetectable through SBE alone.[96] Use of SBE-partitioning formulas to disclosure the effects of chloride on the acid-base status (see Equations 17A to 17C and Merging Traditional and Newer Approaches in this chapter) may be useful.

With regard to parenteral nutrition formulas, they contain weak anions such as acetate, in addition to chloride, and thus they are buffered. However, if an insufficient amount of weak anions is provided, plasma Cl^- will increase, SID decreases, and acidosis may result.[97]

Postpyloric Gastrointestinal Fluid Losses

The gastrointestinal (GI) tract, liver, and pancreas can be envisioned as a giant ion exchanger organ. Through all the sequential segments of the GI tract, distinct groups of ion transporters and channels interact with one another to determine the electrolyte content, pH, and volume of the fluid in the gut lumen. The main transport system is driven primarily by Na^+/K^+-ATPase across the basolateral membrane of the epithelial cells, with the participation of several key apical membrane electrolyte transporters, including Cl^-/HCO_3^- and Na^+/H^+ ion exchangers and the so-called cystic fibrosis transmembrane conductance regulator (CFTR) Cl^- channel.[190] Large masses of cations and anions traverse the specialized epithelia of the gut every day. This transport is adjusted for achieving an efficient absorption of dietary components rather than for acid-base homeostasis.

Under normal conditions, only a small amount of alkali (30 to 40 mmol/day) is lost in the stool, so kidney and lung compensation is generally not problematic. However, disruption of the normal gut function can provoke disorders that vary from severe acidosis (mostly postpyloric losses) to severe alkalosis (prepyloric losses, congenital chloridorrhea), depending on the segment of the GI tract affected and the nature of the losses that ensue.[190] For acid-base and electrolyte abnormalities to occur in diarrheal diseases, the volume of fluid lost must be large enough to overcome the kidney's ability to adjust excretion to maintain acid-base balance. With large losses, any form of diarrhea may lead to a significant fall in extracellular fluid volume, reducing the glomerular filtration rate (GFR) and limiting the ability of the kidneys to compensate for the problem. Secretory diarrheas (cholera, enteropathic *E. coli*, rotavirus, and other infectious diarrheas) most commonly produce this picture, with the typical presentation of hypovolemia, hypotension, acute renal failure, hyperchloremic metabolic acidosis (lost stools are usually rich in sodium, potassium, and bicarbonate, so SID decreases), and hypokalemia. If the hypovolemia and hypotension are not corrected, lactic acidosis superimposes, as a result of tissue hypoperfusion. Then, the AG_{CORR} is initially normal; it may increase gradually, but more frequently will remain normal in spite of lactacidemia. Hence it is always wise to monitor lactate levels.

The mechanism of the acidosis is well defined for cholera diarrhea, but is less defined for other pathogens. *Vibrio cholerae* produces a toxin that increases cAMP levels in intestinal crypt cells, producing a sustained activation of the apical membrane CFTR Cl^- channel leading to excessive Cl^- secretion into the ileum and colon. This increased chloride secretion in turn stimulates the apical Cl^-/HCO_3^- exchanger, increasing bicarbonate concentration in stools and increasing paracellular Na^+ and water entry, resulting in high-volume losses that contain a large amount of HCO_3^- as well as Na^+, Cl^-, and K^+. Replacement of the lost fluid and electrolytes can be achieved with oral solutions (100 mL/kg body weight of a solution containing 60 to 90 mEq/L of sodium).[191] In case of excessive losses or emesis, vigorous intravenous volume repletion must be implemented. Diarrhea due to laxative abuse can be seen in bulimic or anorexic adolescents, and usually does not associate with acid-base derangements. Of course, if excessive diarrheal losses occur, then metabolic acidosis can occur, as with any severe diarrhea.[190]

Both biliary and pancreatic secretions have an alkaline pH. When pancreatic or biliary drainage is required after surgery, the volume is usually low, so despite the loss of a $NaHCO_3$-rich fluid, significant metabolic acidosis does not occur. On the rare occasions in which these drainages are excessive (volume usually around 30 mL/kg/day or greater), metabolic acidosis will develop and be perpetuated by concomitant volume depletion. Repletion with saline solutions is enough for the replenishment of cations, mainly sodium, which restores SID value. Bicarbonate administration is equally effective.[190] Patients with well-functioning ileostomies usually adapt to the obligatory extra fluid loss through subtle changes in salt and water intake, as well as changes in urine volume and electrolyte and acid excretion. If the ileostomy drainage abruptly increases, the resultant salt and water losses can easily lead to clinically significant volume depletion. In this setting, the development of metabolic acidosis is the rule, because HCO_3^- in ileostomy fluid is usually higher than in plasma, causing disproportionate sodium and alkali loss. Hyperkalemia is usually present with this metabolic acidosis, reflecting the fact that K^+ is not secreted in the ileum and therefore the losses contain little K^+. In addition, renal K^+ excretion is impaired by the volume depletion. A similar problem can be seen in patients who have shortened small intestine connected to the colon for any reason, with the additional possibility of D-lactic acidosis (see section on D-Lactic Acidosis in this chapter).

Renal Tubular Acidoses and Drug-Mediated Tubulopathies

RTA comprises a group of disorders characterized by a low capacity for net acid excretion (NAE) and persistent hyperchloremic metabolic acidosis, with normal anion gap and normal or minimally affected filtration rate (GFR). On the basis of functional studies, RTA has traditionally been separated in three main categories: (1) proximal RTA, or type 2; (2) distal RTA, or type 1; and (3) hyperkalemic RTA, or type 4. Sometimes a fourth kind is recognized: combined proximal and distal RTA (mixed RTA), or type 3.[192] Type 4 RTA is of special interest in the critical care setting, as the hyperkalemia may be triggered by some drugs used in intensive care units, such as angiotensin-converting enzyme inhibitors, heparin, trimethoprim, α-adrenergic agonists, β-adrenergic antagonists, digoxin, and others. The classical acid-base approach states that metabolic acidosis arises from a lack of urine excretion of protons (hydrogen ions) or an excessive loss of bicarbonate due to a variety of tubular disorders.[100,192] Molecular studies have identified genetic or acquired defects in transporters of protons and bicarbonate in most varieties of RTA.[192,193] This classical physiological view has been challenged by the physicochemical acid-base interpretation, and is supported by the fact that these transporters are also involved in Cl^- and Na^+ transport through membranes, and that at least certain cases of RTA are clearly associated with primary defects in electrolyte transporters alone.

In a recent study, 12 children with alkali-treated distal RTA were compared to healthy controls. Both groups received a load with hypotonic saline (0.45%), but only the RTA patients developed hyperchloremia and metabolic acidosis, which was shown to be associated with high total and high distal fractional absorption of chloride. Urinary excretion of bicarbonate did not correlate with changes in either blood pH or plasma bicarbonate concentration. Thus, renal tubular avidity for chloride was indeed increased in RTA.[100,182,194] Therefore, tubular transport mechanisms determine the excretion of strong ions, Na^+, K^+, and Cl^-. This determines the balance of the concentration of SID, both in the extracellular compartment, dominated by Na^+ and Cl^-, and in the intracellular compartment, dominated by K^+. SID determines pH, and by way of partly characterized sensor and effector mechanisms, must feed back to the tubular ion transport complexes. Thus, acid-base homeostasis is directly regulated by electrolyte transport in renal tubules, and hence hydrogen and bicarbonate movements reflect ion balance requirements imposed by physical chemistry.[49,100,182,194] This supports the notion that NH_4^+ is more related to the elimination of Cl^- without loss of Na^+ or K^+, rather than in titrating urinary H^+.[49,182,194] According to the physicochemical approach, the underlying defect in all types of RTAs is an inability to excrete chloride in proportion to sodium, although the transporter involved depends on the specific type of RTA.[100,182,194] In the critical care setting, the presence of RTA may complicate resuscitation fluid management and acid-base balance. Previously unknown RTA must be suspected whenever the clinical condition of a given patient does not improve as expected with the proper therapeutic interventions. Treatment largely depends on whether there are losses of sodium that can be replaced with $NaHCO_3$ or whether the kidney will require mineralocorticoid replacement. A more detailed discussion of RTA is beyond the scope of this chapter. It is worth mentioning, however, that urinary AG (uGAP) = $[uNa^+ + uK^+] - [uCl^-]$,[195] more recently known as "urine strong ion difference" (see Equation 14 and Strong Ion Difference in this chapter),[9,55] is useful as a part of the diagnostic workup of a patient with hyperchloremic acidosis. If it is negative ($uCl^- > uNa^+ + uK^+$), it suggests either GI bicarbonate loss, acute infusion of a high volume of saline isotonic fluid (NaCl 0.9%), or a proximal RTA, which will require additional functional tests for diagnostic confirmation once the patient is discharged from intensive care. On the other hand, if the uGAP is positive ($uCl^- < uNa^+ + uK^+$), it suggests the presence of a distal renal defect. Additional functional tests will allow one to identify distal RTA, hyperkalemic distal RTA, or type 4 RTA.

Also of importance to the intensivist is iatrogenic RTA caused by the nephrotoxicity of amphotericin B aminoglycosides and other drugs. Kidney alterations due to amphotericin

B include decreased glomerular filtration rate, distal tubulopathy with urinary loss of potassium and magnesium, RTA, loss of urine concentration ability, and sometimes Fanconi syndrome. Nephrotoxicity is related to treatment duration, schedule, cumulative dosage, and combination with diuretics and other nephrotoxic drugs (aminoglycosides, cyclosporine, tacrolimus, cisplatin, ifosfamide). Each dose increment of 0.10 mg/kg/day has been found to be associated with a 1.8-fold increase in the risk of nephrotoxicity, while infusion rate and concentrations are not related.[196] The mechanisms involved in nephrotoxicity include the deoxycholate vehicle for amphotericin B, reduction in renal blood flow and GFR, increased salt concentration at the macula densa, interaction of amphotericin B with ergosterol in the cell membrane, and apoptosis in proximal tubular cells and medullary interstitial cells. Salt loading, with daily sodium intake higher than 4 mEq/kg/day, is the only measure proven by a controlled prospective study to ameliorate amphotericin B nephrotoxicity in humans, including extremely low-birth-weight infants.[197] Proper hydration must be assured with 10 to 15 mL/kg of normal saline prior to administration of the drug. Lipid formulations of amphotericin B (liposomal, lipid complex, colloidal dispersion) are indicated in all children receiving other nephrotoxic drug, with already reduced GFR, or with previously known adverse effects to regular amphotericin B. Total dose of 35 mg or more, chronic renal disease, concomitant use of cyclosporine or amikacin, and male sex have been identified in adults as risk factors. Patients with more than two risk factors demonstrated an incidence of moderate-to-severe nephrotoxicity of 29%.[198]

Trimethoprim-sulfamethoxazole is another antimicrobial that has been related to RTA and hyperchloremic metabolic acidosis.[199] Topiramate, one of the "new" antinconvulsant drugs, has been reported to cause hyperchloremic metabolic acidosis in pediatric and adult patients. Topiramate inhibits the enzyme carbonic anhydrase, and thus a type 3 or mixed RTA is produced, as it impairs both the normal reabsorption of filtered bicarbonate by the proximal renal tubule and the excretion of hydrogen ions by the distal renal tubule. This topiramate-induced RTA can present acutely with requirement for emergency or critical care, or chronically, producing growth retardation, nephrolithiasis, and osteoporosis.[200] Acute presentation includes drowsiness/lethargy, dizziness/vertigo, agitation, confusion, and nausea/vomiting. These manifestations, in a patient receiving topiramate, should prompt the clinician to evaluate acid-base and electrolyte balance. A significant decrease in HCO_3^- has been documented in roughly 50% of patients receiving topiramate, although the number of affected individuals increases with escalating doses. To date, however, the relationship between bicarbonate concentration and topiramate dosage has not been adequately defined. Depression of bicarbonate levels is usually mild, with serum HCO_3^- typically between 20 and 10 mEq/L. Severe, acute HCO_3^- decrements to values less than 10 mEq/L have rarely been documented. In this setting, AG is normal and is associated with alkaline urine, positive uAG, low urinary citrate excretion, and β_2-microglobulinuria. If the acidosis requires acute correction, or the RTA is persistent, topiramate should be discontinued.

Another rare cause of normal AG metabolic acidosis that may be seen in the ICU is acetazolamide, a carbonic anhydrase inhibitor used occasionally to decrease cerebral spinal fluid production and, more frequently, to stimulate renal bicarbonate wasting.[201] This drug impairs hydrolysis of H_2CO_3 to CO_2 and H_2O, resulting in a decrease of renal HCO_3^- reabsorption. It has recently been described that, both in humans and in an animal model, acetazolamide can produce severe lactic acidosis with an increased lactate-to-pyruvate ratio, ketosis with a low β-hydroxybutyrate-to-acetoacetate ratio, and a urinary organic acid profile typical of pyruvate carboxylase deficiency.[202] This "acquired enzymatic injury" stems from the inhibition of mitochondrial carbonic anhydrase type V, which provides bicarbonate to pyruvate carboxylase and can produce Krebs cycle inhibition. Some of these patients improved dramatically after packed red blood transfusion; the improvement was likely related to the citrate anticoagulant.

Urinary Reconstruction Using Bowel Segments

Children with irreversible lower urinary tract dysfunction due to developmental abnormalities involving the genitourinary (GU) system, neurogenic or myogenic bladder, etc., may require urological surgical procedures for their management, including continuous urinary diversion and enterocystoplasty. Various techniques and bowel segments can be used depending on the clinical situation. The GI tract is a relatively poor substitute for urothelium, and its semipermeability allows nonphysiologic fluid and electrolyte absorption leading to metabolic abnormalities.[203] The significance of these problems is related to the portion of the GI tract used and to the length of time the urine is exposed to the bowel surface. If, in addition, the loss of some portions of the GI tract results in complications such as chronic diarrhea, there may be further metabolic consequences. Jejunal substitution is associated with uniform and profound metabolic instability resulting in hyponatremic/hypochloremic/hyperkalemic acidosis, clinically manifested by nausea, vomiting, anorexia, and muscular weakness. When ileum or colon is used for the GU reconstruction, hyperchloremic/hypokalemic metabolic acidosis may present. Clinically, this may produce weakness, anorexia, vomiting, and Kussmaul breathing, and may progress to coma. In the less severe cases, a chronic metabolic acidosis may go undetected, resulting in growth retardation. In a recent series report, 41% of 44 children required constant prophylactic alkaline replacement,[204] although older reports documented hyperchloremic metabolic acidosis in 68% of ileal conduits, and acidosis being a major problem in 18% of patients with enterocystoplasties.[203] Thus, although acute decompensations may require intravenous correction of the acidosis with bicabornate and/or fluid loads in the emergency department or PICU, most cases will maintain electrolyte balance with lifelong alkalinization with oral bicarbonate, sodium citrate, or citric acid solutions.

Treating Metabolic Acidosis

How is metabolic acidosis treated? Should metabolic acidosis be treated? This topic remains controversial, except in regards to basic approach: treat the underlying cause. Certain acidoses have specific therapies, such as insulin and fluids for the patient with diabetic ketoacidosis, $NaHCO_3$ and citrate for patients with the classic distal RTA, and fomepizole for methanol intoxication. These specific cases are beyond the scope of

this chapter. The following discussion focuses on lactic acidosis, unless otherwise mentioned.

Sodium Bicarbonate

$NaHCO_3$ administration has long been the standard therapy for metabolic acidosis, including lactic acidosis.[107,172] There is consensus regarding the advantages of alkali and sodium bicarbonate therapy in normal anion gap acidosis. However, in the presence of high anion gap acidosis, especially lactic acidosis (in shock and cardiopulmonary resuscitation) but also in diabetic acidosis, there exists negative evidence regarding the safety and efficacy of sodium bicarbonate use . Justification for the persistent use of bicarbonate comes from a variety of sources, many based more on philosophy than on science.[9,107,111,172,205,206]

It seems self-evident that adding bicarbonate to acidic blood will raise the pH. However, the reality is significantly more complex. Consistent with Equations 11A and 11B, administration of $NaHCO_3$ increases the SID (which tends to raise the pH) because sodium is a strong cation and bicarbonate is a weak anion; however, in agreement with Equation 3, it is an anion that rapidly converts to carbonic acid and then to CO_2, which tends to lower the pH.[111,207,208] Therefore $NaHCO_3$ may increase arterial pH if, and only if, alveolar ventilation is not limited.[107,111,205-212] Although the risk of paradoxic intracellular acidosis after bicarbonate administration is not negligible, this neither necessarily occurs nor it is always detrimental to the cell.[107,111,208,209] The final effect of $NaHCO_3$ on intracellular pH depends on changes in PCO_2 in the medium bathing the cells, which are influenced by the extracellular nonbicarbonate buffering capacity.[208] These cells are usually depressed in the critically ill patient in whom $NaHCO_3$ is administered.

In addition, bicarbonate administration may promote metabolic reactions that may themselves alter not only PCO_2, but also the total concentration of weak acids and the SID. In fact, it has been documented that bicarbonate can increase the production of lactic acid in both animals and humans.[111] Mechanisms to explain this remain speculative but include a shift in the oxyhemoglobin-saturation relationship, enhanced anaerobic glycolysis probably mediated by the pH-sensitive enzyme phosphofructokinase, and changes in hepatic blood flow or lactate uptake.[111,142] Altogether, however, animal and human studies and time-honored clinical experience have shown that arterial pH can be raised and even normalized with $NaHCO_3$,[9,107,11,172] yet multiple compartments separated by membranes of differing permeabilities exist. Thus even when $NaHCO_3$ added to the central veins reliably elevates the arterial pH, its effect can be erratic at tissue and cellular levels.

For example, in the cerebrospinal fluid and intracellular spaces the pH may drop further, without concordance with an already alkalemic arterial blood sample. This could happen because CO_2 raised by the bicarbonate infusion may readily diffuse across cell membranes and the blood-brain barrier, whereas bicarbonate cannot. Therefore, despite its ability to increase blood pH when given intravenously, bicarbonate fails to reliably augment the intracellular pH.[208,209] In a classic report, Adrogué et al. demonstrated that bicarbonate administration in the setting of cardiopulmonary compromise actually worsened the pH and PCO_2 in central venous blood samples, indicating persistent acidosis at the tissue level.[124] Results of human studies that examined the impact of bicarbonate administration during cardiopulmonary resuscitation have uniformly shown no benefit in terms of survival and hemodynamic recovery. Several studies have demonstrated a deleterious effect in this setting, and many others have shown no discernable effects.[107,111,124,207] This is why the American Heart Association no longer recommends routine administration of bicarbonate during cardiopulmonary resuscitation. Its use is considered only after effective ventilation, chest compressions, and epinephrine are established in the prolonged arrest scenario and for cases in which bicarbonate is a "specific" therapeutic intervention (e.g., hyperkalemia, hypermagnesemia, tricyclic antidepressant poisoning, and sodium channel blocker poisoning).[213] There is also no evidence of benefit with sodium bicarbonate infusion during resuscitation of infants at birth.[214]

The argued rationale for bicarbonate use in the shock setting is to mitigate the adverse hemodynamic consequences of acidemia. However, adult studies have indicated that bicarbonate is no more effective than saline in improving heart rate, central venous pressure, pulmonary artery pressure, mixed venous hemoglobin oxygen saturation, systemic oxygen delivery, oxygen consumption, arterial blood pressure, pulmonary artery occlusion pressure, and cardiac output.[107] These findings suggested that the commonly observed hemodynamic response to bicarbonate administration in patients treated with inotropic/vasoactive drug infusions may simply be due to preload augmentation rather than enhanced catecholamine responsiveness.[111] These findings persisted in the most severely acidemic subset of patients (pH 6.9 to 7.2), a result that does not support the practice of withholding bicarbonate in patients with "mild" acidemia and allowing its administration in those with "severe" acidemia. On the contrary, it could be expected that this sicker subset of patients would develop a more profound paradoxical intracellular acidosis after bicarbonate administration. It is likely that all these data derived from adult patients can be extrapolated to most pediatric ages, excluding infants and neonates, for whom there is insufficient evidence to determine whether infusion of base or fluid bolus reduces morbidity and mortality from metabolic acidosis.[215] The most recent (2008) Surviving Sepsis Guidelines, based on a thorough evaluation of ancillary therapies in adult sepsis and septic shock, did not recommend the use of bicarbonate for hemodynamic resuscitation or reduction in vasopressors in the setting of lactic acidosis with pH greater than 7.15, while deferring judgment for more severe acidemia. A recent review further recommended a lower target pH of 7.00 or less,[107,211] a position supported by other authoritative reviews,[212] as no reliable argument exists to prove that such acidosis is harmful under these conditions in humans. Experimental data even show that hypoxic cells are able to survive only if the medium is kept acidic. However, the 2007 update of the Clinical Practice Parameters for hemodynamic support of pediatric and neonatal septic shock from the American College of Critical Care Medicine,[216] states that sepsis-induced acidosis and hypoxia can increase pulmonary vascular resistance and thus maintain patency of the ductus arteriosus, resulting in persistent pulmonary hypertension of the newborn (PPHN). Inhaled nitric oxide is the treatment of choice; however, the committee agreed that metabolic alkalinization remains an important initial resuscitative strategy during shock, as PPHN in the setting of septic shock can reverse when acidosis is corrected.

In a recent single-center, prospective, observational study that enrolled 60 adults with either severe sepsis or septic

shock, a quantitative acid-base analysis approach was applied in order to clarify the components of the metabolic acidosis.[217] It was found that at the time of admission to ICU, these patients presented with a complex pattern in their metabolic acidosis, caused predominantly by hyperchloremic acidosis (more pronounced in nonsurvivors), and partially offset by hypoalbuminemia. Acidosis resolution in survivors was attributable to a decrease in strong ion gap and lactate levels. This study is rather small and has some other limitations, but it may imply that a subset of sepsis/septic shock patients (those with hyperchloremic acidosis identified by SIG, AG_{CORR} and partitioned SBE), may indeed benefit from sodium bicarbonate administration.

The clinician must be aware that $NaHCO_3$ is not free of negative side effects, the main being related to fluid and sodium load that can cause hypervolemia, hyperosmolarity, and hypernatremia.[205] $NaHCO_3$ given as a rapid intravenous (IV) bolus can cause a transient decrease in arterial blood pressure and a transient rise in intracranial pressure, probably related to its hypertonicity.[111] This effect is ameliorated when bicarbonate is administered as a slow IV infusion. Regardless of the infusion rate, IV administration of bicarbonate can cause sudden shifts of several cations through cell membrane-mediated mechanisms. This is advantageous in treating hyperkalemia,[213] but it also can be dangerous because bicarbonate lowers ionized calcium. "Overshoot" alkalosis, in which an abrupt and poorly tolerated transition from severe acidemia to alkalemia develops, can result from overly aggressive bicarbonate "correction."[210-212] Therefore the decision whether to use bicarbonate in lactic acidosis may become a difficult one because it is a choice between loyalty to a longstanding but unproven therapy, and congruent scientific behavior that must surrender to the evidence of potential deleterious effects of bicarbonate administration in a variety of acidemic conditions.[107,111,140,142,210-212]

Nevertheless, the urge to give bicarbonate to a patient with severe acidemia may become irresistible for most clinicians. It will always be prudent to adjust the clinical decision to the specific characteristics of each patient, keeping pros and cons in mind. If bicarbonate is used, consideration must be given to employ a slow infusion and a plan for clearing the CO_2 that is produced. Additionally, ionized calcium must be measured and corrected if needed, as the resultant drop may compromise cardiac and vascular contractility and responsiveness to cathecholamines. The amount of bicarbonate to be given should be calculated to raise the pH up to 7.2.[212] Thus the decision to provide "bicarbonate correction" must be based on the best clinical judgment mixed with a knowledge of the available evidence. This science-and-art approach to the individual patient can be summarized in the clinician's answer to the following questions, modified from Forsythe and Schmidt[111]:

1. Is the level of low pH a clear and present hazard to this patient?
2. Is there a reasonable expectation that increasing the blood pH with $NaHCO_3$ will have some beneficial effect?
3. Is there a particular and specific risk to this patient from the known potentially negative effects of $NaHCO_3$?
4. Is the mechanism of the acidosis suitable for treatment with $NaHCO_3$, or might the acidosis be exacerbated?

There are no recipes for answering these questions.

Salicylate intoxication represents a special setting. Because the risk of death and the severity of neurological manifestations depend on the concentration of salicylates in the central nervous system, therapy is directed at limiting further drug absorption by administering activated charcoal in the emergency department and promoting the exit of the drug from the cerebral tissue by increasing the alkalinity of the blood, which also will raise urine pH and therefore inhibit salicylate reabsorption by ion trapping. Thus this represents a special case of lactic acidosis in which $NaHCO_3$ is clearly indicated for two reasons: (1) to establish a high urinary flow rate along with other fluids and (2) to promote salicylate excretion. The target pH of the urine is 7.0 to 7.5. Hemodialysis is reserved for severe cases, especially those involving renal dysfunction.

If the science-and-art decision is to administer $NaHCO_3$, some time-honored clinical clues are valuable. $NaHCO_3$ dose is best estimated with either the SBE or the bicarbonate level derived from PCO_2 measured by the blood gas analyzer:

$$\text{Total body base deficit} = \text{SBE} \times \text{Body weight(kg)} \times 0.3 \quad (18A)$$

$$HCO_3^- \text{ deficit} = 0.3 \times \text{Body weight (kg)} \times [HCO_3^- \text{ expected} / HCO_3^- \text{ observed}] \quad (18B)$$

The distribution volume of bicarbonate is 0.3, or 30% of the lean body weight. The theoretical distribution volume of $NaHCO_3$ equals the extracellular fluid volume, that grossly represents 60% of the body weight (70% in young infants), and therefore it can be argued that the correct arithmetic factor should be 0.6 (or 0.7) rather than 0.3. Time-honored experience has shown, however, that as the starting point, bicarbonate or SBE correction with 0.3 ("half correction") will suffice in most cases and will avoid unnecessary risks from excessive load of solutes and fluid as well as the overshoot alkalemia. It should be taken into account that the usual $NaHCO_3$ preparation available worldwide has a concentration of 0.88 mEq/mL, with pH 8 and 1461 mOsm/kg. Therefore bicarbonate is ideally administered through a central venous line and diluted 1:1 with distilled water. If it has to be infused through a peripheral vein, the dilution must be increased.

Carbicarb

Concern about the CO_2-producing effect of bicarbonate led to the development of Carbicarb, which consists of equimolar concentrations of $NaHCO_3$ and sodium carbonate (Na_2CO_3).[107,140,218-219] Carbicarb raises the SID and thus increases the pH far more than bicarbonate, with much less rise in PCO_2, thereby limiting but not eliminating the generation of CO_2. The risks of hypervolemia and hypertonicity are similar to those of bicarbonate. Animal studies have shown stabilization of serum lactate levels and improved acid-balance profile both in blood and at the intracellular level. Carbicarb administration also resulted in a significant increase in cardiac index when compared with normal saline and $NaHCO_3$, although neither Carbicarb nor $NaHCO_3$ prevented the progressive reduction in myocardial cell pH in an animal model of ventricular fibrillation. Although Carbicarb more consistently increases intracellular pH, studies of its effects on hemodynamics have yielded conflicting results.[140] Carbicarb is not currently available for clinical use, but there is no doubt that after all the years elapsed since its appearance, it deserves further clinical research.

Tris(hydroxymethyl)aminomethane

THAM, also known as tromethamine and tris buffer, is an amino alcohol that behaves as a weak base (pKa 7.8). It exists in neutral form at physiological pH. Protonated THAM is excreted by the kidneys.[220] It crosses lipid membranes and penetrates cells easily. Therefore it has the potential to raise both intracellular and central nervous system pH. In addition, THAM's buffering action occurs without producing CO_2, and thus is not dependent on pulmonary function.[221] Despite THAM being commercially available for several decades, there are few studies establishing its clinical efficacy. In animal models, THAM incompletely buffered metabolic acidosis, but it significantly improved contractility and relaxation in an isolated rabbit heart model.[107] A small adult study in the ICU setting, showed that THAM had an equivalent but shorter lasting alkalinizing effect in comparison to that of bicarbonate, but produced no decrease in potassium and did not elevated sodium, as occurs with bicarbonate.[222] The paucity of information and the report of several serious side effects, including hypekalemia, hypoglycemia, local extravasation injury, and hepatic necrosis in neonates, have limited its widespread use in the lactic acidosis setting.

Dichloroacetate

Of particular relevance for lactic acidosis is dichloroacetate (DCA), a simple compound that reduces plasma lactic acid concentration. DCA is not a buffer but a stimulator of pyruvate dehydrogenase, the enzyme that catalyzes the oxidation of pyruvate to acetyl–coenzyme A (CoA), facilitating its entry to the Krebs cycle and thus decreasing lactate production and promoting the clearance of accumulated lactate.[107,223] In addition, DCA promotes myocardial glucose utilization and contractility. Initial data from both children and adults were promising, but a large controlled clinical trial in adults with severe lactic acidosis showed that DCA treatment resulted in statistically significant but clinically unimportant changes in arterial blood lactate concentrations and pH. It also failed to alter hemodynamics or survival. Renewed interest in DCA has arisen from its potential application in attenuating lactic acidosis in certain congenital errors of metabolism,[224] and lactic acidosis due to severe malaria in children.[225] In regard to shock patients, the physiological "new paradigm" concerning the cell-to-cell lactate shuttle and its metabolic importance raises the possibility that targeting a specific pharmacological reduction of lactate levels through DCA might not be advantageous in this setting.[136-139]

Dialysis Management of Metabolic Acidosis

Dialytic procedures may be indicated in some cases of metabolic acidosis that are refractory to bicarbonate or in cases in which there are serious limitations in the amount of fluid or sodium load that can be administered to the patient, a common situation in the pediatric critical care unit (see Chapter 72) Uncompensated metabolic acidosis (pH <7.1) remains one of the acknowledged criteria for the initiation of renal replacement therapy in the pediatric ICU.[206] Peritoneal dialysis is often not the best choice, particularly in lactic acidosis associated with hypoperfusion. In this setting the hypoperfused peritoneal membranes may not be efficient for supporting enough peritoneal flux, and the increase in intraabdominal pressure may contribute to a further drop in cardiac output. If peritoneal dialysis is chosen, bicarbonate-buffered peritoneal dialysis solution provides some advantages over the conventional lactate-buffered peritoneal dialysis solution in terms of pH control, biochemical monitoring, and mesothelial cell preservation.

Most critically ill patients lack the hemodynamic stability to tolerate intermittent hemodialysis. Hemofiltration and hemodiafiltration are better options. Acute renal replacement therapy may be needed for critically ill patients with metabolic acidosis that is multifactorial in origin. Analysis of the acid-base status of these patients through Stewart-Figge methodology shows that acidemia is present despite the presence of hypoalbuminemic alkalosis, and that this acidemia is mostly secondary to hyperphosphatemia (mainly if there is concomitant acute or chronic renal failure), hyperlactatemia, and the accumulation of unmeasured anions. Once continuous hemofiltration is started, it becomes the dominant force in controlling metabolic acid-base status and profound changes are rapidly achieved. The result is the progressive resolution of acidemia and acidosis, with lowering concentrations of phosphate and unmeasured anions. If the patient stabilizes, this typically results in some degree of metabolic alkalosis, an effect the clinician must take always in account.

Hemofiltration techniques replace plasma water, which is low in bicarbonate concentration, with a solution that contains an above-normal bicarbonate (or lactate or acetate) concentration. Such weak anions free their sodium (which increases SID), buffer hydrogen ions, and then are transformed into CO_2 (lactate and acetate must convert first to bicarbonate in the liver), which is subsequently removed by ventilation. This exchange contributes to the correction of acidosis, along with the increase in SID through the sodium contribution. If such oxidizable anions are not fully extracted and metabolized by the liver and, therefore, accumulate in plasma, the ability to correct acidosis is lost, as they fail to increase the SID. Hence, hyperlactatemia with acidification of plasma occurs. Such iatrogenic hyperlactatemic acidosis is particularly frequent in lactate-intolerant patients (shock with lactic acidosis and/or liver disease), and it is specially marked if high-volume hemofiltration is performed, in which the associated high lactate load may easily overcome the patient's metabolic capacity for taking up lactate. In such patients, use of bicarbonate-based replacement fluids is mandatory.[226] In addition, the effect of lactate-based replacement fluid on blood lactate concentration can be misleading in patients who have sepsis with lactic acidosis. Additionally, it appears that lactate clearance through the hemofilter is small compared with endogenous clearance. Therefore, despite the fact that hemofiltration has been advocated for the treatment of lactic acidosis, kinetic studies of lactate removal do not suggest that such removal can counteract lactate production in any meaningful way.[140]

Metabolic Alkalosis

Metabolic alkalosis is defined as an elevation of plasma HCO_3^- with an arterial pH above 7.45. There is no accurate estimate of the incidence or prevalence of metabolic alkalosis. However, in the critical care setting, it is estimated that metabolic alkalosis is the more common form of acid-base disorder, as it may be present in about 50% of patients with acid-base disorders.

A study in pediatric patients undergoing open-heart surgery, found that 72% of children under 12 months of age developed metabolic alkalosis, in contrast with 30% of those older than 12 months of age. It is difficult to attribute a figure of mortality or morbidity directly to metabolic alkalosis. However, at least one study in adults found that mortality progressively rose with the pH: 47% with pH 7.57 to 7.59, 65% with pH 7.60 to 7.64, and 80% with pH 7.65 to 7.70. This does not necessarily indicate a cause-effect relationship.[227,228] Most of the clinical studies that have examined metabolic alkalosis are now somewhat old, and there is a need for prospective studies of updated design to reassess the incidence, consequences, and other aspects of metabolic alkalosis.

The increased incidence of metabolic alkalosis in patients with severe sepsis and trauma is due to factors related to a vigorous correction of shock, hypotension, and acidosis, where large quantities of citrated blood or lactated Ringer solution are given, as well as to the administration of bicarbonate itself (Table 68-8).[227] Other subsets of patients may arrive in the PICU already with metabolic alkalosis, associated with the chronic use of chloruretic diuretics, excessive exogenous or endogenous steroids, high doses of antacids, or related to elevated gastrointestinal fluid losses (emesis, suction, or chloride-rich diarrhea) or to the posthypercapneic state, the typical pattern of a chronic lung disease after the resolution of an acute episode of decompensation.[228,229] Alkalemia has been classified as mild (pH 7.45 to 7.50), moderate (pH 7.50 to 7.55), or severe (pH > 7.55).[227]

According to the physicochemical approach, metabolic alkalosis results from an increase in SID, or a decrease in A_{TOT}, due to a loss of anions (Cl^- from the digestive tract or through the kidneys, albumin from the plasma) or, rarely, to an excess of cations.[8,10] (see Table 68-6). In the classic approach to acid-base derangements, metabolic alkalosis is generated by net gain of base (primarily bicarbonate) or loss of nonvolatile acid from the extracellular fluid. Despite the fact that this model is not able to explain many of the electrolyte changes associated with metabolic alkalosis nor the reasons for the good results of some therapeutic interventions, it continues to be a practical way to approach metabolic alkalosis.[9,230] The excess of base may be gained through oral or parenteral bicarbonate administration, or by the administration of other weak anions such as lactate, acetate, or citrate, all of them as sodium salts. Thus it is actually the gain of strong cations (mainly sodium) that causes pH to increase. The acid deficit may be due to the hydrochloric acid loss by vomiting or enhanced renal acid excretion promoted by diuretics or aldosterone excess, and is often accompanied by hypochloremia and hypokalemia.[227-229] In a similar way, it is the loss of strong anions (mainly chloride), rather than the direct loss of hydrogen ions, that actually increases pH. There may also be a contraction of the extracellular fluid volume secondary to the chloride loss. Concomitant changes in the intracellular fluid do occur, including a loss of intracellular potassium along with a net gain of sodium and hydrogen. Hence, metabolic alkalosis in the extracellular fluid is usually accompanied by acidosis and potassium depletion in the intracellular compartment. Bicarbonate or base loading is rarely the single cause of metabolic alkalosis. Such a situation may transiently occur during and immediately after an IV infusion of $NaHCO_3$ or an equivalent base (e.g., citrate anticoagulant in transfused packed red blood cells). This situation may also occur after the successful treatment of ketoacidosis or lactic acidosis because these organic anions are metabolized to bicarbonate, and after the resolution of hypercapnia, either permissive or as a part of unintentional respiratory acidosis, before the kidney can excrete the bicarbonate previously "retained for compensation" (actually, HCO_3^- was increased because PCO_2 was increased). It is generally accepted that metabolic alkalosis involves a "generative" stage, during which the relative concentraton of alkali within the body increases, and a "maintenance" stage,[228,229] in which the kidneys fail to compensate by excreting strong cations and HCO_3^-.

Three major factors underlie the maintenance phase in most clinical situations: first, depletion in circulating volume and changes in generalized hemodynamics (e.g., heart failure) and in intrarenal hemodynamics, which combine to reduce the filtered load of bicarbonate traversing the proximal tubule despite the increase in bicarbonate concentration; second, increased aldosterone secretion (and probably endothelin-1), due to volume contraction and increased angiotensin-II, which stimulates acid secretion; and third, total potassium depletion and hypokalemia, which alter glomerular hemodynamics,

Table 68–8 Causes of Metabolic Alkalosis in Critically Ill Patients

I. Chloride-responsive (decreased urine [Cl^-]*)
  A. Gastrointestinal losses of Cl^-
    1. Gastric drainage or persisting vomiting
    2. Chloride-wasting acute diarrheas
  B. Renal losses of Cl^- and K^+
    1. Diuretics (mainly acute use)
    2. High dose of certain penicillin-derivative antibiotics
    3. Posthypercapnia
II. Chloride-resistant (increased urine [Cl^-]†)
  A. Excess mineralocorticoid activity: ongoing losses of K^+ and Cl^-
    1. Primary and secondary hyperaldosteronism
    2. Congenital adrenal hyperplasia (17α-hydroxylase or 11β-hydroxylase deficiency)
    3. Cushing syndrome
    4. Primary renin-secreting tumors
    5. Steroid treatment
  B. Genetic renal tubular defects of electrolyte transport
    1. Problem in chloride reabsorption
      a. Bartter and Gitelman syndromes
    2. Defective epithelial sodium channel (decreased sodium elimination)
      b. Liddle syndrome
  C. Drug-induced hypokalemic alkalosis
    1. Diuretics administered for prolonged time
    2. High-dose glucocorticoids
    3. Fludrocortisone
    4. Aminoglycosides
    5. Toxic effects of licorice (*Glycyrrhiza glabra*)
    6. Ion exchange resin
  D. Excess cation (alkali) gain
    1. Massive blood transfusion
    2. Massive infusion of lactated Ringer's solution
    3. Parenteral hyperalimentation with excessive sodium acetate
    4. Alkali ingestion/treatment and milk-alkali syndrome
    5. Magnesium depletion
III. Miscellaneous group (variable urine [Cl^-]†)
  A. Hypoproteinemia
  B. Cystic fibrosis
  C. Congenital chloride diarrhea
  D. Salt-losing nephropathy

*<20 mEq/L, usually <15 mE/L.
†>20 mEq/L, usually >40 mEq/L.

stimulate the renal H^+-K^+-ATPase, and secondarily increase renal acid secretion in the presence of aldosterone.[230] In other words, the regulation of pH through strong cation (mainly sodium) and bicarbonate elimination, is sacrificed to preserve volume and potassium stores. If volume and potassium are equilibrated, metabolic alkalosis self-corrects.

Metabolic alkalosis has been classified by the primary organ system involved, the response to therapy, or the underlying disease.[229,231] In the critical care setting, it may be more convenient to classify it according to the response to therapy, and use the serum chloride concentration (the most commonly anion involved) as the key variable for such a classification.[8-10,43] Sometimes the loss of Cl^- is temporary and can be treated effectively by replacing it; this type of metabolic alkalosis is known as *chloride responsive*. This represents the most frequently encountered metabolic alkalosis in the pediatric critical care unit, and it is also the most severe.[227-231] This group of disorders is usually the result of Cl^- losses from gastric drainage or persisting vomiting, as in pyloric hypertrophy and other causes of upper gastrointestinal obstruction.[8,98,227-229] Chloride loss also may occur as a consequence of the administration of diuretics.[10] Both persistent vomiting and excessive diuretics generate some degree of dehydration, with volume contraction and secondary stimulation of aldosterone release, which in turn leads to increased tubular Na^+ reabsorption—an alkalinizing process, because it increases the SID and increases urinary loss of K^+, which may yield hypokalemia.[229]

In other cases, hormonal mechanisms leading to an excess of mineralocorticoid activity directly produce ongoing losses of K^+ and Cl^-. Similar urinary losses may be associated with genetic renal tubular defects of electrolyte transport, mainly in chloride reabsorption. Decreased plasma levels of Cl^- and K^+ lead to an increased SID, which in turn yields metabolic alkalosis. In this setting, the Cl^- deficit can be offset only temporarily, at best, by Cl^- administration. Therefore this form of metabolic alkalosis is said to be *chloride resistant*.[8,10,227-231] (see Tables 68-6 and 68-8). The hallmark of this group of disorders is an increased urine Cl^- concentration, more than 20 mEq/L (usually >40 mEq/L).[227-231] Treatment requires a search for the underlying disorder and, if possible, a specific therapeutic intervention. Among the most important causes of chloride-resistant disorders are: (1) diseases with mineralocorticoid excess, including primary and secondary aldosteronism, congenital adrenal hyperplasia (17α-hydroxylase deficiency), renin-secreting tumors, and Cushing syndrome; (2) tubulopathies, including chloride-wasting tubulopathies (Bartter and Gitelman syndromes, and defective epithelial sodium channels (ENaC) leading to a decreased sodium elimination (Liddle syndrome); (3) drug-induced hypokalemic alkaloses, including those caused by diuretics, high-dose glucocorticoids, fludrocortisone, aminoglycosides, and toxic effects of licorice (*Glycyrrhiza glabra*); and (4) the miscellaneous group, which includes 11β-hydroxysteroid dehydrogenase deficiency, salt-losing nephropathy, cystic fibrosis, and congenital chloride diarrhea, among others. For further details about these specific disorders, the reader is referred to other sources.[98,228-235] Random urine chloride may suffice for a quick clinical orientation: uCl^- less than 20 mEq/L (usually <15 mEq/L) is consistent with chloride-responsive metabolic alkalosis; uCl^- greater than 20 mEq/L (usually >40 mEq/L) is consistent with chloride-unresponsive metabolic alkalosis.[228-230] However, this general rule may not apply to other special causes of metabolic alkalosis, which include the extrarenal chloride-resistant forms, such as cystic fibrosis,[234] and congenital chloride diarrhea, which is a recessively inherited disorder of chloride transport in the distal ileum and colon.[235] In both disorders, huge extrarenal chloride loss occurs (through sweat or diarrhea), and urine chloride may be low, normal, or high, depending on the patient's renal function and clinical situation.

Finally, metabolic alkalosis may occur as the SID increases as a consequence of the gain of cations rather than anion depletion. The most common clinical situation in the critical care setting is the IV administration of strong cations without strong anions, such as with massive blood transfusion. In this case, sodium is administered predominantly with citrate (a weak anion) instead of chloride. A similar mechanism of metabolic alkalosis occurs when parenteral nutrition contains excess sodium acetate (another weak anion) and insufficient chloride to balance the sodium load.[8] Excessive infusion of some gelatins used as plasma volume expanders and sodium lactate (as in Ringer's solution) can also cause metabolic alkalosis. The milk-alkali syndrome is now a rare cause of this derangement.

Treating Metabolic Alkalosis

Many clinicians have the perception that metabolic alkalosis is a mild, self-limited acid-base derangement. This can be true in some settings, such as post-hypercapnia and post-citrate or lactated Ringer's infusion in patients with normal renal and hepatic function, but it is not true in all cases. Alkalosis and alkalemia are important because they may increase morbidity and mortality. Increase in blood pH increases neuromuscular excitability, probably related to a decrease in ionized calcium concentration and potassium shifts, leading to alteration of consciousness, increased seizure activity, increased cardiac arrhythmia, decreased oxygen release to tissue from hemoglobin, tetany secondary to hypocalcemia, increased ammonia generation by the kidney, and, in some instances, depression of the respiratory drive. Because mortality is especially high when a pH in excess of 7.6 develops, intervention at a pH of 7.55 and greater is recommended.[227,230]

Regardless of the type of metabolic alkalosis, the first step for its proper management is to moderate or stop the process that generated the problem, even if only temporarily.[227] For example, if continuation of gastric drainage is required, the loss of gastric fluid can be reduced though the administration of H_2-receptor blockers or inhibitors of the gastric H^+/ K^+-ATPase. If it is not possible to withdraw diuretics, it may be possible to use potassium-sparing compounds (e.g., spironolactone, amiloride), that decrease distal acidification and curtail potassium excretion. Administration of bicarbonate or its precursors such as lactate, citrate, and acetate should be discontinued; these compounds are commonly present in IV and dialytic solutions, transfused blood and blood derivatives, and parenteral nutrition. If drugs with mineralocorticoid activity are being administered, their indication and dose should be reassessed.

Up to 10% of the total bicarbonate filtered is reabsorbed or lost to urine in the distal renal tubule. In most patients with metabolic alkalosis, extracellular fluid, altogether with chloride, potassium, and magnesium concentrations, is decreased.

Hence, the blood flow to the kidneys is also decreased, and secretion of both aldosterone and endothelin-1 is stimulated, bicarbonate urine loss is reduced, chloride wasting increases, and urinary hydrogen ions and potassium are decreased even more.

Because potassium, chloride, and magnesium concentrations limit bicarbonate excretion, their low concentrations will make metabolic alkalosis refractory to correction. Thus the restoration of circulating volume and electrolyte composition will allow renal excretion of bicarbonate and the correction of metabolic alkalosis[227] or, in agreement with the physicochemical approach, it really does not matter if the bicarbonate excretion is enhanced, but it is the replacement of Cl^- that corrects the increased SID.[8] Saline plus KCl infusion are usually the best choice because of the typical coexisting volume depletion and hypokalemia. Administration of normal saline is effective despite the release of equal amounts of $Na^+$and Cl^- because it results in larger relative increases in Cl^- concentration compared with Na^+ concentration. Treatment of severe chloride-responsive metabolic alkalosis can be a real challenge without the presence of either volume depletion or hypokalemia as well as in patients with cardiac or renal dysfunction and in the hepatic disease patient with ascites.

It is quite common that this group of patients had been receiving aggressive diuresis. Hence, more often, these patients have developed metabolic alkalosis as a result of the effects of diuretics and will be better treated by the provision of potassium chloride, because their previous treatments have rendered them potassium depleted. However, potassium chloride can induce hyperkalemia in patients with renal failure. In these patients, decreasing or adjusting the diuretic regimen, adding acetazolamide (a carbonic anhydrase enzyme inhibitor that enhances renal sodium bicarbonate loss, increasing urinary SID and decreasing blood SID),[201] and cautiously administering NaCl and potassium chloride may suffice.[9,227] If the pace of correction of the alkalemia needs to be accelerated, hydrochloric acid (HCl) can be infused intravenously as a 0.1 to 0.2 N solution (i.e., one containing 100 to 200 mmol of H^+ per liter). This intervention, which is rarely needed, is safe and effective for the symptomatic rapid relief of severe metabolic alkalosis. Because of its sclerosing properties and its hyperosmotic concentration, HCl must be infused through a central venous line at an infusion rate of no more than 0.2 mmol/kg/hr, up to 20 to 50 mmol/h maximum,[227] with arterial pH monitoring every hour. Although an alternative infusion through a peripheral IV line was described decades ago, this route is not advisable in the pediatric population. Calculation of the amount of HCl solution to be infused is based on a distribution volume equivalent to 30% of the body weight. Thus HCl dosage can be calculated with either the SBE or the bicarbonate difference in a manner similar to the bicarbonate administration formula (Equations 18A and 18B):

$$\text{Total body BE} = \text{SBE} \times \text{Body weight(kg)} \times 0.3 \quad (19A)$$

$$HCO_3^- \text{ excess} = 0.3 \times \text{Body weight (kg)} \times [HCO_3^- \text{ observed} - HCO_3^- \text{ desired}] \quad (19B)$$

In both formulas, the result is expressed in millimoles of HCl to be administered. If this intervention is contraindicated, not effective, or not available, and the alkalemia is severe with no hope of quick control, hemodialysis or hemodiafiltration can rapidly correct severe alkalemia and volume overload, but a dialysis solution low in lactate or bicarbonate must be used to prevent worsening of the alkalemia. Ammonium chloride has similarly been employed to correct chloride in patients with normokalemia or hyperkalemia. In this case ammonium represents a weak cation that does not increase the concentration of strong cations. The only specific treatment for metabolic acidosis available to date is for Liddle syndrome, which is responsive to a decreased dietary sodum intake and to a sodium channel blocker, such as amiloride or triamterene.[230]

Respiratory Acid-Base Derangements

Although the underlying pathological process may vary, the respiratory acid-base derangements always have the same mechanism: alveolar ventilation is increased or decreased out of proportion to CO_2 production. Carbon dioxide arises either from the cellular metabolism or by the titration of HCO_3^- by metabolic acids. Normal CO_2 production by the body (and its excretion by the lungs) is impressive (about 220 mL/min or about 317 L/day in a 70-kg adult, equivalent to 15,000 mmol of carbonic acid per day) compared with the 500 mmol/day of all nonrespiratory acids that are handled by the kidneys and gut.[10] Pulmonary ventilation is adjusted by the respiratory center in the brainstem in response to changes in P_aCO_2, pH, and P_aO_2, although respiratory drive can be influenced by other neural (anxiety, wakefulness) and nonneural factors (e.g., exercise, muscle strength) and can also be altered in some pathological situations (cystic fibrosis, asthma, and congenital central hypoventilation syndrome) (see Chapter 38).[236] The precise and real-time match of alveolar minute ventilation to CO_2 production allows stable P_aCO_2 levels of 35 to 45 mm Hg at sea level. Accuracy of the central control allows the body to adjust P_aCO_2 in compensation for alterations in arterial pH produced by metabolic acidosis or alkalosis in predictable ways (see Tables 68-2 and 68-3). When this normal respiratory system is disrupted or overwhelmed, P_aCO_2 deviates from normal and the respiratory acid-base disturbances are initiated.

Respiratory acidosis is produced by CO_2 retention, leading to hypercapnia (elevation of P_aCO_2). Respiratory alkalosis is produced by hyperventilation, leading to a drop in P_aCO_2 (i.e., hypocapnia). As soon as P_aCO_2 increases or decreases, plasma and intracellular buffers change their dissociation to maintain a stable pH, the effect of which is fully manifested within 15 to 30 minutes. If the alteration in P_aCO_2 is sustained for more than 6 to 12 hours, renal mechanisms induce far larger changes in bicarbonate concentration, reaching maximal impact within 3 to 5 days. These renal effects lead to a new steady state for the pH. The two responses to the primary alterations in P_aCO_2, plasma plus tissue buffers and the renal response, permit description of the respiratory acid-base derangements as acute and chronic phases.[10] Thus acute respiratory acidosis or alkalosis involves the immediate plasma and intracellular buffer response to hypercapnia or hypocapnia, whereas chronic respiratory acidosis or alkalosis involves the renal response.

Respiratory Acidosis

Respiratory acidosis occurs whenever the CO_2 elimination by the lungs is lower than the CO_2 production by the tissues, resulting in a positive balance of CO_2, which in turn increases

P_aCO_2 to a new equilibrium determined by the altered relationship between CO_2 production and alveolar ventilation. Because the increase in CO_2 production alone is not sufficient to overcome the normal ability of the lungs to increase alveolar ventilation,[10] what is central to all forms of respiratory acidosis is a failure of alveolar ventilation and CO_2 excretion to increase in response to a rising P_aCO_2. However, an increase in CO_2 production in the face of fixed ventilation can also result in respiratory acidosis. For example, this may occur in the critical care setting in patients receiving mechanical hypoventilation and a high load of carbohydrates in their parenteral nutrition. This may also happen if a patient with hypoventilated lungs becomes febrile (acute hypermetabolism). Immediately, the increase in P_aCO_2 increases both the hydrogen ion and bicarbonate concentrations in blood (Equations 3 to 5). Here the increase in $[HCO_3^-]$ occurs as a consequence of physicochemical principles and not as a consequence of an adaptive response in order to buffer the increase in H^+.[5,8,13] The only immediate buffering activity in hypercapnia comes from the nonbicarbonate plasma and intracellular buffers.[208]

Because of the increase in bicarbonate (a weak anion), no change in the SID is produced, and thus no change occurs in the SBE. Because CO_2 is produced within the cells and can freely diffuse across the lipophilic cellular membranes, intracellular acidosis always occurs with respiratory acidosis.[208,209] If the P_aCO_2 remains increased, active compensatory mechanisms are activated, and the SID increases to restore H^+ toward normal. Primarily, respiratory acidemia compensation is accomplished by removal of CL^- from the plasma space. Because movement of Cl^- into the tissues or red blood cells results in a drop of intracellular pH, Cl^- must be removed from the body to achieve a lasting effect on the SID. The kidneys are the most important organ for this task. Because every chloride ion that is filtered and not reabsorbed increases the SID (and the pH), Cl^- removal by the kidney must be highly accurate. The role of ammonium in this process is preeminent, not as a hydrogen ion carrier or a potential buffer, but for the excretion of Cl^- without losing Na^+ or K^+.[8,54] Thus when renal function is intact Cl^- is eliminated in the urine, and after a few days, the SID increases to the level necessary to return blood pH near 7.35. This amount of time is required by the physiological constraints of the system, but that is not entirely a disadvantage because this rate of response is useful in order to avoid being oversensitive to transient changes in alveolar ventilation. In any case, the compensation results in an increased pH for any degree of hypercarbia.

According to the Henderson-Hasselbalch equation (Equations 4 and 5), the increased pH will result in an increased HCO_3^- concentration for a given P_aCO_2. Therefore the so-called *adaptive increase* in HCO_3^- to hypercapnia actually results *from* the increase in pH, and *is not the cause of* the increase in the pH, which actually occurred from the increase in the SID as a consequence of the removal of chloride. Although the change in HCO_3^- concentration is a convenient and reliable marker for the metabolic compensation (see Tables 68-2 and 68-3), it is not the mechanism.

Acute respiratory acidosis develops as a consequence of the impaired function of one or more of the three participants in the ventilatory function: central nervous system; neural (peripheral), muscular, and skeletal structures; and lungs (airway and alveoli) (Table 68-9). Airway and parenchymal lung disease are the most common causes of acute CO_2 retention. This last group of conditions not only produces hypercapnia, but also primary hypoxemia. It is hypoxemia, not hypercapnia or acidemia, that poses the principal threat to life. The already mentioned conditions that cause the failure of the lungs to eliminate CO_2 can also be grouped into two types of ventilatory disorders.[10] The first, or "pure," hypoventilation occurs as a result of brainstem or neuromuscular dysfunction or because of extrapulmonary restrictive lung compromise. In this setting, the lung simply fails to move enough air in and out to exchange CO_2 and oxygen. As a result, PaO_2 falls in proportion to the rise in P_aCO_2. In the second and more common situation in the critical care setting, alveolar hypoventilation is the result of the imbalance between perfused and hypoventilated segments of a damaged lung (i.e., ventilation-perfusion [V/Q] inequality; see Chapter 40). In this case, a fall in P_aCO_2 often precedes hypercapnia, and when hypercapnia finally develops, the reduction in P_aO_2 is proportionally greater than the rise in P_aCO_2. With both types of ventilatory defects, however, hypoxemia is a concurrent finding when hypercapnia is present.[10]

Chronic respiratory acidosis is most often associated with chronic lung disease (e.g., bronchopulmonary dysplasia) or chest diseases with abnormal chest wall mechanics (chest congenital deformities, kyphoscoliosis), but it can also be

Table 68–9 Causes of Respiratory Acid-Base Derangements

ACIDOSIS (↑ P_aCO_2)	ALKALOSIS (↓ P_aCO_2)
Central nervous system depression	Hypoxemia
Severe head trauma, brain edema, metabolic diseases, infectious diseases, intentional sedation, pharmacological effect of drugs	High altitudes, pulmonary disease
Neural (peripheral), muscular, and skeletal structures	Pulmonary disorders
Electrolyte disturbances: hypophosphatemia, hypokalemia	Pneumonia, interstitial pneumonitis, fibrosis, edema, pulmonary embolism, vascular disease, bronchial asthma, pneumothorax
Specific diseases: myasthenia gravis, Guillain-Barré syndrome, spinal cord injury, Werdnig-Hoffmann disease, Duchenne muscular dystrophy, etc.	Cardiovascular disorders
	Congestive heart failure, hypotension
	Metabolic disorders
Ventilatory restriction: rib fractures and flail chest, patients with intraabdominal hypertension from ascites, from closure of congenital abdominal wall defects, etc.	Acidosis (diabetic, renal, or lactic), hepatic failure
	Central nervous system disorders
Lungs (airway and alveoli):	Psychogenic or anxiety-induced hyperventilation, central nervous system infection, central nervous system tumors
Respiratory obstructive disease, either acute or chronic: croup, asthma, bronchiolitis, bronchopulmonary dysplasia	Drugs
	Salicylates, methylxanthines, β-adrenergic agonists, progesterone
Alveolar injury: pneumonia, acute lung injury, acute respiratory distress syndrome, cardiogenic pulmonary edema	Miscellaneous
	Fever, sepsis, pain, pregnancy

caused by chronic upper airway obstruction (e.g., obstructive sleep apnea syndrome and craniofacial disorders),[237] chronic neuromuscular diseases, or chronic central nervous system problems (congenital central hypoventilation syndrome).[236] Respiratory decompensation in patients with these conditions usually results from recently acquired infection, use of narcotics, or uncontrolled oxygen therapy.[238] These additional factors superimpose an acute element of CO_2 retention and acidemia on the already elevated CO_2 baseline. Progressive narcosis and coma (i.e., hypercapnic encephalopathy) may ensue. On the basis of the preeminent renal participation in the ultimate compensation of hypercapnia, one should expect that patients with renal disease (with difficulties excreting chloride) will have a defective adaptation to chronic hypercapnia.

Treating Respiratory Acidosis

As the main threat to life in respiratory acidosis comes from associated hypoxemia, and not from the level of hypercapnia or acidemia, oxygen administration represents a critical element in the management of respiratory acidosis. Caution must be taken when uncontrolled concentrations of oxygen are administered to some patients with hypercarbia, particularly those with chronic lung disease, in whom exaggerated oxygen supplementation could depress respiratory drive and provoke further increase in P_aCO_2.[238] This occurs because chronic hypercapnia is thought to downregulate CO_2 chemoreceptor sensitivity, which means that these patients are more dependent on hypoxic drive to maintain adequate spontaneous ventilation. Thus hypoventilation (and hypercapnia), may worsen if unrestricted (and excessive) oxygen is administered. This phenomenon has been described mainly in adults with chronic obstructive pulmonary disease and acute asthma, but it may also occur in children with chronic lung disease. It should be emphasized, however, that the correction of hypoxia overrides strategies to avert oxygen-related hypercapnia, which normally tends to be of little clinical significance in children. Thus, immediate actions should focus on securing a patent airway and restoring adequate oxygenation by delivering an oxygen-enriched gas mixture.

Oxygen administration alone, however, is almost never enough as a single therapeutic measure. Hence hypoventilation must be treated directly. Whenever feasible, treatment must be directed to the underlying cause. Sometimes it is possible to solve the primary cause of hypoventilation rather quickly (e.g., relief of obstruction from croup with racemic epinephrine, reversal of narcotics with naloxone, resolution of bronchial spasm with some β_2 agonist). In such cases, it may be possible to avoid positive pressure ventilation. Generally speaking, mechanical ventilation is indicated when the patient is at risk of instability, the patient is already unstable, or the central nervous system function shows a trend toward deterioration. When respiratory muscle fatigue is impending, further deterioration must be avoided by using positive pressure ventilation. The classic "rule of the 50s" (i.e., 50 mm Hg of P_aO_2 and P_aCO_2 as a guide for endotracheal intubation) should not be interpreted literally. It is not the absolute value of P_aCO_2 (or P_aO_2) that is important but rather the clinical condition and perceived trend of the patient. In chronic hypercapnia, management of the respiratory decompensation depends on the cause, severity, and rate of progression of the hypercapnia. Immediate treatment of pulmonary infection with proper antibiotics, bronchodilator therapy, and removal of secretions can offer considerable benefit. The ventilatory drive can be optimized by minimizing the use of tranquilizers and sedatives, by gradually reducing supplemental oxygen (aiming for a P_aO_2 of about 60 mm Hg), and by correcting a superimposed metabolic alkalosis.

The "aggressive" approach that favors the early implementation of positive pressure ventilation is often appropriate for patients with acute respiratory acidosis[239] (see Chapter 49). For those patients with chronic diseases that limit pulmonary reserve, however, a more conservative approach is often advisable and possible because of the great difficulty often encountered in weaning such patients from ventilators. If the patient is obtunded or unable to cough and if hypercapnia and acidemia are worsening, mechanical ventilation should be instituted. Noninvasive mechanical ventilation (NIV) with a nasal or facial mask is being used with increasing frequency in children, both with moderately severe acute respiratory failure and with hypercapnic respiratory failure resulting from acute exacerbations of chronic lung disease (see also Chapter 50). Despite the limited pediatric experience,[240] its application in children is growing both in acute situations within the critical care unit, even in small children, and in cases of chronic hypercapnic and hypoxemic respiratory failure of various causes that are encountered in intermediate care wards and in children's home environments. When P_aCO_2 is high and minute ventilation is normal or increased, the respiratory muscles are already failing to generate sufficient alveolar ventilation to eliminate the CO_2 being produced. The general strategy for the correction of this problem is to decrease the work of breathing by reducing CO_2 production and to improve alveolar ventilation by increasing tidal volume or respiratory rate through whatever mode of assisted ventilation is appropriate for the patient. Respiratory muscle failure can occur when the work of breathing is normal (e.g., numerous acute or chronic neuromuscular problems) or increased (e.g., patients with asthma or the obesity hypoventilation syndrome), and presumably because of inadequate delivery of oxygen to the respiratory muscles (e.g., patients with cardiogenic pulmonary edema). When P_aCO_2 is increased and minute ventilation is low, the level of consciousness is generally impaired. Such patients usually require intubation for airway protection in addition to ventilatory assistance, unless the hypercapnia can be reversed within minutes with NIV.[241]

Hypoxemia is treated with FiO_2 augmentation (the lower the V/Q, the less the effectiveness) and through the recruitment of air spaces with an increase of the transpulmonary pressure applied at end-expiration. The usual ventilatory strategy for hypercapnia is to increase minute ventilation, which should gradually return the P_aCO_2 toward baseline values, while the excretion of excess bicarbonate by the kidneys is accomplished (on the assumption that chloride is provided). When the ventilator is used to correct respiratory acidosis, the end-inspiratory plateau and auto-PEEP pressures should be monitored routinely to detect any adverse effects of hyperventilation. An overly rapid reduction in the P_aCO_2 risks the development of posthypercapnic alkalosis, with potentially serious consequences. Should posthypercapnic alkalosis develop, the parameters of the mechanical ventilation must be readjusted immediately in order to reduce the minute volume. In addition, the alkalosis can be ameliorated with chloride in the form of sodium or potassium salt with

the aim of decreasing the SID. It is always beneficial to reduce CO_2 production. This can be achieved through reduction of the carbohydrate load in parenteral and enteral nutrition, through aggressive control of hyperthermia, and through adequate sedation or analgesia in anxious or combative patients. What alternatives are there for those patients with intractable hypercapnia? One possible option not yet routinely available is intratracheal pulmonary ventilation, a method in which an intratracheal catheter with a reversed continuous flow of gas at its tip (away from the lungs) facilitates flushing of CO_2 from the proximal dead space. Marked reductions in P_aCO_2, ranging from 37% to 71%, and improvement in baseline pH were achieved with this intervention in five moribund neonatal and pediatric patients with uncontrollable hypercapnia,[242] but major clinical experience is still lacking. Another possible approach is the extracorporeal removal of CO_2. After promising initial experiences in the adult population, successful pediatric case reports have begun to appear.[243]

Permissive Hypercapnia

The ultimate treatment for respiratory acidosis is to increase minute ventilation, a measure that often requires mechanical ventilation support. Because in many patients with respiratory acidosis lung dysfunction already exists, it is usually not possible to achieve normocapnia values without producing ventilator-associated lung injury (see also Chapter 51). More specifically for the critically ill patient with some sort of lung disease, normalization of the P_aCO_2 may come at the cost of volutrauma or barotrauma, that is, the alveolar distension and collapse cycle that is now known to be associated with tissue injury, increased microvascular permeability, and lung rupture.[112] Thus, the current practice for both adults and children favors the use of lower tidal volumes (5 to 8 mL/kg or less), with plateau or peak pressures no higher than 20 cm H_2O above the baseline. With this approach, there is increasing evidence that the lungs may have a better outcome, although a rise in the P_aCO_2 may ensue. This controlled hypoventilation is known as *permissive hypercapnia* (see also Chapter 52).[112,244] A significant body of literature, both clinical and preclinical, confirms the beneficial effects of hypercapnic acidosis in the setting of acute lung injury. Therefore the use of permissive hypercapnia as part of a lung-protective strategy in children should be accepted, and perhaps even desired, provided it does not result in significant hemodynamic instability and there is no coexisting contraindication such as intracranial hypertension (see the section Does Abnormal pH Harm? in this chapter).[244,245]

The "optimal" P_aCO_2 target has not been determined in clinical practice. It has been suggested that hypercapnia be limited to a degree that maintains pH greater than 7.20.[244] Hypercapnic acidosis (HCA) seems to be safe at any age, from preterm newborns to adults.[244-248] Small randomized clinical trials and large amounts of observational data from preterm infants have demonstrated that permissive hypercapnia does not increase risk for brain injury, intraventricular hemorrhage, and impairment among very low birth weight infants, with comparable survival rates and sensorineural outcome in comparison with infants treated with the traditional mechanical ventilation approach. The hypercapnic groups had lower incidence of bronchopulmonary dysplasia and respiratory deaths than that reported with conventional treatment.[247,248] Permissive hypercapnia in the preterm newborn may also protect against hypocapnia-induced brain hypoperfusion and subsequent ventricular leukomalacia.

However, extreme hypercapnia may be associated with an increased risk of intracranial hemorrhage. It may therefore be important to avoid large fluctuations in P_aCO_2 values. It was found that for infants whose Apgar scores were 4 or less, a permissive hypercapnea strategy was associated with a higher risk of intraventricular hemorrhage, whereas for Apgar scores 5 or greater, a permissive hypercapnia strategy was protective. Although this finding is not conclusive due to methodological limitations of the study,[248] it certainly underscores the need to individually assess every case for the potential risk versus benefit of HCA.

In sedated and intubated adults with ARDS, rapid intentional hypoventilation (pH falling from 7.40 to 7.26 in 30 to 60 minutes) lowered systemic vascular resistance and increased cardiac output, while mean systemic arterial pressure and pulmonary vascular resistance did not change.[249] In children, it was shown that hypoventilation improves arterial oxygenation after bidirectional superior cavopulmonary anastomosis.[250] In these patients, moderate hypercapnia with respiratory acidosis was also shown to reduce oxygen consumption and arterial lactate levels.

How low can the pH drop? How high can the P_aCO_2 rise? Actually, in many studies of adult patients undergoing permissive hypercapnia, a pH well below 7.20 has been tolerated.[249] The feared consequences of acidemia, projected from the experience with patients having lactic acidosis, failed to materialize. Available data from adults under consented hypoventilation show that the systemic hemodynamic effects are small, even as the pH falls to 7.15. Patients whose pH falls below 7.0 are fewer in number, so firm conclusions cannot be drawn, but they similarly seem to tolerate their respiratory acidemia. What is the limit of hypercapnia for pediatric patients? In a classical report, supercarbia was defined as P_aCO_2 150 mm Hg or higher.[251] In that study, the time course to development of maximal P_aCO_2 (mean, 206 mm Hg) was between 35 minutes and 2 days. Despite supercarbia, the only pathophysiologic change found was temporary neurologic depression, without consequences on the follow-up. Another report described an episode of near-fatal asthma in which P_aCO_2 rose to 293 mm Hg,[115] with a pH of 6.77 and a P_aO_2 of 65 mm Hg. Despite this supercarbia lasting more than 14 hours, no hemodynamic instability was seen. This case illustrates the cardiovascular and neurological tolerance to prolonged supercarbia in a child with previously healthy cardiovascular and neurological systems. This might not be the case for the typical scenario of a critically ill child with multiple system involvement, particularly one with brain injury, who can tolerate only mild hypercapnia, if any.[252] High levels of P_aCO_2 may cause increased respiratory drive and discomfort in the neurologically intact patient, necessitating heavy sedation and sometimes neuromuscular blockade.

Multiple inflammatory, ischemia-reperfusion, and septic animal models models have repeatedly demonstrated that acute HCA may protect against lung and systemic organic injury independently of ventilator strategy, even when it is instituted after the initiation of the lung or systemic injury process.[245,249] This protective effect has been associated with: (1) inhibition of xanthine oxidase and free radical production; (2) down-regulation of inflammatory cells, as HCA inhibits the release of tumor necrosis factor-α and interleukin-1 from stimulated macrophages; and (3) modulation of endothelial

cell and neutrophil expression of interleukin-8, selectins and intercellular adhesion molecules, attenuating lung neutrophil recruitment after both ventilator- and endotoxin-induced ALI. The mechanism underlying the inhibition of cytokine and chemokine production seems to be mediated, at least partially, through the inhibition of nuclear factor-κB (NFκB).[245,249,253]

Benefits of HCA have been demonstrated throughout the body: (1) attenuation of the stretch component of lung injury; (2) provision of protective effects on the myocardium, with better recovery after prolonged cold cardioplegic ischemia, which attenuates hypoxic/ischemic injury in the immature brain; (3) protection of the porcine brain from hypoxia/reoxygenation-induced injury; (4) modulation of neuronal apoptosis, and reduction of lipid peroxidation.[245,249] Hypercapnic acidosis has also been demonstrated to reduce injury initiated by bacterial endotoxin.[253]

The antiinflammatory effects of HCA underlie its protective effects. This powerful antiinflammatory action may reduce the magnitude of the host inflammatory response, thereby ameliorating host-induced tissue damage, as it occurs in non-sepsis models of lung and systemic organ injury.[253]

However, because immunocompetence is essential to an effective host response to microbial infection, concern have been raised with regard to the safety of hypercapnia and/or respiratory acidosis in the sepsis setting. Hypercapnic acidosis produces a broad-based suppression of proinflammatory events that contribute to microbial killing after phagocytosis, which could be detrimental to the host by facilitating bacterial spread and replication. In addition, HCA inhibits repair of pulmonary epithelial wounds,[254] a fact that raises the potential that it could reduce the barrier to access of bacteria from the lung to the bloodstream. At the present time, evidence from relevant preclinical studies supports the notion that the ultimate effect of HCA on bacterial injury may vary from beneficial to harmful, depending on the stage of injury process, that is, depending whether it is an early, an established, or a prolonged infection.[253,255,256]

Recent studies suggest that HCA is protective in the earlier phases of bacterial pneumonia-induced sepsis but may worsen injury in the setting of prolonged lung sepsis. These findings are possibly related to the fact that, in the setting of an early or established bacterial infection, HCA may reduce lung and systemic organ injury by ameliorating host-induced tissue damage. In contrast, in late or prolonged bacterial infection, it is likely that a large bacterial load may exist and hence direct bacterial tissue invasion and spread may play a greater role in tissue damage. Therefore antiinflammatory and immunosuppressive effects of HCA, particularly neutrophil inhibition, might impair bactericidal host responses and prevent any protective effects of reduced host-mediated tissue damage. However, the use of appropriate antibiotic therapy abolished the deleterious effects of HCA in prolonged infection, reducing lung damage and lung bacterial load.[253,255,256] In contrast to the findings in prolonged pulmonary infection, HCA reduced the severity of early, established, and prolonged systemic sepsis. There is evidence that the protective effects of HCA in acute lung injury are more a function of the acidosis than of elevated carbon dioxide per se. It has been showed that both HCA and buffered hypercapnia attenuate the hemodynamic consequences of systemic sepsis,[257] but only HCA, not buffered hypercapnia, reduced the severity of sepsis-induced lung injury. The conclusion so far is that buffering of HCA seems to confer little or no benefit in the setting of experimental sepsis and worsens pneumonia-induced lung injury.[253,257,258]

Therefore buffering HCA is generally not recommended. If it is decided that a specific patient needs some buffering for the respiratory acidemia, perhaps for associated hemodynamic depression, then THAM could be more useful than bicarbonate because it will not increase the P_aCO_2.[259]

The common knowledge states that the clinician must avoid hypercapnia after global cerebral ischemia in order to prevent secondary brain injury and uncontrolled intracranial hypertension. In immature animals, however, several studies consistently report that hypercapnia is neuroprotective after ischemia. In a recent and elegantly designed animal experiment,[260] it was found that mild-to-moderate hypercapnia (P_aCO_2 60 to 100 mm Hg) is neuroprotective after transient global cerebral ischemia/reperfusion injury, with better protection in the group of animals with moderate hypercapnia (P_aCO_2 80 to 100 mm Hg and pH 7.13 ± 0.09). The protective effect was attributed to the modulation of apoptosis-regulating proteins. In contrast, severe hypercapnia (P_aCO_2 100 to 120 mm Hg, pH 7.05 ± 0.1) increased brain injury, which could potentially be attributed to more pronounced brain edema formation. These results suggests a potential role for therapeutic HCA after global cerebral ischemia, a potential paradigmatic change. However, much experimental and preclinical work is still necessary before a clinical application can be considered.

Respiratory Alkalosis

If alveolar ventilation rises out of proportion to CO_2 production, then arterial PCO_2 falls. For any given rate of CO_2 production, an increase in alveolar ventilation always reduces PCO_2. In the ICU environment, hyperventilation occurs in a number of pathological conditions, including salicylate intoxication, early sepsis, hypoxic respiratory disorders, hepatic failure, fever, certain central nervous system alterations, and pain or anxiety (see Table 68-9). The sole presence of respiratory alkalosis is a bad prognosis sign, because mortality increases in direct proportion to the severity of the hypocapnia.[261] The detrimental effects of hypocapnia have been described in many settings: in premature infants in whom it has been associated with poor neurological outcome; in children after severe traumatic brain injury, in whom a relationship between hypocarbia and cerebral ischemia and infarcts have been described[261]; and in children after a cardiopulmonary bypass procedure.[262]

As in acute respiratory acidosis, acute respiratory alkalosis elicits a secondary change in plasma bicarbonate, which has two components. The first is the occurrence of a small-to-moderate acute decrease in the bicarbonate concentration; this fall is dictated by the Henderson-Hasselbalch equation (Equations 4 and 5) and is also due to some tissue buffering.[8,261,263] With the persistence of the hypocapnia, the second component appears: SID will begin to decrease as a result of renal chloride reabsorption, which is associated with a greater decrease in bicarbonate and a rise in urine pH.[5,9,10] By 48 to 72 hours, SID assumes a new, lower, steady state. This occurs because renal adaptation to hypocapnia "backtitrates" the nonbicarbonate buffers, an action that decreases SID and tends to return pH toward normal values, usually with an increased chloride serum concentration.[5]

Usually, blood pH does not exceed 7.55 in most cases of respiratory alkalosis, and severe manifestations of alkalemia are

unusual. Therefore management is directed at the underlying cause. Marked alkalemia can occur in certain circumstances: inappropriate mechanical ventilation parameters, central nervous system disorders, and some psychiatric diseases, not often seen in children. Typically, mild acid-base changes are clinically more important for what they can alert the clinician to, in terms of the underlying disease, than for any threat they may pose to the patient. Accordingly, specific measures directed to compensate the pH are not usually required. The anxiety-hyperventilation syndrome, more commonly seen in adolescents in the emergency department than in the critical care unit, can be an exception. In such cases, an active therapeutic approach with assistance from the hospital's psychological team is required. In rare cases, sedation may be necessary.

Pseudorespiratory Alkalosis

Arterial hypocapnia does not necessarily imply respiratory alkalosis or the secondary and compensatory response to metabolic acidosis. The presence of arterial hypocapnia in patients with profound circulatory shock has been termed pseudorespiratory alkalosis or, simply, venoarterial carbon dioxide gradient.[124] This condition can be seen when alveolar ventilation is relatively preserved but profound cardiovascular depression exists. In such conditions, the severely reduced pulmonary blood flow limits the CO_2 delivered to the lungs for excretion. On the other hand, the increased ratio of ventilation to perfusion and the increased pulmonary transit time result in the removal of a larger-than-normal amount of CO_2 per unit of blood traversing the pulmonary circulation.[264] Thus, despite decreased CO_2 delivery to the lungs, a situation that provokes a significant elevation of the mixed venous blood CO_2, arterial normocapnia, or frank hypocapnia may be noted. Overall CO_2 excretion is markedly decreased, however, and the CO_2 balance of the body is positive, a phenomenon that is the hallmark of respiratory acidosis. Marked tissue acidosis is reflected in mixed venous blood acidemia, usually involving both metabolic and respiratory components. The metabolic component derives from tissue hypoperfusion and hyperlactatemia. This is accompanied by an arterial pH that ranges from mildly acidic to frankly alkaline. This venous-arterial PCO_2 gradient increases as cardiac index decreases.[124,264,265] In animal models, both venous-arterial PCO_2 gradient and venous-arterial pH difference increase as oxygen delivery declines. In septic shock, an elevated venous-arterial PCO_2 gradient is seen in both those patients with low cardiac output and those with pulmonary disease who cannot eliminate CO_2.[266] In patients with cardiogenic shock, the venous-arterial PCO_2 gradient decreases as hemodynamic variables improve with dobutamine, a phenomenon also seen in pediatric septic shock with myocardial depression. In this setting, arterial oxygen saturation may appear to be adequate despite tissue hypoxemia because of the shift to the left of the oxygen-hemoglobin dissociation curve caused by hypocapnia. This condition may be rapidly fatal unless cardiac output is rapidly corrected.

Mixed Acid-Base Derangements

Coexisting metabolic acidosis and respiratory acidosis can be seen in several clinical conditions, for example during cardiopulmonary arrest, in bronchopulmonary dysplasia complicated with pneumonia and septic shock, in renal and pulmonary insufficiency, and as a consequence of certain toxic agents that may provoke both neural depression (and hypoventilation) and cardiocirculatory collapse (and metabolic acidosis).[10,24,43,51] As usual, treatment must be targeted to the underlying causes. In addition, both components of the acid-base derangement must be addressed. The first step will always be the ABCs: to secure the airway, to provide oxygenation and controlled hyperventilation, and to infuse fluids or vasoactive-inotropic agents according to the clinical condition of the given patient. Administration of an alkalinizing agent should be considered only after ventilation has begun and on the basis of results of the arterial blood gas analysis.

Alkalemia of both metabolic and respiratory origin may occur in several complex settings, such as in patients with chronic liver disease in whom hyperventilation ensues as the initial manifestation of pneumonia.[267] This hypocapnia appears in patients in whom metabolic alkalosis is common because of vomiting or gastric drainage, hypokalemia, diuretics, or alkali administration.[43,267] Mixed alkalosis may also occur in patients with chronic renal insufficiency in whom primary hypocapnia develops. In this setting, inappropriately high plasma bicarbonate levels occur as a consequence of the nonexistent renal adaptive response. This situation is seen despite the patient's dialysis program, because the dialytic procedures exert an alkalinizing influence and are much less effective in compensating alkalemia than acidemia.[226,268] This effect can be minimized by switching the patient from peritoneal dialysis to hemodiafiltration or hemodialysis.

Both the physicochemical (SIG and SID_{EFF}) and the modified SBE approaches are well suited for unmasking coexisting mixed acid-based disorders.

Acid-Base Balance in Special Situations

Hypothermia

Systemic hypothermia is one of the strategies employed for brain preservation and end-organ protection in global ischemia scenarios. Hypothermia is routinely applied in cardiopulmonary bypass for cardiac surgery, and thus anesthesiologists deal with most acid-base derangements during profound hypothermia in the operating room (see Chapter 30).[269] However, pediatric intensivists need to master these concepts, too; therapeutic hypothermia may become more widely used in the management of anoxic neurologic injury, such as after cardiopulmonary arrest or in traumatic brain injury with intracraneal hypertension.[270,271] Hypothermia has also been applied in adult patients with large ischemic stroke, and can occur accidently after near-drowning in ice water, or with other environmental exposures.

As temperature decreases, the dissociation constant ($pK_a = -\log_{10}K_a$) of aqueous systems, such as plasma and cytoplasma, increases. This results in a reduction in the concentration of OH^- and H^+ ions; that is, as temperature drops, H^+ decreases, and pH increases. Hence, the measured pH in an electrochemically neutral cell at 37° C is 7.40, whereas in an electrochemically neutral cell at 20° C, the measured pH will be 7.80. Changes in cellular pH during hypothermia are mediated through PCO_2 homeostasis. As temperature decreases, the solubility of CO_2 in blood increases, which in turn yields a reduction in PCO_2. For example, if the total CO_2 content is held constant, and the measured PCO_2 at 37° C is 40 mm Hg, then the measured PCO_2 at 20° C will be 16 mm Hg. This phenomena causes pH to increase

as temperature decreases and electrochemical neutrality is maintained. When a blood sample is introduced in a blood-gas analyzer, the sample is warmed to 37° C before measurement. The values obtained at 37° C are called the *temperature-uncorrected* values. These values are converted by the blood-gas analyzer to *temperature-corrected* values (actual patient's temperature) using a nomogram that accounts for temperature-induced changes in pH, and in O_2 and CO_2 solubility. If pH and PCO_2 are measured at 37° C, and then corrected to a lower temperature, the corrected pH will be higher and the corrected PCO_2 will be lower than the values at 37° C.

Alpha-Stat and pH-Stat

Alpha-stat and pH-stat are acid-base management methods that directly influence blood flow to the brain and other organs, and they can both be applied using either corrected or uncorrected blood gases. At a patient temperature of 37° C, there is no difference between alpha-stat and pH-stat management. The difference between these two strategies becomes apparent as patient temperature progressively decreases below 37° C, and is not clinically relevant until patient temperature is around 30° C and below. Alpha-stat strategy has solid theoretical foundations. It is well known that functions of proteins are critically dependent on their tertiary and quaternary structures, which in turn depend on the ionic charges of individual amino acid constituents. Thus, intracellular proteins must have a buffer of their own to keep a constant ionizing state in spite of pH change. The imidazole moiety of the amino acid histidine has a pK_a that is similar to pK_a of the water, and hence undergoes ionization with temperature changes in a similar proportion as water. The portion of the histidine imidazole group that loses a proton, acting as a buffer to maintain electrical neutrality is designated alpha-imidazole. Thus while changes in temperature will affect the degree of dissociation (i.e., pH) of water, the ionization state of the proteins will remain the same because it will adapt to the new temperature-influenced pH. Hence, proteins will maintain their structure and function regardless of the temperature.

According to the alpha-stat hypothesis, alpha-stat management is quite simple: electrochemical neutrality is maintained by keeping pH in the alkalotic range in temperature-corrected blood gases and normal in temperature-uncorrected gases. For practical purposes, it is easier to use uncorrected gases and make any necessary adjustment in order to keep pH at 7.4 and P_aCO_2 at 40 mm Hg at 37° C, regardless of the patient's body temperature. On the contrary, in the pH-stat approach, interventions are directed toward maintaining pH 7.4 and P_aCO_2 40 mm Hg, irrespective of patient's core body temperature. This means that the goal is to keep pH and PCO_2 at normal values for 37° C when the patient's body-temperature-corrected gases are used, and at acidotic values when temperature-uncorrected gases are used. For practical purposes, pH-stat is maintained by adding CO_2 to the ventilating gas during hypothermic cardiopulmonary bypass to increase PCO_2 and decrease the pH. In contrast to alpha-stat approach, in which CO_2 content is held constant, pH-stat regulation results in an increase in total CO_2 content.

There is still debate as to whether pH-stat or alpha-stat management should be used during deep hypothermia and circulatory arrest in neonates, infants, and children. Based on the theoretical advantages of maintaining electrochemical neutrality during hypothermia, in the early 1980s, the strategy at Boston Children's Hospital switched from pH-stat management to alpha-stat management. Within a short period, the incidence of severe neurologic injury in the form of choreoathetosis increased markedly following procedures under deep hypothermia cardiac arrest.[269,272] After this negative experience and the clinical trial that resulted from it, and on the basis of other preclinical and clinical data, the current best evidence suggests that the best technique to follow in the acid-base management of patients undergoing deep hypothermic circulatory arrest during cardiac surgery is dependent upon the age of the patient, with better results using pH-stat in the pediatric patient and alpha-stat in the adult patient.[272,273] This is not surprising, as the mechanisms of cerebral injury between adults and young children are quite different. Intraoperative cerebral injury in adults primarily relates to atheromatous emboli or fixed vascular stenoses. In contrast, in neonates and infants, brain injury more commonly results from global hypoperfusion. There are no studies assessing the age in which the switch from pH-stat to alpha-stat approach should occur, nor which type of acid balance management should be used in other scenarios in which therapeutic hypothermia is applied.

Summary

When one approaches a critically ill child with an acid-base imbalance, the first step is to define the nature of the disorder: acidosis versus alkalosis, acidemia versus alkalemia, simple versus mixed, acute versus chronic, severe and harmful versus neither severe nor harmful. The available tools for answering these questions are numerous. The easiest way to screen the acid-base status is to take a glimpse at venous bicarbonate (or CO_{2TOT}) concentration. However, a normal concentration (22 to 26 mEq/L) does not rule out the possibility of an acid-base derangement. So, if the clinical setting raises the suspicion of an illness known to be associated with acid-base imbalances, at the very least plasma electrolyte concentrations must be obtained, along with albumin levels, to calculate the AG_{CORR}. If bicarbonate (or CO_{2TOT}) or AG_{CORR} is abnormal, or a complex, potentially harmful, mixed acid-base disorder is suspected, an arterial blood analysis must be done, which will provide information on pH, $Paco_2$, and SBE. The classical bicarbonate-centered observational patterns must be applied. If available, lactate levels must be obtained too. This is mandatory if metabolic acidosis exists (with or without acidemia). If there is the suspicion of the presence of unmeasured anions and/or a mixed acid-base problem, it is advisable to calculate SID_{APP}, SID_{EFF}, and SIG, to delve deeper into the possible pathophysiological mechanisms underlying the acid-base unbalance. Care must be taken to review the patient's history for hemodynamic resuscitation with large volumes of normal saline solutions. If that is the case, special attention must be given to chloride levels and to analyzing the effect of the different components of acid-base physiology on SBE ("partitioned SBE"). The severity, potential harm of the acid-base derangement, and probable therapeutic intervention must be all defined. There is compelling evidence that abnormal pH by itself may not be as dangerous as once thought. However, an individualized approach must be taken in order to decide if a given patient has the chance of benefit or not from the attempt to modify his/her pH and acid-base status.

Chapter 69

Tests of Kidney Function in Children

Ayesa N. Mian and George J. Schwartz

PEARLS

- As a marker of glomerular function, serum creatinine provides a crude assessment because it is influenced by several factors other than glomerular filtration, of which the amount of muscle mass is clinically most significant.
- Prediction formulas in children provide a better estimate of glomerular filtration rate GFR than serum creatinine alone because they incorporate surrogate variables for muscle mass.
- Neither serum creatinine nor the prediction formula is valid when renal function changes rapidly, yet both are used clinically as better alternatives are not available. It is essential to recognize that use of serum creatinine or creatinine-based equations in the setting of developing acute kidney injury (AKI) and prior to the establishment of a new steady state will result in an overestimation of GFR. On the other hand, in the recovery phase of AKI, their use will result in an underestimation of GFR.
- Formal clearance studies are still clinically essential to assess renal function in select patients with atypical body habitus or diet.
- Novel biomarkers for AKI, when grouped in a panel, may provide improved sensitivity to acute and small changes in renal function, but further studies to validate these markers are still needed.

Renal dysfunction and injury are not unusual in the critically ill child and may develop as a consequence of the underlying disease process (e.g., hypoperfusion secondary to sepsis, progressive glomerulonephritis) or its therapy (e.g., aminoglycoside toxicity). The ability to accurately, precisely, and rapidly assess renal function is essential for the early detection of acute kidney injury (AKI), for dose adjustments of medications excreted by the kidney, in risk assessment for imaging studies involving intravenous contrast agents or gadolinium, and for monitoring for medication-related nephrotoxicity. Until recently, a consensus for defining acute kidney injury (AKI) did not exist. AKI is now recognized to encompass a spectrum of disease ranging from mild, reversible, renal dysfunction to severe, potentially irreversible organ failure with need for dialysis support. In 2004, the Acute Dialysis Quality Initiative proposed the RIFLE (Risk, Injury, Failure, Loss, and End Stage Renal Disease) classification scheme for defining AKI in adults based on changes in serum creatinine or urine output.[1] This has since been modified for use in children (pRIFLE), in whom the severity of AKI is stratified based on changes in estimated GFR or urine output (Table 69-1).[2] The true incidence of AKI in the pediatric intensive care unit (PICU) is not well established due to the absence of a consensus definition, but recent studies suggest it is increasing.[3] Despite advances in pediatric critical care and dialysis, morbidity and mortality rates associated with AKI remain high.[4] Therapeutic intervention trials for AKI have had disappointing results, which can be attributed in part to delays in diagnosis as well as to the heterogeneity of patients enrolled.[5,6] Earlier recognition and intervention for AKI may provide a greater potential for recovery and/or stabilization of renal function. However, the early detection of impending AKI is severely limited by the lack of sensitive and specific tools currently available to assess renal function.

Assessment of Glomerular Function and Injury

Glomerular filtration rate (GFR) is considered the best overall indicator of kidney function but remains challenging to accurately and efficiently measure in clinical practice. Functionally, the total kidney GFR is determined by the cumulative number of nephrons and the GFR within each nephron (single nephron glomerular filtration rate, or SNGFR). Conceptually, it represents the volume of plasma that could be completely cleared of a substance per unit of time. Kidney function may therefore decline due to hypoperfusion, resulting in a decrease in SNGFR, or due to nephron injury, resulting in fewer functioning nephrons. The kidney has a certain degree of reserve and attempts to adapt to nephron loss by increasing the SNGFR of the remaining nephrons, thus maintaining total kidney GFR initially and masking early renal injury. Indeed, by the time the GFR actually falls, significant injury has already occurred. Loss of this renal reserve is one of the earliest manifestations of renal injury but is even more challenging to measure than GFR.[7-9]

Glomerular filtration is a dynamic variable that can fluctuate in a given individual by as much as 7% to 8% from day to day based on differences in hydration status and protein consumption.[10,11] GFR is also influenced by age, gender, and body size and therefore varies between individuals as well. Therefore, to facilitate comparison of GFR amongst children

Table 69–1 Pediatric Modified RIFLE Criteria

	Estimated CCl	Urine output
Risk	eCCl decrease by 25%	<0.5 mL/kg/h for 8 h
Injury	eCCl decrease by 59%	<0.5 mL/kg/h for 16 h

and adults of considerably different size, absolute GFR is normalized to body surface area (BSA), which correlates well with kidney weight, the most direct standard of reference.[12] Appreciation of the maturational increase in GFR that occurs during infancy is also necessary for proper assessment of kidney function in children. At birth, the mean GFR is quite low (20.3 mL/min/1.73 m^2 in term infants), due to renal immaturity, but yet sufficient to meet the metabolic demands of a healthy infant. The GFR doubles within the first 2 weeks of life and then continues to gradually increase to reach a mean of 77 mL/min/1.73 m^2 between 1 and 6 months of age and adult levels of 120 to 130 mL/min/1.73 m^2 by approximately 2 years of age (Table 69-2).[13]

GFR itself cannot be directly measured but can be assessed by measuring the clearance of an ideal filtration marker, or estimated using predictive formulas. Urinary or plasma clearance studies provide the greatest accuracy but are expensive, time-consuming, and labor-intensive. Consequently, they are used mainly for research and in select clinical situations where a very accurate assessment of kidney function is needed (e.g., chemotherapy dosing). For the daily clinical management of patients, serum creatinine and GFR estimating equations are used most commonly. They offer the advantage of being convenient, noninvasive, and inexpensive with timely accessibility of results. However, accuracy and sensitivity to small changes in renal function are sacrificed, making the detection of acute, early renal dysfunction difficult. The search for novel biomarkers of renal function (such as cystatin C) and early renal injury (e.g., neutrophil gelatinase-associated lipocalin [NGAL]) has therefore been a major focus in the field of AKI. However, data regarding these markers have been somewhat conflicting.

Renal Clearance Techniques

Inulin

The renal clearance of inulin remains the gold standard for measuring GFR. Inulin is an uncharged 5.2 kDa polymer of fructose that possesses many characteristics of an ideal filtration marker. It is not protein-bound and is freely filtered at the glomerulus without being reabsorbed, secreted, or metabolized by the kidney. Further, it is eliminated exclusively by the kidney.[14] The filtered load of inulin (GFR × P_{in}) is therefore equal to its urinary excretion ($U_{in} \times V$) where P_{in} and U_{in} are the plasma and urine concentrations of inulin (mg/dL), respectively, and V is the urine flow rate (mL/min). The renal clearance of inulin (C_{in}) can be calculated:

$$C_{in} = GFR = (U_{in} \times V) / P_{in}$$

When used for children, however, this must be scaled for BSA:

$$C_{in} = GFR = [(U_{in} \times V) / P_{in}] \times [1.73\ m^2 / BSA]$$

The classic protocol for inulin clearance is cumbersome, involving an intravenous infusion of inulin over several hours and serial timed blood and urine specimens. Properly done, inulin clearances provide the most accurate measure of GFR; however, the complexity of the protocol introduces a potential for significant error. Incomplete urine collections, for example, diminish the accuracy of the test and can be particularly problematic in children who are not yet toilet-trained or who have urologic disease (e.g., vesicoureteral reflux, bladder dyssynergia) affecting their ability to spontaneously void to completion. Placement of a bladder catheter or use of a bladder scanner may therefore improve accuracy, although the former may pose a small risk of infection and the latter may be of limited benefit in children with vesicoureteral reflux. Limited availability of inulin, technical issues pertaining to its assay, and the laborious nature of the protocol make it impractical for routine clinical use.

Iothalamate

Iothalamate (MW 614 Da) is also freely filtered by the glomerulus and has been studied extensively as an alternative exogenous marker for GFR measurements. Unlike inulin, however, iothalamate has some protein binding (<8%) and proximal tubular secretion (10%) raising concern for overestimation of GFR. Reported correlations between iothalamate and inulin renal clearances in the literature have been variable, with some studies demonstrating good correlation, whereas most suggest that iothalamate overestimates inulin clearance.[15-17]

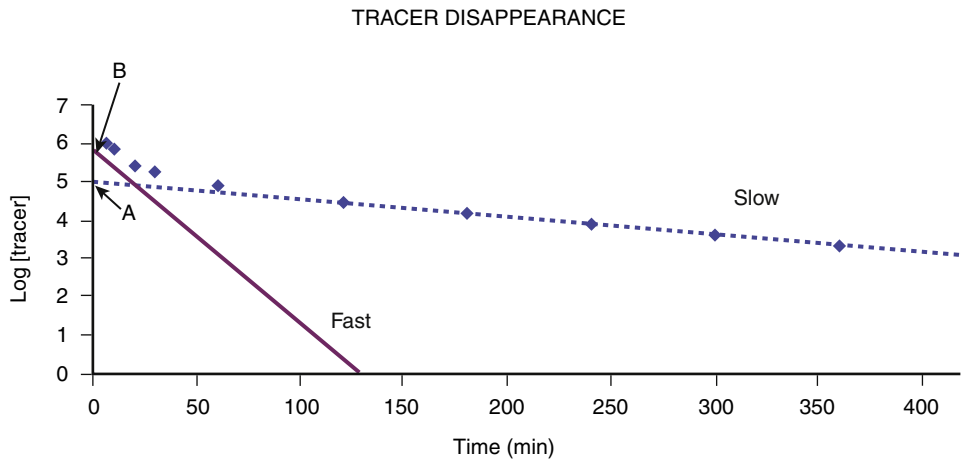

Figure 69–1. Plasma disappearance of filtration marker as a function of time after injection into blood. The curve is composed of two components: the slow curve with slope α and intercept A and the fast curve with slope β and intercept B. *(Modified from Schwartz GJ, Furth SL: Glomerular filtration rate measurement and estimation in chronic kidney disease,* Pediatr Nephrol *22[11]:1839-1848, 2007.)*

Creatinine Clearance

Clearance studies that make use of endogenous markers such as serum creatinine obviate the need for a constant infusion and make the study more amenable to clinical practice. However, the problems associated with timed urine collections persist and accordingly limit the usefulness of this technique, particularly in children. Further, creatinine is a flawed filtration marker. Although it is predominantly eliminated by glomerular filtration, a small but variable amount (~10%) is eliminated by tubular secretion. As renal function deteriorates, the proportion of secreted to filtered creatinine progressively increases, leading to an overestimation of GFR and making creatinine clearance a more unreliable measure of GFR.[11] Administration of oral cimetidine beginning 2 days prior to the study can at least partially circumvent this issue by inhibiting the tubular secretion of creatinine.[18] Although timed urine collections are still necessary, they are typically obtained over a 2-hour period facilitating performance in a monitored clinic setting.

Guidelines from the National Kidney Foundation no longer recommend routine performance of creatinine clearance studies to estimate GFR, as prediction formulas are now felt to be more accurate.[19] Nonetheless, creatinine clearance-based studies can still be helpful when assessing renal function in individuals with atypical body composition (e.g., anorexia, malnutrition) or dietary intake (e.g., vegetarian diet).[20]

Plasma Disappearance Techniques

Plasma disappearance techniques further simplify the measurement of GFR and avoid the need for urine collections. They are most commonly performed using a single intravenous injection technique, although constant infusion and subcutaneous protocols are also available.[15,21,22] Serial blood samples collected at specified times over a several-hour period following injection of the filtration marker are used to generate a plasma disappearance curve. This curve can be well approximated by a double exponential curve that is characterized by an initial "fast" curve and a later "slow" curve as illustrated in Figure 69-1. The initial "fast" curve represents the distribution phase and reflects renal elimination as well as diffusion of the marker into the extravascular space, whereas the late "slow" curve reflects only the renal elimination phase. Renal clearance can be calculated by dividing the delivered dose by the entire area under the plasma disappearance curve.[23] Modification from a two-compartment model to a one-compartment model focusing on the renal elimination phase simplifies the procedure, reducing the number of required blood specimens to two. GFR can then be derived from the slope of the slow curve but requires incorporation of a correction factor to compensate for overestimation of the GFR, which results from exclusion of the area under the fast curve.[23-26] Appropriate timing of the specimens is critical to ensure an accurate estimation of GFR. The first sample must be obtained after the marker has equilibrated, typically 2 hours after injection. The second specimen is obtained approximately 5 hours after injection but, in subjects with more advanced chronic kidney disease, this may need to be delayed further to minimize overestimation of the GFR, which can result from an inaccurate depiction of the lower slope of the plasma disappearance curve.[25] The validity of the single-compartment model may also be compromised in edematous states where the volume of distribution is increased, or with extravasation of the tracer at the injection site, as this decreases the actual dose delivered.[24] Unfortunately, when performed correctly, plasma disappearance studies are time-consuming and perhaps too complex for routine clinical care.

Radioisotopes

Plasma clearance studies are most commonly performed with radioisotopes that are more readily available and easier to assay than inulin. Their major disadvantage is, of course, radiation exposure, which limits their use, particularly in children.[27] ^{51}Cr-EDTA, ^{99m}Tc-DTPA, and ^{125}I-Iothalamate have been extensively studied and compared to inulin renal clearance.[15,28] All are low-molecular-weight compounds that are freely filtered by the glomerulus but which differ slightly in protein binding and renal handling. ^{51}Cr-EDTA (292 Da), appears to have little protein binding, and its plasma clearance correlates well with inulin clearances. It is commonly used in

Europe but is unavailable in the United States.[25] ^{99m}Tc-DTPA (393 Da) is most frequently used in the United States but demonstrates variable accuracy in GFR measurements based on product source, differences in protein binding, and potential dissociation of the chelate ($t_{1/2}$ = 6 hours) during the study.[29] ^{125}I-Iothalamate (614 Da) is a high-osmolar anionic contrast agent with some protein binding that also undergoes active secretion by the proximal tubule, contributing to overestimation of plasma clearance compared to inulin or EDTA.[17] Nuclear GFR studies can also be performed using a gamma camera, which measures the renal uptake of the tracer 2 to 3 minutes after injection and which can provide information regarding differential kidney function; however, the estimated GFR obtained this way is not as accurate as with the plasma-sampling technique.[25] To reduce radiation exposure, plasma clearance studies can also be performed using nonradiolabeled iothalamate which can be measured by high-performance liquid chromatography (HPLC).[30, 31]

Iohexol

Iohexol is emerging as an excellent alternative to inulin and radioisotopes for clearance studies. Iohexol (Omnipaque) is a low-molecular-weight (821 Da), nonionic, low-osmolar intravenous contrast agent used routinely in the United States for radiologic studies at doses appreciably higher than that required for GFR studies.[32,33] It is almost entirely eliminated through glomerular filtration and is not reabsorbed, secreted, or metabolized by the kidney, thus fulfilling many of the desired traits of an ideal filtration marker. Further, it has minimal protein binding and negligible extrarenal elimination even in advanced chronic kidney failure.[32,34] Though it can easily be measured by x-ray fluorescence or high-performance liquid chromatography, the latter is more sensitive and, therefore, requires a significantly lower dose of iohexol for the study.[33,35] Iohexol has been safely used for clearance studies for many years in Scandinavia.[32,36,37] Its excellent safety profile has recently been confirmed in the United States in over 1000 GFR estimations performed as part of the Chronic Kidney Disease in Children (CKiD) study, a multicenter, prospective, observational, cohort study of the progression of chronic renal failure.[26,38] (G.J.S., unpublished observations). Iohexol plasma clearance results appear to be comparable to renal inulin clearance and plasma EDTA disappearance studies across a broad range of GFR.[33,39,40]

Plasma Markers

Creatinine

Serum creatinine is the most commonly used laboratory study to assess renal function in clinical practice. It is simple, convenient, and practical—requiring a single blood sample—and therefore well suited for serial examination. However, the relationship between serum creatinine and GFR is quite complex, being influenced by several factors other than GFR. Therefore, at best, creatinine provides a crude estimate of the GFR. As illustrated in Figure 69-2, serum creatinine bears an inverse, nonlinear relationship with GFR and lacks sensitivity to acute and small changes in GFR. Notably, at low levels of serum creatinine corresponding to normal renal function, a substantial decrease in GFR may occur before being reflected by even a small increase in serum creatinine. In contrast, at higher levels of serum creatinine associated with renal failure, the same absolute rise in creatinine reflects a much smaller loss of remaining renal function. To a first approximation, every doubling of the serum creatinine represents a 50% decline in remaining GFR.

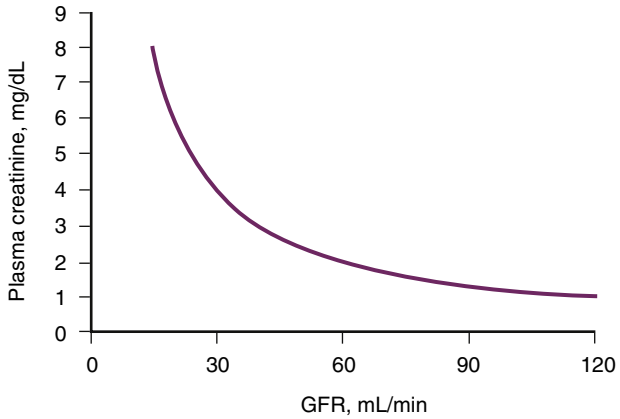

Figure 69–2. Idealized relation between the steady-state levels of serum creatinine and GFR in adults. When renal function is normal, a marked decrease in GFR can be associated with only a mild increase in serum creatinine.

Ideally, an endogenous marker such as creatinine can serve as a useful surrogate for GFR if it is produced at a constant rate and eliminated only via the kidney at a rate equivalent to its production rate such that a steady state exists. Figure 69-3 illustrates the relationship between the plasma level of an endogenous filtration marker, its generation (from cells and diet), and its elimination (renal and extrarenal). Ideally, elimination of the marker must occur exclusively by glomerular filtration. The serum level of the marker would then be expected to rise with renal impairment. Serum creatinine, however, does not strictly fulfill these criteria. Although creatinine production is relatively constant, it varies amongst and within individuals.[41] It is derived from the nonenzymatic dehydration of muscle creatine and hence is highly dependent on muscle mass. Consequently, in children, creatinine generation fluctuates with growth in addition to diet and illness, as seen with adults.[41] The reference range for serum creatinine levels representing normal GFR will thus vary with age, size, and gender after puberty. The relationship between GFR and serum creatinine is therefore particularly complex in children. Maturational changes in serum creatinine and GFR do not parallel one another. GFR is physiologically low at birth, whereas serum creatinine is elevated; however, because of fetal-maternal placental equilibration of creatinine, the elevated creatinine is not indicative of the infant's renal function but rather the mother's. Following birth, GFR steadily increases, reaching adult levels over the next 2 years. Serum creatinine, on the other hand, declines over the first few weeks, becoming reflective of the infant's renal function. The creatinine level then remains stable until approximately 2 years of age as muscle mass accrues proportionally to the increase in GFR. Beyond 2 years of age, when GFR per BSA has fully matured, the ongoing accretion of muscle results in a progressive rise in serum creatinine until adolescence, when adult levels are achieved (0.7 mg/dL for adolescent females and 0.9 mg/dL for adolescent males). Superimposition of a severe or chronic illness associated with malnutrition and muscle wasting makes the interpretation of GFR from serum

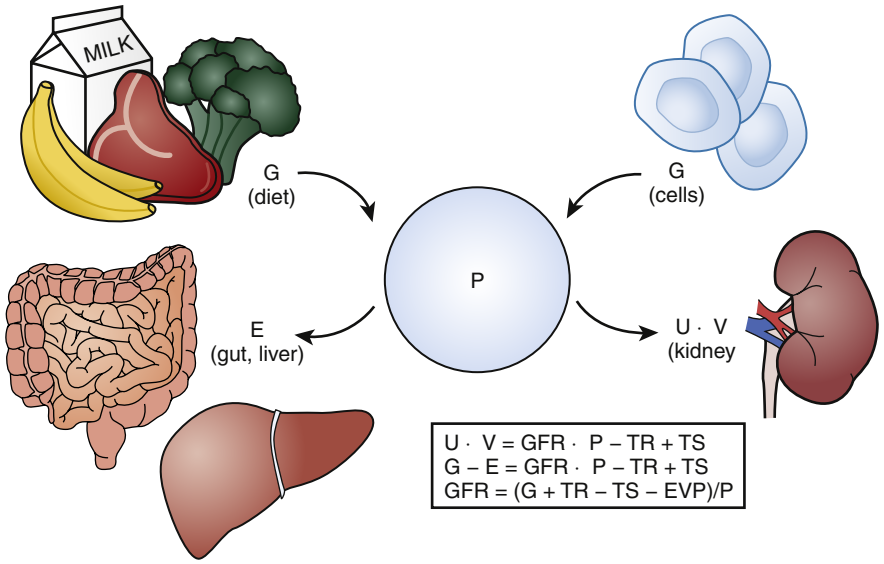

Figure 69–3. Determinants of the serum level of endogenous filtration markers. The plasma level (*P*) of an endogenous filtration marker is determined by its generation (*G*) from cells and diet, extrarenal elimination (*E*) by gut and liver, and urinary excretion (*U* + *V*) by the kidney. Urinary excretion is the sum of filtered load (*GFR* × *P*), tubular secretion (*TS*), and reabsorption (*TR*). In the steady state, urinary excretion equals generation and extrarenal elimination. By substitution and rearrangement, GFR can be expressed as the ratio of the non-GFR determinants (G, TS, TR, and E) to the plasma level. *(Modified from Stevens LA and Levey AS: Measured GFR as a confirmatory test for estimated GFR,* J Am Soc Nephrol *20:2305-2313, 2009.)*

creatinine alone even more difficult in the pediatric patient. For example, at first glance, maintenance of a stable creatinine in a patient with a prolonged ICU course may be reassuring for preservation of renal function; however, if significant muscle atrophy has occurred, this actually suggests deterioration of renal function.

The second requirement, that excretion of the marker occurs only by glomerular filtration, is also flawed in the case of creatinine. Although the majority of serum creatinine is eliminated by glomerular filtration, a small but unpredictable amount is eliminated by tubular secretion and gastrointestinal degradation. Proximal tubular secretion of creatinine typically accounts for approximately 10% of its elimination, although considerable inter- and intra-individual variability exists.[42] At normal levels of GFR, the impact of tubular secretion on GFR is minimal. However, with deteriorating renal function, the proportion of secreted versus filtered creatinine increases, resulting in a lower serum creatinine than predicted for the true level of GFR, thus decreasing the sensitivity for serum creatinine to detect mild decreases in renal function.[42] A similar phenomenon occurs in the setting of moderate-to-severe renal failure, when the bacterial degradation of creatinine within the gastrointestinal tract can become clinically significant, leading to a decrease in serum creatinine concentration.[43,44] Failure to recognize the influence of tubular secretion and gastrointestinal elimination on serum creatinine values can result in overestimation of renal function and may lead to higher, inappropriate dosing of medications. Conversely, in patients with advanced kidney failure, administration of medications (e.g., cimetidine, trimethoprim) that inhibit the tubular secretion of creatinine or administration of antibiotics that mitigate the gastrointestinal degradation of creatinine may result in an elevation of serum creatinine and subsequent underestimation of GFR without any true change in renal function. If not appreciated, this may be misconstrued as worsening renal function and lead to potential underdosing of medications.

Third, the requirement for a steady state cannot be overemphasized. When GFR abruptly declines with AKI, the production rate of creatinine exceeds its clearance rate leading to a gradual rise in serum creatinine that lags behind the true GFR. (Figure 69-4) During this period, serum creatinine does not accurately reflect the true GFR, which is unknown. Nonetheless, serum creatinine is still typically used to crudely estimate renal function as better alternatives do not currently exist. However, it must be recognized that use of the serum creatinine or creatinine-based estimating equations (see below) to estimate GFR prior to the establishment of a new steady state will result in overestimation of the renal function. Similarly, during the recovery phase of AKI, serum creatinine cannot be used to estimate GFR as it will again lag behind the true GFR until the kidney clears the accumulated creatinine and reaches a new steady state. Use of serum creatinine to estimate GFR during the recovery phase of AKI will therefore result in an underestimation of true GFR.

Finally, analytical factors related to the creatinine assay itself provide another potential source of error when assessing GFR. True creatinine levels can be measured by isotope dilution mass spectroscopy (IDMS) or HPLC, but these are expensive and not readily available for routine clinical use.[45] Enzymatic creatinine assays exhibit greater specificity for creatinine than the conventional Jaffe alkaline picrate method, and are now available in many laboratories. Due to the enhanced specificity, enzymatic creatinine levels run closer to HPLC values and approximately 10% to 30% lower than Jaffe creatinine levels. However, enzymatic assays differ in their performance, some being more influenced by interfering substances than others. Although problems with accuracy and precision still persist, the coefficient of variation using new autoanalyzers is now approximately 3%, and significantly lower than for the Jaffe assay.[41,46] Nonetheless, according to the 2007 College of American Pathologists, many laboratories still use a modified version of the Jaffe

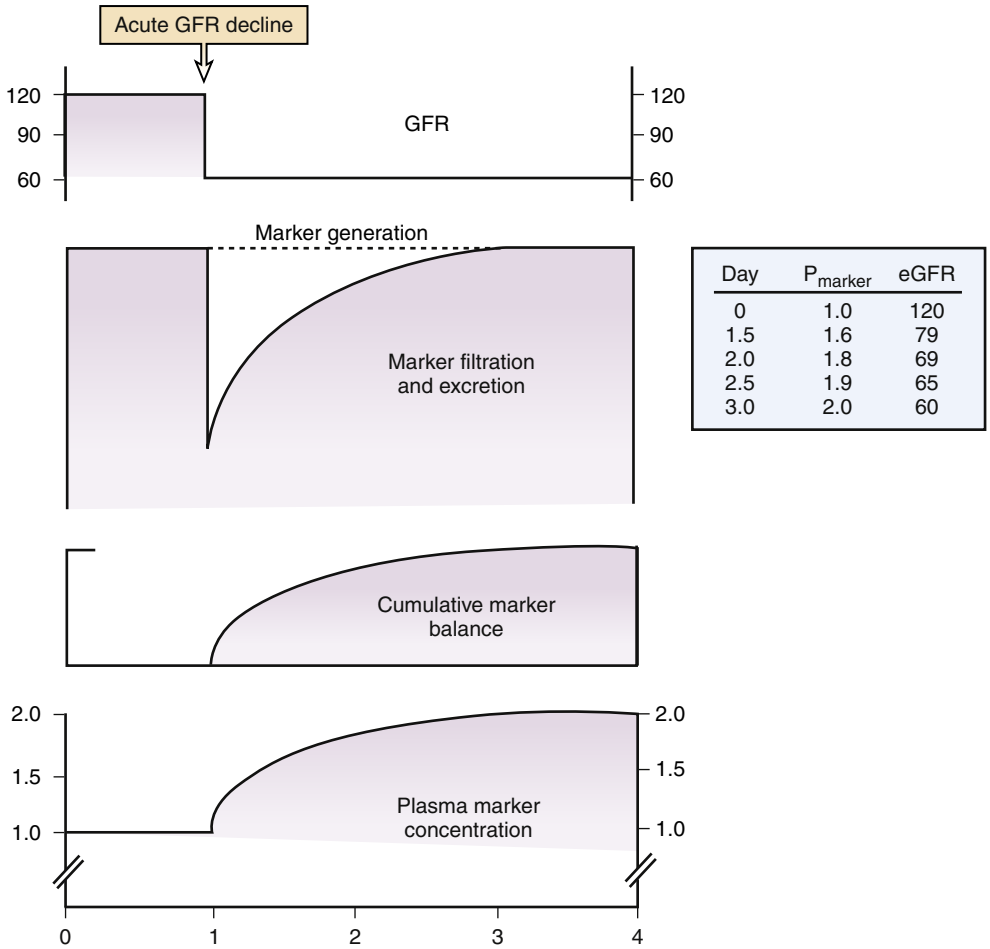

Figure 69–4. Following an acute decline in GFR, filtration and excretion of an endogenous marker (e.g., creatinine) decrease while production of the marker remains constant, leading to a gradual rise in serum marker concentration over several days. During this period, use of the serum level of the marker to assess GFR will result in an overestimate, as illustrated above (where eGFR is expressed in mL/min/1.73 m^2). The increase in serum marker level results in a higher filtered load until a new steady state is achieved such that the production and filtration rates of the marker are again equivalent, assuming tubular secretion and extrarenal elimination are negligible. Once a new steady state is achieved, eGFR approaches GFR. *(Modified from Stevens LA, Levey AS: Measured GFR as a confirmatory test for estimated GFR,* J Am Soc Nephrol *20:2305-2313, 2009; and Kassirer JP: Current concepts: clinical evaluation of kidney function: glomerular function,* N Engl J Med *285[7]:385-389, 1971.)*

assay because it is less expensive than enzymatic assays.[47] The Jaffe method is based on an alkaline picrate colorimetric reaction that tends to falsely elevate the true creatinine by up to 20% (for creatinine ~1 mg/dL) due to the presence of interfering, noncreatinine chromagens. This effect is greatest at the lower levels of creatinine typically observed in children.[48] By falsely elevating the true creatinine, the Jaffe creatinine underestimates the GFR. Indeed, analytical variability is believed to play a greater role than biologic variability in the day-to-day fluctuations of creatinine measurements.[41] An international effort to standardize creatinine measurements in clinical laboratories through use of a uniform assay and calibration materials has recently been launched.[49] Unfortunately, neither a standardized assay for creatinine nor standardized pediatric reference material for use by manufacturers to improve the accuracy and precision of assays in the pediatric range exists at this time.[45]

Proper interpretation of the serum creatinine as a measure of GFR, therefore, requires the physician to be knowledgeable about the clinical variables, physiologic processes, and analytical factors that can affect creatinine levels (Table 69-3). Although the clinical laboratory provides normative reference ranges alongside the results, clinicians should confirm that the reported references are age-appropriate and also realize that if the patient has decreased muscle mass (e.g., spina bifida, anorexia), even these age-appropriate reference ranges will be incorrect.

Cystatin C

The well-established limitations of serum creatinine highlight the critical need to identify alternative biomarkers of renal function that have improved sensitivity and specificity. Low-molecular-weight proteins have been considered potential candidate markers as they are excreted primarily by glomerular filtration. Several low-molecular-weight proteins have been considered but cystatin C, a 13-kDa cationic cysteine protease inhibitor produced at a constant rate by all nucleated cells, has shown the greatest promise. Like creatinine, it is freely filtered at the glomerulus[50] but, unlike serum creatinine, it is not secreted by the tubules; rather, it is completely reabsorbed and metabolized by the proximal tubule epithelial cells.[51] In most studies, the production of cystatin C is not significantly affected by age, gender, and muscle mass, making it

Table 69–3 Non-GFR Factors Affecting Creatine Levels in Children

	SERUM CREATININE LEVEL	
Factor	**Increase**	**Decrease**
Affecting creatinine generation	Age (infancy through adolescence)	Chronic illness Anorexia, malnutrition Neuromuscular disease (spina bifida, muscular dystrophy) Liver disease
	Male gender (after puberty)	Body habitus (amputation)
	Body habitus (muscular)	Diet (vegetarian)
	Diet Consumption of cooked meat Creatine supplements	
Affecting creatinine elimination	Impaired tubular secretion (trimethoprim, cimetidine)	Tubular secretion
	Impaired extrarenal elimination (sterilization of gastrointestinal flora by antibiotics)	Extrarenal elimination (gastrointestinal degradation)

a particularly attractive marker in growing children, subjects with atypical body composition (e.g., malnutrition, anorexia, spina bifida, neuromuscular disease), and subjects experiencing rapid changes in muscle mass.[52-54] Furthermore, in young children, the maturational changes associated with serum cystatin C follow those of GFR better than serum creatinine. Serum cystatin C levels are elevated at birth, presumably due to the physiologically lower GFR. However, cystatin C, unlike creatinine, does not equilibrate across the placenta; hence, the levels early after birth are more representative of the infant's renal function than are creatinine levels, and thus may facilitate the evaluation of renal function in newborns.[55] Concurrent with the GFR increasing after birth, cystatin C levels decline to reach a plateau 0.8 to 1 mg/L by approximately 1.5 to 2 years of age.[56] Beyond this age, serum cystatin C levels remain constant (until age 50 years) as does GFR.[52] Serum cystatin C levels may, therefore, potentially facilitate the recognition of abnormal renal function, as growth is no longer a confounding variable.[54] Furthermore, cystatin C has a shorter half-life than serum creatinine, making it more sensitive to acute and subtle changes in GFR.[57,58]

Studies comparing the use of cystatin C to serum creatinine as a diagnostic marker of kidney function have yielded conflicting results. Nonetheless, two recent meta-analyses including adult as well as pediatric studies suggest cystatin C is superior or equivalent to serum creatinine as a marker of renal function.[59,60] Specifically, cystatin C may be advantageous in populations with low or atypical muscle mass (e.g., spina bifida)[61,62] and mild renal impairment.[63] Changes in serum cystatin C levels may also potentially allow earlier detection of AKI. Herget-Rosenthal[64] found that cystatin C levels rose 1 to 2 days earlier than serum creatinine in patients with AKI. Further investigation in this area is needed. In renal transplant recipients, however, cystatin C levels may underestimate GFR.[56,65]

Although promising, cystatin C is also not a perfect marker for estimating GFR. Data emerging from several recent studies suggest cystatin C levels can be affected by several potentially confounding variables including age, gender, race,[66] obesity,[67] nonrenal elimination,[68] glucocorticoids,[56] and thyroid dysfunction,[56] as well as differences in cystatin C assays.[69] Two automated immunoassays are now available (particle-enhanced turbidometric immunoassay [PETIA] and particle-enhanced nephelometric immunoassay [PENIA]) but differ by as much as 20% to 30% in reported values.[69] This is thought to contribute to the variability in assays for cystatin C concentration.[52,53] Because cystatin C is completely reabsorbed by the proximal tubular cells, urinary clearance studies are not possible. However, cystatin C has been noted in the urine of patients with glomerular and tubular disease, raising questions about its accuracy in estimating GFR.[70]

Estimating Equations

Empirical formulas (Cockcroft-Gault for adults; Schwartz and Counahan-Barratt for children) were developed in the 1970s to enhance the physician's ability to estimate GFR (eGFR) and in particular, to facilitate the recognition of chronic renal impairment.[71-73] The equations were developed in chronic kidney disease populations and based on serum creatinine, but incorporate clinical variables such as height, weight, age, and gender as surrogates for muscle mass. However, because they are creatinine based, they are subject to some of the same constraints as use of serum creatinine alone (for example, physiologic processes such as tubular creatinine secretion and analytical factors related to the creatinine assay itself will influence eGFR results). Nonetheless, these equations perform better than serum creatinine alone, and therefore current national guidelines recommend that estimated GFR (eGFR) be reported alongside the creatinine value.[20] This has recently been implemented for adults and is soon to be available for children.[57]

In pediatrics, the Schwartz formula has been most commonly used to predict GFR. The original Schwartz formula was developed in the 1970s and based on a modified Jaffe creatinine, using inulin clearance as the reference standard. GFR is related to serum creatinine, using length as a surrogate for muscle mass and an empirical constant to account for age- and gender-related differences in body composition:

$$\text{eGFR} = k \times L / S_{Cr}$$

where eGFR is estimated GFR in mL/min/1.73 m^2, L is length in cm, S_{Cr} is serum creatinine in mg/dL, and k is an empirical constant (i.e., 0.45 for term infants through the first year of life, 0.55 for children and adolescent females, and 0.7 for adolescent males).[48,73] The simplicity of the formula makes it convenient and practical for use at the bedside, although knowledge of the patient's height is required. Counahan-Barratt developed a similar formula using ^{51}Cr-EDTA plasma disappearance as the reference standard.[72] This formula, however, uses a single constant with a lower value, attributed to a difference in creatinine assays:

$$\text{eGFR (mL/min/1.73 m}^2) = 0.43 \times L / S_{Cr}$$

It is now well-recognized that Schwartz's original formula systematically overestimates GFR, most likely due to a change in creatinine methodology over the years from the Jaffe assay to an IDMS referenced enzymatic assay.[38] As noted above, enzymatic creatinine levels run approximately 0.2 mg/dL lower than Jaffe creatinine levels.

Other formulas (Leger and British Columbia Children's Hospital) designed to improve the accuracy of eGFR have also been recently proposed for use in children with chronic kidney disease but are considerably more complex, not more accurate, and not as easily utilized at the bedside.[74,75] The adult formulas, Modification of Diet in Renal Disease and Cockcroft-Gault, have also been studied in children but are not accurate.[76,77]

Recently, an updated "bedside" Schwartz formula, based on an enzymatic creatinine assay and using the plasma disappearance of iohexol as the reference standard, was developed using data from the CKiD Study:

$$\text{eGFR} = 0.413 \times \text{L} / \text{S}_{\text{Cr}}$$

where length is in cm and serum creatinine is in mg/dL.[78] Notably, this is the first multicenter study to generate an estimating formula in children. Using the updated Schwartz formula, approximately 80% of eGFR values fell within 30% of the GFR measured by iohexol plasma disappearance and 37% fell within 10%.[57]

Given the limitations of creatinine, cystatin C-based GFR-estimating equations have also been developed in an effort to improve accuracy. Several have been published both for use in adults as well as children. They vary in terms of accuracy and precision, but appear at least as good as the creatinine-based equations. However, cystatin C is not readily available in many hospital laboratories.[56] Incorporation of both creatinine and cystatin C into the formula appears to provide a better estimate. Using data from the CKiD study, Schwartz et al. recently developed a new eGFR equation incorporating both cystatin C and serum creatinine in addition to height, BUN, and gender:

$$\text{eGFR} = 39.1 \times [\text{height (m)} / \text{S}_{\text{Cr}}\ (\text{mg/dL})]^{0.516} \times [1.8 / \text{cystatin C (mg/L)}]^{0.294} \times [30 / \text{BUN (mg/dL)}]^{0.169} \times [1.099]^{\text{gender}} \times [\text{height (m)} / 1.4]^{0.188}$$

where gender = 1 for male and 0 for female. Using this formula, over 85% of the eGFRs were within 30% of the GFR measured by iohexol, the reference standard for this study, and 45% were within 10%.[78] The equation is valid in the range of 15 to 75 mL/min/1.73 m^2 and uses the DAKO cystatin C assay.[57]

As noted above, several creatinine-based as well as cystatin C-based formulas to estimate GFR have been published. Proper use of the prediction formulas to obtain a meaningful eGFR, however, requires the clinician to be cognizant of the specific creatinine assay (or cystatin C assay) used to create the equation as well as that used in one's hospital lab, as levels obtained by different methodologies are not interchangeable, and the coefficients derived for each equation are critically dependent on the assay methodology. Clinicians must also be knowledgeable about the clinical characteristics of the study population to determine whether or not generalizability of the equation is appropriate.

Other Novel Biomarkers of Acute Kidney Injury Under Investigation

Clearly, the currently available tools for assessing AKI are inadequate, both in terms of detecting the onset of renal cellular damage as well as for detecting the onset of renal functional impairment. Recent advances in molecular biology have significantly enhanced our understanding of the pathogenesis of AKI, leading to the identification of several potential candidate biomarkers for AKI. NGAL is the most extensively studied and one of the most promising. NGAL is a ubiquitous 25 kDa protein bound to gelatinase from human neutrophils and constitutively expressed at low levels in the kidneys as well as lung, liver, and gastrointestinal tract.[79] Following ischemia and epithelial cell injury, the expression of NGAL is upregulated, leading to marked increases in serum and urine NGAL levels that precede a rise in serum creatinine.[80,81] Studies of urine NGAL in adults and children following cardiac bypass surgery found a rise in urine NGAL expression beginning 2 to 6 hours after bypass, which was higher and more sustained in those who developed AKI.[81,82] However, the sensitivity and specificity of urinary NGAL as a predictor of AKI was higher in the pediatric study. More recently, studies have focused on the utility of urine and serum NGAL to predict AKI in a heterogeneous group of critically ill children and adults in the ICU for whom the onset of renal injury is unknown. Zappitelli et al.[83] found that urine NGAL concentrations increased 48 hours prior to a serum creatinine increase of 50% or more. They also found that children with sepsis-related AKI had higher urinary NGAL levels than those with AKI unrelated to sepsis. Similarly, Bagshaw et al.[84] found higher levels of plasma and urine NGAL levels in adult patients with sepsis-related AKI versus non-sepsis-related AKI. These studies suggest urinary NGAL may have variable specificity for predicting AKI based on the subtype of AKI. A recent meta-anlaysis including more than 19 studies (adult and pediatric) concluded that despite the variability in predictive value reported for NGAL to diagnose early AKI, NGAL levels appear to have diagnostic value.[85]

Kidney injury molecule-1 (KIM-1) is a transmembrane receptor with unclear function whose expression also appears to be significantly upregulated in proximal tubular cells following ischemia or nephrotoxic injury. After subsequently undergoing cleavage, the extracellular domain is shed into the urine, where it can be detected about 12 to 24 hours following some forms of renal injury. Recent studies suggest urinary KIM-1 is more specific for acute kidney injury secondary to renal ischemia and nephrotoxins.[86] Urinary interleukin-18 (IL-18), a proinflammatory cytokine induced in proximal tubular cells following AKI, is another promising biomarker that also appears to be more specific to ischemic AKI and other types of acute tubular necrosis than to other forms of acute renal disease (e.g., urinary tract infection or prerenal azotemia).[86]

To improve the sensitivity and specificity of these biomarkers, the development of an AKI blood panel (NGAL and cystatin C) and urine panel (NGAL, IL-18, and KIM-1) has been proposed.[86]

Tubular Function

Disorders of electrolyte balance, acid-base homeostasis, and volume regulation are also encountered in the ICU and require assessment of renal tubular function. Although the techniques required to assess tubular function may be easier to perform than techniques needed to assess GFR, the interpretation of test results is not always straightforward. It is essential for physicians to recognize that although lab results may fall within the usual limits reported by the laboratory, this may not represent an appropriate response given the clinical context.

Urine Electrolytes (Sodium and Chloride)

Urine sodium (U_{Na}) and chloride (U_{Cl}) are commonly used to assess intravascular volume status and to help differentiate prerenal azotemia from acute tubular necrosis (ATN). With the prerenal azotemia, U_{Na} is typically less than 20 mEq/L and U_{Cl} less than 15 mEq/L as the kidney avidly tries to reclaim sodium and chloride in addition to water in an effort to restore the extracellular fluid volume, whereas with ATN, the U_{Na} is typically greater than 40 mEq/L due to structural tubular damage. However, overlap can occur as the final concentration of sodium in the urine will depend not only on the amount of sodium reclaimed by the tubules but also on the amount of water reabsorbed in the distal tubule under the influence of antidiuretic hormone. Thus the U_{Na} could exceed 20 mEq/L even in a prerenal state, particularly if oliguria is present. The fractional excretion of sodium (FE_{Na}) accounts for this differential degree of water reabsorption and therefore provides a more accurate reflection of the kidney's ability to conserve sodium. FE_{Na} represents the fraction of filtered sodium that is excreted into the urine: $FE_{Na} = (U_{Na}/S_{Na})/(U_{Cr}/S_{Cr}) \times 100$, where U_{Na} and S_{Na} correspond to the urine and serum sodium (mmol/L), respectively, and U_{Cr} and S_{Cr} (mg/dL) correspond to the urine and serum creatinine, respectively. With prerenal azotemia, the FE_{Na} is generally less than 1%, whereas with ATN it is greater than 1%. In premature infants, due to tubular immaturity, this threshold for FE_{Na} is approximately 3%, not 1%. It should be noted that FE_{Na} is really only meaningful in the setting of oliguric AKI. In euvolemic patients, the urinary excretion of sodium will be more dependent on dietary sodium intake. The accuracy of U_{Na} and FE_{Na} is further compromised when urinary salt-wasting conditions are present (e.g., diuretic use, renal dysplasia, chronic renal failure, cerebral salt wasting, as well as mineralocorticoid deficiency such as congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency). These conditions are associated with elevated urinary chloride levels as well.[87]

Urine Concentration Capacity

The urine specific gravity (U_{SG}) and urine osmolality (U_{Osm}) assess the kidney's ability to concentrate the urine. Urine specific gravity and osmolality bear a linear relationship, with urine specific gravity rising approximately 0.001 for about every 30 to 40 mOsm/kg. When urine is iso-osmotic to serum, the U_{SG} is approximately 1.010. In a healthy kidney, the limits of U_{SG} range from 1.003 to 1.035 and U_{Osm} from 50 to 1400 mOsm. However, due to renal immaturity, infants have a reduced urinary concentration capacity of about 600 mOsm for preterm and 800 mOsm for full term infants. U_{SG} can be easily measured by refractometer and is therefore clinically used more often than U_{Osm}, which requires an osmometer. In general, U_{SG} provides a good estimate of the kidney's concentration ability. However, because U_{SG} compares the density of urine to that of water, the presence of heavier solutes such as glucose and/or protein can increase the urine specific gravity without affecting the urine osmolality. Urine osmolality therefore provides a more accurate assessment of the kidney's response to antidiuretic hormone (ADH). With prerenal azotemia, the appropriate renal response is to retain sodium and water. Classically, the U_{SG} exceeds 1.020, U_{Osm} exceeds 500, and the urine output decreases, with the patient often becoming oliguric (urine output <1 mL/kg/h). With ATN, on the other hand, the conservation of water is impaired secondary to tubular injury resulting in isosthenuria (U_{SG} ~ 1.010, U_{Osm} ~300 to 350 mOsm). It is crucial to remember, however, that children with underlying urinary concentration defects and tubular resistance to ADH (e.g., renal dysplasia, nephrogenic diabetes insipidus, chronic kidney failure) may have a low U_{SG}, low U_{Osm}, and high urine output despite life-threatening intravascular volume depletion.

Urine osmolality is also helpful in evaluation of the child with polyuria. A low osmolality (<150 mOsm/kg) suggests a urine concentration defect such as central or nephrogenic diabetes insipidus whereas a urine osmolality of 300 to 350, associated with a high specific gravity, suggests an osmotic diuresis. The urinary concentrating capacity can be assessed by (1) checking the osmolality of a first morning urine after overnight fluid restriction or (2) by a water deprivation test.

Serum Blood Urea Nitrogen/ Creatinine Ratio

The ratio of serum blood urea nitrogen (BUN) to creatinine is also frequently used to help differentiate prerenal AKI from ATN. Urea, like creatinine, is freely filtered at the glomerulus but, unlike creatinine, has significant tubular reabsorption that further increases with hypovolemia. In prerenal states, therefore, the BUN/creatinine ratio generally exceeds 20 to 1, while it is lower than this with ATN. However, this ratio becomes inaccurate in clinical conditions where the BUN is elevated for nonrenal reasons such as a gastrointestinal bleed, catabolic state, or corticosteroid use; nor is it accurate in clinical conditions associated with a low BUN, such as protein calorie malnutrition or liver disease. The ratio may also be misleading in conditions associated with a particularly low muscle mass and serum creatinine such as muscular dystrophy.

Urine Microscopy

Urine microscopy can aid in determining the etiology for AKI. The presence of muddy brown or renal cellular casts and renal tubular epithelial cells is consistent with ATN. However, the absence of such findings does not rule out less severe ATN. In the setting of prerenal azotemia, urine microscopy is bland; hyaline and granular casts may be seen. Hematuria with dysmorphic red blood cells (RBCs) and red cell casts is consistent with glomerulonephritis, whereas hematuria in the absence of RBCs on a freshly examined urine suggests hemoglobinuria or myoglobinuria. Leukocyturia with white cell casts suggests pyelonephritis or

interstitial nephritis. Eosinophils in the urine can be detected using special stains and are classically associated with interstitial nephritis but can also be seen with pyelonephritis and urinary tract obstruction.[88] Examination of a fresh, concentrated urine specimen optimizes the opportunity for detecting these cellular elements.

Proteinuria

Protein excretion in healthy individuals is minimal (<4 mg/m^2/h in children) but can increase with renal injury. Glomerulopathies are associated with albuminuria and nonspecific proteinuria, while tubulointerstitial disease results in low-molecular-weight proteinuria. Urinary protein excretion can be detected qualitatively by reagent strips. However, these strips detect primarily albumin and are therefore helpful for assessing glomerular proteinuria but not tubular or low-molecular-weight proteinuria. Low-level false-positive results (30 to 99 mg/dL) can be obtained with the dipstick if the urine is very alkaline. Low levels of protein detected by dipstick (30 to 99 mg/dL or 100 to 299 mg/dL) can, however, also represent heavy proteinuria if the patient is polyuric. Quantitative assessments of proteinuria can be obtained using a random urine total protein/creatinine ratio (normal <0.2 for children older than 3 years) measured by the biuret method[89] and are preferred for following glomerular as well as tubular proteinuria. Twenty-four-hour urine collections for protein and creatinine can also be performed but are not believed to be advantageous over the random urine protein/creatinine ratio, particularly in children.

In diabetics, the development of overt proteinuria detectable by reagent strips is preceded by the presence of microalbuminuria, defined as persistent albumin excretion between 30 and 300 mg/g creatinine.[90] Use of the microalbumin/creatinine ratio allows for early detection of glomerular damage.[20]

Renal Acidification

Metabolic acidosis is also commonly encountered in the PICU. When associated with a normal serum anion gap, the major diagnostic consideration is renal tubular acidosis versus gastrointestinal loss of bicarbonate. The appropriate renal response to a metabolic acidosis is to increase proton secretion and ammonium production, which will allow increased net acid excretion (also see Chapter 68). The urine pH in this case should fall below 5.3, ideally measured with a pH meter after collecting a fresh specimen in an airtight syringe. Whereas a urine pH greater than 5.3 in the setting of systemic acidemia is consistent with renal tubular acidosis, a urine pH less than 5.3 does not exclude the diagnosis. Proximal RTA is characterized by bicarbonaturia secondary to a reduced threshold for bicarbonate reabsorption. At low levels of serum bicarbonate (<14 mEq/L), the filtered bicarbonate is able to be reabsorbed, resulting in a low urine pH. However, under conditions of bicarbonate loading, the reabsorptive capacity of the proximal tubule is exceeded leading to fractional excretion of bicarbonate greater than 15% to 20%:

$$FE_{bicarb} = (U_{HCO3}/S_{HCO3})/(U_{Cr}/S_{Cr}) \times 100$$

where U_{HCO3} and S_{HCO3} are the urine and serum bicarbonate concentrations in millimoles per liter and U_{Cr} and S_{Cr} are the urine and serum creatinine concentrations in milligrams per deciliter. Assessment of distal acidification includes calculation of the urine net charge and osmolal gap, both of which provide an indirect assessment of ammonium production, which cannot be routinely measured. The former is simpler to calculate:

$$\text{Urine net charge} = (U_{Na} + U_K - U_{Cl})$$

where U_{Na} is the urine sodium concentration (mEq/L), U_K is the urine potassium concentration (mEq/L), and U_{Cl} is the urine chloride concentration (mEq/L). Assuming chloride is the major anion excreted, an appropriate urine net charge in the setting of acidosis should be negative (−30 to −50), indicating the presence of ammonium, an unmeasured cation. A positive net charge would therefore suggest impaired ammonium production or proton secretion. The urine net charge, however, has limited utility when the urine sodium concentration is low (<25 mEq/L) as occurs with hypovolemia. In this setting, the kidney avidly conserves sodium and chloride (urine chloride <15 mEq/L) leaving less anion available for excretion with ammonium and resulting in a reversible impairment of urinary acidification. The urine net charge is also misleading in the presence of unmeasured anions (e.g., beta hydroxybutyrate and acetoacetate in diabetic ketoacidosis, hippurate from toluene ingestion/glue sniffing, or penicillins). In this setting, the urine net charge is positive and underestimates ammonium excretion because the cations—ammonium, sodium, and potassium—are excreted with the unmeasured anion instead of chloride. In infants, the validity of the urine net charge is also compromised due to considerable variability in the unmeasured ionic composition of the urine.[91] The urinary osmolal gap is more informative because it accounts for the excretion of the unmeasured anions. It represents the difference between the measured and calculated urine osmolalities where the calculated $U_{Osm} = \{2 \times [U_{Na}\ (mmol/L) + U_K\ (mmol/L)]\} + [U_{urea}\ (mg/dL)/2.8] + [U_{glucose}\ (mg/dL)/18]$.[92] Assuming urinary ammonium is the predominant unmeasured cation, the concentration of excreted ammonium is approximately half of the urine osmolal gap. During periods of systemic acidosis, urinary ammonium excretion increases to concentrations greater than 75 mEq/L; a level less than 25 mEq/L in this setting suggests impaired ammoniagenesis.[93]

More sophisticated tests are available to assess distal tubular acidification (proton secretion). Traditional tests include (1) measuring the difference in PCO_2 between the urine and blood during bicarbonate loading and (2) an NH_4Cl loading test. However, these can be difficult to perform and may not be well tolerated. More recently, simultaneous administration of furosemide to enhance distal sodium delivery and fludrocortisone to enhance distal sodium reabsorption as well as stimulate proton secretion has been used as an alternative test for distal acidification. In the presence of intact distal acidification, the urine pH should decrease to less than 5.3. This test has the advantages of being easy to perform and is well tolerated.[94]

Potassium Regulation

Assessment for an appropriate renal response in the setting of hypokalemia or hyperkalemia can also be challenging. Unlike urine sodium, which can be extremely efficiently reclaimed by the tubules, there is an obligate K excretion of at least 5 to 10 mmol/day due to K secretion that occurs in the distal tubule.

Potassium excretion is primarily dependent upon the aldosterone activity and serum K concentration but also requires an adequate urine flow rate and delivery of sodium to the distal nephron. The TTKG (transtubular potassium gradient) provides an assessment of potassium excretion secondary to mineralocorticoid activity and is calculated:

$$TTKG = [U_K S_{Osm}] / [S_K U_{Osm}]$$

where U_K and S_K represent urine and serum concentrations of potassium (mEq/L) respectively and S_{Osm} and U_{Osm} represent serum and urine osmolalities (mOsm/kg). In the setting of hyperkalemia, the TTKG should be elevated; therefore a low TTKG (<4.1 in children; 7 in adults) suggests hypoaldosteronism. In the setting of hypokalemia, on the other hand, the TTKG would be expected to be quite low; levels greater than 2 suggest aldosterone activity is not appropriately suppressed.[87,95]

Generalized Proximal Tubulopathy

Generalized proximal tubulopathies (Fanconi syndrome) can be congenital (i.e., cystinosis, tyrosinemia) or acquired (e.g., aminoglycoside toxicity, ifosfamide, severe ATN) and may be partial or complete. Biochemical abnormalities associated with a complete Fanconi syndrome include hypokalemia, metabolic acidosis, hypophosphatemia, hypouricemia, and low serum carnitine associated with urinary wasting of sodium, potassium, bicarbonate, phosphorus, uric acid, carnitine, glucose, amino acids, and low-molecular-weight proteins. A generalized proximal tubulopathy should be suspected when electrolyte wasting is profound and/or involves several electrolytes.

Renal Pharmacology

Douglas L. Blowey

PEARLS

- For situations when the goal is the maintenance of a serum concentration close to the steady state level throughout the dosing interval, a decrease in the size of the dose while the normal dosing interval is maintained will decrease the variation between the serum drug concentration peak and trough.
- With the exception of spironolactone and arginine vasopressin antagonists, diuretics must reach the renal tubular fluid to produce a pharmacologic effect.
- Loop diuretics decrease sodium reabsorption by inhibiting the electroneutral $Na^+/K^+/2Cl^-$ cotransporter located on the apical cell membrane in the ascending limb of Henle.
- Spironolactone prevents the binding of aldosterone to a cytosolic receptor resulting in decreased activity of Na^+/K^+-adenosine triphosphatase and a decrease in the number of apical sodium channels.
- The continuous infusion of a loop diuretic is more efficient than intermittent high doses and avoids the high and low serum concentrations associated with toxicity and resistance.

The kidney plays a central role in many physiological processes that have a direct impact on drug action and disposition, and the kidney is also an important target for drug therapy in the critically ill child. The key functions of the kidney are the elimination of endogenous and exogenous substances from the body, including drug and drug metabolites, and the maintenance of body fluid composition and volume. The glomerular and tubular mechanisms that carry out these functions are directly and indirectly influenced by the function of other organs. For example, congestive heart failure decreases the adequacy of arterial blood flow and is detected by sensors located throughout the circulatory system. The sensed reduction in effective arterial blood volume triggers a complex neurohormonal response that decreases kidney blood flow, increases sodium and water retention in the kidney, and further aggravates the edema associated with congestive heart failure. Conversely, the accumulation of drugs, drug metabolites, metabolic waste products, and alterations in body fluid composition and volume associated with kidney failure may have deleterious effects on the function of other vital organs and physiological systems.

Kidney Function and Drug Disposition

Many drugs are eliminated by the kidney, and abnormal kidney function can affect the amount of drug present at the site of action and the magnitude of the drug response. A clear understanding of the effects of abnormal kidney function on drug disposition and action is important because abnormal kidney function is common in the critically ill child and alterations in drug disposition or action may result in suboptimal therapeutic efficacy or serious adverse events.

The pharmacologic effect of a therapeutic agent is determined by the amount, and time, that the active drug component (e.g., parent drug or drug metabolite) is present at the site of action and the responsiveness of the target organ to the drug. Only the free, unbound form of a drug can exert a pharmacologic effect through interaction with receptors. The disposition of a drug after administration is determined by the formulation and route of administration, the rate and extent of absorption from the site of administration, the extent of distribution in the body fluids and tissues, the rate and extent of metabolism, and the rate and route of elimination. Drug disposition and response are further influenced by the genetic, physiologic, and pathologic constitution of the ill child.[1,2] Pharmacokinetics is the mathematic expression of drug disposition, and pharmacodynamics describes the magnitude of response to a drug. The determination of pharmacokinetic parameters is an invaluable tool for designing individualized drug-dosing regimens in children with kidney failure or critical illnesses that may alter drug disposition (see also Chapter 116).

Although decreased kidney elimination of drugs and drug metabolites is the most obvious consequence of altered kidney function, kidney failure or the associated coexisting conditions may affect drug absorption, distribution, and metabolism (Table 70-1).[3-5] The mechanisms that govern drug removal by the kidneys are glomerular filtration, tubular secretion, and tubular reabsorption. These processes are altered in children with kidney disease, as well as other organ dysfunction. Each of the kidney's one million nephrons consists of a tuft of capillaries (glomerulus) enveloped by an epithelial-lined capsule (Bowman's space) that drains into a contiguous tubular system. As blood flows through the glomerular capillaries, fluid and small solutes, including drugs and drug metabolites not bound to plasma proteins, pass through the glomeruli into Bowman's space. The volume of water and accompanying solute that is filtered through the glomeruli per unit time is the glomerular filtration rate (GFR) and is the most important measure of kidney function (see Chapter 69). The GFR

Table 70–1 Potential Alterations of Drug Distribution in Kidney Failure

PK PARAMETER	EFFECT	PROPOSED MECHANISM
Absorption	↓	Edema of GI tract, uremic N/V, delayed gastric emptying Drug interaction—phosphate binders, H2blockers Altered GI pH
Distribution	↑	Increased unbound drug fraction Hypoalbuminemia (nephrosis, malnutrition) Uremic changes in albumin structure
Metabolism	↓	Inhibition of CYP 450 metabolism (liver, intestine, kidney) Drug interaction
	↑	Direct inhibition by "uremic" milieu Induced CYP 450 metabolism
Excretion	↓	Decreased GFR Decreased tubular secretion Increased tubular reabsorption

CYP 450, Cytochrome P450; *GFR,* glomerular filtration rate; *GI,* gastrointestinal; *N/V,* nausea and vomiting; *PK,* pharmacokinetic.

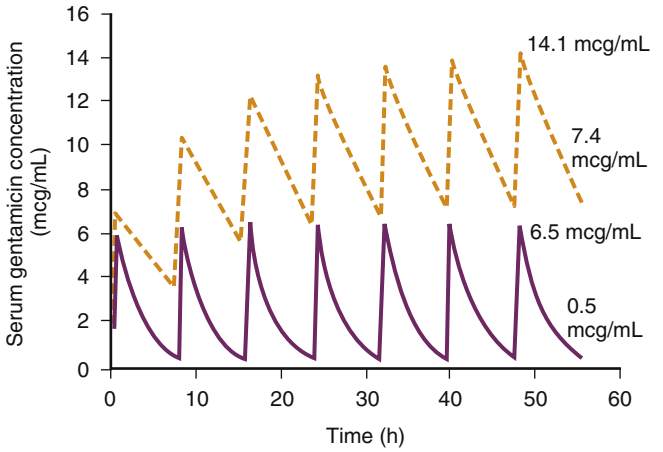

Figure 70–1. Gentamicin time-concentration profile in a 5-year-old child receiving 2.5 mg/kg intravenously every 8 hours. The *solid line* represents the plasma concentration-time profile in a child with normal kidney function (e.g., 120 mL/min/1.73 m^2) and the *dashed line* represents the plasma concentration-time profile in a child with a creatinine clearance of 30 mL/min/1.73 m^2.

is estimated with the measurement of the rate that the kidney removes a substance from the blood (e.g., renal clearance). The measured substance may be an endogenous compound (e.g., creatinine [Cr] or cystatin C), an exogenous compound that is specifically administered to measure the GFR (e.g., inulin, isotope, or iohexol), or a compound primarily eliminated by glomerular filtration that is administered as part of clinical care (e.g., gentamicin).[6] The clearance of Cr corrected for body surface area is the most common method used to estimate the GFR. Creatinine clearance (C_{Cr}), expressed in mL/min/1.73 m^2, is calculated with the measurement of the amount of Cr in an accurately timed urine collection and a mid collection plasma Cr.

$$C_{cr} = \frac{[\text{Urine CR (mg/dL)} \times (\text{Urine volume [mL]/Time [min]})]}{\text{Plasma Cr (mg/dL)}} \times \frac{1.73\ m^2}{\text{BSA } (m^2)}$$

C_{Cr} is low at birth and rapidly increases during the first 2 weeks of life, followed by a steady rise until adult values are reached by 8 to 12 months.[7,8]

Although not as accurate as a timed urine collection, for children aged 1 to 18 years, C_{Cr} can be quickly estimated with the measurement of the child's serum Cr and length with the following equation[9]:

$$C_{cr} = \frac{\text{Length (cm)} \times 0.41}{\text{Plasma Cr (mg/dL)}}$$

where the plasma creatinine is calibrated to the isotope-dilution mass specrometry method of measuring serum creatinine. It is important to understand that the normal relationships among serum Cr, length, and GFR are altered in disturbances of Cr biosynthesis (e.g., muscular disease and malnutrition) or in clinical settings where the serum Cr is rapidly changing (e.g., acute renal failure, recovery from renal failure, and dialysis). In these situations, a timed urine collection is required for an accurate estimate of the GRF.

The total amount of drug eliminated from the body by the kidneys is a composition of the amount of drug filtered across the glomeruli, the amount actively secreted into the filtrate by the renal tubules, and the amount reabsorbed by the renal tubules. Because albumin and other large molecules do not pass through the glomeruli, large drugs and drugs bound to plasma proteins normally do not pass through the glomeruli and are not effectively removed by glomerular filtration but may be efficiently eliminated by the kidney through renal tubular secretion (e.g., furosemide). For drugs and drug metabolites that are primarily eliminated by glomerular filtration, the rate of elimination mirrors kidney function (C_{Cr}). As such, when kidney function declines, the reduced drug elimination results in drug accumulation in the body. For example, gentamicin is an aminoglycoside that is eliminated primarily by glomerular filtration with an elimination half-life of around 2 hours in children and adults with normal kidney function and 4 to 12 hours in infants because of the well-characterized developmental immaturity of kidney function.[7,8] A 75% reduction of the GFR (e.g., C_{Cr} = 30 mL/min/1.73 m^2) in a 5-year-old child receiving intravenous (IV) gentamicin will prolong the elimination half-life to 8 hours. Unless adjustments are made in the dosing regimen to account for the decreased kidney elimination, gentamicin will accumulate to toxic serum concentrations (Figure 70-1).

The active renal tubular secretion of drugs and drug metabolites by relatively nonspecific anionic and cationic transport systems in the proximal tubule can contribute substantially to the amount of drug eliminated by the kidney. The renal tubular secretion of a drug may be inhibited by other

Box 70–1 Guidelines for Drug Dosing in Kidney Failure

1. Estimate the glomerular filtration rate
2. Determine the percentage of drug eliminated by the kidney
3. Calculate the dosage adjustment factor (Q)
4. Adjust the dose size or dosing interval
5. Monitor response
6. Monitor therapeutic drug (when available)

drugs or endogenous substrates that use the same nonspecific transport systems. For example, probenecid blocks the tubular secretion of many drugs by the organic anion transporter and is of clinical utility as an adjuvant to antibiotic therapy and the prevention of drug-induced nephrotoxicity.[10-12] For example, the coadministration of probenecid and penicillin-type antibiotics results in higher and more prolonged serum penicillin levels because of the inhibition of penicillin secretion by the renal tubule. The increased penicillin exposure may enhance the therapeutic efficacy of penicillin.[13,14] Nephrotoxicity is the major dose-limiting adverse effect of the antiviral agent cidofovir and is in part mediated by the proximal tubular transport of cidofovir by the organic anion system. Coadministration of probenecid restricts the proximal renal tubular uptake of cidofovir and decreases the incidence of nephrotoxicity.[11] Reabsorption is the passive diffusion of non-ionized (noncharged) drug from the filtrate into the renal tubular cell. Basic urine (e.g., urine pH >7.5) favors the ionized form of acidic drugs and limits reabsorption, whereas reabsorption of basic drugs is enhanced in basic urine because the non-ionized form of the drug is favored. Urinary alkalinization is used to enhance the renal elimination of salicylates and possibly barbiturates in overdose situations (see Chapters 105 and 106).[15]

Drug Dosing in Kidney Disease

Drugs and drug metabolites that are predominately eliminated by the kidney will accumulate to higher serum drug concentrations in patients with decreased kidney function if adjustments are not made to the drug-dosing regimen. A systematic approach to individualized drug therapy in children with kidney failure will ensure maximal therapeutic efficacy and minimize toxicity (Box 70-1). The first step in designing a rational individualized dosing regimen is an estimation of the child's kidney function with measurement of the C_{Cr} as described in the previous section. The next step is to evaluate the effect of kidney failure on the drug disposition characteristics for all of the drugs prescribed to the child. Reference books such as the *Pediatric Dosage Handbook*,[16] *Physicians Desk Reference*, and *Micro Medex* are excellent beginning sources for information about drug disposition in kidney failure. Unfortunately, because there is little pharmacokinetic information about drug disposition in children with kidney failure, estimates from adult patients with kidney failure are cautiously used, keeping in mind the potential changes in drug disposition that occur with development.[17] The most important information for designing an optimal dosing regimen is the amount of drug that is eliminated by the kidneys in persons with normal kidney function. If one assumes that drug protein binding, distribution, and metabolism are not greatly altered in kidney failure, an assumption that is likely true for most drugs,[5] then a dosage adjustment factor (Q) can be estimated:

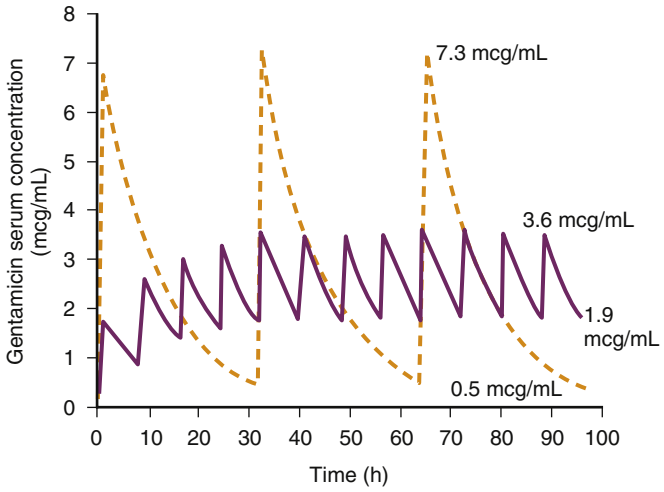

Figure 70–2. Gentamicin concentration-time profile in a child with a creatinine clearance of 30 mL/min/1.73 m^2 receiving intravenous gentamicin. The *solid line* represents the plasma concentration-time profile when the dose remains unchanged (2.5 mg/kg) and the dosing interval is adjusted to 32 hours [normal dosing interval (8 hour) ÷ dosing adjustment factor (0.3)]. The *dashed line* represents the plasma concentration-time profile if the dosing interval remains unchanged (8 hours and the dose is adjusted to 0.625 mg/kg [normal dose (2.5 mg/kg) × dosing adjustment factor (0.3)].

$$Q = 1 - [\%\ \text{excreted unchanged} \times 1 - \frac{(\text{Child's creatine clearance [mL/min/1.73 m}^2])}{\text{Normal creatine clearance (120 mL/min/1.73 m}^2)}]$$

Once the need for a dosage adjustment has been established and the adjustment factor (Q) calculated, the best method of adjustment, whether it be a change in the size of the dose or the length of the dosing interval, is selected on the basis of the known relationships between the peak and trough drug concentrations and clinical response or toxicity. Figure 70-2 shows the concentration-time profiles for two different IV gentamicin dosing regimens in a child with a measured C_{Cr} of 30 mL/min/1.73 m^2. About 95% of gentamicin is excreted unchanged in the urine, and the dosage adjustment factor is calculated as:

$$Q = 1 - [0.95 \times 1 - \frac{(30\ \text{mL/min/1.73 m}^2)}{120\ \text{mL/min/1.73 m}^2}] = 0.30$$

When the dosing interval is increased and the size of the drug dose remains unchanged (see Figure 70-2, *solid line*), the steady state peak and trough drug concentration are similar to those seen in children with normal renal function; however, there is a prolonged period when the serum gentamicin concentration is above and below the average steady state concentration. This dosing regimen may be inappropriate for drugs that should be maintained at a relatively stable serum concentration, such as cephalosporins or antihypertensive medications. For situations when the goal is the maintenance of a serum concentration close to the steady state level throughout the dosing interval, a decrease in the size of the dose while the normal dosing interval is maintained will decrease the variation between the serum drug concentration peak and

trough (see Figure 70-2, *solid line*). The dosing adjustments are estimates based on many assumptions, and the final step in individual therapy is close monitoring of clinical efficacy and toxicity. When available, the measurement of serum drug concentrations and determination of pharmacokinetic parameters is invaluable for individual drug therapy, especially in agents with a narrow therapeutic index.

Dialysis

Some form of dialysis is used in about 3% of children admitted to the intensive care unit. Drug elimination in children receiving dialysis is a composite of nonrenal drug elimination, residual kidney elimination, and the added elimination provided by dialysis. The efficiency of a given dialysis modality to eliminate a drug depends on the physiochemical characteristics of the drug and the form and characteristics of the dialysis procedure. Hemodialysis, peritoneal dialysis, and the varied forms of continuous renal replacement therapies that include continuous veno-venous hemodialysis and continuous veno-venous hemodiafiltration are all used in the intensive care setting (see Chapter 72). It is beyond the scope of this chapter to detail drug disposition in the various forms of dialysis, and the reader is referred to other excellent sources for further information.[4,18] In general, highly protein-bound drugs and drugs with a large volume of distribution are not well removed by dialysis.

The Kidney as a Therapeutic Target: Diuretics

Diuretics are a diverse group of drugs that act on the kidney to increase salt and/or water excretion. In the intensive care setting, diuretics are commonly prescribed for mobilization of excess body fluid and treatment of cerebral edema, ascites, and hypertension. Less common indications include congestive heart failure, disorders of calcium metabolism, glaucoma, and drug overdoses. Diuretics are grouped into six classes according to the primary site of action: osmotic diuretics and carbonic anhydrase inhibitors act in the proximal tubule; loop diuretics act in the thick ascending limb of Henle; thiazide and thiazide-like diuretics act in the distal tubule; potassium-sparing diuretics act in the cortical collecting ducts; and vasopressin receptor antagonists act in the medullary collecting duct.

Renal tubular cells transport solute and water from the apical cell membrane (tubular fluid) to the basolateral cell membrane (blood side). The reabsorption of sodium is central to the kidney's ability to reabsorb water and other solutes (e.g., glucose, amino acids, and bicarbonate). Apical cell sodium entry is mediated by channels that permit sodium to enter by diffusion or transported by specific proteins located on the apical cell membrane. In all renal tubular cells, the sodium-potassium adenosine triphosphatase (ATPase) located on the basolateral membrane maintains the low intracellular sodium concentration that favors sodium movement from the tubular fluid into the renal tubular cell. Diuretics inhibit sodium reabsorption by blocking sodium channels or sodium transport proteins located on the apical cell membrane at discrete sites along the nephron. Because sodium reabsorption occurs in a sequential manner along the nephron, the combination of diuretics with different sites of action (e.g., loop diuretic plus a thiazide diuretic) has a synergistic effect on sodium reabsorption. The additional osmotic force associated with the increased urinary sodium causes a rise in urine volume. The diuresis is associated with a decrease in vascular volume that stimulates movement of sodium and water from the interstitial space into the vascular space, as well as stimulation of counterregulatory pathways (e.g., the renin-angiotensin-aldosterone system) that serve to maintain an adequate extracellular fluid volume.

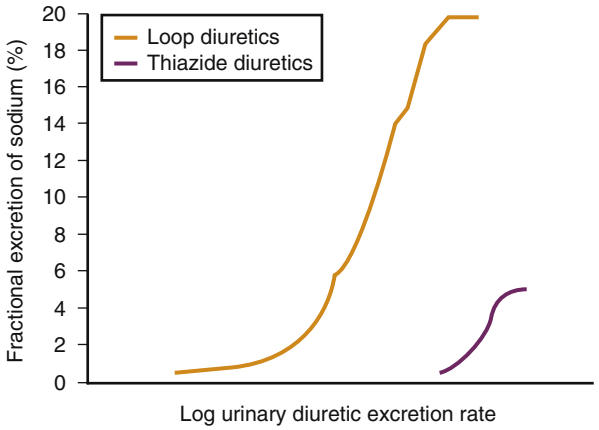

Figure 70–3. Concentration-response curve depicting the relationship between the urinary diuretic excretion rate and the excretion of sodium in the urine.

With the exception of spironolactone and the vasopressin receptor antagonists, diuretics must reach the renal tubular fluid to produce a pharmacologic effect. Because diuretics are extensively bound to plasma proteins, their entry into the tubular fluid depends primarily on proximal tubular secretion. The organic anion transporters actively secrete carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics, whereas the organic cation transporters actively secrete amiloride and triamterene. Mannitol is freely filtered at the glomerulus, and spironolactone has a complex mechanism of action that does not require entry into the tubular fluid for pharmacologic effect. Finally, the nephron delivers a hypotonic fluid to the medullary collecting duct where water is either excreted or reabsorbed based on the presence or absence of apical water channels (e.g., aquaporins). In response to increased plasma osmolality or reduced plasma volume, the posterior pituitary releases vasopressin into the blood that interacts with vasopressin receptors on the basolateral membrane of the collecting duct. Vasopressin mediates the insertion of water channels and the reabsorption of water.

The response to diuretics is determined by the amount and time course of drug reaching the site of action and the sensitivity of the active site to the diuretic. The concentration-response curve (Figure 70-3) depicts the relationship between the urinary excretion rate of loop and thiazide diuretics and diuretic response. The S-shaped curve indicates that for each diuretic there is a minimal concentration that must be reached at the site of action before any response is noted (therapeutic threshold) and that there is a maximal response (ceiling) above which no further response will occur even if more drug reaches the site of action. The amount and time course of drug reaching the site of action, and thus effect, are influenced by the route and frequency of administration, as well as drug and disease states that modify the amount of diuretic reaching the tubular fluid or the tubular response to the diuretic. An example is the twofold to threefold increase in loop diuretic dosage required for response in patients with decreased kidney

function. In kidney failure, the entry of loop diuretics into the tubular fluid is limited by decreased drug delivery to the organic anion transporters due to decreased renal blood flow and competitive inhibition of diuretic transport by "uremic toxins." Adequate tubular fluid diuretic concentration and response can be achieved with the administration of high doses of diuretic[19] but at the risk of increasing ototoxicity, particularly with concurrent aminoglycoside administration.[20,21]

Loop diuretics, such as furosemide, bumetanide, and torsemide, are the most potent diuretics because a large percentage of the filtered sodium is reabsorbed (25%) in the ascending limb of Henle. Loop diuretics decrease sodium reabsorption by inhibiting the electroneutral $Na^+/K^+/2Cl^-$ cotransporter located on the apical cell membrane in the ascending limb of Henle. Loop diuretics increase sodium delivery to the distal tubular segments and diminish water reabsorption by increasing the tubular fluid osmotic force and disrupting the generation of a hypertonic medullary interstitium. The potential for profound fluid and electrolyte loss with loop diuretics mandates close monitoring of body fluid volume and serum electrolytes during therapy.

The increased delivery of sodium to the distal nephron segments has three significant physiologic consequences. First, because sodium reabsorption in the thick ascending limb results in a lumen-positive transepithelial voltage that drives passive magnesium and calcium reabsorption, inhibition of sodium reabsorption by loop diuretics diminishes the transepithelial voltage and causes an increase in the urinary excretion of calcium and magnesium. Long-term use of loop diuretics is associated with hypomagnesaemia, hypercalciuria, and calcium-based kidney stones.[22-24] On the other hand, the enhanced urinary excretion of magnesium and calcium observed with loop diuretics is clinically beneficial in the treatment of hypercalcemia and hypermagnesemia.[25,26]

The second physiologic consequence of increased sodium delivery to the distal nephron segments is enhanced potassium secretion. Sodium reabsorption by the principal cell in the collecting duct favors potassium secretion into the tubular fluid and promotes hypokalemia.[27,28] Finally, the increased sodium delivery to the distal nephron is associated with acute and chronic adaptive processes that enhance distal sodium reabsorption and diminish diuretic efficacy.[29]

Loop diuretics display similar efficacy but differ slightly in pharmacokinetic characteristics. Bumetanide and torsemide are almost completely absorbed after oral administration, whereas the absorption of furosemide is extremely variable, with an average bioavailability of 50%.[30,31] Therefore, when IV furosemide is switched to oral furosemide, the dose is increased to account for the decreased absorption. The onset of diuretic effect is within minutes of IV administration of a loop diuretic and 30 to 60 minutes after oral administration. The duration of diuretic effect is short (2 to 6 hours),[27,32,33] and this short duration often results in the need for multiple doses or a continuous infusion to achieve the desired effect.

Thiazide and thiazide-like diuretics, such as chlorothiazide, hydrochlorothiazide, metolazone, and chlorthalidone, decrease sodium reabsorption by inhibiting the Na^+/Cl^- cotransporter located on the apical membrane in the distal tubule. The thiazide diuretics are less effective than the loop diuretics (see Figure 70-3) because less sodium reabsorption occurs in the distal tubule (5% to 10%) compared with the ascending limb of Henle. Thiazide diuretics have a synergistic effect on fluid and electrolyte excretion when combined with loop diuretics.[34-36] The different thiazide diuretics have similar efficacy, and the main difference resides in potency and duration of action. Metolazone and chlorthalidone display a longer duration of effect than chlorothiazide and hydrochlorothiazide; however, the biologic effect of thiazide agents is prolonged compared with their elimination rates and thus doses usually are administered once or twice a day. Thiazide drugs are relatively ineffective in the setting of renal failure because of the decreased delivery of drug into the tubular fluid and the limited distal tubule sodium reabsorption. In contrast to the calcinuric effect of loop diuretics, thiazide diuretics enhance calcium reabsorption and may have a beneficial effect in children with nephrocalcinosis/nephrolithiasis and hypercalciuria. Thiazides have a greater propensity than other diuretics to cause hypokalemia.

The potassium-sparing diuretics triamterene and amiloride decrease sodium reabsorption by blocking the apical membrane sodium channel in the principal cells of the cortical-collecting duct. Sodium reabsorption in the cortical-collecting duct results in a transepithelial voltage that favors the secretion of potassium and hydrogen ions. Although potassium-sparing diuretics can enhance diuresis, particularly in patients receiving loop or thiazide diuretics, the main clinical benefit of these agents is a reduction in the potassium excretion induced by loop and thiazide diuretics. Spironolactone prevents the binding of aldosterone to a cytosolic receptor, resulting in decreased activity of sodium-potassium adenosine triphosphatase and a decrease in the number of apical sodium channels. Spironolactone is effective in primary and secondary hyperaldosteronism (e.g., liver disease). Potassium-sparing diuretics are not recommended in patients with renal failure because of the propensity for the development of hyperkalemia.

Osmotic diuretics are nonelectrolytes that are freely filtered at the glomerulus and poorly reabsorbed or, in the case of glucose, present in amounts that exceed the tubular reabsorptive capacity. Mannitol is the prototypical osmotic diuretic, and its therapeutic effectiveness is directly related to the mannitol dose being large enough to raise the plasma and tubular fluid osmolality. The extraction of water from the intracellular compartments to the extracellular fluid volume that is associated with mannitol administration is clinically useful in cerebral edema, glaucoma, and the prevention of dialysis dysequilibrium syndrome. The mannitol-induced expansion of the extracellular fluid volume may be sufficient to perpetuate congestive heart failure, pulmonary edema, and significant hyponatremia in patients with renal failure in whom the half-life of mannitol is prolonged and the ability to excrete free water is limited.[37]

Carbonic anhydrase catalyzes the dehydration of carbonic acid to water and carbon dioxide, as well as the reverse hydration reaction. Acetazolamide is the prototypical carbonic anhydrase inhibitor and is more clinically useful for its extrarenal effects than its diuretic effects. Acetazolamide is used to treat glaucoma, acute mountain sickness, and occasionally epilepsy. The effectiveness of the carbonic anhydrase inhibitor is limited by the metabolic acidosis that develops because of the bicarbonate loss in the urine.

The "vaptans" (e.g., conivaptan) are nonpeptide arginine vasopressin antagonists that inhibit the arginine vasopressin–stimulated absorption of free water in the medullary collecting duct. In contrast to other diuretics, the vasopressin antagonists

Box 70–2 Causes of Diuretic Resistance

Noncompliance
- Medication, salt restriction

Poor absorption of medication
- Poorly absorbed formulation (e.g., furosemide oral)
- Disease-induced changes in absorption

Impaired excretion of diuretic
- Renal failure, renal transplant
- Drug interactions: NSAIDs, probenecid

Protein binding in renal tubule
- Nephrotic syndrome

Hemodynamic
- Shock, hypoxemia
- Drugs: NSAIDs, antihypertensive drugs

Change in dose response
- CHF, nephrotic syndrome, cirrhosis

Adaptive responses

CHF, Congestive heart failure; *NS,* nephrotic syndrome; *NSAID,* nonsteroidal antiinflammatory drug.

Box 70–3 Intensive Diuretic Therapy

1. High-dose diuretic therapy
2. Combination of diuretic therapy
3. Continuous infusion diuretic therapy

Box 70–4 Common Adverse Effects Associated with Diuretics

1. Volume depletion
2. Electrolyte abnormalities
   - Hyponatremia
   - Hypokalemia (loop and thiazide diuretics)
   - Hypomagnesemia (loop diuretics)
3. Hypercalciuria (loop diuretics)
4. Ototoxicity (loop diuretics, especially furosemide)

increase urine flow without increasing the renal elimination of sodium. The current use of vasopressin antagonists has been in patients with euvolemic, or hypervolemic hyponatremia, associated with the inappropriate secretion of antidiuretic hormone or congestive heart failure.[38]

Diuretic Resistance

An inadequate diuretic response results from disease- or drug-related alterations in diuretic pharmacokinetics or pharmacodynamics, high dietary salt intake,[39] or adaptive processes[29] (Box 70-2). During diuretic-induced extracellular volume depletion, short-term and long-term adaptive processes serve to protect the intravascular volume; however, when these adaptive processes interfere with the diuretic responsiveness before the desired reduction in the extracellular fluid volume is achieved, they contribute to diuretic resistance.

Short-term adaptation results from enhanced postdiuretic sodium retention. The brisk diuresis associated with diuretics activates counterregulatory pathways that serve to enhance sodium reabsorption and maintain extracellular fluid volume. Counterregulatory mechanisms involved in the short-term adaptation to diuretics include a decrease in atrial natriuretic peptide, increased renal sympathetic activity, increased antidiuretic hormone, a stimulated renin-angiotensin-aldosterone system, and a reduced GFR. The balance favors sodium and water excretion when the diuretic concentration in the renal tubular fluid is sufficient to inhibit sodium reabsorption. When the concentration of diuretic in the tubular fluid is below the threshold needed to elicit sodium excretion, the balance favors sodium and water reabsorption. In patients receiving a generous salt intake, which may be either dietary or associated with obligate fluids or medications, the postdiuretic sodium reabsorption may compensate entirely for the diuretic-induced sodium losses with an end result of no change in the extracellular fluid volume. Long-term adaptation occurs after several days of diuretic use and is characterized by a diminished response to each successive dose of diuretic.[39] The adaptation occurs because of the persistence of short-term counterregulatory mechanisms, as well as functional and structural changes that enhance the sodium reabsorptive capability of the distal tubule.[40,41]

If the response to moderate doses of a diuretic fails to be adequate in patients, several dosing strategies may help overcome the apparent diuretic resistance. Intensive diuretic therapy is achieved through high-dose diuretic therapy, combination diuretic therapy, or a continuous diuretic infusion (Box 70-3).

In patients with edema, the dose-response curve may be shifted to the right so that a greater amount of drug is needed in the renal tubule to produce the desired diuretic response. In patients who have renal failure or patients who receive drugs that inhibit the secretion of diuretic from the blood into the renal tubule, the dose-response curve is normal, but the problem lies in the inability to get a sufficient concentration of diuretic into the renal tubule. In both situations, an intermittent high-dose diuretic regimen may overcome the impaired rate of tubular secretion and increase the urinary diuretic concentration in an amount sufficient to elicit a response. High-dose therapy is associated with an increased risk of fluid and electrolyte abnormalities and a risk of toxicity related to high blood concentrations. Loop diuretic ototoxicity is more common with rapid infusion of high doses, especially when furosemide is combined with other ototoxic drugs.[36]

Because sodium reabsorption in the kidney is sequential and many of the adaptive processes increase sodium reabsorption distal to the site of diuretic action, combination therapy with diuretics that inhibit the distal tubule with loop inhibitors is effective. Part of the effectiveness of combination diuretic therapy resides in the longer duration of effect for thiazides that prevents the postdiuretic sodium reabsorption noted with the shorter-acting loop diuretics. Fluid and electrolyte abnormalities are more common with combination drug therapy (Box 70-4).

The final strategy to overcome diuretic resistance is a continuous infusion of a loop diuretic. The continuous infusion of a loop diuretic is more efficient than intermittent high doses and avoids the high and low serum concentrations associated with toxicity and resistance.[42-45] Continuous infusions result in steady diuretic effect and may avoid the rapid hemodynamic changes and stimulation of counterregulatory process associated with rapid changes in extracellular fluid volume.

A loading dose of diuretic is recommended at initiation and with each upward dosing adjustment to ensure a prompt response. The diuretic response may be further augmented by the addition of a distally acting diuretic.

Prevention/Reversal of Acute Renal Failure

Acute renal failure in the pediatric intensive care unit is generally associated with diminished renal perfusion caused by hypovolemia, hypotension, or decreased cardiac output. In addition, acute renal failure is also associated with nephrotoxins such as radiocontrast agents, antibiotics (e.g., vancomycin), and chemotherapeutic agents (e.g., cisplatin). With the exception of simple saline hydration, little evidence suggests that in humans, mannitol, furosemide, or dopamine prevents the development of acute renal failure in high-risk patients or changes the outcome in patients with established acute renal failure.[46-49] Nevertheless, the use of high-dose furosemide alone or in combination with low-dose dopamine might increase urine output and ease patient care by improving fluid management and permitting increased nutrition.

Glomerulotubular Dysfunction and Acute Kidney Injury

Surender Rajasekaran, Norma J. Maxvold, and Timothy E. Bunchman

PEARLS

- Acute kidney injury (AKI) has replaced the term *acute kidney failure*. There are over 30 definitions of AKI in children. Use of the RIFLE, the pRIFLE, and the AKIN defintions may help in streamlining the definition. In the future, biomarkers may further add clarity to this definition at an earlier time frame than they are presently used.
- In the critically ill child, AKI is often associated with cardiovascular instability, which, if prolonged, exhausts the normal kidney compensatory responses to maintain kidney blood flow and glomerular filtration.
- Because tubular blood flow, and thus oxygen delivery to this vital epithelium, depends on postglomerular blood flow, prolonged vasoconstriction of glomerular arterioles results in tubular necrosis.
- Nephrotoxic drugs, sepsis, and overzealous use of diuretics are common comorbid conditions that further contribute to AKI.
- Attention to cardiovascular status and the avoidance of unnecessary nephrotoxic agents such as aminoglycosides, nonsteroidal antiinflammatory drugs, and contrast agents may avoid further AKI.

Acute kidney injury (AKI) is a frequent problem in the pediatric intensive care unit (PICU), but an accurate incidence is difficult to establish due to the ongoing evolution of a clear definition of renal failure. The classic definition was a 50% reduction of glomerular filtration rate (GFR) accompanied by a 50% increase in creatinine. A RIFLE classification of renal injury to allow earlier appreciation of renal dysfunction is now utilized in adults and a modification of this system (pRIFLE) can also be applied to children.[1-3]

Early detection of renal dysfunction by biomarkers is needed, to allow a more timely awareness of injury and, thereby, modifications to alleviate the renal stress. Recent investigations in this area, although early in their development, postulate a panel approach (plasma panel of neutrophil gelatinase-associated lipocalin [NGAL] and cystatin C or a urine panel of NGAL, interleukin 18, and kidney injury molecule-1 [KIM-1]) may be of help in the future to provide more sensitive and specific detection of early AKI.[4-6]

Acute Kidney Injury Pathophysiology

Physiology of Glomerular Filtration

GFR is the product of the filtration rate of the individual nephron and the number of functioning nephrons.[7] A single nephron glomerular filtration rate (SNGFR), is defined by the Starling forces of the glomerular capillaries and the properties of the glomerular capillary wall.

$$\text{SNGFR} = \text{Kf}\,(\Delta P - \Delta\pi) = \text{Kf}\,P_{uf}$$

where *Kf* is a capillary wall property known as the ultrafiltration coefficient and is the product of the surface area available for filtration and the hydraulic conductivity of the membrane. The Starling forces (or pressures) that affect filtration are the hydraulic pressure in the glomerular capillary (P_{gc}), the hydraulic pressure in Bowman's space (P_{bs}), the oncotic pressure of the glomerular capillary (π_{gc}), and the oncotic pressure in Bowman's space (π_{bs}), which is usually zero because the ultrafiltrate is essentially protein-free.[8] P_{gc} favors filtration; Pbs and π_{gc} are opposing forces to filtration. The mean ultrafiltration pressure (P_{uf}) is the difference between the net change in hydraulic pressure and the net change in the oncotic pressure. Thus SNGFR may be modified by alterations in the glomerular capillary pressures, glomerular membrane characteristics, or the surface area available for filtration.

The kidneys are responsible for plasma water and electrolyte balance through filtration at the glomerular membrane and then reabsorption of this filtrate from the renal tubular epithelium. The loss of filtration and tubular reabsorption in AKI is the result of renal adaptive changes that initially function to preserve renal perfusion and glomerular filtration; however, when these are exhausted, the kidney's compensatory mechanisms fail and renal dysfunction ensues.

Glomerular filtration depends on adequate renal perfusion; the kidneys receive approximately 25% of total cardiac output. The fraction of cardiac output perfusing the kidneys is related to the ratio of renal vascular resistance (RVR) and systemic vascular resistance.[9] Renal blood flow (RBF) is determined by systemic blood pressure (SBP) and RVR, expressed by the formula RBF = SBP/RVR.[9] Kidney autoregulation, which maintains a constant renal perfusion pressure, occurs through alterations in RVR in response to changes in systemic

vascular resistance or intravascular volume. When SBP is within the normal physiological or autoregulatory range, the kidney can maintain constant blood flow and GFR by dilation of the preglomerular or afferent arteriole, which reduces RVR and increases RBF. This afferent arteriole dilation is accomplished by two known mechanisms, smooth muscle relaxation of the afferent arteriole in response to sensing a transmural pressure drop (the myogenic reflex[3]) and the tubuloglomerular feedback system. The tubuloglomerular feedback system is operational following a reduction of plasma flow. When solute and water delivery to the macula densa are reduced, the juxtaglomerular apparatus responds by relaxing the smooth muscle of the adjacent afferent arteriole. Thus a reduction in cardiac output or effective renal plasma flow is accompanied by vasodilation at the preglomerular arteriole, which in turn reduces RVR, thereby restoring RBF.

During states of reduced cardiac output or intravascular volume depletion, the systemic vasoconstrictors, angiotensin II and vasopressin, are released to help preserve vascular tone. The kidney counteracts the renal vasoconstrictor activity of angiotensin II and increased sympathetic tone through the intrarenal production of vasodilatory prostaglandins such as prostaglandin I2.[10] These locally produced substances may attenuate renal vasoconstrictive forces and help preserve renal perfusion. Animal model data of congestive heart failure have provided evidence that enhanced prostaglandin synthesis is required for preservation of renal perfusion and GFR. Patients receiving prostaglandin synthetase inhibitors such as nonsteroidal antiinflammatory drugs (NSAIDs) have potentiation of renal ischemia because of an increase in renal vasoconstriction not antagonized by intrarenal prostaglandin synthesis.[11] Endothelium-derived relaxation factors (EDRFs), which are vasodilatory, and the potent vasoconstrictor endothelin, produced by the endothelium, may also affect the regional vascular tone.[12]

Constriction of the postglomerular capillary sphincter, the efferent arteriole, in the face of reduced RBF serves to increase the filtration fraction and preserve GFR, although this occurs at the expense of renal plasma flow, which may be further reduced. Vasoconstriction at the efferent arteriole is mediated by angiotensin II and, to a lesser extent, by the action of the adrenergic system by epinephrine.[13] Elevation in postglomerular arteriolar resistance may be blocked by the angiotensin-converting enzyme inhibitors. When converting enzyme inhibitors are administered to the patient who requires efferent arteriolar constriction to maintain GFR, renal decompensation often results.[14]

As previously noted, reductions in effective intravascular volume and cardiac output are accompanied by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system and increased circulating levels of vasopressin.[15] Hormonal and neural systems signal the kidneys to increase the reabsorption of sodium and water to help restore the deficient intravascular volume, increase cardiac output, and consequently improve RBF. These, and the kidney's homeostatic mechanism, by afferent arteriolar vasodilation and efferent arteriolar constriction, maintain the kidney's glomerular filtration. The kidney's homeostatic mechanisms, however, are not without limitation. The autoregulatory ability of the afferent arteriole is maximal once the mean SBP falls below 80 mm Hg. The renal autoregulatory range appears to be age-dependent, because younger animals can autoregulate over lower pressure ranges. The range of perfusion pressure over which the kidney can autoregulate may be limited in certain conditions so that vasodilation is maximal with a minor reduction in mean arterial blood pressure. Examples include extracellular fluid depletion, renal ischemia, or renal vascular disease (e.g., hypertension, diabetes, atherosclerosis).

As the stimulus for release of vasoconstrictors continues, afferent arteriolar constriction rather than vasodilation may predominate, and the result is a decrease in renal plasma flow and filtration rate.

Constriction of the afferent arteriole may be stimulated by increased sympathetic nervous system activity and increased levels of endogenous or exogenous circulating catecholamines such as dopamine or norepinephrine. Thus the administration of these vasoactive-inotropic agents may actually compromise the kidney's adaptive mechanisms. Excessive vasoconstriction eventually results in diminished filtration rate and oxygen delivery to the kidney.

Pharmacological agents may alter renal perfusion by changing SBP through an action on systemic vasculature or by direct effects on renal vasculature (Box 71-1). Vasodilators, such as hydralazine, lower SBP without changing renal perfusion pressure, because the decrease in SBP is accompanied by decreased RVR. Conversely, epinephrine increases SBP but decreases RBF by its vasoconstrictor effect on intrarenal blood vessels.

Morphologic Changes in Renal Injury

Morphologic changes seen in acute renal injury, especially those in the tubules, depends on the duration of injury as well the eliciting mechanism.

The kidney's complex structure, with heterogeneous segments within the kidney receiving differential regional perfusion and thereby oxygenation, sets up a common form of renal failure, that of the tubulointerstitium. This region is at greatest risk for ischemia because of its gradient of regional perfusion and oxygenation. In addition, vascular disease, including

glomerular disease, often occurs in children and results in AKI, but there are studies that suggest the extent of damage to the tubulointerstitium has the greatest prognostic implication to the degree of final renal recovery.[16]

Initial structural changes in tubular cells are seen as apical and basal surface changes of simplification, with microvilli of the brush border shortening and disappearing by either detachment from the apical surface or being internalized within the tubular cells.[17]

In this scenario, enzymes of the brush border (alkaline phosphatase and gammaglutamyl transpeptidase), may be found in the urine and may be used as markers of early tubular injury.[18] The loss of microvilli surface area leads to loss of enzymes and transport sites for transcellular absorption and apical uptake. Additionally, loss at the basolateral interdigitating infoldings of the tubular cells then results in further reduction of surface area for transport and loss of the Na-K-adenosine triphosphatase (ATPase) that is localized to this membrane and involved in many transport processes.[19]

Morphologic changes in distal tubules and outer medulla also occur and may be found even when proximal tubular injury is not readily identified on biopsy. Experimentally, the outer medulla has been identified as sensitive to hypoxia, including that induced by toxins such as radiocontrast agents and cyclosporine.[20]

Injury at this outer medulla region may be missed on biopsy since this site often is not sampled. Tubular cell detachment with exposed, denuded regions of the basement membrane can be found on biopsies, as a result of altered cell-matrix attachments.[21]

Renal tubular sensitivity to ischemic injury is primarily influenced by the individual renal cell's energy requirements, its glycolytic capacity, and the extent of hypoxic stress upon the cell. Glycolysis and oxidative phosphorylation both supply the ATP required by the cell to drive its metabolism, and it follows that cells with a greater capacity for glycolysis (distal tubular cells) are less sensitive to oxygen deprivation than the cells that rely mainly on mitochondrial derived energy, (proximal tubular cells).[22]

In vivo and in vitro studies may be discordant in identifying susceptiblity to hypoxia. Medullary straight portions of the proximal tubule have a higher glycolytic capacity than the cortical segments of the proximal tubule but, due to the regional distribution of perfusion within the kidney, the medullary portions operate in a lower oxygen-tension environment and therefore are more susceptible to hypoxia/ischemic injury.[23] The individual cell's energy requirements to conduct its transport activities further influences its risk to hypoxic injury. The outer medullary proximal tubular cell (pars recta), due to the high energy requirements for its transport functions, has a greater injury risk than the deep inner medullary tubular cell with its low-oxygen environment, but also a low energy requirement to maintain its transport function.[24]

When energy stores are rapidly depleted, the normal Na-K ATPase pump begins to fail and the most basic of cell function, membrane integrity, is jeopardized, with resultant accumulation of Na, Cl, and water within the cell; this cell swelling (oncosis) is a hallmark feature of necrosis.[25] Not all cells that fail to maintain their energy requirements die through necrosis; apoptosis, which appears morphologically as cell shrinkage, is also a result of inadequate energy support. Apoptosis is an asynchronous cell death triggered over hours to days, with the earliest cellular element involving mitochondrial changes including loss of transmembrane potential and release of mitochondrial cytochrome c into the cytosol.[30] It is mitochondrial function/dysfunction that primarily determines the fate of the cell for recovery and survival or death, and by what form: apoptosis or necrosis.

Pathogenesis of Reduced Glomerular Filtration Rate in Acute Kidney Injury

The mechanisms responsible for GFR reduction in acute renal injury have been studied extensively with experimental models of AKI. Multiple mechanisms are often operational in mediating hypofiltration. Whereas one factor may have greater importance in the initiation of injury and decreased filtration, others are involved in the sustained reduction in GFR during the maintenance phase of AKI. Four major mechanisms result in reduced GFR during AKI: reduced blood flow, decreased Kf, tubular obstruction, and backleakage of tubular fluid.[31] Each factor is discussed regarding its role in both the initiation and maintenance phases of AKI.

A reduction in RBF can be demonstrated during the initiation phase of many forms of AKI and seems to play a predominant role in ischemic injury and rhabdomyolysis.[31] Proposed theories for the reduction of RBF include (1) a proportional increase in the afferent and efferent arteriolar resistances in response to activation of the renin-angiotensin system; (2) vascular endothelial cell swelling and damage with release of vasoactive peptides such as endothelin; and (3) hyperemic congestion of the medullary peritubular capillaries.

Kf may be reduced in both nephrotoxic and ischemic forms of renal failure. Endothelial or mesangial cell swelling reduces the surface area available for filtration; altered permeability induced by humoral factors such as angiotensin II and vasopressin may also decrease Kf. Circulating levels of both hormones are increased during AKI.

Renal tubular cells are the primary site of injury in both ischemia and nephrotoxin-induced renal injury. Tubular cell injury may be sublethal or lethal and result in cell necrosis or apoptosis. Once this injury occurs, cells detach from the supporting basement membrane and obstruct the tubule lumen. In addition, even with sublethal injury, tight junctions may be disrupted, and the intact layer may be lost. The loss of epithelial integrity allows backleakage of ultrafiltrate, which contains creatinine and urea, through paracellular pathways into the renal interstitium, creating further diminution of excretory function and reduced urine formation. Necrosis of a selected region of the renal tubule is accompanied by tubular obstruction and eventual filtration failure by that entire unit or nephron.

Intratubular obstruction occurs in most forms of acute renal injury, either as a contributing factor in the initiation phase or during the maintenance phase.[31] Tubular obstruction with cellular debris and precipitated protein is a prominent finding in both the initiation and maintenance phases of ischemic injury. In the case of nephrotoxic injury, the degree of injury may determine the extent of tubular obstruction. In an experimental model of gentamicin nephrotoxicity, the drug dose was positively correlated with the contribution of tubular obstruction to reduced GFR.[31] Tubular obstruction and loss of epithelial integrity caused by tubular cell injury result in the backleakage of tubular fluid and solutes. Excretion of solute

and fluid is decreased, and this decrease possibly signals a further reduction in the GFR by stimulation of the tubuloglomerular feedback mechanism.[31] Backleakage of fluid involves tubular factors and is not a result of hypofiltration, although it does impair the excretory function of the kidney. Consequently, a falsely low estimation of actual GFR may occur because tubular fluid containing urea and creatinine leaks back into the vascular space and interstitium. Prevention of the tubular obstruction may alter the course of renal failure, even in those states in which the primary mechanism of injury is not obstruction.

AKI may be viewed as an evolving process into three phases[32]: (1) an initiation phase in which the primary mechanism of injury is operational; (2) a maintenance phase during which renal function remains poor and other factors may contribute to sustained injury; and (3) a recovery phase during which there is regeneration of cells and restoration of function. Although the primary initiating event may be hypoperfusion with ischemia, often it involves multiple contributing factors that mediate additional cellular damage, usually through alterations in energy supply. From a clinical perspective, it may be most helpful to consider acute renal dysfunction syndromes according to the cause of the inciting event; however, it is equally vital to understand the other contributing mechanisms that ultimately affect outcome.

Recently, endothelial injury and vascular dysfunction have been postulated to occur during the initiation and particularly during the maintenance phases of AKI. Although most studies have focused on the tubular cell as the primary site of injury leading to dysfunction, recent studies have provided insight into the potential role for endothelial injury in continued reduced RBF and altered vascular function.[33] Sutton et al. propose that an additional phase be added to the current model for AKI: after the initiation phase, an extension phase occurs that is due to microvascular injury related to ischemic damage to endothelial cells, infiltration of leukocytes, and activation of the coagulation system. This process is thought to predominate in the corticomedullary and outer medullary microvessels and may occur in the face of early tubular cell regeneration so that limiting the extension process provides a potential mechanism for aiding recovery.

Mechanisms of Renal Cell Injury

The renal tubular cell expends energy in the form of ATP to maintain a high intracellular concentration of potassium and a low intracellular concentration of sodium. This concentration gradient depends on the continuous activity of the Na^+/ K^+-ATPase and is the driving force for the reabsorption of sodium. Active reabsorption of sodium is the primary driving force for water reabsorption and the coupled transport of amino acids, carbohydrates, organic acids, and other compounds. Thus all transport functions, as well as many other vital cell functions, depend on normal activity of the Na^+/K^+ pump, which, in turn, depends on an adequate supply of energy. In addition, membrane fluidity or integrity is important to transport functions in tubular cells. Processes that result in alterations in the membrane or in the supply of energy are common final pathways for renal tubular cell death.

A decrease in the cellular ATP content occurs in many forms of renal injury, possibly as the result of primary alterations in the cell's ability to perform oxidative phosphorylation or as the end result of other perturbations. Heterogeneity exists in the susceptibility of nephron segments to oxygen deprivation with more distal segments being relatively resistant. This is related to the greater glycolytic capacity of the distal tubule compared with the proximal tubule, which relies on oxygen-consuming pathways for ATP generation. Therefore the net result of renal injury is usually a depletion of energy in the form of ATP, with the inability of the cell to perform vital functions, including transport and maintenance of cell integrity.

Cellular injury may be modified by the requirements made on its energy stores. If more transport is required of the cell, more energy is consumed, and less energy is left for cell maintenance. Evidence exists to support this theory. If transport requirements are reduced by the administration of diuretics or by the stimulation of the glomerulotubular feedback mechanism, then further injury may be attenuated. The feedback mechanism, whereby there is reduction of GFR in the face of reduced reabsorption by the proximal tubule, is a protective signal that conserves cell energy by reducing metabolic demands made on the cell.

Heat shock proteins (HSPs) are a family of proteins that appear to protect cells from injury as a result of hyperthermia, ischemia, or toxins. The HSP induction by sublethal thermal stress has been found to attenuate subsequent injury in the kidney.[34] Renal transplants from animals that underwent short-term hyperthermia had better initial function and subsequent survival. Furthermore, in cultured inner medullary collecting-duct cells, induction of HSP-1 by preconditioning hyperthermia attenuated the alterations in mitochondrial function and glycolysis that were observed after cells were exposed to high temperatures. Investigations into potential mechanisms to use this natural cell defense mechanism are under way.

The ability of renal tubular epithelial cells to undergo regeneration determines in large part the degree of renal recovery. Therefore much work has recently been done to study ways that cells regenerate and mechanisms that might enhance recovery. Early in ischemic injury there is induction of early response genes such as c-fos and Egr-1.[35] By 2 days after ischemia, the proliferating cell nuclear antigen is detected, followed by expression of other dedifferentiated cell markers, which seem to be a sign of early recovery. Other cells appear to undergo apoptosis or cell death. Postischemic regeneration seems to be a recapitulation of early renal tubular cell development. Growth factors such as insulin-like growth factor-1 (IGF-1) and epidermal growth factor 1 (EGF-1) have been associated with enhanced recovery as well. Renal levels of hepatocyte growth factor (HGF) increase after two models of renal failure, postnephrectomy, and following CCL4 (chemokine [C-C motif] ligand 4) injection, and this increase supports a role for HGF in renal repair.[36] Exogenous EGF has been shown to enhance renal tubular cell regeneration and to lessen the severity and duration of hypoxia and toxin-induced renal failure. EGF receptor levels increase within hours of ischemic injury in the rat. Elevation of soluble EGF occurs along with morphological evidence of tubular injury within 12 hours of ischemia, which is followed by cell proliferation and a decrease in soluble EGF by 24 to 48 hours after ischemia.

Alterations in Cell Membranes

Membrane phospholipids have a structural function and affect membrane permeability, as well as the activity of membrane transport systems.[37] These compounds are regulated in part by

the activity of phospholipases, which release free fatty acids from phospholipids. Several mechanisms related to acute cell injury may alter phospholipase activity and thereby change membrane phospholipids and membrane integrity: altered intracellular calcium homeostasis, depletion of ATP, and lipid peroxidation.[33] Increased phospholipase activity has been associated with an abnormal increase in permeability of the inner mitochondrial membrane, which ultimately results in disruption of mitochondria and loss of the ability to produce adequate energy.

Cellular Calcium Homeostasis

Increased intracellular calcium is commonly found in cell injury. It is not, however, a consistent finding in all models of renal injury.[38] Techniques to study changes in the subcellular distribution of calcium have allowed time-related changes to be assessed. In the rat proximal tubule, steady-state hypoxia is accompanied by a prompt increase in cytosolic free calcium that precedes the appearance of membrane damage. The increase in calcium is reversed with reoxygenation. Increased cellular calcium may activate phospholipases, as previously mentioned; alter the cytoskeleton and cause injury by allowing cell swelling; or affect membrane permeability at the plasma membrane, the mitochondrial membrane, or the endoplasmic reticulum. Alterations in mitochondrial function that occur as a result of calcium loading of this organelle have been extensively studied. Excess mitochondrial calcium is associated with changes in the permeability of the inner mitochondrial membrane with loss of the electrochemical gradient and the capacity for oxidative phosphorylation. In addition, changes in enzyme activity and mitochondrial levels of nucleotides may exist.

Production of Free Radicals

Renal cell damage induced by inflammation or oxygen deprivation may be mediated, in part, by oxygen free-radicals that are generated by several cell processes, including accumulation of long chain acyl CoA as a result of mitochondrial dysfunction. The net result is increased intracellular calcium and ultimately, changes in membrane-related functions.[32]

Tubular Cell Energy Metabolism

After exposure to a variety of nephrotoxins or ischemia, renal cortical ATP levels are reduced even before changes in membrane integrity and cell death occur.[39] In ischemic injury, alterations in renal perfusion may result in decreased oxygen delivery to tubular epithelium. Direct mitochondrial damage has been postulated to be the primary event in many forms of nephrotoxic injury.[32] Other nephrotoxins interfere with energy production by the inhibition of enzymes along the citric acid cycle. In this way, toxins impair energy production. ATP levels decrease immediately after ischemia, with concomitant increases in ATP hydrolysis products. Reflow is associated with a gradual increase in cell ATP levels.

Classification of Acute Glomerulotubular Dysfunction

Hemodynamically Mediated Acute Kidney Injury

Renal hypoperfusion with ischemia is a common form of acute renal damage, especially in the setting of the ICU. This form of renal injury is often accompanied by oliguria and results from alterations in renal perfusion after a period of hypoxia, hypotension, cardiac dysfunction, or any condition that promotes hemodynamic instability, decreased effective plasma volume, or both states. This condition is commonly referred to as acute tubular necrosis because it is characterized by necrosis of tubule cells; however, this is a nonspecific term that may also define nephrotoxic injury. A preferred term is vasomotor nephropathy or hemodynamically-mediated renal failure.[40] The same physiological alterations that initiate renal injury in this form of nephropathy may potentiate renal failure in conditions whose primary inciting event may not have been vascular.

Vasomotor nephropathy commonly follows a period of renal compensatory changes that may be termed prerenal failure,[9] which are discussed in the preceding section on physiology. When the kidney has fully used normal compensatory mechanisms, renal oxygen delivery is critically impaired, and this impairment results in cell damage or tubular cell necrosis. Thus it is apparent that acute tubular necrosis is the end result of a continuum of renal adaptive mechanisms. Acute cortical necrosis is an exaggerated and more advanced form of renal ischemia.

When vascular or hemodynamic abnormalities persist or are profound, renal compensatory mechanisms are unable to preserve RBF and maintain sufficient oxygen delivery and GFR. At a mean renal perfusion pressure of 80 mm Hg, afferent, arteriolar dilation is maximal, and below these systemic pressures, RBF dramatically declines.[9,40] In addition, loss of the ability to autoregulate as a result of ischemia may cause further damage. Renal cell injury develops as the result of deficient oxygen delivery, depletion of cellular energy, loss of membrane integrity, and release of reactive oxygen species. Without sufficient oxygen, the kidney cannot support cell functions that maintain architectural integrity and complex transport functions.

Although total RBF is decreased in vasomotor nephropathy, outer cortical blood flow is preferentially reduced. The medulla is not spared, however, because of its increased susceptibility to alterations in renal perfusion.[41] Oxygen delivery to this segment of the kidney is precarious. Medullary partial pressure of oxygen (PO_2) is approximately 10 mm Hg in the rat and dog. This oxygen level approaches the critical minimum level required to support oxidative phosphorylation and ATP synthesis for cell function. In general, however, the proximal tubule sustains the greatest injury. The renal arteriogram of human subjects with vasomotor nephropathy reveals marked narrowing of the arcuate arteries and absence of peripheral vasculature, providing further evidence for the marked vascular resistance enhancement.[40]

The primary event in vasomotor nephropathy is injury of the renal tubule. The initiation of this injury, however, is microvascular in origin. Maximal renal compensation with marked efferent and afferent arteriolar vasoconstriction reduces glomerular plasma flow with resulting hypofiltration and compromises postglomerular blood supply to the renal tubule. Tubular cell necrosis with sloughing of tubular cells into the lumen results in obstruction of flow and backleakage of filtrate through the injured epithelium. Alterations in tubular cell function in cells receiving sublethal or lethal injury increase fluid and salt delivery distally, and this increase signals the glomerulotubular feedback system to cause vasoconstriction of the afferent arteriole and limit the fraction of plasma filtered at the glomerulus.[40] Although the initial reduction in

GFR is the result of decreased RBF and tubular factors such as obstruction and backleakage, continued hypofiltration during the maintenance phase is related primarily to continued vasoconstriction and renal hypoperfusion.[40] Recovery from postischemic AKI is biphasic. Initially, an increase in GFR occurs with relief of tubular obstruction and subsequently, improved filtration in association with renal vasodilation.

Oliguria in the presence of renal hypoperfusion has been referred to as acute renal success by investigators who propose that the response of an intelligent organ to a perceived reduction in blood flow is to reduce fluid and electrolyte losses by vasoconstriction to reduce the fraction of plasma filtered and by maximal reabsorption of fluid and salt to restore the circulation. In addition, increased distal delivery of water and solutes because of tubular cell necrosis reflects failure of the renal tubule to absorb what is filtered. The appropriate response of an intact nephron is to reduce filtration by release of angiotensin II into the interstitium. Angiotensin II mediates arteriolar vasoconstriction, which decreases glomerular plasma flow, and retraction of the glomerular tuft, which reduces Kf, the net effect being decreased glomerular filtration.[41]

The classic form of hemodynamically-mediated AKI was oliguric, by definition; however, nonoliguric acute vasomotor nephropathy is increasingly recognized.[41,42] This form of less severe disease has been referred to as attenuated acute tubular dsyfunction and has allowed the recognition of three stages of AKI that actually represent a continuum of worsening disease: first, abbreviated renal insufficiency occurs after a single event of renal hypoperfusion, such as aortic cross-clamping, in the face of adequate volume repletion and SBP. This syndrome is characterized by an acute drop in the GFR with gradual return to normal within a few days. The inability to concentrate the urine or to conserve sodium provides evidence of tubular injury. The second phase or form is referred to as overt renal failure. An example of this situation is aortic cross-clamping followed by continued renal hypoperfusion because of poor cardiac function. A more prolonged period of hypofiltration lasts for several days to weeks with a gradual return of the GFR. If recovery of renal perfusion is impaired by repeated episodes of ischemia/hypotension, sepsis, or hypoxia, the third pattern may be observed in which a protracted course may be observed and chances for recovery may be doubtful.[42] One situation in which the last example could exist is aggressive hemodialysis (ultrafiltration) with hypovolemia and, consequently, renal hypoperfusion in the recovering phase of renal failure. Clinical experience has supported this theory. Patients with multiple renal insults have a more protracted course and increased morbidity.[43]

Using the Schwartz formula for estimate of creatinine clearance (GFR) in infants and children, a modified RIFLE classification (pRIFLE) has been developed.

$$\text{Schwartz Formula: eGFR} = \text{eCrCl} = K \times \text{Height (cm)} / \text{serum creatinine (mg/dL)}$$

[K value of premature infants (0.33), infants (0.45) and children > 1 year of age of 0.55][44,45]

The pRIFLE classification is defined by the percent reduction in eCrCl and/or the amount of diminishing urine output[2] (Table 71-1).

Table 71–1 pRIFLE Classification

pRIFLE	Estimated CrCL	Urine Output
Risk	25% decrease	< 0.5 mL/kg/h for 8 hours
Injury	50% decrease	< 0.5 mL/kg/h for 16 hours
Failure	75% decrease	< 0.3 mL/kg/h for 24 hours or anuric for 12 hours
Loss	Persistent failure >4 weeks	
End-stage renal disease	Persistent failure >3 months	

Treatment of Acute Kidney Injury

Prevention/Attenuation of Acute Renal Failure

Prevention or attenuation of ARF has been the subject of numerous studies, as most agree that protection of the kidney from damage or enhancing recovery after damage would be preferable to the currently available supportive therapies. Primary prevention of AKI in the ICU is limited to those conditions in which the timing of injury is predictable, such as exposure to radiocontrast dye, cardiopulmonary bypass, nephrotoxic medications, or chemotherapy. In contrast to most cases of community-acquired AKI, nearly all cases of ICU-associated AKI result from more than a single insult.[46] Protective agents have been studied extensively with animal models of acute renal injury. Some of these agents have ultimately been used in clinical situations with variable success. In general, methods to reduce renal injury have been aimed at manipulation of RVR or alteration of the metabolic processes of the renal tubular cell.

Dopamine

Dopamine, when infused in low intravenous doses, increases RBF, increases GFR, and increases sodium excretion. In the past, clinicians frequently used "renal dose" dopamine in the hopes that such a maneuver might attenuate renal injury and improve survival. In addition, clinicians often interpret an increase in urinary output as proof that these two assumptions are valid. Dopamine stimulates both dopaminergic and adrenergic receptors. As such, dopamine may affect renal blood flow by direct vasodilation (dopamine receptors), by increasing cardiac output (β-receptors), or by increasing perfusion pressure. Of particular interest are its action on Dopamine 1 (D1) receptors, which are abundantly distributed throughout the renal vasculature.[47] Stimulation of D1 receptors results in vasodilation by means of receptor coupling with cyclic adenosine monophosphate (cAMP) and calcium flux generated by protein kinase A. In addition, D1 receptors are also found within the brush border and basolateral membranes of the proximal tubule; medullary ascending limb of the loop of Henle; distal tubule; and cortical collecting ducts where agonist induces decreases in sodium, phosphate, and bicarbonate absorption. D1 receptors have also been localized to the macula densa where they may modify renin production.[47] Dopamine inhibits the Na/K-ATPase along the nephron. Interestingly, this action would be expected to decrease

the oxygen consumption of the renal tubule; thus it would be less susceptible to ischemic or hypoxic injury. Dopamine 2 (D2) receptors are present along the renal tubule. In the inner medulla, a subclass, D2k is coupled to prostaglandin E2 and attenuates the action of antidiuretic hormone (ADH) in this segment.

Dopamine in the dosage range of 0.5 to 2 μg/kg/min increases RBF by 20% to 40%. The GFR increases by 5% to 20%, an effect related to enhanced glomerular ultrafiltration by a preferential vasodilation at the afferent arteriole. This is thought to be related to a dopamine-induced increase in local angiotensin production, which attenuates the dopamine-induced vasodilation at the efferent but not the afferent arteriole. The increase in medullary blood flow observed with dopamine results in a decrease in the urea concentration within the medullary interstitium and contributes to the limited concentrating ability of the dopamine-stimulated renal tubule.

The observed increase in urinary flow is thought to be related primarily to the tubular actions rather than the vascular actions of dopamine. At higher doses, dopamine stimulation of receptors results in decreased sodium and fluid excretion, as well as renal vasoconstriction. Dopamine clearance is decreased in the presence of renal or liver dysfunction.

However, dopamine does have noncardiac effects that complicate its use and should make clinicians rethink its previous role as a vasoactive agent. The group that formulated the 2008 International Guidelines for Management of Severe Sepsis and Septic Shock does not recommend the use of low-dose dopamine as a renal agent, based on available data.[48] They also noted that dopamine may inhibit thyrotropin hormone release from the hypothalamus and have immunosuppressive effects through its inhibition of release of the lymphotropic factor prolactin. Dopamine should be used cautiously in neonates because the renal vascular response to dopamine is age dependent,[49] although administration of dopamine (0.5 to 2 μg/kg/min) to premature neonates with respiratory distress syndrome and renal insufficiency was reported to result in improved creatinine clearance without major side effects.

Diuretics

Intravenous diuretics have been frequently used in the intensive care unit to ameliorate fluid overload by increasing urine output.[50] This widespread use of loop diuretics in the face of impending renal failure has been ascribed to a combination of animal and human data. Loop diuretics decrease renal vascular resistance and increase renal blood flow.[51] In addition, loop diuretics inhibit the sodium/potassium chloride cotransporter system (NKCC2), thereby reducing active oxygen transport and potentially reducing oxygen consumption, and thus limiting ischemic injury to the outer medullary tubules. Indeed, furosemide has been shown to decrease renal oxygen consumption in critically ill patients.

Mannitol may attenuate renal failure if it is given before the insult or immediately afterward.[52] Loop diuretics, such as furosemide, if given along with a potentially nephrotoxic agent, may increase the renal excretion of the agent and reduce associated nephrotoxicity. Mannitol has been shown to ameliorate nephrotoxicity related to gentamicin, amphotericin B, cisplatin, and myoglobin. A specific beneficial effect is doubtful, however, because acute saline loading alone provides similar protection. When tubular obstruction plays a major role, mannitol may increase tubular flow enough to wash obstructing debris downstream. It seems reasonable to use mannitol and potentially furosemide in the initial phases of oliguria when AKI may not be established; however, these agents provide little benefit and may increase toxicity in sustained oliguria as a result of tubular necrosis.

Calcium Entry Blockers

These agents may prevent renal insufficiency through their vasodilatory action on renal vasculature, as well as inhibition of calcium entry. The calcium channel blockers verapamil, nitrendipine, diltiazem, and nisoldipine have been administered to various animal models of ischemic injury with some success in the prevention or attenuation of renal failure. Minimal protection is observed, however, if they are administered after ischemia.[52] Calcium entry blockers had a beneficial effect in endotoxin-mediated AKI. This effect was postulated to be a result of an antagonism of platelet-activating factor.[53] The perfusion of cadaveric renal grafts before transplantation with diltiazem was associated with improved graft survival compared with control subjects.[54] Preoperative administration of calcium channel blockers to adults undergoing cardiac surgical procedures did not provide any obvious protection from the development of AKI.[55]

Prostaglandins

Vasoconstrictive forces in the renal vasculature may result from the action of vasoconstrictor prostaglandins and are counteracted by the vasodilatory substances.[56] Infusion or stimulation of the vasodilatory prostaglandins or inhibition of the vasoconstrictor prostaglandins seems to be a reasonable approach. Prostacyclin provided protection during ischemia in a rat model.[56] Administration of the thromboxane synthetase inhibitor OKY-046 partially ameliorated hypofiltration in a rat model of ischemic renal failure.[57] In addition, the administration of the free radical scavenger's dimethylthiourea and superoxide dismutase attenuated renal insufficiency and reduced thromboxane levels.

Renin-Angiotensin Antagonists

Administration of saralasin, an angiotensin II receptor antagonist, either before or after ischemia was not beneficial in the rat model. Blockade of angiotensin production by the conversion of enzyme inhibition with enalapril or captopril was not successful in preventing AKI.[58] Although captopril did prevent a fall in RBF, in one study the GFR actually dropped.

Adenosine and Adenosine Triphosphate

Renal ischemia results in the depletion of cellular adenine nucleotides and increased levels of adenosine, an agent implicated as a mediator of local renal vasoconstriction.[59] Adenosine may also have protective tubular effects during ischemia because it inhibits solute reabsorption in the medullary thick ascending limb of the loop of Henle. Theophylline, a competitive inhibitor of adenosine receptors, partially prevents the hypofiltration following ischemia in the rat.

Infusion of ATP-magnesium chloride (ATP-$MgCl_2$) after renal ischemia promotes more rapid cellular recovery and attenuates renal injury.[59] In animal models exogenous ATP, adenosine diphosphate (ADP), adenosine monophosphate

(AMP), and adenosine preserve renal tubular cell metabolism during anoxia by protecting the membrane from disruption and providing precursors for rapid synthesis of ATP during reperfusion.

Atrial Natriuretic Factor

Atrial natriuretic factor (ANF) has direct effects on glomerular hemodynamics and GFR.[60] ANF dilates arcuate, interlobular, and proximal afferent arterioles, and it relaxes mesangial cells.[61] In a rat model of rhabdomyolysis, administration of ANF improved GFR and enhanced sodium and water excretion. In addition, ANF improved GFR and maintained cell energy levels during ischemic injury.[62] ANF preserves glomerular filtration and cellular ATP levels in experimental models of AKI by its effect on glomerular hemodynamics.

Free Radical Scavengers

Reactive oxygen species have been proposed as a cause of cellular injury in many forms of AKI. The conversion of xanthine to hypoxanthine during reoxygenation produces reactive oxygen species. Antioxidants and xanthine oxidase inhibition (allopurinol) have proved to attenuate renal injury in many models of ARF.

Thyroxine

Thyroxine reduces renal injury in a number of experimental models when given before the injury, immediately after, or 24 hours after ischemia. The mechanism by which thyroxine preserves both glomerular and tubular function is not completely understood; however, the rate of recovery of cellular ATP levels was much more rapid in animals given thyroxine after ischemic AKI. Isolated mitochondria from rats subjected to 45 minutes of ischemia exhibited decreased mitochondrial ADP transport. Administration of thyroxine was associated with significantly enhanced ADP transport.[63] The investigators speculated that part of the ATP depletion associated with ischemic injury might be the result of decreased mitochondrial uptake of the ATP precursor, ADP. The administration of thyroxine at 5 to 6 ng/kg/day for 5 to 10 days in eight children with AKI resulted in the recovery of renal function in all but one child, who died of the original disease.[64]

Glycine and Alanine

The amino acids glycine and alanine have recently been shown to have cytoprotective effects against injury in anoxia-hypoxia and chemotherapy-induced renal failure. The mechanism of cytoprotection is not understood but does not appear to involve preservation of intracellular ATP levels. Studies performed in cultured proximal tubular cells indicate that glycine and alanine may stimulate the expression of hsp genes and increase HSP proteins, which protect cells from injury. The cytoprotective effect was not observed with other amino acids and was independent of cellular ATP levels in this model of renal injury.[65] Incubation of isolated renal tubules with glycine during hypoxia was associated with increased levels of glutathione, as well as increased cell ATP, although these did not appear to account fully for the protective effect of glycine. In addition, administration of glycine prevented renal injury in rats treated with nephrotoxic doses of cisplatin.[66]

Acute Kidney Injury: Clinical Impact

Severe deterioration of kidney function can have a profound effect on body fluid homeostasis and on blood pressure. The nature of these alterations often requires intensive care management regardless of the precise underlying diagnosis. A wide variety of kidney diseases may result in AKI. The most urgent aspects of AKI are (1) hyperkalemia, (2) severe hypertension, (3) severe plasma and extracellular volume expansion leading to heart failure and pulmonary edema, (4) unremitting metabolic acidosis, (5) hypocalcemia/hyperphosphatemia. Each of these can be viewed as an indication for intensive care and consideration of dialysis.[67] Additionally, over the past decade, the presence and degree of fluid overload (FO) has been shown to be a predictor of survival at the initiation of renal replacement therapy (RRT), and is now considered as an important indication for intervention.[68,69,70,71]

Hyperkalemia

The major reason for the development of hyperkalemia (serum potassium concentration more than 6 mEq/L) is the release (or infusion, or both) of potassium into the extracellular space at a rate greater than the kidney's ability to excrete potassium. Further the intracellular potassium is in the concentration range of 140 to 150 mEq/L, adding to the total source of potassium. The fact that AKI and oliguria have developed does not mean that hyperkalemia will develop. By the same token, hyperkalemia may develop rapidly in situations of extensive tissue destruction even without oliguria and "full-blown" AKI. Thus in the clinical situation of a crush injury or the tumor lysis syndrome, hyperkalemia should be anticipated and careful anticipatory monitoring begun.

Severe Hypertension

Hypertension is frequently associated with kidney disease. The two main mechanisms by which kidney disease leads to hypertension, especially accelerated hypertension, are (1) plasma volume expansion caused by the failure to excrete sodium chloride and water and (2) hyperreninemia associated with decreased kidney perfusion.

Plasma and Extracellular Volume Expansion

Plasma and extracellular volume expansion are associated with kidney failure. With an abrupt decline in GFR, even "normal" amounts of sodium and water intake expand the extracellular and plasma volumes. Depending on the cardiac status of the patient, the serum albumin level, and the degree of capillary permeability, this extracellular and plasma volume expansion may be manifest as peripheral edema, hypertension, or congestive heart failure and pulmonary edema. In situations of hypertension or congestive heart failure, the treatment involves two principles. The first is to reduce to as low a level as possible the amount of sodium and fluid the patient receives. This requires attention to diet, intravenous or hyperalimentation solutions, and drugs. The second principle is to remove extracellular fluid. If the patient's kidney

function permits (glomerular filtration of approximately 15 mL/min or higher), then diuretics, especially loop diuretics such as furosemide, bumetanide, or ethacrynic acid, will help to stimulate a diuresis that should improve the blood pressure or the congestive heart failure. The addition of thiazide diuretics prior to the use of loop diuretics may potentiate the effectiveness of loop diuretics allowing for a greater diuresis.[72] In children with more severe kidney disease, diuretic therapy does not result in diuresis, and dialysis will be necessary.

Severe Metabolic Acidosis

The kidney is responsible for the excretion of hydrogen ion and the regeneration of bicarbonate. When kidney function rapidly deteriorates, then the extracellular concentration of hydrogen ion increases, and this increase leads to acidosis and low serum bicarbonate concentrations. This problem is exacerbated by conditions that increase the production of hydrogen ion and its release into the extracellular fluid. Conditions such as sepsis, severe trauma, burns, extensive abdominal disease or surgery, high chloride-containing intravenous fluids, and hemolysis are all examples in which hypoxia, high hydrogen ion production and/or release into the extracellular space, and a decline in RBF and the GFR are combined. The result is severe metabolic acidosis.

Hypocalcemia/Hyperphosphatemia

Hypocalcemia arises from hyperphosphatemia as a result of dietary load, cellular breakdown, and reduced kidney phosphate excretion; reduced synthesis of calcitriol; downregulation of skeletal cell receptors for PTH; and acidosis.[73]

Hyperphosphatemia may not be recognized, for the plasma phosphorus level is not contained on any of the classic "lab panels" as directed by Medicare; it therefore needs to be thought of and sought out for identification.

Uremia

The symptoms of uremia are frequently vague and difficult to quantitate. They include central nervous system (CNS) manifestations such as lethargy, confusion, seizures, and obtundation and also gastrointestinal manifestations such as anorexia, nausea, and vomiting. These symptoms plus metabolic derangements often lead to the initiation of dialysis.

Renal Disposition of Endogenous and Exogenous Compounds

An important consideration in AKI is the role of the kidney in the metabolism, elimination, and detoxification of endogenous and exogenous materials. Any drugs given must be reviewed because the dosing interval or the dose of drug may need to be altered in AKI. Endogenous substances generally are more slowly metabolized or excreted. For example, the hormone gastrin is metabolized by the proximal tubule after being filtered by the glomerulus. The resultant persistent high circulating levels of gastrin may explain the higher incidence of gastritis and ulcer disease seen in patients with kidney failure.

Specific Kidney Diseases that May Lead to Acute Kidney Injury

Hemolytic-Uremic Syndrome

Hemolytic uremic syndrome (HUS) is considered to be the most common cause of AKI in children in the world.[74] Whereas this may be correct, it should be recognized that within "westernized" medical systems, AKI due to sepsis and cardiac disease as well as in children with other comorbid and chronic underlying conditions are more likely the cause of AKI.[75]

HUS is characterized by thrombotic microangiopathy with platelet aggregation and fibrin deposition in small vessels in the kidney, gut, CNS, and elsewhere. The hemolytic anemia is related predominantly to shearing of red blood cells as they pass through involved vessels. In the typical form of the disease, a triggering infectious agent has frequently been reported. The syndrome is defined by the presence of anemia (hemolysis), thrombocytopenia, and impaired kidney function. *Escherichia coli* (0157:H7) has been implicated in a large number of cases of typical (epidemic) forms of HUS.[76] It should be understood that there exist a myriad of causes of HUS and that in the absence of verotoxin-secreting *E. Coli*, HUS can still occur.

Clinical Signs

Typical HUS usually presents in "epidemics" and is characterized by a prodrome of bloody diarrhea. Children with HUS are older than 1 year and younger than 10 years (typically, 18 months to 3 years). The important presenting features of bloody diarrhea, fever, lethargy, decreased urine output, and paleness should lead to a suspicion of HUS. Laboratory evaluation will verify the diagnosis.

The development of HUS has been associated with bacterial and viral infections, oral contraceptives, cyclosporin A, and complement abnormalities.[76,77] The final common pathway, regardless of the initiating agent, is endothelial cell injury.

Once the endothelium is injured and the subendothelial region is exposed, a sequence of events is set into motion that serves to amplify the initial endothelial damage. Platelets adhere to the subendothelial space, and a release reaction follows that activates additional platelets and initiates fibrin deposition. Both endothelial cell and platelet factors are involved in the propagation of intraglomerular fibrin deposition and coagulation. Direct injury of the endothelial cell may initiate coagulation by release of tissue factor or exposure of the basement membrane. Evidence suggests that the endothelial cells in patients with HUS have reduced ability to produce prostacyclin (PGI_2), a potent vasodilator and inhibitor of platelet aggregation. Some patients with HUS lack a plasma factor that stimulates PGI_2 production. In addition, there is decreased glomerular fibrinolytic activity because of a circulating inhibitor of plasminogen activator. Interestingly, this fibrinolysis inhibitor is removed from the circulation by dialysis.[78] Platelet count and survival time is decreased in patients with HUS, and occasionally there is evidence of platelet activation.

HUS is a heterogeneous group of disorders that have a common result. As a means of differentiating the pathogenesis and

clinical outcome, the following classification scheme has been proposed[79]:

1. The classic form presents in infants or small children after a prodrome of bloody diarrhea that may involve the verotoxin-producing strain of bacteria such as *E. coli*.
2. The postinfectious form is associated with an identified infectious agent such as *Shigella* or *Salmonella* or with endotoxemia.
3. Hereditary forms have been recognized that have both autosomal dominant and recessive modes of inheritance. These patients probably lack a plasma factor necessary for PGI_2 production or have a prostacyclin inhibitor.
4. An immunologically mediated form is characterized by low plasma C3 and activation of the alternative complement pathway. This form may also be familial.
5. A so-called secondary form is related to known predisposing conditions such as lupus, scleroderma, chemotherapy, malignant hypertension, and kidney irradiation.
6. A form related to pregnancy or use of oral contraceptives is characterized by arterial microangiopathy.

Hemolysis may be brisk and may require transfusions on a daily basis. The aim of transfusions during the period of hemolysis should be to prevent heart failure and not to return the hematocrit value to normal. Thrombocytopenia may be severe but only rarely results in significant bleeding, and therefore platelets should not be given unless clearly needed to stop bleeding or in anticipation of invasive (especially vascular) procedures. Some have suggested that platelets play an important role in the pathophysiology of this disorder. It is further suggested that infusing platelets may actually prolong or worsen the intravascular deposition characteristic of HUS.

Complications

Other organ system involvement may lead to serious complications. CNS involvement may reflect the metabolic effects of uremia and can be manifested by lethargy, somnolence, stupor, coma, or seizures. Seizures, paresis, and even CNS hemorrhages can result from vascular damage and CNS vessel occlusion. Gastrointestinal involvement has also been well documented.[79] Liver enzyme elevations; abdominal pain, intestinal obstruction, and bowel perforation have all been reported. These possibilities must be considered and evaluated when appropriate. In some instances, the diagnosis of HUS has been made after abdominal exploration.

Therapy

In recent years therapy has been conservative, aimed at preventing deterioration and carefully managing such complications as AKI, anemia, and CNS and abdominal symptoms. Furthermore, any therapy would have to show a dramatic benefit to improve on a complete recovery rate of more than 90%.

Comprehensive supportive care has clearly resulted in a dramatic decline in the mortality from HUS (40% in the 1950s to 5% to 10% in the 1980s).[77] Nevertheless, therapy specifically aimed at HUS has been attempted because vascular platelet plugging and fibrin deposition in arterioles is part of the pathophysiology.

Heparin, fibrinolytics, and antiplatelet drugs (aspirin, dipyridamole) have all been attempted. In general, reports demonstrate lack of benefit and, in the cases of heparin and fibrinolytics, increased harm from increased bleeding. Fresh-frozen plasma infusion was suggested because of the finding that serum from some patients with HUS cannot generate normal amounts of prostaglandin or does not demonstrate normal antithrombotic and antiplatelet function.[80] All these defects could account for the thrombotic microangiopathy of HUS. Fresh-frozen plasma might provide the missing factors that could ultimately reduce microangiopathy. Unfortunately, studies in patients did not demonstrate a beneficial effect. Plasmapheresis has not been tested as carefully as fresh-frozen plasma infusion in patients with typical HUS.[81]

Vitamin E therapy has been proposed after findings of abnormal lipid peroxidation and low vitamin E activity in patients with HUS. Anecdotal studies suggested some benefit, but controlled, albeit small, studies have not shown benefit.[82]

Further, intravenous immunoglobulin G (IgG) infusions have received attention on the basis of studies in adults that showed IgG can inhibit platelet aggregation.[83] This presumably would diminish thrombotic microangiopathy and reduce the period of time of thrombocytopenia. Controlled studies have not been completed. The preliminary data suggest a shorter period of thrombocytopenia but, as yet, little information on reductions in other morbidities of HUS.

Prognosis

The prognosis for the "typical" form of HUS is good. Most series report 3% to 5% mortality rates and an additional 3% to 5% with chronic changes such as chronic kidney disease, persistent hematuria/proteinuria, and chronic hypertension. Thus more than 90% of children with the typical form of HUS recover completely.

In the face of AKI, many of the therapies (RBC, platelet infusion, fresh frozen plasma) result in volume to the children, potentially increasing the risk of fluid overload. Further, the plasma components of PRBCs are hyperkalemic, acidotic, and hypocalcemic. Therefore, transfusing PRBCs to a patient with AKI may induce not only fluid overload but also significant and even lethal electrolyte disbranches. The use of RRT may be needed to offset these potential risks.

Acute Glomerulonephritis

Nearly every form of glomerulonephritis has been reported to present as AKI (Box 71-2). In some instances the kidney insufficiency may be the result of an immunological process leading to acute inflammation (e.g., acute postinfectious glomerulonephritis). In others, intravascular volume depletion may play a prominent role in AKI (e.g., minimal change nephrotic syndrome).

In general, glomerulonephritis is initiated by immunological events within the glomerulus followed by mechanisms that result in damage to the glomerulus.[84] Glomerular disease results from the deposition of immune complexes composed of (1) antibodies to nonkidney antigens that localize within the glomeruli and form in situ immune complexes; (2) circulating soluble immune complexes that are trapped within the mesangium or subendothelial space; or (3) antibody to antigens within the glomerulus, either as normal glomerular antigens or as neoantigens induced by inflammation or infection.

Postinfectious
Henoch-Schönlein purpura
Immunoglobulin A nephropathy
Membranoproliferative glomerulonephritis

Antibody deposits promote injury by activation of inflammatory cells or by their direct interaction with glomerular cells. The result is mesangial cell proliferation, capillary wall and basement membrane injury, and extracapillary proliferation of epithelial cells, a process known as crescent formation.

Immune complexes mediate glomerular injury in two ways: through direct membrane damage by the membranolytic membrane attack complex (involving complement components, C5b-9) or by stimulation of glomerular localized inflammatory cells.

Salt and water retention commonly observed with acute glomerulonephritis is the result of a decreased GFR, not increased tubular reabsorption, as once proposed. The renin-angiotensin system is thought not to play a role in the positive salt and water balance. In general, the presentation of glomerulonephritis as AKI implies a virulent form of disease known as rapidly progressive or crescentic glomerulonephritis. Although rapidly progressive refers to a clinical characteristic and crescentic to a pathological feature, the two are commonly coincidental in the presentation of AKI. A classification of rapidly progressive glomerulonephritis is presented in Box 71-3. Four prototypical conditions serve as examples of acute kidney disease that may result in the need for intensive care.

Acute Postinfectious (Streptococcal) Glomerulonephritis

This condition is well known to pediatricians. An association between glomerulonephritis and scarlet fever was known in the eighteenth century. In the early twentieth century, however, a clear connection between streptococcal infections and glomerulonephritis was established. The disease most frequent occurs between the ages of 2 and 12 years. It is seen as a sporadic event or in epidemics. It appears that only certain strains of streptococci lead to glomerulonephritis, thus the term nephritogenic streptococcus.[85] Over the past decade the more recent term has moved to postinfectious glomerulonephritis (PIGN) due to the fact that no longer does *Streptococcus* cause the majority of the cases of PIGN.

The mechanism(s) by which nephritogenic streptococci cause glomerular injury is similar to that seen with "shunt nephritis." It is generally accepted that immune complexes, with the participation of complement and other inflammatory mediators, cause glomerular inflammation. The precise nature of the bacterial antigen and its site of formation (circulation compared with in situ in the glomerulus) remain areas of study.

Clinical Signs. The usual sites of infection are the upper respiratory tract, skin, or both. A longstanding observation is that the latent period is 7 to 14 days if the infection is in the upper respiratory tract and 21 to 40 days if the infection is on the skin. Subclinical cases may be common; they are estimated to be 2 to 19 times as frequent as clinical cases. Symptomatic cases usually present with an acute nephritic syndrome: edema, hypertension, hematuria, and oliguria. Other important clinical features include proteinuria, red cell casts, and abnormal urinary red cell morphological findings, all markers of glomerular injury. Pulmonary edema may also be present, especially if significant salt and water retention are present and if hypertension is severe. Nonspecific findings include malaise, anorexia, abdominal pain, nausea, and vomiting. (This presentation is seen with other forms of acute glomerulonephritis.) Patients may have AKI.

Laboratory Findings. Laboratory findings at the time of presentation or early in the course include high serum IgG levels and low serum complement levels, especially C3 and CH50. In general, the alternate pathway of complement is the mechanism of complement activation, although on occasion C2 and C4 may be depressed as well. Complement levels return to normal in 4 to 6 weeks. Therefore if complement levels remain depressed for 6 to 8 weeks after the onset of acute glomerulonephritis, another diagnosis should be strongly entertained (systemic lupus erythematosus or membranoproliferative glomerulonephritis). The definitive diagnosis is based upon renal biopsy that can be performed easily adding clarity to the diagnosis.

Treatment. Treatment is based on the patient's symptoms and is directed at preventing or reducing salt and water retention and hypertension. All patients should have salt and water restriction unless dehydration is obvious (an unusual situation). Approximately 50% to 60% of patients require treatment for hypertension. Diuretics, angiotensin-converting enzyme inhibitors, and potent vasodilators should be considered. Five percent of patients may require dialysis for congestive heart failure, hypervolemia, or encephalopathy.

Prognosis. The long-term prognosis in acute postinfectious glomerulonephritis is a matter of debate. The mortality rate

is approximately 0.5%, and death usually results from severe hypertension and encephalopathy or heart failure. Studies by Baldwin et al.[86] suggested that the long-term prognosis generally thought to be excellent was in fact not necessarily so. They suggested 50% of patients had evidence of kidney disease in long-term studies. Studies with follow-up of 10 to 15 years suggest that chronic AKI develops in approximately 1% of patients. A second consensus conclusion is that the prognosis is better in children than in adults. Longer-term follow-up is needed.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a protean illness affecting many organ systems. In some instances, intensive care is needed for such aspects of SLE as nephritis, cerebritis, carditis, serositis, or sepsis.

Even within a relatively narrow aspect of SLE such as nephritis, great heterogeneity exists. Glomerulonephritis develops in approximately 75% of patients with SLE.[87] This may range from mild hematuria and proteinuria to nephrotic syndrome and rarely to rapidly progressive kidney failure. The patterns of lesions in lupus nephritis are varied. The World Health Organization (WHO) has classified lupus nephritis based upon light microscopy into five categories: (1) minimal disease; (2) mesangial disease; (3) focal proliferative glomerulonephritis; (4) diffuse proliferative glomerulonephritis; and (5) membranous nephropathy. These five categories have been further subdivided to reflect activity (e.g., cellular proliferation, crescents, thrombi, presence of tubulointerstitial disease) and chronicity (e.g., sclerosis, fibrosis, tubular atrophy). Combining these pathological categories with a small number of clinical predictors of poor outcome such as age younger than 24 years, male gender, and decreased kidney function on presentation has permitted a more careful assessment of therapeutic interventions.

Clinical Signs. The broad variation in clinical manifestations may reflect individual expression of similar immunopathological mechanisms or different immunopathological mechanisms presenting as a similar constellation of clinical manifestations.[88] It is clear that SLE represents the overproduction of antibodies against multiple "self"-antigens. Patients with lupus have high titers of antinuclear antibodies and in particular anti-double-stranded DNA antibodies, which are often seen in SLE nephritis. Recent work by the author's group demonstrates a high presence of antiphospholipid antibodies placing the child at risk for clotting. This clotting risk may be accentuated in the face of nephrotic syndrome or the use of birth control pills.[89] The factors that lead to the abundant production and activation of relevant B cells are unclear. Certainly hormonal influence must be important because most patients with SLE are women. Environmental factors may be important in cases of SLE induced by drugs or viruses and the known association of SLE with ultraviolet light exposure. Other important factors are suggested by the higher than normal T helper/T suppressor cell ratio. Many of these act in concert to result in abundant antibody production and the deposition of complexes in target organs such as the kidney.

Clinically, patients with SLE nephritis who require intensive care probably have rapidly progressive glomerulonephritis or AKI. Their presentation includes many of the following features: hypertension; active urinary sediment with proteinuria, hematuria, and casts; oliguria or rarely anuria; intravascular volume expansion; and declining kidney function with rising serum creatinine, hyperkalemia, and metabolic acidosis. Unlike the glomerulonephritis described previously, treatment should include management of kidney dysfunction as previously outlined and management aimed at the SLE itself. Kidney biopsy is useful.[90] When in doubt; a biopsy specimen may help distinguish acute tubular necrosis from glomerulonephritis. A biopsy specimen will ascertain the degree of interstitial involvement, which may suggest drug toxicity. Biopsy can be useful in determining long-term treatment and prognosis.

Treatment. In the intensive care setting, treatment directed at rapidly progressive or diffuse proliferative SLE nephritis consists of high-dose bolus corticosteroid (usually methylprednisolone) at a dosage of 10 to 20 mg/kg intravenously (IV) given 3 to 5 times in a daily or every-other-day regimen.[91] This therapy is associated with hypertension. Other treatments have included plasmapheresis; antiplatelet drugs such as dipyridamole; and immunosuppressives including azathioprine, cyclophosphamide, mycophenolate mofetil or other alkylating agents, and methotrexate. Recent data from the National Institutes of Health and others have suggested significant benefit from cyclophosphamide or mycophenolate mofetil in maintaining kidney function.[92]

Prognosis. The long-term prognosis for children with SLE nephritis is unclear.[88] Regardless, patients and families must expect persistent evidence of kidney injury such as hematuria, proteinuria, hypertension, and even reduced kidney function such as a diminished GFR. Further, patients may have relapsing episodes of nephrotic syndrome or acute glomerulonephritis.

Other Glomerulonephritides

Two other forms of glomerulonephritis may result in the need for intensive care therapy. These are antiglomerular basement membrane (anti-GBM) antibody disease (Goodpasture syndrome) and Wegener granulomatosis. Although rare in children, both conditions can result in AKI. Therapy should be directed at the general condition of AKI as discussed previously in addition to specific therapy.

In the case of anti-GBM antibody disease, patients may have both kidney disease and pulmonary disease, often pulmonary hemorrhage. Treatment includes corticosteroids, plasmapheresis, and immunosuppressives, mainly alkylating agents. Despite therapy, end-stage kidney disease develops in some patients. Recurrences of anti-GBM antibody disease in kidney allografts have also been reported.[93] Vasculitic syndromes associated with kidney disease include Wegener granulomatosis and so-called antineutrophil cytoplasm antibody (ANCA) associated diseases.[94] ANCA is an autoantibody that is found in one of two patterns in many forms of vasculitis and which serves as a potentially useful diagnostic tool. Wegener granulomatosis is characterized by granulomatous vasculitis that attacks the lungs, the respiratory tract including sinuses and trachea, and the kidneys. This condition may be difficult to diagnose, and biopsy may be the only means of determining the diagnosis if the plasma ANCA is negative. Five children with ANCA-associated glomerulonephritis and AKI have been described. Nonspecific systemic illness commonly preceded the presentation of AKI. In two of the five, kidney

function recovered; the other three required long-term dialysis. Cyclophosphamide has been shown to be beneficial in the treatment of the kidney disease of Wegener granulomatosis, and plasmapheresis is also of potential benefit in crescentic forms, although it is not widely used because of frequent complications.

Nephrotic Syndrome and Acute Kidney Failure

AKI is an uncommon complication of primary nephrotic syndrome in children but may occur as a result of intravascular volume depletion, bilateral kidney venous thrombosis, or drug-induced kidney toxicity.[95]

The clinical scenario is one in which the child has a low serum albumin level and edema (increased extracellular volume). These patients have stable and often normal plasma volumes despite low oncotic pressure. Should an acute illness (e.g., gastroenteritis) occur, however, intravascular volume depletion and AKI may develop rapidly. Patients with nephrotic syndrome who have fluid losses or are unable to take in fluids should be admitted to the hospital, and intravenous administration of albumin plus maintenance and replacement fluids should be considered. The use of intravenous albumin helps to maintain the intravascular volume and reduces the edema that might develop during fluid therapy. In some children with nephrosis and AKI, no cause for reduced GFR can be found. In a recent report of four children with idiopathic AKI associated with primary nephrotic syndrome, three had evidence of peritonitis at presentation, two had minimal-change nephrotic syndrome, and two had focal segmental glomerulosclerosis. All four children required dialysis for treatment of marked anasarca. Kidney biopsies performed during AKI in three of the four children showed tubular ischemic injury. Removal of fluid with diuretics or dialysis/hemofiltration was associated with recovery of function. Placing a vascular access for dialysis in a child with nephrotic syndrome is not without risk. In general, children with nephrotic syndrome have a high risk of clotting, independent of vascular access. The large bore vascular access commonly used for dialysis may potentiate this risk. Use of heparin for thrombosis prevention should be considered in certain high-risk situations.

Tubulointerstitial Disease

Acute Tubulointerstitial Nephritis

Acute tubulointerstitial nephritis (ATIN) is a clinical syndrome characterized by inflammation of the kidney interstitium accompanied by interstitial edema and kidney tubular injury. ATIN may be caused by numerous drugs, infectious agents, and systemic illnesses.[96] A partial list of causes can be found in Box 71-4.

In most cases, ATIN is immunological in origin. Most of understanding of the pathogenesis has been obtained from animal models. Three phases have been described for ATIN. The initial phase involves recognition of a nephritogenic antigen located in the interstitium. The antigen may be a normal component of the interstitium, a modified constituent, drug-induced, or infection-induced. Loss of host tolerance is thought to be required for the initial phase to occur. The immune regulatory phase is characterized by the activation of T-helper lymphocytes, which induce differentiation of T and B cells that directly injure the interstitium. The inability of the host to counteract this response with T-suppressor cells permits T- and B-cell activation to go unabated. In the effector phase, both humoral and cell-mediated components contribute to tissue injury. Antibodies to tissue antigens promote injury by activation of the complement cascade, chemotaxis, and cell-mediated cytotoxicity. IgE is also produced, that may recruit eosinophils or mast cells. Mononuclear cell infiltration produces tissue injury by release of proteases and lymphokines. Eosinophils also damage surrounding tissue by release of proteases, leukotrienes, and toxic oxygen species.

Data from Grunfeld J, Kleinknecht D, Droz D: Acute interstitial nephritis. In Schrier RW, Gottshalk CW, editors: *Diseases of the kidney*, ed 4, Boston, 1988, Little, Brown.

Several theories have been proposed to explain the reduced GFR: (1) the "clogged drain," (2) the capillary bed, and (3) vascular tone hypotheses. The clogged drain theory proposes that tubular obstruction caused by luminal debris and interstitial edema results in increased pressure in Bowman's space and decreased pressure favoring filtration. Interstitial inflammation results in injury to the blood supply of the tubules (capillary bed hypothesis). Because these vessels are postglomerular, the increased resistance and reduced surface area associated with vessel injury result in an increase in efferent arteriolar pressure and a reduction in the pressure gradient across the glomerulus with a resultant drop in the GFR. Decreased sodium reabsorption by injured proximal tubular epithelial cells reduces the medullary interstitial osmolality, and impairs the ability to concentrate the urine. Thus an increased volume of filtrate is delivered distally, stimulating the juxtaglomerular apparatus to increase angiotensin II production (vascular tone hypothesis). The net result is vasoconstriction and a diminished GFR.

Pathologically, diffuse or patchy infiltration of the kidney interstitium by lymphocytes, plasma cells, and eosinophils, and edema of the interstitial space is observed. Eosinophils are usually indicative of an acute phase, whereas epithelioid granulomas with giant cells and fibroblasts or fibrosis indicate chronic disease. Tubules may have mild structural alterations or marked necrosis with loss of brush border. Drug-induced interstitial nephritis is the most common form of ATIN in adults and children. Eight of 13 pediatric patients described in one series[96] and 38 of 57 in another series of children[97] with interstitial nephritis had drug-related causes of ATIN. Numerous drugs have been associated with ATIN. The β-lactam antibiotics are the most frequently associated with

ATIN with methicillin being the prototype, although ampicillin is the most common offending drug in pediatric series. NSAIDs are increasingly recognized as a cause of acute kidney dysfunction.

Clinically apparent disease usually develops days to weeks after exposure to the inciting drug or agent but may be immediate.[98] Drug-induced tubulointerstitial disease is localized predominantly to the cortex, whereas infectious or infiltrative disorders more commonly localize to the medulla. The functional abnormality often indicates the primary site of tubular injury. Damage involving mainly the proximal tubule results in the wasting of bicarbonate, phosphate, glucose, amino acids, and uric acid. Distal tubular involvement may be manifest as hyperkalemic kidney tubular acidosis as a result of impaired secretion of both K^+ and H^+. Nephrogenic diabetes insipidus can result with medullary involvement.

Although ATIN is primarily a disease of the kidney interstitium and tubule with lack of glomerular structural alterations, the GRF may also be reduced. Of 13 children described by Ellis et al[96] and Andreoli,[99] 12 had a creatinine clearance of less than 50 mL/min/1.73 m^2. AKI resulting from ATIN may be oliguric. Other clinical signs of ATIN are fever and rash. ATIN usually resolves with removal of the offending agent, although occasionally chronic kidney insufficiency may result.

Cardiorenal Syndrome

Renal insufficiency occurs commonly in adult and pediatric patients with heart failure. Although the mechanisms are not fully understood, diminished cardiac function coupled with renal dysfunction, or the cardiorenal syndrome, has been observed in both the acute and chronic care settings. The phenomenon remains better characterized in adult medicine. Decreased urine output and resultant fluid retention can aggravate heart failure symptoms and contribute to clinical deterioration. Even a modest increase in serum creatinine (i.e., >0.2 mg/dL) can predict mortality in adult patients hospitalized for heart failure.[100] The relationship of renal function and heart failure in children has not been well examined. Retrospective data analysis have shown a high incidence of cardiac disease among children who exhibit renal insufficiency while hospitalized, and clinical experience suggests that as in adults, worsening renal function is associated with worse outcomes among children with heart failure.[101]

Basis for Deteriorating Renal Function

The physiologic interaction of the heart and kidney is complex and not well understood, although it is recognized that disease of one organ system frequently complicates the other. Some have termed this combined cardiac and renal dysfunction the cardiorenal syndrome. Renal insufficiency occurring in heart failure patients is usually attributed to a "prerenal state" resulting from diminished cardiac output and renal perfusion. It is hypothesized that deteriorating cardiac output and decreasing renal blood flow trigger neurohormonal activities that lead to fluid retention and increased systemic vascular resistance, causing further progression of ventricular dysfunction. Data from animal studies show that isolated renal ischemia leads to increased pulmonary vascular permeability, suggesting a bidirectional pathophysiologic interaction between the renal and cardiopulmonary systems.[102] Other mechanisms may also contribute to a decline in a renal function, including medications being used to support cardiovascular function, such as vasoactive drugs. A study by Price et al.[103] reported worsening renal function with the use of dopamine and nesiritide.

There is evidence that right ventricular dysfunction may be associated with the renal venous congestion. Using echocardiographically derived measurements, Testani et al. showed that in 151 patients, RV dysfunction remained a significant predictor of change in glomerular filtration rate after controlling for heart rate, hemoglobin, admission serum urea nitrogen, B-type natriuretic peptide level, diuretic dose, length of stay, ejection fraction, cardiac output, tricuspid regurgitation severity, and inferior vena cava inspiratory collapse.[104]

Cardiac Surgery–Related Acute Kidney Injury

AKI is not uncommon following cardiac surgery, and its presence portends a worse prognosis. In a survey of 542 patients who underwent cardiopulmonary bypass to fix their congenital cardiac disease, the rate of acute kidney injury after congenital cardiac surgery was shown to be about 11%.[105] Other studies have found mortality rates to be four times higher in patients with renal failure compared to those without. Studies have shown that a small rise (less than 50%) in creatinine in the first 48 hours could predict a greater than 50% increase in serum creatinine in the next 48 hours. Significant independent risk factors for AKI were bypass time and longer vasopressor use; there was a tendency toward younger age as a risk factor.[106] Cardiac surgery-related AKI has been characterized and described in adult medicine; however, at this time it remains difficult to characterize the exact nature of the injury in the pediatric population. Cardiac surgery-associated acute kidney injury (CSA-AKI) is a significant clinical problem. It results from the interactions between the complicated interventions required in the process of congenital cardiac surgery such as cardiac bypass, use of blood products, the anatomical variability of the congenital cardiac abnormality such as single ventricles, and the surgical correction/palliation of the lesion. It likely involves at least six major mechanisms: exogenous toxins and cytokines, metabolic factors, ischemia and reperfusion, neurohormonal activation, inflammation, and oxidative stress.[107] These mechanisms of injury are likely to be active at different times with different intensity, and probably act synergistically. There are also some data that suggest that at least some of the injury may be pigment-related, but this is yet to be substantiated.[108] There have also been attempts at ameliorating the injury with interventions such as *N*-acetyl cysteine, but this has resulted in an increase in bleeding with any benefit yet to be established.[109]

There are, however, newer markers of renal injury such as plasma neutrophil gelatinase-associated lipocalin (NGAL) that are more sensitive than serum creatinine in predicting acute kidney injury. In fact, plasma NGAL at 2 hours after cardiopulmonary bypass (CPB) was the most powerful independent predictor of AKI in patients post-CPB.[110,111] Serum creatinine is an inadequate marker because nearly 50% of renal function has to be lost before its levels are elevated, and serum creatinine does not accurately depict kidney function until a steady state has been reached, which may require

Table 71–2 Patient Stratification by Risk

	Risk

several days. Biomarkers such as plasma NGAL may provide for earlier clinical intervention, thereby preventing significant mortality or morbidity. The renal histological changes in cardiac surgery-related AKI are yet to be well characterized.

Porcine data utilizing experimental cardiopulmonary bypass revealed higher tubular injury scores in kidneys post-CPB relative to controls (median score 1.0 [IQR 1.0-1.0], $P = .019$). AKI was associated with endothelial injury and activation, as demonstrated by reduced DBA (*Dolichos biflorus* agglutinin) lectin and increased endothelin-1 and vascular cell adhesion molecule (VCAM) staining.[112]

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is an oncologic emergency that is usually seen when tumor cells undergo rapid decomposition spontaneously or, more often, in response to cytoreductive therapy with the release of large amounts of potassium, phosphate, and nucleic acids into the systemic circulation. Catabolism of the nucleic acids to uric acid leads to hyperuricemia, and a marked increase in uric acid excretion can result in the precipitation of uric acid in the renal tubules and mediate acute renal failure. Despite advances in risk stratification, prophylaxis, and active interventions to reduce the incidence of TLS, up to 6% of at-risk pediatric and adult patients undergoing chemotherapy are believed to develop AKI.[113] Even mild AKI that does not require renal replacement therapy has been associated with increased long-term risk for renal failure and mortality. The levels of phosphorus in malignant cells can be up to four times the levels found in normal cells, and rapid release of these stores can result in hyperphosphatemia, with an increase in serum levels by as much as 2.1 mmol/L in children.[114] Initially, the kidneys respond by increasing urinary excretion and decreasing tubular resorption. However, tubular transport mechanisms eventually become saturated, leading to increasing serum phosphorus levels. Acute renal insufficiency caused by uric acid or other complications may further exacerbate the development of hyperphosphatemia. In 2008, a group of researchers published evidence-based guidelines for the prevention and treatment of tumor lysis syndrome.[115] Their recommendations were based on the type of tumor at the initiation of chemotherapy as discussed in the following section.

Management

Vigorous IV hydration with diuresis has long been the cornerstone to prevention and treatment of tumor lysis syndrome (to achieve urine output of 80 to 100 mL/m^2/h). Increasing intravascular volume and urine output increases the renal excretion of uric acid and phosphate. Alkalization of the urine is no longer recommended, due to the lack of supporting evidence and the potential for enhancing the precipitation of xanthine in the urine.[116] Allopurinol works to lower serum uric acid levels by reducing the production of uric acid from purine precursors by inhibiting xanthine oxidase. Because it does not alter the uric acid already formed, it works best when initiated at least 48 hours prior to chemotherapy.[117] It is generally well tolerated, and can be given orally or intravenously; the dose needs adjustment for preexisting renal impairment.

Rasburicase. Recombinant urate oxidase exerts it pharmacologic activity by enzymatic oxidation of uric acid into allantoin.[118] It works rapidly, often dropping the uric acid level to levels less than normal within hours. Although contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, it is overall well tolerated. The traditional recommended dosage is 0.15 to 0.20 mg/kg per dose IV daily for up to 7 days. Investigators recommend the use of rasburicase as the first line intervention for high-risk patients (see Box 71-1) and as backup therapy for moderate-risk therapy for those patients who go on to develop hyperuricemia despite allopurinol and hydration (Table 71-2).[115]

Rasburicase is remarkably well tolerated. The rare, but serious, adverse events that require prompt and permanent discontinuation of rasburicase are methemoglobinemia and hemolysis.[118] Glucose-6-phosphate dehydrogenase (G6PD) deficiency is regarded as the main predisposing factor for hemolysis and remains a contraindication to its use (the mechanism is related to oxidative stress from the hydrogen peroxide [H_2O_2] produced as uric acid is converted to allantoin), justifying, when possible, the screening for patients at high risk for G6PD deficiency (e.g., African or Mediterranean ancestry).

Recent work by the author's group eliminated reversible AKI in infants associated with elevated uric acid when treated with rasburicase.[119]

Role of Renal Replacement Therapy. The understanding of the optimal start time, method, and dosage of renal replacement therapies (RRT) has evolved. Early intervention is favored, because most AKI survivors leave the hospital with independent kidney function.[120] Once the process of cell turnover is uncoupled, the rapid release of intracellular contents into the bloodstream, including anions, cations, proteins, and nucleic acids occurs. In this clinical paradigm, the early institution of renal replacement interrupts the cascade before the occurrence of tumor lysis-related AKI with life-threatening complications Therefore, the group recommended that for pediatric patients at high risk of TLS, cytotoxic chemotherapy should only be administered in a facility with ready access to dialysis. Although dialysis usage has been reduced since the introduction of rasburicase, as many as 3% of patients (1.5% of pediatric patients and 5% of adult patients) still require RRT.[121] In line with this, the panel recommends that renal consultation be obtained immediately if urine output is low, if there are persistently elevated phosphate levels, or in the case of hypocalcemia.[115]

Pigment Nephropathy

Rhabdomyolysis is a dissolution of skeletal muscles that produces a nonspecific clinical syndrome that causes extrusion of toxic intracellular contents from myocytes into the circulatory system. The possible causes of rhabdomyolysis are myriad; with direct muscle injury remaining the most common cause of muscle injury, additional causes include hereditary enzyme disorders, drugs, toxins, endocrinopathies, malignant hyperthermia, neuroleptic malignant syndrome, heatstroke, hypothermia, electrolyte alterations, diabetic ketoacidosis and nonketotic hyperosmolar coma, severe hypothyroidism or hyperthyroidism, and bacterial or viral infections. Most of the data remains adult-based. In a study of 210 pediatric patients, the most common causes of rhabdomyolysis were viral myositis (38%), trauma (26%), and connective tissue disease (5%). Higher initial creatine kinase levels (>6000 IU/dL) and higher fluid administration rates were associated with higher maximal creatinine levels.[122]

Pathophysiology

Rhabdomyolysis, which literally means "dissolution of striped [skeletal] muscle," is the final pathway of many different processes. Regardless of the underlying mechanism, myocyte dissolution triggers a cascade of events that lead to the rapid release of calcium ions into muscle cells resulting in a pathological interaction between actin and myosin and activation of cell protease, with subsequent myocyte necrosis of muscle fibers, release of potassium, phosphates, myoglobin, creatine kinase (CK), and urates into the extracellular space and into the bloodstream. As such, myoglobin can precipitate in the glomerular filtrate, particularly in an acidic environment, causing tubular occlusion and severe kidney damage. Pigmented myoglobin casts, which characterize the rhabdomyolysis syndrome, are the result of the interaction between myoglobin and Tamm-Horsfall protein in an acid environment.[123] Additional mechanisms causing renal damage include (1) a direct cytotoxic effect of myoglobin on renal cells; (2) urate precipitation, leading to intraluminal casts, increased intratubular pressure, and subsequent decreased glomerular filtration rate; (3) renal vasoconstriction and ischemia due to the heme group of myoglobin causing activation of the cytokine cascade; and 4) oxidant injury through heme-induced reactive oxygen species such superoxide anion, hydrogen peroxide, or hydroxyl radicals causing direct oxidative damage.[124]

The classic triad of symptoms of rhabdomyolysis includes myalgia, weakness, and dark urine, although these findings may be inconsistent.[122]

The definitive diagnosis of rhabdomyolysis requires an elevation of CK levels to greater than five times normal in the absence of significant elevations of brain or cardiac CK fractions. The most dangerous sequela of rhabdomyolysis is AKI, the exact mechanisms of which are unclear but may be attributable to vasoconstriction/hypoperfusion, renal tubular dysfunction/cast formation, and/or myoglobin-induced tubular cytotoxicity. The mainstay of treatment for rhabdomyolysis, directed at preventing AKI, is fluid therapy.[122] Many clinicians advocate alkalinization of urine with sodium bicarbonate (sometimes with concomitant forced diuresis with mannitol). There are no data that suggest that this strategy prevents AKI in children with rhabdomyolysis.

Once the patient has reached the hospital, fluid infusion should be continued, with the goal of maintaining a brisk urinary flow and a urine pH above 6.5 and plasma pH below 7.50.[125] The rate of infusion should be at 150% of maintenance rate, with hemodynamic parameters and urine output monitored closely. Some authors also suggest administering mannitol. This is done to induce osmotic diuresis and to remove liquids from the damaged muscular interstitium, thus relaxing the compartments involved.[126] To force diuresis, some clinicians also recommend the addition of furosemide.

There is little clinical evidence to support the use of bicarbonate, mannitol, and furosemide. It is important to understand that the treatment benchmark is aggressive forced hydration with saline and glucose solutions. Studies in humans show that alkalinization and osmotic and diuretic treatment add little to the beneficial effect of hydration.[123] Forced hydration should be continued until the disappearance of myoglobinuria, which typically occurs after the third day. Hyperkalemia must be managed using the usual techniques, considering that treatment with glucose and insulin may prove to be ineffective in this context due to the damaged muscle's inability to capture potassium from the extracellular space. It is often necessary to treat severe hyperkalemia with renal replacement therapy.

Hypocalcemia

Secondary sequestration of calcium into damaged muscle cells must be viewed critically. Administration of intravenous calcium (either chloride or gluconate) should be used only to treat life-threatening electrocardiographic alterations, secondary to hyperkalemia or extreme hypocalcemia.

Drug-Induced Nephrotoxicity

Many different drugs and agents may cause AKI in children. In the ICU, factors such as age, pharmacogenetics, underlying disease, the dosage of the toxin and concomitant medication all interact and influence the severity of nephrotoxic insults. Pediatric retrospective studies have reported incidences of AKI in PICUs of between 8% and 30%.[127] It is widely recognized that neonates have higher rates of AKI, especially following cardiac surgery, severe asphyxia, or premature birth. While

in most cases the etiology of AKI in the ICU is multifactorial (e.g., sepsis, ischemia/hypoperfusion), several recent large epidemiologic studies have shown that nephrotoxic drugs were contributing factors in 19% to 25% of cases of severe acute renal failure in critically ill adult patients.[128]

NSAIDs, antibiotics, amphotericin B, antiviral agents, angiotensin-converting enzyme (ACE) inhibitors, calcineurin inhibitors, radiocontrast media, and cytostatics are the most important drugs implicated in the etiology of AKI in children. The mechanisms of nephrotoxicity include constriction of intrarenal vessels, acute tubular necrosis, acute interstitial nephritis, and, more infrequently, tubular obstruction.[127]

Aminoglycoside Nephrotoxicity

Aminoglycosides (AGs) are non–protein-bound drugs that are primarily excreted unmetabolized by glomerular filtration. Their cationic nature facilitates binding to the tubuloepithelial membrane in the proximal tubule, resulting in rapid intracellular transport.[129] The molecular number of cationic groups determines the facility with which these drugs are transported across cell membranes and is an important determinant of toxicity[130,131] Neomycin is associated with the most nephrotoxicity; gentamicin, tobramycin, and amikacin are intermediate, and streptomycin is the least nephrotoxic.[132] Several hypotheses have been proposed to explain the nephrotoxic effects of aminoglycosides. Intracellular accumulation of AG within lysosomes is thought to interfere with normal cellular function such as protein synthesis and mitochondrial function, eventually leading to cell death.[133] Aminoglycosides also are known to stimulate the calcium-sensing receptor on the apical membrane thereby inducing cell signaling and eventual cell death.[134]

Risk factors for aminoglycoside nephrotoxicity include the type of AG, high peak serum levels, cumulative dose, the duration and frequency of administration, and patient-related factors such as age, preexisting renal dysfunction, hypoalbuminemia, liver dysfunction, decreased renal perfusion, and the concomitant use of nephrotoxic drugs.[132]

Several approaches have been evaluated in both animals and humans as potential treatments to attenuate the nephrotoxicity of aminoglycosides. Investigators have demonstrated that calcium supplementation reduces the nephrotoxic effect, likely through competitive inhibition of calcium channels in the proximal tubule.[135] Similarly, calcium channel blockers also have been shown to attenuate AG nephrotoxicity.[136] Also the protective effect of concomitant use of β-lactam antibiotics has been recognized for several years, although the mechanism by which this may occur is somewhat unclear.[137,138] More recent investigations have evaluated a possible role for antioxidants in renoprotection.[139] Once-daily dosing of aminoglycosides is the only clinical approach that is commonly used to reduce nephrotoxicity.[140] The rationale for the efficacy of consolidated AG dosing against gram-negative bacteria is based on two pharmacodynamic properties of aminoglycosides: (1) the bacteriocidal mechanism of action is concentration-dependent; and (2) prolonged postantibiotic effect.[132]

Clinical evidence of AG-induced acute tubular necrosis is seen within a week of initiation of aminoglycoside treatment. AG-induced acute renal failure is generally nonoliguric, and may be associated with decreased urine-concentrating ability and urinary magnesium wasting. It is generally reversible after discontinuation of the drug; however, supportive renal replacement therapy may be required. The authors recommend that alternative antimicrobials should be considered when possible in patients at high risk for AG nephrotoxicity. If required and consolidated AG dosing is used, renal function should be assessed daily to monitor for changes in renal function, and trough levels should be followed to guide dosage.

Amphotericin B

The use of antifungals has become more commonplace in intensive care units, as the prevalence of fungemia (specifically candidemia) has increased in critically ill patients. For decades, amphotericin B was the drug of choice because of its broad spectrum of activity and its wide availability; however, its use has been sharply curtailed in recent years because of its considerable side effects (specifically, nephrotoxicity) and the availability of newer, less-toxic agents.

Approximately 80% of patients who receive treatment with amphotericin B will experience some renal dysfunction.[141] There are several mechanisms by which amphotericin B is thought to induce renal dysfunction: (1) by directly binding to tubular epithelial cells in the cortical collecting duct, resulting in altered cell permeability; (2) by causing sodium, potassium, and magnesium wasting; and (3) by directly causing afferent arteriolar (preglomerular) vasoconstriction.[142] Risk factors for amphotericin B nephrotoxicity include preexisting renal insufficiency, hypokalemia, volume depletion, the use of concomitant nephrotoxins, and large individual and cumulative dosages.[143]

A number of strategies have been studied to minimize the associated nephrotoxicity, including sodium loading and longer infusion rates.[144] While some have shown a reduction in nephrotoxicity, these studies are very small and typically enroll low-risk patients. Lipid-based formulations of amphotericin B also are available, which may produce less nephrotoxicity. However, these agents are considerably more expensive. The recent introduction of alternative antifungal agents such as itraconazole, voriconazole, and caspofungin has largely supplanted the use of amphotericin B in high-risk patients with renal impairment; however, it continues to be used widely in patients with normal renal function because of its relatively low cost and broad spectrum of activity.

Given the presence of many underlying risk factors for nephrotoxicity in critically ill patients, it is recommended that amphotericin B should be avoided in this patient population if alternative therapies are available. When it is used, sodium loading with intravenous hydration is recommended to attenuate vasoconstrictive effects, and longer infusion times should also be considered. Renal function and serum electrolytes (specifically potassium) should be monitored during treatment.

Vancomycin

The use of vancomycin hydrochloride has increased considerably over the last decade as it has become the standard therapy for treatment of methicillin-resistant *Staphylococcus aureus* infections. Recent data from the 2004 Centers for Disease Control and Prevention, National Nosocomial Infections Surveillance System indicate that the prevalence of methicillin-resistant *S. aureus* exceeds 50% in U.S. hospitals. The synergistic nephrotoxicity of combination therapy involving vancomycin and aminoglycosides is well established,

with a reported frequency of acute renal failure in the range of 20% to 30%. However, the nephrotoxicity of vancomycin alone increasingly is being recognized as high-dose therapy has become more common for the treatment of methicillin-resistant *S. aureus*.[146]

Vancomycin is excreted by glomerular filtration, 80% to 90% in an unaltered form.[147] It is hard to determine the exact rates of vancomycin-related toxicity because most reported cases have had additional risk factors for acute renal failure, which makes it difficult to determine the true risk of treatment. The mechanism by which it exerts its nephrotoxicity is unknown. Independent risk factors for nephrotoxicity include the use of concomitant nephrotoxic agents, age, duration of therapy, and drug levels achieved.[147] Trough levels higher thank 15 μg/mL are associated with increased risk of nephrotoxicity, and peak levels also have been associated with increased nephrotoxicity. The dosing of vancomycin requires careful consideration of renal function and estimated glomerular filtration rate. Trough levels should be monitored frequently in patients with fluctuating renal function.

Calcineurin Inhibitors

The introduction of calcineurin inhibitors (CNIs) has led to dramatic improvement in both allograft and patient survival. The clinical use of CNIs often is limited by their nephrotoxic effect, which can present as two distinct and well-characterized forms: acute and chronic nephrotoxicity. Calcineurin inhibitor-induced AKI may occur as early as a few weeks or months after initiation of therapy. The clinical manifestations of CNI-induced renal dysfunction include reduction of GFR, hyperkalemia, hypertension, renal tubular acidosis, increased resorption of sodium, and oliguria. The acute adverse effects of calcineurin inhibitors on renal hemodynamics are thought to be directly related to the cyclosporine (CsA) or tacrolimus dosage and blood concentration and can be managed by dose reduction. This is in contrast to calcineurin inhibitor-induced chronic nephropathy, which is largely irreversible and can occur independently of acute renal dysfunction, CNI dosage, or blood concentration.

Although the exact mechanism of nephrotoxicity is not fully understood, several factors have been implicated in the pathogenesis of CNI nephrotoxicity.[148] Experimental models of acute CsA toxicity revealed that CsA administration is associated with afferent and efferent arteriolar vasoconstriction, which results in a significant reduction of renal plasma flow and GFR.[149,150] The precise mechanism by which CsA induces renal vasoconstriction has not been established clearly. Results from several studies indicate that vascular dysfunction induced by CsA results from an increase in vasoconstrictor factors that include endothelin, thromboxane, and angiotensin II, as well as a reduction of vasodilator factors such as prostacyclin and nitric oxide.[150,151]

Cyclosporine and tacrolimus differ with respect to side effects; however, the available data comparing nephrotoxicity are conflicting. While some studies have suggested that tacrolimus may be associated with a decreased severity of renal dysfunction in comparison to CsA[132] other investigators have demonstrated no difference between the two CNIs.[152]

Studies have been conflicting on the protective effect of calcium channel blockers on the preservation of renal function for patients receiving CNIs. In a multicenter, prospective, randomized, placebo-controlled study in 118 cadaveric renal transplant recipients receiving CsA, the use of a calcium channel blocker resulted in a significantly better allograft function at 2 years and demonstrated an improvement in graft function, as assessed by serum creatinine and GFR, that was independent of lowered blood pressure.[153] Currently, more research is being done with goals of improving the safety profile of CIs and identifying safer alternatives.

Sirolimus

Sirolimus is an mTOR (mammalian target of rapamycin) inhibitor that is becoming increasingly used in allograft preservation. Its target protein, mTOR, is a serine/threonine protein kinase that regulates cell growth, cell proliferation, cell motility, cell survival, protein synthesis, and transcription in transplantation.[154] As its use in transplant medicine is increasing, it was hoped that its lack of nephrotoxicity in animal models would be translated in humans to improve immunosuppression with minimal effect on renal function. Unfortunately, several recent studies suggest that sirolimus has inherent nephrotoxicity, such as development of proteinuria and delay in recovery from ischemia-reperfusion injury. In addition, several studies have shown that the nephrotoxicity associated with CNIs is exacerbated when used in combination with sirolimus.[155]

Nonsteroidal Antiinflammatory Drugs

In most circumstances, NSAIDs do not pose a significant risk to patients with normal renal function. However, in situations in which renal perfusion is compromised (which are relatively common with critically ill patients), the inhibition of prostaglandin-induced vasodilation with the use of NSAIDs may further compromise renal blood flow and exacerbate ischemia.[156] The renal effects of NSAIDs do seem to be dependent on the type, dose, and duration of treatment.[156] Indomethacin is thought to be the most likely drug to impair renal function, and aspirin the least likely.[156] Patients at high risk of NSAID-induced nephrotoxicity include patients with preexisting renal dysfunction, severe cardiovascular or hepatic failure, or the concomitant use of other potentially nephrotoxic medications, such as aminoglycosides, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.[156]

Contrast-Induced Nephropathy

Contrast-induced nephropathy (CIN) acute kidney injury is an important complication in the use of iodinated contrast media that accounts for a significant number of cases of hospital-acquired AKI. The occurrence of AKI as a result of contrast will continue to increase, as there is growing use of imaging and interventional procedures in pediatric intensive care patients.[157] At the same time, many patients in intensive and critical care units have compromised renal function, representing the most important risk factor for contrast-induced AKI.

Three core elements are intertwined in the pathophysiology of CIN: (1) direct toxicity of iodinated contrast to nephrons; (2) microshowers of atheroemboli to the kidneys; and (3) contrast- and atheroemboli-induced intrarenal vasoconstriction.[158] Direct toxicity to nephrons with iodinated contrast has been demonstrated and seems to be related to the osmolality of the contrast.[159] Hence, low-ionic or nonionic,

and low-osmolar or iso-osmolar contrast agents were shown to be less nephrotoxic in vitro. Microshowers of cholesterol emboli are believed to occur in up to 50% of percutaneous interventions where a guiding catheter is passed through the aorta. Most of these showers are clinically silent; however, in approximately 1% of high-risk cases, acute cholesterol emboli syndrome (CES) can develop, which is manifested by AKI, mesenteric ischemia, decreased microcirculation to the extremities, and in some cases, embolic stroke.[160] Finally, intrarenal vasoconstriction as a pathologic vascular response to contrast media, and perhaps an organ response to cholesterol emboli, is a final hypoxic/ischemic injury to the kidney.[161] Hypoxia triggers activation of the renal sympathetic nervous system and results in a reduction in renal blood flow, especially in the outer medulla.[160] There is disagreement about the direct vasoconstrictor or vasodilator effects in the kidney of contrast agents when given to animals.[162] It is likely that in completely normal human renal blood vessels, contrast agents provoke a vasodilation and an osmotic diuresis. When there is vascular disease, endothelial dysfunction, and glomerular injury, however, contrast and the multifactorial insult of renal hypoxia provoke a vasoconstrictive response, and hence mediate, in part, an ischemic injury.[162] The most important predictor of CIN is underlying renal dysfunction. The "remnant nephron" theory postulates that after sufficient chronic kidney damage has occurred, the remaining nephrons assume the remaining filtration load, require increased oxygen demands, and are more susceptible to ischemic and oxidative injury. Understanding the pathophysiology of CIN is key to devising a preventive strategy.

Role of Renal Replacement Therapy. Contrast media is removed by dialysis, but there is no clinical evidence that prophylactic dialysis reduces the risk of AKI, even when carried out within 1 hour or simultaneously with administration. Hemofiltration performed before and after contrast adminstration deserves further investigation given reports of reduced mortality and need for hemodialysis but the high cost and need for prolonged ICU care will also limit the utility of this prophylactic approach.[163]

There are no currently approved pharmacologic agents for the prevention of CIN AKI. With iodinated contrast, the pharmacologic agents tested in small trials that deserve further evaluation include theophylline, statins, ascorbic acid, and prostaglandin E_1.[164] Although popular, N-acetylcysteine has not been consistently shown to be effective. Nine published meta-analyses document significant heterogeneity between studies and pooled odds ratios for *N*-acetylcysteine approaching unity.[165] Importantly, only in those trials in which *N*-acetylcysteine reduced serum creatinine below baseline values because of decreased skeletal muscle production did renal injury rates seem to be reduced. Thus *N*-acetylcysteine seems to falsely lower creatinine and not fundamentally protect the kidney against injury. However, a recent study suggested that the use of volume supplementation with sodium bicarbonate together with *N*-acetylcysteine was more effective than *N*-acetylcysteine alone in reducing the risk of CIN. Fenoldopam, dopamine, calcium channel blockers, atrial natriuretic peptide, and L-arginine have not been shown to be effective in the prevention of contrast-induced AKI. Furosemide, mannitol, and an endothelin-receptor antagonist are potentially detrimental.[165]

Acute Renal Failure After Stem Cell Transplantation

One of the most frequent complications of bone marrow transplant (BMT) is renal failure, with 5% to 15% of all BMT patients developing AKI and 5% to 20% of the survivors developing chronic renal failure (CRF).[166] Hematopoietic stem cell transplantation is a common procedure for the treatment of malignancies and some nonmalignant hematologic disorders. The process of stem cell transfusion predisposes these patients to renal failure because of prior chemotherapy, irradiation, sepsis, and exposure to nephrotoxic agents. Complicating outcomes are newer conditioning regimens which allow for reduced intensity and nonmyeloablative regimens, thereby allowing patients with significant comorbidities to undergo transplantation with reduced morbidity and mortality. These have led to challenges in the ICU management of these patients, because they already have residual organ injury. A recent study of 29 pediatric patients who required CRRT in the ICU showed an almost 100% mortality at 6 months post-ICU admission due to transplant-related illness. This study demonstrated the management and ethical difficulties being posed by hematopoietic stem cell transplant patients becoming critically ill and requiring organ support at tertiary care centers. In contrast with the improving survival rates following stem cell transplantation, there are a greater numbers of children surviving and progressing to end-stage renal disease (ESRD). Some of these patients are being treated with renal transplantation.[167]

A better understanding of the underlying histopathologic changes in renal morphology would perhaps lead to a better control of the renal insults that occur during the process of stem cell transfusion. Some histopathology-based studies have shown a variety of findings in patients post-stem cell transplantation, including features of tubulitis and peritubular vasculitis. These studies also show that kidneys from adult patients who had grade III-IV GVHD were more likely to have tubulitis and peritubular capillaritis.[168] Other studies have shown membranous glomerulonephritis and thrombotic microangiopathy to be common histologic features post-stem cell transplantation.[169] However, there still remains a paucity of pediatric studies examining renal histopathology in patients posttransplantation.

Urinary Tract Obstruction

Obstruction of urine flow may result in AKI, although unilateral obstruction rarely causes AKI unless there is a single kidney or disease in the other kidney. Both unilateral and bilateral ureteral obstruction is accompanied by an initial increase in RBF caused by afferent arteriolar vasodilation.[170] Relaxation of the preglomerular capillary sphincter is mediated by the local release of vasodilatory prostaglandins.[171] Administration of indomethacin, a cyclooxygenase inhibitor, results in a marked reduction in the GFR after a decrease in glomerular plasma flow and an increase in both afferent and efferent arteriolar resistances.[172] This indicates an important role of vasodilatory prostaglandins in the maintenance of the GFR.

If the obstruction persists, RBF progressively decreases as afferent arteriolar resistance increases because of the overriding action of angiotensin II and thromboxane. This vasoconstriction may actually protect the kidney from damage during

Table 71–3 Management of Electrolyte Abnormalities

Abnormality	Management Recommendation
HYPERPHOSPHATEMIA	
Moderate (≥2.1 mmol/L)	Avoid IV phosphate administration Administration of phosphate binder
Severe	Dialysis, CAVH, CVVH, CAVHD, or CVVHD
Hypocalcemia (≤1.75 mmol/L)	
Asymptomatic	No therapy
Symptomatic	Calcium gluconate 50–100 mg/kg IV administered slowly with ECG monitoring
HYPERKALEMIA	
Moderate and asymptomatic (≥6.0 mmol/L)	Avoid IV and oral potassium ECG and cardiac rhythm monitoring Sodium polystyrene sulphonate
Severe (>7.0 mmol/L) and/or symptomatic	Same as above, plus: Calcium gluconate 100–200 mg/kg by slow IV infusion for life-threatening arrhythmias Regular insulin (0.1 U/kg IV) + D25 (2 mL/kg) IV Sodium bicarbonate (1–2 mEq/kg IV push) can be given to induce influx of potassium into cells. However, sodium bicarbonate and calcium should not be administered through the same line. Dialysis
Renal dysfunction (uremia)	Fluid and electrolyte management Uric acid and phosphate management Adjust renally excreted drug doses Dialysis (hemodialysis or peritoneal) Hemofiltration (CAVH, CVVH, CAVHD, or CVVHD)

Data from Zaffanello M, Antonucci R, Cuzzolin L, et al: Early diagnosis of acute kidney injury with urinary biomarkers in the newborn, *J Matern Fetal Neonatal Med* 3(suppl 22):62-66, 2009; and Coiffier BJ: Guidelines for the management of pediatric and adult tumor lysis syndrome: an evidence-based review, *Clin Oncol* 26(16):2767–2778, 2008.

the period of obstruction. Intratubular pressure rises after ureteral obstruction; this pressure is translated to the glomerulus as increased pressure in Bowman's space. The contribution of this increased force opposing filtration to the decrease in the GFR is probably inconsequential because the intratubular pressure rise is transient.[170] In addition, the elevation in Bowman's space pressure is negated by an increase in the glomerular capillary pressure that increases the GFR. RBF is redistributed from the outer to the inner cortex and results in relative ischemia of the kidney medulla.[170]

Various clinical causes of urinary tract obstruction are listed in Table 71-3. The most important factors determining recovery of kidney and tubular function are the degree and severity of the obstruction. Treatment consists of decompression of the urinary collecting system by removal of the obstruction or by urinary diversion. Relief of obstruction is accompanied by a marked diuresis resulting from increased RBF and abnormal tubular function. The increase in urine volume is related to a concentrating defect caused by loss of the medullary gradient and unresponsiveness of the kidney tubule to vasopressin.[173] Hydrogen ion and potassium secretion may also be impaired, and the result is a distal type of kidney tubular acidosis with hyperkalemia.[174]

This chapter has reviewed the major factors that contribute to the development of AKI, both in its oliguric and nonoliguric forms. Also indicated are the clinical settings in which AKI may occur. In addition, treatment modalities have been discussed. Clearly, the challenge in AKI is the development of novel therapeutic strategies that will more directly intervene in the disease process and which can have an impact on the cellular and metabolic mechanisms that contribute to kidney cell injury. Certain current investigations were discussed because they may lead to clinical trials during the next 10 years. Included among these agents are calcium channel blockers, adenine nucleotides, thyroid hormone, and oxyradical scavengers because they may modulate the full expression of kidney cell injury. Only with understanding of the pathophysiological mechanisms in AKI can these potential therapeutics be applied in a clinical setting to the care of pediatric patients.

Chapter 72

Pediatric Renal Replacement Therapy in the Intensive Care Unit

Jordan M. Symons and Stuart L. Goldstein

PEARLS

- Patients receiving renal replacement therapy require careful monitoring of fluid and electrolyte balance and nutritional needs.
- Coordination between the critical care and nephrology staff is essential for the successful care of patients requiring renal replacement therapy.
- Earlier initiation of renal replacement therapy may improve outcome.
- Peritoneal dialysis remains an excellent form of acute pediatric renal replacement therapy.
- Hemodialysis is the modality of choice for rapid correction of fluid or metabolic imbalance.
- Continuous renal replacement therapy can establish and maintain fluid and metabolic control in unstable patients.

Renal replacement therapy has an established role in the pediatric intensive care unit (ICU).[1] Volume overload and metabolic imbalance can complicate the course of critically ill patients, especially those with multiorgan dysfunction.[2] Some patients with normal kidney function may have metabolic imbalance or intoxication that overwhelms baseline endogenous clearance capacity, necessitating extracorporeal clearance techniques. Improvement of techniques coupled with the realization that early supportive therapy may improve outcomes have led to expanded use of renal replacement therapy for critically ill pediatric patients.

Renal Failure and Other Indications for Renal Support

Acute Kidney Injury

Acute kidney injury (AKI) can be defined as an acute decrease in the glomerular filtration rate. Oligoanuria is a frequent, but not essential, component of AKI. Common causes of AKI in the critically ill patient include renal hypoperfusion (leading to so-called *prerenal azotemia*), hypotension or shock causing renal ischemic injury or acute tubular necrosis, nonspecific renal involvement as part of a sepsis syndrome or multiorgan dysfunction, and renal injury from nephrotoxins such as antibiotics and radiocontrast media (see Chapter 71).

Patients with even mild AKI can have volume overload, electrolyte imbalance, and metabolic derangement with associated poor outcomes.[3-5] Such complications can be particularly detrimental to the care of the critically ill patient. While all modalities of renal replacement therapy can correct these abnormalities, certain modalities may be better suited for specific pediatric clinical situations.

Acute Intoxication and Metabolic Disorders

Hemodialysis can rapidly remove many exogenous toxins (e.g., as the result of poisonings and drug overdoses) and endogenous toxins (such as those seen in persons with inborn errors of metabolism), and it is often the therapy of choice for severe life-threatening intoxication. Hemodialysis can be followed by continuous renal replacement therapy (CRRT) for intoxications where a rebound phenomenon may occur (see Chapters 76 and 105).

Renal Support

Diminished renal function is a common component of multiorgan dysfunction syndrome. AKI is highly correlated with poor outcome in hospitalized adults and children.[4,6] In pediatric patients, studies demonstrate increased mortality in critically ill children with excessive levels of fluid overload in the setting of concomitant AKI.[7-10] These observations, coupled with advanced capabilities for renal replacement therapy, lead many clinicians to consider early initiation of renal support. In this model, traditional indicators for dialysis, such as profound azotemia, oligoanuria, massive fluid overload, or significant electrolyte imbalance, may occur too late in the clinical course to alter outcome. Earlier intervention, either with renal replacement therapy or perhaps through careful conservative management, may prevent complications associated with serious metabolic disarray and volume overload and permit vigorous nutritional and medical support. The concept of early "renal support" for patients in the ICU to limit metabolic derangement and prevent volume overload has gained wider acceptance in both the adult and pediatric critical care arenas.

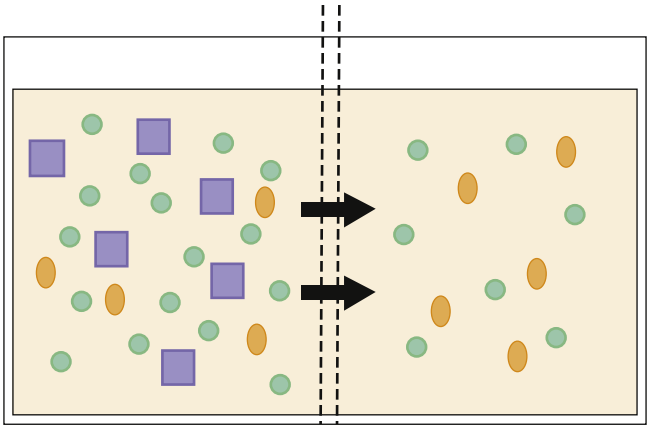

Figure 72–1. Diffusion. Particles move across the semipermeable membrane from an area of higher concentration to an area of lower concentration. Smaller particles diffuse more freely, whereas larger particles are relatively restricted.

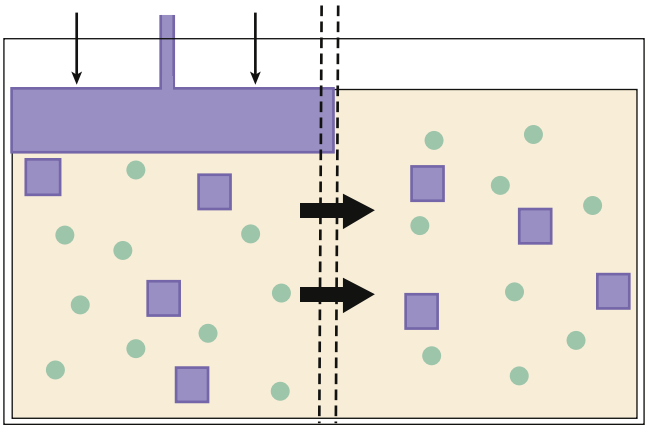

Figure 72–2. Convection. Particles move across the semipermeable membrane, carried by ultrafiltered water, because of the effect of pressure. All particles up to the cutoff size of the membrane move relatively equally. The concentration of the effluent is equal to that of the original solution.

Conservative Management

Conservative management of AKI includes optimization of clinical status with the maintenance of fluid balance, renal perfusion, cardiac output, and adequate blood pressure. Nephrotoxin exposure should be limited. Judicious use of diuretics can greatly augment the patient's ability to maintain fluid homeostasis. After initial early and goal-directed fluid resuscitation in patients with hemodynamic shock, fluids may need to be restricted to prevent worsening degrees of fluid overload.[11,12] Patients require careful dietary management to provide sufficient nutrition in a smaller daily fluid volume and to avoid excess delivery of substances normally cleared through the kidney (e.g., potassium and phosphorus).

Conservative management avoids the potential risks associated with renal replacement modalities; the cases of many pediatric patients with milder renal dysfunction can be managed successfully without renal replacement therapy. As noted previously, however, support exists for the use of renal replacement early in the ICU course. Data show improved outcomes for pediatric patients receiving CRRT who demonstrated less fluid overload at initiation of therapy,[7-10,13] suggesting a survival advantage for patients who begin CRRT earlier rather than later. Although the best time to initiate renal replacement for the patient in the ICU remains unclear, there is a growing consensus to avoid unnecessary delay.[14]

Basic Physiology of Dialysis and Ultrafiltration

The physical principles of molecular movement across a semipermeable membrane underlie peritoneal dialysis, hemodialysis, and CRRT modalities. The following brief review summarizes the basic mechanisms of particle and water removal for all forms of renal replacement therapy.

Diffusion describes the movement of dissolved particles across a semipermeable membrane from an area of high concentration to an area of low concentration (Figure 72-1). This physical principle operates in all renal replacement modalities in which dialysis fluid is used. Diffusion favors the movement of smaller particles and is most rapid when the concentration gradient across the semipermeable membrane is greatest; diffusion stops when the concentrations achieve equilibrium.

Convection occurs when dissolved particles pass across a semipermeable membrane because of the effects of a pressure gradient (Figure 72-2). Particles that are smaller than the pores of the membrane can pass freely, whereas larger particles are restricted. Because particles and water are moving together, the removed solution is isotonic to the original.

Ultrafiltration describes the movement of water across the semipermeable membrane due to pressure. Convection occurs with ultrafiltration.

Peritoneal Dialysis

Peritoneal dialysis (PD) has been a standard form for renal replacement therapy for many years. Despite improving techniques that permit the application of other modalities to even the smallest patients, PD remains an effective method of renal replacement therapy and may represent the best choice in selected cases.[15] Even the most experienced centers may have difficulty achieving vascular access in some patients. Children with vascular abnormalities, certain types of cardiac disease, or hemodynamic issues may be suboptimal candidates for extracorporeal perfusion through a hemodialysis or hemofiltration circuit. In such circumstances, PD can be the best choice for renal replacement therapy.

Physiology

It has been known for many years that the peritoneum can be used as a dialyzing membrane.[16] Instillation of a dialysis fluid into the peritoneal space permits diffusion of particles out of the blood and into the dialysis fluid across the peritoneum, which acts as a semipermeable membrane. Through the use of a hypertonic solution, water also passes across the membrane, generating an ultrafiltrate. Water movement will also tend to drag particles across the peritoneum by convection. After the dwell is complete, the spent dialysate is drained from the abdomen and fresh dialysis fluid is introduced.

Indications

PD can remove excess fluid and provide volume control in patients with oligoanuria. Compared with fluid removal with intermittent hemodialysis, fluid removal with PD is much

slower. Manipulation of dialysis fluid osmolality and dwell time can adjust the quantity of volume removed. The slow, steady ultrafiltration achieved with PD may be preferable to the rapid fluid removal that occurs in intermittent hemodialysis, particularly in unstable, critically ill patients.

Similar to volume control, PD provides slow and relatively continuous metabolic control. It is an effective method for correction of uremia. Manipulation of the PD prescription can improve clearances.

Technique

The basic technique for PD involves instilling a sterile dialysis fluid into the peritoneal cavity and allowing it to dwell for a specified period, during which particles diffuse across the peritoneal membrane and water moves across by ultrafiltration. At the end of the dwell time, the fluid is removed from the peritoneal space and the process is repeated.

Flexible catheters are most often used for chronic PD in pediatric patients. For acute PD, either this form of a surgically placed catheter or percutaneously inserted temporary PD catheters may be used; some data suggest that fewer complications occur with surgically placed catheters.[17] Catheters come in a variety of sizes, depending on the size of the patient. Local practice often determines who will insert the catheters when they are needed; the procedure requires expertise to ensure proper functioning of the catheter.

PD fluid comes in standardized, sterile bags with premixed formulations, and thus pharmacy preparation is unnecessary. Because most patients with renal failure have metabolic acidosis, the dialysis fluid contains base, usually in the form of lactate. Thus the PD system will remove unwanted particles and also can act as a source of electrolytes. Lactate absorption can lead to confusion regarding acid/base interpretation, especially in critically ill infants. In such settings bicarbonate-based dialysis fluid may be preferable,[18] although this fluid may require extemporaneous preparation by the local pharmacy.

Ultrafiltration in PD is accomplished by osmotic pressure, usually through the presence of dextrose in the dialysis fluid. Dialysis fluids contain standardized concentrations of dextrose; the choices vary somewhat between the United States and other countries. Dialysis fluid with higher concentrations of dextrose will cause greater ultrafiltration for each exchange of fluid.

Dialysis fluid should be warmed to body temperature before instillation. This step is particularly important in small patients, in whom hypotension associated with cold dialysis fluid infusion can develop.[19]

Initial exchanges with a new PD catheter should use relatively lower volumes of dialysis fluid (10 to 20 mL/kg; <500 mL/m^2) to limit the chance of leakage from the catheter entrance operative site. Volumes may increase gradually during the next few days or weeks to 1100 mL/m^2.[19]

Longer dwell periods between exchanges provide more time for equilibration of dialyzable particles and for ultrafiltration. Although shorter dwell times may not maximize mass transport for given dwell periods, they may permit more dialysis and ultrafiltration in a 24-hour period by allowing more exchanges per day. Initial dwell periods of 30 to 60 minutes can be adjusted later on the basis of clinical status.

PD fluid can be instilled by hand or with the use of a cycler, a device that will automatically fill and empty the patient's abdomen with dialysis fluid on a preprogrammed schedule. The cycler also contains a warmer for the dialysis fluid and monitoring systems to record effluent volumes. Several brands of cyclers are currently available. Programming limitations may prevent the use of a cycler for some patients who require very small fill volumes or very short dwell times.

Disadvantages and Complications

The PD technique requires placement of a peritoneal catheter and a sufficiently maintained intraabdominal status to permit infusion of dialysis fluid with successful diffusion and ultrafiltration. Patients who have undergone an abdominal operation or have had abdominal complications may be poor candidates for PD.

Invasion of the peritoneal space puts the patient at risk for peritonitis, a potentially serious complication. The importance of sterile technique when performing PD cannot be overemphasized. Appropriate technique limits the risk of infectious complications, which could be fatal in a critically ill patient.

Peritonitis must always be considered in a patient undergoing PD who has a fever or cloudy effluent. Dialysate should be analyzed for cell count, Gram stain, and bacterial culture if infection is suspected. Empirical or specific antibiotic therapy can be placed in the dialysate to treat peritonitis via the intraperitoneal route.[20]

Dialysate can fail to fill or drain through the PD catheter because of a number of potential problems, including kinking of the catheter, fibrin plugs, omental obstruction, or catheter malposition. Percutaneously inserted temporary dialysis catheters are more prone to malfunction than are surgically placed catheters.[21] Abdominal x-ray images can confirm appropriate positioning and permit checks for kinks in the catheter. Some success has been reported with thrombolytic agents to treat fibrin plugging.[22-24] Revision or replacement of the catheter may need to be considered if simple maneuvers do not correct the malfunction.

Perforation of abdominal or pelvic structures can occur, either at the time of initial catheter placement or later.[21] Although this event is relatively uncommon, significant morbidity can result.

PD is a suboptimal choice for patients who require rapid correction of metabolic abnormalities, immediate removal of circulating toxins, or rapid ultrafiltration for acute complications of fluid overload. For the latter indications, hemodialysis would be the preferred modality. Effectiveness of PD may be suboptimal in settings of low cardiac output where splanchnic circulation is compromised. However, this does not preclude the use of PD in selected cases, such as for infants following surgery for congenital heart disease.

Fluid leakage is seen most often with dwell volumes that are too large, especially in the period immediately after catheter placement.[25] Lower fill volumes should be used. Fluid leakage into the thorax can compromise respiration. External fluid leakage around the catheter increases the risk of infection.

Intensive Care Unit Issues

Patients undergoing PD can lose protein into the dialysate. Nutritional support must provide sufficient protein to compensate for this loss. High dextrose concentrations in the

dialysis fluid can cause hyperglycemia; administration of insulin may be necessary. Indwelling dialysis fluid causes increased intraabdominal pressure that can complicate care of the critically ill patient. Diaphragmatic excursion may be limited, and venous return can be reduced. Stomach compression can lead to gastroesophageal reflux. Although patients undergoing long-term PD who receive fewer daily exchanges usually require maximal fill volumes to achieve adequate dialysis, patients undergoing short-term PD may do better using submaximal fill volumes with more frequent exchanges provided around the clock.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) has been the traditional form of renal replacement therapy in the ICU. The technique is well established for pediatric patients.[26] IHD offers the advantages of high efficiency for rapid metabolic correction and fluid removal. Its very advantages, however, may limit IHD's usefulness in the critically ill patient. IHD for infants and small children can be technically difficult and demanding. IHD may be the preferred modality for some critically ill pediatric patients; successful treatment in this setting requires experienced personnel.

Physiology

The dialyzer used in IHD is an artificial semipermeable membrane. The most common design used today is the hollow-fiber dialyzer. It consists of a plastic cartridge traversed by several thousand thin hollow fibers, each with microscopic fenestrations that permit the passage of water and other small molecules. Dialyzers vary in their surface area, permeability, priming volume, and membrane composition; numerous dialyzers are available commercially. Choosing different dialyzer characteristics permits adjustment of the dialysis prescription to the clinical situation.

Successful hemodialysis requires sufficiently high blood flow to allow adequate dialysis and ultrafiltration with a minimal risk of clotting. Dialysis efficiency falls off dramatically with lower blood pump speeds; this may require extended time on dialysis to compensate. Consequently, high-quality vascular access is essential for successful hemodialysis.

While blood flows through the hollow fibers of the dialyzer, dialysis fluid flows through the cartridge in the space surrounding the hollow fibers. Particles move by diffusion from the blood across the semipermeable membrane into the dialysate. Use of high-flow dialysis fluid with maximal blood flow through the dialyzer permits intermittent hemodialysis to remove particles more efficiently than any other renal replacement therapy.

Increasing blood flow, dialysis fluid flow, or dialyzer size will increase the rate of diffusion. Because diffusion favors the movement of small particles over large particles, large molecules or small molecules bound to larger molecules (such as albumin) will not dialyze well. In addition, intracellular particles will move into the vascular compartment on the basis of individual cell membrane transport characteristics, which may limit the rate at which dialysis can remove particles that do not reside within the vascular compartment.

Ultrafiltration on hemodialysis occurs because of hydrostatic pressure across the membrane that forces water out of the blood. Dissolved particles will travel with the water, leaving by convection. With use of IHD, dialysis staff can control the rate of ultrafiltration with precision and can achieve high rates of ultrafiltration.

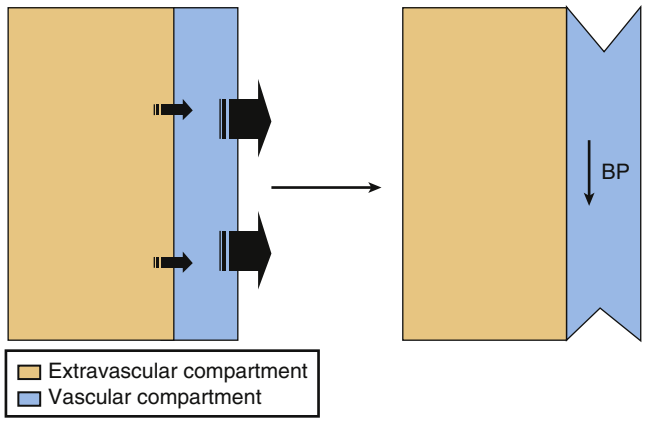

Figure 72–3. Two-compartment model of ultrafiltration. The rate of water removal from the vascular compartment by ultrafiltration (*large arrows*) exceeds the rate of refilling from the extravascular compartment (*smaller arrows*), and this process leads to relative vascular volume depletion and hypotension.

Analogous to the process of diffusion, ultrafiltration during IHD removes fluid only from the vascular compartment. Extravascular or "third space" fluid must move into the vascular compartment for removal by ultrafiltration. When the rate of movement from the extravascular space is slower than the rate of ultrafiltration, intravascular depletion can occur even though total body water remains elevated (Figure 72-3). This "two-compartment" model represents a potential limitation of rapid ultrafiltration during IHD, especially in the critically ill patient.

Indications

Thanks to its high efficiency, hemodialysis is the best modality for rapid particle removal. IHD is indicated for the treatment of toxic ingestions, many serious drug overdoses, and metabolic derangements that lead to the overproduction of endogenous toxins such as ammonia (see Chapters 76 and 105).[27-30]

The IHD system can perform ultrafiltration more rapidly than any other renal replacement modality. Consequently it is often the best choice for the treatment of critical volume overload but may be limited by the patient's ability to tolerate rapid fluid removal. Recent technology to guide ultrafiltration by the noninvasive monitoring of hematocrit changes during IHD may prevent and/or mitigate hypotension associated with ultrafiltration.[31]

Profound metabolic imbalance, such as that seen with critical hyperkalemia, can be corrected most quickly with IHD. Patients with oncologic problems such as tumor lysis syndrome may require IHD to rapidly correct the multiple metabolic abnormalities and to aid clearance of uric acid, which can cause renal failure (see Chapters 81 and 83).[32,33]

Technique

Vascular access is the first step for successful hemodialysis. Double-lumen catheters for hemodialysis come in a variety of sizes; occasionally, two single-lumen catheters at separate

sites are needed for small infants, although recent data suggest that these catheters do not perform as well.[34] Catheters can be placed in jugular, femoral, or subclavian positions (see Chapter 15). The internal jugular vein is preferred for access that will be required for more than a few sessions. Surgical support may be needed for patients when percutaneous placement is difficult.

Most patients receiving IHD will require heparin for anticoagulation. Some may be able to undergo successful dialysis with little or no heparin because of coagulopathy related to their systemic disease. Staff members often monitor clotting times during the IHD session to determine the need for heparin.

The blood pump rate is chosen based on the patient's clinical status and the quality of the vascular access. In smaller patients with smaller catheters, blood pump speeds often must run at less than 100 mL/min; in infants, speeds may run as low as 25 to 50 mL/min. Larger patients can tolerate faster blood pump speeds. Higher blood flow rates permit greater mass transfer of particles out of the patient in a given period.

The chosen dialyzer should provide sufficient clearance to achieve the goals of the dialysis session. Smaller patients receive dialysis with smaller dialyzers to limit extracorporeal blood volume and reduce the risk of dialyzer clotting with slower blood flow rates.

Small patients or those with unstable blood pressure may require priming of the IHD circuit with saline solution, albumin, or reconstituted whole blood. Dialysis machines with precise volumetric ultrafiltration control permit accurate and safe IHD in neonates and infants, for whom small inaccuracies in ultrafiltration volumes could potentially lead to severe fluid imbalances. Dialysis fluid concentrations of electrolytes can be adjusted to some extent on the basis of the clinical situation. The length of the IHD session will vary depending on the clinical situation and goals of the therapy. Mathematical models permit estimation of dialytic clearance and can be used to structure session length. The rate at which the patient can tolerate ultrafiltration is often the limiting factor in IHD for critically ill patients. Sessions may need to be extended to achieve ultrafiltration goals without significant hypotension.

Disadvantages and Complications

The principal disadvantage of IHD is the requirement for vascular access. Acceptable access can be difficult to achieve in critically ill children. Complications related to the access can include infection, bleeding, and thrombosis.

IHD's benefit of high efficiency with rapid fluid and particle removal can lead to difficulties in the ICU setting. Critically ill patients may not tolerate the rapid ultrafiltration and metabolic shifts of IHD.

Smaller patients or those with unstable blood pressure may require priming of the extracorporeal circuit to limit hemodynamic stress at dialysis initiation. For infants in whom the extracorporeal volume is relatively much larger, priming may need to be done with a blood/albumin mix, which exposes the patient to blood products.

Most IHD sessions require systemic anticoagulation with heparin, which can be difficult to manage in a critically ill child. Heparin exposure can complicate bleeding and cause heparin-induced thrombocytopenia. With careful monitoring of clotting times and circuit performance during the session, it is possible to perform IHD without heparin. The risk of clot formation in the IHD circuit rises, however, when heparin is not used.

Intensive Care Unit Issues

Patients receiving IHD as ongoing renal replacement therapy in the ICU require special attention to fluid and electrolyte balance. One should limit potassium and phosphorus delivery and may need to limit total daily fluids because ultrafiltration only occurs intermittently. Medication doses and schedule may require adjustment because of poor excretion with renal failure and subsequent rapid removal with dialysis (see Chapter 70).

Continuous Renal Replacement Therapy

CRRT is a generic term applied to several techniques of extracorporeal renal support. Similar to IHD in the use of a blood pump and hemofilter, the various subcategories of CRRT differ in their reliance on diffusion, convection, or a combination of the two for molecular clearance.

CRRT is becoming more popular as a method of renal support for pediatric patients.[1,35] Technological improvements in catheters, blood pumps, and ultrafiltration control mechanisms permit the application of CRRT to even the smallest infants.[36,37]

Physiology

The CRRT hemofilter is similar to that used for IHD. CRRT membranes traditionally have been more porous to permit greater removal of water. Numerous hemofilters are available commercially.

Both convection and diffusion can be used to remove particles during CRRT. Dialysis fluid allows diffusion, which favors the movement of smaller molecules. High rates of ultrafiltration will remove both small and larger particles by convection, up to the limits of the membrane. With high ultrafiltration rates to achieve better convective clearance, the patient may need to receive replacement of volume and electrolytes to compensate for that lost in ultrafiltrate.

Because of slower flow rates, the clearance achieved with CRRT may be lower than that of IHD. Continuous therapies, however, make up for this lower efficiency through the extended time of the treatment. Compared with a 3- or 4-hour IHD session, CRRT running 24 hours a day can achieve equivalent daily clearance with less metabolic variation. Newer CRRT devices can run at flow rates approaching those seen in IHD, greatly increasing the potential for rapid molecular clearance.

Nomenclature for the various subcategories of CRRT is based on the vascular access and the primary method of particle clearance (convection, diffusion, or both). Because most CRRT in pediatric patients uses a pump-assisted venovenous method, the most commonly used terms are continuous venovenous hemofiltration, which uses high convective clearance requiring replacement fluids; continuous venovenous hemodialysis, which uses dialysis fluid for diffusion, but minimal additional convection; and continuous venovenous hemodiafiltration, which uses both dialysis fluid and replacement fluids for combined diffusion and high-grade convection.

Indications

As a result of the slow, continuous removal of fluid, CRRT is particularly well suited to the treatment of volume overload in critically ill patients. Whereas IHD will attempt to reach an ultrafiltration goal within a relatively short therapeutic session, CRRT allows continuous ultrafiltration that can help maintain cardiovascular stability.

CRRT is useful to maintain metabolic balance through ongoing removal of unwanted particles. Although it is less efficient than IHD, CRRT's continuous nature can avoid daily fluctuations inherent in the use of an intermittent modality. In addition, CRRT can be used as a secondary method to maintain metabolic balance after rapid correction with IHD.[38]

For patients with diminished renal function and decreased urinary output, CRRT can allow administration of the daily load of fluids required to deliver medication and nutrition. With this modality the patient can be maintained in a more stable balance compared with IHD, in which the patient has progressive volume overload between IHD sessions and then must achieve the ultrafiltration goal in a brief treatment period.

Technique

As in IHD, successful CRRT requires adequate vascular access (see Chapter 15). Given the relatively large extracorporeal volume, smaller patients may require priming of the CRRT circuit with blood/albumin mix. In larger, more stable patients, CRRT can be initiated successfully with saline prime.

Earlier methods that entailed arteriovenous access have largely been abandoned in favor of venovenous CRRT. Older systems with adapted blood and fluid pumps linked together extemporaneously have been replaced by dedicated CRRT machinery. Several CRRT systems are available at this time; this latest generation of CRRT machines permits much greater accuracy for blood pump speed, fluid delivery, and ultrafiltration control.

Anticoagulation

Adequate anticoagulation is essential for successful CRRT. Currently, most patients treated with CRRT receive systemic heparin, regional citrate, or no added anticoagulation.

Systemic heparinization has been the traditional form of anticoagulation used in CRRT. This method is proven and functions well. Disadvantages include systemic anticoagulation with risk of bleeding, risk of heparin-induced thrombocytopenia, and the need for frequent monitoring and adjustment of the heparin dose.

Regional citrate anticoagulation has become popular for CRRT in both adult and pediatric patients. Citrate, introduced into the CRRT circuit, chelates calcium, which is a required cofactor in both the intrinsic and extrinsic arms of the clotting cascade. Calcium is infused back into the patient through a central access to prevent systemic hypocalcemia. Citrate is metabolized to bicarbonate, acting as a source of base. Several protocols have been developed for regional citrate anticoagulation in CRRT.[39-42] The systems are stable and require less monitoring than heparin-based anticoagulation. Disadvantages include the potential for acid/base imbalance, the risk of hypercalcemia or hypocalcemia, citrate overload due to poor metabolism or diminished clearance, and the need for additional central access for high rates of calcium delivery.

Many critically ill patients have disorders of coagulation as a part of their multiple organ system injury and can undergo CRRT without exogenous anticoagulation. Increased clotting of the CRRT circuit in such patients may be a sign of improving clinical status. A study of pediatric CRRT suggested that circuits that are run without anticoagulation have a significantly shorter life span; thus it may be appropriate to consider the use of anticoagulation even in the coagulopathic patient to ensure continued delivery of the therapy.[43]

Patient and vascular access size can limit blood pump rate. The current generation of CRRT machines can run at lower blood pump speeds with greater accuracy than did earlier systems.

Many brands of hemofilter are available for CRRT. Larger surface areas will permit more rapid ultrafiltration and clearance by convection. Of particular interest in the pediatric patient are reports of profound hypotensive events related to the use of a type of polyacrylonitrile hemofilter known as the AN-69 membrane.[44] This reaction, occurring rapidly when the patient's blood comes in contact with the hemofilter, is thought to be related to the release of bradykinin in response to the low pH of blood used to prime the CRRT circuit. Smaller patients and those with metabolic acidosis seem to be at greatest risk. Maneuvers to adjust pH within the circuit and limit this reaction have been described.[44-46] Some practitioners prefer to avoid use of the AN-69 membrane to limit the risk of complication, while others choose to tolerate this potential complication in patients with sepsis in light of the relatively high IL-6 clearance provided by AN-69 membranes.[47]

Dialysis Fluid and Infused Fluids

Nearly all of the current CRRT machines use premade, fully compounded dialysis or hemofiltration fluid rather than generating dialysis fluid online from concentrates (during IHD the dialysis fluid is generated online). Commercially available dialysis and hemofiltration fluid, compounded under quality-controlled conditions and delivered in premixed sterile bags, has largely replaced the use of extemporaneously prepared dialysis fluid from local pharmacy services. Several manufacturers offer dialysis fluid for CRRT; the products come in a variety of electrolyte concentrations to suit differing clinical needs. Commercially prepared options are also available for replacement fluids in CRRT. It has been suggested that the use of commercial CRRT solutions, rather than those made by a local pharmacy, can reduce the likelihood of errors related to solution preparation.[48]

Replacement fluids are infused to the CRRT system either before the hemofilter ("prefilter" or "predilution") or after ("postfilter" or "postdilution"). Prefilter delivery will reduce convective clearance at a given ultrafiltration rate because the blood entering the hemofilter will be diluted by the replacement fluid. This reduction, however, can be easily overcome with an increase of the ultrafiltration rate. Furthermore, prefilter replacement may permit higher ultrafiltration rates because it limits hemoconcentration within the hemofilter and thus lessens the chances of filter clotting. Some CRRT machines will permit either prefilter or postfilter delivery of replacement fluids, whereas others have a fixed location for replacement fluids.

Clearance

CRRT blood pump, dialysis fluid, and replacement fluid rates traditionally have been lower overall than those used in IHD. Consequently, clearance rates are lower but total daily clearance increases because the therapy is continuous. In most prescriptions, the limiting factor in CRRT clearance is the dialysis fluid or replacement fluid flow rate; greater rates of clearance

often can be achieved with an increase in the rate of dialysis fluid or replacement fluid. Newer CRRT machines are capable of higher dialysis and replacement fluid rates than in the past. Slower blood pump speeds can also potentially limit clearances; some newer devices are capable of higher blood pump speeds. Controversy exists in adult patients regarding appropriate goals for clearance. An influential single-center study suggested better outcomes with higher rates of clearance, [49] but this finding has not been reproduced in subsequent multicenter trials.[50,51] This question has not been fully studied in children.

Slow, steady ultrafiltration to gradually achieve fluid balance and then maintain it is the hallmark of CRRT. Slow ultrafiltration can permit movement of extravascular fluid into the vascular space at a rate roughly equal to the ultrafiltration rate, which allows greater mobilization of fluid while the risk of acute intravascular volume depletion and hypotension is limited. Ultrafiltration rates must be chosen on the basis of clinical status of the patient and fluid balance goals; frequent reevaluation is often necessary.

Disadvantages and Complications

Like IHD, CRRT requires vascular access, which can be difficult to obtain in infants and small children. Recent data can provide guidance regarding catheter size choice based on patient size and suggest that 5 Fr single-lumen catheters should not be used for CRRT because they are associated with significantly shorter functional CRRT circuit survival.[34] Continuous extracorporeal perfusion and anticoagulation carry risks of bleeding and infection. Some patients experience blood pressure instability despite the slow method of ultrafiltration. Continuous exposure to heparin can lead to heparin-induced thrombocytopenia. Patients receiving citrate anticoagulation are at risk for acid/base disturbance or hypocalcemia. Citrate overload can cause low patient ionized calcium with normal or high total calcium levels, the so-called *calcium gap* or *citrate lock*,[40,52] which occurs when excess citrate binds free calcium in the patient. Under these circumstances, citrate delivery should be reduced or clearance through the CRRT system should be increased.

Intensive Care Unit Issues

Continuous clearance on CRRT, particularly with convective modalities, can cause profound electrolyte deficiencies. Careful attention must be paid to appropriate replacement of electrolytes lost through CRRT. Similarly, nitrogen losses on CRRT can be high.[53] Patients require increased nutritional support during CRRT therapy, and careful consideration of the nutritional prescription is required.[54] Medication dosages often require adjustment because of losses through the CRRT system. Coordination between the ICU staff and nephrology staff is essential to establish appropriate goals for fluid removal and metabolic control.

Extended Daily Dialysis

IHD sessions can be extended in length to provide therapy that approaches CRRT. Variously referred to as slow low-efficiency dialysis or slow extended daily dialysis, such techniques can provide improved molecular clearance with better tolerance of ultrafiltration when compared with conventional schedules for IHD. Sessions may run 6 to 8 hours or more on a daily basis.[55]

Some institutions may prefer extended daily dialysis methods because they obviate the need to purchase and maintain separate, dedicated CRRT equipment, using instead standard IHD machines that have been adapted for longer session length. In addition, disposable materials for IHD are usually less expensive than are those for CRRT, potentially leading to cost savings. Because the patient is not connected to the device 24 hours a day, patient mobility for tests or surgical procedures may be facilitated and risk of treatment-related complications may be reduced. Online generation of dialysis fluid, as for standard IHD, greatly simplifies the question of solutions compared with premixed bags that must be frequently exchanged for CRRT. However, most online dialysis fluid is not sterile, raising a theoretical risk for the critically ill patient. Newer devices capable of extended therapies can be adapted to provide ultrapure dialysis fluid, which may mitigate this potential concern. Individual institutions may need to consider staffing requirements related to tending an IHD device for extended sessions.

While use of extended daily dialysis techniques for both adult and pediatric patients is growing, the literature has a dearth of information regarding efficacy in the pediatric population. This modality is often chosen for pragmatic reasons rather than because of proven superiority. It remains a reasonable option under the appropriate circumstances.

Outcomes of Renal Replacement in Critically Ill Children

Outcome data comparing modalities for pediatric renal replacement are sparse. The majority of studies are from single centers and are limited by small numbers of subjects.

The most recent studies in pediatric renal replacment therapy have centered on CRRT. Findings from five studies, comprising an aggregate of more than 400 patients, demonstrate an association of higher mortality for patients with more severe levels of volume overload.[7-10,13] A multicenter observational registry has provided insight on outcomes in pediatric CRRT.[37] Overall survival on CRRT in this cohort of more than 300 critically ill children was 58%; this percentage is superior to previously reported outcomes and likely represents improvement in CRRT techniques as well as overall critical care for the pediatric patient. Outcomes in the subpopulations of children with multisystem organ dysfunction and stem cell transplant who required CRRT also were noted to be improved compared with historical reports.[7,56] Because these studies did not compare CRRT to other interventions, no specific evidence-based comments can be made regarding choice of modality in the modern era, and this decision is largely based on experience and opinion.

Summary

Pediatric patients who require renal replacement therapy represent a special challenge. Multiple modalities are available, and the best choice may be dictated by the clinical situation and local expertise. Careful attention to fluid and electrolyte balance and appropriate nutritional support and close interaction between critical care and nephrology personnel will yield the best outcomes.

Hypertension in the Pediatric Intensive Care Unit

Ronald C. Sanders Jr., Arno Zaritsky, and Karen McNiece-Redwine

PEARLS

- Systemic hypertension, an often underappreciated condition that is increasing at an alarming rate in part because of the obesity epidemic, leads to long-term morbidity, mortality, and poor quality of life.
- A hypertensive emergency exists when there is evidence of end organ damage along with a severely elevated systolic or diastolic blood pressure. Consequently, prompt therapy and intensive monitoring are required.
- Treatment of a hypertensive emergency requires balancing the desire to quickly lower pressure against the potential harm from dropping pressure and thus organ blood flow too rapidly (e.g., cerebral, coronary, or renal ischemia). In clinical practice, mean arterial pressure during a hypertensive crisis should be lowered no more than 25% within the first hour.
- Although hypervolemia is a common cause of hypertensive urgencies or emergencies, the high perfusion pressure that occurs during a hypertensive emergency can lead to pressure diuresis, rendering some patients relatively hypovolemic, with hemoconcentration and activation of the renin-angiotensin-aldosterone system. Consequently, persistent hypovolemia may trigger a vicious cycle of further stimulation of the renin-angiotensin-aldosterone system, thus increasing systemic vascular resistance.
- Hypertension, when present in children in the pediatric intensive care unit, is most often related to pain, anxiety, positive fluid balance, drug effect (e.g., steroids or immunosuppression), or occasionally unrecognized seizure activity. In children with long-standing hypertension admitted to the pediatric intensive care unit, renal causes are most frequent and may be clinically silent, such as renovascular hypertension.

When confronted with a child with abnormally "high" blood pressure (BP) in the medical setting, the pediatrician is immediately confronted with two vexing issues. One is whether this abnormality will lead to immediate organ- or life-threatening consequences, and the second is whether the potential intervention itself will result in a worse outcome. Systemic hypertension (HTN) is a major lifelong condition that begins in childhood and is one of the leading causes of premature death in developed countries and developing nations.[1] The current obesity epidemic along with other lifestyle choices have likely led to the increasing numbers of children now being diagnosed with HTN.[2] Current estimates suggest that up to 5% of children have HTN compared with estimates of approximately 1% just a decade ago, while another 10% to 25% have prehypertension.[3-13] If untreated, HTN is associated with a 10-year survival rate of about 50% in adults depending on the degree of retinal changes and/or level of diastolic pressure.[14,15]

Several questions are commonly posed to the intensivist when managing the case of a child with acute HTN: What is acute HTN in the pediatric intensive care unit (PICU)? Is this level of HTN dangerous? Does the HTN represent a transient acute response? Is it important to manage high BP at this moment? How aggressive do I need to be in monitoring and managing it? It is the objective of this chapter to set the foundation for understanding the deleterious effects of systemic HTN, recognize when invasive versus noninvasive monitoring is warranted, and appreciate the importance of a prompt but measured response in management.

Definition of Terms

The most recent recommendations for diagnosing HTN in children were published in 2004 by the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents (Task Force) and were designed to mirror recommendations for diagnosing HTN and pre-HTN in adults according to the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. However, unlike adult definitions that are based on the observations reported by Volhard and Fahr in 1914 as well as epidemiologic studies showing a clear risk for cardiovascular morbidity and mortality with BPs at a certain level, pediatric definitions are based on epidemiological thresholds generated from a population of more than 60,000 children and adolescents across the United States.[16,17] Therefore in children systemic hypertension is defined as an average systolic BP (SBP) and/or diastolic BP (DBP) that is ≥95th percentile for gender, age, and height on three or more separate occasions[16,18] (see Appendix at www.expertconsult.com). In addition, children with an average SBP and/or DBP that is at the 90th percentile or higher (or ≥120/80 mm/Hg when a patient's 90th percentile exceeds this value) should be considered prehypertensive.[16] This classification of prehypertension is not meant to be considered

Table 73–1 Description of Youngest Patients Diagnosed with Malignant Hypertension

Age (Yr)	Gender	Blood Pressure (mm Hg)		History of Present Illness	Survival After Admission (Mo)
9	Female	190/130	180/130	Periodic attacks of headache and projectile vomiting ×5 years; nine convulsions 5 months ago	Alive
15	Female	200/140	170/115	Headache ×4 years, albuminuria ×2 years; left facial paralysis ×2 months	11
18	Male	240/180	220/140	Periodic severe headache ×3 years; convulsions; blurred vision; albuminuria ×8 months	Alive
19	Female	270/150	220/150	Headache, hypertension, and periodic blurring of vision ×2 years; dyspnea and nervousness ×1 year; albuminuria ×8 months	1.5

Modified from Keith N, Wagener H, Kernohan J, et al: The syndrome of malignant hypertension, *Arch Intern Med* 41:141-188, 1928.
DBP, Diastolic blood pressure; *SBP*, systolic blood pressure.

a definitive diagnosis such as with HTN. Rather, the goal of classifying children as prehypertensive is to identify those who may be at risk for developing HTN in the near future in the hopes that interventions may prevent its establishment. Note that these definitions refer to threshold BPs measured in a resting, nonstressed child; elevations in BP are commonly associated with a patient's stress response, which will normalize when the stress is eliminated. Nevertheless, the health care community has performed poorly in managing patients who have already been diagnosed with HTN, and vigilance must be practiced across all age groups.[19-21]

The clinical state of a "malignant sclerosis" or "bösartig hypertension" was first reported by Volhard and Fahr in 1914 in patients with mainly HTN and "hypernephrosclerosis."[17] In 1928, Keith et al: described 81 cases of what was termed "the malignant hypertension syndrome" that was a diagnosis made before end-stage damage of retinal, cerebral, cardiac or renal function occurred.[22,23] It was also the first description of pediatric patients with significantly uncontrolled hypertension (Table 73-1). The term "hypertensive crisis or emergency" is defined as a rapid and elevated level of either systolic or diastolic BP that is associated with end-organ damage (Box 73-1).[24-26] The terms "hypertensive crisis" and "hypertensive emergency" have been used interchangeably in the literature; "hypertensive emergency" is used in this chapter. Organs commonly affected include the central nervous system (CNS) (hypertensive encephalopathy, retinal vasculopathy-induced visual changes, cerebral infarction, and hemorrhage); the cardiovascular system (congestive heart failure, myocardial ischemia, aortic dissection); and the kidneys (proteinuria, hematuria, and acute renal insufficiency). The term "hypertensive urgency" is reserved for the condition where end-organ damage has not yet occurred despite an increase in BP.[25,26] Historically, a patient with a hypertensive urgency could be managed with oral medications and the BP corrected over a 24-hour period.[27] In contrast, a patient with a hypertensive emergency requires parenteral therapy and continuous BP monitoring.[27]

Etiology and Evaluation

Hypertension may be either primary (essential) or secondary to another underlying medical condition. While primary HTN is unusual in the PICU, its frequency is increasing with the current epidemic of obesity, although hypertensive urgency and emergency are almost always secondary to another condition.[16] Children with primary HTN are frequently overweight and have positive family histories for HTN and cardiovascular disease. The prevalence of HTN increases progressively with a rise in body mass index, with approximately 30% of overweight children (body mass index >95th percentile) exhibiting hypertension.[28] Being overweight and hypertensive are signs of the insulin-resistance syndrome or metabolic syndrome, a condition associated with multiple metabolic risk factors for cardiovascular disease as well as type 2 diabetes.[29]

Secondary causes of HTN can be both transient and sustained. The most common reasons for elevated BP in a critical care unit are inadequately treated pain and agitation. Without a high degree of suspicion, this can be difficult to detect, particularly if neuromuscular blockade is administered. Tachycardia as well as eye tearing with noxious interventions are two useful clues to this condition. Drug-induced HTN is also common in the critical care setting, especially when high-dose corticosteroids are used in patients with organ transplantation and other immunologic conditions. A number of other drugs associated with elevated BP are listed in Box 73-2. A review of all medications taken by the patient, as well as considering illicit drug use, is indicated for all patients with an elevated BP. A patient's fluid balance for several days also should be reviewed when HTN develops while in the ICU. Apparently innocuous discrepancies between input and output for a single day can cumulatively produce significant fluid overload after several days, although this alone is not typically enough to cause HTN in the absence of other renal, cardiovascular, or CNS problems that raise systemic vascular resistance

Secondary hypertension
Renal diseases
- Acute GN (postinfectious, tubulointerstitial, rapidly progressive GN)
- Acute tubular necrosis
- Chronic glomerulonephritides
- Chronic pyelonephritis and reflux nephropathy
- Chronic renal failure
- Congenital renal anomalies (dysplasia)
- Hemolytic uremic syndrome
- Henoch-Schönlein purpura nephritis
- Nephrotic syndrome (if hypervolemic)
- Inherited parenchymal disease (ADPKD, ARPKD)
- Obstructive uropathy
- Renal trauma
- Relapse of nephritis associated with systemic disease (lupus, vasculitis)

Vascular disorders
- Arteriovenous fistulae
- Coarctation of the aorta
- Neurofibromatosis
- Patent ductus arteriosus
- Renal artery compression (abdominal compartment syndrome)
- Renal artery stenosis (fibromuscular dysplasia, congenital)
- Renal transplant arterial stenosis
- Renal vein/artery thrombosis/embolization
- Trauma

Neurologic causes
- Dysautonomia (Riley-Day syndrome)
- Guillain-Barré syndrome
- Increased intracranial pressure (tumor, hydrocephalus)
- Poliomyelitis
- Seizures
- Spinal cord injury

Endocrine disorders
- Adrenal hemorrhage
- Congenital adrenal hyperplasia (11-hydroxylase deficiency, 17-hydroxylase deficiency)
- Conn syndrome
- Cushing disease and syndrome
- Hyperparathyroidism
- Hyperthyroidism

Renal tumor associated
- Wilms tumor
- Hamartomas
- Hemangiopericytoma

Catecholamine-secreting tumors
- Neuroblastoma
- Paraganglioma
- Pheochromocytoma

Low-renin hypertension
- Apparent mineralocorticoid excess
- Glucocorticoid remediable aldosteronism
- Gordon syndrome
- Liddle syndrome

Drug-induced hypertension
- Drug withdrawal (narcotic, benzodiazepine)
- Cyclosporine and tacrolimus
- Erythropoietin
- Glucocorticoids and mineralocorticoids
- Heavy metals
- Maternal drug use (cocaine, heroin)
- Nonsteroidal antiinflammatory agents
- Oral contraceptive agents
- Rebound after withdrawal of antihypertensives (especially clonidine and β-blockers)
- Sympathomimetic drugs (amphetamines, cocaine, ephedrine, lysergic acid diethylamide, phenylephrine)
- Theophylline/caffeine

Diet-mediated causes
- Alcohol
- Caffeine
- Licorice

Miscellaneous disorders
- Bronchopulmonary dysplasia
- Burns
- Congenital rubella syndrome
- Hypercalcemia
- Orthopedic procedures (leg traction)
- Polycythemia
- Preeclampsia/eclampsia
- Sickle cell anemia
- Stevens-Johnson syndrome
- Williams syndrome

ADPKD, Autosomal dominant polycystic kidney disease; *ARPKD,* autosomal recessive polycystic kidney disease; *BP,* blood pressure; *GN,* glomerulonephritis.

(SVR), cardiac output (CO), or both. Finally, postoperative HTN is common in the ICU setting, occurring in up to 75% of patients. Initially, factors such as hypoxia, hypercarbia (through its sympathomimetic effects), and pain should be promptly and adequately addressed.[30] Afterward, pharmacotherapy is indicated if HTN is refractory or sustained despite adequate ventilation, sedation, and analgesia.

Box 73-2 shows a list of other potential causes of transient and sustained HTN in children. Evaluation should be targeted at both identifying the etiology as well as any potential signs of injury to the cardiovascular, neurologic, renal, or ocular systems. A detailed history and thorough examination should be obtained for all patients, with special care paid to findings suggestive of an underlying hypertensive disorder or end-organ damage (Table 73-2). Signs and symptoms are often reflective of the severity and rapidity of onset of HTN. Chronic HTN is more commonly asymptomatic or characterized by low-grade generalized symptoms such as fatigue and recurrent headaches. Neurologic symptoms, however, are the most common presenting complaints in children with hypertensive emergency; congestive heart failure and renal insufficiency also are reported.[16] Hypertensive encephalopathy typically manifests as a severe headache with dizziness and changes in mental status ultimately culminating as seizures; other reported symptoms include facial palsies and visual changes that may lead to blindness and coma.[31-33] An abrupt presentation of chest or back pain along with HTN should trigger the consideration of aortic dissection.[34] Rarely, children can present with abdominal pain or vomiting as the only symptoms of a hypertensive emergency.[35]

Table 73–2 History and Physical Examination Findings in HTN

Finding	Possible Significance
HISTORICAL FINDINGS	
Complaint/Review of Systems	
Headaches, dizziness, epistaxis, visual changes	Nonspecific with respect to etiology of HTN
Abdominal/flank pain with hematuria	Renal artery or vein thrombosis
Hematuria, swelling, decreased urine output	Acute glomerulonephritis
Dysuria, frequency, urgency, nocturia, enuresis	Underlying renal disease
Joint pains/swelling, edema, rashes	Autoimmune mediated disease/glomerulonephritis
Weight loss, sweating, flushing, palpitations	Pheochromocytoma or hyperthyroidism
Muscle cramps, weakness, constipation	Hypokalemia associated with hyperaldosteronism
Delayed puberty	Congenital adrenal hyperplasia
Snoring	Sleep apnea
Prescription, over-the-counter, or illicit drug use	Drug-induced HTN
Medical History	
Umbilical artery catheterization	Renal artery thrombosis/renal embolus
Previous urinary tract infections	Renal scarring
Thyroid cancer, neurofibromatosis, von-Hippel Lindau disease	Pheochromocytoma
Family History	
HTN	Inherited forms of hypertension (AME, Gordon syndrome, Liddle syndrome, GRA), essential HTN
Renal disease	Polycystic kidney disease, Alport syndrome
Tumors	Familial pheochromocytoma, multiple endocrine neoplasia type II
PHYSICAL EXAMINATION FINDINGS	
Vital Signs	
Tachycardia	Hyperthyroidism, pheochromocytoma, neuroblastoma, primary HTN
Bradycardia	Increased intracranial pressure (tumor, hydrocephalus)
Drop in blood pressure from upper to lower extremities	Coarctation of aorta
General	
Growth retardation	Chronic kidney disease
Truncal obesity	Cushing disease, insulin resistance
Head and Neck	
Moon facies	Cushing disease
Elfin facies	Williams syndrome
Proptosis/goiter	Hyperthyroidism
Web neck	Turner syndrome
Adenotonsillar hypertrophy	Sleep disorders
Fundal changes	Chronic or severe HTN
Cardiovascular	
Friction rub	Systemic lupus erythematosus, collagen vascular disease, uremia
Apical heave	Left ventricular hypertrophy
Disparity in pulses	Coarctation
Lungs	
Crackles/rales	Heart failure
Abdomen	
Masses	Obstructive nephropathy, Wilms tumor, neuroblastoma, pheochromocytoma, polycystic kidney disease
Hepatomegaly	Heart failure

Continued

Table 73–2 History and Physical Examination Findings in Hypertension—cont'd

Finding	Possible Significance
Bruit	Renal artery stenosis, abdominal coarctation
Genitalia	
Ambiguous, viralized	Congenital adrenal hyperplasia
Extremities	
Edema	Underlying kidney disease
Joint swelling	Autoimmune disease
Rickettsial changes	Chronic kidney disease
Dermatologic	
Neurofibromas	Neurofibromatosis
Tubers, ash leaf spots, adenoma sebaceum	Tuberous sclerosis
Bronzed skin	Excessive adrenocorticotropic hormone
Acanthosis nigricans	Insulin resistance/metabolic syndrome
Striae, acne	Cushing disease
Rashes	Vasculitis/nephritis
Needle tracks	Drug-induced HTN
Neurologic	
Mental status changes	Severe HTN
Cranial nerve palsy	Severe HTN

AME, Apparent mineralocorticoid excess; *GRA,* glucocorticold-remediable aldosteronism.

Physical examination should include BP measurements in all four extremities as a screening for coarctation of the aorta, which should be suspected if upper extremity pressures are higher than lower extremity pressures and lower extremity pulses are weak or absent. Special attention also should be paid to pulse rate because HTN with associated bradycardia is suggestive of increased intracranial pressure (ICP). Rapidly lowering BP in this scenario could lead to decreased cerebral perfusion and its associated sequelae. A thorough cardiac examination to identify signs of heart failure, a search for carotid or abdominal bruits, a funduscopic examination, evaluation of cutaneous lesions, and a neurologic examination also are essential in the initial evaluation of patients with severe HTN.

Initial laboratory studies for all patients should include electrolytes, blood urea nitrogen, creatinine, complete blood cell count with peripheral smear, and urinalysis. Renal disease is the most common cause of secondary HTN in children, and both chronic and acute renal conditions may present with severe HTN. Anemia associated with chronic disease or a microangiopathic anemia resulting from disseminated activation of the coagulation system or hemolytic uremic syndrome may be seen as well. Finally, a hypokalemic metabolic alkalosis may develop with volume depletion and secondary hyperaldosteronism. This condition also may be seen in children with inherited monogenic forms of HTN.[36]

Renal ultrasonography is indicated for most patients to evaluate for renal parenchymal lesions such as small scarred kidneys, polycystic kidney disease, or other structural anomalies. Doppler evaluation of blood flow to the kidneys also should be performed, although this evaluation is less sensitive than in adults at identifying subtle renal artery stenosis in smaller children. Although both computed tomography (CT) and magnetic resonance angiography have shown some promise as a screening tool for renal artery stenosis, angiography remains the gold standard for identifying this lesion.[37-39] Further imaging such as a dimethylsuccinic acid (DMSA) scan may be indicated in children who are suspected of having renal scarring; plasma renin and aldosterone levels also may help discern the etiology of HTN, although typically they are not rapidly available.

A chest radiograph and electrocardiogram should be done at presentation to look for signs of heart failure and electrocardiographic evidence of ventricular hypertrophy, strain, or both. An echocardiogram is now recommended for all children with HTN to assess for congenital anomalies such as a coarctation of the aorta as well as for left ventricular hypertrophy, a common finding in children with long-standing HTN that correlates with blood pressure severity.[40-42] An echocardiogram may not need to be performed emergently if the child has no other signs of heart failure.

A head CT scan should be done in patients with concern for increased ICP. In children with cerebral edema or increased ICP, increased BP may develop as a strategy to preserve cerebral perfusion due to the increased resistance to cerebral blood flow. Initially, a child with traumatic brain injury will often maintain sufficient cerebral blood flow over a range of BPs because of the brain's capacity for autoregulation, as depicted in Figure 73-1.[43] However, if the resistance to cerebral blood flow increases, such as when ICP rises from swelling, then the patient may compensate through cerebral vasodilation or increased CO to meet the metabolic needs of the brain. Cerebral vasodilation, however, will only increase ICP further. To attempt to maintain adequate cerebral blood flow, the perfusion pressure must increase as noted in the following mathematical relationship: Cerebral perfusion pressure = Mean arterial pressure (MAP) − ICP. In such situations, it is prudent to undertake measures

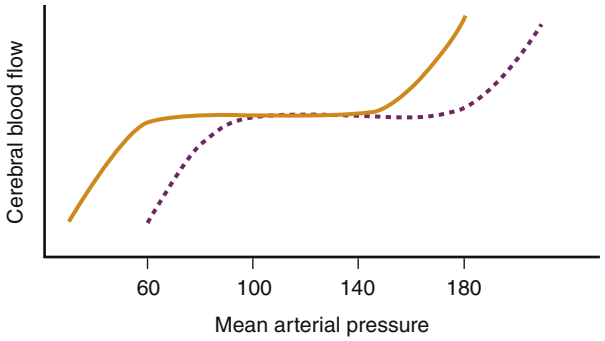

Figure 73–1. Cerebral blood flow autoregulation. Schematic representation of autoregulation of cerebral blood flow (CBF) in normotensive (*solid line*) and hypertensive (*dashed line*) patients. In both groups, within a range of about 100 mm Hg, increases or decreases in mean arterial pressure are associated with maintenance of CBF because of appropriate changes in arteriolar resistance. Changes in blood pressure outside this range lead to reduction (hypotension) or an elevation (with marked hypertension) in CBF. It is important to understand that hypertensive encephalopathy (increased blood flow with pressures exceeding the autoregulatory range) may occur with a mean arterial pressure below 200 mm Hg in the normotensive individual, but it may require a much higher mean arterial pressure in patients who have sustained hypertension. Conversely, lowering blood pressure to the "normal range" of a mean arterial pressure of 80 mm Hg (equivalent to 120/80 mm Hg) may produce a clinically significant decrease in CBF, especially in patients with preexisting cerebrovascular stenosis. *(Modified from Posner J, Saper C, Schiff N, et al: Examination of the comatose patient. In* Plum and Posner's diagnosis of stupor and coma, *ed 4, Oxford, UK, 2007, Oxford University Press. Reprinted by permission of Oxford University Press, Inc.)*

to control brain edema through hyperosmolar therapy, judicious sedation/analgesia, and minimizing the noxiousness of laryngoscopy while securing the airway to control oxygenation and ventilation. Efforts to directly lower systemic BP can undermine the patient's ability to support injured but viable cerebral tissue.

A magnetic resonance image also may be considered for patients with other neurologic symptoms. The most common brain-associated finding in children with a hypertensive emergency is posterior reversible encephalopathy syndrome (PRES). PRES is a syndrome characterized by the sudden onset of HTN, headaches, altered mental status, seizures, visual loss, and even cortical blindness.[156] Neuroimaging studies during PRES typically demonstrate cerebral edema affecting the white matter in a parieto-occipital distribution.[157] PRES is associated with immunosuppressive therapy (especially cyclosporine and tacrolimus), acute glomerulonephritis, eclampsia of pregnancy, and hypertensive encephalopathy (Figure 73-2).[44] Hypertensive emergencies and tonic-clonic seizures were presenting features in 59% of renal transplant patients who were found to have PRES on further work-up.[45] In addition, nearly half of the patients with PRES had no history of uncontrolled chronic HTN.[45] This constellation of symptoms and pathology, which has also been called reversible posterior leukoencephalopathy by other authors,[46] typically resolves once the HTN is treated, but it may take weeks to months for the imaging abnormalities to normalize.[45]

Pregnancy associated with preeclampsia also must be considered in patients experiencing a hypertensive emergency. Preeclampsia is a state of hypertensive proteinuria in a

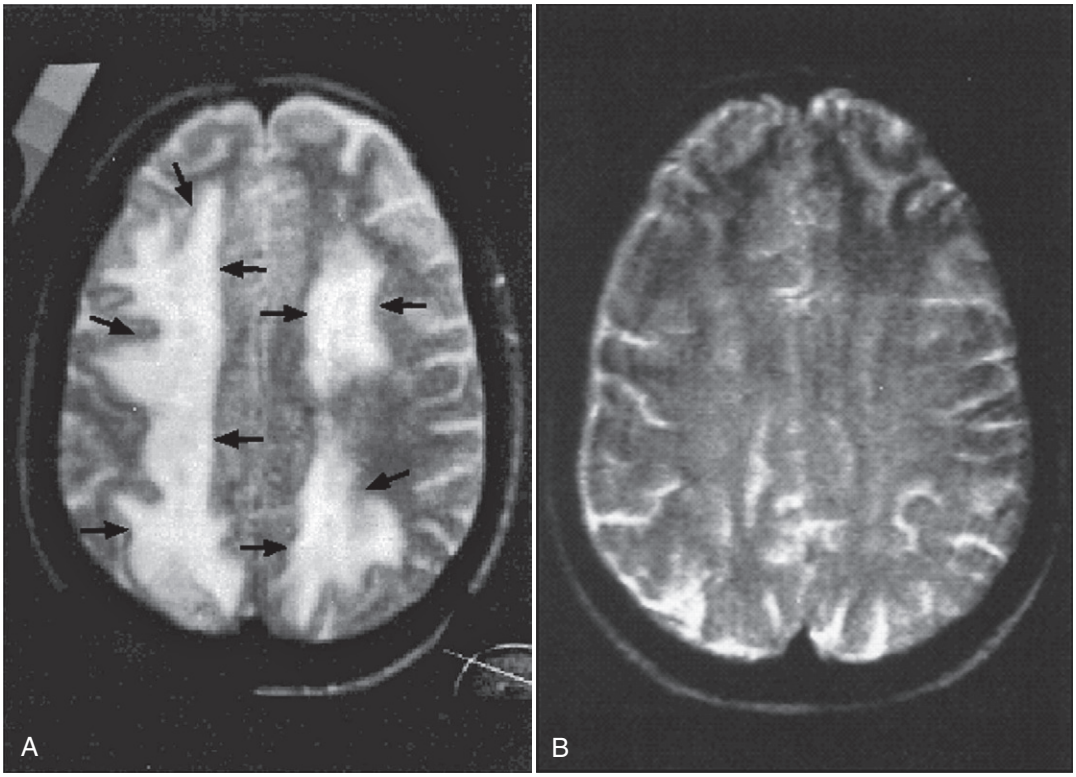

Figure 73–2. Posterior reversible encephalopathy in a patient with a renal transplant receiving cyclosporine and experiencing severe hypertension. **A**, The initial image shows widespread white-matter signal abnormalities (*arrows*). **B,** A follow-up scan shows that the abnormalities have resolved. *(From Hinchey J, Chaves C, Appignani B, et al: A reversible posterior leukoencephalopathy syndrome,* N Engl J Med *334[44]:494-500, 1996. Copyright 1996 Massachusetts Medical Society. All rights reserved.)*

pregnant woman who is at greater than 20 weeks' gestation.[47] Clinically, the classic triad of preeclampsia consists of HTN, proteinuria, and edema, although now it is accepted that edema should no longer be considered a prerequisite for making the diagnosis of preeclampsia.[47] Under these circumstances, an elevated BP separated by a minimum of 4 hours (maximum 7 days) is considered adequate for making a diagnosis for HTN (>140/90 mm Hg) or severe HTN (>160/100 mm Hg). Proteinuria is considered significant when two random urine samples collected at least 4 hours (but <7 days) apart have a level of 30 mg/dL or higher (1+) or 300 mg or more of protein are present in a 24-hour urine collection.[47] In the absence of proteinuria, pregnancy-induced HTN, gestational HTN, or chronic HTN must be considered. The goal of managing preeclampsia is to meticulously control the blood pressure in order to protect the fetus from insufficient placenta-utero blood flow (via overly aggressive antihypertensive therapy) and to avoid eclampsia (the condition characterized by tonic-clonic seizure activity culminating in coma).

Further evaluation for the cause of symptomatic HTN should be targeted based on history and physical findings. In many cases thyroid studies, a drug screen, cortisol levels, and plasma or urinary catecholamines/metanephrines may help elicit the cause of elevated BP.

Pathophysiology

MAP is approximately equal to the product of CO and SVR, as expressed mathematically by the following equation: MAP ≅ CO × SVR, where *MAP* is the mean arterial pressure, *CO* is the cardiac output, and *SVR* is the systemic vascular resistance (central venous pressure should be subtracted from the MAP in this equation but is usually so small it can be ignored). Organ-specific blood flow can be substituted for CO, such as considering the effects of increased resistance to flow from intracranial HTN in the CNS. Thus factors that increase either CO or SVR lead to elevated BP if the other does not decrease proportionally. In addition, chronically, these factors have an interdependent interaction that is still poorly understood. For example, while the initiating event leading to HTN may cause a rise in CO, a compensatory rise in peripheral vascular resistance often develops that may persist even after CO returns to baseline.

A hypertensive emergency can occur in patients with essential HTN, secondary HTN, or without any history of HTN.[24] The mechanisms responsible for generating and maintaining a hypertensive crisis continue to be elucidated. What seems plausible is that there is a triggering event that precipitates a dramatic increase in BP over a short period in a patient who is hypertensive at baseline. This event then leads to further arteriolar damage that prolongs the hypertensive state. The foundation for understanding this process can be drawn from knowledge regarding the existence of arteriolar damage caused by the mechanical stresses of long-standing HTN.[48] In the presence of systemic HTN, endothelial cell damage occurs, encouraging platelet activation, aggregation, and fibrin deposition followed by intravascular hemolysis.[48] Over time, the arterioles exhibit fibrinoid necrosis with fine subendothelial lipid inclusions and hyaline thrombi formation with little evidence of an inflammatory infiltrate.[49]

Endothelial Homeostasis

Endothelial health plays a central role in the HTN continuum. The endothelium is on the receiving end of the excessive pressures and shear stress generated from high blood flows along with concomitant increased resistance imparted by the vascular architectural scaffolding and surrounding smooth muscle cells. Aside from structural trauma, endothelial cell function is also affected. For instance, the stressed endothelial cell increases intracellular levels of nuclear factor-κB (NF-κB).[50] In turn, NF-κB results in expression of vascular cell adhesion molecule-1 that binds to monocytes and T-lymphocytes (facilitating invasion through the vascular wall that normally does not occur) and contributes to the inflammatory state.[50,51] The proinflammatory mediators interleukin-1β and tumor necrosis factor-α also induce vascular cell adhesion molecule-1 expression in endothelial cells through the NF-κB pathway.[50] In addition to vasoconstrictor mediators, the coagulation system also has been implicated in the HTN story; injured endothelial cells locally activate the coagulation cascade and promote platelet aggregation that leads to a prothrombotic surface.[24,50,52,53]

Adults with essential HTN who experienced a hypertensive emergency demonstrated a significant decline in BP when given L-arginine (a precursor of nitric oxide [NO]) compared with patients who also had essential HTN but had not experienced a hypertensive emergency event. This observation underscores the importance of the endothelium in the pathogenesis of a hypertensive emergency because an intact functional endothelial cell surface is necessary to respond to L-arginine.[54] Von Willebrand factor (a surface marker of endothelium), P-selectin (platelet activation), and fibrinogen serum levels were all increased in hypertensive adult patients with a hypertensive emergency compared with control subjects with HTN, suggesting that alterations in the homeostasis of the endothelial and/or the coagulation system occur during a hypertensive emergency.[55]

Hemodynamics of the Kidney

Regulation of sodium, the principal extracellular solute, controls extracellular fluid volume. As extracellular fluid volume increases, BP increases, particularly if SVR simultaneously increases in response to angiotensin II, sympathetic nervous system activation, and increased vasopressin release that often accompany renal dysfunction. In the normal kidney, an increase in BP augments renal excretion of sodium and water, which are respectively termed *pressure natriuresis* and *pressure diuresis*. With prolonged HTN, extracellular fluid may be depleted, leading to a somewhat paradoxical state of HTN and hypovolemia. In addition to the hydrostatic effects of increased BP on the glomerulus, a number of vasoactive substances may alter the glomerular filtration rate and renal blood flow by modulating resistances of the afferent and efferent arterioles, which affects the hydrostatic driving pressure at the glomerulus level.

The Autonomic System: Sympathetic Activation

A common cause of increased CO is activation of the sympathetic nervous system, often in concert with an increase in intravascular volume. At the same time, sympathetic nervous

system activation further increases SVR, exacerbating the rise in BP. The therapeutic approach to HTN depends on reducing SVR and often suppressing or reducing sympathetic nervous system activation. Without the latter being suppressed, the drop in SVR mediated by a vasodilator may be compensated by an increase in sympathetic activation with a resultant increase in CO and no net reduction in BP.

Renin-Angiotensin System

The renin-angiotensin system is thought to play a prominent role in many patients during a hypertensive emergency.[48,52,56] Renin is a proteolytic enzyme synthesized in the juxtaglomerular cells of the afferent renal arterioles that cleaves angiotensinogen (an α_2 globulin synthesized in the liver) to create angiotensin I (a decapeptide). In turn, angiotensin-converting enzyme (ACE) coverts angiotensin I to angiotensin II (an octapeptide), which acts at the angiotensin type 1 receptor (a G-coupled receptor found in renal afferent and efferent arterioles) to cause vasoconstriction, increased aldosterone release, and enhanced sodium and water reabsorption.[57] Interestingly, ACE also degrades the vasodilator bradykinin. Increased serum renin levels can reflect a primary condition, such as renovascular disease, or be secondary to renal parenchymal ischemia, hypotension, hypovolemia, increased sympathetic effects, β-adrenergic agonists, or a combination of these factors.[56,57] Ultimately, increased renin levels raise BP through a number of mechanisms primarily mediated through angiotensin II. Aside from its vasoconstrictive properties, angiotensin II increases the expression of aldosterone that leads to increased renal sodium and water retention, thus augmenting CO by increasing intravascular volume. Angiotensin II also induces the expression of interleukin-6 and NF-κB that in turn leads to elevated levels of tumor necrosis factor-α and increases nicotinamide adenine dinucleotide phosphate oxidase activity; the latter generates reactive oxygen species, promoting oxidative stress, and inhibits the cytokine-mediated activation of inducible-nitric oxide synthase (iNOS) that attenuates vasodilation.[58-61] Over time the collective result of these processes is enhanced and sustained endothelial cell trauma, vascular dysfunction, and ultimately end-organ damage.

Focal impairment of renal blood flow with release of renin and a subsequent increase in circulating angiotensin II underlie many types of childhood HTN.[62] For example, thromboemboli from umbilical or central vascular catheters may impair renal perfusion, and coarctation of the aorta is associated with high peripheral renin activity.[62,63]

Nitric Oxide

NO, now recognized as a ubiquitous biologic effector, is a labile, short-lived chemical produced from arginine via NO synthases.[64-66] These synthases are distinguished by cellular distribution and by the requirement for calcium as a cofactor. The constitutive isoform of NOS is believed most responsible for basal vasomotor tone, although iNOS may have a role. NO is released continuously from arteries and arterioles but not from veins. In addition, other mediators function through the NO system. For instance, bradykinin stimulates the release of NO to produce vasodilation. NO diffuses from the endothelium to the vascular smooth muscle cell, where it produces its vasodilatory effect in part by increasing the intracellular concentration of cyclic guanosine monophosphate (cGMP) through stimulation of soluble guanylate cyclase. NO that diffuses from the local endothelial environment reacts with hemoglobin, forming nitrosohemoglobin and methemoglobin. Thus HTN need not be attributed only to a direct vasoconstrictor effect but also may be related to loss of basal NO vasodilation. Therapeutic agents such as sodium nitroprusside and nitroglycerin produce their systemic vasodilator action by stimulating NO production (see HTN management section that follows).

Hypervolemia

An acute increase in intravascular volume is a frequent cause of acute decompensation of BP control in a patient with chronic HTN, particularly in the setting of stimuli that increase sympathetic nervous system and/or renin-angiotensin-aldosterone system activation. Although hypervolemia is a common cause of hypertensive urgencies or emergencies, pressure diuresis may render some patients relatively hypovolemic, producing hemoconcentration and further marked activation of the renin-angiotensin-aldosterone system.[56] Further volume depletion may actually worsen HTN by stimulating a further increase in SVR with the potential for organ ischemia. Thus diuretics and fluid restriction are not standard therapy for patients who present in hypertensive crisis; they are reserved for patients with clinically apparent fluid overload.[53,56,67]

Clinical Symptoms

The presentation of a patient with a hypertensive emergency depends on underlying medical conditions, baseline systemic BP, rate of rise and degree of BP elevation, as well as effects on end organs. The range of both SBPs and DBPs can be quite large in patients with hypertensive emergency, but long-standing baseline systemic HTN is a common attribute in many cases.[48] Headache is a common presenting complaint in patients with a hypertensive emergency. Approximately 60% of patients had a headache during presentation and an additional 28% reported dizziness.[68] Visual impairment is another common presenting complaint in patients with a hypertensive emergency. In children, essential HTN was associated with some form of retinopathy diagnosed by means of retinal photographs in up to 50% of patients[69]; however, in a separate study, only 8.6% had evidence of retinopathy diagnosed with an ophthalmoscope.[70] Nevertheless, evidence indicates that the pattern of retinal lesions can offer some information related to the onset of HTN. For instance, generalized arteriolar narrowing and arteriovenous nicking were associated with long-standing systemic HTN, whereas focal arteriolar narrowing, retinal hemorrhages, microaneurysms, and cotton-wool spots were indicative of recent significant increases in BP.[71]

From a pathophysiological perspective, the retinal changes associated with HTN can proceed through a few stages. The first stage (vasoconstrictive stage) is characterized by vasospasm (i.e., increased arteriolar tone and narrowing of arterioles). In time, the retinal vasculature undergoes intimal thickening, medial wall hyperplasia, and hyaline degeneration.[71] If allowed to progress, then the damage proceeds to the sclerotic stage, which is represented by generalized narrowing of retinal arterioles, arteriovenous nicking (restricted junctions between the arterioles and venules), and an abnormal arteriolar light

reflex characterized as "copper wiring" or widening and accentuation of the central light reflex.[71] Some cases evolve into the exudative stage that is attributed to a breakdown of the blood-retina barrier with smooth muscle and endothelial cell necrosis, ischemic changes, and extravasation of blood. Clinically this results in microaneurysms, hemorrhages, hard exudates, and cotton-wool spots.[71] During a hypertensive emergency, papilledema may be evident.

Perhaps the strongest link between HTN and consequent retinal changes has to do with their relationship with stroke risk. The retinal blood flow shares embryologic, anatomic, and physiologic attributes with the cerebral circulation.[71] In fact, some retinal lesions such as retinal hemorrhages, microaneurysms, and cotton-wool spots were associated with newly diagnosed strokes in one multicenter cohort trial of adults.[72]

In children with HTN left ventricular hypertrophy (LVH) often commonly develops, with obesity being the most prevalent associated factor.[73,74] The incidence of LVH is higher in children with established HTN as well as in patients who have HTN confirmed with 24-hour ambulatory BP monitoring.[42] The correlation between HTN and LVH is lower when only casual BP measurements are used to diagnose HTN.[75] Fifteen percent to 41% of children with essential HTN have LVH, depending on whether one uses adult or pediatric criteria, respectively.[41] Furthermore, geometric features of the left ventricle demonstrate ethnic tendencies such as concentric LVH that occurs more frequently in Hispanic and African American children.[41] Eight percent of patients with a hypertensive emergency experienced other cardiac manifestations, such as acute heart failure with pulmonary edema.[76]

Children with HTN can exhibit evidence of renal damage such as hematuria, albuminuria, and uremia. In fact, the degree of proteinuria can be correlated with the severity of HTN, as seen in Figure 73-3. Attempts to determine the renal effects of severe HTN is fraught with difficulties because of the frequent association of renal parenchymal and/or renovascular disease with systemic HTN. Moreover, hypertensive pathology is not usually limited to a single organ like the kidney; other end-organ abnormalities usually can be seen, such as left ventricular hypertrophy and neurologic sequelae (such as mental status changes, seizures, and cerebrovascular accidents).[77] Nevertheless, children with HTN resulting from vasculitis have been found to have nephrotic range proteinuria, microscopic hematuria, elevated creatinine levels, and diminished glomerular filtration rates.[77-79] Renal pathology may reveal renal arterial stenosis and small kidney as well as histologic evidence of arteriolar sclerosis and focal glomerulosclerosis.[77]

Illicit cocaine abuse in adults has provided an interesting window on the acute renal effects associated with a hypertensive emergency.[80] Clinically, elevated serum creatinine and urea nitrogen levels were found to be accompanied with segmental glomerular fibrinoid necrosis and prominent fibrinoid necrosis of afferent and efferent arterioles on biopsies.[80]

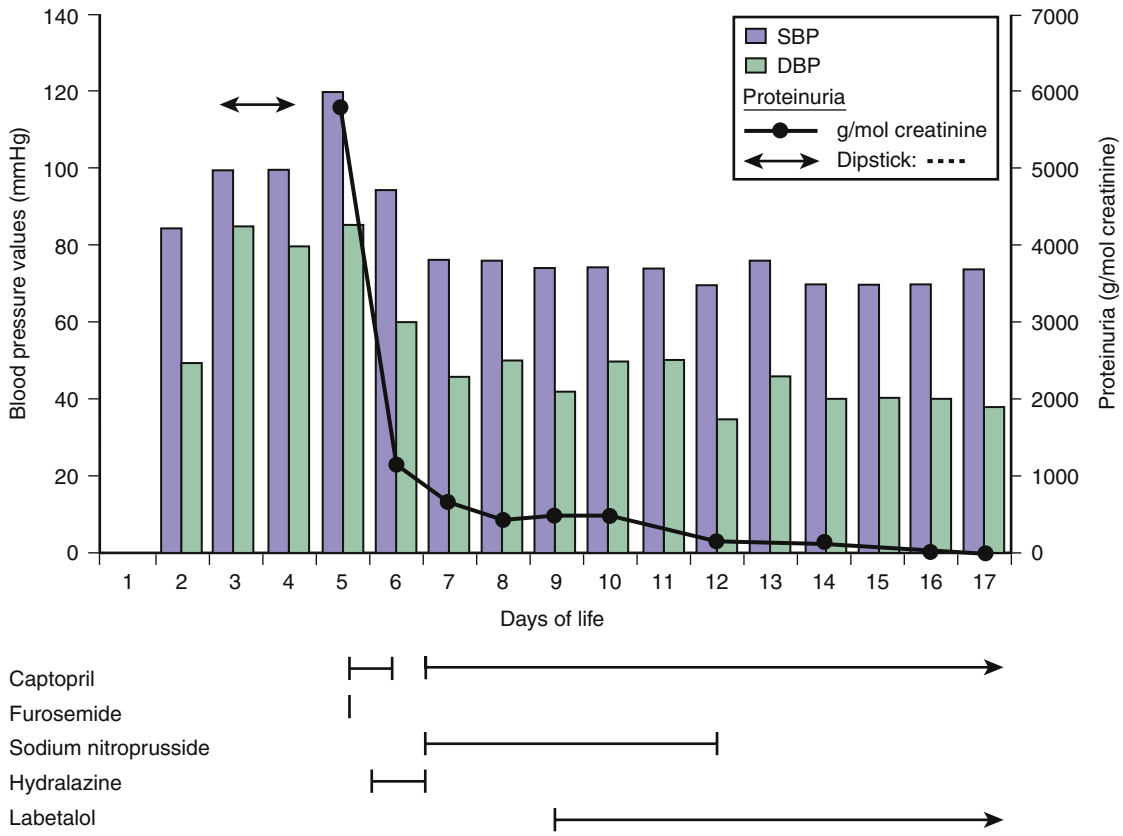

Figure 73–3. Variation of proteinuria with blood pressure control. Effects of nitroprusside in conjunction with other agents in the control of systemic hypertension in an infant with renal artery stenosis. The infant also had left ventricular failure that resolved according to echocardiography performed 3 months after discharge. *(From Cachat F, Bogaru A, Micheli JL, et al: Severe hypertension and massive proteinuria in a newborn with renal artery stenosis,* Pediatr Nephrol *19:544-546, 2004.)*

Management Strategy

Monitoring

The most critical component of identifying and monitoring hypertensive emergencies is accurately measuring BP. Both noninvasive and invasive techniques may be used in the ICU setting and are commonly used together to complement the strengths and weaknesses of each method. The main techniques used to determine BP in the ICU are the auscultatory method, oscillometric method, Doppler method, and invasive hemodynamic monitoring.

Auscultatory, oscillometric, and Doppler BP methods are noninvasive techniques that are based on the return of blood flow through a major artery after compressing it with an inflatable cuff. *Auscultatory methods* require an observer to listen to the Korotkoff sounds generated as the cuff deflates. Korotkoff sounds 1 and 5 should be used to represent SBP and DBP, respectively. It should be noted that current normal values were generated using this technique over the brachial artery and it is thus the preferred method for diagnosing chronic HTN. To obtain accurate measurements, it is important that the appropriate cuff size be utilized, and it should cover approximately 75% of the upper arm.[16] *Oscillometric techniques* utilize a similar technique except that a MAP is determined from oscillometric wave forms generated as blood flow returns through the artery. SBP and DBP are then calculated using a proprietary formula specific to the monitor. For this reason, it is important to ensure that the specific oscillometric device has been validated in the patient population in which it is being used.[16] *Doppler devices* use changes in ultrasound frequency to infer velocity of blood flow. The Doppler shift corresponds to the turbulent flow, as signified by the Korotkoff sounds, that diminishes as laminar flow predominates.[81] As with the auscultatory method, selection of an appropriate cuff size is paramount.

Invasive arterial lines are fluid-filled tubes attached to a pressure transducer, a device consisting of a thin flexible diaphragm connected to a strain gauge and capable of converting the pressure transmitted to an electrical signal (see Chapter 21). The most common source of inaccuracy is the influence of electrical damping on reported BP. An overdamped signal underestimates both SBP and DBP, although MAP may be accurate. On the other hand, an underdamped system overestimates SBP, especially with a hyperdynamic circulation, but does not affect MAP.[82] This phenomenon is recognized as a narrow peaked pressure wave and wide pulse pressure. Moreover, invasive blood pressure measured in the lower extremity is higher than in the upper extremities because of the nature of BP wave transmission, which results in an increase in SBP reading the further away from the heart it is measured.[83]

Generally, children with sustained levels of HTN as seen in hypertensive emergencies need to be closely monitored in a controlled setting such as the ICU, and the ideal way to continuously follow BPs is with the aid of an indwelling arterial catheter. Arterial lines can be placed in a variety of locations, but usually they are placed in peripheral arteries that supply areas with robust collateral blood flow; common sites include the radial, dorsalis pedis, and posterior tibial arteries. As a rule, patients experiencing a hypertensive crisis need to have continuous intra-arterial BP monitoring because of the lability of BP when continuous medications are utilized. However, using noninvasive techniques to confirm that transduced values are accurate is a quite common practice because electrical damping of the transduced signal can cause inaccuracies in SBP and DBP, although MAP is likely to be less affected.

Pharmacotherapy

The therapeutic strategy for hypertensive emergencies depends on the clinical context of elevated BPs. Hypertensive children returning from surgery need to be adequately sedated and given sufficient analgesia postoperatively for comfort and to control sympathetic activation. It is not uncommon for children to return to recovery areas, floors, and ICUs with variable levels of anesthetics still circulating that can permit pain, anxiety, and emergence phenomena that could be accompanied with elevated BPs. This situation by no means minimizes the potential detrimental effects of severely elevated systolic or diastolic pressures if they are inadequately treated or ignored.

Initially, it is prudent to ascertain fluid status while determining the best approach to a hypertensive child. Some situations, such as the presence of pulmonary edema and renal failure, clearly identify the child with probable fluid overload conditions. On the other hand, other children with significant HTN exhibit a pressure-induced diuresis associated with secondary activation of the renin-angiotensin system during HTN, and these patients may need judicious volume replenishment while managing their HTN.

The child with altered mental status, unequal (anisocoric) pupils, and systemic HTN needs agents directed at managing increased ICP such as mannitol or hypertonic saline solution, along with careful rapid sequence intubation and controlled ventilation. The goal here is to prevent cerebral herniation and not to directly lower BP too rapidly, which may be deleterious.

Finally, the strategic pharmacologic goal for a patient experiencing a hypertensive crisis is to aim for a controlled decrease in BP as opposed to a sudden rapid fall. As a rule, one should aim to promptly lower the BP no more than 20% to 25% over 60 minutes in acute situations.[1] One group reported the occurrence of permanent neurologic deficits in adults treated with bolus antihypertensive therapy resulting in rapid BP reduction,[84] and similar catastrophes have occurred in children as well.[85,86]

Table 73-3 lists the attributes of specific antihypertensive medications while Table 73-4 suggests choices based on the etiology of HTN. The indications, pharmacology, adverse effects, and dosage are reviewed for the medications commonly used to treat hypertensive emergencies and urgencies in children.

Sodium Nitroprusside

Sodium nitroprusside (SNP) lowers systemic BP as an arteriolar (peripheral resistance vessel) and venous (peripheral capacitance vessel) dilator. Consequently, this effect often results in a reflexive tachycardia because of the fall in arteriolar BP. SNP lowers right atrial pressures through relaxation of venous capacitance vessels, thus increasing venous compliance. In addition, SNP reduces right ventricular afterload through its pulmonary arterial vasodilator activity.[87] Its potent pulmonary vasodilation inhibits hypoxic-mediated pulmonary vasoconstriction.[88] Generally, when used in a hypertensive emergency, SNP reduces CO in patients with normal left ventricular function through its venous pooling (e.g., increased

Table 73–3 Overview of Antihypertensive Agents

Drug	Mechanism	Dose	Route	Comments
Captopril	ACE inhibitor	Infants: 0.1–0.5 mg/kg/dose Child: 0.3–0.5 mg/kg/dose	Oral every 6–12 h	Contraindicated if obstruction to renal blood flow Monitor potassium (hyperkalemia risk) Cough and angioedema
Clonidine	Central α_2-adrenergic agonist	3–10 μg/kg/dose up to 25 μg/kg/day	Oral every 6–8 h	Caution if altered mentation Frequently causes sedation Useful when high sympathetic activity contributes to HTN
Diazoxide	Direct vasodilator	1–3 mg/kg (maximum 150 mg)	IV infusion; may repeat in 5–15 min	Hypotension and reflex tachycardia Hyperglycemia (inhibits insulin release)
Enalapril/ enalaprilat	ACE inhibitor	Enalapril: 0.1–0.5 mg/kg/day Enalaprilat: 5–10 μg/kg/dose	Oral: every 12 h IV: repeat every 6–8 h as needed	Same as captopril, except cough and angioedema are rare
Esmolol	Selective β_1-adrenergic blocker	500 μg/kg bolus followed by infusion of 125–250 μg/kg/min	IV bolus and infusion	Avoid in patients with asthma, chronic obstructive pulmonary disease, bradycardia and heart failure May cause profound bradycardia
Fenoldopam	Dopamine receptor agonist	0.2–1.2 μg/kg/min	IV infusion	Increases renal perfusion and urine output
Hydralazine	Direct vasodilator	0.1–0.2 mg/kg/dose initially (maximum initial dose 20 mg) up to 1.7–3.5 mg/kg/day divided in 4–6 doses	IV, IM	Give every 4 h by IV bolus Associated with lupus-like reaction in slow acetylators Reflex tachycardia and fluid retention common
Isradipine	Inhibition of L-type calcium channels	0.05–0.1 mg/kg/dose 3 to 4 times a day (maximum dose 0.8 mg/kg/day up to 20 mg/day)	Oral	Adverse effects include headache, dizziness, flushing, and tachycardia
Labetalol	Combined α- and β-adrenergic receptor blocker (7:1 relative potency for β- over α-antagonism)	0.2–1 mg/kg bolus (up to 40 mg initial dose); repeat 0.15 mg/kg every 5–15 min Infusion of 0.25–3 mg/kg/h	IV bolus or infusion	Contraindicated in asthma and overt heart failure May cause infusion-limiting bradycardia
Nicardipine	Inhibition of L-type calcium channels	0.5–5 μg/kg/min; increase by 0.5 μg/kg/min every 10–15 min as needed	IV infusion	May cause reflex tachycardia Should be infused centrally (high incidence of phlebitis peripherally)
Nifedipine	Inhibition of L-type calcium channels	0.25 mg/kg (maximum dose 10 mg)	Oral or feeding tube (not sublingual)	May cause significant decrease in blood pressure
Nitroprusside	Stimulation of NO in both arterial and venous circulation	0.5–10 μg/kg/min	IV infusion	Reflex tachycardia occurs frequently Monitor cyanide levels (or lactate) Consider coadministration of sodium thiosulfate
Nitroglycerin	Relatively selective NO stimulation in veins	0.5–5 μg/kg/min	IV infusion	No active metabolite, but relatively weak arterial dilator
Phentolamine	Nonselective α-adrenergic receptor blocker	0.05–0.1 mg/kg IV bolus 5–15 mg in adults	IV bolus	Used for pheochromocytoma
Trimethaphan camsylate	Blocks acetylcholine in both sympathetic and cholinergic ganglia reducing sympathetic activity; also a peripheral vasodilator	50–150 μg/kg/min	IV infusion	Reflex tachycardia May cause weakness and apnea with high doses

Medications are listed alphabetically and compiled from several sources.[16,152-155]
ACE, Angiotensin-converting enzyme; *IM,* intramuscular; *IV,* intravenous; *NO,* nitric oxide.

Table 73–4 Drug Selection Based on Etiology of Hypertensive Emergency/Urgency

Type of Emergency	Drugs of Choice	Alternate Second Line	Relative Contraindications
Hypertensive encephalopathy	Nicardipine Nitroprusside	Labetalol	Trimethaphan, clonidine
Intracranial hemorrhage	Labetalol Nicardipine	Nitroprusside	Vasodilators with reflex sympathetic stimulation (e.g., hydralazine, diazoxide, short-acting nifedipine)
Left ventricular failure and pulmonary edema	Nitroprusside ± loop diuretics ± ACE inhibitor	Nitroglycerin, fenoldopam	Labetalol, β-adrenergic blockers, verapamil
Adrenergic crisis	Nitroprusside ± β-blockers, phentolamine Clonidine (if centrally mediated HTN such as narcotic withdrawal)	Labetalol	Monotherapy with β-adrenergic blockers Contraindicated with cocaine-induced HTN
Dissecting aortic aneurysm	β-adrenergic blockers ± nitroprusside, trimethaphan	Labetalol, verapamil	Vasodilators with reflex sympathetic stimulation
Eclampsia	Hydralazine, labetalol nicardipine	Nifedipine	ACE inhibitor, nitroprusside
HYPERTENSIVE URGENCIES			
Acute renal failure	Labetalol, minoxidil ± β-adrenergic blockers	Nicardipine, diuretics, or hemofiltration (if volume overloaded)	Nitroprusside (to limit risk of thiocyanate toxicity)
Perioperative HTN (if not a result of pain, agitation)	Nitroglycerin, nitroprusside ± β-adrenergic blockers Enalaprilat or nicardipine for coarctation of the aorta	Labetalol, nicardipine, fenoldopam	

venous capacitance) effects. On the other hand, SNP improves CO in patients with poor left ventricular function and diastolic ventricular distension mainly by decreasing afterload by means of relaxing arteriolar resistance vessels.[89]

SNP has a prompt onset of action and a very short half-life, making it ideal for meticulous titration. Its prowess as a BP-lowering agent was first observed in the 1920s through the 1950s, but it was not commercially available until the mid 1970s.[87] Later, SNP was used not only in patients with severe HTN but also in the operative theater to induce arterial hypotension and in the hospital setting to lower afterload in patients with heart failure.

SNP is an unstable compound that breaks down under alkaline conditions and when exposed to ambient light.[89] Immediately during infusion, SNP interacts with oxyhemoglobin to yield methemoglobin, cyanide, and NO. In contrast to the organic nitrates (e.g., nitroglycerin) that require thiol-containing compounds to generate NO, SNP spontaneously generates this chemical, thus functioning as a prodrug.[90] Once generated, NO activates the enzyme guanylate cyclase found within vascular smooth muscle, resulting in increased levels of cGMP, which inhibits calcium entry into vascular smooth muscle cells and may increase calcium uptake by the smooth endoplasmic reticulum to produce vasodilation. Its onset of action is 30 seconds, it peaks at 2 minutes, and it is eliminated 3 minutes after cessation.[89]

The cyanide that is produced is rapidly cleared by nonenzymatic means by reacting with sulfhydryl groups on proteins in surrounding tissue and in erythrocytes.[88] In addition, the liver enzymatically metabolizes cyanide to thiocyanate by means of rhodanese. Because the liver is the major source of rhodanese, in patients with liver failure, signs and symptoms of cyanide intoxication may develop upon nitroprusside administration. Adverse effects from methemoglobinemia generated by SNP metabolism are rare, even in patients with a congenital inability to convert methemoglobin to hemoglobin (i.e., methemoglobin reductase deficiency). In any event, any patient receiving SNP in whom CNS dysfunction, cardiovascular instability, and/or increasing metabolic acidosis develops should be evaluated for cyanide toxicity.[88] If cyanide toxicity is suspected, SNP infusion should be stopped and therapies directed toward cyanide toxicity should be considered. Because the rate-limiting step of cyanide detoxification to thiocyanate usually entails the need for a sulfur donor, coadministration of sodium thiosulfate as a sulfur donor increases the rate of reaction of rhodanese, removing cyanide from circulation so that it no longer binds to cytochrome C.[89] A solution of 0.1% sodium nitroprusside and 1% sodium thiosulfate or a 1:10 ratio by weight in light-protected tubing is administered according to the usual dosing guidelines for sodium nitroprusside.[91-93] Alternatively, hydroxocobalamin (vitamin B_{12a}) can be used to trap the cyanide ion by exchanging the hydroxyl group for cyanide and forming cyanocobalamin, which is excreted unchanged in the urine.[94] Cyanocobalamin is the synthetic form of vitamin B12 (cobalamin) that is used for food additives and is not harmful. Of note, intravenous (IV) methylene blue is contraindicated in treating methemoglobinemia attributable to cyanide toxicity because the conversion of methemoglobin to hemoglobin may liberate large amounts of cyanide.[94]

Thiocyanate is eliminated in the urine with an elimination half-life of 3 days in patients with normal renal function.[89] Because thiocyanate accumulates in patients with renal failure and can result in renal toxicity, nitroprusside is often used

only briefly and in limited doses in children with renal failure. Clinically, patients with thiocyanate toxicity exhibit anorexia, nausea, fatigue, disorientation, and psychosis.[89] Thiocyanate also inhibits iodine uptake by the thyroid and may produce hypothyroidism. Thus thiocyanate levels should be monitored with prolonged infusion (>24 hours).

In one study evaluating the effectiveness of nitroprusside in children presenting with hypertensive emergencies of renal origin, target levels of BP were achieved within 1 to 20 minutes in all patients. In addition, symptoms of cardiac failure resolved in all patients, and neurologic symptoms abated in 80% of children within 24 to 48 hours.[95] Even in neonates with structural causes of HTN such as renal artery stenosis, nitroprusside was shown to be a formidable adjunctive agent in controlling BP and reversing signs of heart failure and proteinuria.[96] The disadvantages of sodium nitroprusside include not only the potential for cyanide and thiocyanate toxicity but also acute hypotension, rebound HTN, increasing cerebral blood flow/ICP, oxygen desaturations (via inhibition of hypoxic vasoconstriction), and in time, tachyphylaxis.[52,89,97] However, it is important to note that nitroprusside was effective in children experiencing HTN after bidirectional superior cavopulmonary shunts without altering cerebral blood flow.[98] It should be started at doses of 0.3 to 0.5 μg/kg/min; the usual dose is 3 μg/kg/min and can be titrated up to 8 to 10 μg/kg/min if necessary.[16]

Nitroglycerin

Nitroglycerin is principally a venodilator, although arteriolar dilation occurs at higher doses. Once nitroglycerin is converted to NO, it activates guanylate cyclase within smooth muscle (like nitroprusside) and stimulates the production of cGMP. The result is venous capacitance pooling with a predictable decrease in myocardial preload.[99] In volume-depleted patients, a condition typical of hypertensive emergencies other than acute pulmonary edema or acute renal failure, a reduced myocardial preload reduces CO and is undesirable, especially in patients with compromised myocardial, cerebral, or renal perfusion.[100,101]

Onset of action of IV nitroglycerin is 1 to 2 minutes, with a duration of action of 3 to 5 minutes.[102] In adults and adolescents, nitroglycerin should be started at a low rate to avoid hypotension, typically 5 to 20 μg/min, and increased by 5 to 10 μg/min every 5 minutes up to a maximum of 200 μg/min.[102] In children, the initial recommended dose is 0.25 to 0.5 μg/kg/min and can be adjusted by 0.5 to 1 μg/kg/min every 3 to 5 minutes to a maximum of 5 μg/kg/min, although doses up to 20 μg/kg/min may be used.[103] Common adverse effects include headache, orthostatic hypotension, nausea, palpitations, and flushing.[102] The hemodynamic effects of nitroglycerin may be deleterious in patients with anatomically restrictive cardiac lesions such as aortic stenosis or other left-sided obstructive cardiac lesions. Furthermore, nitroglycerin should be avoided in patients with increased ICPs because of its cerebral vasodilatory properties.

Nicardipine

Nicardipine is a dihydropyridine calcium channel blocker that is specific for L-type calcium channels and is primarily an arteriolar vasodilator. It is selective for L-type calcium channels in vascular smooth muscle as opposed to cardiac myocytes. Moreover, nicardipine has profound coronary and cerebral vasodilatory activity.[104] Its potent BP actions are without negative inotropic effects or suppression of cardiac conduction; it has minimal effects on automaticity and no appreciable venodilation.[105-107]

Nicardipine is used increasingly for hypertensive urgencies and emergencies in children and was found to be both safe and effective. The vasodilatory effects appear to be greater in patients with HTN than in patients with normal BP.[108] In addition, it has gained a role in various cardiovascular, neurosurgical, and general surgery procedures as well as in the postoperative period.[108,109]

In head-to-head trials for treatment of hypertensive emergencies in adults, nicardipine was as effective as nitroprusside. Unlike nitroprusside, nicardipine does not pose the risk for cyanide or thiocyanate toxicity and can be used for a longer duration than nitroprusside. Plasma levels of nicardipine increase rapidly in the first few hours of a continuous infusion but then reach a steady state thereafter.[108] The elimination half-life is a few hours with normal renal function and prolonged with decreased clearance during renal failure.[110] It is highly protein bound,[107,108,111] a property that may be associated with increased cyclosporin levels and lower vecuronium requirements.[112,113] In children the recommended starting dose is 0.5 to 1 μg/kg/min, titrated in 0.5 μg/kg/min increments up to 5 μg/kg/min.[114,115] It is usually effective at 1 to 4 μg/kg/min with a slightly longer onset of action and a much longer elimination half-life compared with nitroprusside.[108]

Because nicardipine may cause thrombophlebitis when given through a peripheral intravenous line, central venous administration is recommended. Like other arterial vasodilators, nicardipine has the potential to increase ICP, although another dihydropyridine (nimodipine) is neuroprotective and is often used in patients with subarachnoid hemorrhage.

Esmolol

Esmolol is a pure β_1-blocker that decreases blood pressure by reducing CO. In a study of 17 children (6 months to 14 years), esmolol was shown to lower BP along with cardiac index, shortening fraction and heart rate, while SVR remained unaffected.[116] It has a rapid onset of action and short half-life (2 to 4 minutes), which makes it ideal for critically ill patients who require judicious titration for BP management.[116,117] Because esmolol is rapidly hydrolyzed by esterases in the cytosol of red blood cells, its clearance is not dependent on organ blood flow or function.[118]

Like labetalol, esmolol has the advantage of not increasing ICP. It should not be used in patients with obstructive lung disease, such as asthma, and should be used with caution if the patient has congestive heart failure. It can cause profound bradycardia.[16] In addition, the use of β-blockers alone should be avoided in children with suspected neuroendocrine catecholamine secreting tumors because the stimulation of α-receptors from these catecholamines without opposing β-stimulation can severely worsen BP.

Because of its short half-life, a loading dose of 300 to 500 μg/kg/min is followed by an infusion of 125 to 500 μg/kg/min in children.[16,119] In a small study examining seven children after they underwent a coarctation of the aorta repair, the mean dose was 173 μg/kg/min.[120] A larger multicenter,

double-blind, randomized, dose ranging study of 116 pediatric patients (younger than 6 years) with postoperative HTN after coarctation of the aorta repair revealed efficacy with doses ranging from 125 to 500 μg/kg/min.[119] Esmolol has been used successfully for the intraoperative management of HTN during pheochromocytoma resection in children.[121,122] Nevertheless, published experience on esmolol therapy in children without cardiovascular lesions is limited.

Labetalol

Labetalol is a combined α and β-blocker that can be given as a continuous infusion or as an IV bolus. It lowers systemic vascular resistance with minimal effect on CO.[123] It provides nonselective β-adrenergic blockade, which reduces reflex tachycardia and increased cardiac contractility that may be seen with vasodilators. β_2-Adrenergic blockade would increase SVR, but this effect is counterbalanced by α-adrenergic blockade, which is selective for the α_1-receptor, resulting in vasodilation. The α-to-β blocking ratio of the oral preparation is 1:3, whereas it is 1:7 for the IV form.[97] Labetalol is therefore most useful in situations where HTN is produced by excessive sympathetic nervous system activity. Labetalol has an onset of action of 2 to 5 minutes with a peak at 5 to 15 minutes, and it can last up to 4 hours. It is metabolized in the liver through glucuronide conjugation and excreted in the urine, bile, and stool.[124]

The infusion is effective at doses of 0.5 to 3 mg/kg/hr, and the agent has a longer duration of action than nitroprusside or nicardipine.[52] Adverse effects include bradycardia and bronchospasm, although in one report a pediatric patient with a history of asthma experienced no breathing problems when given labetalol for HTN.[124] Nevertheless, published experience in the use of labetalol in children is limited.

Hydralazine

Hydralazine causes direct relaxation of arteriolar smooth muscle. It does not dilate capacitance vessels or relax venous smooth muscle.[89] However, this arteriolar vasodilation triggers a compensatory sympathetic response characterized by tachycardia and increased contractility; it also increases renin levels leading to fluid retention.[125] The positive inotropic effects of hydralazine exhibit both cyclic adenylate monophosphate–dependent and independent mechanisms, yet the importance of each remains elusive.[126] Nevertheless, it is known that intracellular calcium homeostasis is altered when hydralazine mediates its effects.[125,127]

Hydralazine, when given orally, has low systemic bioavailability (16% in fast acetylators and 35% in slow acetylators). Consequently, the dose needed to achieve therapeutic levels is higher in fast acetylators because the acetylated form is inactive. *N*-acetylation of hydralazine occurs in the bowel and/or the liver.[125] The half-life is a function of genetically determined acetylation rates, but on average it is approximately 60 minutes; it is cleared hepatically, and elimination is a function of hepatic blood flow.

The initial dose of hydralazine in persons with acute HTN is 0.1 to 0.2 mg/kg/dose given slowly (maximum initial dose, 20 mg) every 4 to 6 hours as needed up to a total of 1.7 to 3.5 mg/kg/day divided in four to six doses.[100,128] BP begins to decrease within 10 to 30 minutes and lasts 2 to 4 hours.[100] Consideration should be given to add a β-blocker to attenuate reflex sympathetic activity. Hydralazine also may be given intramuscularly.[129] The onset of action after IV administration is 5 to 20 minutes, with a duration of 1 to 4 hours.[129] While hydralazine's half-life is variable, its effect on BP generally persists for 2 to 4 hours.[100] Adverse effects are related to the reflexive sympathetic activity and include tachycardia, palpitations, flushing, headache, and dizziness.

Clonidine

Clonidine is a mixed agonist that stimulates both central α_2 adrenergic and imidazoline (I_1) receptors.[130] The stimulation of α_2 adrenergic receptors in the CNS inhibits peripheral sympathetic activity that results in vasodilatation.[131] Its effects are targeted primarily toward arterioles at lower doses.[131] This centrally acting agent is known as an antihypertensive agent with a favorable hemodynamic profile, especially because of the infrequency of postural hypotension. Typically, it is given orally for the management of acute HTN and its onset is within 15 to 30 minutes.[97] It is metabolized hepatically into inactive forms and excreted unchanged in the urine with some gastrointestinal excretion because of enterohepatic recirculation.[132]

In children, the initial dose is 5 to 10 μg/kg/day in divided doses every 8 to 12 hours and, if needed, the dose can be increased to 5 to 25 μg/kg/day in divided doses every 6 hours to a maximum of 0.9 mg/day.[133] For adolescents (age ≥12 years), the recommended dose begins at 0.1 mg/dose orally twice a day and may be increased by 0.1 mg/day on a weekly basis to a total of 0.8 mg/day.[97,134] Adverse effects include bradycardia, dry mouth, and sedation.[130] In addition, severe rebound HTN may occur in patients treated chronically with clonidine if the drug is abruptly stopped.

Enalaprilat

Enalaprilat is an IV form of an ACE inhibitor that blocks the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor.[135] Thus ACE inhibition leads to vasodilation because of decreased levels of angiotensin II.[135] Enalaprilat is also the active form of enalapril that is given by mouth and immediately hydrolyzed by hepatic esterases to the active dicarboxylic acid, enalaprilat.[135] Interestingly, ACE also metabolizes bradykinin; hence bradykinins increase during ACE inhibition, and this effect may contribute to vasodilation as well.[136] In any event, ACE inhibitors decrease systemic vascular resistance and thus afterload and systolic wall stress. Consequently, CO and stroke volume improve.[135] The rationale behind the use of an ACE inhibitor is to attenuate renal damage caused by hyperfiltration and subsequent proteinuria from activation of the renin-angiotensin system.[77]

ACE inhibitors are cleared predominantly by the kidneys. Therefore doses of these agents need to be reduced in patients with renal insufficiency.[135] ACE inhibitors are most potent in patients with high renin levels; significant decreases in BP can occur in this population. Thus patients with elevated renin levels need to be monitored closely after receiving IV enalaprilat. Enalaprilat should not be used in patients with myocardial infarction, bilateral renal artery stenosis, pregnancy, or preeclampsia/eclampsia.[137] Use in preterm infants before glomerular development is complete is also controversial.

The pediatric dose for enalaprilat is 5 to 10 μg/kg/dose IV every 8 to 24 hours as determined by BP response.[138] The adult dose for enalaprilat is 0.625 mg to 1.25 mg IV every 6 hours.[139]

Fenoldopam

Fenoldopam is the first available peripheral dopamine$_1$ receptor (DA1) agonist, the newest class of antihypertensive agents available to treat hypertensive crisis. Stimulation of the DA1 receptor causes vasodilation of peripheral arteries as well as the mesenteric and renal vasculature with less effect in the cerebral and coronary circulation. Thus it lowers BP and peripheral vascular resistance while maintaining renal blood flow.[140]

DA1 receptor stimulation leads to vasodilatation by increasing cAMP, which promotes smooth muscle relaxation. Interestingly, cAMP also inhibits the sodium-hydrogen exchanger and the sodium/potassium-adenosine triphosphatase pump in the renal tubule.[141,142] This feature gives fenoldopam the advantage of maintaining or increasing renal perfusion and is associated with short-term increases in urine output, sodium excretion, and creatinine clearance.

In one blinded, randomized, prospective study of children ranging from 3 weeks to 12 years of age who were scheduled for surgery with a planned induction of hypotension, fenoldopam rapidly lowered mean arterial BP compared with placebo at an infusion rate up to 1.2 μg/kg/min.[143] A retrospective analysis of 13 patients aged 4 months to 18 years with primarily cardiac lesions demonstrated increased urine output with fenoldopam without the need to increase fluid intake; no increase in serum creatinine levels or adverse hemodynamic effects were observed.[144]

Like other drugs that act through adrenergic receptor stimulation, tolerance develops in patients who take fenoldopam for longer than 48 hours. With respect to toxicity, fenoldopam has the potential to increase intraocular pressure and is known to cause a dose-dependent tachycardia.[140,143] It has a half-life ranging from 5 to 10 minutes.[140] It is usually effective at doses between 0.8 to 1.2 μg/kg/min and has an onset and duration of action similar to that of IV nicardipine.[52,143] There are few pediatric case reports of hypertensive urgencies and emergencies that have responded to fenoldopam.[145] In addition, one case has been reported of a child with severe HTN resulting from renal graft rejection who did not respond to fenoldopam.[146] Thus few data support the use of fenoldopam in the treatment of hypertensive emergencies in children.

Isradipine

Isradipine is a second-generation dihydropyridine calcium channel blocker that is specific for the L-type calcium channel found in smooth muscle. It lowers BP by relaxing arteriolar smooth muscle, leading to decreases in peripheral vascular resistance. As a result, the calcium channel blockers elicit a sympathetic discharge that causes stimulation of the sinoatrial node and consequent tachycardia.[147] It is an orally administered agent that has a rapid onset of action with a peak effect that can last as long as 3 hours. It has been reported to be effective in children with chronic HTN and secondary forms of HTN.[148,149]

In one retrospective study examining 80 children with secondary HTN over a 5-year period, isradipine was used individually or in combination with other antihypertensive medications. Isradipine monotherapy decreased SBP by a mean of 13 mm Hg and DBP by 10 mm Hg over a broad range of ages from 1 week to 16.8 years of age.[149] Adverse events attributed to isradipine occurred in 9.5% of patients and included headache, dizziness, flushing, and tachycardia.[149] Similar responses to isradipine (a decrease in systolic pressure of 11.8% and diastolic pressure of 17.4%) were seen retrospectively in 53 children (ages 1 day to 16 years) treated with an average dose of 0.4 mg/kg/day.[150]

Isradipine undergoes extensive first-pass metabolism in the liver by the cytochrome 450 isoenzyme CYP3A4.[151] It is highly protein bound and is excreted essentially as inactive metabolites in the urine (two thirds) and feces (one third).[151] The recommended dosage based on a few reports is 0.05 to 0.1 mg/kg/dose orally three to four times a day; the usual dose is 0.3 to 0.4 mg/kg/day divided every 8 hours, with a maximum of 0.8 mg/kg/day up to 20 mg/day.[16,97]

Summary

Hypertensive urgencies and emergencies are an underappreciated cause of morbidity and mortality in children. The intensivist needs a heightened awareness for factors that predispose children to severe hypertensive events as well as an understanding of the clinical symptoms that may reflect end-organ damage from critically high BPs.

It behooves the astute clinician to remain vigilant of extremes in BP, whether they are significantly low or high. The emphasis of didactics (e.g., Pediatric Advance Life Support and Advanced Trauma Life Support) is on the rapid recognition of sentinel signs of hypotension in children and the adverse effects of delayed therapy. Other than the clinical manifestations of increased intracranial HTN, little attention is given to hypertensive-initiated damage to the CNS, cardiovascular system, or renal system.

The appropriate evaluation of the hypertensive child includes prompt recognition of elevated BPs that may acutely compromise organ function versus BPs that afford more time for management. Understanding the conditions that commonly occur in the acute care setting will enable the practitioner to anticipate and respond carefully before organ health is threatened.

Chapter 74

Cellular Respiration

Jerry J. Zimmerman, Amélie von Saint André-von Arnim, and Jerry McLaughlin

In every one of us there is a living process of combustion going on very similar to that of a candle, and I must try to make that plain to you. For it is not merely true in a poetical sense.

Michael Faraday, *A Course of Six Lectures on the Chemical History of a Candle* (1861)

PEARLS

- Mitochondria are responsible for the generation of more than 95% of adenosine triphosphate synthesized to support aerobic respiration. Mitochondria are also involved in intracellular signaling, intracellular calcium regulation, cellular differentiation and growth, and cellular death pathways. An independent mitochondrial genome is located within the mitochondrial matrix.
- There are three paramount regulatory steps along the respiration metabolic pathways:
  1. Oxygen availability to serve as the ultimate electron acceptor.
  2. Availability of nutrient metabolism to generate reducing equivalents in the form of reduced nicotinamide adenine dinucleotide (NADH) and the reduced form of flavine dinucleotide ($FADH_2$).
  3. Overall cellular energy state defined by the ratio of adenosine triphosphate/adenosine diphosphate.
- Lactate metabolism in critical illness is complex and often does not necessarily indicate ischemic tissues. A common clinical scenario occurs during volume and vasoactive-inotropic resuscitation of patients with normal saline and epinephrine, in which a chloride load (iatrogenic hyperchloremia) and type B lactic acidosis may be interpreted as recalcitrant shock requiring further escalation of fluid and vasoactive-inotropic support. This scenario may initiate a vicious cycle and potential overresuscitation.
- If any of the five sources of hypoxemia—hypoventilation, diffusion impairment, low inspired oxygen, shunt, ventilation/perfusion mismatch—impairs adequate oxygenation of hemoglobin and limits cellular respiration, hypoxemic dysoxia results.
- Cytopathic dysoxia occurs when oxygen delivery is normal but cellular pathophysiology prevents utilization of oxygen as the terminal electron transport acceptor.

In 1920, Haldane was credited with the observation that hypoxemia not only stops the [respiration] machine, but wrecks the [respiration] machinery as well. Indeed, the priorities of pediatric advanced life support are to avoid shock and respiratory failure, and the focus of cardiopulmonary resuscitation is restoration of airway, breathing, and circulation, all targeted to maintain or reestablish oxygen delivery to tissues and cells. During critical illness, marginal oxygen delivery and/or oxygen consumption frequently manifest as the rate-limiting step for efficient energy production in the form of adenosine triphosphate (ATP). Inadequate ATP impairs the translation of cellular structure to cellular function, a defining characteristic of life.[1] A working knowledge of cellular respiration basically summarizes the key tenets of critical care medicine. This chapter reviews the metabolism of respiration, summarizes various modalities for monitoring respiration, and provides clinical correlation of alterations in respiration that are addressed by intensive care.

Metabolism of Respiration

Oxygen Chemistry

It is appropriate to initiate a discussion of respiration by describing the relevant characteristics of the rate-limiting substrate, namely molecular oxygen, that serves as the terminal electron acceptor in cellular respiration.[1] Because of the paramount role of oxygen in facilitating efficient production of ATP, oxygen has played a central role in terms of evolution of complex multicellular life.[2] In the biosphere, the concentration of oxygen is carefully regulated by the processes of photosynthesis and respiration, the former producing—and the latter consuming—atmospheric dioxygen. Premolecular oxygen appeared on Earth's surface approximately 2 billion years ago and now represents the most abundant element on Earth's crust. At its baseline triplet state, oxygen is a diradical with two unpaired electrons with parallel spin occupying the outer orbital. In its role as the ultimate electron accepter in cellular respiration, molecular oxygen undergoes a four-electron reduction to water. With the benefit of multiple redox electron exchanges, this process permits controlled release of energy from carbohydrate, fat, and protein energy substrates. Successive one-electron additions to molecular oxygen result in the production of superoxide anion, hydrogen peroxide, hydroxyl radical, and water, respectively (Figure 74-1). These partially reduced oxygen compounds are referred to as *reactive oxygen species* and identify the so-called *antagonistic pleiotropy* characteristic of oxygen.[3]

Derivation of the parent toxic reactive oxygen species, superoxide anion, occurs by multiple mechanisms, but the following four are prominent:

1. Mitochondrial electron transport bleed (approximately 1% to 2% of all electrons shuttled across mitochondrial complexes I, II, and III produce partially reduced oxygen species)[4]

2. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidoreductases and the related cytochrome P-450 oxidation reactions[5]
3. Xanthine oxidase during reperfusion following ischemia events[6]
4. Cyclooxygenase and lipoxygenase pathways in the metabolism of arachidonic acid[7]

Oxygen toxicity was first predicted by both Priestly and Lavoisier in 1729. It has been estimated that approximately 2 billion molecules of superoxide anion and hydrogen peroxide are produced per cell per day. An antioxidant repertoire that includes superoxide dismutase, catalase, glutathione peroxidase, uric acid, vitamin C, and vitamin E counteracts this oxidant stress to minimize a tendency toward "rust and rancidity." However, oxidant stress plays an important role in generalized aging as well as inflammation and ischemia-reperfusion pathophysiology. As Fridovich[8] has noted, "the aerobic lifestyle offers great advantages but is fraught with danger."

Nitrogen chemistry is also involved in the generation of reactive molecular species. Nitric oxide (NO) is known to be generated from at least four NO synthase isoenzymes, including constitutive, inducible, neuronal, and mitochondrial forms. Figure 74-2 depicts the reaction catalyzed by nitric oxide synthase.[9]

Production of NO is particularly prominent during periods of inflammation. At least in septic patients, intensity of inducible NO production as measured by blood or urine end catabolic products nitrate and nitrite, is directly associated with various measures of illness severity reflecting multiple organ dysfunction syndrome and death. Particularly in the setting of tissue hypoxia, NO is believed to play a role in regulation of mitochondrial respiration through nitrosyl complexes with various iron-sulfur center enzymes as well as direct competition with oxygen for binding at the heme active site of cytochrome oxidase.[10,11] Competitive inhibition of NO with oxygen at cytochrome oxidase results in decreased oxygen consumption, decreased binding affinity for oxygen, and reduced ATP production.

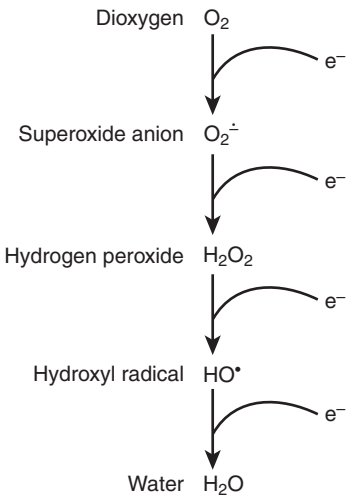

Figure 74–1. Successive one-electron reductions of molecular dioxygen to water.

Under specific conditions superoxide anion and NO can condense to form the powerful oxidant peroxynitrite with diffusion-limited kinetics: $7 \times 10^9\ M^{-1} \times sec^{-1}$.[12] Behavior of NO, superoxide anion, and peroxynitrite in clinical biochemistry has been characterized as "the good, the bad, and the ugly."[13] For example, nitrotyrosine and dityrosine represent tissue markers of peroxynitrite histopathology.[14] Peroxynitrite has been demonstrated to be involved in lipid peroxidation of cell and organelle membranes, damage to various elements of the mitochondrial electron transport chain and ATP synthase, inhibition of glyceraldehyde 3-phosphate dehydrogenase, injury of the sodium-potassium ATPase pump, disruption of plasmalemma sodium channels, production of DNA strand breaks, and activation of the poly-adenosine ribosyl phosphate system.[15] Again in reference to cellular respiration, peroxynitrite can mediate irreversible inhibition of the Krebs cycle enzyme aconitase; mitochondrial complexes 1, 2 and 3; cytochrome oxidase; ATP synthase; and creatine kinase as well as increase wasteful proton leakage. Reduced suflhydryls represent another important target of peroxynitrite oxidation, resulting in alteration of protein structure and function.[16] Peroxynitrite is known to directly alter pulmonary surfactant and injure human myocardial protein.[14,17]

Reactive oxygen and nitrogen species are also known to affect intracellular signaling through a number of redox-sensitive transcription factors, notably nuclear factor-κB (NFκB) and activator protein-1 (AP-1).[18] For example, as an aspect of the pathophysiology of gram-negative sepsis, interaction of endotoxin, toll-like receptor-4, and NADPH oxidase result in an increased flux of reactive oxygen species and subsequent activation of NFκB associated with transcription activation of a host of proinflammatory mediators.[19] In addition, peroxynitrite is known to modulate cell signaling by both phosphorylation as well as oxidation of critical protein tyrosine residues along the mitogen-activated protein kinase pathways.[20]

Mitochondria

It has been estimated that more than 1 billion years ago some aerobic bacteria invaded and subsequently colonized some form of primordial eukaryotic cells that themselves lacked the ability to use oxygen. At some point a symbiotic relationship developed between the cell and the aerobic bacteria, and this relationship has remained steadfast through evolution.[21,22] Evidence for the persistence of this endosymbiotic relationship suggesting that mitochondria have retained many aspects of their bacterial origins includes the observations that mitochondria only arise from other mitochondria; that mitochondria maintain their own genome; that the mitochondrial chromosome

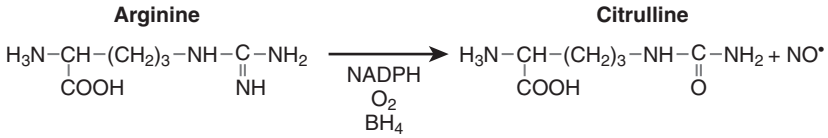

Figure 74–2. Synthesis of NO by NO synthase. *BH4,* Tetrahydrobiopterin.

is bacteria-like, circular in structure, and without associate histones; that mitochondria synthesize their own proteins; and that these mitochondrial proteins, like bacterial proteins, exhibit *N*-formyl methionine; and that antibiotics that inhibit protein synthesis in bacteria are also toxic to mitochondria.[23]

Mitochondria are responsible for the generation of more than 95% of ATP synthesized to support aerobic respiration (Figure 74-3). Enormous oxygen consumption by "power plant" mitochondria represents a double-edged sword, on the one hand permitting efficient production of ATP, but on the other hand a potential source of high quantities of reactive oxygen species. Assuming 388 L of oxygen consumed per day by a normal adult, this would require 2×10^{19} molecules of cytochrome oxidase. Considering this requirement as well as that of other members of the mitochondrial electron transport chain outlined below, the surface area of mitochondrial cristae inner membrane to scaffold this quantity of respiration elements[24] is approximately 14,000 m^2.

In addition to their role in facilitating aerobic respiration, mitochondria are also involved in intracellular signaling, intracellular calcium regulation,[25] cellular differentiation and growth, and cellular death pathways.[26,27] With respect to the latter function, the mitochondria provide close monitoring for a number of cellular "danger signals." These include loss of transmembrane potential, decreased ATP production, increased influx of reactive oxygen and reactive nitrogen species, leakage of mitochondrial proteins into the cytoplasm via mitochondrial permeability transition pores, activation of hypoxia-responsive genes, and recognition by the cell of mitochondrial proteins with signature *N*-formyl methionine.[23] Mitochondria in cells may undergo cycles of both fusion and fission.[28] If the mitochondria "senses" overwhelming cell damage as manifested by excessive reactive oxygen species, DNA damage, denatured protein, ongoing inflammation, hypoxia, or even deprivation of growth factors, the mitochondrial pathway of cellular apoptosis may be initiated.[29,30] If apoptosis is initiated by excessive reactive oxygen species, activation of the sphingomyelin/ceramide cycle precedes apoptosis.

Critical mitochondrial damage results in increased mitochondrial permeability, the mitochondrial permeability transition that results in release of proapoptotic proteins, including cytochrome c from the mitochondria into the cytoplasm. This results in activation of various caspase cascades and resultant DNAase activation and DNA dissolution.[31] Activation of the apoptotic pathway orchestrating cell death is also governed by the relative concentrations of proteins BCL-2 and BCL-X. Integrity of the mitochondrial transport chain complexes defines a fine line between maintaining mitochondrial homeostasis and efficient respiration versus excessive oxygen free radical production, mitochondrial dysfunction, and mitoptosis. This balance is maintained through multiple feedback signals related to mitochondrial proton and calcium concentrations, reactive oxygen species, overall mitochondrial redox state, mitochondrial membrane potential, and mitochondrial matrix pH, all of which affect the cascade of electron transfer along the mitochondrial transport chain.[23] It has been demonstrated that pathologic metabolic downregulation of cytochrome oxidase, such as in the setting of excessive mitochondrial production of reactive nitrogen and oxygen species, manifests as multiple organ dysfunction syndrome.[32]

Alterations in mitochondrial function in the setting of shock have been extensively scrutinized.[33-35] In addition to decreased activity of specific mitochondrial enzymes previously indicated, altered translocase activity and mitochondrial calcium transport are also coincident with actual changes in mitochondrial morphology. In sepsis, increased NO production has been associated with activation of the poly-adenosine ribosyl phosphorylase (PARP) pathway, the former associated with impaired binding of oxygen to cytochrome oxidase and the latter associated with cellular depletion of NADH.[36] In various models of multiple organ dysfunction syndrome and sepsis, mitochondrial permeability transition has been shown to result in collapse of the mitochondrial electrochemical gradient and impairment of ATP synthesis coincident with calcium influx into the mitochondria. Sepsis inflammation can induce a vicious cycle of oxidative mitochondrial damage leading to an increased flux of reactive oxygen species that further damage mitochondrial respiration components, resulting in mitochondrial glutathione depletion, enhanced mitochondrial membrane lipid peroxidation and decreased copy number, increased deletions, and decreased messenger RNA transcripts from mitochondrial DNA (Figure 74-4).[37]

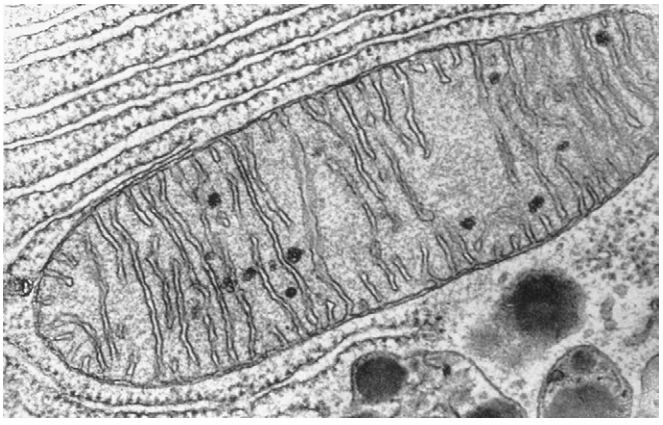

Figure 74–3. Electron micrograph of a mitochondria at the site of cellular respiration. An invaginated cristae membrane provides the scaffolding for components of the electron transport chain.

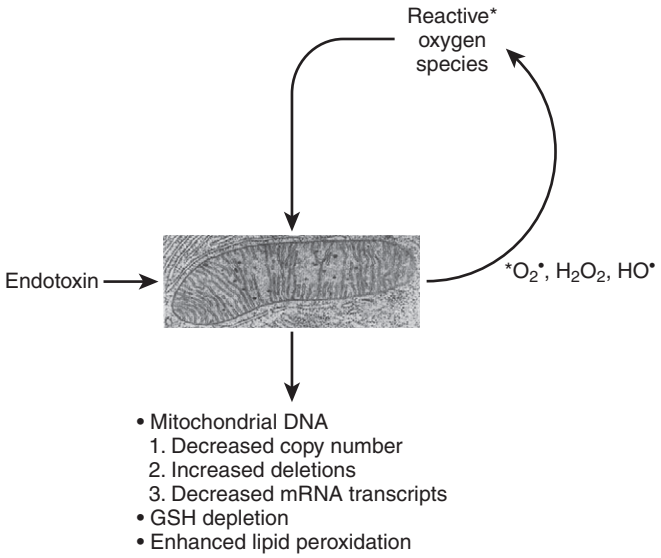

Figure 74–4. Vicious cycle mitochondrial injury in the setting of excessive reactive nitrogen/oxygen species.

The independent mitochondrial genome; located within the mitochondrial matrix, is comprised of double-stranded, circular DNA of 16.6 kb and codes for 37 genes, including proteins involved in various redox reactions, oxidative phosphorylation, ATP synthesis, and enzymes comprising the Krebs cycle, fatty acid beta-oxidation, and pyruvate oxidation.[38] Mitochondrial DNA mutations associated with the gene coding for cytochrome oxidase have been clinically linked to Leigh syndrome; mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke (MELAS); encephalomyopathy; lactic acidosis; and mitochondrial proliferation in muscle biopsies, the so-called *characteristic histopathology of ragged red fibers*.[21]

Adenosine Triphosphate

ATP is considered the molecular unit of intracellular energy currency. ATP derives its inherent energy secondary to anhydride bonds connecting adjacent phosphate functional groups. Hydrolysis of ATP energy generates energy for all cellular processes. In addition ATP also serves as a cofactor for signal transduction reactions using a variety of kinases as well as adenyl cyclase. Normally cellular ATP concentration is maintained in the range of 1 to 10 mmol/L, with a normal ratio of ATP/ADP of approximately 1000. Totally quantity of ATP in an adult is approximately 0.10 mol/L. Approximately 100 to 150 mol/L of ATP are required daily, which means that each ATP molecule is recycled some 1000 to 1500 times per day. Basically, the human body turns over its weight in ATP daily.[39]

Transmembrane proton flux through the mitochondrial ATPase synthase complex occurs at an estimated rate of 3×10^{21} protons per second. This corresponds to ATP reformed at a rate of 9×10^{20} molecules/sec, or approximately 65 kg ATP recycled per day in a normal resting adult (Figure 74-5).[24]

Respiration, Metabolic Pathways

Glycolysis

As previously indicated, cellular respiration allows controlled release of free energy from carbohydrate, fat, and protein energy substrate. Cellular respiration consists of three related series of biochemical reactions:

1. Degradative reactions resulting in the formation of acetyl coenzyme A and reducing equivalents
2. Metabolism of acetate to carbon dioxide in the Krebs cycle with generation of additional reducing equivalents
3. Shuttling of electrons generated from reducing equivalents along the mitochondrial electron transport chain

Acetate coupled to coenzyme A (AcCoA) is derived from carbohydrates, lipids, and proteins. Glucose is transported into cells via glucose transporter (GLUT) receptors and osmotic gradients (see Chapter 77). Ten enzymatic reactions within the cell cytoplasm define the metabolic pathway, termed *glycolysis*. These initial series of reactions ultimately generate two net molecules of ATP, two molecules of NADH, and two molecules of pyruvate.

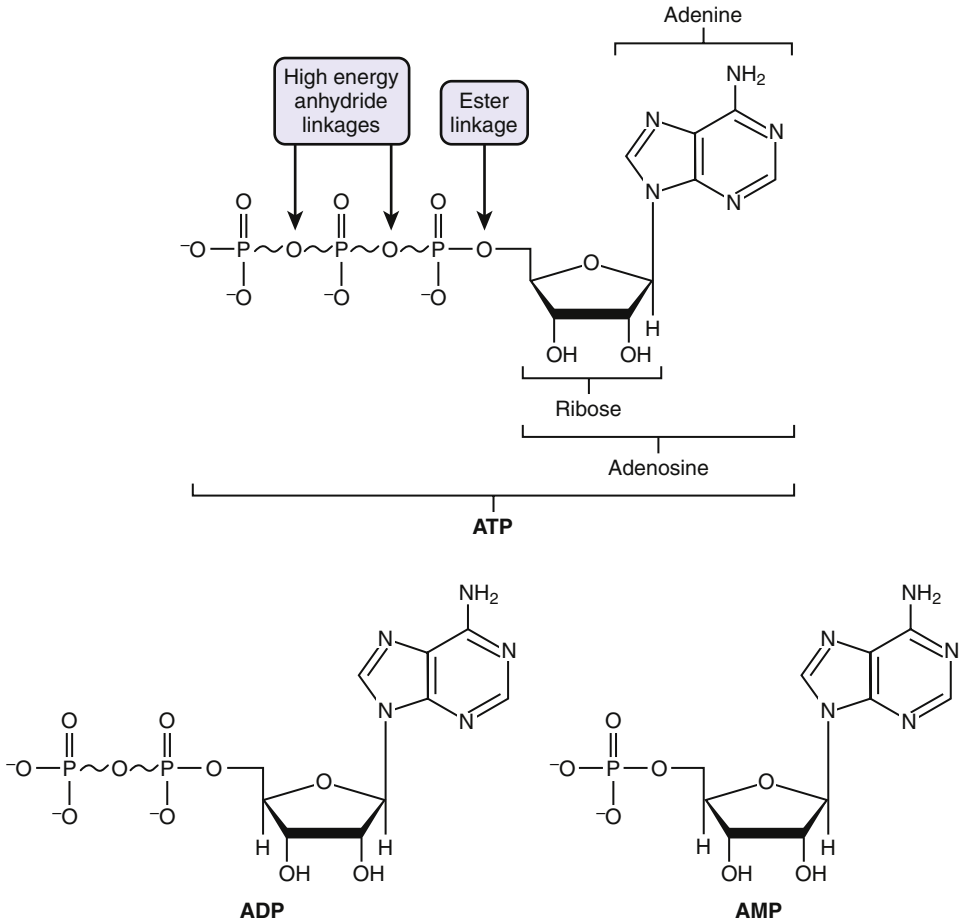

Figure 74–5. Structure of ATP. *(Modified from Baynes JW, Dominiczak MH:* Medical biochemistry, *New York, 2009, Mosby Elsevier.)*

The fates of pyruvate is multiple. Under anaerobic conditions, pyruvate may be reduced by NADH to lactate to regenerate NAD^+. Alternatively, pyruvate is shuttled to the mitochondria, where it is further metabolized to carbon dioxide (CO_2) and AcCoA. Pyruvate transamination yields alanine, whereas pyruvate carboxylase generates oxylacetate (Figure 74-6).

Catabolism of fatty acids by β-oxidation generates one molecule of AcCoA and one molecule each of $FADH_2$ and NADH for each two-carbon fatty acid fragment cycle. These reactions occur in the mitochondria after fatty acid transport by a carnitine transport system. It should be appreciated that generation of AcCoA by fatty acid β-oxidation occurs independent of pyruvate dehydrogenase that can be rate limiting for complete glucose metabolism. Particularly as an aspect of the metabolic stress response mediated by cortisol, catecholamines, and interleukins 6 and 2, protein degradation can occur with release of amino acids. All amino acids may be catabolized to either AcCoA or some Krebs cycle intermediate. Accordingly, amino acids can be mobilized for energy production as well as de novo protein synthesis. Alternatively, amino acids can undergo gluconeogenesis, a costly process that basically requires four ATP molecules plus two GTP molecules and two NADH molecules to regenerate one molecule of glucose from two molecules of pyruvate (see Chapter 77). ATP and GTP for these series of reactions are provided by β-oxidation of fatty acids.

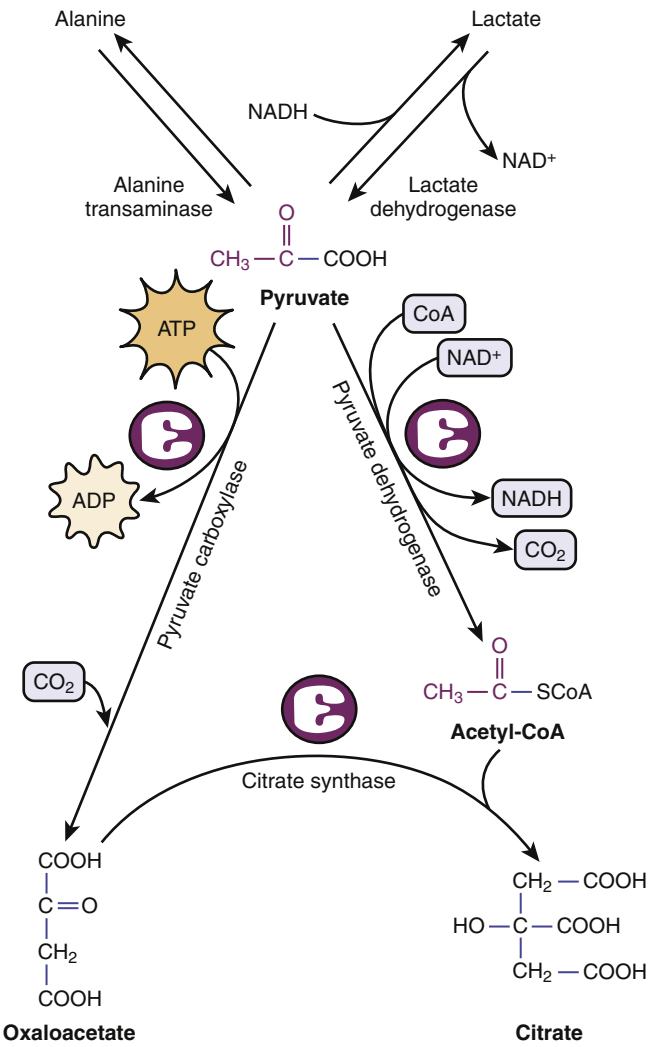

Figure 74–6. Metabolic fates of pyruvate, end product of glycolysis. *(Modified from Baynes JW, Dominiczak MH:* Medical biochemistry, *New York, 2009, Mosby Elsevier.)*

Pyruvate is metabolized in the mitochondria to AcCoA and CO_2 via pyruvate dehydrogenase, a large polyhedral protein complex with molecular weight of 10×10^6 Da. Thiamin, lipoic acid, magnesium, and coenzyme A serve as cofactors for this reaction, which represents the first irreversible step in terms of mitochondrial oxidation of pyruvate. This key reaction is regulated by a family of pyruvate dehydrogenase kinases. As noted above, AcCoA is also generated within the mitochondria by β-oxidation of fatty acids. Two molecules of AcCoA may condense to form acetyl acetate, which can subsequently be metabolized to β-hydroxy butyrate and acetone, all of which may be used as energy substrate by the heart, brain, and skeletal muscle during fasting after a depletion of glycogen stores.

Krebs Cycle

The Krebs cycle summarizes a circular series of reactions in the mitochondria to metabolize AcCoA to two molecules of CO_2 with resultant generation of one molecule of GTP, three molecules of NADH, and one molecule of $FADH_2$. GTP is equivalent to ATP in terms of energy charge. Although oxygen itself is not part of the Krebs cycle, its presence at the end of the mitochondrial electron transport chains ensures recycling of NAD^+ and FAD required in the Krebs cycle (Figure 74-7).

AcCoA, derived from glucose, fatty acids, or protein catabolism, condenses with oxaloacetate in step 1. One rotation of reactions in the mitochondria metabolizes the AcCoA to two molecules of CO_2, generates one ATP equivalent in the form of GTP, and generates reducing equivalents in the form of NADH and $FADH_2$.

Electron Transport Chain

Electrons derived from reducing equivalents NADH and $FADH_2$ are shuttled along the mitochondrial electron transport chain, ultimately reducing molecular oxygen to water. Basically, for each pair of electrons involved in one hydride equivalent, three molecules of ATP are produced. Five complexes of proteins and cytochromes comprise the mitochondrial electron transport chain and facilitate a step-down flow of $FADH_2$ and NADH reduction potential along the inner membrane of the mitochondria. These redox reaction complexes include NADH dehydrogenase–ubiquinone oxidoreductase (complex 1), succinate dehydrogenase–ubiquinone oxidoreductase (complex 2), ubiquinone–cytochrome C oxidoreductase (complex 3), cytochrome c oxidase (complex 4), and ATP synthase (complex 5). Electrons in the form of hydride ions from NADH and $FADH_2$ cascade along these protein/cytochrome complexes toward molecular oxygen. Protons generated during these reactions are pumped across the inner mitochondrial membrane matrix into the intermembrane space, generating a proton motive force. The proton electrochemical gradient across the inner mitochondrial membrane drives ATP synthesis by a reaction that has been termed *chemiosmosis*.[41] Energy for ATP synthesis arises from an influx of these protons back into the matrix, literally through the rotary motor of ATP synthase.[42]

The proton pore involves the c-ring and the a-protein. The rotary component is the coiled-coil γ-subunit, which is bound

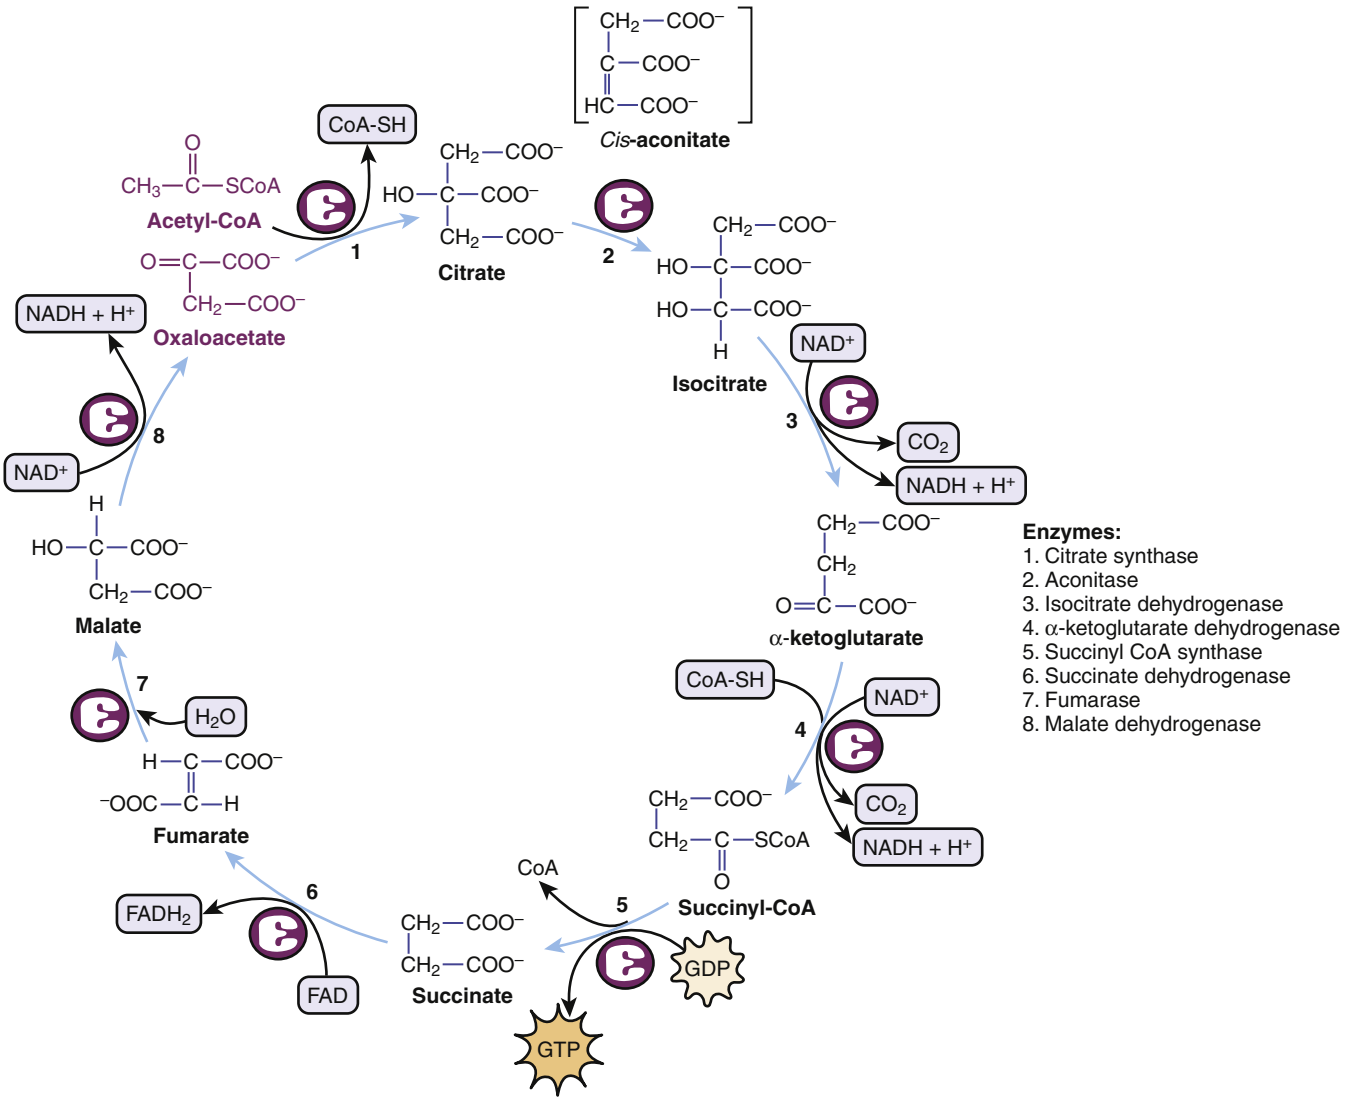

Figure 74–7. Circular series of reactions involved in the Krebs cycle. *(Modified from Baynes JW, Dominiczak MH:* Medical biochemistry, *New York, 2009, Mosby Elsevier.)*

to the ε-subunit and to the c-ring. The stationary component is the hexameric $\alpha_3\beta_3$ unit and is fixed by the δ, b, and a proteins (Figure 74-8).

Although multiple regulatory steps exist along the respiration metabolic pathways, the following three are prominent:

1. Oxygen availability to serve as the ultimate electron acceptor. This will depend on oxygen delivery to the tissue as well as regulation of oxygen binding to the heme moiety of cytochrome oxidase by NO, as previously discussed.
2. Availability of nutrient metabolism to generate reducing equivalents in the form of NADH and $FADH_2$, as previously noted. Depletion of NADH can occur in instances of severe cellular stress after activation of the PARP.
3. Overall cellular energy state defined by the ratio of ATP/ADP.

Specific adenine nucleotide translocase on the inner mitochondrial membrane as well as a voltage-dependent ion channel representing the most abundant protein of the outer mitochondrial membrane facilitate ATP transport out of the mitochondria for use as energy currency for all cellular functions.

Monitoring of Tissue Oxygenation

Blood Lactate Monitoring in Critically Ill Patients

In general, lactic acidosis occurs when there is an imbalance between production and clearance of lactate. Measurement of lactate in human blood was first described in 1843 in a lethal case of fulminant septic shock due to puerperal fever in a young woman.[43] Blood lactate monitoring is frequently performed in critically ill patients, usually with the aim of detecting tissue hypoxia[44] with resultant anaerobic hyperlactatemia, traditionally termed *type A lactic acidosis*. However, other processes not related to tissue hypoxia can also result in increased blood lactate levels,[45] such as aerobic hyperlactatemia or type B lactic acidosis that complicates clinical interpretation and therapy in cases of elevated lactate concentration. Although lactic acidosis is often associated with a high anion gap and is generally defined as a lactate level greater than 5 mmol/L and a serum pH less than 7.35, the presence of hypoalbuminemia may mask the anion gap and concomitant alkalosis may raise

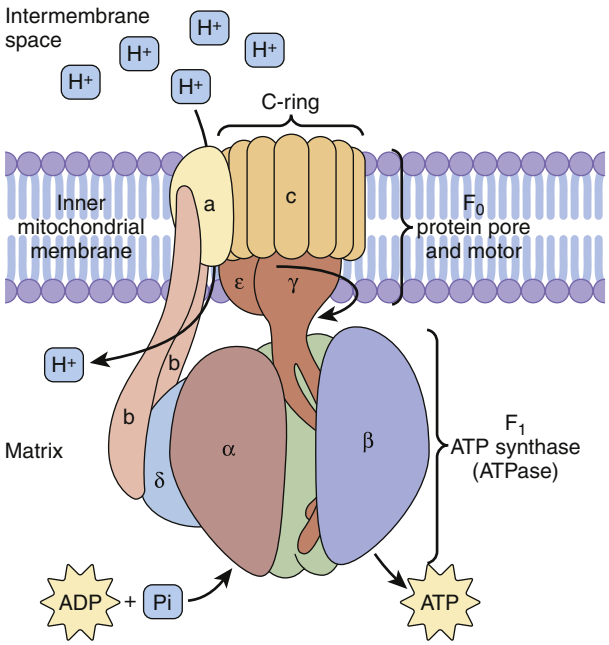

Figure 74–8. ATP synthase complex consists of a motor (proton gradient pore, F_0) and generator (ATP synthase, F_1). *(Modified from Baynes JW, Dominiczak MH:* Medical biochemistry, *New York, 2009, Mosby Elsevier.)*

the pH. As originally reported by Huckabee,[45a] normal arterial blood lactate is approximately 0.620 mmol/L and venous lactate is slightly higher at 0.997 mmol/L.

Anaerobic Hyperlactatemia

During anaerobic conditions, pyruvate derived from the conversion of glucose cannot enter the Krebs cycle via AcCoA to produce energy. Instead, pyruvate is converted into lactate, known as the *Pasteur effect*. The normal lactate/pyruvate ratio is approximately 20:1, and it rises under hypoxic conditions. The causal relationship between anaerobic hyperlactatemia and tissue hypoxemia has been confirmed by experimental[46,47] and clinical[44] studies; decreasing systemic oxygen delivery (DO_2) until oxygen demand can no longer be met and limiting oxygen consumption by DO_2 coincides with a sharp increase in lactate levels. Accordingly, in the early phase of septic shock hyperlactatemia is accompanied by oxygen supply dependency.[48] In severe sepsis or septic shock prior to resuscitation, hyperlactatemia coincides with a low central venous oxygen saturation[49] and increased lactate/pyruvate ratios,[50] whereas increases in DO_2 are associated with reductions in lactate.[49] No critical level of DO_2 or SvO_2 could be associated with hyperlactatemia. This could represent regional differences in DO_2 and demand.[51] However, improving capillary perfusion was shown to correlate with a reduction in lactate levels in patients with septic shock, independent of changes in systemic hemodynamic variables.[52] The latter observation illustrates the hypothesis that, in the absence of low systemic DO_2 relative to systemic metabolic demand, microcirculatory processes hampering oxygen use at the tissue level may raise lactate levels.

Aerobic Hyperlactatemia

Various studies demonstrate that mechanisms other than tissue hypoxia can account for hyperlactatemia, including (1) mitochondrial dysfunction[35,53,54]; (2) decreased lactate clearance in liver dysfunction,[55,56] status post liver surgery[57] and cardiac surgery,[58] as well as in sepsis,[59,60] where it was shown to predict poor outcome[61]; (3) increased aerobic glycolysis resulting in amounts of pyruvate exceeding the pyruvate dehydrogenase capacity that can be triggered by cytokine-mediated uptake of glucose[62,63] or catecholamine-stimulated increased Na-K pump activity[45,64-67]; (4) impaired activity of pyruvate dehydrogenase, essential for the conversion of pyruvate into AcCoA, that can be inhibited in sepsis,[68,69] as well as in thiamin deficiency (beriberi)[70]; (5) alkalosis[71] by increasing cellular lactate efflux due to an H^+-linked lactate carrier mechanism across the cell membrane; (6) acute lung disease[55,72]; (7) several drugs and intoxications such as epinephrine (by increased glycogenolysis, glycolysis, and stimulation of the Na-K pump),[73,74] metformin (particularly in the presence of renal insufficiency), and nucleosidic reverse transcriptase inhibitors for the treatment of HIV (by inducing mitochondrial cytopathy)[75-77]; and (8) intoxications with methanol, cyanide (by inhibition of oxidative phosphorylation),[78] or ethylene glycol (by artifactual reaction of lactate electrodes).[79]

In summary, during critical illness, the source of lactate is often assumed to be ischemic tissues that use anaerobic metabolism. This is superficially supported by lactate as an adverse prognostic marker.[80,81] However, lactate metabolism in critical illness is complex and often does not indicate ischemic tissues.[82,83] A common clinical scenario occurs during volume resuscitation of patients (iatrogenic hyperchloremia) or epinephrine infusions, in which a chloride load and type B lactic acidosis are interpreted by the body as "shock," requiring more fluid and more vasoactive-inotropic support. This scenario may initiate a vicious cycle and potential over-resuscitation.[84] It is essential to diagnose this syndrome correctly and adjust management accordingly.

Given the available evidence, patients presenting with hypotension and an elevated lactate level (>5 mmol/L) have a grave prognosis with a high mortality rate (>80%). Likewise, patients who are critically ill and do not clear lactate by 48 hours have a similarly high mortality rate.[85] There are no data currently available, however, to suggest that monitoring lactate levels beyond this time frame is prognostically useful. Early goal-directed therapy in severe sepsis is an example of outcome benefit that arguably targets the patient's primary pathophysiology rather than lactic acidosis per se.[49,86] Hence, there are no current data demonstrating that therapeutic maneuvers specifically targeted at decreasing lactate levels are beneficial. The treatment of the patient with lactic acidosis should therefore be aimed at the underlying disease and the maintenance of organ perfusion and not the lactate concentration itself. Accordingly, the routine daily measurement of serum lactate levels in critically ill patients remains controversial.

Continuous Central Venous Oxygen Saturation Monitoring

Monitoring of the mixed venous oxygen saturation (SvO_2) is used as a surrogate for quantifying the balance between systemic oxygen delivery and consumption during the treatment of critically ill patients.[87] Measurement of SvO_2 requires placement of a pulmonary artery catheter with a risk/benefit ratio that is still a matter of controversy in adult patients[88-90] and rarely performed in pediatric patients. However, measuring

central venous oxygen saturation ($ScvO_2$) only requires a central venous catheter, routinely inserted in critically ill patients, and a fiber optic catheter with a spectrophotometer for continuous $ScvO_2$ assessment. $ScvO_2$ largely reflects the degree of oxygen extraction from the brain and the upper part of the body since the catheter tip usually is located in the superior vena cava. At baseline, $ScvO_2$ is about 2% to 3% less than SvO_2 because, overall, the lower body extracts less oxygen than the upper body, resulting in a higher inferior vena cava oxygen saturation. Readings may be taken intermittently by blood sampling and co-oximetry or continuously with a fiberoptic catheter. However, beneficial effects on patient outcome to date[49] have only been demonstrated with continuous measurement of $ScvO_2$.

Low values of SvO_2 or $ScvO_2$ indicate a mismatch between oxygen delivery and tissue oxygen need.[91] Monitoring $ScvO_2$ has been successfully used as a hemodynamic goal in the management of early sepsis. Rivers et al.[49] demonstrated in a prospective randomized study in adult patients with severe sepsis and septic shock that, in addition to maintaining central venous pressure in the range of 8 to 12 mm Hg, mean arterial pressure above 65 mm Hg, and urine output higher than 0.5 mL/kg/hr, maintenance of an $ScvO_2$ above 70% resulted in an absolute reduction of mortality by 15%. Thus the guidelines of the Surviving Sepsis Campaign[92] stated that the use of SvO_2 and $ScvO_2$ is equivalent in the management of adult patients with severe sepsis and septic shock. In pediatric patients with septic shock, directing treatment to the end point of $ScvO_2$ at 70% or greater was also associated with a significant decrease in the 28-day mortality rate from 39.2% to 11.8%.[93] $ScvO_2$ goal-directed therapy resulted in more crystalloid, blood product, and inotropic support during the first 6 hours compared with the control group receiving standard resuscitation.

Continuous monitoring of SvO_2 is interesting, but clear indications for this technique in children as well as $ScvO_2$ target values remain to be determined. It has been shown that exact numeric values of SvO_2 and $ScvO_2$ saturations are not equivalent in various hemodynamic conditions.[94] Some authors have therefore argued that $ScvO_2$ cannot be used as surrogate for SvO_2 under conditions of circulatory shock.[95] However, for clinical purposes, the trends between these values were found to be reliable and clinically valuable.[96] Based on the evidence available, the primary indication for the use of central venous oximetry is as part of the early resuscitation in severe septic and septic shock patients. Further research is needed to elucidate the efficacy of venous oximetry in other patient groups as well as to assess whether an intermittent measurement using central venous blood gas analysis is as effective as continuous measurement of $ScvO_2$ using fiberoptic catheters.

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) is a noninvasive technique for measuring brain activity. It works by detecting the changes in blood oxygenation and flow that occur in response to neural activity. When a brain area is more active, it consumes more oxygen; to meet this increased demand, blood flow increases to the active area.[97,98] Hemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated. This difference in magnetic properties leads to small differences in the MR signal of blood depending on the degree of oxygenation. Since blood oxygenation varies according to the levels of neural activity, these differences can be used to detect brain activity. This form of MRI is known as *blood oxygenation level–dependent* (BOLD) imaging, which is the most widely used method of fMRI with T2*-weighted imaging revealing changes in vascular oxygenation. A limitation is that the technique is also sensitive to changes in hemoglobin concentration that may result from alterations in vascular volume and flow as well as interconversion of oxyhemoglobin and deoxyhemoglobin. Therefore this technique provides qualitative assessment of changes in oxygenation rather than quantitative measurements. Thought to primarily reflect changes in blood flow, BOLD is widely used for functional brain mapping.[99-101] BOLD is starting to be applied to tumor studies.[102-104] BOLD is particularly responsive to oxygen manipulation accompanying hyperoxic gas breathing as a simple way to ameliorate hypoxia.[105,106] This technique may also allow direct estimates of PO_2, such as in the superior mesenteric vein or heart of children. A recent study in pediatric patients with complex congenital heart disease showed a strong correlation between oxygen saturations measured in the cardiac catheterization lab and saturations obtained noninvasively by BOLD MRI.[107] However, fMRI remains difficult to perform in critically ill unstable patients; consequently, few teams have acquired the equipment and experience necessary to apply this technique.[108]

Magnetic Resonance Spectroscopy

MRI provides anatomic images and morphometric characterization of disease, whereas magnetic resonance spectroscopy (MRS) provides noninvasive metabolite/biochemical information about tissues in vivo. MRS has been used clinically for more than 2 decades. The major applications of this advanced tool include investigation of neurologic and neurosurgical disorders, including blood vessel distribution and architecture, blood flow velocity, regional perfusion and blood volume, blood and tissue oxygenation, lactate production and intracellular pH, Krebs cycle activity, and mitochondrial oxidative phosphorylation.[109] Phosphorus-31 MRS detects compounds involved in energy metabolism such as creatine phosphate, ATP and inorganic phosphate, and certain compounds related to membrane synthesis and degradation. Proton MRS is most commonly used. Four main markers related to O_2 metabolism are studied: the peak of *N*-acetyl-aspartate (NAA), an amino acid present in neurons that reflects the status of neuronal tissue; creatine, found in glia and neurons, that serves as a point of reference because its level is believed to be stable; choline, a constitutive component of cell membranes that reflects glial proliferation or membrane breakdown[110]; and lactate, a marker of anaerobic metabolism and therefore of ischemia.[111] Elevated lactate and decreased NAA are associated with worse neurologic outcome in neonates with asphyxial injury.[112,113] Increased lactate may persist up to 1 week after asphyxial injury.[114] Compared with positron emission tomography (PET), which is frequently used to evaluate tumor hypoxia but requires injections of radioactive isotopes, multiple acquisitions, and, therefore, extended imaging times, fMRI and MRS have a number of advantages. Both MRI and MRS are currently used primarily for outcome prediction and not minute-to-minute patient management.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) enables continuous, noninvasive bed-side monitoring of oxygenation. As with pulse oximetry, it is based on the principle that the oxygen-carrying pigments hemoglobin and cytochrome aa_3 have well-defined absorption spectra that are influenced by oxygen binding. NIRS technology thus uses a modification of the Beer-Lambert law, which describes the relationship between absorption of light and the concentration of intravascular (deoxygenated hemoglobin [Hb] and oxygenated hemoglobin [HbO_2]) and intracellular (cytochrome aa_3) chromophores. Key factors in the Beer-Lambert calculation are the absorption coefficient, tissue concentration of chromophore, distance between sensors, differential path length factor (described below), and scattering losses.[115] The distance that the light travels, known as the *optical path length,* must be determined to obtain quantitative concentration changes from the light absorption data. Path length differs due to variable tissue scattering that is reflected by the differential path length factor (DPF). The DPF is a correction factor that is multiplied by the inter-sensor distance to obtain the true path length. NIRS uses light between the 700 nm and 1000 nm wavelength. Measurement of scaled hemoglobin concentrations, reported as the tissue oxygenation index, is also available.

Clinically, NIRS is mainly accomplished by a continuous-wave spectrometer with the two sensors placed on the patient's forehead at a fixed distance that emit and detect the near-infrared light. NIRS has a greater tissue penetration than pulse oximetry and provides a global assessment of oxygenation in all vascular compartments (arterial, venous, and capillary).[116] Range of baseline cerebral oxygen saturation values is very wide. In healthy children, cerebral oxygen saturations are reported to be 68% ± 10%, whereas in children with cyanotic heart disease, baseline values range from 38% to 57%.[117] NIRS technology differs from pulse oximetry in that it does not require a pulse; therefore cerebral NIRS monitoring can be used during cardiopulmonary bypass. Perhaps the most common application of NIRS is in intraoperative neurophysiologic monitoring in children who have undergone repair of a congenital cardiac condition.[118] Therapeutic changes as a result of NIRS have lead to decreased rates of neurologic complications.[118] Also, NIRS monitoring applied in the first 48 hours after neonatal asphyxia has been shown to be useful in predicting outcome at 3 months.[119]

In addition to blood flow, evaluation of HbO_2 and Hb, NIRS can assess the cytochrome aa_3 (cyt-aa_3) redox state. cyt-aa_3 is the terminal component along the oxygen transport chain that reduces oxygen to water and remains in a reduced state during hypoxemia. The absorption spectrum of cyt-aa_3 in its reduced state shows a weak peak at 700 nm, whereas the oxygenated form does not. Therefore monitoring changes in the cyt-aa_3 redox state can provide a measure of the adequacy of oxidative metabolism. The use of NIRS in deltoid muscle during resuscitation of severe trauma patients has recently been reported.[120,121] A strong association was found between elevated serum lactate levels and an elevated cyt-aa_3 redox state during 12 hours of shock resuscitation and the development of multiorgan failure.[120] A good relationship was also shown among tissue O_2, systemic oxygen delivery, and lactate during and after resuscitation in severely injured patients during the first 24 hours.[121]

Limitations of NIRS technology include its inability to account for patients' varying ratios of brain and extracranial tissues and the fact that DPF values vary with age and pathologic state.[122,123] Icteric patients exhibit depressed regional cerebral oxygen saturation values, presumably due to absorption of light by bilirubin.[124] Ongoing blood loss also is associated with a decrease in regional cerebral oxygen saturation that may indicate that a changing hemoglobin concentration confounds cerebral oximetry measurement.[125] Furthermore, in infants the reproducibility of cerebral oxygenation measurements is poor.[126] The major limitation is that no target or critical values exist with which to compare NIRS-derived regional oxygen saturations. Poor-to-moderate correlation is seen in comparing regional cerebral oxygen saturations to global cerebral oxygenation measures, such as jugular venous saturation,[127] central venous saturation,[128,129] and invasively monitored cortical brain tissue PO_2.[130] However, NIRS measurement of continuous oxygen saturation on the brain surface could theoretically provide relative real-time alterations in brain oxygenation, which can be useful in terms of titration of therapies. A pediatric pilot study reported good agreement between NIRS and jugular venous saturations in the normal pediatric brain.[131]

Optical Spectroscopy

An extension of NIRS has been developed to allow interrogation of specific anatomic and physiologic compartments of the body. Optical spectroscopy also uses absorption of light by tissues to assess concentration of various analytes of interest. By using an entire spectral region in the visible and/or near-infrared spectral region that includes many (up to hundreds) of wavelengths of light, improved distinction between similar molecules is possible. In particular, oxygenation of myoglobin can be measured distinctly from hemoglobin, even in blood-perfused tissues. Myoglobin is an intracellular protein found in skeletal and cardiac muscle cells and is involved in the transport of oxygen from the cytoplasm to the mitochondria where oxygen is used. Because myoglobin and hemoglobin have very similar absorption spectra, it has generally been held that distinction using optical methods is not possible. Quantification of myoglobin saturation (percentage of total myoglobin bound with oxygen) directly yields intracellular PO_2 per the myoglobin oxygen dissociation curve that defines oxygen binding to myoglobin modified by temperature and pH.[132]

Advances in optical spectroscopy have made it possible to distinguish myoglobin saturation from hemoglobin saturation by using multi-wavelength spectral analysis, despite their very similar absorbance spectra. Measurements of myoglobin saturation in the presence of hemoglobin,[133-138] hemoglobin saturation in the presence of myoglobin,[139,140] and cytochrome oxidation states,[141,142] have been made from optical reflectance spectra acquired from muscle. These advances remove the ambiguity present in conventional near-infrared spectroscopic methods in which hemoglobin and myoglobin absorbances are combined.[143,144] Optical spectroscopy thus allows identification of oxygenation in anatomically and physiologically distinct tissue regions: in the vascular space (hemoglobin), at the cellular level (myoglobin), and at the mitochondrial level (cytochromes).

Direct measurement of oxygenation at the cellular level in skeletal muscle, based on distinct myoglobin saturation, has

several advantages for metabolic monitoring: it is noninvasive, it facilitates early diagnosis of shock, and it may enhance resuscitation strategies. During shock, blood and oxygen delivery are diverted to the critical organs (brain, heart, and kidneys), whereas blood flow to the physiologically "expendable" tissues (muscle and skin) is sacrificed.[145,146] Low muscle cellular oxygenation may be the "canary in the coal mine" for the presence of shock—an early, sensitive indicator of inadequate systemic perfusion. Vital signs are not accurate in early shock assessment because compensatory mechanisms often mask changes in these variables.[147] Metabolic indexes such as arterial base deficit and lactate have been found to correlate with the severity of shock.[148-150] However, since lactate levels and base deficits are metabolic responses to the presence of shock, these serum values lag changes in cellular oxygenation.

During resuscitation, the optimal therapeutic end points remain unclear.[146,151,152] Restoration of blood pressure, heart rate, and urine output alone may result in under-resuscitation because patients may remain in compensated shock after these traditional end points have been achieved.[153] Patients with occult hypoperfusion, in whom tissue acidosis persists even after resuscitation appears to have been successful, are at increased risk for multiple organ dysfunction syndrome (MODS), respiratory complications, and death.[154] Accurate assessments of cellular oxygenation are needed to refine therapy and decrease the incidence of MODS.

There is a varied and confused literature on the optical measurement of skeletal muscle oxygenation.[155-158] The problem with these attempts is that a combination of hemoglobin and myoglobin oxygen saturation was determined, with hemoglobin being the dominant signal.[143,144,159] Anything that increases the venous blood volume in the muscle (e.g., venous congestion) may be erroneously recorded as hypoxia. In addition, the intracellular oxygen tension remains unknown. Direct cellular oxygenation measurement by optical spectroscopy distinguishes myoglobin oxygen saturation from hemoglobin saturation and is thus capable of measuring intracellular tissue oxygen tension, independent of changes in blood volume.

Carbomyl Phosphate Synthase—A Marker of Mitochondrial Damage

Mitochondrial damage and dysfunction are thought to play an important role in the pathogenesis of sepsis-induced organ failure. Specific markers of mitochondrial damage in vital organs do not currently exist. Recently, carbomyl phosphate synthase (CPS)-1, a protein localized primarily in liver mitochondria, was found to be present in high concentrations in the plasma of septic humans and could serve as a novel marker of mitochondrial damage in sepsis.[160]

Clinical Correlations in Altered Cellular Respiration

Biochemical pathways and cellular energetics may seem far removed from the daily care of patients in the PICU, where discussions about the respiratory and circulatory systems seem to dominate. However, at its core, the goal of critical care medicine is to maintain and support the basic physiologic functions of the patient until their own homeostasis returns. This means the real goal is the support of cellular function, and that function requires energy derived from the metabolism of oxygen. Therefore the foundation of critical care medicine is the understanding and support of oxygen delivery and utilization.

The role of inadequate oxygen delivery in the pathogenesis of disease has been recognized for more than 80 years. In 1920, Joseph Barcroft wrote in *The Lancet* about three types of hypoxia: deficient delivery of oxygen to blood, or *hypoxic* (hypoxemic) *hypoxia*; deficient oxygen carrying capacity, or *anemic hypoxia*; and deficient circulatory delivery of oxygen, or *stagnant* (ischemic) *hypoxia*.[161] Later this century it became recognized that under certain states, even in the presence of normal or supranormal oxygen delivery, there was an apparent inability of cells to appropriately extract or utilize oxygen. This was most apparent in sepsis and certain poisonings. In 1997, Fink coined the term "cytopathic hypoxia" to describe such states.[162] In 1997, as the study of oxygen supply and utilization evolved, Robin proposed the general term "dysoxia" to describe abnormal tissue oxygen metabolism, and this is the term used in this chapter.[163] Now four classifications are recognized: hypoxemic dysoxia, anemic dysoxia, ischemic dysoxia, and cytopathic dysoxia.

Abnormal tissue oxygenation can be divided into three theoretic thresholds. In the first, cellular oxygen levels are below normal but ATP production matches ATP utilization through cellular adaptation. Cellular metabolism and mitochondrial energy production shift but aerobic metabolism is maintained. In the second level, cellular oxygen levels are so low that ATP production and utilization can only be matched through supplementary production of ATP via anaerobic metabolism. An increased supply of glucose is required, and lactate will be produced. The third level describes a state where ATP production has become oxygen limited. Neither cellular adaptation nor glycolysis is sufficient to provide adequate cellular energy. Without additional oxygen, or an increase in the cell's ability to utilize oxygen, cellular structure and function will fail. Some researchers have proposed that the third level be referred to as "dysoxia."[164] However, levels one and two represent abnormal cellular states that can generate intracellular and extracellular signals that result in altered physiologic function. Therefore "dysoxia" is used to describe any of the three states.

This section reviews examples of abnormal cellular respiration using common clinical scenarios, including hypoglycemia (substrate deficiency), the four dysoxias, and specific respiratory poisons such as cyanide, aspirin, and propofol. In addition, sepsis is used throughout as a model to demonstrate the complex interplay of oxygen delivery and altered cellular metabolism.

Substrate Deficiency (Hypoglycemia)

Hypoglycemia is probably more common in the neonatal intensive care unit (NICU) than the PICU. However, it represents the most basic form of altered energy production—inadequate energy substrate—and certainly requires recognition and therapy when it occurs (see Chapter 77). Although the clinical manifestations of acute hypoglycemia are well known to physicians, cellular hypoglycemia is a more complex problem.

As described earlier in this chapter, ATP can be produced from the metabolism of fats, proteins, and carbohydrates.

However, carbohydrates represent the dominant energy source in the regular diet of most humans, and the levels of enzymes necessary for conversion of various macronutrients into energy are skewed in favor of glucose metabolism.

There are two primary advantages of carbohydrate when compared with fat as a metabolic fuel. First, carbohydrate metabolism is the only mechanism by which cells can produce ATP in the absence of oxygen, that is, the anaerobic state. The metabolism of glucose to pyruvate yields a net of two molecules of ATP per molecule of glucose. This is obviously important to cells in crisis where oxygen delivery may be impaired. However, it is also important in the normal physiologic state for cells that have lost their mitochondria, such as red blood cells, and to cells that have high energy demands and operate under conditions of low O_2 tension even in the healthy state, such as renal tubular medullary cells. A second advantage of carbohydrate as fuel is efficiency. The ratio of ATP production to oxygen consumption is higher with glucose than with fats. Thus glucose is a more efficient fuel for ATP production yielding a 10% to 15% advantage.[165] This advantage may seem small but may become quite significant in states of high energy requirement or limited oxygen delivery such as seen in exercise or critical illness.

Glucose is important to other aspects of cellular function as well. Its participation in the pentose phosphate pathway facilitates reduction of $NADP^+$ to NADPH, a reaction product linked to many important cellular metabolic functions. It is also the source of the 5-carbon sugar ribose, which is necessary for DNA and RNA synthesis and repair.

Besides red blood cells and renal tubular cells, glucose is the preferred energy source for various other tissues in the body, including the central nervous system and the testes. Although the brain can adapt to using ketones as an energy source, this enzymatic transition takes time. Lack of immediate availability of these enzymes is readily seen in the severe central nervous system effects manifested with acute hypoglycemia. In the testes, the metabolism of glucose to lactate is necessary for healthy spermatogenesis.[166]

The Four Dysoxias

Before reviewing the various dysoxias, a brief review of DO_2 and oxygen consumption (VO_2) is in order (see Chapter 20). Oxygen delivery is defined as the product of the arterial oxygen content of the blood (CaO_2) and the cardiac output (CO) and is often indexed to the body surface area in square meters (BSA):

$$DO_2 \text{ index} = [(1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)] \times CO \times 1/BSA \quad (1)$$

Given that the amount of dissolved O_2 is so small, it is often dropped from the calculation for simplicity. Derivation of cardiac output is described elsewhere in this text (see Chapters 19 through 22).

Oxygen consumption is defined as the amount of oxygen extracted by the body from the blood and, according to the Fick principle, is calculated by the difference between the CaO_2 and the CvO_2 (the oxygen contents of arterial and mixed venous blood) multiplied by the cardiac output. It, too, is often indexed to BSA:

$$VO_2 \text{ index} \cong [1.34 \times Hb \times (SaO_2 - SvO_2)] \times CO \times 1/BSA \quad (2)$$

In the normal, healthy state DO_2 is in significant excess of VO_2. That is, the blood is carrying an excess of oxygen compared with the amount of oxygen the body needs. The ratio of consumption to delivery is called the oxygen extraction ratio (ERO_2) and is calculated as follows:

$$ERO_2 = (CaO_2 - CvO_2)/CaO_2 \cong (SaO_2 - SvO_2)/SaO_2 \quad (3)$$

Given that typical SvO_2 is approximately 65% to 75%, this ratio is typically 0.25 to 0.35. This means that delivery exceeds consumption by a factor of 2 to 3. Thus a buffer exists where decreases in cardiac output are well tolerated across a certain range. In this setting, VO_2 remains unaffected by changes in DO_2; this is accomplished by an increase in ERO_2.

There is a point, however, at which the oxygen extraction capabilities of the tissues are exceeded. At that point, VO_2 becomes dependent on DO_2. This biphasic relationship of DO_2/VO_2 is shown in Figure 74-9.

The importance of this concept cannot be overemphasized as it relates to cellular respiration. DO_2 and VO_2 can be altered in many physiologic and pathologic states. Sleep, exercise, pain, anxiety, and fever are just a few examples. Drugs, too, can have simultaneous effects on VO_2 and DO_2, such as with catecholamines and shock.[167] With certain poisons and with cytopathic dysoxia, oxygen consumption can be directly affected by the tissues' ability to extract oxygen from the blood and use it as the terminal mitochondrial electron acceptor. In these situations, tissue oxygen extraction, not DO_2, represents the limiting factor; DO_2 may be normal or even elevated.

Accordingly, a complicated interplay exists among DO_2, VO_2, and ERO_2. Although described in text and graphs in what appear to be straightforward ways—just as with preload, afterload, contractility, and stroke volume—their practical measurement remains exceedingly difficult. Bedside evaluation of DO_2 and VO_2 would be of great value to the clinician. Unfortunately, most of the methods of calculating VO_2 rely on cardiac output (via the Fick principle), which results in a situation where a single measured variable is included in two parts of a regression analysis, so-called *mathematical coupling*. This dependency leads to amplification of any error in that measurement and may result in an apparent relationship between variables that does not truly exist.[168] As in many areas

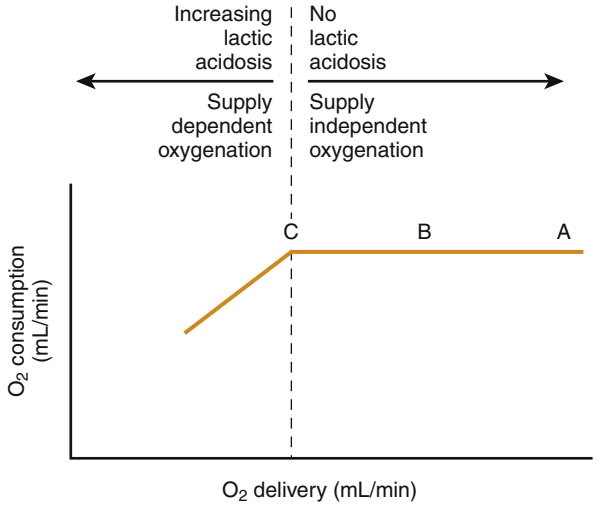

Figure 74–9. Biphasic relationship between oxygen delivery and oxygen consumption.

of critical care medicine, when something cannot be measured directly, a surrogate measure must be used.

Anemic Dysoxia

The majority of oxygen delivered to tissues is carried by hemoglobin in the red blood cells. The dissolved component of oxygen represents a very small, and usually insignificant, portion. It is therefore reasonable to postulate that in severe anemia, the decreased oxygen carrying capacity of blood may result in a severe limitation in DO_2, perhaps severe enough that VO_2 may be limited. Such limitation would represent *anemic dysoxia*.

How anemic must a child be to suffer from anemic dysoxia? A clinical scenario is instructive:

> Assuming that a normal child, approximately 1 m^2, has a VO_2 of 200 mL/min and a normal cardiac output of about 4 L/min, the formula for VO_2 (Equation 2) may be rearranged to obtain the minimum hemoglobin concentration necessary to deliver that amount of oxygen. An extreme oxygen extraction, 80%, is also assumed (this would reflect an SvO_2 of 20%!):

$$Hb = VO_2 / (1.34 \times (SaO_2 - SvO_2) \times 10 \times CO) = 5.2 \text{ g/dL}$$

This equates to a hematocrit of just over 15%. Additional manipulation of the numbers reveals that to maintain an SvO_2 in the normal range of approximately 70%, CO would have to increase by a factor of 2.7! (It should be appreciated that the increased CO itself increases VO_2.)

Oxygen content of such a patient's blood is next considered. Using the data from above and a normal PaO_2 of 90 mm Hg:

$$CaO_2 = (1.34 \times 5.2 \times 0.96) + (0.003 \times 90) = 7.0 \text{ mL/dL}$$

Notice that the dissolved portion in this patient, 0.27mL/dL, represents less than 4% of the total CaO_2. If the same patient were administered 100% FiO_2, a PaO_2 of approximately 600 mm Hg would be likely. In this case:

$$CaO_2 = (1.34 \times 5.2 \times 1.00) + (0.003 \times 600) = 8.8 \text{ mL/dL}$$

This represents an increase in CaO_2 of 22%, with the dissolved portion now representing more than 20% of the total CaO_2.

This example illustrates the need for significant tachycardia in children with severe anemia and the significant contribution of dissolved O_2 in such patients. Anemic dysoxia alone is not a common source of problems in the pediatric population. However, anemic patients are frequently encountered in the PICU, and the increased VO_2 caused by acute illness coupled with the decreased DO_2 of anemia may indeed lead to significant negative impact on cellular respiration.

Hypoxemic Dysoxia

With a normal cardiac output and a normal oxygen carrying capacity, effective oxygenation of red cell hemoglobin ensures adequate tissue delivery of oxygen. If any of the five sources of hypoxemia—hypoventilation, diffusion impairment, low inspired oxygen, shunt, ventilation/perfusion mismatch—impairs adequate oxygenation of hemoglobin and limits cellular metabolism, *hypoxemic dysoxia* results.

Respiratory diseases represent a significant portion of pediatric illness, and hypoxemia is a common finding in the PICU. In addition, such patients often have fever and increased work of breathing. Thus they exhibit increased VO_2 and diminished DO_2. This altered ratio of VO_2/DO_2 can lead to impaired cellular respiration and a shift toward anaerobic metabolism.

Another example is outlined below:

> An infant with bronchiolitis has a fever of 40° C, a pulse of 180 beats/min, and a respiratory rate of 80 breaths/min. Her hemoglobin is 10 and her oxygen saturation on arrival is 75%. Fever increases metabolism by approximately 14% per 1° C temperature increase. Work of breathing accounts for about 15% of oxygen consumption in a resting infant and can double or triple in severe states. Thus a conservative estimate of this infant's current VO_2 is:

$$\begin{aligned} VO_2 \text{ (current)} &= \text{Baseline } VO_2 + 0.42 \text{ baseline (for fever)} + \\ &\quad 0.15 \text{ baseline (for work of breathing)} \\ &= 1.57 \ VO_2 \text{ (baseline)} \end{aligned}$$

If the patient's hemoglobin oxygen saturations were normal, the 50% increase in her heart rate (assuming a normal of 120 beats/min) would just offset her increased VO_2. However, her hypoxemia causes a 25% reduction in CaO_2. A quick calculation reveals:

$$\begin{aligned} DO_2 \text{ (current)} &= 1.50 \times CO \text{ (baseline)} \times 0.75 \ CaO_2 \text{ (baseline)} \\ &= 1.12 \ DO_2 \text{ (baseline)} \end{aligned}$$

It is immediately apparent in this example that the increase in VO_2 has not been offset by the increase in DO_2. This generates a state in which the VO_2/DO_2 curve has shifted, and the threshold at which VO_2 becomes limited by DO_2 is lowered. The treatment in this case is obvious. Application of supplemental O_2 will likely alleviate her hypoxemia, and with her tachycardia, CaO_2 will return to a normal or even increased level.

As another example, children with right-to-left intracardiac shunting are frequently encountered in the PICU. These patients live in a chronic state of hypoxemia, yet grow and develop. Again, examining the equation for DO_2:

$$DO_2 \text{ index} = [(1.34 \ \mathbf{Hb} \ SaO_2) + (0.003 \ PaO_2)] \ \mathbf{CO} \ 1/\text{BSA} \quad (4)$$

To maintain adequate oxygen delivery in the face of persistent hypoxemia, these patients must increase cardiac output, hemoglobin, or both. It is worth remembering that because CaO_2 is a product of hemoglobin concentration, SaO_2, and CO, a reduction in one can be fully compensated for by an appropriate increase in the other(s). Some quick math reveals that for a patient whose arterial oxygen saturation is chronically 75%, a cumulative increase in hemoglobin and/or cardiac output of 30% is necessary to equate an SaO_2 of 100%. An increase in hemoglobin of 3 to 4 g/dL is obviously less stressful to a system than a chronic increase in CO of 1.0 to 1.5 L/min/m^2. This is especially true when one recalls that many of these patients have some element of heart failure and are not capable of long-term significant increases in cardiac output. It should also be recalled that for such patients any increase in CO results in an increase in VO_2 assuming that cytopathic dysoxia is not operative. It is obvious why these patients are so fragile. They have a limited ability to increase DO_2. Essentially, they live close to point C on the VO_2/DO_2 curve shown in Figure 74-9. Any illness or acute stressor that results in an increase in VO_2 can lead to a state at which VO_2 becomes limited by DO_2 and cellular respiration begins to suffer.

In summary, although hypoxemia is a common finding in the PICU, patients typically compensate through an increase

in cardiac output. For chronically hypoxemic patients, part of their compensation derives from elevated levels of hemoglobin. It is in those patients whose ability to increase cardiac output or whose level of VO_2 is significantly elevated that the physician must be most concerned that limited CaO_2 will cause an inability to meet VO_2 and cellular respiration will fail.

Ischemic Dysoxia

It is obvious that in tissues for which blood supply is eliminated, oxygen delivery will be eliminated and cellular energy production will fail—not only from a lack of oxygen, but also from a deficiency of substrate. This represents the most extreme form of *ischemic dysoxia*. However, this is less frequently encountered than are situations in which blood supply is merely compromised. At some point (point C on Figure 74-9), the decrease in DO_2 may fall below the level of VO_2 and cellular respiration will falter.

Ischemic dysoxia can occur on a macroscopic level, and this is how it is usually considered. A patient with severe bradycardia but normal SaO_2 suffers from global ischemic dysoxia purely as a result of inadequate cardiac output. DO_2 is severely limited and cannot meet VO_2. Anaerobic metabolism begins, and if the bradycardia is not reversed, cellular function will begin to fail. In another example, a patient develops a subdural hematoma after a fall. The increased intracranial pressure creates regional ischemia and inadequate DO_2 to that area. Draining the hematoma relieves the pressure and DO_2 returns to normal or even increased levels. There is, indeed, injury associated with the restoration of DO_2, a so-called *reperfusion injury* (see Chapter 62).

In contrast to the macroscopic examples above, ischemic dysoxia occurs much more frequently on a microscopic level. In many ways, this concept is only on the threshold of understanding. Even in good health, many areas of the body demonstrate "marginal" DO_2, with limited oxygen supply relative to metabolic needs. Classic examples include the renal medulla and corticomedullary junction and the centrilobular regions in the liver.[169-171]

In the kidney, the tubular cells of the medullary region contain a high concentration of mitochondria to provide energy for pumping ions against a strong gradient. However, the cells exist near the end of the peritubular capillaries where DO_2 is at or nearly at the limits of VO_2. In the liver the centrilobular cells lie at the end of the sinusoids, just proximal to the venous system. In addition, more than half of the liver's blood supply is provided by the portal vein with its already low oxygen tension. Once again, DO_2 hovers close to VO_2. In these examples any situation in which blood pressure or cardiac output is compromised can lead to significant insult to these areas; VO_2 simply cannot be met, cellular energy production falters, and cell functions fail. Clinically this is reflected as acute renal insufficiency due to acute tubular necrosis or hepatic dysfunction due to ischemic hepatitis—so called "shock liver."[172]

The structure of the microcirculation, a network of vessels less than 100 to 150 μm in diameter, is important when considering dysoxia. It is composed of arterioles, capillaries, and venules and represents the functional unit of the circulation, supplying tissues with oxygen and substrates and removing metabolites. It is also important to understand two aspects of the microcirculation as they relate to dysoxia. First, in the classic Krogh model of microcirculation, oxygen exchange occurs in the capillary bed. However, research reveals that a significant amount of oxygen can be lost through the arterioles.[173] This is important because it suggests that as blood enters the capillary bed, it may have already released a significant amount of oxygen to the periarteriolar tissues and may be relatively desaturated. Oxygen diffusion from the arteriole toward the capillary may or may not be able to compensate for this. This means that any state of ischemic dysoxia may be complicated by hypoxemic dysoxia at the capillary level.

The second aspect of the microcirculation to note is its overall structure. Progressively smaller vessels supply progressively larger areas of tissue. In addition, precapillary sphincters and thoroughfare channels are present. Accordingly, there exist multiple opportunities for blood to partly or entirely bypass regional capillary beds. Dysregulation of the arterioles or precapillary sphincters shunts blood directly from arteriole to venule. In sepsis, plugging of capillaries due to endothelial swelling, microscopic clots, activated white blood cells, or nondeformable red cells does the same. These scenarios all give rise to microscopic regional ischemia and potentially regional ischemic dysoxia. Much research has been devoted to the microcirculation and its role in critical illness. It is believed by many to be the pathophysiologic basis for MODS, and in sepsis its role is believed by some to be so important as to be deemed the "motor of sepsis."[174-178] Throughout the tissues there seem to be areas in the microcirculation fundamentally vulnerable to ischemic dysoxia; these areas have been termed *microvascularly weak units*.[179,180]

Cytopathic Dysoxia

The term *cytopathic hypoxia* arose just over 10 years ago to describe "diminished production of ATP despite normal (or even supranormal) PO_2 values in the vicinity of the mitochondria."[162] This term arose because of increasing evidence that in sepsis there was insufficient energy production in cells despite adequate oxygen delivery. Indeed, this does occur in sepsis, and increasing research points to it as a fundamental cause of the multiple clinical manifestations of sepsis. There are also chemicals and drugs that, despite adequate intracellular oxygen, can lead to cellular energy failure via direct functional inhibition of or damage to the mitochondria. These include cyanide, 2,4-dinitrophenol (DNP), aspirin, and propofol.

Cytopathic dysoxia during sepsis is an active area of research, and many proposed theories abound. No single pathway to cellular energy failure has proved dominant, and some proposed hypotheses have yielded conflicting results. It is beyond the scope of this chapter to review all of these in detail, but some theories bear discussion.

Inhibition of pyruvate dehydrogenase complex (PDC) has been implicated in some of the altered cellular metabolism and increased lactate production in sepsis.[181,182] Glycolysis is stimulated in many cells during sepsis. For glycolysis to be linked to oxidative phosphorylation and cellular respiration in the mitochondria, glucose must be converted first to pyruvate then irreversibly to AcCoA, which subsequently enters the mitochondria. This conversion of pyruvate to AcCoA is accomplished through the action of PDC. During sepsis, this enzyme complex is inhibited by stimulation of a PDC-kinase. The trigger for this is poorly understood. When pyruvate cannot be converted to AcCoA, energy production in the mitochondria diminishes due to a lack of substrate entering the

Krebs cycle. In addition, when pyruvate cannot be converted to AcCoA, its fate is to be converted to lactate via lactate dehydrogenase.

NO and other reactive nitrogen species (RNS) have been demonstrated in several studies to play active roles in the pathogenesis of sepsis.[183-185] As previously discussed, NO acts as a reversible inhibitor of cytochrome c oxidase. At increased concentrations, NO reacts to form $OONO^-$ (peroxynitrite), NO_2, and nitrosothiols. Increased concentrations of NO and these compounds can cause irreversible inhibition of respiratory chain components, uncoupling of oxidative phosphorylation, enhanced permeability of the mitochondrial membrane, and ultimately death of the cell.[186] In some research, the degree of mitochondrial dysfunction in sepsis was directly related to extent of NO production.[35]

A final theory of sepsis-induced mitochondrial dysfunction involves PARP.[187,188] This enzyme is involved in various aspects of cellular function, but with respect to sepsis, its most important function involves repair of single-strand breaks in DNA. During sepsis there is an increase flux of reactive oxygen and nitrogen species that mediate induce single-strand breaks in DNA. PARP is activated to repair these breaks. Activation of PARP leads to massive depletion of cellular NAD^+/NADH. Because NADH is the primary reducing equivalent transfer molecule used in cellular respiration, its depletion results in marked impairment of aerobic metabolism.

Drug Effects on Cellular Respiration

Cyanide

Cyanide ion is highly toxic via inhibition of cellular respiration. It binds to the iron atom within the heme group of cytochrome c oxidase, effectively shutting down aerobic metabolism. Rhodanese is a mitochondrial enzyme that functions to detoxify cyanide into relatively nontoxic thiocyanate. In critical care medicine, sodium nitroprusside is used as a vasodilator because of its ability to serve as an NO donor. However, on exposure to light and degradation within the body, a cyanide ion is released. Patients receiving high-dose, long-duration sodium nitroprusside infusions should be monitored for cyanide toxicity.

Aspirin

Salicylates have been used therapeutically since at least the fifth century BCE. Aspirin (acetylsalicylic acid) was synthesized in the mid-nineteenth century and has been manufactured and sold since. Toxicity to cellular respiration from aspirin overdose has been recognized for decades, but the mechanism has remained elusive. Some researchers have demonstrated an uncoupling of oxidative phosphorylation.[189] In this mechanism aspirin induces mitochondrial permeability transition (MPT). This transition allows the proton gradient established across the inner mitochondrial membrane to depolarize in a manner not linked to ATP production—hence the "uncoupling." This energy release manifests as heat. It may be part of the pathophysiology of fever in salicylate toxicity, though effects on hypothalamic function may also play a role. Recently, another mechanism of salicylate toxicity has been elucidated.[190] This research demonstrated reversible and irreversible inhibition of α-ketoglutarate dehydrogenase (AKDH) in the Krebs cycle by salicylate and acetylsalicylic acid, respectively, resulting in diminished production of NADH and failure of cellular respiration.

2,4-Dinitrophenol

DNP is a chemical compound used in the 1930s as a diet pill. Today it is rarely used as such but frequently used in research on membrane transport. Its popularity for both is due to its ability to induce depolarization of the inner membrane of the mitochondria. Just as with salicylates, this results in uncoupling of oxidative phosphorylation. Energy is released as heat rather than used for production of ATP.

Propofol

Propofol is a frequently used anesthetic in the PICU and the operating room. Although generally considered safe, there have been increasing reports of patients developing metabolic acidosis, rhabdomyolysis, refractory bradycardia and cardiac failure, renal failure, and death from propofol infusion syndrome.[191] The pathophysiology of this syndrome remains partially unexplained, but multiple studies show at least some aspects related to propofol's effects on the mitochondria.[142,192-194] Some studies demonstrate leakage of protons across the inner mitochondrial membrane similar to uncoupling of oxidative phosphorylation by DNP and aspirin. Others show inhibition of enzymes along the electron transport chain. Given that propofol infusion syndrome usually occurs in the ICU in critically ill patients, some researchers have looked at the possibility of an interaction between propofol and reactive oxygen and nitrogen species as a potential mechanism.[193] Other researchers have suggested that unrecognized mitochondrial disease may predispose patients to this syndrome, though no such association has yet been ascertained.[195] Whatever the ultimate pathway is for development of this syndrome, it almost certainly involves the mitochondria on some level. The mechanism of action of DNP, aspirin, and propofol are suggested in Figure 74-10.[40]

Complex IV with cyt-aa_3 uses four electrons from cytochrome c and eight protons from the matrix. Four protons and electrons reduce oxygen to water. Four additional protons are pumped out of the matrix.

An electrochemical gradient consisting of protons and other factors constitutes the mitochondrial membrane potential. Uncouplers transport protons into the mitochondrion, dissipating the proton gradient. DNP, aspirin, and propofol are examples of exogenous uncouplers. Endogenous uncoupling proteins in the inner mitochondrial membrane also exist and are regulated by hormones.

Sepsis and Dysoxia

Historically, sepsis is typically regarded in macroscopic dimensions. Intensivists support blood pressure, perfusion, and oxygenation because correction of these abnormalities has shown improvement in outcome. However, the cellular microscopic milieu constitutes the mechanistic focus for any macroscopic abnormalities. The microcirculation and mitochondria are at the core of organ failure and death in sepsis, although the details remain sketchy. Currently, they also remain far from therapeutic reach. Their increasingly recognized role in the pathogenesis of sepsis has led to the term *microcirculatory and mitochondrial distress syndrome* (MMDS), a term highlighting the complex interplay between circulation and cellular

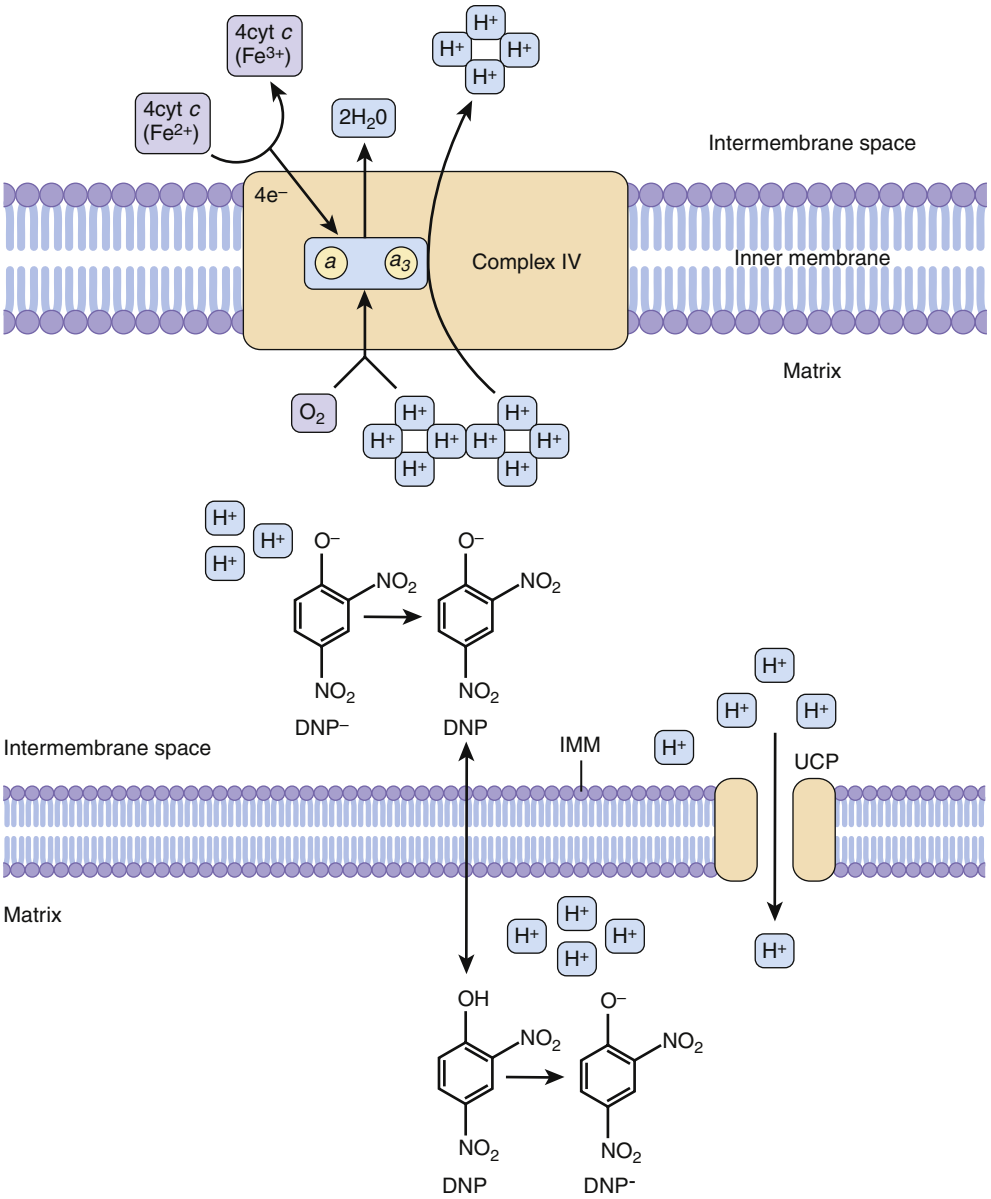

Figure 74–10. Schematic depiction of proton coupling to drive oxidative phosphorylation and decoupling activity of drugs such as DNP, aspirin, and propofol. *(Modified from Baynes JW, Dominiczak MH:* Medical biochemistry, *New York, 2009, Mosby Elsevier.)*

metabolism in sepsis.[175] Studies examining cellular energy, microcirculation, and mitochondria in sepsis have yielded conflicting results regarding the exact mechanisms and contributions each plays in sepsis pathogenesis. As with most areas in medicine, it is likely that the answer overlaps with multiple contributions, with no single element emerging as the definitive problem.

Hibernation Physiology in Sepsis

One final aspect of cellular metabolism and energetics worth mentioning is that of hibernation. Although sepsis often progresses to MODS and death, tissue examination frequently reveals little histologic evidence of cell injury and death.[196] Some research indicates a form of cellular hibernation is triggered in sepsis. Energy metabolism is altered to preserve cell life, but physiologic cell function nearly ceases. The exact mechanism is not understood, and its role in sepsis has not been extensively evaluated.[32,197] However, it does provide an explanation for extreme organ dysfunction in the absence of cell death and a platform for future study.

Nutrient Metabolism and Nutrition Therapy During Critical Illness

Nilesh M. Mehta

PEARLS

- Accurate assessment of nutritional status and provision of individually tailored optimal nutrition to the critically ill child are important but elusive goals of pediatric critical care.
- Malnutrition is associated with increased physiologic instability and the need for increased quantity of care in the ICU. Careful assessment of nutritional status on admission to the PICU allows identification of at-risk or malnourished children.
- The hypermetabolic stress response places variable energy demands on the critically ill child that must be met with evidence-based strategies. The metabolic response to critical illness results in glucose and lipid intolerance and increased protein breakdown, resulting in weight reduction and loss of lean body mass.
- Supply of adequate glucose and protein does not reduce protein breakdown and nitrogen loss during the metabolic stress response. However, protein balance may be improved by increased protein synthesis in the presence of relentless protein catabolism. In starvation, protein catabolism can be reversed if adequate energy intake is provided. This characteristic differentiates starvation from a hypermetabolic state.
- Failure to accurately estimate or measure energy expenditure during critical illness results in both underfeeding and overfeeding, with significant and unintended energy imbalances over the course of illness. Indirect calorimetry targeted at high-risk patients helps prevent energy imbalances in the PICU.
- Early enteral nutrition (EN) in patients with a functioning gastrointestinal tract is desirable. It has been shown to decrease infectious episodes and decrease length of hospital stay in critically ill patients.
- The gastric route is preferred for enteral nutrition. Postpyloric (small bowel) feeding may be considered in patients at risk of aspiration or when gastric feeding has not been tolerated.
- A significant number of patients experience interruptions to EN during their PICU course. Fluid restriction, prolonged fasting for procedures, feeding tube blockage or dislocation, perceived feed intolerance (due to abdominal distension, discomfort, or high gastric residual volumes), vomiting, diarrhea, and overall failure to prioritize nutritional support in the PICU are some of the factors that make EN challenging at the bedside.
- Although widespread in its application, parenteral nutrition is associated with mechanical, infectious, and metabolic complications and hence should be used only in carefully selected patients where EN is contraindicated, not tolerated, or has failed to provide adequate nutrition.

Malnutrition is prevalent in critically ill children at the time of admission to the pediatric intensive care unit (PICU).[1,2] Further nutritional deficiencies during the course of their illness are often incurred due to the burden of illness or suboptimal nutritient intake and may result in poor outcomes. Safe provision of optimal nutrients during hospitalization is an important goal of pediatric critical care. The changing metabolic state during the course of critical ilness results in unpredictable energy demands that need to be carefully matched with evidence-based nutritional strategies. However, prediction, estimation, and measurement of true energy expenditure in PICU patients can be challenging. Failure to accurately estimate or measure energy expenditure can potentially result in unintended underfeeding or overfeeding. While underfeeding has long been recognized as a problem, a significant proportion of critically ill children are at the risk of being overfed.[3] Furthermore, there exist a myriad of barriers that impede the delivery of prescribed nutrients to the critically ill child and result in a delay or a failure to achieve the prescribed energy goal. The complexities of critical care or the nature of illness frequently conflict with nutrient provision. However, many barriers to bedside nutrient delivery may be avoidable. Examination of existing literature, audits of bedside practice, and multidisciplinary collaborations have helped identify optimal nutritional strategies, illuminated areas of practice deficiencies or knowledge gaps, and highlighted future priorities for research. There has been a resurgence in awareness and an increase in our understanding of the role of nutrition therapy during pediatric critical illness. However, the perceived benefits of novel therapies such as immunonutrition, tight glycemic control, and hormonal modulation of the stress response have not yet been realized in the general PICU population. Future studies will clarify the role of these strategies in improving patient outcomes in the PICU. Until then, careful screening for malnutrition, awareness of the metabolic state during

the course of illness, accurate assessment of energy demands with attention to energy balance, multidisciplinary efforts to overcome common barriers to nutrient intake at the bedside, and a commitment to prioritizing nutritional support during critical illness are necessary to meet nutritional goals.

Malnutrition in the Critically Ill Pediatric Patient

Critical illness increases metabolic demand on the host in the early stages of the stress response, when nutrient intake may be limited. As a result, children admitted to the PICU are at risk of deteriorating nutritional status and anthropometric changes with increased morbidity.[1] This effect is more pronounced in a subgroup of patients who are already malnourished or at risk of malnutrition on admission. The prevalence of malnutrition in children admitted to the ICU has remained largely unchanged over the last two decades. One in every four children admitted to the PICU shows signs of acute and/or chronic malnutrition on admission.[1,2] A majority of PICU patients present with conditions that impede normal growth. Nutritional status affects physiologic responses and influences outcome. Malnutrition is associated with increased physiologic instability and the need for increased quantity of care in the ICU.[4] Despite its high prevalence and consequences, medical awareness of malnutrition is lacking. The nutritional status of hospitalized patients is not routinely assessed, and only a minority of patients are referred for expert nutritional consultation or support.[5] Careful nutritional evaluation at admission to the PICU will allow identification of children at risk for further nutritional deterioration and, hence, candidates for interventions to optimize nutrient intake.

Assessment of Nutritional Status

Assessment of the nutritional status in the critically ill child is vital but often challenging. Clinicians use a combination of anthropometric and laboratory data to diagnose undernourishment. Carefully elicited past history with details of weight gain, dietary history, recent illness, and medications allows identification of risk factors for preoperative malnutrition. Weight on admission to the hospital is important and may be the only measure of the actual dry weight before capillary leak syndrome results in edema and weight gain. Unless regular and accurate weights are obtained, acute changes in nutritional status may be missed or detected late.[6] Children in the PICU are often not weighed as the procedure is deemed to be unsafe or not important. The lack of availability of reliable weight trends in PICU patients reflects the overall low priority among health care workers for nutritional assessment and, as a result, the true incidence of malnutrition in this cohort may indeed be underestimated. Physical examination should be directed toward specific signs of nutritional and metabolic deficiencies. Hair, skin, eyes, mouth, and extremities may reveal stigmata of protein-energy malnutrition or vitamin and mineral deficiencies.

A variety of other measurements including arm anthropometry (mid-upper arm circumference and triceps skin fold), body length, and body mass index have been used to monitor growth in children. In a study of infants and children admitted to the PICU, significant anthropometric abnormalities were detected by changes in mid-arm circumference and weight in correlation with energy deficits.[1] These anthropometric abnormalities accrued during the PICU admission returned to normal by 6 months after discharge. Using reproducible anthropometric measures, other investigators detected malnutrition in a majority of children on admission to their PICU.[7] Children with malnutrition had increased mortality compared with those without malnutrition.[7] On follow-up, a significant portion of children with malnutrition had further deterioration in nutritional status. Although bedside anthropometric methods are inexpensive, they are sporadically applied in hospitalized children, may be insensitive in the setting of critical illness, and are limited by significant interobserver variability. Weight changes and other anthropometric measurements in critically ill children should be interpreted in the context of edema, fluid therapy, volume overload, and diuresis. In the presence of ascites or edema, ongoing loss of lean body mass may not be evident using weight monitoring alone.

Body Composition

Body composition is emerging as a primary determinant of health and a predictor of morbidity and mortality in children. Preservation and accrual of lean body mass during illness are important predictors of clinical outcomes in patients with sepsis, cystic fibrosis, and malnutrition.[8,9] Body composition is measured by a variety of techniques including body densitometry by underwater weighing, neutron activation analysis, total-body potassium determination, bioelectrical impedance assessment (BIA), and dual-energy x-ray absorptiometry (DXA). Most of these methods are not practical for application in the clinical management of a critically ill child. DXA is a radiographic technique that can determine the composition and density of different body compartments (fat, lean tissue, fat-free mass, and bone mineral content) and their distribution in the body. DXA has been used extensively in pediatric practice for determining fat-free mass, fat mass, and lean mass, and it is recognized as a reference method for body composition research.[10] Its results correlate well with direct chemical analyses, and there is good agreement between percentage body fat estimated by hydrodensitometry and DXA.[11] However, DXA is not practical for application in the PICU. BIA, in contrast, is a bedside technique that can be applied to pediatric patients without exposure to radiation and with ease.[12,13] Electrical current is conducted by body water and is impeded by other body components. BIA estimates the volumes of body compartments, including extracellular water and total body water (TBW). TBW measures can be used to estimate lean body mass by applying age-appropriate hydration factors. BIA has not been validated in critically ill populations; hence, its use outside clinical studies is not recommended in the PICU. The ideal bedside body composition measurement technique in critically ill patients remains elusive.

Biochemical Assessment

The nutritional status can also be assessed by measuring the visceral (or constitutive) protein pool, the acute-phase protein pool, nitrogen balance, and resting energy expenditure (REE). Visceral proteins are rapid-turnover proteins produced in the liver. Low circulating levels of visceral protein are seen in the setting of malnutrition, inflammatory states, and impaired hepatic synthetic function. The reliability of serum albumin as

a marker of visceral protein status is questionable. Albumin has a large pool and a half-life of 14 to 20 days, and is not an indicator of the immediate nutritional status. Serum albumin may be affected by changes in fluid status, albumin infusion, sepsis, trauma, and liver disease, and these changes are independent of nutritional status. Prealbumin (also known as transthyretin or thyroxine-binding prealbumin) is a stable circulating glycoprotein synthesized in the liver. It binds with retinol-binding protein and is involved in the transport of thyroxine and retinol. Prealbumin, so named by its proximity to albumin on an electrophoretic strip, is readily measured in most hospitals and is a good marker for the visceral protein pool.[14,15] It has a half-life of 24 to 48 hours and reflects more acute nutritional changes. Prealbumin concentration is diminished in liver disease. Acute-phase reactant proteins are elevated proportional to the severity of injury in response to cytokines released during stress response and have been used to longitudinally monitor the inflammatory response. Serum levels of acute-phase protein are elevated in children within 12 to 24 hours after burn injury, due to hepatic reprioritization of protein synthesis.[16] When measured serially, serum prealbumin and C-reactive protein (CRP) are inversely related (i.e., serum prealbumin levels decrease and CRP levels increase, with the magnitude proportional to injury severity, and then return to normal as the acute injury response resolves). In infants after surgery, decreases in serum CRP values to less than 2 mg/dL have been associated with the return of anabolic metabolism and are followed by increases in serum prealbumin levels.[17] Proinflammatory cytokines such as interleukin 6 (IL-6) are recognized as early markers of the systemic inflammatory response syndrome (SIRS) in several disease models. Serum concentrations of IL-6 may be useful in identifying patients at risk for nutritional deterioration and to determine whether the inflammatory response is intact.

Chemistry profiles should be monitored on admission and repeated periodically. Serum electrolytes, blood urea nitrogen, glucose, coagulation profile, iron, magnesium, calcium, and phosphate levels are routinely monitored. Adequacy of cellular immunity can be estimated through the measurement of total lymphocyte count and by delayed-type hypersensitivity testing with a series of common antigens (e.g., *Candida*, *Trichophyton*, tuberculin).

Nutritional Requirements During Critical Illness

Metabolic Consequences of the Stress Response

The energy burden imposed by the metabolic response to injury, surgery, or inflammation may be proportional to the severity and duration of the stress, but cannot always be accurately estimated and varies in intensity and duration between individuals.

Importantly, nutritional support itself cannot reverse or prevent the metabolic stress response. Failure to provide optimal calories and protein during the acute stage of illness can result in an exaggeration of existing nutritional deficiencies or further exacerbate an underlying poor nutritional status. Respiratory compromise involving loss of respiratory muscle mass, cardiac dysfunction and arrhythmias involving loss of myocardial muscle tissue, and intestinal dysfunction involving loss of the gut barrier contribute to the morbidity and mortality of critical illness. In some cases, overestimation of this energy cost of metabolic stress may result in provision of energy in excess of requirement. Hence, large energy imbalances attributable to underfeeding and overfeeding in critically ill children must be avoided.[3] This requires an individualized nutritional regimen that must be tailored for each child and reviewed regularly during the course of illness. A basic understanding of the metabolic events that accompany critical illness and surgery is essential for planning appropriate nutritional support in critically ill children.

The unique hormonal and cytokine profile manifested during critical illness is characterized by an elevation in serum levels of insulin, glucagon, cortisol, catecholamines, and proinflammatory cytokines.[18] Increased serum counterregulatory hormone concentrations induce insulin and growth hormone resistance, resulting in the catabolism of endogenous stores of protein, carbohydrate, and fat to provide essential substrate intermediates and energy necessary to support maintenance energy and micronutrient needs in addition to the ongoing metabolic stress response. Figure 75-1 illustrates the basic pathways involved in the metabolic stress response.

In general, the net increase in muscle protein degradation, characteristic of the metabolic stress response, results in a large amount of free amino acids in the circulation. Free amino acids are used as the building blocks for the rapid synthesis of proteins that act as inflammatory response mediators and are used for tissue repair. Protein breakdown may continue for an extended period of time, in an attempt to channel the amino acids through the liver, wherein their carbon skeletons are used to create glucose through gluconeogenesis and for production of glucose as the preferred energy substrate for the brain, erythrocytes, and renal medulla. Reprioritization of protein during the metabolic stress results in increased synthesis of acute-phase reactant proteins such as C-reactive protein, α_1-acid glycoprotein, haptoglobin, α_1-antitrypsin, α_2-macroglobulin, ceruloplasmin, and fibrinogen. Plasma concentrations of other proteins, including transferrin and albumin, decrease with injury or sepsis. Overall intense protein catabolism outstrips anabolism with a net negative protein balance. This condition results in weight reduction and rapid loss of lean body mass. The intense catabolism seen in metabolic stress cannot be suppressed by supplying calories, and negative protein balance continues relentlessly. This is one of the principal differences between stress response and starvation. Starvation, or protein-calorie malnutrition, may be caused by socioeconomic, psychosocial, disease-related, or iatrogenic factors. The metabolic response to starvation involves decreased secretion of insulin and thyroid hormones, normal secretion of glucocorticoids and catecholamines, and decreased oxygen consumption. In starvation states, the body tries to preserve itself by using less energy for basic metabolic functions; thus, overall metabolic rate decreases. Metabolism shifts to use fat as a primary energy source, and the corresponding ketones help provide fuel for the brain and spare glucose and protein utilization. However, body tissues still must be broken down to supply amino acids for other critical functions, eventually leading to loss of lean body mass and vital organ wasting, and possibly death. Although, provision of additional proteins does not suppress protein catabolism, it may decrease the negative protein balance by increasing protein synthesis. Table 75-1 summarizes the basic differences between starvation and metabolic stress.

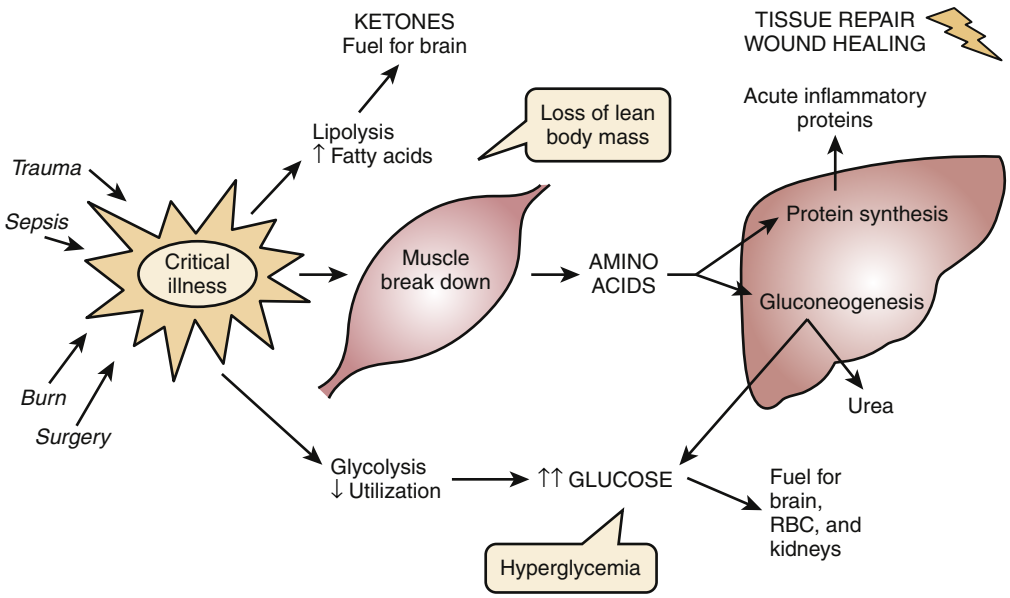

Figure 75–1. The metabolic response to stress. *(Modified from Mehta N, Jaksic T: The critically ill child. In: Duggan C, Watkins JB, Walker WA, editors:* Nutrition in pediatrics, *Hamilton, ON, 2008, BC Decker.)*

Table 75–1 Metabolic Stress vs. Starvation

	Metabolic Stress	Starvation
BMR	↑↑	↔↓
Oxygen consumption (Vo_2)	↑↑	↓
Protein catabolism	↑↑↑	↔
UUN	↑↑	↔
Weight loss	Rapid	Slow
LBM loss	Early	Late
Response to caloric intake	Protein catabolism continues	Protein catabolism halted
Insulin, cortisol, and catecholamines	↑↑	↓
Ketones	↑↑	↔
Gluconeogenesis	↑	↓

BMR, Basal metabolic rate; *UUN,* urinary urea nitrogen; *LBM,* lean body mass.

Supply of adequate nutritional intake under these circumstances is challenging, and yet recovery of critically ill patients depends on their ability to utilize energy substrates and synthesize new proteins. Carbohydrate turnover is simultaneously increased during the metabolic response, with a significant increase in glucose oxidation and gluconeogenesis. The administration of exogenous glucose does not blunt the elevated rates of gluconeogenesis, however, and net protein catabolism continues unabated.[19] A combination of dietary glucose and protein may improve protein balance during critical illness, primarily by enhancing protein synthesis. The stress response to injury stimulates lipolysis and increased rates of fatty acid oxidation.[20] Increased fat oxidation reflects the premiere role of fatty acids as an energy source during critical illness. Triglycerides in adipose tissue are then cleaved by hormone-sensitive lipase into fatty acids and glycerol. Fatty acids are oxidized in the liver for energy via the tricarboxylic acid or Krebs cycle. As seen with the other catabolic changes associated with stress response, the provision of dietary glucose does not decrease fatty acid turnover in times of illness. The increased demand for lipid use in the setting of limited lipid stores puts the metabolically stressed neonate or previously malnourished child at high risk for the development of essential fatty acid deficiency.[21,22] Preterm infants are most at risk for developing essential fatty acid deficiency after a short period of a fat-free nutritional regimen.[22,23] The beneficial effects of the acute metabolic response to illness/injury must be considered in relation to the harmful consequences of a persistently severe catabolic response. Nutritional therapy should aim to support the metabolic changes occurring during the acute catabolic stage. With resolution of a hypermetabolic stress response, an anabolic phase typically follows, with increased release of GH and IGF-1. Supply of adequate nutrition is essential for this recovery phase. In summary, the metabolic response to critical illness results in glucose and lipid intolerance and increased protein breakdown.

Underfeeding and Overfeeding in the Pediatric Intensive Care Unit

Individual assessment of energy requirements and provision of optimal nutritional support should be the standard of care. Both underfeeding and overfeeding are prevalent in the PICU, with resultant nutritional deficiencies that are associated with complications.[4,24] True energy expenditure during acute illness may not be easily predicted and several studies have documented discrepancies in measured versus equation-estimated energy expenditure.[25-27] Children with severe burn injury demonstrate extreme hypermetabolism in the early stages of injury. Standard equations have been shown to underestimate the measured REE in this population.[28] Unless increased energy requirements during the acute stage of such illnesses are accurately measured and matched by adequate intake,

cumulative energy deficits will ensue with decrease in weight, loss of critical lean body mass, and a worsening of existing malnutrition. Physicians have reported significantly escalated energy demands in a child with severe paroxysmal dysautonomia associated with ischemic brain injury. Failure to estimate this increased energy need resulted in underfeeding in this patient with severe weight loss during the course of illness in the PICU.[6] A variety of barriers, both unavoidable as well as some avoidable, exist that impede optimal nutrient delivery at the bedside and contribute to the likelihood of underfeeding in the PICU.[29,30] In the setting of fluid shifts, edema, and capillary leak in acute illness, some of these negative anthropometric outcomes may not be detected by the existing crude assessment techniques. Underfeeding during acute illness, with cumulative negative energy balance, has been associated with poor outcomes in critically ill adults.[31] However, energy imbalance in of the PICU population may also present in the form of cumulative energy excess due to unintended overfeeding. Indeed overfeeding in the PICU may be an underrecognized entity with a potential impact on patient outcomes.

Children do not predictably mount the characteristic hypermetabolic stress response as is seen in adults. The metabolic response to stress from injury, surgery, or illness is variable and the degree of hypermetabolism is unpredictable and unlikely to be sustained during a prolonged course in the PICU.[32] Critically ill children cannot be presumed to be hypermetabolic following acute illness or injury and energy expenditure may actually be decreased in some groups of patients.[33,34] While a sustained increase in metabolism has been reported for weeks after burn injury, REE peak returns to baseline within 12 hours after some surgical procedures.[35,36] Indeed children on extracorporeal life support or after surgery have failed to show any significant hypermetabolism, and measured energy expenditure is close to resting energy expenditure in these populations.[37] Critically ill children who are sedated and mechanically ventilated may have significant reduction in actual total energy expenditure, due to multiple factors. Decreased activity during illness, attenuation of insensible fluid losses in the controlled PICU environment, and transient absence of growth during the acute illness all keep total REE close to the basal rate, even in critically ill children. Historically, stress or activity correction factors have been traditionally factored into basal energy requirement estimates to adjust for the nature of illness, its severity, and the activity level of hospitalized subjects.[38,39] These patients may be at a risk of overfeeding when estimates of energy requirements are based on age-appropriate equations developed for healthy children, and especially if stress factors are incorporated in an attempt to account for the perceived hypermetabolic effects of the illness. Indirect calorimetry testing to determine the true metabolic state must be considered before incorporating stress factor correction to energy estimates in critically ill children. While the problems with underfeeding have been well documented, overfeeding too has deleterious consequences.[24,40] Overfeeding increases ventilatory work by increasing carbon dioxide production and can potentially prolong the need for mechanical ventilation. Overfeeding may also impair liver function by inducing steatosis and cholestasis, and increase the risk of infection secondary to hyperglycemia. There are no data in general pediatric populations for the role of hypocaloric feeding.[41] In general, the energy goals should be assessed and reviewed regularly in critically ill children.

Table 75–2 Recommended Energy and Protein Allowances During Critical Illness

	Age (Yr)	Energy (kcal/kg/day)	Protein (g/kg/day)
Infants	0–0.5	115	2.2
	0.5–1.0	105	2.0
Children	1–3	100	1.8
	4–6	85	1.5
	7–10	86	1.2
Males	11–14	60	1.0
	15–18	42	0.8
Females	11–14	48	1.0
	15–18	38	0.8

Data from the Food and Nutrition Board, National Academy of Science, National Research Council, ed 9, Washington, DC, 1980.

Assessing Energy Expenditure in Critically Ill Patients

Although the Food Agricultural Organization and the World Health Organization (WHO) have recommended that energy requirements and dietary recommendations be based on measurements of energy expenditure, the resources and expertise for such measurements are not easily available in all units. Current recommendations for nutritional requirements of the critically ill child are derived from limited data, based on studies in healthy children and based on limited methodologic approaches. Table 75-2 summarizes recommended energy and protein intake for critically ill children. Recommendations for pediatric nutritional requirements have traditionally focused on the supply of nutrients for growth. The components of total energy expenditure in children include (1) basal metabolic rate (BMR) 70%, (2) diet-induced thermogenesis (DIT) 10%, (3) energy expended during physical activity (PA) 20% and (4) energy expended for growth. The sum of these components determines the energy requirement for an individual. The traditional components of energy expenditure in healthy children may not apply during critical illness (see Table 75-3). Thus, prescribing optimal energy for the critically ill child requires careful review of each component of total energy expenditure.

Previous recommendations for energy requirements were based on estimates of basal metabolic rate or REE derived by either indirect calorimetry or standard equations.[34,42] Studies examining the performance of estimated energy needs in relation to measured REE in critically ill children are small-sized prospective or retrospective cohort studies. REE estimates have a large individual variability, and predictive equations are unreliable, particularly in underweight, overweight, or critically ill children.[27,43,44] Newer equations have attempted to improve the prediction of REE in children by accounting for weight-based groups or by including pubertal staging, with variable success.[44,45] These equations have not been satisfactorily validated in critically ill children.[46]

Table 75–3 Components of Energy Expenditure: Normal Health vs. Critical Illness

Component	Normal Health	Critical Illness
BMR (60%–70%)	Energy needed for maintaining vital processes of the body Measured in a recumbent position, in a thermoneutral environment after 12–18 hours fast, when the individual has awakened before starting daily activities Not practical for bedside Sleeping energy expenditure, a component of BMR was shown to be equal to REE = 0.9 Corresponds to lean body mass	Related to metabolic state May be increased in conditions such as inflammation, fever, acute or chronic disease (e.g., cardiac, pulmonary) Related to lean body mass
REE (50%–60%)	BMR + 10% Usually measured instead of BMR REE is measured at rest in a thermoneutral environment, after 8–12 hours fast and not immediately after awakening	Measured by indirect calorimetry with steady-state conditions
DIT or TEF (10%)	Reflects the amount of energy needed for food digestion, absorption, and part of synthesis	Increased energy needs following enteral feeding return to baseline approximately >4 hours of feeding
Growth (variable)	Energy for growth may be higher is healthy infants <2 years and during catch-up growth	Probably halted?
PA (variable)	Depends on age, activity level Decreased in hospitalized patients	Sedation, muscle relaxants, decreased activity
Stress	—	Variable Probably overestimated during critical illness
Total energy expenditure	REE + DIT + PA + Growth	Probably close to REE in most critically ill children Addition of stress factors may be necessary where relevant

BMR, Basal metaboic rate; *REE,* resting energy exenditure; *DIT,* diet-induced thermogenesis; *TEF,* thermic effect of food; *PA,* physical activity.

The variability of the metabolic state may be responsible for the failure of estimation equations in accurately predicting the measured REE in critically ill children. The application of stress factors might predispose some patients to the risk of overfeeding. Hence, it might be prudent to refrain from using these corrections in the absence of an accurate measurement of REE. Application of hypocaloric feeding has been recommended in critically ill adults.[47] There is not enough evidence to recommend its general use in critically ill children.

Indirect Calorimetry

Historically, indirect calorimetry (IC) has been regarded as the gold standard for accurate measurement of REE. Energy expenditure is obtained by measuring the volume of oxygen consumed (Vo_2) and the volume of CO_2 produced (Vco_2) over a period of time.[48] From this estimate the 24-hour energy intake is derived. Measurements of Vo_2 and Vco_2 are used to calculate REE using the modified Weir equation: REE = [Vo_2 (3.941) + Vco_2 (1.11)] × 1440. This technique has been validated in healthy children by using a whole-body chamber to allow 24-hour measurement. For obvious reasons, the whole-body chamber cannot be used in critically ill children.

The application of IC in different PICU populations has shown the variability in energy expended during illness. Weekes and Elia showed a relatively higher resting metabolic rate in critically ill children (37% higher than the resting metabolic rate of age-matched healthy controls).[49] However, the total energy expenditure was reduced in a group of head-injured children receiving enteral nutrition. Energy expenditure was noted to decrease over time and returned to normal after the second week of injury. In critically ill mechanically ventilated children, use of sedation and muscle paralysis decreases the component of energy requirement related to physical activity,[50] and caloric needs in the critically ill child may be lower than previously considered. IC continues to be only sporadically applied in critically ill children, despite mounting evidence of the inaccuracy of estimated basal metabolic rate using standard equations. This could potentially subject a subgroup of children in the PICU to the risk of underfeeding or overfeeding. However, IC application is not feasible in all patients due to (1) specific subject requirements, (2) device limitations, and (3) need for expertise and resources. Table 75-4 describes some of the common problems associated with IC testing in critically ill children. In the era of resource constraints, IC may be applied or targeted for certain high-risk groups in the PICU.[3] Selective application of IC may allow many units to balance the need for accurate REE measurement and limited resources (see Box 75-1 for suggested criteria for targeted IC).[51] While IC application has illuminated our understanding of energy expended during critical illness, this has yet to be translated into improving patient outcomes. Studies examining the role of simplified IC technique, its role in optimizing nutrient intake, its ability to prevent overfeeding or underfeeding in selected subjects, and the cost-benefit analyses of its application in the PICU are desirable. The effect of energy intake on outcomes needs to be examined in pediatric populations, especially in those on the extremes of body mass index (BMI).

Table 75–4 Factors Associated with Inaccurate or Unreliable Indirect Calorimetry Measurements

Error in V_{CO_2} Measurement	Limitations or Mechanical Issues with the Device	Failure to Reach Steady State
Air leak >10% around endotracheal tube	High inspired F_{IO_2} (>60%)	Recent interventions (suctioning, painful procedure)
Air leak in the circuit	Calibration issues	Fever, seizures, dysautonomia
Chest tube for pneumothorax	Moisture or obstruction due to water in the circuit	Recent change in ventilator settings
		Study period too short

Box 75–1 Suggested Criteria for Targeted Indirect Calorimetry[3,51]

Children at high risk for metabolic alterations who are suggested candidates for targeted measurement of REE in the PICU include the following:

- Underweight (BMI <5th percentile for age), at risk of overweight (BMI >85th percentile for age), or overweight (BMI >95th percentile for age)
- Children with >10% weight gain or loss during ICU stay
- Failure to consistently meet prescribed caloric goals
- Failure to wean, or need to escalate respiratory support
- Need for muscle relaxants for >7 days
- Neurologic trauma (traumatic, hypoxic, and/or ischemic) with evidence of dysautonomia
- Oncologic diagnoses (including children with stem cell or bone marrow transplant)
- Children with thermal injury
- Children requiring mechanical ventilator support for >7 days
- Children suspected to be severely hypermetabolic (status epilepticus, hyperthermia, systemic inflammatory response syndrome, dysautonomic storms, etc.) or hypometabolic (hypothermia, hypothyroidism, pentobarbital or midazolam coma, etc.)
- Any patient with ICU length of stay >4 weeks may benefit from IC to assess adequacy of nutrient intake

Another method of energy expenditure determination is based on the use of doubly labeled water; however, at this time the technique remains confined to research settings. Stable isotope technique has been available for many years and was first applied for energy expenditure measurement in humans by Schoeller and van Santen[78] in 1982. Isotope studies using doubly labeled water have since been validated and, following intense and skeptical scrutiny, have now been established as a "gold" standard for total energy expenditure estimation with widespread application.[43,74–77] In this method, stable isotopes of water (^2H_2O and $H_2{}^{18}O$) are administered orally. They mix with the body water and the ^{18}O is lost from the body as both water and CO_2, while the ^2H is lost from the body only as water. The difference in the rates of loss of the isotopes ^{18}O and ^2H from the body reflects the rate of CO_2 production, which can be used to calculate the total energy expenditure. This method has advantages in children because of its noninvasive nature. However, isotope decay is measured over two half-lives of the isotope, and hence the technique only gives an average estimate of total energy expenditure over a period of a few days. Analytical errors in the mass spectrometric estimation of isotope enrichment, isotope fractionation during CO_2 formation or vaporization of water, and the calculation of total body water or respiratory quotient are factors that might introduce errors in the estimation of total energy expenditure with this technique. If the necessary conditions are met, the doubly labeled water technique is currently the best method for estimating energy expenditure, because expired gas analysis is not required, and serial measurements of stable isotopes in urine samples provide an objective assessment of energy expenditure over a period of 4 to 21 days. However, the doubly labeled water technique for determination of energy expenditure is difficult to use in critically ill children because it requires fluid balance in the steady state. This is a major problem in the critically ill child with active capillary "leak" syndrome. Hence decreased urinary output, capillary leak syndrome, use of diuretics, or fluid overload exclude the use of this technique. The isotope costs and availability may be concerns, and the doubly labeled water technique cannot measure brief periods of peak energy expenditure.

Recently, investigators have proposed hypocaloric diets in critically ill adults.[58,66] Administration of high-calorie (glucose-load) diets during the acute phase of illness may exacerbate hyperglycemia, increase carbon dioxide generation with increased load on the respiratory system, promote hyperlipidemia resulting from increased lipogenesis, and result in a hyperosmolar state. Hypocaloric diets may have a protein-sparing effect, and have demonstrable benefits in critically ill obese patients. Overfeeding critically ill children is associated with net lipogenesis, hepatic steatosis, liver dysfunction, and increased CO_2 production and difficulty in ventilator weaning.[55] However, it is uncertain if administration of energy intake lower than the measured expenditure is appropriate for the critically ill pediatric patient.

In summary, energy expenditure must be carefully evaluated throughout the course of critical illness using measurements where available. In patients meeting the requirements for this test, IC provides an accurate measurement of REE. IC may be applied in specific patient groups targeted due to risk of metabolic instability and may help prevent unintended underfeeding and overfeeding in these patients. In the absence of measured REE, equation-estimated REE may be used. However, the uniform application of stress factors is not advisable and must only be used in individual cases after careful evaluation. Once energy needs are determined, the optimal substrate required for maintenance of energy needs is mixed fuel (glucose and fat). The proportion of each varies according to the clinical situation. See Table 75-2 for recommended macronutrient requirements for critically ill children.

Protein Requirements

Protein turnover and catabolism are increased several-fold in critically ill children. An advantage of high protein turnover is that a continuous flow of amino acids is available for the synthesis of new proteins. Specifically, this process involves a redistribution of amino acids from skeletal muscle to the liver, wound, and other tissues involved in the inflammatory response. This allows for maximal physiologic adaptability at times of injury or illness. The catabolism of muscle protein to generate glucose

and inflammatory response proteins is an excellent short-term adaptation, but it is ultimately limited because of the reduced protein reserves available in children and neonates. Although children with critical illness have increases in both whole-body protein degradation and whole-body protein synthesis, it is the former that predominates during the stress response. Children, especially preterm infants, have reduced macronutrient reserves, with less than half the protein content of adults.[52] The ill effects of negative protein balance may not be tolerated by infants and malnourished children with already decreased or depleted lean body mass reserves.

Unlike during starvation, the provision of dietary carbohydrate alone is ineffective in reducing the protein catabolism or endogenous glucose production via gluconeogenesis in the metabolically stressed state.[19] Therefore, without elimination of the inciting stress for catabolism (i.e., the critical illness or injury), the progressive breakdown of muscle mass from critical organs results in loss of diaphragmatic and intercostal muscle (leading to respiratory compromise) and the loss of cardiac muscle.[53,54] The amount of protein required to optimally enhance protein accretion is higher in critically ill than in healthy children. Infants demonstrate 25% higher protein degradation after surgery and a 100% increase in urinary nitrogen excretion with bacterial sepsis.[53,54] The provision of dietary protein sufficient to optimize protein synthesis, facilitate wound healing and the inflammatory response, and preserve skeletal muscle protein mass is the most important nutrition intervention in critically ill children. A supply of adequate proteins and energy intake improves protein balance by increasing protein synthesis, although protein breakdown is not affected. The amount of protein required to maintain a positive nitrogen balance may vary according to the severity of illness. Furthermore, the ideal amount and proportion of amino acids required during critical illness are not known. This is relevant because amino acids and other nutrients not only serve a nutritional role but also are actively involved in physiologic and pathophysiologic processes and may act as pharmacologic agents. Nitrogen balance varied in critically ill patients receiving different amounts of branched-chain amino acids in parenteral formula.[55] Sulfur amino acid metabolism in septic children is impaired, and the rates of cysteine oxidation are decreased and plasma cysteine fluxes are increased, suggesting increased protein breakdown to supply cysteine and spared cysteine catabolism by decreased rates of oxidation.[56] Further studies to determine the individual requirement of specific amino acids under catabolic conditions are necessary, particularly in view of the important functions of amino acids, not only in protein synthesis but as signaling molecules[57] and precursors for important substrates such as glutathione[58] and methyl group donors.[59] Alternatively, excessive protein administration could be deleterious, particularly in children with marginal hepatic or renal function. Neonates with higher protein intakes have been shown to develop azotemia, pyrexia, and possible long-term detrimental effects on cognitive development.[60,61] Hence further studies on specific nutritional and functional requirements of amino acids are needed.

Lipid Requirements

Nonprotein calories are commonly provided as carbohydrates (55% to 65%) and fat (35% to 45%). In the absence of adequate lipid supplementation in the diet, critically ill children, who have depleted lipid stores at baseline, are likely to suffer essential fatty acid deficiency.[67] Lipid administration is generally restricted to 30% to 40% of the total calories, and after an initial prescription of 1 g/kg/day, it may be gradually increased to 2 to 4 g/kg/day, depending on the tolerance level. Triglyceride levels should be regularly monitored for lipid tolerance. Concentrated lipid formulas (Intralipid 20%) should be used, given the limitation on fluid volume for administration of nutritional support.

Micronutrient Requirements

Micronutrients play significant physiologic roles. Beneficial effects of micronutrients such as fat-soluble vitamins (A, D, E, and K), water-soluble vitamin (C), zinc, selenium, and folic acid have been described in selected groups of patients in well-defined settings. The presumed safety of micronutrients and probably exaggerated efficacy and generalized applicability to heterogeneous populations are factors that may be responsible for the widespread prescription of these compounds.[62] Commercially available antioxidant nutrients need to be scrutinized for optimal dosage and side effects in the clinical setting where they are most likely to be beneficial. Hospitalized patients, especially those with critical illness, currently receive these additives in accordance with Food and Nutrition Board recommendations for daily allowances.

The antioxidant properties of certain micronutrients have renewed interest in their role during critical illness.[63] Vitamins C and E have important antioxidant activities. Selenium has also been shown to be a critical micronutrient with antioxidant functions in patients with thermal injury and trauma.[64] A complex system of special enzymes, their cofactors (selenium, zinc, iron, and manganese), sulfhydryl group donors (glutathione), and vitamins (E and C) form a defense system to counter the oxidant stress seen in the acute phase of injury or illness. Critically ill patients may have variable deficiencies of micronutrients in the early phase of illness. Vitamins and trace elements are redistributed from the central circulation to tissues and organs during the systemic inflammatory response syndrome (SIRS).[63] Levels of trace elements, such as iron, selenium, and zinc, and water-soluble vitamins are decreased, whereas copper and manganese levels may be increased.[65] In addition, trauma and thermal injuries are characterized by extensive losses of biologic fluids through wound exudates, drains, and hemorrhage, which cause negative micronutrient balances. The reduced stores of these enzyme cofactors, vitamins, and trace elements decrease rapidly after injury and remain at subnormal levels for weeks. Low endogenous stores of antioxidants are associated with an increase in free radical generation, augmented systemic inflammatory response, cell injury, and increased morbidity and mortality in the critically ill.[66,67]

Recently, there has been increased interest in the role of vitamin D as an antioxidant. Serum levels of vitamin D are decreased in children with severe burns.[68] Vitamin D status may be compromised for months after burn injury. Indeed, recent studies have reported the prevalence of vitamin D deficiency in the general population.[69-73] Future studies examining the associations between vitamin D deficiency and altered immunity, infectious risk, and illness severity are under way. These studies are expected to highlight the application of vitamin D replacement in deficient subjects and its role in influencing outcomes from illnesses. The concept of early

micronutrient supplementation to prevent the development of acute deficiency, to rectify the oxidant-antioxidant balance, and to reduce oxidative-mediated injuries to organs has driven recent trials in critically ill patients.[74] Antioxidant research in the critically ill has focused on copper, selenium, zinc, vitamins C and E, and the vitamin B group. Most of these studies were performed in relatively small patient populations presenting with heterogeneous diseases, such as trauma, burns, sepsis, or acute respiratory distress syndrome, however, and thus are underpowered to detect a treatment effect on clinically important outcomes. Heyland and colleagues performed a systematic review of trials supplementing critically ill patients with antioxidants, trace elements, and vitamins with an aim to improve survival.[63] They concluded that trace elements and vitamins that support antioxidant function, particularly high-dose parenteral selenium alone or in combination with other antioxidants, are reportedly safe and may be associated with a reduction in mortality in critically ill patients.

Electrolyte management in critically ill children can be complicated because of existing deficiencies, fluid shifts, increased insensible losses, drainage of bodily secretions, and renal failure. Intravenous fluids or parenteral nutrition (PN) prescriptions need to be reviewed daily in light of the basic electrolyte and blood sugar levels. In children with significant gastrointestinal fluid loss (gastric, pancreatic, small intestinal, or bile), the actual measurement of electrolytes from the drained fluid may assist in prescribing replacement fluids. Acute changes in serum electrolytes that require urgent electrolyte replacement must not be managed by changes in the PN infusion rate or composition, because this method may be imprecise and potentially dangerous. Phosphate and magnesium levels are often abnormal in critically ill children, especially in those with existing nutritional deficiencies, sepsis, or ongoing nutritional deprivation.

Enteral Nutrition in Critically Ill Children

Enteral nutrition (EN) is the preferred mode of nutrient intake in critically ill patients with a functional gastrointestinal system, due to its lower cost and complication rate when compared to parenteral nutrition (PN).[51] Early institution of EN is associated with beneficial outcomes in animal models and human studies[63] and has been increasingly implemented during critical illness, often using nutrition guidelines or protocols.[75] Early enteral nutrition has been shown to decrease infectious episodes and decrease the length of hospital stay in critically ill patients.[76] Pediatric studies have shown successful implementation of early enteral nutrition using institutional protocols.[75,77] Figure 75-2 provides an example of an approach to instituting and maintaining EN in the PICU. Although early EN has been adopted in most units, subsequent maintenance of enteral nutrient delivery remains elusive, as EN is frequently interrupted in the intensive care setting for a variety of reasons, some of which are avoidable.[30,78] Frequent interruptions in enteral nutrient delivery may affect clinical outcomes secondary to suboptimal provision of calories and reliance on PN. It has been reported that EN is interrupted in a third of patients in the PICU who were started on EN.[29] EN was frequently interrupted for avoidable reasons. Patients experiencing avoidable EN interruptions had more than a threefold increase in the use of PN and significant delay in reaching caloric goals. This collaborative study, examining bedside nutrition practice, illustrates some of the challenges to the provision of nutrition support and highlights opportunities for practice modification. Fasting for procedures and intolerance to EN were the commonest reasons for prolonged EN interruptions. Interventions aimed at optimizing EN delivery must be designed after examining existing barriers to EN and directed at high-risk individuals who are most likely to benefit from these interventions. Knowledge of existing barriers to EN, such as those identified in this study, will allow appropriate interventions to be planned. Intolerance to enteral feeds may be a limiting factor, and supplementation with parenteral nutrition (PN) in this group of patients allows earlier optimal nutritional intake. Taylor and colleagues reviewed nutritional delivery in a group of 95 children in a PICU over a 12-month period and made similar observations.[79] Children received a median of 58.8% (range 0% to 277%) of their estimated energy requirements in this investigation. Enteral feeding was interrupted on 264 occasions to allow clinical procedures. Rogers and colleagues reviewed nutritional intake in 42 patients admitted to an Australian tertiary-level PICU over 458 ICU days.[30] When actual energy intake was compared with estimated energy requirement, only 50% of patients had received their full estimated energy requirements after a median of 7 days in the ICU. Prolonged fluid resuscitation is a major factor hindering the achievement of estimated energy requirements, despite maximizing the energy content of feeds. Other contributing factors included interruption of feeds for procedures, enteral feed intolerance, and cooling. Protocols for use of transpyloric feeding tubes and changing from bolus to continuous feeds during brief periods of intolerance are strategies to achieve estimated energy requirements in this population. Box 75-2 summarizes some of the barriers to successful enteral feeding in the PICU.

The role of enteral nutrition has expanded beyond that of growth and nutritional rehabilitation. Newer components introduced in enteral feeds include l-arginine, glutamine, taurine, nucleotides, omega-3 and omega-6 fatty acids, carnitine, growth factors, probiotics, and probiotics. Disease- and health-modulating effects of these additives are becoming increasingly understood, and they may have application in the management of a subset of critically ill children with specific illnesses.

Enterally administered feeds meet nutritional requirements in critically ill children with a functional gastrointestinal system and have the advantages of cost, manageability, safety, and preservation of gastrointestinal function. Early introduction of enteral feeds in critically ill patients helps to achieve positive protein and energy balance and restores nitrogen balance during the acute hypermetabolic state of illness. Enteral nutrition elicits release of growth factors and hormones that maintain gut integrity and function.[8] Despite its perceived benefits, current practice in ICUs indicates a significant proportion of eligible patients are deprived of enteral feeds.[36] An aggressive protocol for early intragastric feeding was applied to 71 critically ill children, using full-strength enteral formula started within 12 hours of enrollment and advanced to target volumes of energy intake.[10] In this study, increases in caloric intake were well-tolerated by the children and reached predicted basal metabolic rate by day 1 and predicted REE by day 4. Children who were successfully fed had a lower mortality than those who did not respond to the early poststress intragastric feeding. The majority

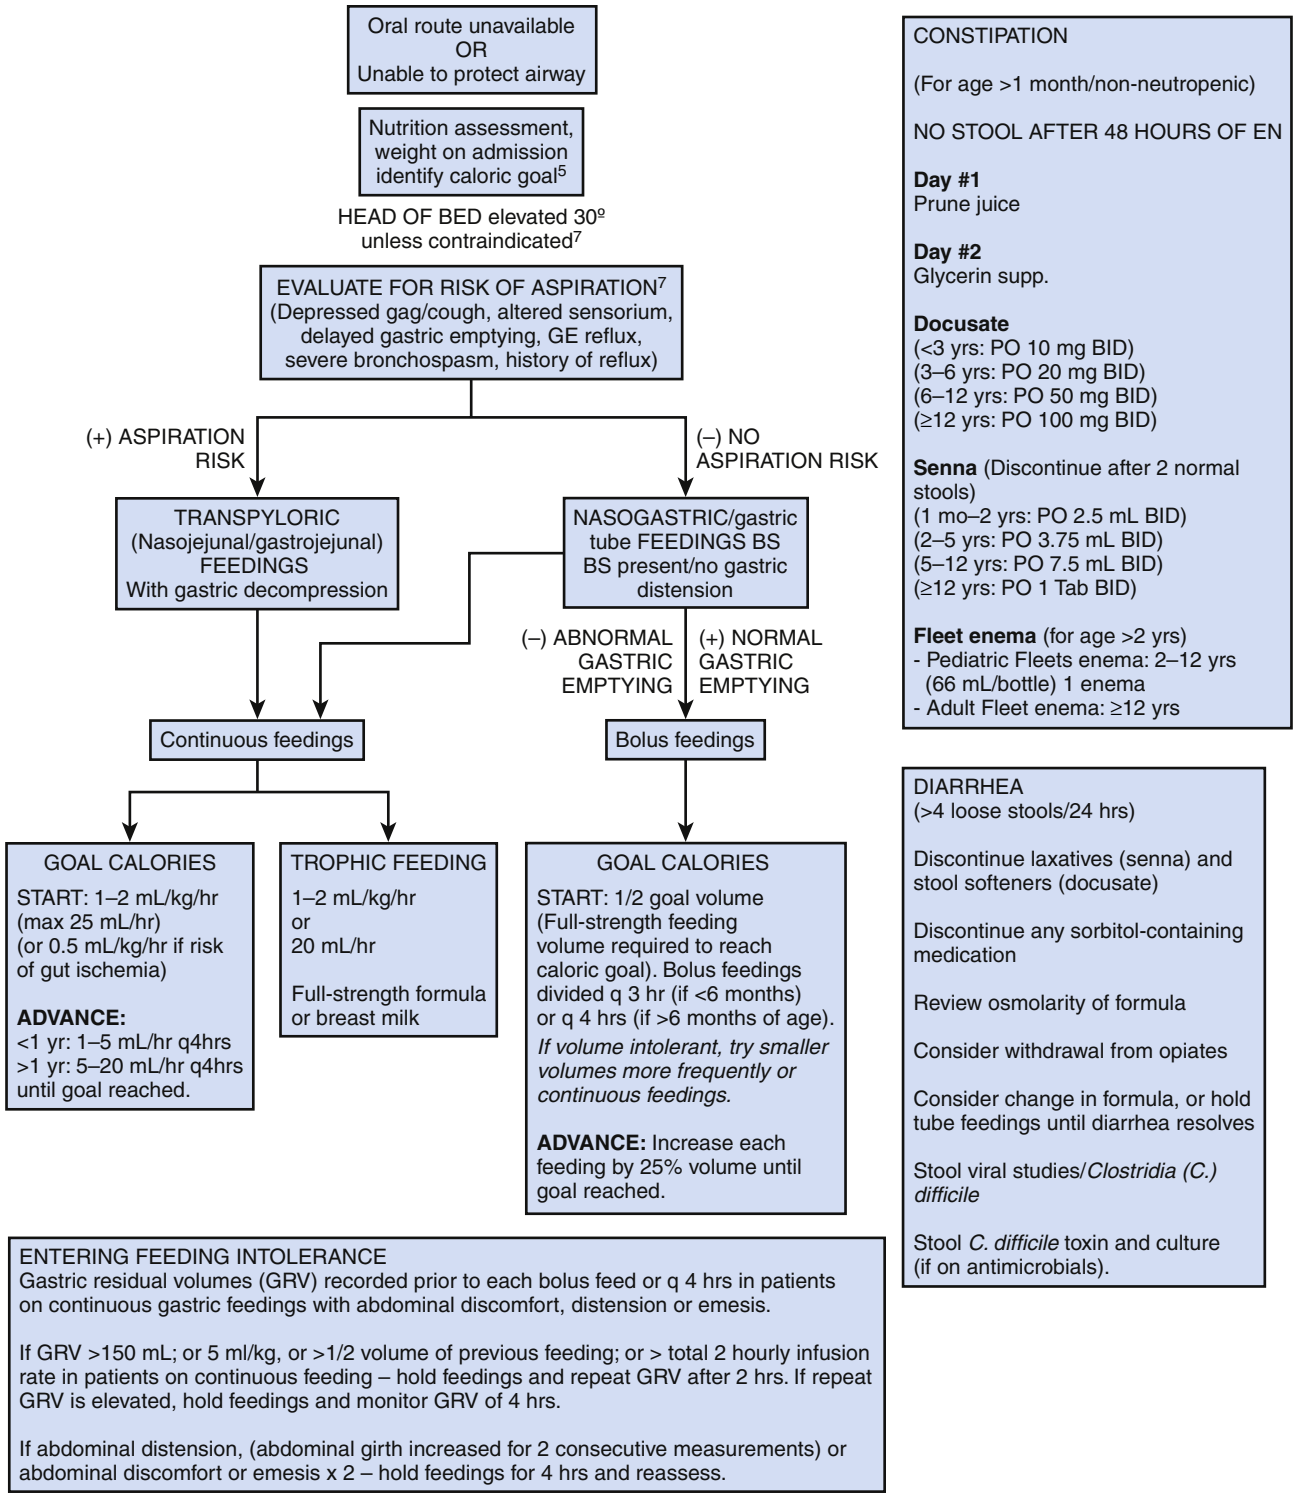

Figure 75-2. Enteral nutritional support algorithm. *(Modified from Mehta NM: Approach to enteral feeding in the PICU,* Nutr Clin Pract *24:377, 2009.)*

of children who did not respond to the early enteral feeding strategy were sicker and exhibited nonreversible septic shock and significantly lower ejection fractions on echocardiography.

Enteral feedings are indicated early in the course of critical illness if peristalsis has been established. Postpyloric feedings are recommended because of gastric distension and hypomotility. Feeds can be administered into the stomach or jejunum with the aid of feeding tubes inserted nasally or orally. Intragastric or intrajejunal feeding tube tip placement should be confirmed by radiography. Softer tubes constructed from silicone or polyurethane may be inserted using stylets at the bedside. Insertion of jejunal feeding tubes may require fluoroscopic or endoscopic guidance.

Postpyloric tubes provide the opportunity to feed a subset of children for whom intragastric feeding has not succeeded or is deemed unsafe. Postpyloric feeding is increasingly

Box 75–2 Barriers to EN Delivery in the PICU

Fasting before procedures
- Endotracheal tube–related procedures (intubation, extubation)
- Major operative procedures
- Other procedures requiring general anesthesia
- Bedside procedures requiring sedation
- Radiology suite or interventional radiology procedures

Fluid restriction

Delay in establishing enteric tube for feeding
- Delay or difficulty in enteric tube placement
- Malpositioned, obstructed, or displaced enteric tube

Gastrointestinal dysfunction
- Malabsorption, diarrhea, or severe constipation
- Ileus associated with opioid use or postoperative status

Patients at risk of aspiration of gastric contents

Holding EN for perceived intolerance
- High gastric residual volume
- Abdominal distension or discomfort
- Vomiting or diarrhea

Failure to implement evidence-based uniform algorithmic approach to EN
- Delay in initiating EN

adopted to feed children with reflux or delayed gastric emptying who are at risk for aspiration. Placement is not always successful, and a variety of novel techniques have been used to facilitate postpyloric placement. These methods rely on gravity and gut peristalsis to advance the tube tip past the pylorus. Because difficulty in tube placement can be anticipated in some patients, endoscopy or fluoroscopy guidance should be used, which avoids the rare occurrence of adverse events (such as perforation) and pancreatitis seen during blind enteral tube placement.

Surgical placement of gastrostomy or jejunostomy tubes allows long-term enteral feeding and administration of drugs in selected patients during intensive care and after discharge from the ICU. The advent of percutaneously placed gastric and jejunal tubes has minimized cost, time, and morbidity. Stoma site infection, obstruction, and tube dislodgment are common complications and must be identified and managed early. Tube tip malposition is frequently encountered with any of these devices either at placement or during the course of their use. Bedside screening methods for ascertainment of correct tip position range from auscultation during air insufflation to ultrasound-guided tip localization. However, feeds should be held when malposition of tip is suspected; when in doubt, radiographic confirmation of correct tip position should be obtained before recommencing feeds.

Immune-Enhancing Diets for the Critically Ill Child

In 1996, Bone and colleagues[80] outlined the role of the compensatory antiinflammatory response (CARS), which follows the initial proinflammatory response by the body challenged with an insult or infection. The antiinflammatory response was believed to be the second phase of a biphasic, highly coordinated inflammatory response and was aimed at keeping the proinflammatory response under control. It is clear that immunomodulation plays a significant role in the nature of response to infectious insult and impacts outcome in children with sepsis admitted to the ICU. Therapies aimed at modulating or stimulating the immune response have yet to be validated in children.

Immune-enhancing diets (IEDs) have been available for many years, and their role in the care of critically ill patients remains controversial. An increasing number of studies examining the effect of IEDs in various clinical populations and related meta-analyses continue to provide conflicting conclusions. Methodological flaws in conducting initial studies and the heterogeneous nature of the IED formulations used do not allow for dispelling current doubts regarding the safety and efficacy of these diets. The commercially available diets contain a mixture of compounds in varying doses, and the role of individual compounds is impossible to interpret. The immunomodulating effects of individual compounds are dose-dependent, and mixtures of different immunomodulating nutrients may have synergistic but also antagonistic effects. However, the compositions of the products compared in the meta-analyses are considerably different.

In a meta-analysis of randomized clinical trials examining the efficacy of enteral immunonutrients in adult patients, Heyland and colleagues selected 22 human studies, which included 2419 subjects.[81] There was no difference in mortality between the two groups, although patients who received enteral immunonutrition had a decreased incidence of nosocomial infections and decreased length of hospital stay compared with patients who received a standard enteral formula. The authors analyzed a subgroup of 13 trials involving critically ill patients. Duration of hospital stay was decreased in the experimental arm in this subgroup (treatment effect ~0.47 days; 95% confidence interval [CI] ~0.93 to ~1.01 days). When this subgroup of investigations was further subdivided into trials using experimental formulas with high arginine versus those using lower arginine content, mortality was noted to be higher in the studies using relatively lower arginine content formulas (risk ratio, 2.13; 95% CI, 1.08 to 4.21). A statistically insignificant trend toward decreased infectious complications in the high arginine group was reported. The high arginine group was associated with a shorter duration of hospitalization. This overview did not address the issue of the cost of intervention. Although an overall effect on mortality was not seen with immunonutrition intervention, some studies in the overview showed contrasting results. The study by Bower et al.[82] (n = 296) comparing IMPACT with Osmolite HN formula in critically ill adults demonstrated increased mortality (15.7%) in the immunonutrition (IMPACT) group versus the control group (8.4%). A subgroup analysis of patients designated as septic at baseline showed that mortality in the experimental arm (IMPACT) was almost three times higher (11/45 [25%]) than that in the control arm (4/45 [8.9%]).

A multicenter trial comparing enteral immunonutrition with PN conducted an interim subgroup analysis based on some reports suggestive of increased mortality in critically ill patients receiving immunonutrition.[83] Interestingly, the study was discontinued after the interim analysis. Analysis of 39 patients with sepsis or septic shock included in this interim analysis indicated mortality in the immunonutrition enteral arm (8/18 [44.4%]) was three times higher than that in the PN arm (3/21 [14.3%]).

Decreased length of hospital stay and decreased nosocomial infections in the treatment group were beneficial secondary

Table 75–5 Individual Immunonutrients and Potential Effects in Specific Critically Ill Adult Populations

Nutrient	General	Septic	Trauma	Burns	Acute Lung Injury
Arginine	No benefit	Harm	No benefit	No benefit	No benefit
Glutamine	PN beneficial (? receiving EN)	—	EN possibly beneficial	EN possibly beneficial	—
Omega-3 FFA	—	—	—	—	Beneficial
Antioxidants	Possible benefit	—	—	—	—

FFA, Free fatty acids.

outcomes reported by each of the three reviews/meta-analyses of studies examining the use of IEDs. In summary, no conclusive data on the beneficial effects of IEDs have been established. Proponents of immunonutrition argue that the inability to achieve goal volume of enteral feeds in most of the studies may be responsible for the lack of favorable effect on outcomes. ICU patients are heterogeneous, and the timing of intervention may be important in this subgroup of patients. The severity of illness in some patients may not be amenable to manipulation by immunonutrients, and careful selection of patients is essential to demonstrate benefit in subgroups. Future research should investigate the role of individual nutrients in select groups of patients. The novel concept of pharmaconutrition has been proposed where a disease-dedicated nutrition therapy is developed following a rigorous step-by-step procedure.[84] Nutrients are selected according to their pharmacological properties and after an in-depth evaluation of their biological interactions when mixed together. Table 75-5 summarizes a list of nutrients and their beneficial effects in specific populations in critical illness. The optimum administration schedule (i.e., dose, route, timing and duration) of the new formulae is then determined in well-conducted projective clinical trials where it is administered apart from the standard nutrition to ensure full delivery of the expected doses. Dose-response effect then identifies the essential components of immunonutrition at the correct doses. Future studies are required to prove if a critical volume must be reached in order to demonstrate a beneficial effect of these immunonutrients. There are insufficient pediatric studies evaluating the role of nutrition-based immunonutrition in critically ill children. The generalized use of immunonutrition for children in the PICU cannot be recommended.

Parenteral Nutrition

PN, or hyperalimentation, bypasses the gut, and instead utilizes intravenous administration of macronutrients and micronutrients to meet the nutritional requirements of the body, either partly (as a supplement to enteral feeds) or entirely (total PN). PN is indicated in children who are unable to tolerate enteral feeds for prolonged periods. In the setting of intact intestinal function, PN is not indicated if enteral feeds alone can maintain nutrition. Although widespread in its application, PN is associated with mechanical, infectious, and metabolic complications and hence should be used only in carefully selected patients.

Fluid and electrolyte status guides the initial PN prescription. Fluid restrictions limit the amount of calories delivered, despite use of a concentrated formula. PN should not be used for replacing ongoing losses. PN should be prescribed daily and after reviewing levels of electrolytes and blood sugar in order to allow adjustments in the macronutrient and micronutrient composition. The patient's hydration, size, age, and underlying disease dictate the amount of the fluid to be administered. Box 75-3 describes the calculations use to determine calories obtained from macronutrients in PN.

Box 75–3 Calculating Parenteral Nutrition Calories

Total carbohydrate (g): CHO/day × 3.4 kcal/g = CHO calories
1 g dextrose provides 3.4 kcal (most other CHO provide 4 kcal/g)
10% dextrose = 10 g dextrose/100 mL
Total protein (g): Protein/day × 4 kcal/g = Protein calories
1g protein provides 4 kcal
Total fat (20% lipids) (mL) × 2.0 kcal/mL = Lipid calories
(10% lipids = 1.1 kcal/mL)
Total calories = CHO + Protein + Lipid calories
Total nonprotein calories = CHO + Lipid calories

Carbohydrates

Carbohydrates are the major nonprotein source of energy. D-glucose is provided in the monohydrate form for intravenous administration and yields 3.4 kcal/g. The concentration of the dextrose solution should not exceed 10% for peripheral administration. In the setting of central venous access, a range of concentrations (5% to 40%) can be prepared. Higher glucose concentration makes the solutions hyperosmolar and may cause phlebitis or thrombosis and decrease the lifespan of the vessel when PN is administered peripherally through a vein. Blood glucose estimations must be followed carefully given the increased incidence of hyperglycemia, especially in young infants. Carbohydrate is started at 5 to 8 mg/kg/min. Gradually increasing the carbohydrate load allows an appropriate endogenous insulin response and prevents fluctuations in blood sugar. Abrupt cessation of PN may result in hypoglycemia and should be anticipated and avoided.[85] Fat is supplied as intralipid, which provides the other source of calories in PN and reduces carbon dioxide production and the water retention that is seen when carbohydrate is the sole source of calories.

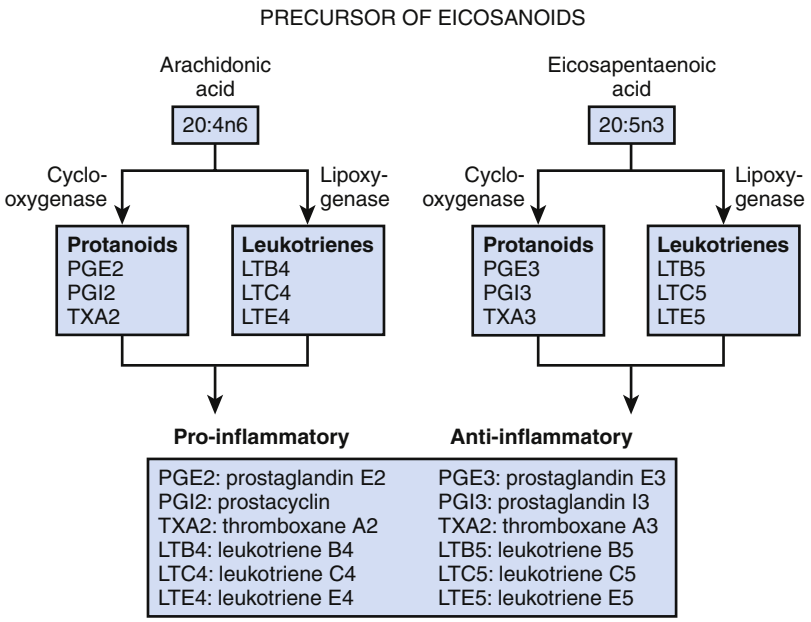

Figure 75–3. Omega-3 and omega-6 Fatty acid metabolites. *(Adapted from Lee S, Gura KM, Kim S, et al: Current clinical applications of omega-6 and omega-3 fatty acids,* Nutr Clin Pract *21[4]:323-341, 2006.)*

Amino Acids

One gram of protein yields 4 kcal. The initial recommended dosage range from 0.5 to 3 g/kg/day is based on age, disease state, and individual requirements. The usual available concentrations are between 1% and 4%, although patients with hepatic disease, renal insufficiency, and children with metabolic diseases (e.g., maple syrup urine disease) should receive appropriately modified concentrations. TrophAmine contains a higher percentage of branched-chain amino acids and a small amount of glycyl-cysteine. This solution is mainly used in the neonatal population. It is recommended and used in patients with hepatic encephalopathy and in children on long-term PN (e.g., short bowel), although data supporting this application are scarce. There is an increasing interest in the use of glutamine in PN. Glutamine, along with cysteine as glycyl-cysteine, is a precursor for glutathione, which is a major antioxidant. Glutamine is also a precursor for nucleotide synthesis, and although it is a nonessential amino acid, it can become conditionally essential, especially in catabolic states such as sepsis and trauma. Glutamine has a short shelf life. However, its applicability has been widespread. It has been introduced in PN solutions for its presumed benefits, such as restoration of protein and nitrogen balance, attenuation of gastrointestinal mucosal atrophy, and reduction of bacterial translocation and bacteremia after chemotherapy. The National Institute of Child Health and Development (NICHD) neonatal research network did not find significant differences in outcomes when a multicenter study randomized 1430 extremely low-birth-weight neonates to PN containing 20% glutamine or an isonitrogenous control. However, pediatric burn patients have been shown to have deficient peripheral glutamine production. In a double-blinded randomized control trial, glutamine-enhanced PN reduced gram-negative bacteremia in severely burned patients.[86]

Lipids

Lipids represent an integral part of PN and provide energy derived through fatty acid oxidation. Lipids are usually started at 0.5 to 1 g/kg and advanced to a maximum intake of 3 g/kg or a maximum 60% of total kilocalories. Lipid calories allow for a lower concentration of carbohydrate (lower osmolarity of PN). Lipid emulsions are available as 10% (1.1 kcal/mL) or 20% (2 kcal/mL). Intralipid prevents or treats essential fatty acid deficiency. The total lipid usually is delivered over an 18- to 24-hour period through separate tubing, using a Y-connector near the infusion site. Delivery of amino acid, glucose, and lipid (three-in-one) is no longer recommended for neonatal patients because of the risk of calcium phosphate precipitation being obscured by lipid in the preparation.

Lipids are a crucial source of nutrition in parenteral formulas. Traditionally considered a calorie-dense nutrient and a source of essential fatty acids, lipids in intravenous feeding regimens have added advantages, such as providing a more balanced energy expenditure and facilitating better respiratory function parameters. Fatty acid derivatives are major biologic modulators.[87] Figure 75-3 illustrates the basic pathways and inflammatory effects of fatty acid metabolites. The linoleic acid load, as a consequence of predominantly soy-based lipid in current formulations, results in increased arachidonic acid production and decreased production of eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA).[88] Increased arachidonic acid levels may increase the proinflammatory cytokine production and activity. EPA levels may influence the production of antiinflammatory cytokines,[87] and DHA has been shown to lower blood pressure, improve endothelial function, and elevate levels of high-density and low-density lipoproteins.[89] Thus DHA and EPA, found in fish and fish oils, are essential fatty acids for humans. In an attempt to decrease the linoleic acid intake, soy-based oil has been partly replaced by medium-chain triglycerides, olive oil, or fish oil in intravenous emulsions. The metabolic roles of omega-3 polyunsaturated fatty acids are emerging. Parenteral fish oils may have immune modulatory function and have been applied for their beneficial effect in the perioperative period following major abdominal surgery.[34,86] Further research examining the efficacy and safety of different triglycerides, derived from medium-chain triglycerides, olive oil, and fish oils, will allow their application in specific disease conditions. Furthermore, in this era of nutrigenomics, the effect of fatty acids on genes

and proteins is being increasingly elucidated and will influence clinical practice. In the future, designer lipid formulations and molecules may be applied in parenteral or enteral nutrition regimens for their beneficial effects in specific disease conditions.

Electrolytes/Minerals and Trace Elements

All solutions are typically prepared with minimum acetate (i.e., all salts are added as chloride) unless prescribed otherwise. It is possible to prescribe an all-acetate solution with no chloride. Calcium and phosphorus precipitate when their concentrations exceed an allowable limit, related to the solubility index of $(Ca)_3(PO_4)_2$ and the pH of the solution. Selenium may not be routinely added to PN. A serum selenium level should be obtained if a patient requires PN for more than 30 days without enteral intake. Multivitamins and trace elements are routinely added to the PN, and recommended intakes are elucidated elsewhere.[90] Heparin usage in PN is practiced in many centers and has been shown to decrease catheter-related sepsis.[91] Heparin in concentrations of 0.5 to 1 U/mL is thought to prevent thrombosis and possibly phlebitis in peripheral lines, although there are no controlled trials showing significant benefit of heparin usage in PN.

Biochemical Monitoring

A PN profile is recommended at initiation of therapy and weekly thereafter. The profile includes serum levels of sodium, potassium, chloride, glucose, carbon dioxide, blood urine nitrogen, creatinine, albumin, magnesium, phosphate, total and direct bilirubin, and transaminases. For children requiring PN for more than 30 days, selenium, iron, zinc, copper, and carnitine levels should be checked. Daily vital statistics and routine anthropometry must be monitored to ensure adequate growth and development. Critical care units benefit from the expertise of a dedicated nutritionist, who should be consulted on a regular basis to guide optimal nutritional intake of patients.

Central venous access is required for delivery of hyperosmolar PN solutions into a large-bore vein with high-volume blood flow, to prevent thrombosis and phlebitis (see Chapter 15). The incidences of infective and life-threatening complications related to indwelling central lines have necessitated extreme caution with central PN use.[92,93] Central lines should be placed by experienced operators and line tip position confirmed by radiography before the lines are used for PN delivery. It is recommended that central line tips be positioned outside the cardiac chambers at all times. Central lines are recommended for delivery of infusates with osmolarity greater than 900 mOsm/L (10% dextrose, 2% amino acids with standard additives).

Refeeding Syndrome

Aggressive nutritional rehabilitation in malnourished patients or after prolonged starvation results in a constellation of biochemical and clinical features with cardiopulmonary complications. This well-described entity is called refeeding syndrome and is often unrecognized. Hypophosphatemia is the hallmark of refeeding syndrome, which is also associated with hypomagnesemia, hypokalemia, and fluid retention. Patients admitted to the PICU with nutritional deficiencies, those with chronic conditions causing malnutrition or those fasted for 10 to 14 days are at risk of refeeding syndrome following aggressive oral, enteral, or parenteral nourishment. Introduction of nutrition in these patients stimulates anabolism, with a switch from protein and fat catabolism to predominantly carbohydrate metabolism. Glucose becomes the primary energy source, leading to insulin release. Insulin-mediated cellular uptake of glucose causes intracelular shift of phosphate, potassium, and magnesium, thus rapidly lowering their serum levels. Insulin also causes sodium and fluid retention with rapid expansion of extracellular fluid volume. The clinical manifestations of refeeding syndrome are a result of the dyselectrolytemia and fluid overload, and involve cardiorespiratory, neuromuscular, and hematologic complications. Hypotension, respiratory failure, muscular weakness, confusion, seizures, coma ,and even death may result from refeeding syndrome.

Awareness of this syndrome, identification of at-risk patients and gradual introduction of nutrition in these individuals help prevent the refeeding syndrome. Calories may be introduced at 25% to 50% of requirement and increased 10% to 25% daily until the caloric goal is met. Careful monitoring of electrolytes and vigilance for clinical manifestations of the syndrome allow early detection of complications, and feeds are advanced in the setting of biochemical stability. Prompt correction of electrolyte abnormalities, close attention to fluid balance, and supplementation with multivitamins will help avoid the cardiorespiratory sequelae from refeeding in the critically ill child.

Nutritional Support of Obese Critically Ill Children

Overweight/obesity continues to increase in children and adolescents, and annual obesity-related hospital costs in 6- to 17-year-olds have reached $127 million per year. The severity of obesity is classified based on BMI into the following three categories: (1) overweight = BMI 25 to 30 kg/m^2, (2) obesity = BMI 30 to 40 kg/m^2, and (3) morbid obesity = BMI greater than 40 kg/m^2. Overweight children and adolescents are increasingly being diagnosed with impaired glucose tolerance and type II diabetes, and they show early signs of the insulin resistance syndrome and cardiovascular risk. Centralized distribution of body fat is associated with the risk of metabolic syndrome. Metabolic syndrome is observed in obese children and is characterized by visceral obesity, insulin resistance, and dyslipidemia. There is a high risk for type 2 diabetes and cardiovascular complications in patients with metabolic syndrome. Grossly overweight patients are prone to sleep apnea syndrome, restrictive lung disease, venous thrombosis, musculoskeletal degenerative disorders, hepatic steatosis, and metabolic disorders associated with bariatric surgery.

The metabolic response to stress in obese critically ill patients is complex, given that it occurs in a population with preexisting major metabolic and endocrine alterations. In critically ill obese patients, the pattern of substrate oxidation is mainly protein and glucose, with decreased fat oxidation.[94] The extent of protein breakdown is greater than in nonobese critically ill adults. No data on metabolic abnormalities of obese children are available. In the adult critically ill population, hypocaloric nutrition estimated for ideal weight has been recommended.[47] The limited adult literature suggests that

Box 75–4 Guidelines for Pediatric Critical Care Nutritional Support

Number	Guideline Recommendations	Grade
1A	Children admitted with critical illnesses should undergo nutrition screening to identify those with existing malnutrition and those who are nutritionally at risk.	D
1B	A formal nutrition assessment with the development of a nutrition care plan should be required, especially in children with premorbid malnutrition.	E
2A	Energy expenditure should be assessed throughout the course of illness to determine the energy needs of critically ill children. Estimates of energy expenditure using available standard equations are often unreliable.	D
2B	In a subgroup of patients with suspected metabolic alterations or malnutrition, accurate measurement of energy expenditure using indirect calorimetry (IC) is desirable. If IC is not feasible or available, initial energy provision may be based on published formulas or nomograms. Attention to imbalance between energy intake and expenditure will help prevent overfeeding and underfeeding in this population.	E
3	There are insufficient data to make evidence-based recommendations for macronutrient intake in critically ill children. After determination of energy needs for the critically ill child, the rational partitioning of the major substrates should be based on understanding of protein metabolism and carbohydrate and lipid-handling during critical illness.	E
4A	In critically ill children with a functioning gastrointestinal tract, EN should be the preferred mode of nutrition provision, if tolerated.	C
4B	A variety of barriers to EN exist in the PICU. Clinicians must identify and prevent avoidable interruptions to EN in critically ill children.	D
4C	There are insufficient data to recommend the appropriate site (gastric vs. postpyloric/transpyloric) for enteral feeding in critically ill children. Postpyloric or transpyloric feeding may improve caloric intake compared with gastric feeds. Postpyloric feeding may be considered in children at high risk of aspiration or those who have not responded to a trial of gastric feeding.	C
5	Based on the available pediatric data, the routine use of immunonutrition or immune-enhancing diets/nutrients in critically ill children is not recommended.	D
6	A specialized nutrition support team in the PICU and aggressive feeding protocols may enhance the overall delivery of nutrition, with shorter time to goal nutrition, increased delivery of EN, and decreased use of parenteral nutrition. The effect of these strategies on patient outcomes has not been demonstrated.	E

protein requirements are higher in critically ill adult obese patients. It is recommended that fat be administrated sparingly, mainly to prevent essential fatty acid deficiency.[95] No data on the best nutritional support of critically ill obese children are available. Routine equations for tend to overestimate energy expenditure in obese patients. Energy requirement in this group should be guided by IC measurement of REE, where available. When REE is estimated, there is no consensus on the use of ideal body weight versus adjusted body weight. As the incidence of obesity in children admitted to the PICU is rising, future research aimed at addressing some of these knowledge gaps is desirable.

Guidelines for Pediatric Critical Care Nutrition

Due to the complexities of critical care, nutrient intake during critical illness is challenging (Box 75-4). The lack of robust evidence for many of the bedside decision-making around nutrition support in the PICU has resulted in heterogeneity in practice. Optimal nutrition support in the PICU cannot be achieved unless there is some uniformity in practice based on evidence or consensus and an attempt to systematically evaluate practice parameters for feasibility, efficacy, and impact on patient outcomes. However, the direct effect of nutritional strategies in a heterogeneous cohort of patients with varying degrees of illness severity is difficult to assess. Multiple factors influence outcome during critical illness. Due to these challenges, current literature is scarce and guidelines for pediatric critical care nutrition have been based on few good studies but mainly on smaller studies of expert opinion. In 2009, the American Society of Parenteral and Enteral Nutrition published the revised guidelines for pediatric critical care nutrition practice.[51] These guidelines were based on the best available evidence and help clarify the principles guiding nutrition therapy in the PICU population. Early enteral nutrition is recommended in critically ill children with a functional gastrointestinal tract. Careful assessment or measurement of energy expenditure with attention to unintended energy imbalance (due to underfeeding or overfeeding) seems prudent. Health care workers must work in a collaborative fashion to identify and prevent common barriers to nutrition support in the PICU. The application of indirect calorimetry and postpyloric feeding is currently limited to centers with available expertise and resources.

Conclusions

The accurate assessment of nutritional needs and the provision of individually tailored optimal nutrition support to the critically ill child are important goals of pediatric critical care. Malnutrition

and obesity are prevalent in the critical care population and have a significant influence on the outcome of critical illness. Furthermore, the hypermetabolic stress response places demands on the critically ill child that must be met with evidence-based nutrient supplementation. Intensivists must remain alert to the possibility of both underfeeding and overfeeding in order to prevent unintended cumulative energy imbalances in critically ill children. A multidisciplinary effort to overcome common barriers to nutrient delivery and the use of evidence-based algorithms will help achieve nutrition goals in the PICU.

Interest in immune-modulating effects of nutrients, micronutrient supplementation, and the role of newer sources of lipid formulations has introduced the concept of pharmaconutrients, but its benefits on outcome in the PICU have not been realized yet. Strict glycemic control is associated with a significant increase in the incidence of hypoglycemia. The feasibility of this strategy in the PICU will need to be examined in the setting of carefully designed studies. In the future, patients will benefit from individually tailored nutritional regimens suited to the type and stage of their illness. There are a number of knowledge gaps that need to be addressed by collaborative research. Until then, a multidisciplinary effort must be made to increase awareness of nutritional issues, adherence to institutional guidelines, and prioritization of nutrition support in the PICU.

Inborn Errors of Metabolism

Laurie Smith and Cary O. Harding

PEARLS

- Unexpected and unexplained clinical deterioration in a previously healthy infant or child is an important clue to the presence of an inborn error of metabolism (IEM).
- Loss of previously attained developmental milestones during childhood is an important clue to the presence of a neurodegenerative disorder such as lysosomal storage disease.
- Blood glucose less than 40 mg/dL is distinctly unusual after the first 24 hours of life, particularly in infants who have started feeding, and should be thoroughly investigated.
- Laboratory evaluation for inborn errors of metabolism should be undertaken in any child with a suggestive clinical history regardless of the results of newborn screening. A normal newborn screen, although perhaps reassuring, does not rule out the possibility of an IEM.
- With catastrophic illness in a previously well child without signs of any particular IEM, the "shotgun" diagnostic evaluation should minimally include plasma amino acid analysis, urine organic acid analysis by gas chromatography-mass spectrometry, and a so-called *urine metabolic screen*.

Metabolism can be defined as the sum of all biochemical processes that convert food to smaller molecules and energy for the purposes of structure and function. An inborn error of metabolism (IEM) is an inherited deficiency of any critical step in metabolism. Although genetic deficiency of catalytic enzymes in intermediary metabolic pathways is the classic paradigm for IEM, the pathophysiology of metabolic disorders may involve abnormalities of any number of cellular processes, including transmembrane transport, cell signaling, cell differentiation and development, energy production, and others. Many IEMs are individually rare, although a few, including phenylketonuria (PKU) and medium-chain acyl-coenzyme A (acyl-CoA) dehydrogenase deficiency (MCADD), a defect in fatty acid oxidation, exhibit a population incidence approaching 1:10,000 live births.[1,2] Specific IEMs may be more common in certain ethnic groups with a history of relative reproductive isolation. Collectively, the population incidence of all IEMs may approach 1:1500 live births, depending upon how broadly IEM is defined. Many IEMs are associated with catastrophic illness necessitating advanced life support. Although IEMs may present very rarely within the professional lifetime of the average medical practitioner, critically ill children with IEMs will not be uncommon visitors to the pediatric intensive care unit (ICU), especially in a tertiary care center.

The key to successful treatment of IEMs is the initial suspicion and timely diagnosis of the disorder. Certain features of the clinical history, physical signs and symptoms, and results of routine laboratory studies often suggest the possibility of IEM. Second-tier screening metabolic studies provide further evidence for the presence of a disorder. The results of routine neonatal screening studies may suggest a specific disorder prior to development of any diagnostic suspicion on the part of the clinician or even prior to the onset of symptoms in the neonate. In the case of a critically ill child with a suspected metabolic disease or with an abnormal neonatal screening test result for a specific metabolic disorder, immediate consultation with a biochemical geneticist, even if only by telephone, is paramount. The genetic consultant helps direct the diagnostic laboratory evaluation and recommends nonspecific emergency treatment, if any is warranted, prior to the availability of the definitive diagnostic studies. Communication among the intensivist, genetic consultant, and biochemical genetic diagnostic laboratory is critical to achieving the timely and correct diagnosis of IEM. A satisfactory clinical outcome for the affected child is completely dependent upon the collaborative efforts of this tripartite team approach.

Other published textbooks on the diagnosis and treatment of IEM provide an exhaustive list of known disorders.[3,4] Rather than recapitulate an encyclopedia of possible diseases, this chapter presents a diagnostic rationale based upon specific clinical symptom complexes that are likely to occur in the critically ill child. Algorithms for the differential diagnosis of specific clinical scenarios are given in support of this rationale. Symptoms often begin during early infancy in the biochemically most-severe IEMs; naturally, these IEMs with neonatal onset are the focus of our discussion in this chapter. However, "milder" or late-onset variants of virtually every IEM have been described, with onset of symptoms occurring at all ages, even during adulthood. Some IEMs uniformly present after the neonatal period; age of symptom onset (late infancy, childhood, or adulthood) often is an important clue to the specific diagnosis. The clinical presentation, diagnostic workup, and treatment of neonatal onset disorders provide a paradigm for the evaluation and management of possible IEM in a child of any age.

Pathophysiology of Inborn Errors of Metabolism

Under the classic paradigm, an IEM is associated with deficiency of a specific protein, often a catalytic enzyme, involved in a critical metabolic pathway (Figure 76-1). This deficiency leads to a block in the pathway and the accumulation of the

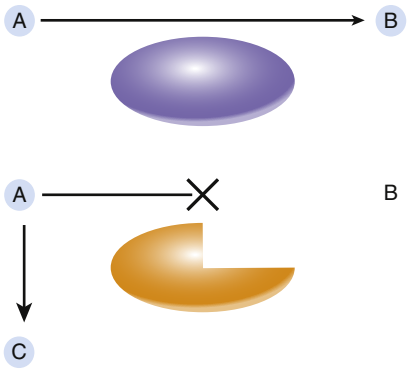

Figure 76–1. Inborn error of metabolism paradigm. Normally, in a given step of intermediate metabolism with intact enzymatic activity, the substrate A is efficiently converted to the product B. In an inborn error of metabolism, deficiency of enzyme activity may lead to excessive accumulation of the substrate; critical deficiency of the product; or production of an alternative, potentially toxic metabolite C through normally quiescent pathways.

enzyme substrate. In this model, three distinct pathogenic mechanisms are possible proximate causes of the symptoms associated with an IEM. The specific pathogenic mechanism involved in any given IEM dictates the appropriate treatment strategy. First, accumulation of the substrate may lead to toxic effects at very high levels; successful therapy requires effective elimination of the substrate or a method to block its toxic effects. An appropriate example for this mechanism is PKU, in which elevated phenylalanine levels adversely affect neuronal development, and the reduction of tissue phenylalanine content through dietary phenylalanine restriction largely prevents the major clinical features of PKU.[5] Second, deficiency of the reaction product, should it be a critically important metabolite, may lead to disease. Supplementation with the essential metabolite, if possible, may cure the disease. Biotin is a required cofactor for four distinct carboxylase enzymes. Deficiency of free biotin develops in the face of genetic biotinidase deficiency and leads to symptoms of multiple carboxylase deficiency. Supplementation with oral biotin completely prevents the clinical manifestations of biotinidase deficiency.[6] The final pathogenic mechanism involves the conversion of the enzyme substrate, through normally quiescent alternative pathways, to toxic secondary metabolites. Elimination or decreased production of these secondary metabolites may improve disease symptoms. For example, tyrosinemia type I (fumarylacetoacetate hydrolase [FAH] deficiency) is associated with recurrent attacks of abdominal pain and paresthesias reminiscent of acute intermittent porphyria. The accumulating substrate, fumarylacetoacetic acid, is converted through secondary pathways to succinylacetone, and succinylacetone in turn inhibits the heme synthetic pathway and causes porphyria-like symptoms. Pharmacologic inhibition of the tyrosine catabolic pathway proximal to the block at FAH decreases the production of fumarylacetoacetic acid and succinylacetone and alleviates the pathology associated with these toxic compounds.[7]

Inheritance of Inborn Errors of Metabolism

IEMs are heritable disorders. The majority of diseases are inherited in an autosomal-recessive pattern, yielding a 25% recurrence risk in future offspring. The gene defects associated with several IEMs are located on the X chromosome. These IEMs, such as ornithine transcarbamoylase deficiency and glycerol kinase deficiency, are inherited in an X-linked pattern. These IEMs are most severe in males, but carrier females may be symptomatic, although usually with less severe or late-onset disease as a result of skewed X-chromosome inactivation. Mutations for several mitochondrial disorders are found on mitochondrial deoxyribonucleic acid (mtDNA). Because mtDNA is exclusively passed from mothers to their offspring, these IEMs exhibit a maternal inheritance pattern but often with variable penetrance and expressivity. Prenatal diagnosis is possible for many IEMs. In addition to allowing for appropriate medical therapy, the timely diagnosis of an IEM in a sick infant or child is important for genetic counseling purposes.

BOX 76–1 Signs And Symptoms of Inborn Errors of Metabolism

Acute illness after period of normal behavior and feeding (hours to weeks)
Recurrent decompensation with fasting, intercurrent illness, or specific food ingestion
Unusual body odor
Persistent or recurrent vomiting
Failure to thrive
Apnea or tachypnea
Jaundice
Hepatomegaly or liver dysfunction
Lethargy or coma
Sepsis
Unexplained hemorrhage or strokes
Developmental delay with unknown etiology
Developmental regression
Seizures, especially if seizures are intractable
Hypotonia
Chronic movement disorder (ataxia, dystonia, choreoathetosis)
Family history of unexplained death or recurrent illness in siblings

Signs and Symptoms of Inborn Errors of Metabolism
